The Synthesis and Properties of New Complex-forming Thiophen Derivatives

Ya.L.Gol'dfarb and M.A.Kalik

The review deals with the methods of synthesis and properties of new heterocyclic ligands-mercaptoaldimine derivatives of thiophen, thienothiophen, and thionaphthene. Data on the preparation and certain reactions of metal chelate complexes of mercaptoaldimines are presented. The tautomerism and the ^{1}H NMR spectra of mercaptoaldimine derivatives of thiophen are discussed.
The bibliography includes 100 references.

I. INTRODUCTION

In recent years there has been a fresh spurt in the development of the chemistry of complex compounds. New experimental techniques, in particular infrared, ^{1}H NMR, and ESR spectroscopy, and especially the exceptional importance which complex formation has acquired as a special method of activating simple molecules acting as ligands, have undoubtedly played a significant role in stimulating interest in the field of complex compounds. Complex formation also makes it possible to transfer a metal from one part of a biological substrate to another or to remove from the organism a metal with toxic properties [1]. A new branch of organic chemistry, based on the modification of the organic molecule by coordination with a metal, has been developing at an increasing rate and attention has been concentrated on the organic part of the complex, while previously interest was directed almost exclusively to the study of the properties of the coordinated metal ions. Many relevant problems have been discussed in reviews and monographs [2-7].

Chelate compounds, the chemical and physical properties of which vary within extremely wide limits as a function of the coordinating centres of the ligands and the nature, valence state, and the coordination number of the central atom, are of special interest. In Collman's extensive studies [8], this has been demonstrated for a large number of metal acetylacetonates. Functional groups, in particular nitro-, acyl, and chloromethyl, and other groups, can be introduced into some of these compounds by electrophilic substitution reactions, the properties of the group becoming sharply altered as a result of the bond formed with the chelate ring. For example, the aldehyde group loses its capacity to form oxides, hydrazones, etc. and does not react with methylmagnesium iodide; the sulphide group is not oxidised by hydrogen peroxide. In view of the chemical behaviour of acetylacetonates, some investigators refer to their properties as pseudoaromatic. In this connection one can mention the recent work of Japanese investigators [9], who, wishing to compare the aromatic properties of the furan and chelate rings, studied the nitration and bromination of chromium(III) and cobalt(III) trisfuroylacetonates and obtained only the chelate ring substitution products.

Chelates the ligand component of which is a bifunctional derivative of a heteroaromatic compound constitute a group which has so far been little investigated. New possibilities have arisen in practice and in research not only as a result of the ability to vary the ring heteroatom but also owing to its capacity for involvement in complex formation together with atoms outside the ring. This branch of the chemistry of complex compounds has attracted the attention of the authors of the present review.

II. SYNTHESIS AND PROPERTIES OF SULPHIDE DERIVATIVES OF THIOPHEN

Thiophen is a heterocyclic compound with pronounced aromatic properties. During the decades elapsed since its discovery (1883) by Victor Meyer, the chemistry of thiophen has been treated in terms of the concept of its complete analogy with benzene. This approach, which is in many respects justified and is to some extent in keeping with the present general concept of aromaticity, suffers from the disadvantage that certain specific features of the chemical behaviour of thiophen remained undiscovered or were ignored. However, with the development of new theoretical views in organic chemistry and the adoption of modern physical methods for the investigation of organic molecules, differences between the properties of the thiophen and benzene systems were discovered; these are due, in particular, to differences between their geometry or the influence of the heteroatom as a unit different from the other units in the closed chain of the heterocycle.

In the light of these data, it is of considerable interest to investigate analogous bifunctional benzene and thiophen (or furan, etc.) derivatives as regards their capacity to form chelates and the chemical behaviour of the latter. One of the types of ligands for this purpose may be analogues of salicylaldehyde and its Schiff bases containing the mercapto-group instead of the hydroxy group [structures (I) and (II)].

It is noteworthy that in recent years there has been an increasing interest in complexes where one of the coordinating centres is a sulphur atom [10]:

(I) (II)

It appeared useful to employ 2-alkyl-5-mercaptothiophens for the synthesis of compounds of type (I). [11] However, it is known that in the analogous thiophenol system a second functional group cannot be introduced into the ring because, under the influence of both electrophilic and nucleophilic agents, the mercapto-group is the first to be altered. For example, under nitration and bromination conditions, thiophenol is converted into a disulphide [12,13] and in the Friedel–Crafts acetylation it yields phenyl thioacetate, which does not react further even at 150°C. [14] Individual cases of the ring alkylation of aromatic thiols in the presence of boron trifluoride have been described but under these conditions too the intermediate products are complexes of the thiol and the catalyst in which the mercapto-group is blocked [15].

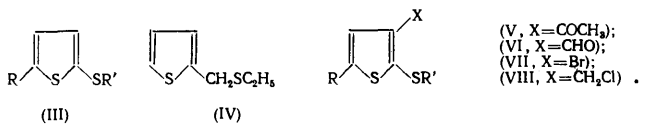
Thus, it is evident that, in order to introduce a second functional group into the molecule of an aromatic mercaptan, it is necessary to protect the mercapto-group by substituents which can be readily eliminated in the final stage. However, the use for this purpose of the corresponding mercaptals, disulphides or *S*-acylated mercaptothiophens did not yield satisfactory results [14,16,17]. On the other hand, alkyl aryl sulphides readily undergo electrophilic substitution but the dealkylation necessary for the above purpose has been rarely employed [18].

Ring-substituted thiophenols have been synthesised from sulphides formed by the reaction of thiophenols with 3-nitrobenzylideneacetophenone [16]. The use of this method for the synthesis of 3-substituted mercaptothiophens proved relatively inaffective. Thus the reaction of *N*-methylformanilide and phosphoryl chloride did not result in the introduction of the formyl group into the thiophen ring of β-[(5-ethyl-2-thienylmercapto)-β-(3-nitrophenyl)]propiophenone and the acetylation of this sulphide led to the formation of its cyclodehydration products [11].

The required result was achieved only when alkyl thienyl sulphides were employed as the starting materials. In this case the problem reduced to the introduction of the corresponding functional group into the 3-position of the thiophen ring and the subsequent dealkylation of the alkylthio-group in such a way that the resulting mercapto-group remained linked to the ring. Since alkyl thienyl sulphides are key compounds in this process, it is desirable to examine initially the methods of their synthesis and some of their properties.

Alkyl 2-thienyl sulphides are formed in high yields when thiophen and its homologues with at least one substituted α-position are treated in succession with butyl-lithium, elemental sulphur, and an alkyl halide [19,20]. Other methods of synthesis of similar sulphides, which also do not require a preliminary halogenation of the thiophen, are based on the use of thiyl radicals [21,22] or thiocyanatothiophens [23].

When 2-alkyl-5-alkylthiothiophens (III) were acetylated with acetyl chloride in the presence of $SnCl_4$ or with acetic anhydride and phosphoric acid [19], formulated by the Wilsmeyer method† [24], and brominated, the corresponding derivatives (V), (VI), and (VII) containing a new substituent in the 3-position were isolated:



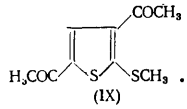
(III) (IV) (V, X=$COCH_3$); (VI, X=CHO); (VII, X=Br); (VIII, X=CH_2Cl).

where R and R′ = alkyl.

This is evidence that alkylthio-groups have a more powerful activating effect than alkyl groups. It is interesting to note that, on competitive acylation of a mixture of thiophen and 2-methylthiothiophen with acetyl chloride [26], 2-acetothienone and 5-methylthio-2-acetothienone were isolated in yields of 15 and 48% respectively.

On chloromethylation of type (III) sulphides, a 3,4-di-(chloromethyl)-substituted derivatives was isolated together with the monochloromethyl-substituted derivative (VIII). [27]

When 2-methylthiothiophen was acetylated, a small amount of a diacetyl derivative, probably with structure (IX), was detected in addition to 5-methylthio-2-acetothienone:



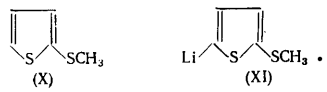
(IX)

Kinetic data for hydrogen exchange between an acid and 2- and 3-methylthiothiophens deuterated in specified positions may serve as a measure of the activating effect of the alkylthio-group in electrophilic substitution reactions of methylthiothiophens [28]. The results obtained show that in 2-methylthiothiophen the second α-position is strongly activated and the 3-position less so. The methylthio-group in the 3-position increases the rate of exchange in the 2-position by two powers of 10 more than in the 4-position. The rates of exchange of β-atoms in 2-ethylthio-5-methylthiophen also differ by approximately two powers of 10. The data quoted above for the site of acetylation, formylation, and bromination of 2-alkyl-5-alkylthiothiophens are also at least qualitatively consistent with these findings.

As already mentioned, the capacity of thiophen and certain types of its alkyl- or aryl-substituted derivatives for metallation, for example when treated with lithium alkyl, is important for synthetic purposes in the thiophen series. According to hypotheses put forward at one time [29,30], the first stage in this reaction is coordination of the metallating agent to the heteroatom with a lone electron pair; this determines the site where the metal is introduced and limits or excludes the effect of substituents [31]. Therefore the problem of the site of metallation of alkyl thienyl sulphides, the molecules of which contain two formally bivalent sulphur atoms, cannot be solved unambiguously *a priori*, particularly since their benzene analogue (thioanisole) yields on metallation exclusively the product of substitution in the side chain [32,33].

† Sulphides of type (IV) have an interesting property: when acted upon by *NN*-dimethylformamide or phosphoryl chloride, they do not yield the corresponding aldehydes but are cleaved with the formation of thienyl chloride and amidomercaptals [25].

In contrast to methyl phenyl sulphide, methyl 2-thienyl sulphide (X) readily gives the lithio-derivative (XI) when acted upon by butyl-lithium. Similar results were obtained also for the sulphide (IV) [34] although the possibility of substitution in the thiophen ring appeared unlikely in this case:



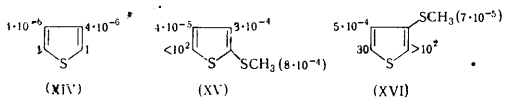
(X) (XI)

In a similar reaction involving protophilic substitution the alkylthio-group also has an activating effect. This is evident, for example, from the finding that, in an experiment involving the metallation of an equimolar mixture of thiophen and the sulphide (X) with a deficiency of butyl-lithium followed by carboxylation, it is possible to isolate only the acid (XII): [20]

(XII) (XIII)

The β-hyrodgen atoms in the thiophen group are not substituted at all under the influence of butyl-lithium, as in the case of 2,5-dimethylthiophen, or are substituted only with difficulty. The acid (XIII) could be obtained in only 27% yield from 2-methyl-5-methylthiothiophen [20].

All these observations are consistent with measurements of the rate of hydrogen–deuterium exchange between bases and methylthiothiophens containing a deuterium atom in a specified position in the molecule [35]. The formulae quoted below characterise the relative mobilities of the hydrogen atoms in all the C–H bonds in thiophen and isomeric methylthiothiophens:



(XIV) (XV) (XVI)

The rate constant for the exchange of the deuterium atom in the 2-position of unsubstituted thiophen with dimethyl sulphoxide catalysed by an alkali metal t-butoxide was adopted as a unit in formulae (XIV), (XV), and (XVI). Attention should be drawn to data concerning the mobility of hydrogen atoms in the methylthio-groups themselves. Evidently the rate of exchange involving these groups is smaller by several powers of ten than the rate of exchange of the ring α-hydrogen atom. In the case of thioanisole the opposite relations are obtained [36].

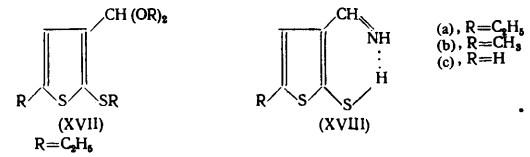
III. MERCAPTOALDIMINE DERIVATIVES OF THIOPHEN

1. Effect of Sodium in Liquid Ammonia on the Diethylacetals of 5-Alkyl-2-Alkylthiothiophen-3-aldehydes

As mentioned above, in order to obtain substituted mercaptothiophens of types (I) and (II) from β-substituted sulphides of type (VI), it is necessary to have an effective means of dealkylating the alkylthio-groups without affecting the bond between the exocyclic sulphur atom ahd the thiophen ring.

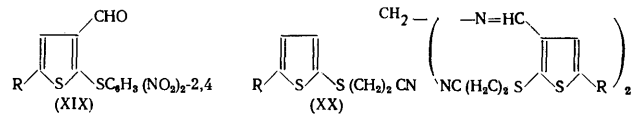
In the search for such a method, the discovery of the capacity of alkyl thienyl sulphides for dealkylation under the influence of sodium in liquid ammonia (Na/NH_3) with formation of the corresponding mercaptans in yields of 50–80% [37] (depending on the nature of the alkyl group) has played an important role. In order to "protect" the aldehyde group under the dealkylation conditions, compound (VI) was converted into the acetal (XVII), since it is known that aliphatic acetals do not react with aqueous and liquid ammonia and with aliphatic amines up to 130°C and are stable also in relation to sodium in liquid ammonia [38,39].

When two equivalents of sodium in liquid ammonia were allowed to react with the acetal (XVII) and the resulting aqueous alkaline solution was treated with HCl, a high yield was obtained of a nitrogen-containing crystalline compound—the mercaptoaldimine (XVIIIa)‡—instead of the expected mercaptoacetal (or aldehyde). [40] Its homologues (XVIIIb) [41] and (XVIIIc) [42] were obtained similarly:



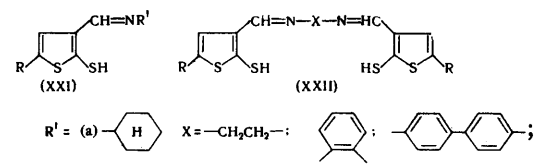
(XVII) (XVIII) (a), R=C2H5 (b), R=CH3 (c), R=H

When the mercaptoaldimine (XVIIIa) is treated with acid or alkali, ammonia is split off, which is consistent with its structure; in an acid medium, the product is a coloured polymer without nitrogen, which retains the capacity to form derivatives via the mercapto- and aldehyde groups, identical with the analogous derivatives obtained directly from (XVIIIa). On reduction with lithium aluminium hydride, (XVIIIa) is converted in high yields into 5-ethyl-2-mercapto-3-thenylamine [43]. One of the typical properties of compound (XVIIIa), reflecting the characteristics of its structure, is its instability under conditions where the hydrogen atoms of the mercapto-group are substituted under the influence of any reagent. For example, the reaction with 1-chloro-2,4-dinitrobenzene in an alkaline medium results in the formation of the formylsulphide (XIX) and the reaction with acrylonitrile gives the hydramide (XX): [40]



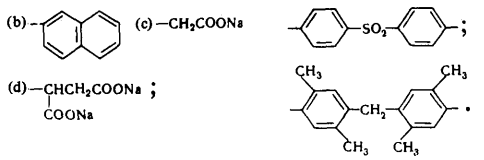
(XIX) (XX)

The formation of hydramides is known to be characteristic of extremely unstable aromatic imines [44] and is observed also when ammonia acta on thiophen-2-aldehyde and furfural [45]. On the other hand, reaction of compound (XVIIIa) with primary amines results in the formation, with evolution of ammonia, of stable di- and tetra-functional *N*-substituted mercaptoaldimines of types (XXI) and (XXII)—the thiophen analogues of the Schiff bases of thiosalicylaldehyde [40,41]. In the light of the above data, it becomes evident that the very existence and stability of compounds of type (XVIII) may be attributed to the formation of an intramolecular hydrogen bond stabilising the molecule (see Section III, 2):



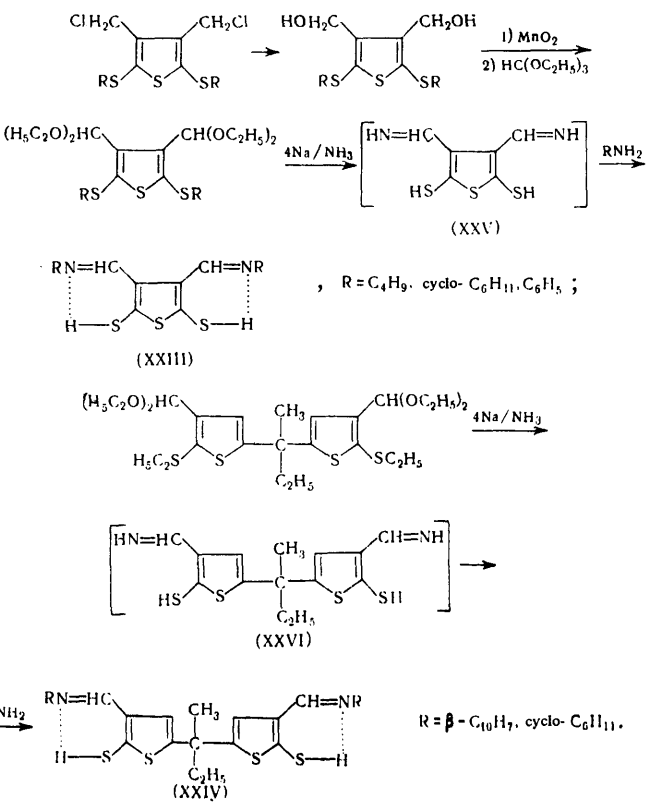
(XXI) (XXII)

‡ For brevity, here and henceforth compounds of type (XVIII) are called mercaptoaldimines although it has been shown [61] that they exist predominantly in another tautomeric form.



Compounds (XXIc) and (XXId), obtained from sodium glycinate and aspartate [41], are readily soluble in water, which in some cases may be an important condition for the applicability of a complex-forming agent.

Apart from the mercaptoaldimines described above, the derivatives (XXIII) and (XXIV) with analogous structure and four coordinating centres in one or in two thiophen rings separated by a methylene bridge have been obtained [46,47]. Such tetrafunctional compounds may be of interest in the synthesis of coordination polymers. The pathways in their synthesis are illustrated below:



It is noteworthy that satisfactory analyses have not been obtained for the bismercaptoaldimines (XXV) and (XXVI), since they are infusible powdery substance, probably with an oligomeric structure, and are difficult to purify. However, their capacity to evolve ammonia under the influence of alkalis and amines with formation in the latter case of readily crystallisable Schiff bases (XXIII) and (XXIV) may serve as confirmation of the structure attributed to them. One can therefore postulate that, when Na/NH_3 is allowed to act on compounds containing two acetal and two sulphide groups, reactions similar to those observed for the acetal (XVII) take place.

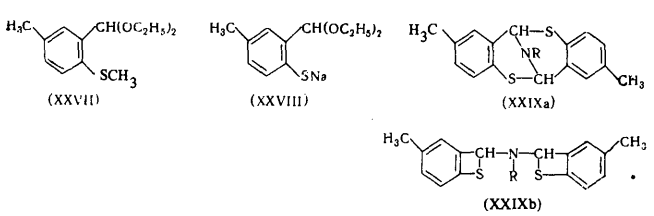
The problem of the mechanism of the formation of mercaptoaldimines of type (XVIII) cannot yet be regarded as finally elucidated. Nevertheless the available data [48] permit certain conclusions concerning the process.

1. When two equivalents of sodium in liquid ammonia are allowed to act on the alkylthioacetal (XVII), the acetal group is unchanged and only the dealkylation of the alkylthio-group with formation of the corresponding mercaptide takes place. (The mercaptoacetal was isolated as mercury mercaptide.)

2. The mercaptoaldimine (XVIII) is a product of the conversion of the mercaptide in the presence of an acid and ammonia.

3. The stability of mercaptoaldimines is due to the specific relative positions of the mercapto- and aldimine groups, which make possible the formation of a hydrogen bond or an inner salt. For other relative positions of the groups in the initial alkylthioacetal, for example, in the acetal of 5-ethylthiothiophen-2-aldehyde, a mercaptoaldimine is not formed. In this case the reaction reaches completion only after the addition of six equivalents of sodium, since sodium is consumed in the dissociation of the C–S bonds and in the reduction of the acetal group to a methyl group. Examples of similar reduction reactions have been described for certain aromatic ketals [49,50].

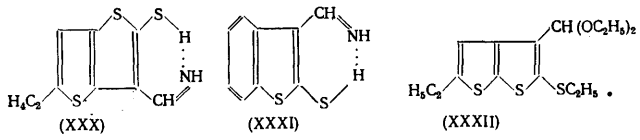
In the light of the foregoing facts, the results obtained in the study of the effect of sodium in liquid ammonia on benzene analogues of the alkylthioacetals (XVII) are of interest. When two equivalents of sodium in liquid ammonia are allowed to act on the acetal (XXVII), the product is, as for the thiophen acetal (XVII), the mercaptide (XXVIII) (obtained in quantitative yield), which reacts with ammonia and amines to give compounds (XXIXa) or (XXIXb). [51] Compound (XXIX, R = H) is formed also when Na/NH_3 is allowed to act on 3-methyl-6-methylthiobenzaldehyde [52]. Therefore in such cases the final product is not a benzene analogue of mercaptoaldimines of type (XVIII):



This may be due to differences between the geometries of the thiophen and benzene rings. Indeed, when a hydrogen atom in the benzene ring is substituted by a sulphur atom, a molecular model analogous to that of compound (XVIIIa), in which the nitrogen and sulphur atoms are linked by a hydrogen bond§, cannot be constructed. In thiophen, such a possibility exists, since its external valence angles are larger. An indirect confirmation of this interpretation comes from the fact that furan, the geometry of which is similar to that of thiophen, forms stable mercaptoaldimines as a result of the reactions described above [57].

§ Here one must again emphasise that these considerations apply only to mercaptoaldimines unsubstituted at the nitrogen atom. The synthesis, infrared spectra, and certain metal chelates of Schiff bases of *o*-mercaptobenzaldehyde were described recently [55,56].

Using the above method for the synthesis of mercaptothenylideneamines (XVIII), the mercaptoaldimines (XXX) and (XXXI), derived from 2-ethylthieno[3,2-*b*]thiophen and thionaphthene respectively, were obtained[58]:



(XXX) (XXXI) (XXXII)

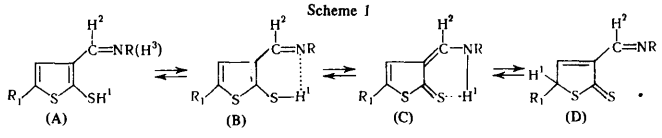
They are coloured crystalline compounds and, like (XVIIIa), form Schiff bases with β-naphthylamine and the corresponding chelates with zinc and nickel salts.

The attempt to synthesise the mercaptoaldimine from the acetal (XXXII) obtained from 2-ethylthieno[2,3-*b*]thiophen was unsuccessful[59].

2. Tautomerism of Mercaptoaldimine Derivatives of Thiophen

In a discussion of problems concerning the structure and chemical behaviour of mercaptoaldimines, one cannot exclude from consideration the possibility of a tautomeric equilibrium (see Scheme 1).

Scheme 1



(A) (B) (C) (D)

Together with the tautomeric forms A, C, and D, there is also a form B, which differs from A only by the presence of a hydrogen bond. Its inclusion in the scheme appears to be valid, since it can be regarded as intermediate between forms A and C.

The tautomerism of mercaptoaldimines in solution has been investigated by proton magnetic resonance (^{1}H NMR).[60,61] The signal from the ^{1}H proton has a chemical shift of 12–14 p.p.m., which indicates the presence of a strong intramolecular bond between H^1 and N or S. The formation of a chelate ring (structures B and C) is also confirmed by data for compounds in which R = H. In the spectra of these compounds both protons linked to the nitrogen atom have different shifts. The H^1 proton, the signal of which is at a lower field (by 2–2.5 p.p.m.), is rigidly fixed, while the other proton is involved in intermolecular exchange, since, on replacement of the ^{14}N isotope by ^{15}N, the H^1 signal becomes a well resolved quartet, while the H^3 signal remains broad.

The values of δH^1 leads to the conclusion that there are no appreciable amounts of the tautomer A and the fine structure of the signal due to the thiophen ring protons and the substituent R_1 shows that there are no appreciable amounts of the tautomer D.

The problem of the location of the H^1 proton within the limits of the chelate ring is of considerable interest. Namely whether it is linked by a covalent bond to the sulphur atom and hence by a hydrogen bond to the nitrogen atom or conversely, i.e. whether we are dealing with structure B or C. Experimental data confirmed the second hypothesis. The fact that the H^1 proton is located predominantly at the nitrogen atom is confirmed by the following observations.

a. In the spectra recorded at frequencies of 60 and 100 MHz, the distance between the signal lines corresponding to the H^1 and H^2 protons remained unchanged, which indicates the occurrence of spin–spin coupling between them (J_{H^1,H^2} = 13–15 Hz).

b. The study of the ^{1}H NMR of the products of the substitution of H^1 by a methyl group or deuterium leads to the same conclusion. Such substitution results in the merging of the components of the H^2 doublet into a singlet in addition to the disappearance of the H^1 signal.

c. When the ^{14}N isotope is replaced by ^{15}N, a constant $J_{^{15}N,H^1}$ = 85–87 Hz is observed for the spectrum. Consequently, even if there is an equilibrium at room temperature (see Scheme 1), it is appreciably displaced towards the tautomer C. This equilibrium may be shifted somewhat towards A or B by increasing the temperature.

Thus the compounds initially assigned to the class of mercaptoaldimines can be more correctly regarded as substituted 4-thiolen-2-thiones.

It is noteworthy that a change of solvent hardly affects the parameters of the spectra of these compounds.

The H^1 chemical shifts depend appreciably on the nature of the substituent at the nitrogen atom. The highest value of δH^1 and probably the longest hydrogen bonds are observed for aromatic substituents[61]. δH^1 increases in the sequence

$$H < n\text{-}C_4H_9 < \text{cyclo-}C_6H_{11} < C_6H_5 < \beta\text{-naphthyl.}$$

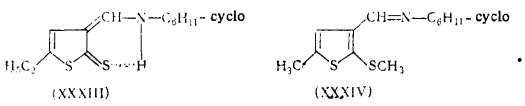
A significant change in the spectra of mercaptoaldimines is observed when they are heated above room temperature: the fine structures of the H^1 and H^2 signals disappear, the H^1 signal broadens so much that it vanishes altogether, and the H^2 signal is converted from a doublet into a broad signal, which is converted into a narrow singlet as the temperature is raised. These findings may be accounted for on the hypothesis that an increase of temperature entails a change in the contents of different forms in the equilibrium mixture.

The study of the H^1 NMR spectra of mercaptoaldimines of the furan series[62] showed that, as in the analogous thiophen derivatives, they have a strong intermolecular hydrogen bond C–S...HN. The H^1 proton (the numbering of the protons and the designation of the tautomeric forms is the same as for the thiophen derivatives) in the chelate ring is located predominantly at the nitrogen atom.

In general, when carbon tetrachloride and dioxan are employed as solvents, a situation similar to that for the analogous thiophen compounds is observed, but in polar solvents, for example in dimethyl sulphoxide (DMSO), the dipole moment of which is 4.3 D,[63] they exist in two forms. Under the influence of DMSO, the spectrum becomes "doubled". One can therefore postulate that, under the influence of this solvent, the intramolecular bond dissociates in some of the type C molecules, but the spin–spin coupling between the H^1 and H^2 protons persists. Thus the replacement of sulphur in the ring by oxygen leads to a weakening of the hydrogen bond in the chelate ring.

The characteristics of thiophen mercaptoaldimines as compounds with an intramolecular hydrogen bond are reflected in their polarographic behaviour. This has been shown for 5-ethyl-2-mercapto-3-thenylidenecyclohexylamine (5-ethyl-3-cyclohexylaminomethylene-1-thiolen-2-thione) and compound (XXXIII).[64] As a result of the protonation of the azomethine atom, it is reduced in

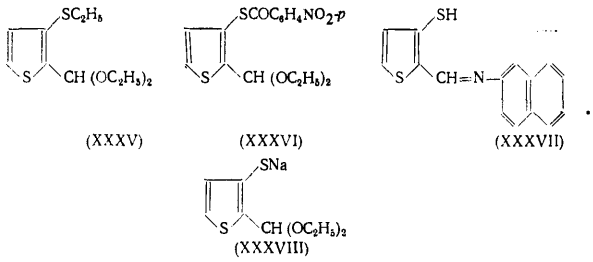
dimethylformamide (DMF) much more readily than compound (XXXIV), in which the hydrogen atom has been substituted and therefore the formation of an intermolecular hydrogen bond is ruled out:



(XXXIII) (XXXIV)

3. Effect of Sodium in Liquid Ammonia on the Diethylacetal of 3-Ethylthiothiophen-2-aldehyde

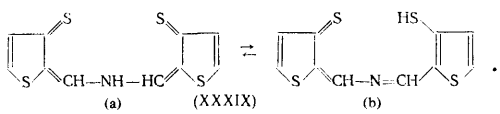
If the possibility of the occurrence of structures of types A–C (Scheme 1) depended ultimately only on the geometry of the ring, one might expect that the acetals of 3-alkylthiothiophen-2-aldehydes (XXXV) should be converted into the isomeric mercaptoaldimines (XVIII). However, the different relative positions of the functional groups in the thiophen ring might entail differences in reactivity. In contrast to the observations for the acetal (XVII), with the acetal (XXXV), the reaction reached completion after the addition of six equivalents of sodium and a high yield of 3-mercapto-2-methylthiophen was obtained[65]:



(XXXV) (XXXVI) (XXXVII) (XXXVIII)

If the amount of added sodium is restricted to two equivalents, it is possible to isolate from the resulting mixture 20–30% of the initial acetal and the dealkylation product in the form of the *p*-nitrobenzoyl derivative (XXXVI) or the Schiff base (XXXVII). Thus the processes involving two equivalents of sodium are in broad outline analogous for the acetals (XVII) and (XXXV) and lead to identical products, but they differ as regards quantitative relations.

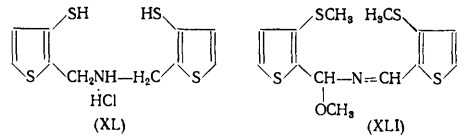
A different situation is observed when an acid is allowed to act on an alkaline solution of the mercaptide (XXXVIII) in the presence of ammonia. At pH ~ 8, under conditions analogous to those in the formation of compound (XVIII), a substance with the composition $C_{10}H_7NS_4$ is isolated and not the mercaptoaldimine. The structure of this compound can be best represented by the formulae (XXXIXa) and (XXXIXb), which reflect its tautomeric nature[66]:



(a) (XXXIX) (b)

This representation is supported by the following data. The molecule of compound (XXXIX) is found to have one active hydrogen atom; its infrared spectrum contains absorption bands in the region 1135–1157 cm^{-1}, which are characteristic of the –C=C–C=S group[67] and a band in the region of 3300 cm^{-1}, which may be assigned to the stretching vibrations of the secondary amino-group. The ^1H NMR spectrum of compound (XXXIX) in dimethyl sulphoxide corresponds better to structure (XXXIXa) than to structure (XXXIXb).

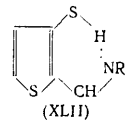
When compound (XXXIX) was treated with lithium aluminium hydride, an amine was obtained, isolated as the hydrochloride (XL). Compound (XXXIX) also yields an acetyl derivative, the reductive desulphuration of which with Raney nickel yields *NN*-dipentylacetamide. All these findings are consistent with formula (XXXIXa), although, as already mentioned, one cannot rule out a tautomeric equilibrium (see above):



(XL) (XLI)

An interesting reaction, confirming the presence in the molecule of (XXXIX) of an $\alpha\beta$-unsaturated thione group, occurs with methyl iodide in a methanol solution of potassium hydroxide. The resulting product probably has the structure (XLI), the formation of which can be accounted for by the 1,4-addition of methanol to the C=C–C=S molecular fragment.

On reaction with amines, compound (XXXIX) yields Schiff bases (XLII), one molecule of (XXXIX) giving two molecules of a new base. This process may be interpreted in different ways, in particular by regarding it as the aminolysis of (XXXIX) with a stage involving addition to the C= N bond[68] or it can be treated, by analogy with the reaction of (XXXIX) with methanol, as 1,4-addition:



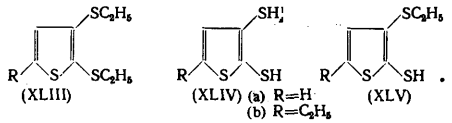
(XLII)

IV. SYNTHESIS OF DIMERCAPTOTHIOPHENS

An interesting type of complex, formed by α-dithiones or α-dithiols, which have unusual physical and chemical properties owing to their specific electronic structure, was discovered comparatively recently[69–75]. Compounds of this type, in particular the dimercapto-derivatives of benzene[76], can also be used as starting materials for further syntheses.

Of the four possible dimercaptothiophens, Gronowitz described 3,4-dimercaptothiophen[77]. His attempts to obtain the 2,4- and 2,3-isomers from the corresponding bromomercaptothiophens and also 2,5-dimercaptothiophen

from 2,5-dilithiothiophen or from magnesium bromide derivatives were unsuccessful[77,78]. The synthesis of 2,3-dimercaptothiophen derivatives was achieved by the dealkylation of di(alkylthio)-compounds of type (XLIII) with sodium in liquid ammonia[79]:



(XLIII) (XLIV) (a) R=H (b) R=C_2H_5 (XLV)

The reaction takes place smoothly and treatment with four equivalents of sodium per mole of the bis-sulphide resulted in the isolation of the corresponding dithiols (XLIVa) and (XLIVb) in a yield of 60–80%. These are viscous, coloured, liquids which vacuum-distil with decomposition. Since the bis-sulphides (XLIII) contain two identical functional groups in different positions in the thiophen ring, the problem arises whether they are dealkylated by sodium in liquid ammonia in any specific order.

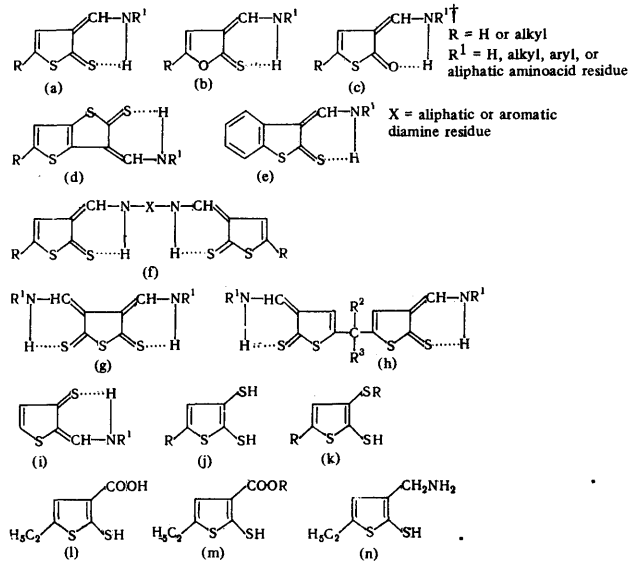
Comparatively recently it has been suggested[80,81] that the mode of cleavage of an organic sulphide by alkali metals depends to a considerably degree on the numerical values of the acidities of the mercaptide ions and carbanions formed. In the case of di(alkylthio)thiophens of type (XLIII), which have the same aliphatic group linked to the sulphur atom, the principal factor determining the order of dealkylation is probably the stabilities of the resulting thiophen-2-thiol or thiophen-3-thiol. Evidently the first is stabilised to a greater extent, since the delocalisation of the negative charge extends over the entire aromatic ring, while in the 3-isomer the delocalisation is restriced to the π-electron 1,3-system[82]:

In fact when 2,3-di(ethylthio)thiophen and 4,5-di(ethylthio)-2-ethylthiophen were treated with two equivalents of sodium in liquid ammonia, the corresponding mercaptosulphides (XLVa) and (XLVb) were isolated in a yield up to 80%.[83] That the latter are α-mercapto-derivatives of thiophen was confirmed by ^{1}H NMR data. It was found that the cleavage products (XLIIIa) and (XLIIIb) have chemical shifts and spectra identical with those of 3-ethylthio-2-mercaptothiophen and 2-ethyl-4-ethylthio-5-mercaptothiophen respectively, which were obtained by an independent method.

The delocalisation effect probably plays a decisive role in determining the mode of cleavage of bis-sulphide derivatives of thiophen with different alkylthio-substituents, for example 2-butylthio-3-ethylthiothiophen. If it is assumed that the ease of removal of the primary alkyl group as carbanions decreases in the sequence $CH_3 > C_2H_5 > C_4H_9$,[81] then the ethyl group should be preferentially eliminated from this bis-sulphide with formation of 2-butylthio-3-mercaptothiophen. However, the only product isolated in the reaction of this bis-sulphide with sodium in liquid ammonia was 3-ethylthio-2-mercaptothiophen.

V. TYPES OF LIGANDS AND CERTAIN CHELATE COMPOUNDS

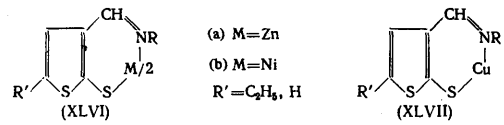
The formulae of the principal types of di- and tetrafunctional complex-forming compounds synthesised by the authors are given below¶:



5-Ethyl-2-mercaptothiophen-3-carboxylic acid (l)—the thiophen analogue of thiosalicylic acid—was obtained in 90% yield by the action of two equivalents of sodium in liquid ammonia on 5-ethyl-2-ethylthiothiophen-3-carboxylic acid[41]. The acid (l) forms a disulphide and in an alkaline medium is alkylated at the mercapto-group. Esterification in the presence of hydrogen chloride results in the formation of the corresponding esters (m).[85]

Some of the synthesised thiophen derivatives of types (a), (b), (c), (d), (e), (f), (i), (k), and (m) have been used to prepare chelate complexes with copper, zinc, and nickel ions. They were obtained by the reaction of the ligands in a suitable solvent with aqueous methanol solutions of the metal acetate or by the "method of nascent reagents"[86]. The data concerning the chelate complexes isolated are described in the literature[41,42,59].

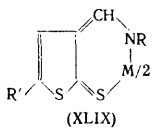
Compounds of the type (a) form with zinc and nickel ions the chelates (XLVIa) and (XLVIb) in which the ligand : metal ratio is 2 : 1, while in the copper complexes (XLVII) and in the complexes (XLVIII) of tetradentate ligands of type (f) the ratio is 1 : 1.



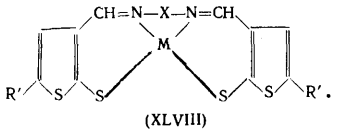
(XLVI) (a) M=Zn (b) M=Ni R′=C_2H_5, H (XLVII)

¶ For brevity only one of the possible tautomeric forms is quoted. For compounds (d), (e), and (h), the ^{1}H NMR spectra were not investigated and the thione structures are quoted by analogy.

† Compounds with the structure (c), which are oxygen analogues of mercaptoaldimine derivatives of thiophen, are formed when primary amines react with *NN*-disubstituted 5-alkyl-3-aminomethylene-4-thiolen-2-ones[84].



(XLIX)

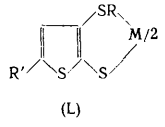


(XLVIII)

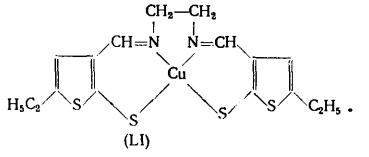
These are brightly coloured crystalline compounds fairly readily soluble in the usual organic solvents, for example in benzene and chloroform.

The infrared spectra of chelates of type (XLVI) contain stretching vibration bands in the region 1595–1610 cm^{-1}, which may be assigned to the vibrations of the coordinated C=N group[41] (cf. Trompson and Busch[87]). However, one should bear in mind that the structure of the metal chelates represented by formulae (XLVI), (XLVIII), etc. is not the only one possible, since the tautomerism characteristic of the corresponding ligands can also obtain in the chelate complexes formed by them. The problem of which form, (XLVI) or (XLIX), predominates under particular conditions must be regarded as open at the present time.

On interaction with nickel and copper acetates in methanol, dimercaptothiophen (j) forms black infusible powders insoluble in the usual solvents[79]. Probably they are polymeric (oligomeric) complexes analogous to the polymeric bisdithioglyoxalnickel complexes[69]. On the other hand, alkylthiomercaptothiophens (m) form with nickel acetate the chelate compounds (L) in which the metal : ligand ratio is 1 : 2. In contrast to the complexes formed by dimercaptothiophen (j), they have definite melting points:



(L)



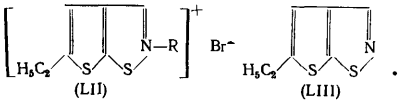
(LI)

Valuable information about the type of metal–ligand bond in complexes may be obtained from ESR spectra. This of course applies only to paramagnetic compounds incorporating a metal atom (ion) with one or several unpaired electrons. An example of such a compound is [bis-(5-ethyl-2-mercapto-3-thenylidene)ethylenediaminato]copper(II) (LI), in which the immediate environment of the central metal atom resembles that in copper(II) complexes with the Schiff bases of salicylaldehyde.

The ESR spectrum of this complex[88] contains, apart from the four lines generated as a result of the interaction of the unpaired electron spin with the spins of the copper nuclei[63,65], an additional hyperfine 11-line structure. Detailed analysis of the spectrum combined with a comparison with the literature data led to the conclusion that these 11 additional hyperfine structure lines are due to the pair interactions of the unpaired electron spin with the spins of the nuclei of ^{14}N and the CH protons.

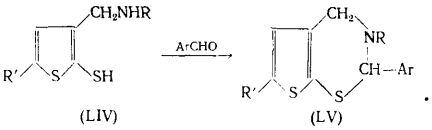
VI. SOME REACTIONS OF THE MERCAPTOALDIMINES AND THEIR CHELATES

The presence in mercaptoaldimines of type (XVIII) of two highly reactive functional groups linked to adjacent carbon atoms of the thiophen ring creates interesting possibilities for the synthesis of new condensed bicyclic compounds. One of the ways in which such systems can be obtained consists in simple bromination of compound (XVIII) by an equimolar amount of bromine in chloroform. The reaction is accompanied by the evolution of hydrogen bromide and probably proceeds via a stage involving the formation of sulphene bromide, which undergoes ring closure to the bicyclic system (LII):[43]



(LII) (LIII)

As a result of hydrolysis, compound (LII, R = H) loses HBr, yielding 5-ethylthieno[3,2-*d*]isothiazole (LIII), which has also been obtained by the oxidation of 5-ethyl-2-mercapto-3-thenylamine (LIVa) with iodine. Mercaptothenylamines (LIVa) and (LIVb), formed in high yields when the corresponding mercaptoaldimines are reduced with lithium aluminium hydride[43], are also capable of entering into reactions leading to the formation of condensed systems. Thus they react with aldehydes to form derivatives belonging to the class of 3,4-dihydrothieno-1,3-thiazines (LV):[89]



(LIV) (LV)

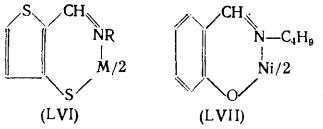
(a) R = H
(b) R = cyclo-C_6H_{11}; R′ = C_2H_5.

The above examples do not of course exhaust the possibilities of the use of different types of thiophen derivatives in syntheses. They illustrate only one of the developments in the chemistry of these compounds.

At the same time, as noted in the introduction, the study of the reactivities of the coordinated ligands examined is of greatest interest. Here we may note that we are at present only at the beginning of the development of this field.

On the basis of studies related to this field, Jones[90–93] arrived at the following most general conclusion: coordination does not alter the orientation of the substitution in the organic part of the ligand, but, by influencing the nature of the transition state, can cause appreciable changes in the rate of reaction. For example, many electrophilic substitution reactions of bis-(8-hydroxyquinolinato)copper take place more readily than with the free ligand[93].

Chelates of type (XLVI) and (LVI) can be regarded as condensed systems, one of the rings of which includes a metal ion as a unit. The problem of the reactivity of such compounds, which are readily susceptible to the action of both electrophilic and nucleophilic agents since they incorporate the thiophen ring, is of considerable interest:



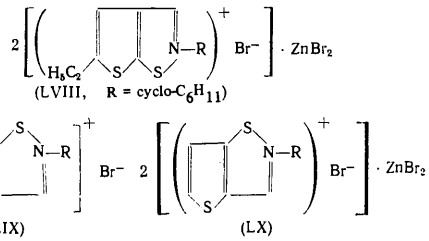
(LVI) (LVII)

(a) M = Zn; (b) M = Ni; R = cyclo-C_6H_{11}.

Treatment of bis-(salicylidenebutylaminato)nickel (LVII) with *N*-bromosuccinimide (NBS) is known to yield a dibromo-derivative[94,95], but the question of its structure remains open. It has been shown only recently[96] that initially bromine enters the 5-position of each ring and on subsequent bromination also the 3-position. The complex with cobalt(III) reacts similarly. Thus, when bromine is introduced by treatment by NBS, the chelate ring (LVII)

is not cleaved. A different behaviour is observed when the chelates (XLVI) and (LVI) are subjected to attack by bromine and NBS.[97] The nickel chelate (XLVIb, R = cyclo-C_6H_{11}, R′ = C_2H_5) reacts with two moles of bromine in chloroform to form 2-cyclohexyl-5-ethylthieno[3,2-*d*]-isothiazolium bromide, which is isolated from the mixture as the perbromide; as stated above, this compound is also obtained by the direct action of bromine on the corresponding ligand. The results are similar when NBS is employed as a brominating agent. When the zinc chelate (XLVIa, R = cyclo-C_6H_{11}, R′ = C_2H_5) is treated with bromine, a complex of thienoisothiazolium bromide with zinc bromide (LVIII) is formed.

In contrast to (XLVI), in the complexes (LVI) there are two hydrogen atoms in each thiophen ring potentially capable of being substituted by electrophilic agents. Consequently, one might expect here the formation of bromination products if the rate of substitution exceeded the rate of reaction of the electrophilic agent with the chelate ring. However, when the nickel chelate (LVIb) is treated with two moles of bromine or NBS in chloroform, the chelate ring is in fact also cleaved and 2-cyclohexylthieno[2,3-*d*]isothiazolium bromide (LIX) is formed in a mixture with its perbromide[97]:



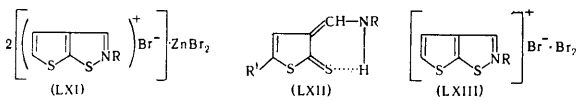
(LVIII, R = cyclo-C_6H_{11})

(LIX) (LX)

The zinc chelate (LVIa) reacts with bromine similarly to the nickel chelate, forming the complex (LX).

Summarising, one may say that the nickel and zinc chelates of both types (XLVIa and XLVIb, R = cyclo-C_6H_{11}, R′ = C_2H_5) and (LVI) are unstable under conditions corresponding to bromination with bromine and NBS.

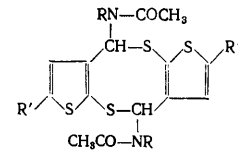
The study of the action of bromine in chloroform on the chelate (XLVIa, R = cyclo-C_6H_{11}, R′ = H)[42] showed that, as for the homologue substituted in the 5-position, the chelate ring is the primary site of attack, which ultimately leads to the formation of the complex (LXI) with zinc bromide. A similar bicyclic system is obtained also when the Schiff base (LXIIa) is brominated, the reaction product being isolated as the perbromide (LXIII). Consequently in both cases the α-hydrogen atom in the thiophen ring is not substituted:



(LXI) (LXII) (LXIII)

(a) R′ = H; (b) R′ = C_2H_5, R = cyclo-C_6H_{11}.

Together with bromination, the action of acetic anhydride in the presence of boron trifluoride-ether was investigated; this method has been successfully employed for the acetylation of metal acetylacetonates[98]. However, it proved impossible to introduce the acetyl group into the thiophen ring of the chelate (XLVIa, R = cyclo-C_6H_{11}, R′ = H) under these conditions. The final product isolated was a substance for which the structure of dithienodithiocine (LXIVa) was proposed on the basis of infrared spectra and data for reductive desulphuration; it is also formed when compound (LXIIa) is treated with acetic anhydride. A homologue of compound (LXIVa), compound (LXIVb), was obtained under the same conditions:

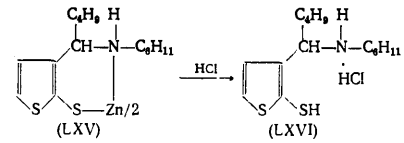


(LXIVa, R′ = H); (LXIVb, R′ = C_2H_5, R = cyclo-C_6H_{11})

Summarising, one can also say that the presence of an unsubstituted α-position in chelates of type (XLVI) does not entail a change in the direction of electrophilic attack compared with their substituted analogues. In such systems the process involving the chelate ring, which ultimately results in its decomposition, also predominates. The deactivation of the thiophen ring probably plays a significant role in this phenomenon, but one cannot rule out *a priori* an effect of the geometrical parameters of the condensed chelate ring, which may influence its stability.

It is quite evident that organometallic compounds behaving as nucleophilic agents can act also on other centres in the molecule of the type (XLVIa) complex. In principle, these chelates may be capable of coordination via the thiophen sulphur atom. As mentioned above, some investigators believe that such a process is a preliminary stage in the metallation of the thiophen ring by organometallic compounds, for example n-butyl-lithium.

By treating the chelate (XLVIa, R = cyclo-C_6H_{11}, R′ = H) with an excess of butyl-lithium, compound (LXV) was obtained[42], which on treatment with hydrogen chloride yields the hydrochloride (LXVI). The formation of compound (LXV) might have been regarded as an example of the addition of an organometallic compound to the azomethine bond, which is characteristic of aromatic and aliphatic aldimines[99] and pyridine bases[100]:



(LXV) (LXVI)

However, since the nitrogen atom in the initial chelate is coordinated, forming a unit of the chelate ring, compound (LXV) is probably formed by another mechanism. In order to determine whether butyl-lithium is coordinated to the ring sulphur atom at any stage, a study was made of the reaction of the chelate (XLVIa, R′ = H) with butyl-lithium and carbon dioxide but carboxylic acid was never detected.

Here one should note that, in an examination of the reactions of type (XLVI) chelates, one cannot rule out the possibility of their involvement in the reactions in the tautomeric form (XLIX).

---o0o---

In undertaking this review, the authors wished to draw attention to the methods of preparation and certain properties of complex-forming compounds which in a certain sense may be regarded as new. The metal chelates mentioned in the review, the number of which is fairly limited have been treated mainly as derivatives indicating the complex-forming properties of the compounds synthesised. The problem of their steric structure and other physical properties as well as the synthesis of other chelate compounds of this series will be the subject of future investigations.

Advances in the Chemistry of Aliphatic Diazoketones

A.L.Fridman, G.S.Ismagilova, V.S.Zalesov, and S.S.Novikov

The review deals with the methods of synthesis of aliphatic diazoketones and gives a systematic account of the extensive literature data on their chemistry. The work on the physical properties, structures, and ultraviolet, infrared, and NMR spectra of diazoketones is summarised in a separate section where problems of $p-\pi$ conjugation and rotational isomerism are also discussed. The concluding section deals with the hitherto few but interesting data on the biological activity of diazoketones.
The bibliography includes 295 references.

V. Some aspects of practical applications.	385

INTRODUCTION

The remarkable part which aliphatic diazoketones have played in the development of organic chemistry is well known. Numerous original papers, reviews, and monographs have been devoted to these compounds[1-10].

The aim of the present review is to give a systematic account of the literature data for the methods of synthesis, spectra, structure, and chemical properties of diazoketones. Earlier such attempts were not made, although they merit special consideration in view of some of their characteristics.

The earlier reviews emphasise primarily the fact that aliphatic diazo-compounds have common properties. Therefore these reviews and the present review are not mutually exclusive but complement one another. The inevitable repetition may be justified in each case by the novelty of approach to the analysis of literature data and by the authors' wish to give a complete presentation of the available information.

In recent years interesting data were obtained on the structure of diazoketones, which, in contrast to diazoalkanes, have many structural characteristics and show an unusual chemical behaviour owing to the presence of the α-carbonyl group. $p-\pi$ conjugation, which involves a chain of five atoms in the $COCH_2N_2$ fragment, leads to the appearance of partial bonds. As a result, free rotation about the C–C bond is hindered and *cis–trans* conformers are produced. In the discussion of the structure of diazoketones, ultraviolet, infrared, and NMR spectroscopic data, dipole moments, and also calculations by the molecular orbital method are invoked.

The present review gives a brief account of the methods of synthesis of diazoketones. In order to demonstrate the large number and great variety of procedures, we have described both well known methods developed long ago as well as methods which have appeared recently. In the discussion of chemical reactions, certain reactions of diazoketones have been omitted. In particular the large series of studies on the addition of diazoketones to double bonds is not dealt with, since many excellent reviews have been devoted to this reaction[8,9]. On the other hand, we considered the reactions which have not as yet been developed adequately but have undoubted interest for the further development of the chemistry of diazo-compounds.

The last section of the review deals with data on the biological activity of diazocarbonyl compounds. The fact that certain diazoketones inhibit the growth of malignant tumours is noteworthy.

II. METHODS OF SYNTHESIS

The methods of preparation of diazoketones may be divided into seven principal groups: (1) *C*-acylation of aliphatic diazo-compounds; (2) reaction of organic azides with active methylene compounds; (3) oxidation of monohydrazones of α-aldehydoketones and α-diketones; (4) diazotisation of primary amines containing a carbonyl group; (5) diazotisation of ketoximes; (6) alkaline cleavage of *N*-acyl-*N*-nitrosamines; (7) alkaline cleavage of tosylhydrazones of α-carbonyl compounds. Within the limits of the scope of the present review, each of the above methods is discussed below.

1. *C*-Acylation of Aliphatic Diazo-compounds

The method consists of the direct acylation of diazo-derivatives by carboxylic acid halides and anhydrides. The nature of the product formed depends considerably on the reaction conditions and on the structure of the diazo-compounds and acylating agents. For example, acetyl chloride reacts with diazoacetic ester according to the mechanism[11]

$$ClCOCH_3 + N_2CHCOOC_2H_5 \longrightarrow C_2H_5COOCN_2COCH_3.$$

The reaction of carboxylic acid chlorides with diazo-compounds without an activated α-hydrogen atom takes place differently[11]:

$$R{-}COCl + N_2C(C_6H_5)_2 \rightarrow R{-}\overset{\overset{O}{\|}}{C}{-}\overset{\overset{Cl}{|}}{C}(C_6H_5)_2 + N_2 .$$

The reaction of aromatic acid chlorides with diazomethane at room temperature using equimolar amounts of the reactants leads to the formation of aryl chloromethyl ketones[12-15]:

$$C_6H_5COCl+CH_2N_2\longrightarrow C_6H_5COCH_2Cl+N_2\,.$$

C-Acylation of diazoalkanes takes place in the presence of an excess of the latter at a reduced temperature (0–5°C) and may be described by the following mechanism[16-19]:

$$R-COCl+2CH_2N_2\longrightarrow R-COCHN_2+HCl,$$
$$HCl+CH_2N_2\longrightarrow CH_3Cl+N_2\,.$$

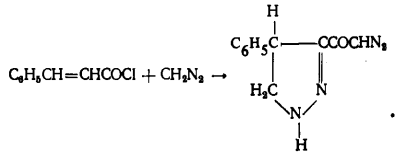
In the presence of a deficiency of diazoalkane, a side reaction leading to the formation of a chloromethyl ketone is possible:

$$HCl+R-COCHN_2\longrightarrow R-COCH_2Cl+N_2\,.$$

Triethylamine may be used to combine with hydrogen chloride[20]. An excess of diazoalkane promotes the formation of an azine[21,22].

The method of *C*-acylation of diazo-compounds (the Arndt–Eistert method) has been developed in fair detail and is widely used to synthesise not only primary but also secondary diazoketones[23]. It constitutes the basis of the synthesis of mono-, bis-, and tris-diazoketones[24,25]. Thus 1,3,5-tridiazoacetylbenzene has been obtained by treating trimesoyl chloride with an excess of diazomethane[25].

The reaction of diazomethane with unsaturated acid chlorides results in its 1,3-cycloaddition to the double bond simultaneously with *C*-acylation[26-28]:



Many different diazoketones, including derivatives with heterocyclic and perfluoroalkyl substituents[29-32] and also with heteroatoms in the chain, have been obtained by the Arndt–Eistert method[33,34]:

$$ClCOCH_2N(NO_2)CH_2COCl+CH_2N_2\rightarrow N_2CHCOCH_2N(NO_2)CH_2COCHN_2\,.$$

A systematic account of all past studies on the Arndt–Eistert reaction is given in a review by Bachmann and Struve[1].

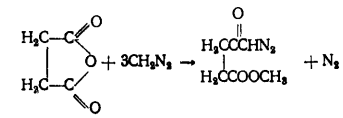
While *C*-acylation of diazo-compounds by carboxylic acid chlorides and bromides has been investigated in fair detail, acid fluorides are rarely used for this purpose. The synthesis of diazoacetaldehydes may serve as an example[35]:

$$HC(=O)F+CH_2N_2\rightarrow HC(=O)CHN_2\,.$$

There are also only a few examples of the *C*-acylation of diazo-compounds by carboxylic acid anhydrides[5,36-40]. Benzoic acid anhydride reacts with diazomethane to form diazoacetophenone[36]. Trifluorodiazoacetone is formed in the reaction between diazomethane and the mixed anhydride of acetic and trifluoroacetic acids[5]:

$$F_3CC(=O)-O-C(=O)CH_3+2CH_2N_2\rightarrow F_3CC(=O)CHN_2+CH_3COOCH_3+N_2\,.$$

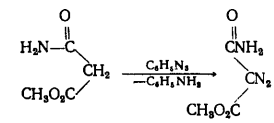
Anhydrides of dibasic acids are converted into monodiazoketones[37]:



The mechanism of the *C*-acylation of diazoalkanes has been frequently discussed in the literature and therefore we do not consider it here[2-4].

2. Reactions of Organic Azides with Active Methylene Compounds

The reaction involving the introduction of diazo-groups into an active methylene group with the aid of phenyl azide was discovered in 1910 by Dimroth[41]:



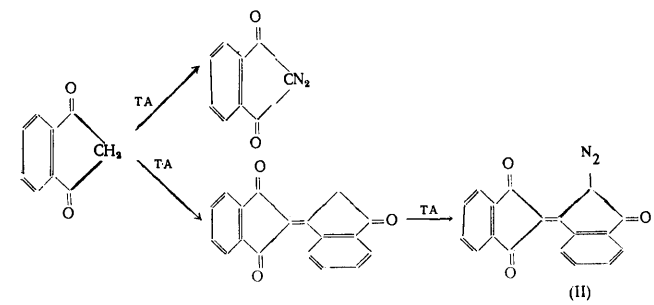
Later it was shown that *p*-tosyl azide can also be used to transfer the diazo-group[42]. However, at the time this interesting method of preparing diazo-compounds did not attract attention and its detailed development began as late as 1953[43-50]. The method proved to be suitable for the synthesis of cyclic diazo-compounds[44-48], including diazoketones[49,50]. The reaction is carried out in ethanol in the presence of potassium ethoxide, triethylamine[51,52], or potassium hydroxide[53] and also in methanol in the presence of sodium methoxide[54].

Diazoketones are not always obtained in a pure form owing to the formation of secondary reaction products. Thus, in the reaction of *p*-tosyl azide with benzoyl-(*p*-nitrobenzoyl)methane in methylene chloride in the presence of pyridine, the process does not stop at the stage involving the formation of product (I):

$$C_6H_5COCH_2C_6H_4NO_2\text{-}p\longrightarrow C_6H_5COCN_2C_6H_4NO_2\text{-}p\,.$$
(I)

The product is partly cleaved into benzoyl diazomethane and *p*-nitrobenzoyldiazomethane. The separation of the mixture of diazo-derivatives is difficult[55]. Pure diazoketone (I) may be obtained when the reaction is carried out in ethanol with added catalytic amounts of triethylamine[53,55].

The formation of a mixture of diazo-compounds was also noted in the synthesis of 2-diazoindan-1,3-dione. The principal reaction product is 2-diazo-1′,3,3′-trioxo-1,2′-bisindanylidene (II), which arises as a result of the self-condensation of indan-1,3-dione under the influence of a base. The self-condensation product reacts further with tosyl azide (TA)[51]:



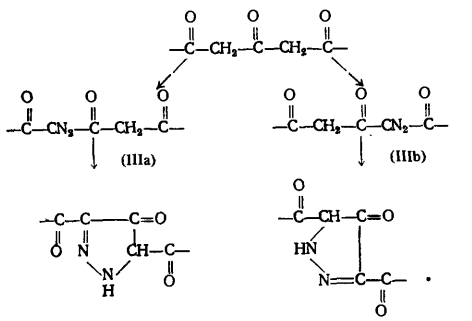
(II)

Carbonyl compounds of the type $-CH_2C(=O)-$ react with sulphonyl azides to form diazo-derivatives when the C–H group is sufficiently activated[56-61].

β-Oxoaldehydes are convenient acceptors of the diazo-group. Ketones, which are unsuitable for the direct introduction of the diazo-group, are converted by the Claisen condensation into β-oxocarbonyl compounds. The latter are smoothly converted into diazoketones, with elimination of the formyl group[62,63]:

α-Formylcycloalkanones are also readily converted into diazocycloalkanones[62-65]:

In the reaction of 1,3,5-triketones with tosyl azide, pyrazolones were isolated in high yields, instead of the expected bisdiazoketones. The formation of the pyrazolones is due to an intramolecular reaction of the intermediate diazoketone (IIIa,b)[66]:



However, when the reactants are mixed slowly, the reaction can be driven towards the formation of bisdiazoketones[67]:

$$C_6H_5COCH_2COCH_2COC_6H_5 + CH_3C_6H_4SO_2N_3 \rightarrow C_6H_5COCN_2COCN_2COC_6H_5 .$$

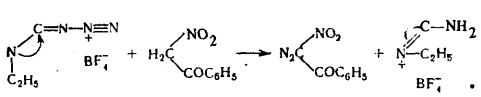
Diazoketones are formed in the reaction of enamines with arenesulphonyl azides[68,69]:

$$C_6H_5COCH{=}CHN(CH_3)C_6H_5 \xrightarrow{TA} C_6H_5COCHN_2 .$$

The method involving the transfer of the diazo-group to active methylene compounds has proved suitable for the synthesis of diazoaldehydes[68] and other diazo-compounds: diazosulphones[54,70], α-diazophosphinoketones, and α-diazophosphinoethers[71,72]. For example, diazoaldehydes are formed according to the mechanism:

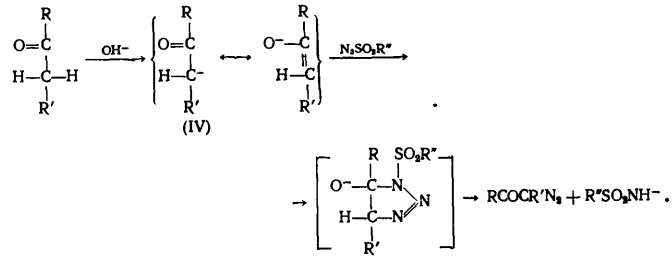
$$(H_3C)_2N{-}CH{=}\overset{R}{\overset{|}{C}}{-}CHO \xrightarrow{TA} RCN_2CHO .$$

Attempts to extend this method to the synthesis of nitrodiazoketones have been described. Azidinium salts were used as donors of the diazo-group. The reaction takes place in methanol at room temperature in the presence of sodium acetate[73]:



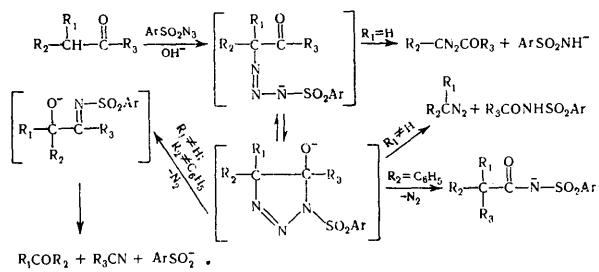
Various mechanisms for the reaction of organic azides with active methylene compounds have been proposed[56,58,74].

The cyclic mechanism is the most probable. In the first stage the diazo-group acceptor is converted under the influence of the base into a carbanion in which a double bond may be formed. The subsequent addition of the sulphonyl azide to the anion (IV) leads to the formation of a triazoline which dissociates into a diazo-compound and a sulphonamide[56,58]:



Some workers believe that the formation of a cyclic intermediate product is possible only when the activated methylene group contains one hydrogen atom[74].

A general mechanism has been proposed for the transfer of the diazo-group, which can explain the formation of diazoketones, amides, ketones, cyano-derivatives, and sulphonate salts[74]:



3. Oxidation of Monohydrazones of α-Aldehydoketones and α-Diketones

In 1889 Curtius obtained benzoylphenyldiazomethane by oxidising benzilhydrazone with yellow mercury(II) oxide in cold benzene solution[75]:

$$C_6H_5COC{=}N{-}NH_2 + HgO \rightarrow \underset{\displaystyle C_6H_5}{\overset{\displaystyle O}{\overset{\|}{C}}}{-}\overset{\displaystyle C_6H_5}{\overset{|}{C}}{-}CN_2 + Hg + H_2O .$$

Subsequently mercury(II) oxide was used for this purpose also by other investigators[76-86].

Other metal oxides are also widely used for the synthesis of diazoketones. The oxidation of diacetyl monohydrazone with silver oxide in the presence of anhydrous sodium sulphate has been described[87]:

$$\underset{\displaystyle O\ \ CH_3}{\overset{\displaystyle O}{\overset{\|}{C}}}{-}C{=}N{-}NH_2 + Ag_2O \xrightarrow{Na_2SO_4} \underset{\displaystyle O\ \ N_2}{\overset{\displaystyle O}{\overset{\|}{C}}}{-}CCH_3 + Ag + Na_2SO_4 \cdot H_2O .$$

As a rule, in the presence of drying agents such as sodium or magnesium sulphate silver oxide is used only in those cases where other oxidants (HgO, CuO, PbO) are ineffective[88].

A mixture of sodium hydroxide and calcium hypochlorite in aqueous methanol has been used to synthesise 3-diazo-D-camphor[89]. Recently activated manganese dioxide has been suggested as an oxidant. The reaction was carried

out in chloroform at room temperature, diazoketones being formed in quantitative yields[89-91]:

$$RCOCH=N-NH_2+MnO_2\longrightarrow RCOCHN_2 .$$

It is noteworthy that the oxidation of hydrazones by metal oxides is used mainly for the preparation of acyclic monodiazoketones and aryl-substituted diazomethanes[92].

4. Diazotisation of Primary Amines

This method has been used to synthesise diazoacetophenone[93]:

$$C_6H_5COCH_2NH_2\cdot HCl+NaNO_2\longrightarrow C_6H_5COCHN_2 .$$

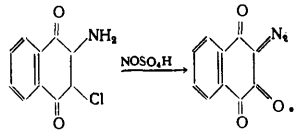
Later the method was employed to synthesise many cyclic diazoketones[93-97]. Diazotisation of an amino-group located between two carbonyl groups leads to the formation of the corresponding diazoketones[98-101]:

$$RC(=O)-CH(NH_2)-CR(=O)\rightarrow RC(=O)-CN_2-CR(=O) .$$

Intermediates obtained by the reduction of nitration, nitrosation, or azo-coupling products and not the pure amines are as a rule employed in the reaction[5]. The diazotisation takes place via a diazohydroxide, which, depending on the mobility of the α-atom, is converted either into a diazo-compound or an alcohol is formed with evolution of nitrogen[3]. In the case of α-aminoketones and α-aminoacid esters, an activated methylene group removes a proton with formation of diazoketones or diazoesters:

$$RCOCH_2NH_2\cdot HCl+NaNO_2\xrightarrow{H^+}RCOCH_2NH{-}NO\rightarrow RCON{=}NOH\rightarrow RCOCHN_2+H_2O .$$

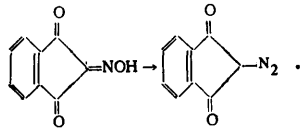
The use of nitrosylsulphuric acid as a nitrosating agent has been described[102,103]. The diazotisation of 2-amino-3-chloro-1,4-naphthoquinone with this reagent is accompanied by oxidation, which leads to the formation of 2-diazo-1,3,4-trioxotetralin[102]:



Similarly 2,5-diamino-3,6-dichlorobenzoquinone forms 1,4-bisdiazotetraoxocyclohexane[102].

5. Diazotisation of Oximes

Several examples of the conversion of cyclic ketoximes into α-diazoketones under the influence of chloramine via the familiar Forster reaction[104] have been described:



The reaction is carried out in a cooled alkaline medium. The method is used to synthesise a wide variety of cyclic diazoketones[105-108]. The synthesis of condensed polycyclic bisdiazoketones was described recently[109].

6. Alkaline Cleavage of *N*-Acyl-*N*-nitrosamines

Diazoketones with the structure $H_3CCOCN_2CH_2R$ may be obtained via the mechanism[110]

$$RCH(NH_2)COOCH_3 \xrightarrow[\text{pyridine}]{Ac_2O} RCH(COCH_3)-NH-COCH_3 \xrightarrow{N_2O_3} RCH(COCH_3)-N(NO)-COCH_3 \xrightarrow{NaOCH_3} RC(=N_2)-COCH_3 .$$

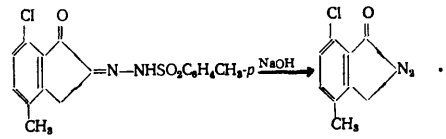
The conversion of aminoacids into *N*-acylaminoketones has been investigated in detail[111]. *N*-Nitroso-derivatives are formed in the nitrosation of *N*-acylaminoketones with N_2O_3 in glacial acetic acid. They are subsequently decomposed to diazoketones with sodium methoxide[110]. Benzoylphenyldiazomethane with a labelled carbonyl carbon atom was obtained by the above mechanism[111].

Alkaline cleavage of nitrosourethanes containing the sulphone group makes it possible to obtain diazosulphones[112]:

$$H_3CCOC_6H_4SO_2CH_2NHCOOC_2H_5 \xrightarrow{KOH} H_3CCOC_6H_4SO_2CHN_2 .$$

7. Alkaline Cleavage of Tosylhydrazones of α-Carbonyl Compounds

The method was first used to synthesise 7-chloro-2-diazo-4-methylindan-1-one[105]:



The reaction proved convenient for the synthesis of cyclic diazoketones. It takes place in pentane, ether, and methylene chloride at a low temperature in the presence of sodium hydroxide or basic alumina. A series of papers dealing with detailed studies of this reaction have been published[25,113-118].

Other methods of synthesising diazocarbonyl compounds are also known. For example, the synthesis of *N*-acetyldiazoacetamide by the reduction of *N*-acetyl-3-benzylsydnoneamine in methanol in the presence of palladised charcoal has been described[119].

In choosing the method of synthesis of diazoketones, it is of course necessary to take into account the specific features of the method and the characteristics of the structure of the diazo-derivatives. The Arndt–Eistert method and the reactions of organic azides with active methylene compounds are the most common and universal.

III. SPECTRA AND STRUCTURE

1. General Characteristics

The lowest representatives of the diazoketone series are liquids. For example, diazoacetone is a mobile pale-yellow liquid with b.p. 46–47°/13 mm and d_4^{20} = 1.0864.[120] 1-Diazo-2,3-dimethylbutan-2-one is a brick-red liquid with b.p. 69°/15 mm, d_4^{25} = 0.9630, and n_D^{25} = 1.4709.[121] The higher diazoketones are crystalline substances. Depending on the substituents, their colour

varies from lemon-yellow to white. As a rule, diazoketones are readily soluble in organic solvents. The accumulation of electronegative substituents in the diazoketone molecule, for example of carbonyl and nitro-groups, leads to an increase of the melting point, a "lightening" of the colour, and an increase of chemical stability.

Certain diazoketones have a specific odour, for example diazoacetophenone and diazoacetone.

In contrast to diazoalkanes, diazoketones can be stored for a long time in the dark at 0–20°C; they decompose under the influence of sunlight. The liquid compounds may decompose on coming into contact with a rough surface. Special care is necessary in the distillation of diazoketones: rapid heating (at about 100°C) leads to explosion[5].

2. Spectra and Structure

The ultraviolet spectra of diazoketones have two absorption bands: in the range 240–270 nm and in the range 270–301 nm.[122–125] Table 1 shows the dependence of the electronic spectra on solvents. In protic solvents, the intensity of the first band diminishes relative to that of the second[126].

Table 1. Ultraviolet spectra of certain diazoketones[51,122].

Diazoketone	λ_{max}, nm		ϵ_{max}*, litre mole^{-1} cm^{-1}	Solvent
$N_2CHCO(CH_2)_4COCHN_2$	247		24 800	Dioxan
	248	273	21 200	Chloroform
	248	270	19 100	Ethanol
			16 700	
$(CH_2)_3COCHN_2$	251		6 840	Methylene chloride
	250	270	6 990	Ethanol
	247	275	6 600	Water
			4 600	
	244		4 550	Methanol

* $\epsilon max = (1/bc)\ lg_{10}(I_0/I)$.

The absorption spectra of 1,8-bisdiazo-octane-2,7-dione recorded in an acetonitrile–water solvent mixture intersect at an isosbestic point[122]. It would appear that this can be readily accounted for by iso–diazo (1) or diazoketo–diazoenol (2) tautomerism:

$$R{-}CO\overline{C}H{-}\overset{+}{\overline{N}}{\equiv}N \rightleftarrows R{-}CO{-}\overline{C}{=}\overset{+}{\overline{N}}{=}NH, \quad (1)$$

$$R{-}CO\overline{C}H{-}\overset{+}{\overline{N}}{\equiv}N \rightleftarrows R{-}C(OH){=}\overline{C}{=}\overset{+}{\overline{N}}{=}\overline{N}. \quad (2)$$

However, the ultraviolet spectra of benzoyldiazoacetic ester and dimethyl $\alpha\alpha'$-bisdiazo-$\beta\beta'$-dioxoadipate, which show no tendency towards tautomeric conversion, also have an isosbestic point[125]. Fahr rejected the possibility of an intramolecular rearrangement and explained the presence of the isosbestic point by the reaction of the diazocarbonyl compound with the hydroxyl-containing solvent[125].

Special studies on the ultraviolet spectra of diazoketones in hydroxyl-containing solvents showed that Fahr's hypothesis of an intermolecular reaction between the diazoketone and the solvent cannot account for the spectra. The shift of the absorption band from 250 to 300 nm cannot be explained solely by an intermolecular reaction between the diazoketone and the solvent, since the energy difference between the two bands is fairly large (11.0 kcal mole^{-1}). It is most probable that in this case the band splits owing to a conformational equilibrium[127].

The spectra of diazoacetone in hydroxyl-containing solvents also have an isosbestic point. It could be accounted for by the presence of the *cis*- and *trans*-isomers of the diazoketone owing to the different $\pi \rightarrow \pi^*$ transitions for each isomer. However, similar effects of the solvent were observed for 2-diazocyclohexanone, 3-diazonorcamphor, and 3-diazocamphor, for which the existence of *trans*-isomers is impossible. Consequently, the effect of the solvent on the spectra of acyclic diazoketones cannot be accounted for by the occurrence of conformational isomerism[128].

In a study of the ultraviolet spectra of *para*- and *meta*-substituted derivatives of diazoacetophenone, a linear relation was observed between the shift of the 250 nm band in hexane for different *para*-substituted (F, Cl, Br, CH_3, NO_2, CH_3O, and C_2H_5O) derivatives relative to the unsubstituted compound and the activity constant σ_S for the corresponding substituent[126].

Thus, in the interpretation of the ultraviolet spectra of diazoketones, it is necessary to bear in mind that they may be significantly influenced not only by the structure of the diazo-derivatives but also by the experimental conditions. At the present time there is no unique hypothesis which would account for the above characteristics of the ultraviolet spectra of diazocarbonyl compounds. Nevertheless, on the basis of data derived from electronic absorption spectra, one may conclude that, depending on the compound investigated, the absorption bands of diazoketones correspond either to $\pi \rightarrow \pi^*$ or $\pi \rightarrow \sigma^*$ transitions or to their combination. Since α-diazoketones exhibit *s*-isomerism, the absorption bands represent the sum of the superimposed spectra of the *s-cis*- and *s-trans*-isomers[128].

The study of the electronic spectrum of diazoacetone and quantum-mechanical calculations for this compound make it possible to illustrate the $\pi \rightarrow \pi^*$ and $\pi \rightarrow \sigma^*$ transitions with the aid of the orbital energy levels. The diazoacetone molecule may be excited by ultraviolet irradiation in four ways, two of which (Figs. 1 and 2) occur in the region observed.

Fig. 1 presents the principal spectroscopic orbital energy levels and transitions for *s-cis*-diazoacetone[128]. Fig. 2 shows the predicted transition energies for *s-cis*- and *s-trans*-diazoacetones. The low and high vertical lines represent respectively the allowed and the overlap forbidden transitions[128].

In α-diazoketones with different substituents, the number of ways in which the molecule may be excited increases and the electronic spectra are more complex.

The diazo-group gives rise to a distinct band in the infrared spectra of diazoketones in the region 2058–2170 cm^{-1}, which is characteristic of the stretching vibrations of the N–N bond[125,129]. This confirms the linear structure of the diazoketones, otherwise the N–N stretching vibration would give rise to absorption in the region of 1636 cm^{-1}.[129] Moreover, in the spectra of diazoketones and diazoesters an intense absorption is observed in the region 1429–1335 cm^{-1}.[130] This band was assigned to the symmetrical stretching vibrations of the diazo-group, which are markedly displaced owing to conjugation and interaction with skeletal vibrations.

The infrared spectra of diazoacetone, diazoacetophenone, and benzoylphenyldiazomethane have been investigated in carbon tetrachloride and butanol. A change of solvent almost does not affect the position of the maximum of the band due to the N–N bond in the infrared spectrum and has little effect on its integral intensity. However, the peak intensity of this band in butanol is much lower than in carbon tetrachloride and its half-width is greater in butanol. Since this effect is observed not only for diazoacetone and diazoacetophenone but also for benzoylphenyldiazomethane which has no mobile hydrogen, it cannot be due to tautomerism but must be caused by hydrogen bonding, dipole–dipole interaction, and rotational isomerism. The formation of hydrogen bonds between the above diazoketones on the one hand and phenol and pyrrole on the other has been observed on the basis of the shift of the OH and NH absorption bands. The appearance of new absorption bands due to the carbonyl group in the low-frequency region in the spectra of diazoketones in the presence of butanol or phenol is associated with the rotational isomerism of these compounds[127].

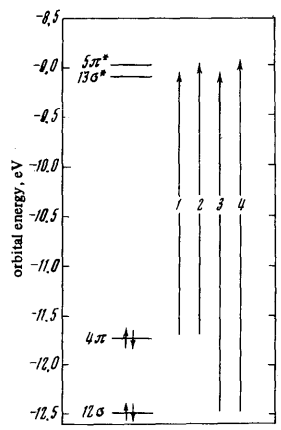


Figure 1.

Using the infrared spectroscopic data for the N–N stretching vibrations, it is possible to assess unambiguously the multiplicity of the bonds between the nitrogen atoms in the diazo-group. If the bond multiplicity is close to 3, the diazo-group absorbs at high frequencies but if the multiplicity is less than 3 the absorption shifts towards lower frequencies. This agrees well with calculations on the distribution of π-electron density in the C–N–N fragment in diazo-compounds (Table 2).

In diazomethane the π-electron cloud is appreciably displaced towards the extreme nitrogen atom and the multiplicity of the bond between the nitrogen atoms is a minimum. If the diazo-compound has substituents with –I and –C effects at the α-carbon atom, the p-electrons at this atom are delocalised over the orbitals of the atoms of the substituents, which leads to a shift of electron density from the orbital of the extreme nitrogen atom. The introduction of a carbonyl group into aliphatic diazo-compounds in the α-position relative to the diazo-group, causes a shift of the absorption bands of the diazo-group towards higher wave-numbers, on average by 40 cm^{-1}. For example, the diazo-group in diazomethane absorbs in the region of 2088 cm^{-1} and in acetyldiazomethane in the region of 2107 cm^{-1}. The introduction of a chlorine atom into the methyl group of diazoacetone promotes, owing to its inductive effect, an even greater shift of the absorption bands due to the diazo-group towards higher wave-numbers (2114 cm^{-1})[132]. The diazo-group in benzoylphenyldiazomethane absorbs in the region of 2072 cm^{-1}, which is evidence that the phenyl group at the carbon atom linked to the diazo-group behaves as an electron donor and reduces the multiplicity of the N–N bond[133]. The diazo-group in diazoacetophenone absorbs in the region of 2108 cm^{-1}.[134] The multiplicity of the bond between the nitrogen atoms increases. An example of the limiting shift of electron density in the diazo-fragment is provided by aromatic diazo-compounds.

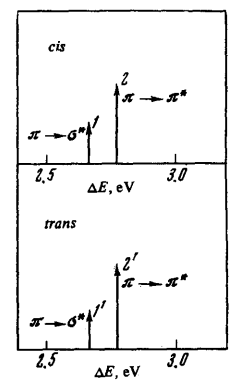

Figure 2.

Table 2. Distribution of π-electron density in the diazo-fragment[131,140].

Diazo-compound	Distribution of π-electron density in C–N–N diazo-fragment	Multiplicity of N–N bond (Ref.140)	Wave-number cm^{-1}
Diazomethane	–0.4995 +0.8418 –0.3423	2.7441	2088
Diazoacetone	–0.4214 +0.8679 –0.2095	2.8194	2103
Diazomalonic ester	–0.3869 +0.8779 –0.1486	2.8543	2188
Phenyldiazonium	+0.0062 +0.8800 +0.0772	2.9284	2304–2237

The introduction of a nitro-group in the α-position relative to the diazo-group has a considerable effect on the position of the band due to its stretching vibrations. Thus $\Delta\nu$ for diazomethane and its nitro-derivatives is 27 cm^{-1},[135] while for diazoacetophenone and its nitro-derivatives $\Delta\nu$ increases to 47 cm^{-1}.[73] A similar behaviour is observed also with N-nitraminodiazoketones[136].

The carbonyl group in diazoketones gives rise to two absorption bands in the region 1755–1620 cm^{-1}. The shift of the bands towards lower wave-numbers (1652–1620 cm^{-1}) is associated with a decrease of the multiplicity of the C=O bond[129,137], which is caused by a shift of electron density to the carbonyl oxygen atom.

The carbonyl absorption band in the spectra of diazoketones has undergone significant changes relative to the spectra of unsubstituted ketones. Thus in the spectrum of diazoacetone it is displaced towards lower wave-numbers by 60 cm^{-1}, which is due to the effect of the $p-\pi$ conjugation in the $COCHN_2$ fragment[137]. A similar shift is observed also in diazoacetophenone relative to acetophenone[134,138]. The phenyl group in diazoacetophenone increases the electron density at the oxygen atom in the carbonyl group owing to its conjugation with the ring and the carbonyl absorption band in the spectrum of diazoacetophenone is displaced towards lower wave-numbers by 26 cm^{-1} compared with diazoacetone. A negative inductive effect of substituents in diazoketones promotes a shift of the absorption bands of the carbonyl group towards higher wave-numbers. Thus, for diazoacetone and trichlorodiazoacetone, this shift is 20 cm^{-1}.[132]

The presence of two carbonyl absorption bands and several absorption bands of different intensities due to the diazo-group in the region of higher wave-numbers is due to the existence of the *s*-isomers in diazoketones[128,137].

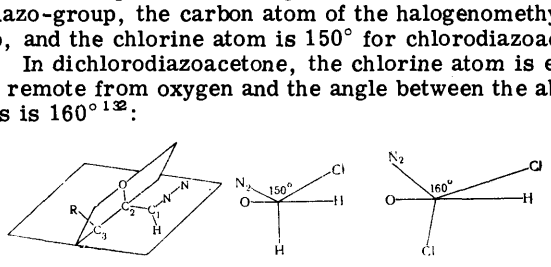
Important evidence in support of the *s*-isomerism of diazoketones was obtained in a study of NMR spectra. Kaplan and Meloy demonstrated that the NMR spectrum of diazoacetone varies with temperature, which indicates the existence of *cis*- and *trans*-isomers[139]. The NMR spectra of other diazocarbonyl compounds, recorded in the temperature range between 71° and −40°C, also confirmed the occurrence of conformational isomerism. In the temperature range investigated, the ratio of the *cis*- and *trans*-isomers of diazoacetaldehyde varied from 9 : 1 to 7 : 3.

The dipole moments of diazoketones agree with the rigid planar structure of the $COCHN_2$ fragment, where CO and CN_2 can be either in the *cis*- or the *trans*-configuration[132] (Table 3).

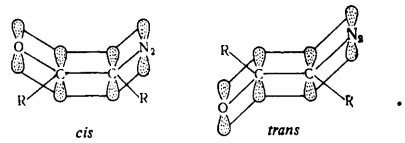
Table 3. Dipole moments of diazoketones[132].

Diazoketone	Dipole moment, debyes
CH_3COCHN_2	3.37
$ClCH_2COCHN_2$	2.80
$Cl_2CHCOCHN_2$	2.65
$Cl_3CCOCHN_2$	2.46

In diazoacetone an equilibrium is observed between the *cis*- and *trans*-conformers, while chloro-derivatives of diazoacetone are mainly in the *cis*-form. Free rotation of the halogenomethyl group about the R–CO bond is hindered by steric and electrostatic effects. The optimum angles between the planes in which the diazo-fragment is located and the plane containing the carbon atom joined to the diazo-group, the carbon atom of the halogenomethyl group, and the chlorine atom is 150° for chlorodiazoacetone. In dichlorodiazoacetone, the chlorine atom is even more remote from oxygen and the angle between the above planes is 160°[132]:



s-Isomerism in diazoketones is the result of the limited free rotation about the central carbon–carbon bond, which is caused by the interaction of the electron pair of the α-carbon with the π-electron-system of the carbonyl group:



cis *trans*

The barrier to free rotation in diazoketones about the carbon–carbon bonds is between 9 and 18 kcal $mole^{-1}$. For diazoacetone and diazopropanone, it amounts to 15.5 and 16.1 kcal $mole^{-1}$ respectively[35].

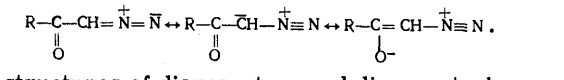
Table 4. Multiplicity of the bonds in the $COCHN_2$ fragment[132,149].

C–O	C–C	C–N	N–N
1.80	1.50	1.54	2.81
—	—	1.70	2.77

$p-\pi$ Conjugation in the $COCHN_2$ system leads to the appearance of fractional bond orders. Table 4 lists the calculated bond multiplicities in the $COCHN_2$ fragment.

Recently the molecular orbital method was used to demonstrate the occurrence of *cis–trans* isomerism in the diazoketone series. The calculations were made for diazoacetone and diazoacetophenone. The author succeeded in demonstrating convincingly the occurrence of rotational isomerism in these compounds. The geometrical configuration of diazoacetone used in the calculation is presented in Fig. 3†, which also gives the results of the calculation of the distribution of charges and dipole moments in the *s-cis* and *s-trans* diazoacetone isomers[128].

Studies in recent years have made it possible to describe the structure of diazoketones in the following way. The $COCHN_2$ ($OC^2-C^1-N^2-N^1$) fragment is coplanar, the C^1 atom is sp^2-hybridised, the C^1-N^2 bond is formed as a result of the withdrawal of the lone electron pair of the nitrogen atom to the sp^2 orbital of the carbon atom (singlet), and the lone electron pair in the p orbital of the C^1 carbon atom is conjugated with the π orbitals of the carbonyl and diazo-groups. This results in a conjugation chain involving five atoms. The above effect is illustrated in Fig. 2. It can also be described by the canonical structures‡



The structures of diazoacetone and diazoacetophenone have been discussed from the standpoint of the molecular

† The *Z* axis is not shown in Fig. 3; it is perpendicular to the plane and demonstrates the planarity of the molecule.

‡ Another interpretation of the bond types is possible. In particular, the C^1-N^2 bond is regarded as covalent and conjugation in the CNN fragment arises owing to the p electron of the carbon atom, the two p electrons of the middle nitrogen atom, and the p electron of the extreme nitrogen atom[132].

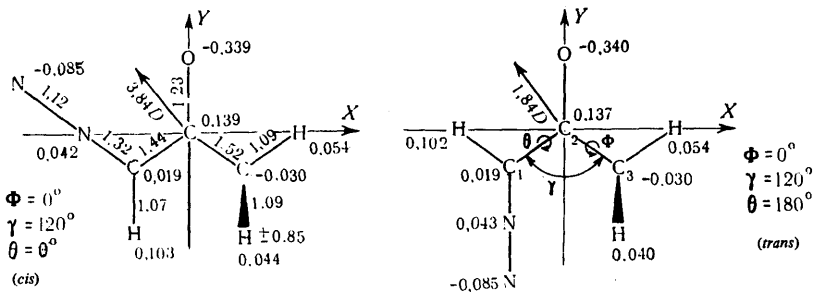


Figure 3.

orbital theory[128]. In the diazoacetone molecule there are 28 molecular orbitals: 21 of these are σ orbitals and 7 are π orbitals. Six π orbitals are formed from the $2p_Z$ orbitals of the nitrogen, carbon, and oxygen atoms. The seventh π orbital is formed from the orbitals linking in the methyl group the two hydrogen atoms located above and below the plane in which the diazoketone is located (the pseudo-π-orbital). Of the seven π orbitals, four are populated and three are vacant. The π orbital with the lowest energy (1π) embraces the π bond of the carbonyl group. A higher π orbital (2π) embraces the CNN fragment and has no vertical nodal plane between the three atoms. The third π orbital constitutes a pseudo-π-bond. The fourth π orbital has the highest energy, is also linked to the CNN bond, and has no nodal plane between the nitrogen atoms. The first antibonding π^* orbital (the $5\pi^*$ molecular orbital) embraces the entire diazoketone and has nodal planes between O and C, C and N, and N and N bonds. Of the 21 σ molecular orbitals, the first 12 are populated and the remaining 9 are vacant.

In the study of the mass spectra of diazoacetone, chlorodiazoacetone, trichlorodiazoacetone, and diazoacetophenone, the ionisation potentials of the compounds were determined as 9.40 ± 0.03, 9.92 ± 0.1, 9.95 ± 0.06, and 9.22 ± 0.04 eV respectively. From the ionisation potentials and the appearance potentials of the fragment ions, the bond dissociation energies in the above diazoketones were obtained: 3.3 eV for diazoacetone, 2.9 eV for chlorodiazoacetone, and 2.2 eV for trichlorodiazoacetone[141].

The above characteristics of the structure of diazoketones are responsible for their high chemical reactivity.

IV. CHEMICAL PROPERTIES

An intense investigation of the chemical reactions of diazoketones was begun in 1928, when Arndt and Amende discovered the reaction in which diazoalkanes are acylated by carboxylic acid halides[17]. Since then diazoketones have become readily available. They undergo reactions of the following characteristic types: (1) reactions with evolution of nitrogen; (2) reactions involving the nitrogen atoms of the diazo-group; (3) reactions in which the mobile α-hydrogen atom is substituted. Examples of these reactions are given below.

1. Reactions involving the Formation of Carbonium Ions

This group of reactions includes the reactions of diazoketone with water, alcohols, acids, halogens, *N*-halogeno-derivatives, and nitrogen oxides. Under the usual conditions, diazoketones are as a rule inert with respect to water. However, a few drops of acid (usually inorganic) are sufficient for the evolution of nitrogen to begin and an α-hydroxyketone to form. Sometimes the reaction takes place on heating. For example, an acetylmethanol may be obtained in this way from diazoacetone[94]. The hydrolysis of higher diazoketones with water is usually carried out in dioxan in the presence of catalytic amounts of inorganic acids.

Despite the fact that the decomposition of diazoketones in water has been known for a long time, the mechanism of this reaction remained controversial until recently. Wolff[94] and Bredig and Frankel[142] described the decomposition of diazoketones in an acid medium by the following process:

$$RCOCHN_2+H^++H_2O\longrightarrow RCOCH_2OH+N_2+H^+.$$

In other studies a different reaction mechanism was proposed by analogy with the hydrolysis of diazoalkanes, which has an A-SE2 mechanism[143–145]:

$$RCOCHN_2+H^+\longrightarrow RCOCH_2N_2^+, \quad (a)$$

$$RCOCH_2N_2^+ + H_2O \rightarrow RCOCH_2OH + H^+ + N_2. \quad (b)$$

The rate of hydrolysis is determined by stage (a). The role of catalytic amounts of acid reduces to the protonation of the diazoketone.

Ingold suggested a mechanism including the protonation of the diazoketone (c) in the pre-equilibrium stage[146] with a subsequent slow stage (d) involving its decomposition—an A – SE1 mechanism:

$$RCOCHN_2 + H^+ \rightleftharpoons RCOCH_2N_2^+, \quad (c)$$

$$RCOCH_2N_2^+ \rightleftharpoons RCOCH_2^+ + N_2, \quad (d)$$

$$RCOCH_2^+ + H_2O \rightarrow RCOCH_2OH + H^+. \quad (e)$$

However, he did not reject the possibility that diazoketones may be converted into hydroxyketones via the bimolecular mechanism involving reaction (a) and (b).

Whereas previously it was believed that the role of acid reduces to the protonation of the diazoketone, in recent studies it has been suggested that the catalyst protonates water[147,148]. The hydronium ion reacts with primary diazoketones via the mechanism

$$RCOCHN_2 + H_3O^+ \rightleftharpoons RCOCH_2N_2^+ + H_2O. \qquad (f)$$

Subsequently the diazonium ion is converted into a hydroxyketone via mechanism (b) (an $A - SE2$ mechanism)[149-152].

In contrast to primary diazoketones, secondary diazoketones are protonated irreversibly [stage (g)]. This stage is rate-determining. The hydroxyketone is formed from the diazonium ion via mechanisms (d) and (e):

$$RCOC(R)N_2 + H_3O^+ \rightarrow RCOCH(R)N_2^+ + H_2O. \qquad (g)$$

This reaction mechanism has been demonstrated for arylbenzoyldiazomethanes[153,154] and cyclic diazoketones[155,156].

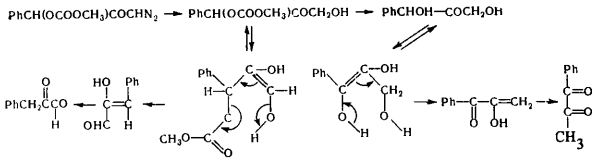
Acid hydrolysis of primary diazoketones does not result in the formation of α-hydroxymethylketones only. In the decomposition of 3-diazo-1-methoxycarbonyl-1-phenylpropan-2-one by dilute sulphuric acid, Bradley and Eaton isolated benzylglyoxal in 12% yield, the formation of which they believe may be due to an anionotropic migration of the phenyl group and the elimination of the second substituent[157]. Weygand et al. repeated this reaction with the diazoketone containing labelled carbon atoms and isolated benzylglyoxal in 6% yield[158]. On the basis of the measurements of the radioactivity of the products, they established that the phenyl residue does not migrate:

$$C_6H_5{}^{14}CH(OCOOCH_3)COCHN_2 \rightarrow C_6H_5{}^{14}CH_2COCHO.$$

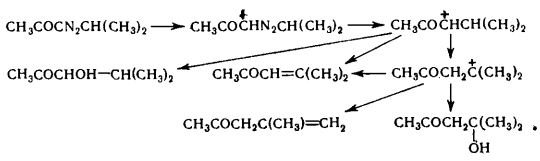
This reaction was investigated in greater detail by Dahn et al.,[159] who employed 10% phosphoric acid for the hydrolysis and obtained benzylglyoxal in 44% yield. In addition to the aldehyde, benzoylacetyl was also isolated. Hydrolysis of the diazoketones in which the carbon atom linked to the diazo-group was labelled confirmed that the phenyl group does not migrate from the first to the third atom, since the benzoic acid thus obtained is not radioactive:

$$\begin{matrix} C_6H_5 \\ | \\ CH{-}CO{-}{}^*CHN_2 \\ | \\ OCOOCH_3 \end{matrix} \rightarrow C_6H_5CH_2CO{-}{}^*CHO \rightarrow C_6H_5COOH + CO_2 + {}^*CO_2.$$

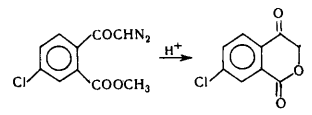
The authors explain the formation of benzylglyoxal and benzoylacetyl by the intermediate formation of a hydroxyketone and a diol:



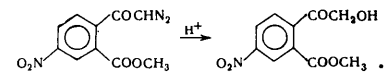
Unsaturated ketones were isolated in the acid hydrolysis of 3-diazo-1-methylpentan-2-one together with hydroxymethyl ketones[160]:



In the acid hydrolysis of diazoketones, the stabilisation of the carbonium ion depends both on the nature of the substituents and on their distribution relative to the diazo-group. For example, p-chloro-ω-diazo-o-methoxycarbonylacetophenone gives 7-chloro-1,4-dioxoisochroman on treatment with 3% sulphuric acid[161]:

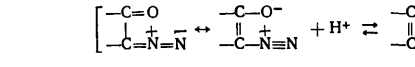


ω-Diazo-o-methoxycarbonylacetophenone undergoes a similar reaction[162]; under the hydrolysis conditions, ω-diazo-o-methoxycarbonyl-p-nitroacetophenone is converted into ω-hydroxy-o-methoxycarbonyl-p-nitroacetophenone[163]:



The acidity of alcohols is insufficient for the decomposition of diazoketones. Therefore the reaction with alcohols is as a rule carried out in the presence of catalysts. Inorganic acids, boron trifluoride, and metallic copper are employed for this purpose[153,164-166]. The reaction results in the formation of alkoxy-derivatives of α-hydroxyketones.

In contrast to diazoalkanes, diazoketones are more stable in relation to electrophilic agents. Many of them do not react with organic acids such as benzoic and cold acetic acids. Bisdiazoketones in which the diazo-group is between two carbonyl groups are not decomposed by concentrated nitric acid[137]. The authors explain this unusual behaviour of bisdiazoketones by the fact that the proton attacking the nucleophilic α-carbon atom is captured by the oxygen of the carbonyl group[137]:

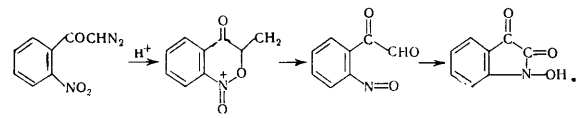


The inertness of diazoketones with respect to cold acetic acid makes it possible to carry out certain reactions in it[167].

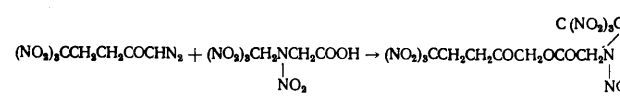
On heating with acetic acid, diazoketones form ketoesters[168-171]:

$$RCOCHN_2 + CH_3COOH \rightarrow RCOCH_2OCOCH_3.$$

An analogous synthesis was carried out using copper dioxide as a catalyst[172]. After refluxing 1-diazo-3-(o-nitrophenyl)acetone in glacial acetic acid, N-hydroxyisatin was isolated. The authors suggest that the initial reaction stage is cyclisation of the intermediate carbonium ion with formation of a six-membered ring followed by its deprotonation and cleavage to o-nitrosophenylglyoxal. Cyclisation of the latter leads to the formation of N-hydroxyisatin[173]:



Strong organic acids decompose diazoketones at room temperature[5]. ω-Nitrodiazoketones react with polynitrocarboxylic acids when the reactants are fused together[174]:



Platter and Heusser[175] achieved an interesting reaction of diazoketones. Starting with diazoketones and bromoacetic acid, they obtained butenolides:

$$RCOCHN_2+BrCH_2COOH\longrightarrow RCOCH_2OCOCH_2Br\longrightarrow \text{butenolides}\ .$$

Thiocarboxylic acids also decompose diazoketones with formation of the corresponding hydroxyketone esters[176].

The reaction of diazoketones with aliphatic and aromatic mono- and di-sulphonic acids led to the isolation of sulphonates derived from the α-hydroxyketones. The reaction is carried out in dioxan in the presence of a catalyst ($CuCl_2$) at 60–70°C[177] in polar solvents or acetic anhydride[34,178,179]. In the latter case the sulphonates are isolated after the hydrolysis of acetic anhydride with water. p-Toluenesulphonates derived from α-hydroxyketones are formed in high yield, readily crystallise, have distinct melting points, and may be used for the identification of diazoketones[178,179,180]:

$$RCOCHN_2+CH_3C_6H_4SO_2OH\longrightarrow RCOCH_2OSO_2C_6H_4CH_3+N_2\ .$$

Diazoketones undergo unusually interesting reactions with inorganic acids. However, only isolated examples of such reactions have been described. The reaction with nitric acid results in the formation of the corresponding nitric acid esters[34,138,167,181]:

$$RCOCHN_2+HNO_3\longrightarrow RCOCH_2ONO_2+N_2\ .$$

The reaction of diazoketones with sulphuric acid leading to the formation of sulphates derived from α-hydroxyketones has been described[34,153,182]:

$$2RCOCHN_2+H_2SO_4\longrightarrow (RCOCH_2O)_2SO_2+N_2\ .$$

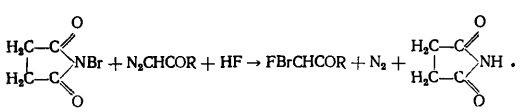
The reaction of diazoketones with phosphoric acid also yields the corresponding hydroxyketone esters[183].

In the reaction with inorganic acids, diazosulphones behave analogously to diazoketones. The synthesis of perchloric acid esters involving the mechanism

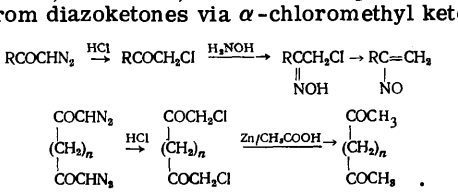
$$H_3CC_6H_4SO_2CHN_2+HClO_4\longrightarrow H_3CC_6H_4SO_2CH_2OClO_3+N_2$$

was described recently[184].

Hydrogen halides, except hydrogen fluoride, readily decompose diazoketones. Interesting experiments have been performed on the decomposition of diazoketones in hydrofluoric acid in the presence of N-bromosuccinimide[185]:



When diazoketones are treated with dry hydrogen chloride, α-chloromethyl ketones, which are starting materials for various syntheses, are obtained[5]. For example, nitroso-olefins, diketones, and other compounds have been obtained from diazoketones via α-chloromethyl ketones:



α-Bromomethyl ketones, formed in the reaction between diazoketones and hydrogen bromide, are also important starting materials for the synthesis of polyfunctional compounds[186]:

$$C_6H_5COCHN_2\xrightarrow{HBr}C_6H_5COCH_2Br\xrightarrow[CH_3CN]{AgNO_3}C_6H_5COCH_2ONO_2\rightarrow C_6H_5COCHO\ .$$

Hydriodic acid causes a far-reaching transformation of diazoketones leading to the formation of methyl ketones[187]. The conversion of the diazomethyl into the methyl group was first achieved by Wolfrom and Brown[187] for 1-diazoglucoheptulose[187]:

$$AcOCH_2(CHOAc)_4COCHN_2\xrightarrow{HI}AcOCH_2(CHOAc)_4COCH_3+N_2\ .$$

α-Iodomethyl ketones are formed according to the mechanism[138]

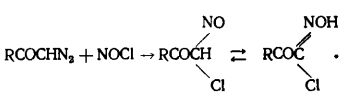
$$RCOCHN_2+HCl\rightarrow RCOCH_2Cl\xrightarrow{NaI}RCOCH_2I\ .$$

When diazoketones are decomposed in the presence of an excess thiocyanate, nitrate, and chloride anions in the reaction mixture, α-thiocyanato-, α-nitroxy-, and α-chloro-methyl ketones respectively are readily formed[138,188].

Treatment of diazoketones with chlorine, bromine, or iodine in inert solvents leads to the formation of $\alpha\alpha$-dihalogenomethyl ketones[187]. Iodobenzene dichloride may be employed as the chlorinating agent[189]:

$$ClCH=\underset{Cl}{C}COCHN_2+C_6H_5ICl_2\rightarrow ClCH=\underset{Cl}{C}COCHCl_2+C_6H_5I+N_2\ .$$

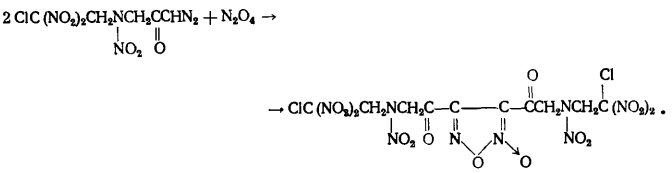
The reaction of a number of diazoketones with nitrosyl chloride has been investigated[190]. The resulting chloronitrosoketones are in tautomeric equilibrium with hydroxamic acid chlorides:



Benzoylphenyldiazomethane reacts with nitrogen tetroxide to form phenyldinitromethane[191]:

$$C_6H_5COCN_2C_6H_5+N_2O_4\longrightarrow HC(NO_2)_2C_6H_5\ .$$

It was established recently that ω-nitrodiazoketones are converted under the influence of nitrogen tetroxide into furoxans[192]:



In the series of diazoketones only a few examples of this interesting reaction have been carried out and it undoubtedly requires further study.

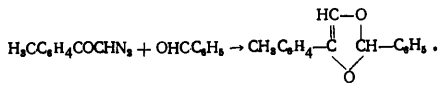
2. Reaction of Diazoketones with Carbonyl Compounds

This group of reactions includes those of diazoketones with aldehydes and ketones. The reaction of diazoketones with aldehydes was investigated for the first time by Diels and Ilberg[193]. On mixing 2-diazo-3-butanone with formaldehyde, they observed a vigorous evolution of nitrogen and heat. The reaction resulted in the isolation of o-hydroxy-2-methylbut-2-en-3-one:

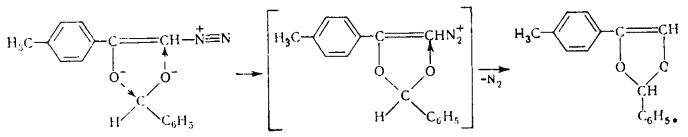
$$CH_3COCN_2CH_3+O=CH_2\rightarrow CH_3\underset{CH_3}{C}OC=CHOH+N_2\ .$$

The reaction of diazoketones with higher aldehydes occurs under more severe conditions. Thus on heating

with benzaldehyde in xylene for 18 h, *p*-methylbenzoyldiazomethane was converted in 39% yield into 2-phenyl-5-tolyl-1,3-dioxole[194]:

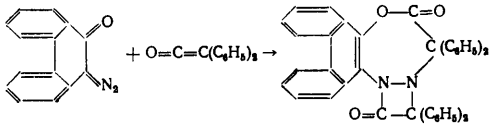


According to the authors, the condition governing the formation of dioxoles is the addition of the electrophilic carbon of the aldehyde group to the carbonyl oxygen of the diazoketone before the elimination of the diazo-group; otherwise the Wolff–Schroeter rearrangement is possible:

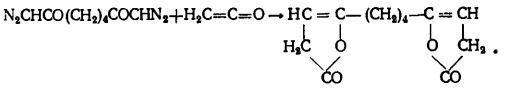


It is noteworthy that the reaction takes place smoothly only with *p*-methyl- and *p*-methoxy-benzoyldiazomethane. Benzoyldiazomethane having substituents with a +*C* effect either does not undergo the reaction or the reaction leads to the formation of diacylethylenes in high yields[194].

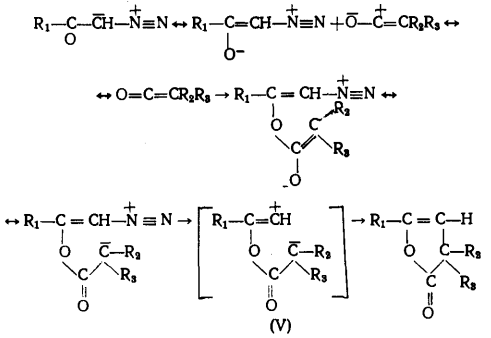
Diazoketones readily react with ketens. After allowing azibenzil to react with diphenylketen, Staudinger and Reber isolated a nitrogen-containing crystalline adduct[195]. Ried and Dietrich made a detailed study of the reaction of *o*-quinone diazides with ketens and showed that it results in the formation of polycyclic nitrogen-containing systems[196,197]:



Primary diazoketones react with ketens with evolution of nitrogen. This leads to the formation of $\beta\gamma$-butenolides, which split off a lactone and are converted into keto-acids[198]. The reaction of bisdiazoketones with ketens leads to the formation of bisbutenolides[198]:



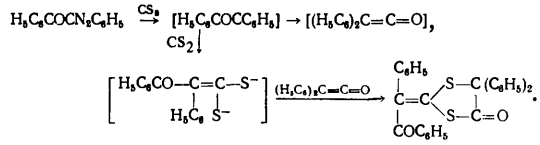
The reaction proceeds via the intermediate formation of a dipolar ion (V), which readily cyclises to a lactone[198]:



(V)

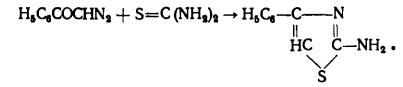
3. Reaction of Diazoketones with Sulphur-containing Compounds

In a study of the reaction of hydrogen sulphide with azibenzil, Meyer isolated 5-oxo-2-(2-oxo-1,2-diphenylethylidene)-4,4-diphenyl-1,3-dithiolane in 90% yield. Evidently, after the evolution of nitrogen, this reaction involves the formation of a carbene, part of which adds to the hydrogen sulphide and another part undergoes the Wolff–Schroeter rearrangement and adds to both sulphur atoms of the intermediate adduct[199]:

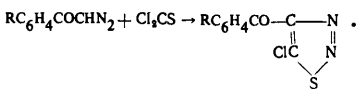


Analogous syntheses have been carried out by other investigators[200,201].

Benzoyldiazomethane reacts with thiourea to form a heterocyclic compound according to the mechanism[202]

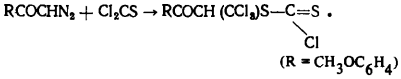


Depending on the position and nature of the substituent, ring-substituted benzoyldiazomethane derivatives can react with thiophosgene to form 1,2,3-thiadiazoles, substituted thiopropionic acid chlorides, and trichloroethanethiol derivatives. Thus *p*-nitro-, *p*-chloro-, and *p*-methyl-benzoyldiazomethane and *m*-nitrobenzoyldiazomethane react with thiophosgene to form 1,2,3-thiadiazoles[203]:



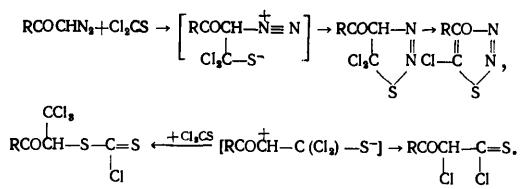
m-Methyl- and *m*-methoxy-benzoyldiazomethanes form β-aryl-α-chloro-β-oxothiopropionic acid chlorides:

In the presence of an excess of thiophosgene, chlorothiocarbonic acid esters are formed:



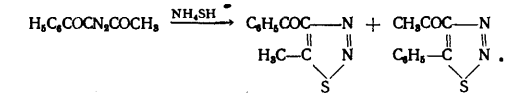
Azibenzil reacts with thiophosgene to form a thiafuran derivative via a thi-iran.

The authors suggest that the products enumerated above are obtained by the following mechanism:

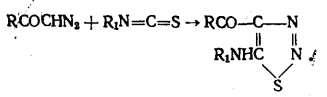


When secondary diazoketones react with hydrogen sulphide, thiadiazole derivatives are formed[92,204]. Thus treatment of azibenzil with hydrogen sulphide in ethanol in the presence of a small amount of ammonia leads to the

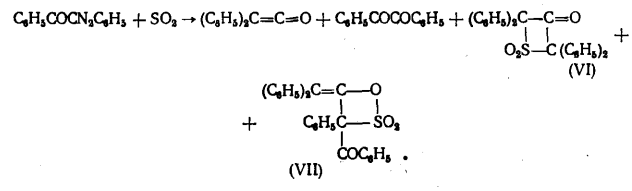
formation of 4,5-diphenyl-1,2,3-thiadiazole[205,206]. The reaction of asymetric 2-diazo-1,3-diketones with hydrogen sulphide in the presence of ammonia yields two isomeric 1,2,3-thiadiazolyl ketones: 4-benzoyl-5-methyl-1,2,3-thiadiazole and 4-acetyl-5-phenyl-1,2,3-thiadiazole[95]:



Ried and Beck obtained 1,2,3-thiadiazole by the reaction of primary diazoketones with mustard oils[207]:



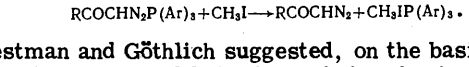
Thermolysis of azibenzil in benzene in the presence of sulphur dioxide yielded cyclic sulphones (VI, VII), benzil, and diphenylketen. Photolytic decomposition of azibenzil in the presence of sulphur dioxide at temperatures between −5° and −20°C leads to the formation of the above sulphones and benzil[208]:



4. Reaction with Phosphines and Organophosphorus Compounds

The reaction of diazo-compounds with tertiary phosphines, in particular with triphenylphosphines, which was discovered by Staudinger, has been described in a number of publications[209-211]. It was investigated in detail by Bestman's school[143,212]. It results in the formation of triphenylphosphazines[212]. α-Ketoaldehydes[213], ketoesters[214], methyl ketones[212], and heterocyclic compounds[25,143,184,215,216] may be obtained via the phosphazines.

It is striking that very pure diazoketones may be obtained by the cleavage of phosphazines with methyl iodide[212,217]:

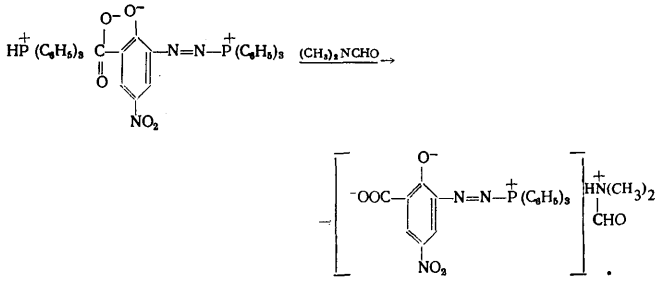


Bestman and Göthlich suggested, on the basis of the chemical and thermal behaviour of phosphazines, that the following equilibrium occurs[211,212]:

The accumulation of electronegative substituents in the diazoketone promotes a shift of the equilibrium to the right. To demonstrate the occurrence of the equilibrium, the authors carried out an exchange between the diazo-component of the phosphazine and a diazoketone containing a labelled carbon atom and isolated a radioactive phosphazine. This involved a complete exchange of the inactive diazo-component for the radioactive component:

Infrared spectroscopic data also confirmed this conclusion. The phosphazine spectra, recorded using potassium bromide discs, do not have absorption bands characteristic of the diazo-group, while in chloroform solution the band does appear[218].

Quinone diazides (*o*- and *p*-derivatives) react with triphenylphosphine to form the corresponding phosphazines[217,219]. *o*-Quinone diazides with electronegative substituents in the 4- and 6-positions of the ring behave anomalously[184,217]. In some cases it proved possible to isolate stable yellow adducts with the composition *o*-quinone diazide: $P(Ar)_3 = 1:2$. The diadducts are salt-like. This was confirmed by the finding that the triphenylphosphine molecule in the diadduct, which is linked by an anionic bond, is readily substituted by a dimethylformamide molecule:



Apart from triphenylphosphine, the more nucleophilic triaminophosphines may be employed as the second component in the formation of phosphazines. In this case the reaction takes place instantaneously[220].

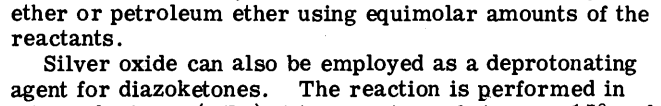
Phosphazines are synthesised in ether[211,212], acetonitrile[106], isopropyl ether[216], ethyl acetate[55], or in a mixture of benzene and ether[221]. Sometimes anhydrous zinc chloride is employed as a catalyst[213].

5. Electrophilic Substitution of α-Hydrogen in Diazoketones

Diazoketones are known to undergo a reaction in which electrophilic substitution of the hydrogen at the carbon atom linked to the diazo-group takes place. The reaction was first discovered by Buchner[221] when he allowed diazoacetic ester to react with yellow mercury(II) oxide:

The reaction has now been described in connection with the synthesis of mercury derivatives of 2,4,6-trimethylbenzoyldiazomethane, diazoacetone, and 4-methyldiazopentan-2-one[130,222]. The synthesis was carried out in anhydrous ether or petroleum ether using equimolar amounts of the reactants.

Silver oxide can also be employed as a deprotonating agent for diazoketones. The reaction is performed in tetrahydrofuran (THF) at temperatures between −15° and 0°C. Silver derivatives of diazoketones are excellent alkylating agents and serve as intermediates for the synthesis of unsaturated diazoketones[223]:



Organotin derivatives of diazoacetic ester, formed in the reaction of the latter with organotin derivatives of alkylamines, have been recently described[224].

An interesting example of this range of reactions of diazo-derivatives was recently discovered by Schollkopf and coworkers[225,226]. They succeeded in synthesising α-nitrodiazo-compounds. Thus nitrodiazoacetic ester was obtained by nitrating diazoacetic ester with nitrogen pentoxide[225]. Benzoyldiazomethane reacts with nitrogen

pentoxide in carbon tetrachloride at −30°C to form benzoylnitrodiazomethane[226]:

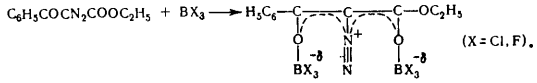
$$C_6H_5COCHN_2 + N_2O_5 \longrightarrow C_6H_5COC(NO_2)N_2 .$$

By nitrating nitrodiazomethane[135] with nitrogen pentoxide, it proved possible to isolate a most interesting α-nitrodiazoalkane: dinitrodiazomethane[227].

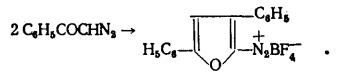
We believe that a more detailed study of the above reactions and subsequent transformations of the resulting products should lead to a further development of this interesting field in the chemistry of diazo-compounds.

6. The Complex-forming Capacity of Diazoketones

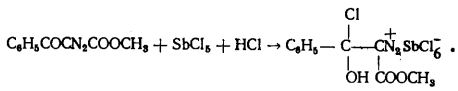
The synthesis of internal diazonium complexes of diazocarbonyl compounds was first reported by Fahr[228], who found that benzoyldiazoacetic ester reacts with boron trifluoride or trichloride to form colourless, stable, but moisture-sensitive compounds. The following structure was attributed to them:



Benzoyldiazomethane reacts with boron trifluoride-ether in toluene at 60–70°C with evolution of nitrogen and the formation of 2,4-diphenyl-furan-5-diazonium fluoroborate, the first example of compounds with a diazonium group at the furan ring[229–231]:



Benzoyldiazoacetic ester reacts with antimony pentachloride in methylene chloride in the presence of hydrogen chloride, forming a diazonium salt[232]:



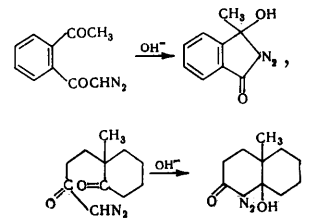
A complex of diazobarbituric acid with di(trinitromethyl)mercury was described recently. It is interesting that the reaction of 9-diazofluorene and diphenyldiazomethane with di(trinitrophenyl)mercury led to the isolation of 1-biphenylene-2,2-dinitroethylene and 2,2-dinitro-1,1-diphenylethylene[233].

7. Reactions of Diazoketones under the Influence of Bases

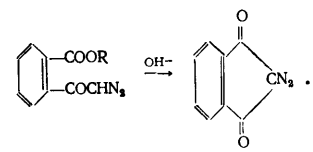
The reactions of diazoketones with bases have been inadequately investigated, evidently owing to their complexity. The reaction takes place unambiguously in the case of the amide of diazoacetic ester[234] and 2-diazo-3-pentanone[235]. In the first case the product is 5-oxo-1,2,3-triazole and in the second 1-(3,3-dimethyl-2-oxobutyl)-5-(2,2-dimethyl-1-oxopropyl)tetrazole. The reaction of ω-diazoacetophenone with sodium hydroxide or sodium methoxide in dioxan and ether leads to the formation of benzoic acid, 4-phenylbenzoylpyrazole, 3-benzoyl-5-hydroxy-4-phenylpyrazole, acetophenone, hydrogen cyanide and hydroxylamine. In concentrated sodium methoxide solutions the products are 3-benzoyl-4-hydroxy-5-phenylpyrazole and 5-benzoyltetrazole[236]. The reaction of diazoacetophenone with potassium t-butoxide yields a dimer of diazoacetophenone, 5-benzoyl-1-phenyltetrazole, and 5-benzoyl-2-phenylacyltetrazole. 1-Phenylacyltetrazole is obtained in ether in the presence of ammonium chloride[237].

On treatment with bases, diazodicarbonyl compounds decompose into diazomonocarbonyl derivatives[238]. No hypotheses have been put forward concerning the mechanism of the reaction of diazoketones with bases. A detailed study of the process is necessary in order to elucidate the causes of the formation of such a large number of reaction products.

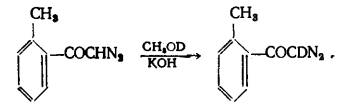
It was found recently that diazoketones undergo intramolecular condensation on treatment with alkalies[239]



Under the influence of bases, alkoxycarbonyldiazoketones undergo the Dieckmann condensation:



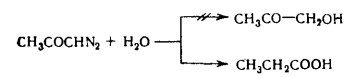
Diazoketones which are incapable of undergoing the above condensations, readily exchange their α-hydrogen atom for deuterium in an alkaline medium, which indicates an anionic mechanism of the above condensation[239]:



8. Reactions of Diazoketones via Ketocarbenes

A characteristic reaction of diazoketones is decomposition via ketocarbenes on irradiation and under the influence of heat and light. The intermediate species with an incomplete octet at the α-carbon atom, formed after the elimination of nitrogen, can be stabilised in different ways.

Wolff, who studied the reaction of diazoacetone and diazoacetophenone with water in the presence of silver oxide, isolated, instead of the expected α-hydroxyketones, propionic and phenylacetic acids[94,120].



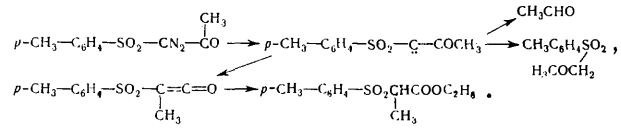
Somewhat later and independently of Wolff, Schroeter studied a similar reaction of phenylbenzoyldiazomethane and isolated diphenylacetic acid. By thermolysing azibenzil, he succeeded in obtaining diphenylketen—an intermediate in the formation of diphenylacetic acid[240,241]:

$$C_6H_5COCN_2C_6H_5 \rightarrow C_6H_5COC\ddot{C}C_6H_5 \rightarrow (C_6H_5)_2C{=}C{=}O .$$

Subsequently the conversion of α-diazoketones into acids or their derivatives, which takes place on heating under the influence of catalysts or on irradiation with

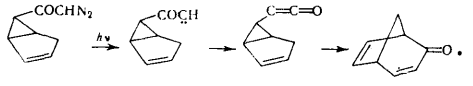
ultraviolet light in the presence of water, alcohols, ammonia, amines, etc. was called the Wolff–Schroeter rearrangement (more often this reaction is referred to as the Wolff rearrangement). Excellent reviews dealing with various reactions of diazo-compounds describe in detail both the theoretical and experimental aspects of this rearrangement[6,8,242–251]. A systematic account of work published recently is given below.

The catalysis of *p*-tosyl(acetyl)diazomethane in ethanol leads to the formation of ethyl α-methyl-α-tosylacetate, acetaldehyde, and tosylacetone[252]:



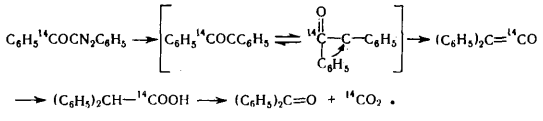
The reaction proceeds via the intermediate formation of a ketocarbene.

Recently the Wolff–Schroeter rearrangement has been intensively investigated for diazoketones with cyclic substituents[253–257]. The photolysis of *endo*-6-diazomethyl-oxobicyclo[3,2,0]hex-2-ene in tetrahydrofuran yielded bicyclo[3,2,1]octa-3,6-diene-2-one—the product of the intramolecular cyclisation of the keten formed as a result of the normal Wolff rearrangement[254]:

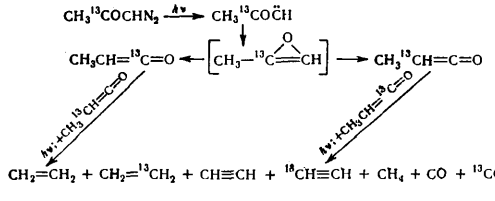


In contrast to the mechanism proposed previously for the Wolff–Schroeter rearrangement, where the formation of the intermediate keten was assumed to take place via a ketocarbene, it has been shown[258] that the ketocarbene is converted into the keten via acetylene oxide [oxiren].

Franzen achieved the photochemical decomposition of azibenzil containing a labelled carbon atom in the carbonyl group. The position of the labelled atom was established by the oxidative decarboxylation of the resulting diphenylacetic acid. Subsequently the radioactivity of the carbon dioxide formed was measured. The author concluded that the ketocarbene is stabilised as a result of the migration of the phenyl group with formation of diphenylketen[259]:

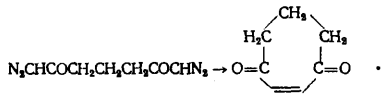


The results of this study agree with earlier data[260]. The gas-phase photolysis of diazoacetone and 2-diazo-3-butanone with a labelled carbon atom in the carbonyl group leads to the formation of a large number of products[258]: non-radioactive and radioactive unsaturated hydrocarbons, carbon monoxide, and methane. The appearance of these compounds can be accounted for by the intermediate formation of an oxiren according to the mechanism



Evidently additional studies are necessary to prove unambiguously the validity of the above mechanism.

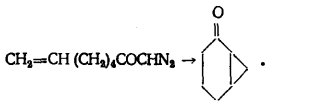
The rearrangement of a ketocarbene into ketens is not the only possible stabilisation pathway. For example, the decomposition of benzoyldiazomethane in the presence of copper(I) chloride in an inert solvent gives a 60% yield of 1,2-dibenzoylethylene[261], which is a valuable product for the synthesis of heterocyclic compounds[262,263]. Thermolysis of 1,7-bisdiazo-2,6-heptanedione in benzene in the presence of copper(II) oxide leads to the formation of 3,7-dioxocycloheptene[264]:



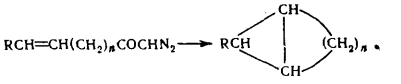
Under analogous conditions, cyclic diazoketones form polymeric products in addition to the dimers[265–267]. When diazoketones in which a CH group adjoins the diazo-group decompose under the influence of light or silver oxide, αβ-unsaturated ketones are formed as a rule[21]. The ketocarbene is stabilised as a result of the migration of the hydrogen atom:

Recently a number of unsaturated ketoesters were synthesised in this way[268]:

If the decomposition of unsaturated diazoketones is carried out in inert solvents, the ketocarbene formed may be stabilised in yet another way, namely via intramolecular addition of the carbon atom with an incomplete octet to the double bond, resulting in the formation of a cyclic product. Thus, when 1-diazo-oct-7-en-2-one is refluxed in cyclohexane in the presence of copper bronze, bicyclo-[0,1,4]-2-heptanone is formed[299]:

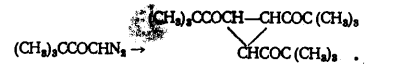


The intramolecular reaction of unsaturated diazoketones was investigated in greater detail by Fawzi and Gutsche[270], who note that substituents at the double bond do not have a significant influence on this reaction:



If the diazomethyl group is separated from the double bond by a benzene ring or the double bond is located in a ring, polycyclic systems are formed[271–274].

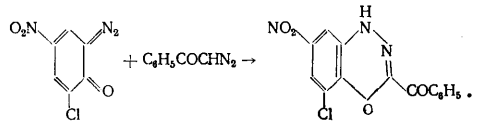
Low yields of cyclopropanes may be obtained by the thermal decomposition of diazoketones[275]. When the reaction is carried out in thioanisole in nitrogen and in the presence of copper bronze, the yield of the cyclic compound may be increased[276]:



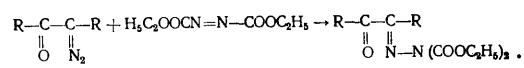
The decomposition of diazoketones in the presence of liazoalkanes leads to the formation of azines[259,277]:

The decomposition of *o*-quinone diazides in the presence of α-diazoketones and diazoacetic ester does not terminate at the stage involving the formation of azimes but leads to

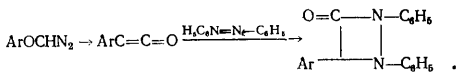
the formation of bicyclic products[278]. Thus, when 6-chloro-4-nitrobenzoquinone 2-diazide [6-chloro-2-diazo-4-nitro-1-oxobenzene?] was heated with diazoacetophenone, 2-benzoyl-8-chloro-6-nitro-4*H*-benzo-1,3,4-oxadiazine was isolated:



α-Diazoketones react with azodicarboxylic acid diesters on heating with formation of the monohydrazones of 1,2-dicarbonylcompounds[279,280]:



The reaction with azobenzene takes place under the influence of ultraviolet light. This involves the formation of ketens which are subsequently coupled to the azo-group with formation of heterocyclic compounds[281]:



2-Diazo-1,3-dicarbonyl compounds react similarly with azo-derivatives[282].

V. SOME ASPECTS OF PRACTICAL APPLICATIONS

In a discussion of the practical applications of diazoketones, one must emphasise in the first place their great preparative value for the synthesis of various classes of organic compounds: aliphatic, aromatic, heterocyclic, and heterochain compounds, and polymers. The possibilities of diazoketones in the synthesis of products which are difficult and sometimes impossible to obtain by other methods are unsurpassed. In this sense comparison of aliphatic diazocompounds with the "Genie of Aladdin's Lamp", made in one of Huisgen's studies, describes graphically and accurately their role in organic chemistry.

The biological activity of certain diazoketones has been investigated. 6-Diazo-5-oxonorleucine inhibits the metabolic process in photosynthesis in algae[283]. The same compound, diazotetronic acid, and *O*-diazoacetyl-L-serine inhibit the growth of malignant tumours[284-288]. The antileukaemic action of 1,2-bisdiazoacetylethane has been studied. The preparation exhibits a wide spectrum of antitumour activity, inhibits or completely suppresses the growth of many experimental tumours (sarcoma-45, Geren [spelling uncertain (Ed. of Translation)] carcinoma, Walker carcinosarcoma, carcinoma-755, sarcoma-180, and Ehrlich ascites tumour)[289]. It was noted recently that certain diazoketones exhibit antitumour activity against three ascites tumours in mice: ARE-G, S-180, Nkly, and haematocytoblastosis La in mice of strain C_{57}bl.[136]

1,8-Bisdiazo-octane-2,7-dione shows a powerful mutagenic activity over a wide spectrum of mutations[290-293].

It is interesting that 1,7-bisdiazo-4-nitro-4-azaheptane-2,6-dione exhibits a weak antibacterial activity, is relatively non-toxic, and does not show neurotropic, anticonvulsant, antitremor, analgesic, and soporific effects[294].

Unfortunately we were unable to find any publications dealing with systematic studies of the biological activity of diazoketones, although, as pointed out by Berlin and Yaguzhinskii[295], they are of undoubted interest in this respect.

Application of Proton Magnetic Resonance to the Investigation of Organophosphorus Compounds

B.I.Ionin and T.N.Timofeeva

Methods of analysing the p.m.r. spectra of organophosphorus compounds are examined, the chief features of the chemical shifts of protons and the proton-proton and proton-phosphorus spin-spin interaction constants are summarised, and the main lines of investigation of organophosphorus compounds by the p.m.r. method are discussed. A list of 167 references is included.

I. INTRODUCTION

The vigorous development of nuclear magnetic resonance (n.m.r.) spectroscopy, especially of proton magnetic resonance (p.m.r.) spectroscopy, is due to the wide possibilities for its application in chemistry both for structural and physicochemical investigations and for a more thorough understanding of the electronic structure of complicated organic molecules. The fundamental difference between n.m.r. and other widely used spectroscopic methods is the presence in the spectra of two groups of cross parameters—the chemical shifts of equivalent nuclei and the spin–spin coupling constants between magnetically non-equivalent nuclei—which leads to a significant enhancement of the reliability and the concreteness of the information obtainable. During the past decade the n.m.r. method has rightly occupied a leading position among spectroscopic methods for investigating organic compounds, and in fact now constitutes an independent branch of science.

The n.m.r. method is especially useful in the investigation of organophosphorus compounds because the stable phosphorus-31 isotope (natural content 100%) possesses a magnetic moment and a nuclear spin of $\frac{1}{2}$, which enables additional parameters—chemical shifts of phosphorus δP and spin–spin coupling constants of phosphorus with protons and other magnetic nuclei of the molecule—to be obtained. Interest in these parameters had already appeared in the first fundamental n.m.r. investigations[1,2]. The modern n.m.r. technique enables chemical shifts of phosphorus to be obtained both by direct resonance at ^{31}P nuclei (^{31}P n.m.r.) and by use of double nuclear resonance methods ($^{1}H-\{^{31}P\}$ and $^{19}F-\{^{31}P\}$ d.n.m.r.).[3-5] As a consequence of the accumulation of comprehensive experimental results on chemical shifts of phosphorus[2,4-11] combined with theoretical analysis[11-15], this parameter can be used widely with the various phosphorus compounds investigated.

At the same time the investigation of organophosphorus compounds by single resonance on protons (p.m.r.) retains its value, since proton resonance is accompanied with the simplest of apparatus, accessible to a wide circle of investigators, and will reveal most parameters of the spectrum. Besides the investigation of the effect of phosphorus-containing groups on the proton chemical shifts δ_H and the proton–proton interaction constants J_{HH}, the p.m.r. method will usually yield the spin–spin coupling constants of protons and phosphorus J_{HP}, and in isolated cases also the spin–spin coupling constants between the phosphorus nuclei J_{PP}. In his excellent reviews Mavel[16,17] has carefully collected the literature on this problem up to 1965 inclusive; the subsequent voluminous literature has described the application of p.m.r. both for the identification of organophosphorus compounds and to reveal the main features of the spectra. The chief purpose of the present Review is to summarise these regularities, and also to examine features of the analysis of p.m.r. spectra applied to those of organophosphorus compounds. For this reason the Review does not claim to cover exhaustively all papers on the proton magnetic resonance of organophosphorus compounds. However, it does consider the results of some of the most comprehensive investigations outside the scope of the actual p.m.r. of these compounds.

II. ANALYSIS OF COMPLEX p.m.r. SPECTRA OF ORGANOPHOSPHORUS COMPOUNDS

The relation between the position and intensity of lines and the parameters of the p.m.r. spectra of organophosphorus compounds conforms to the general rules of nuclear magnetic resonance[18]. The main difficulty in the analysis is that single resonance of protons leaves transitions in the resonance range of phosphorus outside the spectrum. Nevertheless, the use of special procedures enables most of the spectral parameters to be determined in individual cases when the molecules contain a small number of ^{31}P nuclei (one or two).

In the case of compounds containing one phosphorus atom the *method of subspectra* provides a such procedure. The complete proton spectrum of these compounds $(A_mB_nC_kX)$† can be regarded as the superimposition of two simpler subspectra $(A_mB_nC_k)'$ and $(A_mB_nC_k)''$,

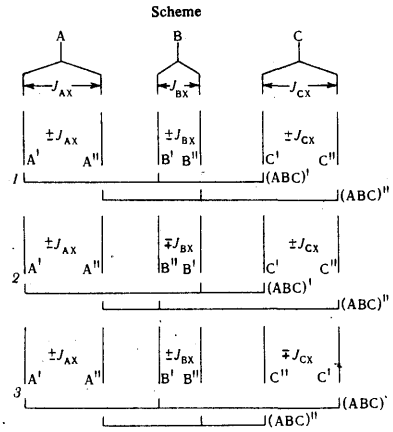
†The letters A–C denote protons, and X is a phosphorus nucleus. The symbol ν_K indicates the chemical shift (in c/s) of the K nucleus with respect to a reference point.

defined by the spin–spin coupling constants *only* between protons and the so called *effective shifts*, which are connected with the true proton chemical shifts and proton–phosphorus spin–spin coupling constants by the simple relations[19]

$$\nu'_A = \nu_A + \frac{1}{2}J_{AX};\ \nu'_B = \nu_B + \frac{1}{2}J_{BX};\ \nu'_C = \nu_C + \frac{1}{2}J_{CX}\ldots$$

$$\nu''_A = \nu_A - \frac{1}{2}J_{AX};\ \nu''_B = \nu_B - \frac{1}{2}J_{BX};\ \nu''_C = \nu_C - \frac{1}{2}J_{CX}\ldots$$

Subspectra provide a very graphic method of determining the relative signs of the constants J_{HP}. Indeed, the lines of the complete spectrum should be distributed between the subspectra according to the relative signs of J_{AX}, J_{BX}, and J_{CX}:.



where in (1) the three constants have the same sign, in (2) the constant J_{BX} is opposite in sign in sign to J_{AX}, and in (3) the constant J_{CX} is opposite to sign to J_{AX} and J_{BX}. If the experimental spectrum enables lines to be assigned unambiguously between subspectra, it is possible also to choose the relative signs of the spin–spin coupling constants.

Fig. 1 shows the experimental and theoretical spectra of the ethylenic protons in vinylphosphonic bisdimethylamide[20]. It is readily seen that the relative intensities agree well with the distribution among subspectra assumed to correspond to constants J_{AX}, J_{BX}, and J_{CX} having the same sign. The spectra of allenic derivatives having a three-coordinated (Fig. 2) or a four-coordinated (Fig. 3) phosphorus atom[21] clearly show how the line intensity ratio varies with the signs of the constants. Thus in the p.m.r. spectrum of propadienylphosphonous bisdimethylamide the constants have the same sign, whereas in the spectrum of propadienylphosphonic bisdimethylamide the signs are different. Most of the parameters in the spectra can be obtained by direct measurement.

If, however, the subspectrum is highly symmetrical (e.g. the AB subspectrum in ABX, or AA'BB' in AA'BB'X[21]), unambiguous distribution of lines among subspectra is impossible. Complete analysis of the spectrum then requires a change in the relation between chemical shifts and spin–spin coupling constants, which can be achieved by using a spectrometer having a different working frequency[23] or by the employment of specific solvents to change the chemical shifts of individual protons[24].

Subspectra can be analysed in various ways depending on their complexity—manually[23] and by the use of previously calculated standard data[25], e.g. Corio's tables[26] (also Ref. 27, p. 587) or tables taking into account the resolving power of the spectrometers[28], and also with the application of electronic computers and special programmes[20,24,29,30].

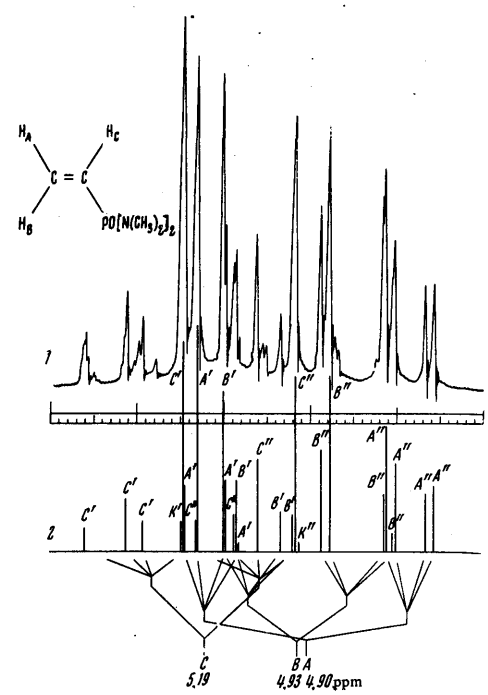


Figure 1. Proton magnetic resonance spectrum of ethylenic protons of vinylphosphonic bisdimethylamide (spectrum of type ABCX, with J_{CX} = 30.9, J_{BX} = 28.6, J_{AX} = 58.0, J_{AB} = 1.25, J_{BC} = 18.25, and J_{AC} = 12.35 c/s): 1) experimental spectrum at 100 Mc/s; 2) theoretical spectrum.

The presence of two phosphorus atoms in a molecule may produce considerable complication of the spectrum. Nevertheless, partial or complete analysis is possible in individual cases without the use of computers. Harris[31] used certain symmetry properties of the $A_nXX'A_h$ system to show that all parameters governing the form of such a spectrum can be obtained by direct measurement and simple calculation. If the spin–spin coupling constant between two groups of protons $J_{AA'} = 0$, the spectrum theoretically contains $2n + 1$ pairs of lines symmetrically arranged about $\nu_{A'}$, the chemical shift of $2n$ chemically equivalent protons. Since the nuclei are magnetically equivalent within each group of protons A and A', the spin–spin coupling constant between protons within a group does not affect the form of the spectrum, and therefore cannot be determined. The three remaining parameters of the spectrum J_{AX}, $J_{AX'}$, and J_X are elucidated by means of the relations

$$N = |J_{AX} + J_{AX'}|;\ L = |J_{AX} - J_{AX'}|\ .$$

The parameter N is easily determined from the distance between the pair of most intense lines in the spectrum (Fig. 4), representing half the total intensity. The remaining lines can be grouped into quartets, each corresponding to a definite value of the parameter χ, which assumes

integral values from 1 to n. The distance between the more intense inner lines of a quartet is connected with the parameters of the spectrum by the relation

$$S_{\text{inn}}(\chi) = (\chi^2 L^2 + J_X^2)^{1/2} - [(\chi - 1)^2 L^2 + J_X^2]^{1/2}.$$

The outer lines of the quartet are weak; the distance between them is determined by the similar expression

$$S_{\text{out}}(\chi) = (\chi^2 L^2 + J_X^2)^{1/2} + [(\chi - 1)^2 L^2 + J_X^2]^{1/2}.$$

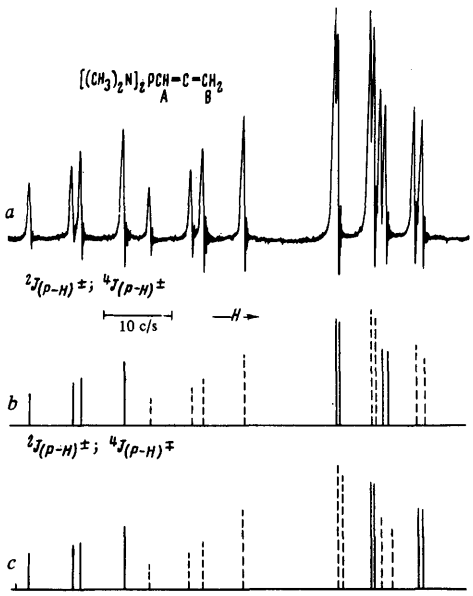

Figure 2. Proton magnetic resonance spectrum of allenic protons of propadienylphosphonous bisdimethylamide (spectrum of type AB_2X): *a*) experimental spectrum at 60 Mc/s; *b*) theoretical spectrum with the constants $^2J_{HP}$ and $^4J_{HP}$ having the same sign; *c*) theoretical spectrum with the constants having opposite signs.

The distance between the inner lines of the quartets increases with increase in χ, but does not exceed L, so that the latter can be determined roughly from the spectrum by finding the limit to which values of Sinn converge. At the same time the intensity of these lines drops rapidly. This applies also to the outer lines of the quartet, which diverge from the value $2L$. Since these lines are in general weak, in some cases only the first pair of lines ($\chi = 1$) can be observed. The constant $|J_X|$ is then determined by direct measurement from the distance between outer and inner lines of the first quartet ($\chi = 1$); from the results the parameter L is readily determined by means of the above formulae. If the outer lines cannot be observed, $|J_X|$ and L can be determined only from the inner lines of the first and second quartets, but the accuracy is considerably lower.

It is significant that, in spectra of this type, the form of the quartets depends only on the two parameters L and $|J_X|$, so that their appearance is completely determined by the ratio $L/|J_X|$. Fig. 4 shows the variation in the spectrum of $A_3XX'A_3'$ with change in this ratio. The general pattern is preserved in the spectra of compounds having a different number of protons [32].

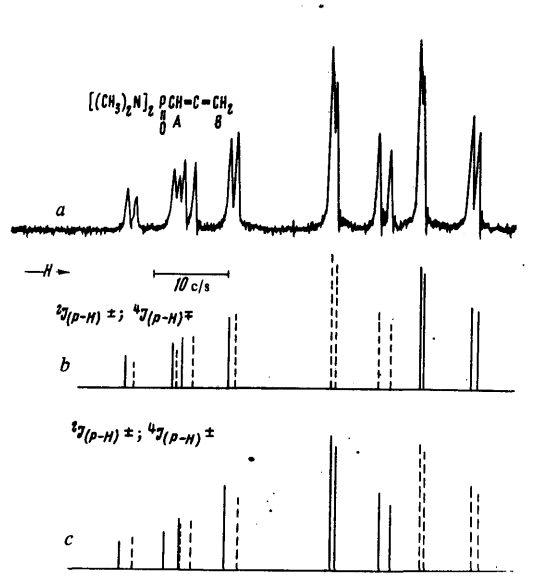

Figure 3. Proton magnetic resonance spectra of propadienylphosphonic bisdimethylamide.

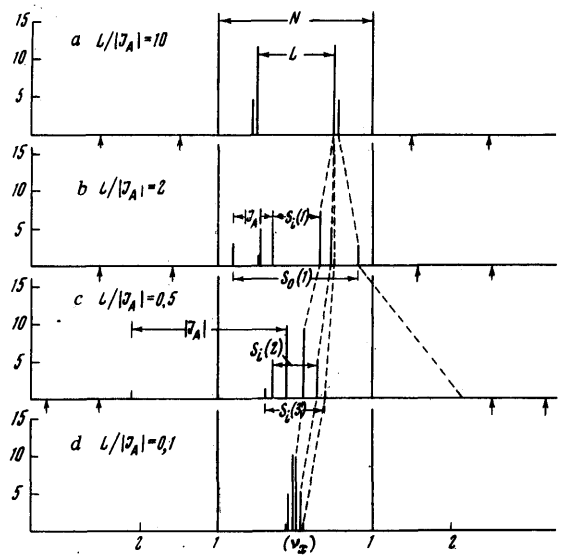

Figure 4. Theoretical spectra of the $A_3XX'A_3'$ system.

Complete analysis of the $A_nXX'A_n'$ spectrum enables only the absolute magnitude of the constant J_X to be determined. However, the relative signs of J_{AX} and $J_{AX'}$ can be ascertained: if any of the inner lines of the quartets lie outside the doublet N, these two constants are opposite

in sign; otherwise, they have the same sign. If the constant J_A is not zero, it is small, the general appearance of the spectrum is preserved, and each line in the quartets is split further; J_A can be evaluated from the magnitude of this splitting, although the calculation is fairly complicated[33]. A particular case is the simple AA'XX' spectrum: its complete analysis involves no theoretical difficulties, and all four spin–spin coupling constants can be determined without the use of tables or electronic computers[34].

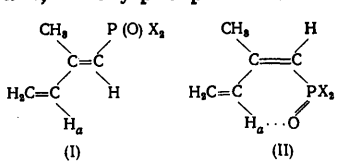
The present Section has considered ways of analysing the complicated p.m.r. spectra of organophosphorus compounds. It is noteworthy that in many cases the p.m.r. spectra are simple, first-order spectra not requiring special analysis. However, additional methods can be used for the analysis, in particular homonuclear and heteronuclear double and triple resonance, the method of two-quanta transitions[35–37], and also replacement of the magnetic nuclei by isotopes with analysis of the signals of ^{13}C satellites, but discussion of these aspects lies outside the scope of the present Review.

III. CHEMICAL SHIFTS OF PROTONS

According to Pauling (see 2.I in Ref. 38) the electronegativity of phosphorus coincides with that of hydrogen, and the chemical shift of the methyl protons in trimethylphosphine is consistent with the correlation found between the chemical shifts of the methyl protons in a methyl derivative of an element and the electronegativity of that element[39]. However, Table 1 shows that phosphonic, thiophosphonic, and phosphonium groups have a considerable deshielding effect, due primarily to the atomic contribution of the phosphorus-containing groups to the proton chemical shifts (transmissible through chemical bonds) and governed by the electron-accepting properties of such groups in comparison with the phosphinous (P^{III}) group. On the whole, estimates of the atomic contribution[25,40] are consistent with the Hammett constants, which indicate that phosphonate groups possess weak electron-accepting properties (close to those of the carboxy-group or the bromine atom). The greater deshielding effect of thiophosphonate than of phosphonate groups, in spite of the lower electronegativity of sulphur than of oxygen, definitely indicates considerable magnetic anisotropy of the P=S group.

Although in Mavel and Martin's estimation[41] the P=O group should also possess considerable magnetic anisotropy, this has not been confirmed by later work. In particular, the almost complete coincidence of the chemical shifts of the terminal protons (*cis* and *trans* with respect to phosphorus) in the spectra of derivatives of vinylphosphonic acid (Table 2),[20,24,42] and also the small difference between the chemical shifts of *cis*- and *trans*-protons in isomeric propenylphosphonates[43] and other analogous derivatives[24,44], indicate that magnetic anisotropy plays an insignificant part in the spectra of these compounds.

The Reviewers have investigated the chemical shifts of protons H_a and the methyl protons in isomeric derivatives of 2-methylbuta-1,3-dienylphosphonic acid of types



($X = Cl$, F, OR, NR_2, C_2H_5), and established that the polar effect of the phosphonic group is decisive in these compounds, leading to formation of an intramolecular hydrogen bond between H_a and the phosphoryl oxygen in isomer (II).[45,46] Whereas the difference between the chemical shifts of the methyl protons in the two isomers lies in the range 0.15–0.22 ppm, the difference for the protons H_a is considerably larger (1–1.5 ppm), although the changes in the geometrical arrangement of H_a and CH_3 in the two isomers are approximately equivalent. The addition of trifluoroacetic acid, which ruptures intramolecular hydrogen bonds, halves the difference for H_a. On the whole it can be accepted as a general principle that protons located spatially closer to a phosphoryl or a thiophosphoryl group resonate at lower field. However, the situation is more complicated in cyclic esters of phosphoric and phosphonic acids[47–53] and in five-membered rings containing phosphorus[54–56]; in particular cyclic oxygen atoms evidently exert no less effect than does phosphoryl oxygen.

Table 1. Chemical shifts and spin–spin coupling constants J_{HP} in the p.m.r. spectra of organophosphorus compounds[17].

	Type of compound	ν, ppm	J, c/s
PH	PH_3	—	182.2
	P^+H	—	495—515
	P (O) H	—	490—710
	P (S) H	—	490—650
PCH	$P(CH_3)_3$	0.9	2.8
	$P^+(CH_3)_4$	2.5	14.4

	P (S) $[N(CH_3)_2]_3$	2.6	10.8—11.1
PSCH	$P(SCH_3)_3$	2.3	9.8
	P (O) $(SCH_3)_3$	2.3	15.1—15.6
	P (S) $(SCH_3)_3$	2.4	17.5

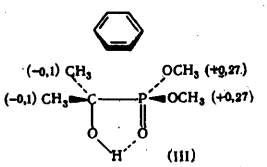
The tendency of phosphoryl compounds to form intramolecular and intermolecular hydrogen bonds is evidently the most characteristic feature distinguishing the proton resonance of these compounds. An intramolecular hydrogen bond is assumed to be the cause of the magnetic non-equivalence of the protons in compounds containing an asymmetric phosphorus atom[57,58]. The tendency of organophosphorus compounds to intermolecular hydrogen bonding has been assessed from the chemical shift of the proton in chloroform dissolved in these compounds[17]. This showed that, with compounds of the type $X_3P=O$, the tendency increases with the accumulation on the phosphorus of substituents X situated towards the end of the sequence

$$Cl < AlkS < AlkO < Alk < Alk_2N.$$

Thus the chemical shift of chloroform (7.08 and 7.28 ppm for a solution in cyclohexane and for the pure liquid)

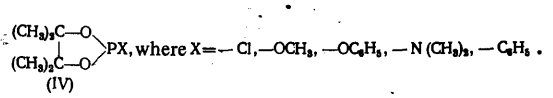
has the values 7.53, 8.00, 8.25, 8.61, and 9.11 ppm when dissolved in $Cl_3P{=}O$, $(CH_3S)_3P{=}O$, $(CH_3O)_3P{=}O$, $CH_3PO(OC_2H_5)_2$, and $((CH_3)_2N)_3P{=}O$ respectively.

The tendency to form hydrogen bonds involving the phosphoryl group determines in some measure the effect of various solvents on the proton chemical shifts. The effect of trifluoroacetic acid on the chemical shifts of protons in derivatives of 2-methylbutadienylphosphonic acid[45] has already been noted. The intramolecular hydrogen bond in dimethyl 1-hydroxyalkylphosphonates fixes the molecules in a definite conformation. When such compounds (III) are dissolved in benzene



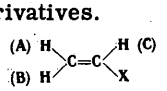
(III)

the solvent molecules are preferentially oriented in such a way that the magnetic anisotropy of the benzene ring produces shielding of methoxyl protons and deshielding of methyl protons[59]



(IV)

Table 2. Parameters δ (ppm) and J(c/s) of p.m.r. spectra of vinylphosphorus derivatives.



P-containing group X	δ_A	δ_B	δ_C	J_{AB}	J_{BC}	J_{AC}	J_{AX}	J_{BX}	J_{CX}
$POCl_2$	6.41	6.51	6.60	0.3	18.2	12.3	77.6	35.0	41.6
$PO(OCH_3)_2$	6.19	6.45	6.19	2.4	18.4	12.8	49.9	24.8	21.0
$PO(OC_2H_5)_2$	6.14	6.18	6.15	2.3	18.7	12.7	50.4	25.0	21.9
$PO[N(CH_3)_2]_2$	4.90	4.93	5.19	1.2	18.2	12.3	58.0	28.6	30.9
$PO(C_6H_5)_2$	5.10	5.10	5.35	2.3	17.9	13.2	36.3	20.4	26.3
$\dot{P}(C_2H_5)_2$	—	—	—	0.05	19.0	12.8	43.8	21.7	21.2
$\dot{P}(CH_3)_2C_6H_5$	—	—	—	0.4	18.6	12.8	48.5	25.3	24.0
$P(CH{=}CH_2)_2$	5.62	5.50	6.15	2.0	18.4	11.8	30.2	13.6	11.7

In the spectra of tetramethyldioxaphospholans of type (IV) the two pairs of methyl groups are not chemically equivalent. Dissolution in benzene increases the difference between their chemical shifts, which indicates the absence of rapid invertion relative to the phosphorus[60].

Use as solvents of strong acids capable of protonating organophosphorus compounds also causes a significant change in the chemical shifts of protons in groups located close to the centre of protonation. Correlation of the change in chemical shifts with the acid function of the solvent enabled protonation constants to be determined for a series of phosphines[61], phosphonates, phosphine oxides, and andions of phosphorus acids[62-64]. In the monomethylphosphonate, which is incapable of further protonation, the proton chemical shift of the methoxyl is independent of the acidity of the solution[64].

Thus examination of proton chemical shifts of organophosphorus compounds shows that in many cases this parameter depends significantly on the state of the phosphorus atom in the molecule and on the relative positions of the proton and the phosphorus-containing group. This enables proton chemical shifts to be used to establish the structure, the geometrical configuration, and the conformational equilibria of organophosphorus compounds, as well as for physicochemical investigations. However, there are no specific differences in the chemical shifts of protons that are caused by the presence of the phosphorus-31 nucleus: the above regularities are general in character and are due to the chemical characteristics of the phosphorus-containing groups, not to the magnetic properties of the phosphorus nucleus. From this point of view the spin–spin coupling of protons and phosphorus, to be considered in the next Section, is a considerably more valuable and interesting parameter for organophosphorus compounds.

IV. SPIN–SPIN COUPLING IN ORGANOPHOSPHORUS COMPOUNDS

1. Proton–Proton Interaction Constants

Neither proton chemical shifts nor proton–proton spin–spin coupling constants are specific in character, but conform to general rules. As a consequence of the low electronegativity of phosphorus, the constants J_{HH} are of the same order of magnitude as in hydrocarbons. The geminal constant $^2J_{HH}$ between protons attached to a carbon atom bound to phosphorus is ~ 10 c/s, as also in the fragment HPH (in chloromethylphosphine $ClCH_2PH_2$ these two constants are 10.4 and 9.8 c/s, the assignment being uncertain[22]); the constant is apparently negative in both cases[65]. In vinyl derivatives of phosphorus $^2J_{HH}$ varies in the range 0.05–2.34 c/s (positive),[20,24,35,36] the lowest value corresponding to the phosphonium compound $(C_2H_5)_3P.CH:CH_2$.[36] The vicinal constant $^3J_{HH}$ between protons in an ethyl group attached to phosphorus also lies near the usual value of 7–7.5 c/s,[29,30,65] independently of the state of the phosphorus; and in ethylenic derivatives it is ~ 12.5 c/s for *cis*-protons and 18.5 to 19 c/s for *trans*-protons[20,24,35,36], an appreciable change in the values of these constants being observed only when other substituents are present at the double bond[36,43,44,66-68]. This fact has been used[69,70] for the quantitative determination of the contents of *cis*- and *trans*-enolic forms in solutions of several substituted diethyl formylmethylphosphonates of the type $R.CH(CHO).PO(OC_2H_5)_2$.

The constants $^3J_{HH}$ between *ortho*-protons in aromatic phosphine oxides also have the usual values of 8–9 c/s.[40,71,72] Values are known for the constant $^3J_{HH}$ in the H–P–P–H system which are close to the vicinal constant in a hydrocarbon fragment (10.5 and 6.8 c/s for the two vicinal constants in diphosphine $H_2P{-}PH_2$[65]). In the H–C–P–H system, however, it varies within fairly wide limits, decreasing as electron-accepting groups accumulate on the phosphorus atom[65,73]:

Compound	CH_3PH_2	$(CH_3)_3\overset{+}{P}H$	$CH_3P(O)(H)(OH)$
$^3J_{HH}$, c/s	7.98	5.48	2.0

Allenic derivatives containing phosphorus show the long-range spin–spin coupling between protons, well known with allenic systems[74], having constants $^4J_{HH}$ and

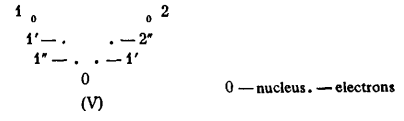
$^5J_{HH}$ of 6–7 ~ 3 c/s respectively[21,25,75–77]. Propenylphosphonic acid derivatives develop allylic spin–spin coupling between protons, with $^4J_{HH}$ being ~ 1 and ~ 1.5 c/s for *trans*- and *cis*-positions of the methyl group and the ethylenic proton[43,46,78].

The spin–spin coupling constants of protons and phosphorus are of considerably greater value for the p.m.r. investigation of organophosphorus compounds, and their intensive study during recent years has enabled the main regularities in their variation to be established. On the whole the principle rules governing magnitude and sign of the constants J_{HP} are the same as those for proton–proton spin–spin coupling, but proton–phosphorus interaction is greater in absolute magnitude and usually remains evident with a larger number of bonds separating the interacting atoms.

2. Sign of Spin–Spin Coupling Constants of Protons and Phosphorus

The relative signs of spin–spin coupling constants in molecules can be determined by analysis of complicated n.m.r. spectra, double and triple resonance, and the method of two-quanta transitions. Theoretical calculations[79] predict a positive (absolute) sign of the constant for directly bound ^{1}H and ^{13}C nuclei and for $^3J_{HH}$. During recent years new methods have been elaborated for determining the absolute signs of spin–spin coupling constants: relaxation times and saturation parameters of individual spectral lines have been shown[80] to depend on the absolute signs of the coupling constants; the dependence of the change produced by the field resulting from the action of the solvent, on the dipole moment of the test substance, has been established for the constants $^2J_{HH}$ and $^2J_{HF}$, which also enables the absolute signs of these constants to be determined[81,82]. Although the absolute signs of the constants have not been determined directly for proton–phosphorus interaction, comparison of available data on the absolute and relative signs of the constants in the spectra of various compounds enables us to elucidate for most cases the absolute signs of the spin–spin coupling constants involving ^{31}P nuclei (Table 3)[83–86].

The occurrence of particular signs of the constants (in saturated compounds) is explained theoretically[87] on the basis of Hund's multiplicity principle. In the case of two magnetic nuclei combined through two chemical bonds (V)



(V)

the Fermi contact interaction of the nuclear spins[88], which makes the chief contribution to the spin–spin coupling constant[89], can be accomplished in two ways.

(*a*) Direct overlapping of the orbitals of electrons 1′ and 2″. This leads to antiparallel pairing of the electron spins, as a result of which the nuclear spins 1 and 2, being oriented antiparallel to the electron spins, are paired together antiparallel, so that the spin–spin coupling constant between them is positive.

(*b*) Overlapping of orbitals with insertion of an intermediate atom. The spins of electrons 1′ and 1″, and independently of them the spins of electrons 2′ and 2″, are antiparallel. Since, however, 1″ and 2′ belong to the same atom, they will tend, according to Hund's rule, to be mutually parallel, the net effect of which is that electron spins 1′ and 2″, as well as nuclear spins 1 and 2, will tend to be parallel, so that the constant has a negative sign.

Table 3. Signs of spin–spin coupling constant of magnetic nuclei with phosphorus $^nJ_{PX}$.

X	n=1	n=2	n=3	n=4	X	n=1	n=2	n=3	n=4
^{1}H ^{13}C	+ +and−	+and− +and−	+ +	+and−	^{19}F ^{31}P	− −and+	+ +	+	+

Competition between the two mechanisms may lead in the case of geminal interaction to either a positive or a negative constant. Extension of this principle to other cases leads to the conclusion that, with an odd number of chemical bonds linking the interacting magnetic nuclei, the spin–spin coupling constant should assume positive values, whereas, with an even number of bonds, it may be either positive or negative. This principle is fully consistent with experimental data on the proton–phosphorus interaction constants[90], but with heavy nuclei directly attached to phosphorus negative constants are observed, for the most part contrary to predictions. The appearance of negative constants between directly bound nuclei was explained by Pople and Santry[91] by applying the molecular orbital method to spin–spin interaction. On the other hand, negative constants may also arise if not only contact interaction but also other contributions play an appreciable part in spin–spin coupling[92–94].

3. Spin–Spin Coupling of a Directly Bound Proton with Phosphorus $^1J_{HP}$

The constant $^1J_{HP}$ varies over a very wide range—from 138 c/s in the dihydrogen phosphide anion PH_2^-[95,96] to 1092 c/s in hydrogen tetrafluorophosphate HPF_4[97]—and is probably positive in all cases. The ease of identification in the spectra and the characteristic values of the constant $^1J_{HP}$, which vary fairly exactly with the valency state of phosphorus and the nature of the substituents, make this parameter extremely convenient both for establishing the structure and for assessing the electron distribution in phosphorus hydrides by means of proton magnetic resonance.

By analogy with the spin–spin coupling constant of directly bound ^{1}H and ^{13}C nuclei, the constant $^1J_{HP}$ has been generally recognised as depending on the *s*-character of the orbital in the H–P bond: $^1J_{HP} = 29.30 s_{PH}$, where s_{PH} is the *s*-character of the P–H bond in phosphine[67].

This relation explains satisfactorily the change in $^1J_{HP}$ on passing from three-coordinated compounds ($^1J_{HP} \simeq$ 200 c/s) to four-coordinated compounds (400–700 c/s), since in the former the P–H bonds are formed predominantly by p-electrons of the phosphorus with slight addition of *s*-character, whereas in four-coordinated compounds, with hybridisation of phosphorus close to sp^3,

these bonds contain 25% and more of s-character. The substantial variations in $^1J_{HP}$ within a group of compounds having the same coordination of phosphorus can be explained by the different electronegativities of the substituents: according to Bent's rule [98] the replacement of substituents on the central atom by more electronegative substituents leads to a concentration of p-character in orbitals in the direction of these electronegative substituents, with a resultant enhancement of the s-character of the coupling with hydrogen atoms. However, this approach is open to criticism.

Whereas with compounds of three-coordinated phosphorus hybridisation can vary within wide limits owing to transition of the lone pair from the s-state to sp^3-hybridisation, with phosphonium salts a significant change in hybridisation is improbable. Yet, whereas in phosphines $^1J_{HP}$ varies within comparatively narrow limits (182 to 216 c/s on passing from phosphine to diphenylphosphine [61]), phosphonium salts show a considerably larger variation (436, 506–510, and 870 c/s for $[(t\text{-}C_4H_9)_3PH]^+$, [61] $[(C_6H_5)_3PH]^+$, [61,94] and $[(C_6H_5O)_3PH]^+$ [94] respectively). The increase in $^1J_{HP}$ on passing from phosphonium salts to dialkyl hydrogen phosphites (695.5 c/s in $HO.P(CH_3O)_2$ [92,99]) and to compounds containing five-coordinated phosphorus, for which the $^1J_{HP}$ constants are especially large

R—PF_2(OR′)	RPF_2(NHR′)	ArPF_2	HPF_4
730—830 c/s[100]	850—858 c/s[101]	739—780 c/s[100–104]	900 c/s[105]	1075—1092 c/s (depending on temp.) (Ref.97)

is still less explicable from this point of view. Although increase in the s-character of the bonding orbitals occurs on passing from three-coordinated to more highly coordinated phosphorus compounds, a decrease in s-character is rather to be expected in four-coordinated compounds with electronegative substituents having a lone pair of electrons (Cl, O, N) and in compounds with five-coordinated phosphorus, owing to hybridisation involving d-orbitals [106].

An explanation of this variation in $^1J_{HP}$ was given by McFarlane and White [94], who suggested, and confirmed experimentally on protonated phosphines, that, by analogy with the behaviour of $^1J_{HC}$, [107] not only the s-character of the P–H orbital but also the charge on the phosphorus atom greatly affects the magnitude of $^1J_{HP}$. It had been shown theoretically [107,108] that the spin–spin coupling constant of directly bound nuclei depends on the cube of the charge, so that small changes in the charge may have a substantial effect on the constant. This new approach opens up wide possibilities of explaining the effects of substituents on $^1J_{HP}$ and elucidating the distribution of electron density in organophosphorus molecules. Thus the effect of solvents on $^1J_{HP}$ in dimethyl hydrogen phosphite (this parameter varies from 627.9 c/s in solution in an ammoniacal buffer (pH 11.4) to 734.3 c/s in trifluoroacetic acid [99]) can be explained by a difference in solvation of the P=O group and the accompanying change in the charge on the phosphorus. The increase in $^1J_{HP}$ in the above five-coordinated phosphorus compounds is obviously due to the accumulation of electronegative substituents, which produce an increase in the positive charge on the phosphorus.

The above regularities in the spin–spin coupling of directly bound ^1H and ^{31}P atoms can be extended in considerable measure to the longer-range interaction of these nuclei, but their relative positions in space then play a considerably greater part.

4. Spin–Spin Coupling of Proton and Phosphorus in a Geminal Position $^2J_{HP}$

Geminal proton–phosphorus spin–spin coupling constants are of considerable interest both for the identification of organophosphorus compounds and for establishing general n.m.r. rules in connection with the electron distribution in them. It is usually easy to elucidate these constants in the proton spectra, and often their signs relative to $^1J_{HP}$, $^3J_{HP}$, etc. can often be determined, which facilitates the establishment of their absolute signs. The limits of variation in $^2J_{HP}$ are fairly wide, from +59.0 c/s in *cis*-propenylphosphonic dichloride [43] to between −21 and −22 c/s in compounds of the type $R.CH_2.PO(OC_2H_5)_2$, where R is an electron-accepting group having a multiple bond (C=O, C≡N, C≡C). [109,110] It is interesting that these limits exceed only slightly the known limits of variation in geminal proton–proton constants [111], but they will undoubtedly be extended for proton–phosphorus interaction.

At least three factors—the state of hybridisation at substituents on the phosphorus atom, the substituents attached to the carbon atom, and the configuration of the molecule—govern the value of $^2J_{HP}$ in the H–C–P system. In saturated four-coordinated phosphorus compounds this parameter is usually negative, varying in the vicinity of −15 to −20 c/s, [37] but it has been found recently [29] that $^2J_{HP}$ and $^3J_{HP}$ have the same signs in ethylphosphonic dichloride and difluoride, which indicates a positive absolute sign of the geminal proton–phosphorus constant $^2J_{HP}$ (+19.6 and +14.1 c/s in $C_2H_5POF_2$ and $C_2H_5POCl_2$ respectively‡). Comparison of the relative signs of the constants in ethylenic [20,24,35,36,43] and allenic [21,76,85] organophosphorus compounds shows convincingly that the geminal H–C–P constant at an unsaturated carbon atom is always positive. On the whole substituents at a carbon atom have the same effect on $^2J_{HP}$ as on the proton–proton coupling constant $^2J_{HH}$: [111] the introduction of electronegative substituents, change in the hybridisation of carbon from sp^3 to sp^2, and also the introduction of electron-donating substituents—all produce a change in $^2J_{HP}$ towards *positive values*. Substituents on the phosphorus obviously conform on the whole to the same rule in their effect on $^2J_{HP}$: electronegative substituents, capable of moving electrons to d-orbitals of phosphorus by a conjugation mechanism, produce a change in the geminal constant towards positive values.

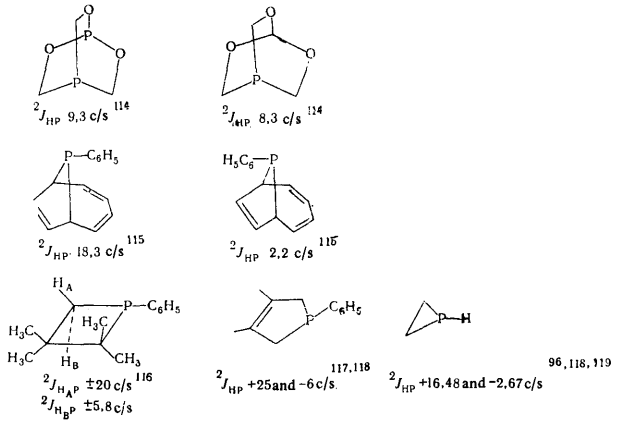
The effect of substituents on $^2J_{HP}$ is considerably smaller in three-coordinated phosphorus derivatives, although the attachment of chlorine atoms to the phosphorus or the transition from an sp^2- to an sp^3-hybridised carbon atom increases the parameter, as with the four-coordinated compounds:

Compound	$(CH_3)_3P$	$(CH_2{=}CH)_3P$	$CH_3CH_2PCl_2$
$^2J_{HP}$, c/s	+2.66[65]	+11.74[25]	+15.0§[113]

‡These results differ somewhat from the values obtained in an unpublished paper [112].

§We have adopted a positive sign for $^2J_{HP}$ in ethyldichlorophosphine on the basis that the geminal and vicinal constants in the spectrum of this compound [113] have the same sign.

In phosphines containing aliphatic and aromatic substituents $^2J_{HP}$ varies only within the narrow limits of zero to +4 c/s, but considerable departures from these limits are observed in compounds containing the phosphorus atom in a strained ring:



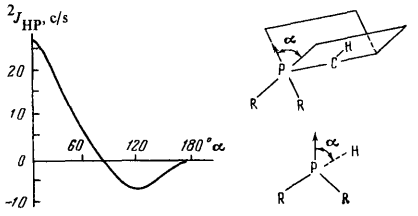


Figure 5. Angular dependence of constant $^2J_{HP}$ in phosphines.

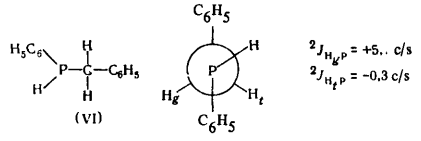
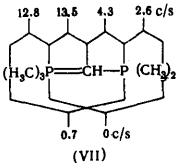
Albrand et al. [118] have analysed the above and other similar data, and have shown convincingly that the geminal constant $^2J_{HP}$ in phosphines is determined mainly by the mutual arrangement of the proton and the substituents on the phosphorus (Fig. 5). Data for compounds having a rigid configuration extend also to benzylphenylphosphine



in which the non-equivalence of the two methylene protons is due to inhibited rotation. Comparison of the proton–proton and proton–phosphorus constants enables us not only to determine the absolute signs of the latter but also to assign them to certain protons [118].

Unfortunately, so few data are available on the spin–spin coupling constants of five-coordinated phosphorus compounds that no general conclusions can be drawn.

It is interesting that the geminal constants $^2J_{HP}$ in the phosphinophosphorane



correspond exactly to the above values for three- and four-coordinated phosphorus [120].

5. Spin–Spin Coupling of Proton and Phosphorus in the Vicinal Position $^3J_{HP}$

Vicinal proton–phosphorus constants are evidently always positive, and on the whole depend on the same factors as do the geminal constants, but the mutual positioning of the interacting nuclei plays a still greater part. Analysis of vicinal constants in cyclic and unsaturated compounds [121–123], for which it is possible to estimate the dihedral angle Φ between the HC^1C^2 and C^1C^2P planes in the $H–C^1–C^2–P$ system, showed that the dependence of $^3J_{HP}$ on Φ is completely analogous to the corresponding relation for proton–proton interaction [124] (Fig. 6): (i) $^3J_{HP}$ has its maximum value at Φ = 180°; (ii) $^3J_{HP}$ has its minimum value or is zero when Φ = 90°; (iii) when Φ = 0° the constant $^3J_{HP}(0°) = (0.5–0.33)^3J_{HP}(180°)$; (iv) with other values of the angle Φ the parameter $^3J_{HP}$ assumes intermediate values.

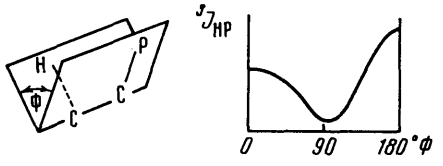


Figure 6. Angular dependence of constant $^3J_{HP}$.

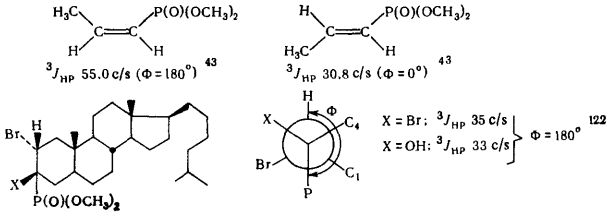
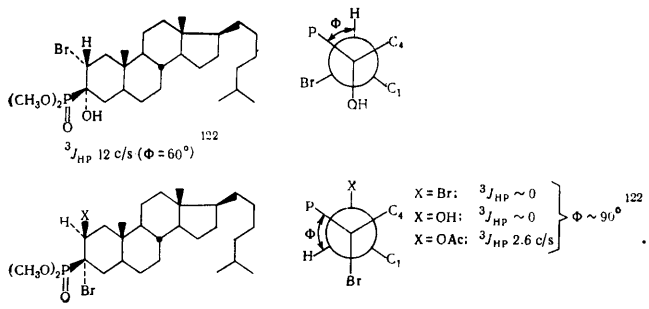
The spin–spin coupling constant of the phosphorus atom in the dimethoxyphosphinyl group and a vicinal proton varies from 9 to 55 c/s with different values of Φ:





The above dependence on the dihedral angle and the considerable range of variation in $^3J_{HP}$ make elucidation of the vicinal proton–phosphorus interaction constant especially valuable in stereochemical investigations.

Substituents attached to carbon atoms have the same effect on $^3J_{HP}$ as in proton–proton interaction: electronegative substituents produce a decrease in the parameter. Thus for the bisdimethylamides of a series of vinylphosphonic acids $^3J_{HP}$ varies as follows [20,74]:

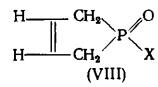
X = H	CH_3	$N(CH_3)_2$	OCH_3
$^3J_{HP}$ = 28.7	18.4	14.0	10.5 c/s

On the other hand, introduction of electronegative substituents at the phosphorus atom and the change from tervalent to four-coordinated phosphorus compounds produce increases in $^3J_{HP}$, as with geminal proton–phosphorus interaction. In a series of derivatives of vinylphosphonic acid, for example, the parameter falls in the sequence [20,21,24,35,36,43–45]

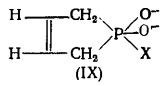
$$P(O)Cl_2 > P(O)(SC_2H_5)_2 > P(O)[N(CH_3)_2]_2 > \overset{+}{P}R_3 > P(O)R_2 > PR_3,$$

and in *cis*-prop-1-enylphosphonic dichloride the constant $^3J_{PH,trans}$ = 85.0 c/s [43] assumes the maximum value known at present for constants of this type. Electronegative substituents, capable of conjugation involving vacant *d*-orbitals of phosphorus, evidently cause rehybridisation of the orbitals and enhancement of the *s*-character in the direction of the phosphorus–carbon bond. It is possible also that the variation in the parameters is associated with a change in the charge on the phosphorus. However, variation in the substituents attached to three-coordinated phosphorus in the allenic derivatives $CH_2:C:C(CH_3).PX_2$ is accompanied by variation in $^3J_{HP}$ in the opposite sequence—8.9, 7.8, and 3.4 c/s when X represents C_6H_5, $N(CH_3)_2$, and Cl respectively [21].

Although no considerable spin–spin coupling in the =CH–C–P system has been detected in open-chain allyl compounds, the parameter $^3J_{HP}$ is quite large (36 to 40 c/s) in cyclic phospholens of the type



(VIII)



(IX)

and varies little with the coordination number of the phosphorus [124–126].

Considerable values of $^3J_{HP}$ are found also in systems containing a heteroatom, and depend more on the nature of the heteroatom than of the substituents attached to phosphorus [17,127–130]:

H–C–O–P	H–C–N–P	H–C–S–P
8–12 c/s	11–12 c/s	14–22 c/s

As with other vicinal constants this parameter, too, has been found to depend on the dihedral angle [48,58], and $^3J_{HCOP}$ is apparently also maximal with the interacting nuclei in the *trans*-position.

Thus the parameters $^3J_{HP}$, usually easily identifiable in the p.m.r. spectra of organophosphorus compounds, are extremely sensitive to their electronic structure and especially their geometrical structure, and can therefore be widely used in analysing the structure of compounds.

6. Long-range Proton–Phosphorus Spin–Spin Coupling $^nJ_{HP}$

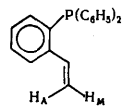
Long-range spin–spin coupling $^nJ_{HP}$ is observed in many cases through 4–8 bonds in allenic and acetylenic systems containing phosphorus atoms. A series of acetylenic phosphonates show a uniform decrease in $^nJ_{HP}$, proportional to the cube of the distance between the hydrogen and phosphorus nuclei [131], as *n* increases from 3 to 6; with *n* = 6 the constant $^6J_{HP}$ is still considerable (2.15 c/s). The long-range spin–spin coupling constant of protons and phosphorus is lower in phosphines and their oxides and sulphides than in phosphonates, but even in heptatriynyldiphenylphosphine $(C_6H_5)_2P.[C:C]_3.CH_3$ spin–spin coupling $^8J_{HP}$ = 0.7 c/s is observed [132,133]. Unfortunately, the absolute signs of the constants in such systems have not been studied in detail; double resonance has shown that the constants $^4J_{HP}$ and $^1J_{FP}$ in prop-1-ynylphosphonic acid $CH_3.C:C.POF_2$ have opposite signs [134], so that the proton–phosphorus constant is positive.

Considerable spin–spin coupling $^4J_{HP}$ and $^5J_{HP}$ is observed in allenic compounds containing a three- and four-coordinated phosphorus atom [21,25,75,77]. In compounds of the type $CH_2:C:CH.POR_2$ the constants $^4J_{HP}$ vary between –10 and –18 c/s with increase in the Taft inductive constant σ_1 of the substituents (R = Alk, Ar, NAlk$_2$, OAlk, Cl). [21] In the analogous compounds containing three-coordinated phosphorus the constant $^4J_{HP}$ is proportional to the Hammett constant σ_n, and has a negative sign in all cases except when at least one of the substituents is a dimethylamino-group; this is probably due to the ability of the lone pair of the nitrogen to conjugate with vacant 3*d*-orbitals of phosphorus [21].

The constant $^5J_{HP}$ in the allenic phosphonate $(CH_3)_2C::C:CH.POX_2$ with X = Cl is +12.1 c/s, [21,135] but in compounds with other substituents attached to phosphorus it is lower (6.1, 6.3, 7.8, 9.7, and 5.4 c/s when X = $N(CH_3)_2$, C_6H_5, [21] OC_2H_5, [136] F, [77] and C_2H_5 [75] respectively). The constant may be assumed to be positive in all compounds of this type. It is interesting that, as in other cases, the proton–proton interaction parameter in this system is considerably smaller and more constant: $^5J_{HH}$ varies in the range 3.1–3.5 c/s.

The analogy between proton–phosphorus and proton–proton long-range interaction is apparent in the considerably lower long-range coupling constants in allylic and aromatic than in acetylenic and allenic systems. In $CH_3.CH:CH.POX_2$ the constants $^4J_{HP}$ = 0–3.5 c/s (probably negative), the splitting being greater with methyl and phosphorus-containing groups in the *cis*-position than in the *trans*-isomers [43,45,66,137]. Derivatives of phosphonic acids with 1,3-diene substituents $CH_3XCH:CH.CH:CH.POY_2$ (*trans*, *trans*) exhibit splitting of the $C_{(3)}$ proton signal with the constant $^4J_{HP}$ = 1.6–1.7 c/s. [138] The constants for the methyl protons in *o*-tolylphosphorus derivatives and for the ring *meta*-protons in various phenylphosphorus compounds lie in the range 1–4.2 c/s. [40,71,72]

However, the discovery of long-range spin–spin coupling in *o*-vinylphenyldiphenylphosphine



(X)

$^5J_{H_AP}$ 1.1 c/s

$^5J_{H_MP}$ 0.1–0.05 c/s

is quite unexpected. In this case interaction is attributed to direct overlapping of the electron clouds of the proton and phosphorus through space. Such interaction is not observed in the corresponding phosphonium iodide [139].

Long-range spin–spin coupling constants in systems containing a heteroatom are extremely small [140–144]. Nevertheless, it has been possible to establish by means of double resonance that they may have different signs depending on the substituents attached to the phosphorus [140]:

Compound	$(C_2H_5O)_3P$	$(C_2H_5O)_3P{=}O$	$(C_2H_5O)_3P{=}S$
$^4J_{HCCOP}$, c/s	−0.55	+0.84	+0.73

The variation in sign may be due to the conformational constitution of the compounds, since the above constants result from the averaging of all possible conformational structures.

In the fragment P.CO.N.CH.CH the constant $^5J_{HP}$ exceeds $^4J_{HP}$, and this serves to confirm the hypothesis of two simultaneous mechanisms of spin–spin coupling, making opposite contributions to the latter constant [144].

The above relations of the proton chemical shifts and the proton–phosphorus spin–spin coupling constants with the molecular and electronic structures of organophosphorus compounds present wide possibilities for the p.m.r. investigation of these compounds. The next Section examines the most important lines of research.

V. MAIN LINES OF THE p.m.r. INVESTIGATION OF ORGANOPHOSPHORUS COMPOUNDS

The practical application of p.m.r. spectroscopy is concerned primarily with establishing the molecular and geometrical structure of organic compounds.

Proton magnetic resonance has recently been widely used to confirm the structure of five-membered phosphorus-containing heterocycles, which result from the reaction of tervalent phosphorus derivatives with conjugated systems. As already remarked, the constants $^3J_{HP}$ are quite considerable in cyclic compounds, which enables the latter to be distinguished unambiguously from open-chain compounds [124–126,145–148]. Close attention has been paid to esters of phosphonic acids with groups, potentially capable of keto–enol tautomerism [109,149,150] or containing a mobile hydrogen atom [109,151,152], which are distinguished by a considerable $^2J_{HP}$ constant (10–21 c/s). Several esters, thioesters, and amides of phosphoric, thiophosphoric, and phosphonic acids of interest as insecticides have been identified by p.m.r. for analytical purposes [127–129].

Widespread use is made of p.m.r. for the easy establishment of the geometrical structure of organophosphorus compounds, especially ethylenic derivatives. In effect only this method has provided an approach to the problem of the *cis–trans* isomerism of ethylenic phosphonates [43,66,68,121–123]; establishment of the *trans*-structure of 2-cyanovinylphosphonic esters necessitated reconsideration of the mechanism of their formation [153].

Application of this method enabled a study to be made of the aldo-*cis–trans*-enol tautomerism of substituted formylmethylphosphonates in solution [69,70].

Extremely interesting results have been obtained on the conformations of open-chain organophosphorus compounds, made possible by the phenomenon of molecular asymmetry and governed by the difference in the chemical shifts and the spin–spin coupling constants for protons in the various conformations [118,154–156]. Study of the effects of temperature and the solvent on the spectra provides additional opportunities for investigating the problem [157]. Development of research on these lines includes the question of the pseudorotation of systems that are stable at ordinary temperatures [158,159].

The appearance of the p.m.r. method gave a sharp impetus to the development of research on interactions such as hydrogen bonding and intermolecular association. The Reviewers established the presence of an intramolecular hydrogen bond in derivatives of 2-methylbutadienylphosphonic acid [45,46]; an intramolecular hydrogen bond explains the molecular association effect in the spectrum of 2,4-dichlorophenyl methyl isopropylphosphoramidate [160]; an intermolecular hydrogen bond affects the chemical shift of the proton of chloroform dissolved in organophosphorus compounds [17]. This aspect is closely connected with the problem of chemical exchange in complexes with organophosphorus ligands [161]. The investigation of complexes of organophosphorus compounds with metals is inherently a fairly complicated problem, solution of which requires the application not only of p.m.r. but also of other types of nuclear resonance spectroscopy [161–166].

We note in conclusion that the p.m.r. method has found a valuable application for studying the protonation of organophosphorus compounds by strong acids [61–64,94]. In individual cases it is possible to determine the lifetime of molecules in the protonated state [167].

Base-catalysed Rearrangements of Epoxides

V.N.Yandovskii and B.A.Ershov

The principal characteristics of the rearrangements of epoxides due to the elimination of α-, β-, γ-, δ-, and ϵ-protons under the influence of bases have been considered.
The bibliography includes 135 references.

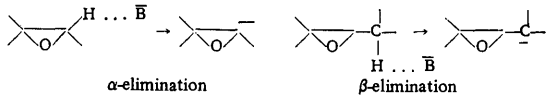
V.	Elimination of δ- and ϵ-protons	408

I. INTRODUCTION

Numerous monographs and reviews have been devoted to the reactions of epoxides[1-7]. Two types of reactions—addition and isomerisation—are the most characteristic of epoxides. Until recently, the study of the chemistry of epoxides was confined in most cases to reactions in which nucleophilic agents added to them and to their acid-catalysed isomerisations to carbonyl compounds. Recently new reactions of epoxides catalysed by strong bases were discovered. This review is a first attempt at a systematic account of the data which have accumulated on the isomerisation of epoxides in the presence of strong bases, i.e. processes which are not accompanied by the intermolecular addition of any external agents to the epoxides.

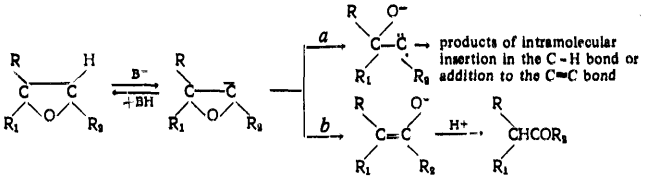
In a study of a base-catalysed isomerisation of the so called "non-functional" epoxides, i.e. epoxides without any other functional groups, Crandall showed that, depending on the reaction conditions, strong bases abstract a proton from the α- or β-position in relation to the oxygen atom of the epoxy-ring[8,9]:



When the epoxide molecule contains an electron-accepting functional group, there is a possibility of the elimination of the proton from the carbon atom adjoining this group (processes involving the elimination of a proton from a heteroatom in the functional group are not discussed in this review). In general one can consider the elimination of α-, β-, γ-, δ-, and ϵ-protons, etc. and the various reactions of epoxides due to these processes.

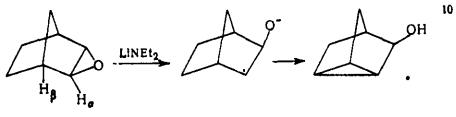
II. ELIMINATION OF AN α-PROTON

The majority of the cases of elimination of the α-proton described hitherto have been observed with non-functional epoxides or epoxides having aromatic substituents, since the introduction of any functional group into the side chain of the epoxide favours the removal of a proton from other parts of the molecule. The α-elimination results in the formation of an epoxide anion which subsequently isomerises according to a carbenoid (*a*) or an anionic (*b*) mechanism†, depending on the reaction conditions and the structure of the initial epoxide:



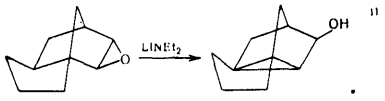
In the presence of hydrogen atoms in the α- and β-position, β-elimination takes place as a rule. Two cases constitute exceptions.

1. The approach of the base to the β-proton is greatly hindered as a result of which α-elimination takes place. For example, epoxynorbornane (I) isomerises to a nortricyclanol as a result of the intramolecular insertion of β-alkoxycarbene in the C — H bond[10], so that the approach of the base to the β-H atom is sterically hindered:



(I)

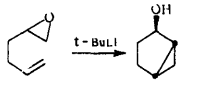
The epoxide (II) reacts similarly:



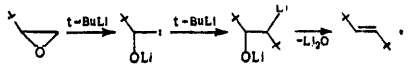
(II)

2. α-Elimination is observed with epoxycycloalkanes containing 8 — 10 carbon atoms in the ring. A characteristic property of such rings is transannular reactions owing to the closeness in space of the opposite carbon atoms[12,13]. Thus the epoxy-derivatives of *cis*- and *trans*-cyclo-octenes isomerise on treatment with $LiNEt_2$ to the corresponding bicyclo-octanols as a result of a transannular carbenoid insertion[14,15].

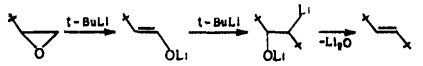
The attempt to trap the carbene in an intermolecular reaction involving addition to the C=C bond was unsuccessful, while the analogous attempt in the intramolecular reaction succeeded[16]:



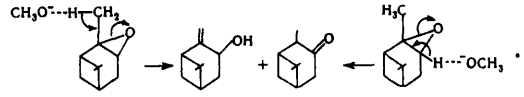
Crandall and coworkers[17] observed that, when t-butyl-epoxyethane is treated with t-butyl-lithium, *trans*-di-t-butylethylene is formed in high yield. The authors explain this finding by the formation of a carbene and its subsequent insertion in the t-butyl-lithium molecule:



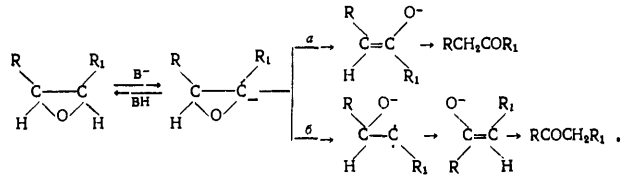
The simpler pathway for the formation of di-t-butylethylene via the intermediate formation of the product of the addition of t-butyl-lithium to the epoxide is rejected, since the product of this reaction (an alcohol) would not be dehydrated under the reaction conditions. We believe that the recently observed[18] enhanced tendency of lithium alkoxides derived from allyl alcohols to undergo addition reactions with lithium alkyls makes it unnecessary to postulate the insertion of a carbene in the t-butyl-lithium molecule, since the reaction can take place according to the mechanism



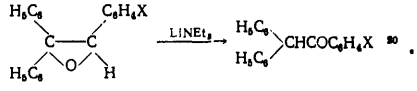
The isomerisation of alkyl-substituted epoxides in the presence of strong bases to allyl alcohols (β-elimination, see p. 405) is usually accompanied by the formation of ketones as a side reaction. For example, the isomerisation of the epoxy-derivative of α-pinene in the presence of sodium methoxide leads to pinocarveol and pinocarvone[19]:



A control experiment showed that pinocarveol isomerises only slightly to pinocarvone under the reaction conditions. Similar results were obtained also in a few other cases[8,16]. All these findings suggest that ketones are formed mainly via a pathway involving the initial elimination of the α-proton from the epoxide[8]. Further conversion of the epoxidecarbanion into the ketone can theoretically take place via two mechanisms:

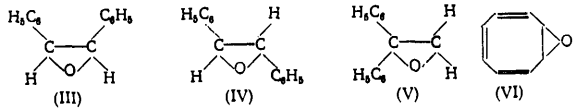


As a rule the reaction follows pathway *a*, as can be seen from the following example:



However, it is noteworthy that aryl substituents may stabilise the carbanion.

Carbonyl compounds are the main products of the base-catalysed isomerisation of the epoxides (III) — (VI)[20-22]:

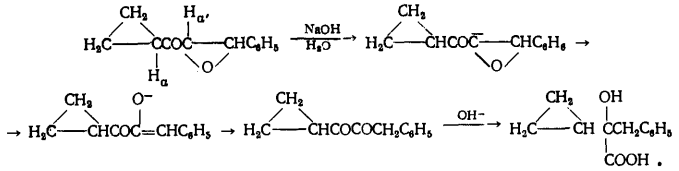


(III) (IV) (V) (VI)

The isomerisation of α-ketoepoxides in an alkaline medium does not usually stop at the stage involving the

† The mechanisms quoted do not imply that a "free" carbene or carbanion is formed during the isomerisation. The reactions are classified on the basis of the final products.

formation of a α-diketone[23-29], since the latter undergoes the benzil rearrangement under the reaction conditions[29]:

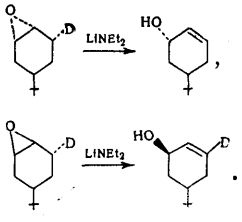


Of the two possible pathways for the conversion of the ketoepoxide—the Favorskii rearrangement (with the abstraction of a proton from the α-carbon atom as the initial stage) and the benzil rearrangement (with the abstraction of a proton from the α'-carbon atom as the initial stage)—in the above example the second actually occurs, owing to the greater mobility of the hydrogen atom in the α'-position.

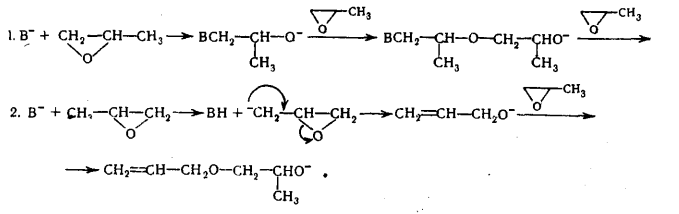
In conclusion we may note a unique case of the isomerisation of epichlorohydrin and its homologues to α-chloroketones as a result of the elimination of the α-proton under the influence of lithium orthophosphate. β-Elimination products were not detected in these reactions. According to Sheng[30], this is evidence of a considerable increase of the mobility of the proton linked to the carbon atoms in the epoxy-ring under the influence of the adjacent chloromethyl group.

III. ELIMINATION OF A β-PROTON

In a study of the mechanism of the base-catalysed isomerisation of the epoxy-derivatives of *cis*- and *trans*-oct-4-enes (labelled with deuterium in 4- and 5-positions) to allyl alcohols, Cope and Heerin demonstrated unambiguously that the first reaction stage is the abstraction of a proton from the β-position of the epoxide[31]. However, it is not clear whether the process proceeds via the intermediate formation of a carbanion or via a concerted mechanism. A further step towards the understanding of the β-elimination mechanism was taken by Thummel and Rickborn[32], who showed that the conversion of epoxides into aryl alcohols is a *cis*-elimination reaction:

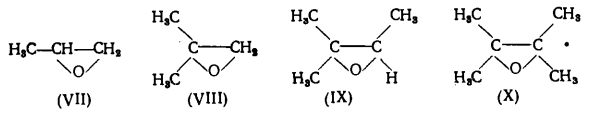


A study of epoxide polymers obtained in the presence of alkaline catalysts revealed a high content of unsaturated terminal groups[33]. It has been suggested[34] that the initiation and propagation of the polymer chain may be represented by mechanism (1), while the unsaturated terminal groups are formed as a result of the competing reaction (2):



The latter leads to a lowering of the molecular weight, since the abstraction of a proton from the β-position of the monomer by the growing polymer chain leads to chain termination[35].

In a study of the polymerisation of epoxides in dimethyl sulphoxide catalysed by potassium t-butoxide, Price and Carmelite[36] showed that the yield of the polymer and its molecular weight decrease in the series of epoxides (VII) > (VIII) > (IX) > (X). The yield of allyl alcohols increases simultaneously in the same sequence:



The ratio of the addition and β-elimination products is determined to a large degree by the basicity of the alkaline agent. As a rule, the stronger the base the lower the yield of the addition product. For example, in the presence of n-propyl-lithium or n-butyl-lithium epoxycyclohexane isomerises to cyclohex-3-enol and a small amount of 2-alkylcyclohexanol, while in the presence of allylsodium and allylmagnesium bromide, only the alkylation products were obtained[37] (see also Bedos[38,39]).

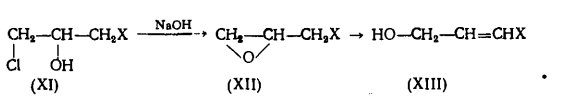
A comparative study of the effects of base strength on the relative amounts of the alkylation and β-elimination products from epichlorohydrin was made by Fabris[40].

The bulk of the base and the steric accessibility of the reaction centre have a considerable influence on the proportions of the addition of β-elimination products. It has been shown[41] that the rates of abstraction of a proton from primary, secondary, and tertiary alkyl groups decrease in the series primary $\gg$ secondary $\gg$ tertiary. The introduction of a methyl group into the epoxy-ring greatly facilitates the conversion of these epoxides into allyl alcohols. The epoxy-derivatives of 1-methylcycloalkenes[42], α-pinene[8,43-46], Δ^3-carene[44-47], β-diisobutene[8], and many others[48,49] isomerise in this way.

Methyl-substituted epoxides can isomerise to allyl alcohols under very mild conditions, for example in chromatography on alumina[50-54] and on treatment with aluminium alkoxides[55,56] and di-isobutylaluminium[57] and methoxyaluminium[58] hydrides.

The isomerisation of a series of epoxycycloalkanes to allyl alcohols as a result of the elimination of a β-proton has been described[8,43,59-64].

The elimination of a β-proton is greatly facilitated in the presence of an electron-accepting substituent in the methylene (or methylidyne) group attached to the epoxy-ring. It was noted long ago that the principal products of the dehydrohalogenation of the chlorohydrins (XI), where X = SO_2Ar,[65] CN,[66] $COOCH_3$,[67] and C≡C – R[68-72], are not the epoxides (XII) but the alcohols (XIII):

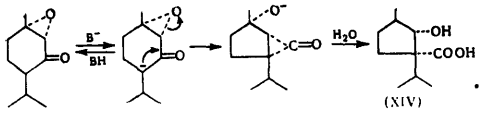


It has been shown in a number of studies that epoxides of type (XII), where X = Cl [40] (c.f. Sheng[30]), NO_2,[73] PR,[74] and CH = CHR [75] also readily isomerise to allyl alcohols.

IV. ELIMINATION OF A γ-PROTON

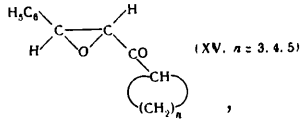
The base-catalysed abstraction of a proton from the carbon atoms in the epoxy-ring (α-elimination) is facilitated by the presence in the ring of a heteroatom and the shift of electron density towards it. Since the epoxy-ring exhibits an *I* effect[76-79], the relative ease of β-elimination is understandable. The abstraction of a proton from a carbon atom in the side chain of the epoxide is particularly easy when an adjoining electronegative group is present (C = O, CN, COOR). Rearrangements of "functional" epoxides of this kind will be considered in the present section.

The Favorskii rearrangement of α-epoxyketones is a well known example of the base-catalysed isomerisation of epoxides as a result of the elimination of a γ-proton. For example, it has been shown in a number of investigations[80-86] that, in the presence of bases (OH^-, OR^-), the epoxy-derivative of piperitone rearranges to the hydroxy-acid (XIV):



(XIV)

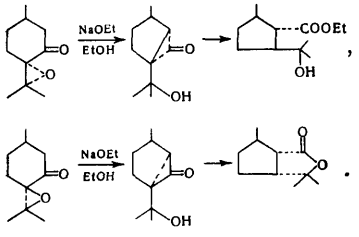
Analogous reactions of the epoxy-derivatives of isophorone and α-epoxyketones of type (XV),



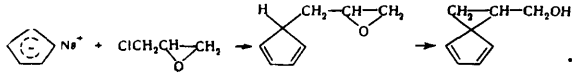
(XV, n = 3, 4, 5)

have been described[29,86].

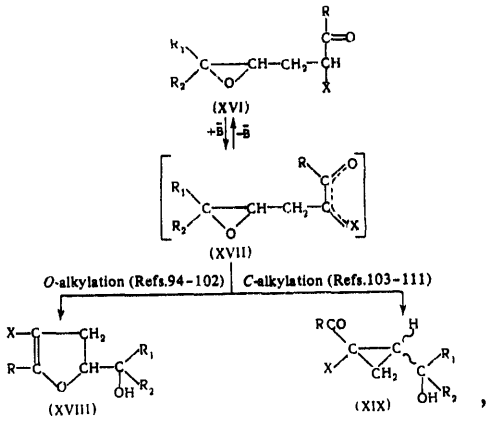
The study of the Favorskii rearrangements of the epoxy-derivatives of *cis*- and *trans*-pulegones showed that in both cases the process is stereospecific[87-90]:



Yet another example of the base-catalysed isomerisation of an epoxide as a result of the elimination of a γ-proton has been described[91]:

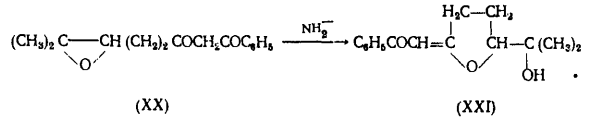


In a series of studies, Temnikova, Ershov, and coworkers investigated in detail the isomeric conversions of epoxides of type (XVI) containing in the side chain the RCO—CH—X fragment, which is capable of mesomerism. Depending on the nature of the substituents R and X, in an alkaline medium the epoxides (XVI) isomerise as a result of the intramolecular *O*-alkylation of the RCO—CH—X fragment with formation of 4,5-dihydrofurans (XVIII) or the *C*-alkylation products of the same fragment—derivatives of cyclopropane (XIX)‡:



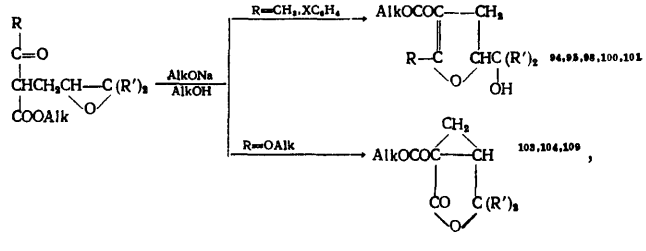
where R = CH_3, XC_6H_4, OCH_3, or OC_2H_5, X = C_6H_5, CH_3 H, OCH_3, OC_2H_5, CN, $COCH_3$, or COC_6H_5, and R_1, R_2 = H, CH_3, or XC_6H_4.

The base-catalysed isomerisation of the γε-diketo-epoxide (XX) results in the formation of exomethylene-tetrahydrofuran (XXI)[112]:



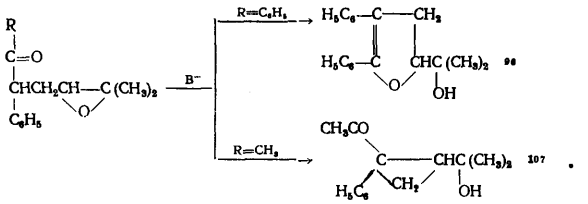
In contrast to the analogous intermolecular processes leading exclusively to *C*-alkylation products[3], intramolecular alkylation in systems of type (XVI) results as a rule in the formation of *O*-alkylation products[94-102,112,113-116]. This can be accounted for by the dominant role of steric factors in the above intramolecular reactions[118,119], since the steric requirements which must be met by the geometry of the transition state in *O*-alkylation are usually less rigorous than in *C*-alkylation; moreover, *O*-alkylation leads to less strained systems than does *C*-alkylation.

Another important factor determining the mode of intramolecular alkylation in systems (XVI) with a similar structure is the degree of delocalisation of the charge in the intermediate carbanion (XVII). A high degree of delocalisation of the charge in the anion leads to the formation of *O*-alkylation products, i.e. in this case alkylation takes place at the most electronegative reaction centre[117]:



‡ The possibility of the base-catalysed isomerisation of cyclopropyl ketones to 4,5-dihydrofurans has been discussed[92,93].

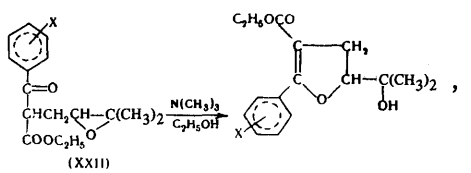
where R' = CH_3 or XC_6H_4 and Alk = CH_3 or C_2H_5.



Experimental data agree qualitatively with the calculations by the LCAO-MO method[120].

The mode of base-catalysed isomerisations of epoxides (XVI) is determined mainly by internal (structural) factors. A change in external conditions (the solvent, the basic catalyst, and temperature) does not as a rule affect the site of intramolecular alkylation.

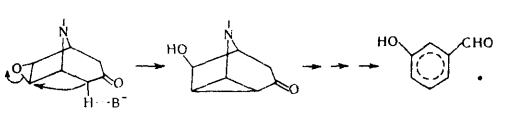
Kinetic studies on the mechanism of the isomerisation reaction[121]



(XXII)

where X = H, *p*-CH_3, CH_3O, Br, or *m*-Cl, show that the reactions of epoxides (XXII) having electron-donating substituents (particularly with X = *p*-CH_3O) involve predominantly a relatively non-polar transition state and a synchronous mechanism including the abstraction of a proton from the carbon atom of the keto-form (XXII) with the subsequent intramolecular *O*-alkylation accompanied by a transfer of the reaction centre. In the case of epoxides (XXII) with electron-accepting substituents, a proton is abstracted in the first stage from the oxygen atom of the enolic form of the β-ketoester (XXII); subsequently the oxygen atom of the enolate anion formed attacks the carbon atom of the epoxy-ring. A characteristic feature of the last transition state is the *cis*-orientation of the negatively charged oxygen atom and the residue containing the epoxy-rings§.

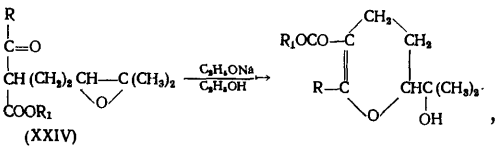
The above reactions include certain rearrangements in the benzonorbornene series and certain alkaloids[123-125]. For example the alkaloid skopinone (XXIII) is converted into *m*-hydroxybenzaldehyde in the presence of bases. It is suggested that the initial stage in this rearrangement is the elimination of a γ-proton with subsequent intramolecular *C*-alkylation[124,125]:



(XXIII)

V. ELIMINATION OF δ- AND ε-PROTONS

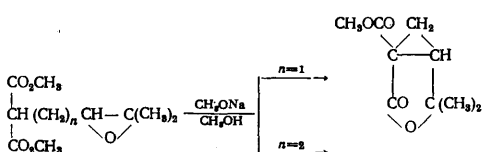
Temnikova, Ershov, and coworkers showed that epoxides of type (XXIV) isomerise in an alkaline medium as a result of intramolecular *O*-alkylation with formation of 5,6-dihydro-1,4-pyrans[113-116,126]:



(XXIV)

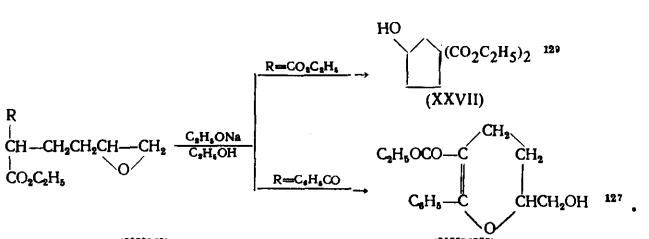
where R = CH_3 or XC_6H_4 and R_1 = CH_3 or C_2H_5.

According to a kinetic study, the first stage of the process is the elimination of a δ-proton under the influence of the base. This results in the formation of a mesomeric carbanion, which isomerises to the corresponding dihydropyran[127]. Derivatives of cyclobutane or cyclopentane, i.e. *C*-alkylation products, were not detected in the reactions investigated[113-119]. Nor are they formed on treating with bases under severe conditions the epoxide (XXV, *n* = 2), the homologues of which, for example (XXV, *n* = 1), isomerise under analogous conditions to cyclopropane derivatives[103,104,109]:



(XXV)

Another homologue of the epoxide (XXV, *n* = 2), namely (XXVI, R = $COOC_2H_5$), readily rearranges to a substituted cyclopentane (XXVII), while the epoxide (XXVI, R = C_6H_5CO) isomerises under analogous conditions as a result of intramolecular *O*-alkylation with formation of the dihydropyran (XXVIII):



(XXVI) (XXVIII)

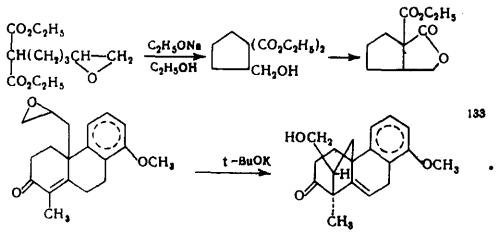
This difference in the mode of isomerisation emphasises yet again the relation between the degree of delocalisation of the charge in the intermediate mesomeric anion and the mode of isomerisation of epoxides with mobile hydrogen atoms in the carbon side chain[118] (cf. p. 406).

The difference between the reactivities of the epoxides (XXV, *n* = 2) and (XXVI, R = $COOC_2H_5$) may be accounted for by steric hindrance to cyclisation. It is noteworthy that derivatives of cyclobutane are not formed in either case owing to the comparative difficulty of the formation of a four-membered ring[130].

Several examples of the isomerisation of epoxides to allyl alcohols as a result of the elimination of a δ-proton have been described[131,132].

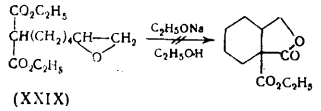
§ ^1H NMR spectroscopic data indicate rotation about the C=C bond in the enolate anions of carbonyl compounds even at comparatively low temperatures[122].

The elimination of a ϵ-proton with subsequent intramolecular *C*-alkylation leads as a rule to the formation of cyclopentanes[129,133-135]:



In the examples quoted intramolecular attack is directed to the sterically more hindered secondary carbon atom of the epoxy-ring. These results agree with kinetic studies[130], according to which the rate of formation of a five-membered ring in the intramolecular *C*-alkylation reaction is approximately 1000 times faster than the rate of formation of a six-membered ring.

The difficulty of the formation of a six-membered ring is demonstrated by the unsuccessful attempts at the isomerisation of the epoxide (XXIX):



(XXIX)

In conclusion we may note that the study of the base-catalysed rearrangements of epoxides is not only of purely chemical interest, since epoxides are biogenetic precursors of many natural products[131-135]. The isomeric transformations discussed above can probably serve as models of certain natural processes.

Reactions of Derivatives of Phosphorus(III) Acids with Carbonyl Compounds

I.V.Konovalova and A.N.Pudovik

The review describes the reactions of fully esterified phosphorous acids, phosphoramidites, and the mixed anhydrides of dialkylphosphorous and carboxylic acids with carbonyl compounds not containing halogens: unsaturated and saturated aldehydes and ketones, α-diketones, and carbonyl compounds activated by ethoxycarbonyl, phosphoryl, nitrile, or any other electronegative group. The modes and mechanisms of these extremely varied and interesting reactions, which are important for progress in the chemistry of organophosphorus compounds and theoretical organic chemistry, have been examined.
The bibliography includes 188 references.

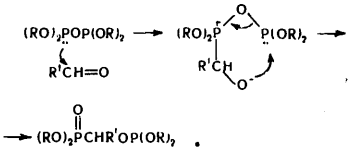
I. INTRODUCTION

One of the most important and interesting reactions in the chemistry of organophosphorus compounds is the Arbuzov reaction (A.E. Arbuzov) in which fully esterified phosphorus(III) acids react with alkyl halides and other halogen-containing organic compounds. However, in recent years there has arisen another extremely interesting and promising trend in the research on the chemistry of organophosphorus compounds involving reactions of fully esterified phosphorous acids, phosphoramidites, and mixed anhydrides with various organic compounds not containing halogen atoms. These reactions lead to the formation of compounds with a tetra- or penta-coordinate phosphorus atom. Reactions of this type proved to be extremely varied owing to the fact that the phosphorus atom exhibits biphilic properties under these conditions, which allows both electrophilic and nucleophilic interactions. Vigorous study of these reactions greatly extended synthetic possibilities in organic chemistry, led to the discovery of a number of extremely interesting types of reactions of organophosphorus compounds, and resulted in the introduction of many new features in the investigation of their mechanisms. A particularly large number of studies have been made on the reactions of derivatives of phosphorus(III) acids with various carbonyl compounds, which are the most important and interesting reactions of this type. Despite their specificity, in many cases they may be regarded as varieties of the Arbuzov reaction, proceeding via a general two-stage mechanism in which the first or both phases of the Arbuzov reaction take place. It is noteworthy that individual reactions of carbonyl compounds, mainly with phosphites, have been described in monographs dealing with particular aspects of the chemistry of organophosphorus compounds published abroad in previous years[1,2] and also in reviews and research reports in which the results of the investigators' own work are discussed[3-8]. In the present review, the authors' aim was to examine fully and systematically the reactions of derivatives of phosphorus(III) acids with carbonyl compounds without halogen atoms which have been described in the literature. Reactions of this type with phosphorus(III) acid chlorides were discussed in the review of Pudovik and Khairullin[9].

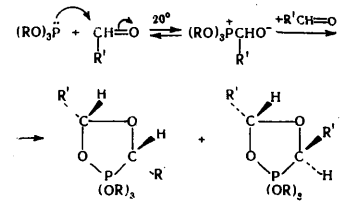
II. REACTIONS OF DERIVATIVES OF PHOSPHORUS(III) ACIDS WITH ALDEHYDES AND KETONES

1. Reactions with Saturated Aldehydes and Ketones

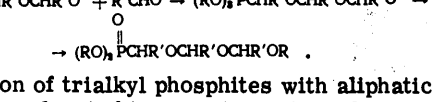
The reactions of phosphorus(III) acid esters with aldehydes were investigated for the first time by Arbuzov and Alimov, who established that pyrophosphites react with aldehydes to form products containing tri- and tetracoordinate phosphorus atoms[10]:



At room temperature aliphatic aldehydes react extremely slowly with trialkyl phosphites[11]. As a result of attack by the phosphorus atom on the carbon atom of the carbonyl group, an unstable 1:1 adduct is formed, further reaction of which with a second aldehyde molecule leads to diastereoisomeric 1,2,4-dioxaphospholans[11]:



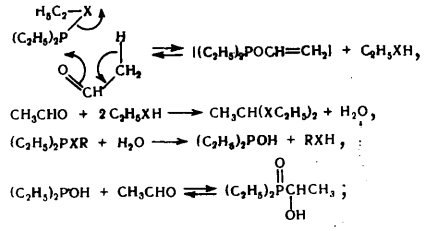
In the presence of an excess of the aldehyde, a 3:1 adduct is formed, which is stabilised by conversion via intramolecular dealkylation into the corresponding phosphonate[4]:



The reaction of trialkyl phosphites with aliphatic aldehydes at an elevated temperature also takes place with formation of products resulting from the addition of two

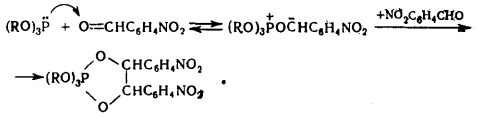
and three aldehyde molecules and having a linear structure[12].

The esters of diethylphosphinous and diethylphosphinothious acids react differently with acetaldehyde: the products are α-hydroxyethyldiethylphosphine, and diethylphosphine oxides and the diethylmercaptal or diethylacetal of acetaldehyde[13]. According to the authors, these reactions involve nucleophilic substitution with formation of a cyclic transition complex:

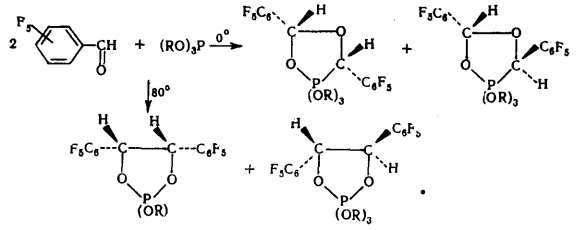


where X = O or S and R = C_2H_5 or CH = CH_2.

In contrast to data published previously[14], Ramirez showed that *o*- and *p*-nitrobenzaldehydes condense under mild conditions with trialkyl phosphites to form 1,3,2-dioxophospholans[15]. He postulates that the presence of electronegative substituents in the aldehyde molecule may be responsible for the direct attack of the phosphorus atom on the oxygen atom of the carbonyl group, which leads to the formation of an intermediate adduct with a P — O — C linkage:

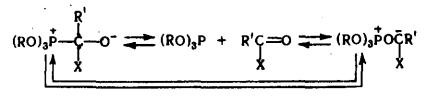


However, the possibility of the attack by the phosphorus atom also on the carbon atom of the carbonyl group, by analogy with unsubstituted aldehydes, resulting in the formation of an intermediate adduct having a P — C bond, which subsequently rearranges further to an adduct with a P — O — C linkage, is not ruled out in these reactions. This hypothesis is confirmed by the reaction of pentafluorobenzaldehyde with trialkyl phosphites which takes place with formation of 1,4,2-dioxophospholans at a low temperature and 1,3,2-dioxaphospholans at an elevated temperature[16,17]:

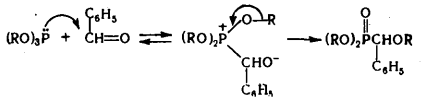


On dissolution, 1,4,2-dioxophospholan may be converted into 1,3,2-dioxaphospholan. It is suggested that this process involves the dissociation of the P — O and C — O bonds in 1,4,2-dioxaphospholan with regeneration of the aldehyde molecule and the formation of a 1 : 1 adduct with a P — C — O linkage, which rearranges into a 1 : 1 adduct with a P — O — C linkage; this adduct subsequently reacts with an aldehyde molecule to form 1,3,2-dioxaphospholan.

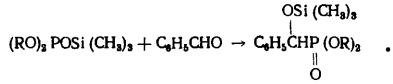
Thus it proved possible to demonstrate for pentafluorobenzaldehyde the initial formation of an adduct with a P — C — O linkage and its transformation into one with a P — O — C linkage. The mechanism proposed is probably general for reactions of tervalent phosphorus with activated carbonyl compounds. Possibly in these reactions there is equilibrium between the initial reactants and the adducts with P — C — O and P — O — C linkages[18]:



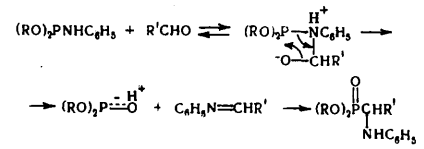
m-Nitrobenzaldehyde and aromatic aldehydes with electropositive substituents are inert with respect to trialkyl phosphites below 100°C.[18] At elevated temperatures aromatic aldehydes react with trialkyl phosphites via a mechanism involving the Arbuzov rearrangement with formation of alkoxyalkylphosphonic acid esters[19]:



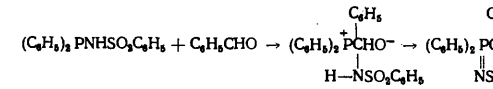
These reactions are accompanied by the oxidation of phosphites to phosphates[20]. Reactions of aromatic aldehydes with alkyl trialkylsilyl phosphites take place similarly[21]:



The reactions of aldehydes with phosphoramidites are extremely interesting and varied. Dialkyl *NN*-dialkylphosphoramidites and phenylphosphonamidous acids[24] react with aldehydes to form esters of α-aminoalkylphosphonic acids[25]. Evdakov postulated that in these reactions the phosphorus atom attacks the carbon atom of the carbonyl group, but subsequently Hudson and other investigators showed that in most cases these reactions involve the initial attack by the nucleophilic nitrogen atom on the carbon atom of the carbonyl group. Dialkyl *N*-phenylphosphoramidites react with aldehydes similarly. The intermediates formed are dialkyl phosphites and Schiff bases, the interaction of which leads to the final reaction product[26-28]:

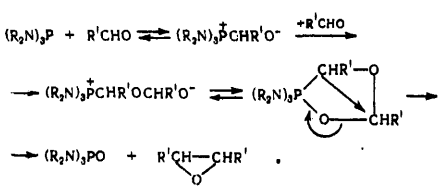


Earlier another reaction mechanism was suggested for dialkyl *N*-phenylphosphoramidites[29,30]. Pudovik and Batyeva showed that the reaction of *N*-diphenylphosphinobenzenesulphonamide and benzaldehyde takes place differently. In the benzenesulphonamide the nucleophilic activity of the nitrogen atom is reduced owing to the electron-accepting group linked to it, as a result of which the reaction takes place via the phosphorus atom[31]:



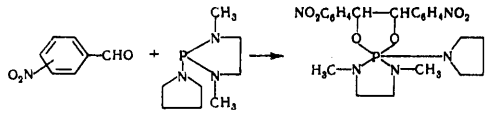
Phosphorous tris(dialkylamides) react with aliphatic, aromatic, and heterocyclic aldehydes with formation of various products. When there are electropositive substituents in the aldehyde, a 1 : 1 adduct having a dipolar structure and a P — C bond is formed. The presence of electronegative substituents promotes the interaction of the 1 : 1 adduct with a second aldehyde molecule to form *NNN*-tris(dialkyl)phosphoramides and epoxy-compounds.

It is suggested that the epoxy-compounds are formed via an intermediate 1,4,2-dioxaphospholan[32]:

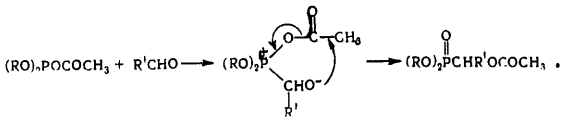


According to Ramirez[18], the formation of an epoxide in the reaction of phosphorous tris(dimethylamide) with nitrobenzaldehyde takes place via intermediate 2:1 adducts which have the structure of dipolar ions with a P—O—C linkage.

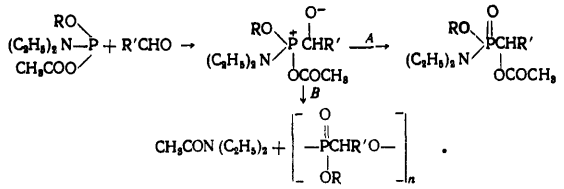
When nitrobenzaldehyde reacts with cyclic phosphorous triamides, stable spiro-1,3,2-dioxaphospholans are formed[18]:



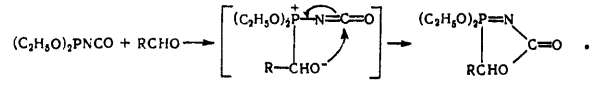
Mixed anhydrides of phosphorous and carboxylic acids readily react with aldehydes via a mechanism involving the Arbuzov rearrangement with formation of acyl derivatives of α-hydroxyalkylphosphonic acid esters[33-36]. In this case the attack by the negatively charged oxygen atom in the intermediate dipolar ion is directed to the electrophilic and sterically accessible carbon atom of the acetyl group:



When phosphoramidoacetatidites react with aliphatic aldehydes, the reaction takes place predominantly according to mechanism *A*, while with benzaldehyde mechanism *B* obtains[36]:

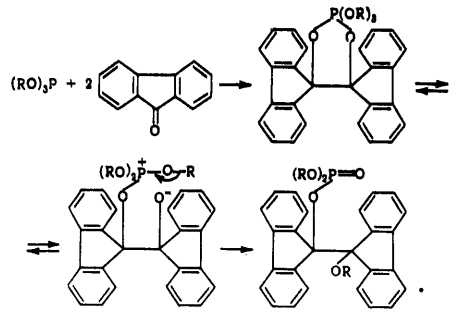


Diethyl phosphoroisocyanatidite reacts with benzaldehyde, *p*-chloro-, *p*-bromo-, and *p*-methoxy-benzaldehydes, and butyraldehyde to form cyclic esters of alkyldiethoxyphosphazocarbonic acid and polymeric 1:1 adducts; the cyclic bromobenzyldiethoxyphosphazocarbonic acid ester is converted on heating into a polymeric adduct[37]:

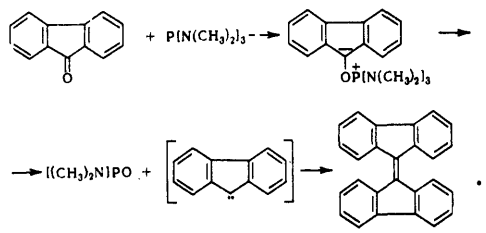


In many cases ketones react with trialkyl phosphites somewhat differently than aldehydes. Thus the reactions of tri-isopropyl phosphite with benzophenone and 4,4′-dichlorobenzophenone take place slowly on prolonged heating with formation of tri-isopropyl phosphate, di-isopropyl diphenylmethylphosphonate, and propene[38]:

Fluorenone reacts with trialkyl phosphites at room temperature to form 1,3,2-dioxaphospholans. In a polar solvent the phospholan may exist partly in an open-chain dipolar form and may be converted into phosphate as a result of dealkylation[39]:

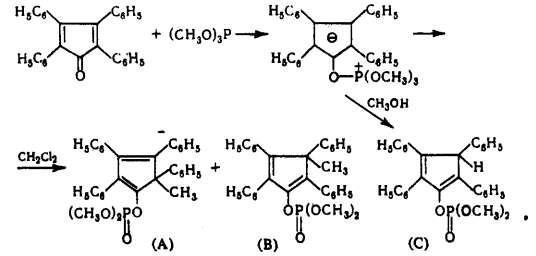


In the reaction with tri-isopropyl phosphite, tri-isopropyl phosphate and phenanthrone were isolated[38], while in the presence of an excess of phosphite the reaction proceeds via a mechanism analogous to that described above for benzophenone[38]. The reaction of fluorenone with phosphorous tris(dialkylamide) results in the formation of *NNN*-tris(dialkyl)phosphoramide and dibiphenyleneethylene, the latter probably resulting from the dimerisation of a carbene[40]:



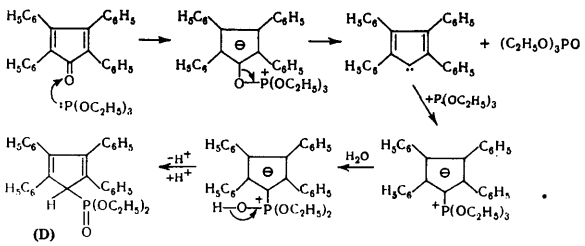
Cyclic phosphorous triamides form with fluorenone spiro-1,3,2-dioxaphospholans[40].

The mode of reaction of trialkyl phosphites with tetraphenylcyclopentadienone depends on the conditions[41,42]: a mixture of isomeric enol phosphates (A) and (B) is formed in dichloromethane and in methanol the product is compounds (C)[41]:

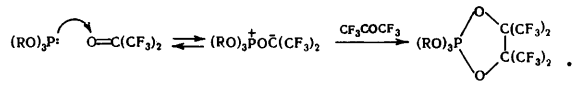


When tetracyclone reacts with trialkyl phosphites in aqueous ethanol, a more complex mixture of products is

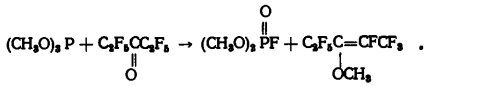
formed, the main component of which is the phosphonate (D). The proposed reaction mechanism includes the formation of a carbene and an ylide as intermediates[42]:



The reaction of derivatives of phosphorus(III) acids with perfluoroketones takes place very readily. Hexafluoroacetone reacts with trialkyl phosphites, phosphonites, phosphinites[43-46], *NN*-dialkylphosphoramidites[47], phosphorous tris(dialkylamides)[40,46], and cyclic phosphorous triamides[40] at low temperatures with formation of 1,3,2-dioxaphospholans:

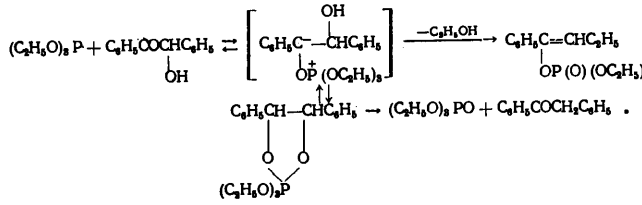


At an elevated temperature perfluoroketones form with trialkyl phosphites dialkyl phosphorofluoridites and enolic ethers derived from ketones[48]:

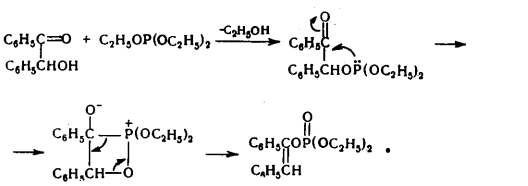


A more complex mixture is formed at an elevated temperature with phosphorous tris(dialkylamides)[46,49]: the main product is bis(dialkylamino)difluorophosphorane[46]. Trialkyl phosphites were found to react differently with hexafluorothioacetone[50]:

Reactions of trialkyl phosphites with α-hydroxyketones and their derivatives have been described. Benzoin reacts with triethyl phosphite at 180°C: the formation of an intermediate dipolar ion, which is stabilised by conversion into an enol phosphate with elimination of an alcohol or is converted into 1,3,2-dioxaphospholan, has been suggested. 1,3,2-Dioxaphospholan decomposes under the reaction conditions into triethyl phosphate and deoxybenzoin[51]:

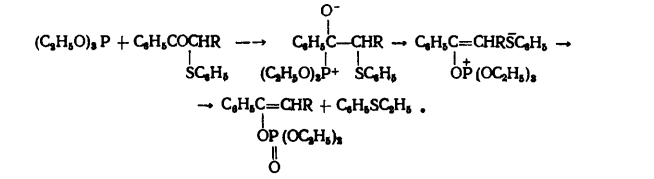


An enol phosphate is formed in the reaction of benzoin with triethyl phosphite in the presence of sodium[52]. In this case a somewhat different mechanism has been proposed:

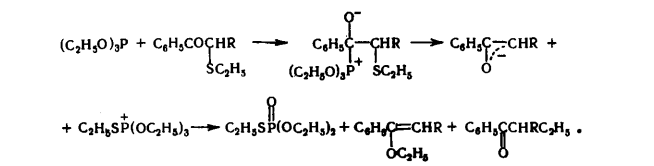


Benzoin acetate also reacts with the phosphite to form an enol phosphate[51].

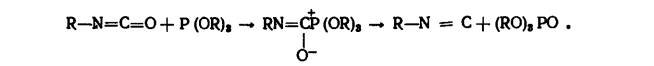
Depending on their structure, α-ketosulphides react with triethyl phosphite in two ways[53]. If the alkyl(aryl)-thio-group can be split off as an anion, the corresponding enol phosphate and ethyl phenyl sulphide are formed:



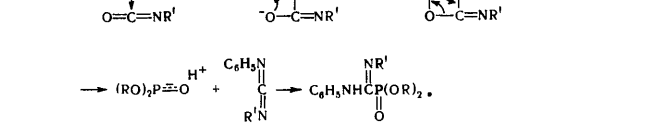
In the case of benzyl ethyl sulphide, the ethylthio-group is split off as an anion with greater difficulty and the reaction proceeds preferentially with formation of a vinyl ether or ketone derivatives[53]:



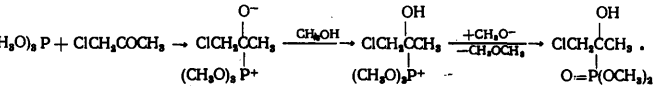
The reactions of isocyanates with trialkyl phosphites result in the formation of trialkyl phosphates and isonitriles[54]:



Dialkyl *N*-phenylphosphoramidites react with aromatic isocyanates to form dialkyl *NN'*-diphenylamidinophosphonates[55]. The reaction proceeds according to a mechanism involving the initial attack by the nitrogen atom on the carbon atom of the carbonyl group:



When the reactions of aldehydes and ketones with trialkyl phosphites are carried out in the presence of proton-donating agents, the intermediate dipolar ions are stabilised by the addition of a proton; the subsequent intramolecular dealkylation leads to the formation of α-hydroxyalkylphosphonates[56]:



Similar reactions probably occur also between triphenyl phosphite and aldehydes and ketones in an aqueous medium[2,57]:

When carbonyl compounds react with trialkyl phosphites in the presence of phosphorus trichloride or other acid chlorides, the intermediate addition product reacts with them to form tris-(α-dialkoxyphosphonoalkyl) phosphites[58]:

Ivanov showed recently that trialkyl phosphites are capable of condensing with formaldehyde and compounds containing a mobile hydrogen atom in the methylene group, forming the corresponding phosphonomethyl derivatives[59-61]:

$$(RO)_3P + CH_2O + HCHXY \rightarrow (RO)_2\overset{O}{\overset{\|}{P}}CH_2CHXY + ROH .$$

Aliphatic and aromatic aldehydes and furfural undergo this reaction. It is suggested that it proceeds according to the following mechanism[60]:

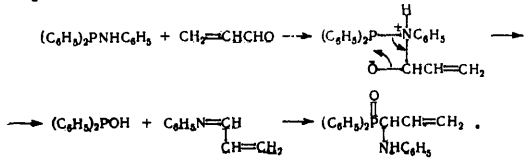
$$(RO)_3P + R'CHO \rightleftarrows (RO)_3\overset{+}{P}CHR'O^- \rightarrow [(RO)_3\overset{+}{P}CHR'OH] \rightarrow$$

$$\rightarrow [(RO)_3\overset{+}{P}CHR'CHXY]OH^- \rightarrow (RO)_2\overset{O}{\overset{\|}{P}}CHR'CHXY + ROH .$$

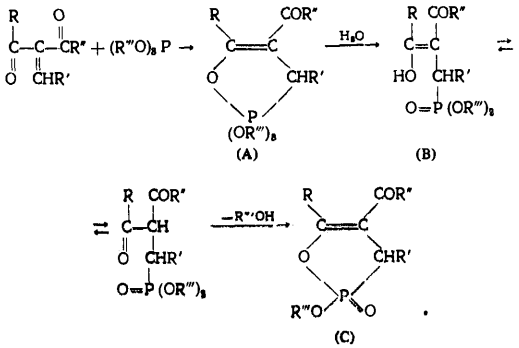
2. Reaction with $\alpha\beta$-Unsaturated Aldehydes and Ketones

The reactions of phosphites and phosphoramidites with $\alpha\beta$-unsaturated aldehydes and ketones proved to be extremely interesting; in many cases it was possible to follow clearly the formation of intermediate dipolar ions and to elucidate the effect of structural factors on their stability. Extensive studies in this field have been carried out by B. A. Arbuzov and coworkers. In a study of the reaction of triethyl phosphite with the simplest unsaturated aldehyde—acrolein—they showed that under mild conditions the reaction leads to the formation of 2,2,2-trialkoxy-Δ^4-oxaphospholen[62-64]. The earlier hypothesis of the isomerisation of Δ^4-phospholens to esters of γ-alkoxyalkenylphosphinic acids was not confirmed[65-67].

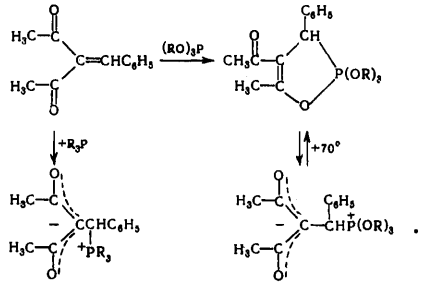
Pudovik and Batyeva showed that in reactions of $\alpha\beta$-unsaturated aldehydes with diphenylphosphinous anilide, products with the phospholan structure are not formed. The reactions probably take place with initial attack by the nitrogen atom on the carbonyl carbon atom and leads to the formation of α-arylamino-γ-aryl(alkyl)allyl(diphenyl)phosphine oxides[28]:



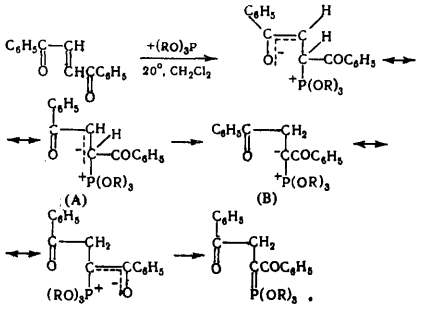
The reaction of trialkyl phosphites with ethylideneacetylacetone and with ethylidene- and benzylidene-acetoacetic esters leads to very stable 1,2-oxaphospholens[68,69]. On hydrolysis, the phospholen rings (A) are opened and the enols (B) are formed; on vacuum distillation, these split off an alcohol molecule and are converted into cyclic phosphonates (C)[70]:



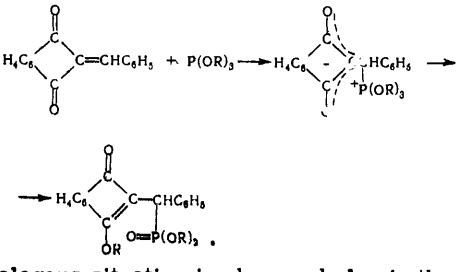
Stable phospholens with a P—C bond in the ring were also obtained by Ramirez in the reaction of 3-benzylidenepentane-2,4-dione with triethyl phosphite[71], phenylphosphonite, and diphenylphosphinite[72]. The study of the NMR spectra of solutions of the phospholens showed that at 70°C they are in equilibrium with dipolar ions, while at 125°C they have been fully converted into the dipolar form. Stable dipolar ions are formed by the reaction of 3-benzylidenepentane-2,4-dione with tertiary phosphines[73]:



The products of the reaction of trialkyl phosphites, phosphonites, and phosphinites with dibenzoylethylene have the structure of alkylidenephosphoranes[74-77] and not Δ^4-oxaphospholens as suggested earlier[78,79]. The reaction proceeds via the dipolar ion (A) which isomerises as a result of proton migration to the more stable dipolar ion (B):

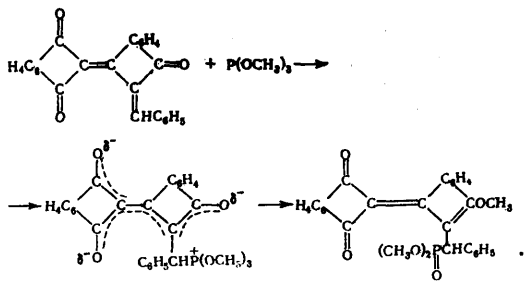


The reaction of dibenzoylethylene with a trialkyl phosphite in alcoholic solution and at an elevated temperature yields a complex mixture of products containing a trialkyl phosphate, 2,5-diphenylfuran, 1,2,3,4-tetrabenzoylbutane, and 1,2-dibenzoylethane[78,79]. The products of the addition of trialkyl phosphites to 2-benzylideneindan-1,3-dione at a low temperature exist in the form of dipolar ions, isomerising readily to esters of the enolic form of 1,3-dioxoindan-2-ylbenzylphosphonic acid[80]. At room temperatures the esters are formed immediately[81,82]:



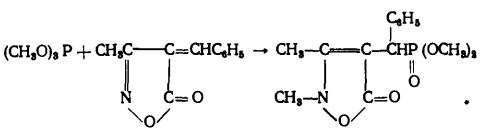
An analogous situation is observed also in the reaction of trimethyl phosphite with 2-benzylidene-3(2*H*)-thianaphthenone-1,1-dioxide[83,83]. As a result of the increase in the length of the conjugated chain and the equalisation

of electron density, even more stable dipolar ions are formed in the reactions of trialkyl phosphites with benzylidenebindone[82], 5-benzylidenebarbituric acid, and 5-benzylidene-1,3-diphenylbarbituric acid[84]

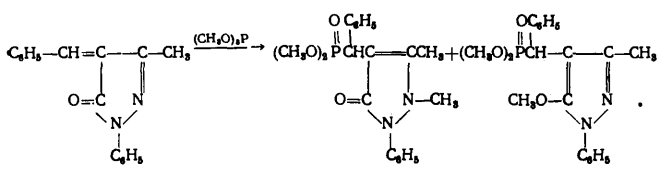


The reactions of phosphorous tris(dimethylamide) with 2-benzylideneindandione, 1,3,2-benzylidene-3(2*H*)-thianaphthenone-1,1-dioxide, benzylidenebindone, 5-benzylidenebarbituric acid, and 5-benzylidene-1,3-diphenylbarbituric acid also yielded stable crystalline dipolar ions with a P — C bond, the structure of which has been demonstrated by infrared, ultraviolet, and NMR spectroscopy and by dipole moment measurements[82,84,85].

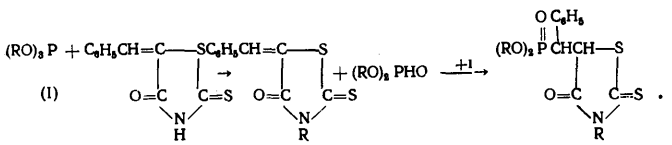
Heterocyclic carbonyl compounds containing a semicyclic double bond in the α-position relative to the carbonyl group do not form dipolar ions or phospholens on reaction with trialkyl phosphites. The reaction with 4-benzylidine-3-methyl-5-isoxazolone involves the $-N=C-C=C-$ system of conjugated bonds and leads to phosphonates[86]:



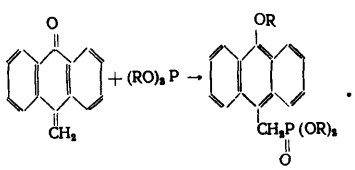
In the reaction with 4-benzylidene-3-methyl-1-phenyl-5-pyrazolone, trimethyl phosphite adds simultaneously to the $C=C-C=N-$ and $C=C-C=O$ bonds[87]:



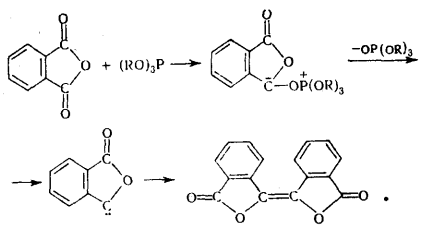
In the reaction with benzylidenerhodanine, the latter was found to be *N*-alkylated, the dialkyl phosphite formed in this process adding to the benzylidene double bond[88]:



Trialkyl phosphites react with methyleneanthrone via the conjugated system incorporating the methylene group[89]:

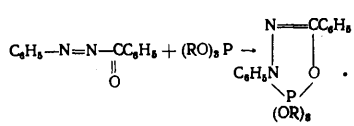


Phthalic anhydride does not react with trialkyl phosphites at room temperature; after prolonged heating, biphthalyl is formed[90]. The intermediate formation of a carbene which subsequently isomerises to biphthalyl is postulated. An alternative mechanism involves the formation of an epoxide, which is reduced by phosphite to an olefin[91]:

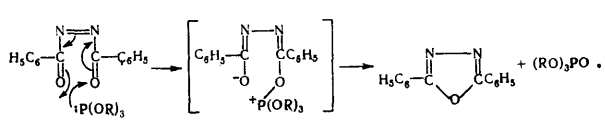


Similarly, thiophthalic anhydride undergoes reductive dimerisation by triethyl phosphite with formation of *trans*-bithiophthalide[91]. The reaction of thiophthalic anhydride with phosphorous tris(diethylamide) takes place via a different mechanism and leads to a mixture of lactones and thiolactones[91]. Dimethyl- and diphenylmaleic anhydrides react with triethyl phosphite to form the corresponding bifurandiones[92].

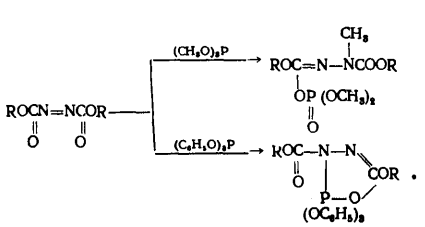
B. A. Arbuzov and coworkers showed that the conjugated system $-N=N-\underset{|}{C}=O$ may be also involved in the formation of cyclic phosphoranes[93,94]:



In the reaction of azodibenzoyl with trialkyl phosphites, the intermediate dipolar ions decompose into a trialkyl phosphate and diphenylfurodiazole owing to the difficulty of the closure of a seven-membered phosphorane ring[94,95]:

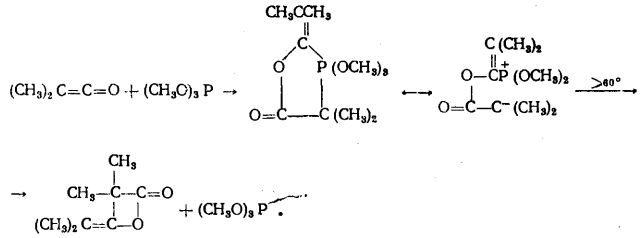


According to the data of Ginsburg and Yakubovich[95], the reaction of diethyl azodicarbonate with trimethyl and triphenyl phosphites yields linear phosphates and cyclic phosphoranes: their structure was recently confirmed by infrared and NMR spectroscopy[94]:

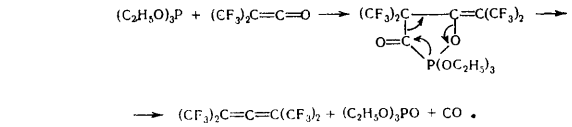


Ketens readily enter into reactions with phosphites, but the addition products are frequently unstable and undergo further reactions. Dimethylketen forms with

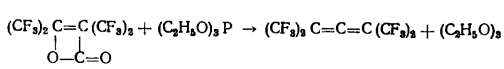
trimethyl phosphite a 2 : 1 adduct with a cyclic phosphorane structure, which is converted at 60°C into a dimer of dimethylketen and trimethyl phosphite[97,96]:



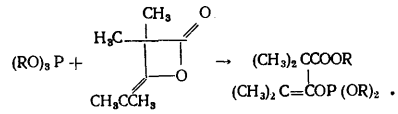
The product of the reaction of trimethyl phosphite with diphenylketen probably also has a phosphorane structure[96-98]. Bis(trifluoromethyl)keten reacts with triethyl phosphite to form tetrakis(trifluoromethyl)allene, triethyl phosphate, and carbon monoxide[99]:



Possibly the first stage in this reaction is the formation of a β-lactone dimer, since this dimer yields the same products on reaction with triethyl phosphite[99]:

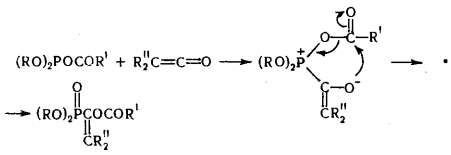


Dimethylketen dimers form with trialkyl phosphites 1 : 1 adducts containing a tervalent phosphorus atom. The reactions involve ring opening and migration of the alkoxy-group[100]:



Trialkylsilyl dialkyl phosphites react with ketens very readily[21]:

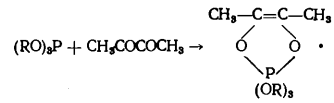
The reactions of mixed anhydrides of dialkylphosphorous and carboxylic acid anhydrides with keten and diphenylketen result in the formation of α-acyloxyvinylphosphonic acid esters[101,102]:



III. REACTIONS OF DERIVATIVES OF PHOSPHORUS(III) ACIDS WITH ALDEHYDES AND KETONES ACTIVATED BY ELECTRONEGATIVE GROUPS

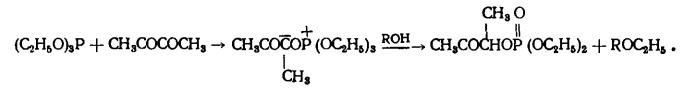
1. Reactions with α-Diketones

The reactions of trialkyl phosphites with α-dicarbonyl compounds have been investigated by a number of workers using diacetyl, the simplest α-diketone, as an example[103-107]. They take place very vigorously and result in the formation of 1 : 1-adducts for, which Ramirez et al.[107] and Kukhtin et al.[108] suggested and later proved the structure of 1,3,2-dioxaphospholens:

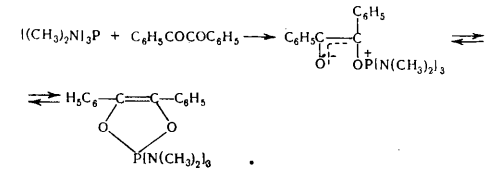


1,3,2-Dioxaphospholens are formed when trialkyl phosphites react with benzil, phenanthrenequinone[109,110], pentane-2,3-dione[106,107,111], dibenzoyl ketone[112], phenylglyoxal[112], 1,2-naphthoquinone[109,113], cyclohexane-1,2-dione[114], methylphenylglyoxal[115], and *o*-chloranil[109], and also when *NN*-dialkylphosphoramidites and phenyl- and methyl-phosphinous amides react with diacetyl[24,116], benzil[46,117], and cyclohexane-1,2-dione[118]. Cyclic phosphites and phosphoramidites form with α-diketones stable spirodioxaphospholens[5,119-121].

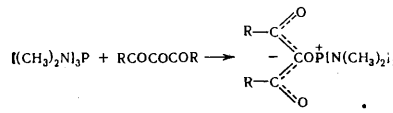
The reactions of trialkyl phosphites with α-diketones in proton-donating solvents lead to the corresponding phosphates, which confirms the intermediate formation of dipolar ions[122]:



In many cases it proved possible to demonstrate that 1,3,2-dioxaphospholens are in equilibrium with the dipolar ions. Thus phosphorous tris(dialkylamides) form with benzil a 1 : 1 adduct having the dioxaphospholen structure, which in solution is in equilibrium with the open-chain dipolar form. These data were obtained from a study of ^{31}P NMR spectra[120,121,123].

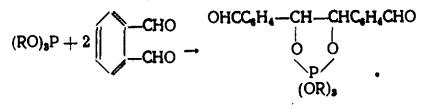


In benzene the main product is 1,3,2-dioxaphospholen but in methylene chloride the equilibrium is displaced towards the open-chain dipolar form[5,121]. The products of the reaction of phosphorous tris(dialkylamide) with dibenzoyl ketone[124] and 9,10-phenanthrenequinone[124] are generated only in the dipolar form[124]:

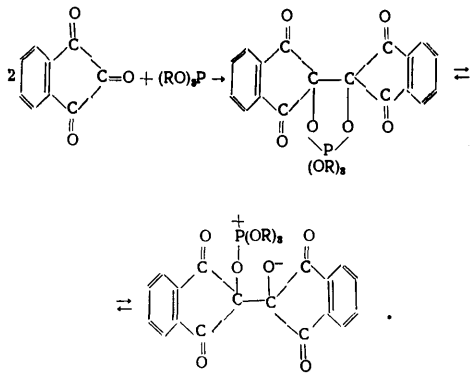


In reactions of phosphorous tris(dialkylamides) with polycarbonyl compounds, the cyclic phosphorane structure predominates over the dipolar structure on passing from α-diketones to *o*-quinones and triketones. An increase of the degree of delocalisation of the negative charge at the carbon atom promotes the formation of the open-chain dipolar form[121]. The stability of the dioxaphospholen structure increases on passing from acyclic phosphoramidites to five-membered cyclic phosphoramidites[125]. In the reaction of trialkyl phosphites with acenaphthenequinone[126], isatin[127], and phthalalhyde[128], 1 : 1 adducts were not isolated, since at the dipolar ion stage

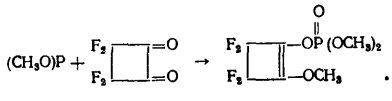
they react rapidly with a second molecule of the carbonyl compound and form 1,3,2-dioxaphospholans:



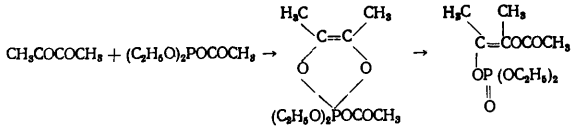
In the reaction with indantrione, 1,3,2-dioxaphospholans are in equilibrium with dipolar ions[129]:



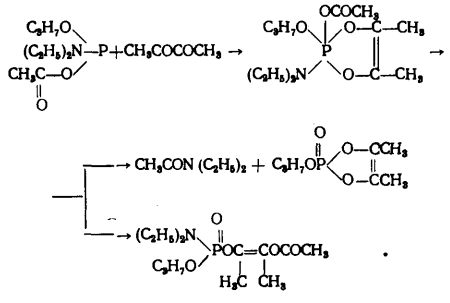
In the reactions of trialkyl phosphites with alloxan[130] and tetrafluorocyclobutane-1,2-dione[48], the intermediate dipolar ions are stabilised as a result of dealkylation to enol phosphates:



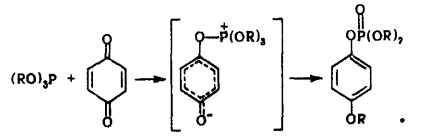
Dialkyl phosphoracetatidites react with α-diketones like trialkyl phosphites and phosphoramidites. The intermediate products of the addition of diethyl phosphoracetatidite to diacetyl—1,3,2-dioxaphospholen with a pentaco-ordinate phosphorus atom—was detected by ^{31}P NMR.[131] However, the presence of the anionoid acetyl group makes dioxaphospholens unstable and they react further via the mechanism of the second stage of the Arbuzov rearrangement with ring opening and the formation of an $\alpha\alpha$-endiol phosphate[36,131]:



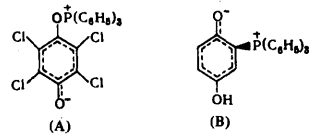
When phosphoramidoacetatidites react with α-diketones, two competing processes occur; the process leading to the retention of the dioxaphospholen ring predominates[36]:



The reactions of trialkyl phosphites with *p*-quinones are of considerable interest. *p*-Benzoquinone, 2,5-dimethylbenzoquinone, duroquinone, 1,4-naphthoquinone, anthraquinone, and 1,8-dichloroanthraquinone react with trialkyl phosphites via the 1,6-conjugated system with formation of *p*-alkoxyphenyl dialkyl phosphates[24,27,89,109,132-139] and not via a 1,4-addition mechanism as suggested previously[140,141]:



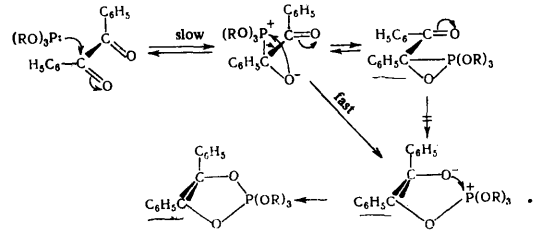
The intermediate dipolar ions were not isolated owing to their rapid conversion into phosphate esters. A stable dipolar ion (A) with a P—O—C linkage is formed when triphenylphosphine reacts with chloroanil and in the reaction of triphenylphosphine with *p*-benzoquinone the product is a dipolar ion (B) with a P—C bond[142,143]:



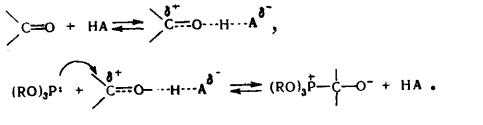
In the reaction of chloroanil with tri-isoalkyl phosphites, the substitution of all the chlorine atoms by di-isoalkoxyphosphono-groups was observed[144].

A spectrophotometric kinetic study of the reactions of trialkyl phosphites with benzil in anhydrous dioxan and benzene showed that the reaction is of second order with an activation energy of 8.41 kcal mole^{-1} and an activation entropy of −47.5 e.u.[145]. The rate of reaction increases in the following series of trialkyl phosphites: $(CH_3O)_3P < (s\text{-}C_4H_9O)_3P < (C_2H_5O)_3P < (iso\text{-}C_3H_7O)_3P$, which agrees with the increasing nucleophilicity of the phosphorus atom in these compounds.

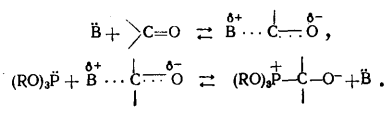
In the reaction involving tri-s-butyl phosphites, the steric effect has a significant influence. The following reaction mechanism was proposed on the basis of the results:



The nucleophilic attack by the phosphorus atom on the carbonyl carbon atom determines the rate of reaction. When an acid is added, the carbonyl group is activated by the formation of a hydrogen bond and the rate increases:



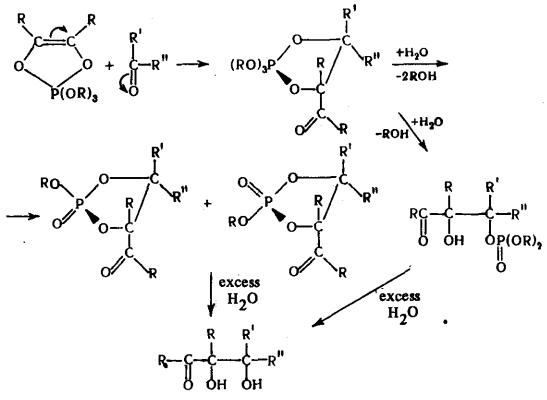
When a base adds to the carbonyl carbon atom it reduces its electrophilicity, which results in a lowering of the rate of reaction:



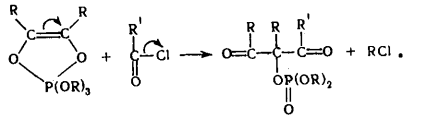
The low activation energy shows that the rate-determining stage does not require much energy and probably does not involve the dissociation of the P — C bond. The high negative activation entropy indicates a high degree of orientation of the transition state. The relatively slight dependence of the rate of reaction on solvent polarity can be accounted for by the fact that the transition state resembles an ion pair with a minimal charge separation owing to $2s - 3p$ bonding between the oxygen and phosphorus atoms. The conversion of the ion with a P — C bond into one with a P — O — C linkage takes place as a three-centre rearrangement with nucleophilic attack by the negatively charged oxygen on the phosphorus atom. The rearrangement of the ion with intermediate formation of a three-membered ring is less likely since the energy barrier preventing the complete dissociation of the P — C bond is higher.

However, there is as yet no unanimity concerning the mechanism of the reactions of phosphites, phosphoramidites and mixed anhydrides with dicarbonyl compounds. Together with the hypothesis of the initial attack by the phosphorus atom on the carbonyl carbon atom with subsequent isomerisation of the dipolar ion with a P — C bond, developed in the work of Ogata and Yamashita[145] discussed above and in the present authors' earlier investigations[146,147], it has been suggested in the literature, mainly in the publications of Ramirez, that there is a possibility of an initial attack by the phosphorus atom on the oxygen atom with direct formation of a P — O — C linkage. Such attack is most likely in the reactions of phosphites with quinones and also in the reactions of phosphorous tris(dialkylamides) with α-dicarbonyl compounds[38]. The possibility of synchronous or almost synchronous transfer of the lone electron pair of the phosphorus atom to the conjugated system of the α-diketone with subsequent incorporation of π electrons in the phosphorus d orbitals has also been suggested. Depending on the groups surrounding the phosphorus atom, the latter can exhibit in the initial reaction step both nucleophilic and electrophilic properties[131]. It is extremely probable that, depending on the nature of the reactants and the conditions, these reactions can involve different mechanisms.

1,3,2-Dioxaphospholens formed from α-diketones and phosphites are extremely reactive. They enter into condensation reactions involving the carbonyl groups of symmetrical[148-150] and asymmetric α-diketones[151], monoaldehydes[151-153], phthalaldehyde and terephthalaldehyde[154], monoketones[155], $\alpha\beta$-unsaturated aldehydes[156,157], phenyl isocyanate[158], p-quinones[159], and keten[160] with formation of 1,3,2-dioxaphospholans. Cyclic and linear phosphoric acid esters and also polyoxycarbonyl compounds were obtained from the latter by hydrolysis and alcoholysis[152,161-163]. The nucleophilic addition of 1,3,2-dioxaphospholens to the carbonyl group of mono- and polycarbonyl compounds constitutes a new stereoselective method of formation of a carbon — carbon bond; it has been called the oxyphosphorane condensation[156,157]:



The 1,3,2-dioxaphospholen ring opens on interaction with carboxylic acid chlorides, phosgene[161], bromine[164], oxygen[107], and ozone[165,166]:

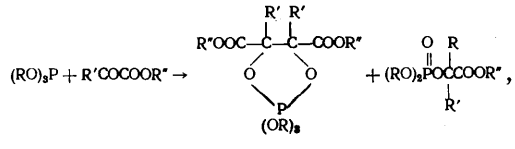


On irradiation with light, 1,3,2-dioxaphospholens decompose into a trialkyl phosphite, an α-diketone, and a trialkyl phosphate[167]. When acted upon by an excess of a trialkyl phosphite at 215°C, they give rise to a trialkyl phosphate and diaryl- or alkylaryl-acetylenes[98]. In the reactions with alcohols, there is partial exchange of substituents in the alkoxy-groups[168].

Ramirez has made interesting studies on the structure and stereochemistry of dioxaphospholens[4,5,8].

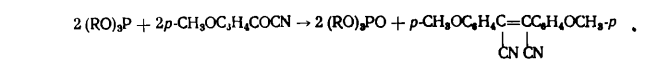
2. Reactions with Aldehydes and Ketones Activated by Alkoxycarbonyl, Phosphoryl, and Nitrile Groups

Reactions of derivatives of phosphorus(III) acids with carbonyl compounds in which the carbonyl group is activated by electron-accepting substituents are of considerable interest. The present authors' studies showed that the reactions of trialkyl phosphites with pyruvate, glyoxylate, and mesoxalate esters take place in two ways. At a low temperature trialkyl phosphites react preferentially with two molecules of the carbonyl compound forming 1,3,2-dioxaphospholans; at an elevated temperature, the corresponding α-substituted dialkyl alkyl phosphates are formed together with the dioxaphospholans[146,147,169-171]:

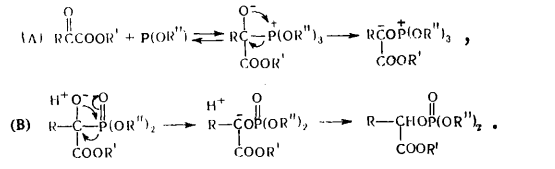


where R′ = H, CH_3, or COOAlk, and R, R″ = alkyl.

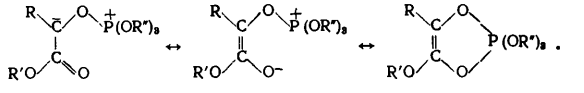
In reactions of trialkyl phosphites with pyruvate[172] and mesoxalate esters[5], Ramirez observed the formation of dioxaphospholans alone. Knunyants and coworkers demonstrated the formation of 1,3,2-dioxaphospholans in reactions of phosphites with trifluoropyruvate esters[173]. The reactions of trialkyl phosphites with the nitriles of benzoylformic and *p*-nitro-, *p*-chloro-, and *p*-methylbenzoylformic acids[174] also give rise to 2:1 adducts with the dioxaphospholan structure. The nitrile of *p*-anisoylformic acid gives an unstable addition product, as a result of which a trialkyl phosphate and $\alpha\alpha$-dicyano-*pp'*-dimethoxystilbene were isolated from the reaction mixture[174]:



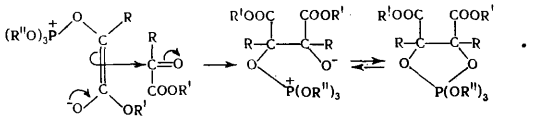
We suggested[146,147] that in reactions of trialkyl phosphites with α-ketoesters the rate-limiting process is nucleophilic attack by the lone electron pair of the phosphorus on the carbon atom of the carbonyl group as the most electrophilic centre in the molecule, which results in the formation of a dipolar ion [reaction (A)] with a P—C bond. Next there is a rapid intramolecular rearrangement of the type of nucleophilic substitution at the phosphonium centre with formation of a dipolar ion having a P—O—C linkage. This reaction resembles the phosphonate—phosphate rearrangement (B) of α-hydroxyalkylphosphonate esters, which was investigated in detail by the present authors for carbonyl compounds of the same type; the decisive role of electron-accepting substituents in this rearrangement has been demonstrated[175,176]:



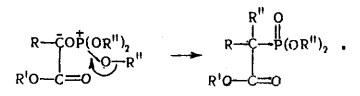
This mechanism has found definite confirmation in the work of Ogata and Yamashita[145], mentioned above, who investigated the kinetics of the reactions of trialkyl phosphites with benzil. However, there is as yet no direct proof for this mechanism, which does not allow a complete elimination of the possibility that these reactions take place also via the oxygen atom of the carbonyl group. The resulting dipolar ion with a P—O—C linkage can be stabilised further in two ways: (a) there is a possibility of the conversion of this ion into the more stable enolate—phosphonium system with a definite contribution by a pentacovalent structure[2]:



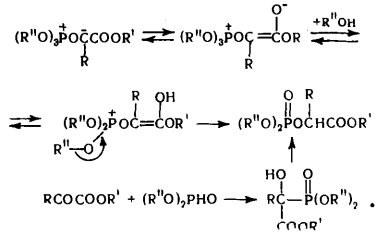
As a result of the attack by the carbon atom of the enolate group on the carbonyl group of a second α-ketoester molecule, a new dipolar ion is formed and stabilised by conversion into 1,3,2-dioxaphospholan:



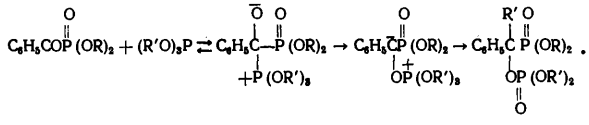
(b) The dipolar ion can also be stabilised in a different way—as a result of dealkylation in accordance with the second stage of the Arbuzov rearrangement:



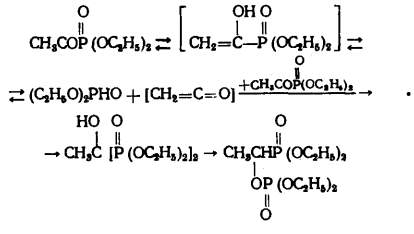
When reactions of trialkyl phosphites with pyruvate esters are carried out in proton-donating solvents (acetic acid, methanol), the dipolar ions are stabilised as a result of protonation with subsequent dealkylation to the corresponding phosphates; the formation of dioxaphospholans is not observed[177]:



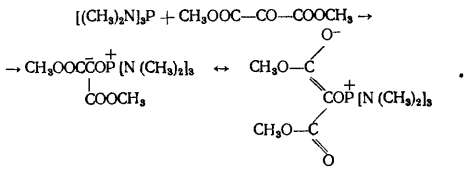
The phosphates formed proved to be identical with those obtained in the isomerisation of dialkyl α-alkoxycarbonyl-α-hydroxyalkylphosphonates[178]. The tendency towards the formation of phospholans in the reactions of phosphites with carbonyl compounds depends on the structure of the carbonyl compounds and diminishes in the series $RCOCOOR' > HCOCOOR' > R'OOC-CO-COOR' \gg RCOP(OR')_2$. The esters of α-ketophosphonic acids are relatively unreactive in reactions with trialkyl phosphites—they do not form products of the phospholan type. The esters of benzoylphosphonic acids react with trialkyl phosphites after prolonged heating of the reaction mixture. In contrast to earlier data[179], the present authors showed that the intermediate dipolar ions are stabilised as a result of their intramolecular dealkylation and conversion into dialkyl α-phenyl-α-dialkoxyphosphonoalkyl phosphates[180]:



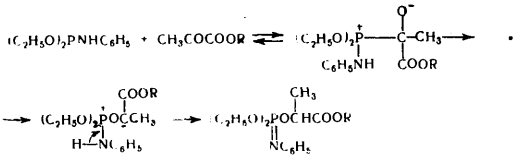
The reactions of phosphites with acetylphosphonic ester takes place similarly[181]. At a high temperature, thermal cleavage of the acetylphosphonic ester and the formation of diethyl α-(diethoxyphosphono)ethyl phosphate predominate[181]:



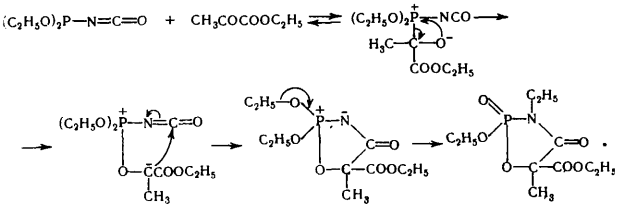
The mode of reaction depends also on the structure of the phosphorus(III) derivative. Thus, on passing from trialkyl phosphites to phosphoramidites and aminophosphines, the tendency towards the formation of dioxaphospholans is reduced[169,182]. One of the causes responsible for this decrease may be steric hindrance arising in the trigonal-bipyramidal configuration and increasing when the alkoxy-substituents at the phosphorus atom are replaced by dialkylamino-substituents. This lowers the stability of the phospholan structure relative to the open-chain dipolar form. Accordingly, the product of the addition of phosphorous tris(dialkylamide) to mesoxalate ester exists in the form of a dipolar ion[124] and not in the form of phospholen as suggested previously[183]:



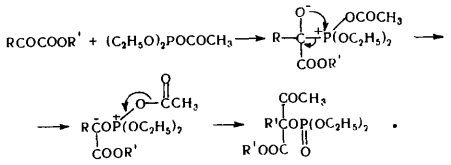
In the reaction of phosphorous tris(dialkylamides) with pyruvate and glyoxylate esters, only oxidation products were isolated[184]. The formation of 1,3,2-dioxaphospholans was not observed also in the reactions of pyruvate esters with dialkyl *N*-phenylphosphoramidites. In this case the dipolar ions are stabilised as a result of the migration of the anilino-proton to the carbanion with formation of dialkyl α-alkoxycarbonylalkyl *N*-phenylphosphorimidites[185]:



The present authors showed that pyruvate esters react vigorously with diethyl phosphoroisocyanatidite. In this case the dipolar ion is stabilised as a result of the attack by the carbanion on the electrophilic carbon atom of the isocyanate group and leads to the closure of a five-membered ring. Subsequent dealkylation yields an addition product—2-ethoxy-5-ethoxycarbonyl-3-ethyl-5-methyl-2-oxa-2-phosphaoxazolidin-4-one[186]:



Mixed anhydrides of phosphorous and carboxylic acids react with α-ketoesters in only one way with formation of substituted dialkyl α-acetylalkyl phosphates. In this case the dipolar ion is stabilised as a result of the migration of the acetyl group to the carbanion[187]:



The reactions of mixed anhydrides of diethylphosphorous and carboxylic acids with α-ketophosphonates yielded alkylbis(diethoxyphosphono)methyl acetates[101,188]:

Effect of d_π–p_π Interaction in Organic Compounds of Group IVB Elements

A.N.Egorochkin, N.S.Vyazankin, and S.Ya.Khorshev

The behaviour of organic derivatives of Group IVB elements is markedly influenced by d_π–p_π interaction in the ground and excited states. Chemical and physical techniques are nowadays widely used to investigate d_π–p_π interaction. This review deals with the results of certain spectroscopic (NMR and infrared) studies on this effect. The experimental data obtained by NMR and infrared spectroscopy have been compared in a number of cases with the results obtained by other research techniques. The bibliography includes 222 references.

CONTENTS

I. Introduction 425
II. NMR study of d_π–p_π interaction 425
III. Study of d_π–p_π interaction by vibrational spectroscopic methods 428

I. INTRODUCTION

Silicon, germanium, tin, and lead atoms have vacant d orbitals in contrast to carbon. The orbitals have energies close to those of the s and p orbitals in the outer electronic shell. As a result, organic derivatives of these elements have some chemical and physical properties which are not typical of the carbon analogues with the same structures and are due to the presence of d orbitals in the central atom[1]. Of these properties, the present review deals only with the phenomenon of d_π–p_π bonding. The formation of a bond of this type is possible only if the substituent X in the M–X (M = Si, Ge, Sn, or Pb) group is an atom with lone electron pairs (F, Cl, O, N, etc.) or a group with multiple bonds (CH=CH$_2$, C≡C–H, etc.). The atom M in the M–X group may be regarded as an acceptor of the p electrons of the atom X, the electron transfer process resulting in the formation of a dative d_π–p_π bond. The idea of partial double bonding involving silicon using d levels was put forward by Brockway and Wall[2]. The concept of d_π–p_π conjugation was introduced by Pauling[3], who suggested this phenomenon in order to account for the shortening of the Si–Hal and Si–O bonds. d_π–p_π interaction was considered theoretically by Craig[4–7] Jaffé[8], Moffitt[9], and Cruickshank[10,11]. Calculation of the overlap integrals shows[4,5,8,9] that the outer d orbitals can form a strong directed π bond. The degree of double bonding can then be considerable only in the presence of a partial positive charge at the silicon atom. Moreover, the degree of d_π–p_π interaction depends markedly on the steric disposition of the d orbitals relative to the σ bonds. Fairly effective overlap can be achieved only when the σ bond coincides with the plane of the maximum density of the d orbital. This is indicated by the significant dependence of the d_π–p_π overlap integrals on molecular geometry[8]. We may also note quantum-chemical data[12–14] indicating the occurrence of d_π–p_π interaction in Si–aryl and Si–vinyl bonds.

The reviews by Stone and Seyferth[15], Bürger[16], Ebsworth[1], and Attridge[17] deal with the problems of the experimental study of d_π–p_π interaction involving elements of the silicon subgroup. In these reviews the problem of d_π–p_π interaction has been considered as a whole, but, because of the large amount of new spectroscopic data on this problem, these reviews have become to a large extent obsolete. We decided to examine the results obtained by NMR and infrared spectroscopic methods, since we believe that these procedures are the most fruitful in spectroscopic studies on d_π–p_π interaction. We confined ourselves to the consideration of studies which appear to be the most significant. At the same time we may note that a fairly large number of publications have appeared in which the effect of d_π–p_π interaction is either ignored or is taken into account incorrectly. The reasons for the incorrect or invalid conclusions concerning d_π–p_π interaction are failure to take into account all the factors influencing the chemical shift in ^{1}H NMR spectra[18,19], the complex mode of the C=C stretching vibration in the infrared spectra of the vinyl derivatives of Group IVB elements[20–22], incomplete allowance for the factors influencing the frequencies of the C=O stretching vibrations and =CH$_2$ deformation vibrations in the vibrational spectra of organic derivatives of the elements[23–28], failure to take into account other conjugation effects[29,30], and low sensitivity of spectroscopic parameters to the effect of substituents[31,32]. Thus the necessary conditions for a correct interpretation of d_π–p_π interaction include the following: (1) allowance for the polarity of the chemical bond influenced by the inductive effect of substituents and conjugation effects other than d_π–p_π interaction; (2) the availability of fairly large series of compounds in which the spectroscopic parameters of the molecular fragments (a) depend only on the electronic effect of the substituents and (b) are fairly sensitive to these effects.

So far there have been no Russian reviews of spectroscopic studies on d_π–p_π interaction.

II. NMR STUDY OF d_π–p_π INTERACTION

There have been three main trends in studies of the effect of d_π–p_π interaction in organic derivatives of Group IVB elements by NMR: (1) analysis of the spin–spin coupling constants; (2) analysis of the chemical shifts in the proton magnetic resonance (^{1}H NMR) spectra; (3) the study of the basic and acidic properties of organic derivatives of Group IVB elements. We shall examine the results of studies of each type.

1. Analysis of the Spin–spin Coupling Constants

The extensive data accumulated on the spin–spin coupling constants (SSCC) between the nuclei of the ^{13}C and ^{1}H isotopes in compounds of the type $CH_{4-n}X_n$ show that the constants $J(^{13}C-^1H)$ are proportional to the amount of s

character of the carbon orbital in the direction of the C–H bond. However, the relation between $J(^{13}C-^{1}H)$ and the parameters of the polarisation of the C–H bond under the influence of substituents X (for example, the electronegativity of X) does not hold for all substituents without exception [33]. Moreover, it has been shown that, for strongly electronegative substituents (X, Y, and Z) in the molecules CHXYZ, the experimental values of the SSCC differ from the constants calculated assuming additivity on the basis of the SSCC for compounds of the type CH_3X, CH_3Y, and CH_3Z. The above remarks should be borne in mind in the interpretation of the ^1H NMR data for organic derivatives of Group IVB elements within the framework of $d_\pi-p_\pi$ interaction. We shall now consider certain SSCC data in the Table.

Spin–spin coupling constants.

Compound	$J(^{13}C-^{1}H)$, Hz	Compound	$J(^{13}C-^{1}H)$, Hz
$(CH_3)_4Si$	118.0	$(CH_3)_3SiOPb(CH_3)_3$	115.0
$(CH_3)_3SiOLi$	116.0	$(CH_3)_3SiSSi(CH_3)_3$	119.5
$(CH_3)_3SiONa$	115.0	$(CH_3)_3SiSeSi(CH_3)_3$	120.5
$(CH_3)_3SiOSi(CH_3)_3$	118.0	$[(CH_3)_3Si]_3N$	118.0
$(CH_3)_3SiOGe(CH_3)_3$	117.8	$[(CH_3)_3Si]_2NGe(CH_3)_3$	118.0
$(CH_3)_3SiOSn(CH_3)_3$	116.8	$[(CH_3)_3Si]_2NSn(CH_3)_3$	118.0

The constancy of the SSCC on passing from tetramethylsilane to hexamethyldisiloxane, despite the replacement of the methyl groups by the electronegative oxygen atom, is striking. These data are usually regarded as evidence of a strong effect of $d_\pi-p_\pi$ interaction in the Si–O bond [34]. In compounds with Si–O–M groups, the variation of M in the series Ge–Sn–Pb results in a lowering of the amount of s character of the C–H bond in the $(CH_3)_3Si$ fragment and the contribution of $d_\pi-p_\pi$ interaction to the Si–O bond increases. The degree of double bonding in the Si–O fragment increases also on passing from hexamethyldisiloxane to alkali metal trimethylsilanoxides [35].

The characteristics of the $d_\pi-p_\pi$ interaction in the Si–O bonds of heterosiloxanes have been investigated by NMR and infrared spectroscopic methods also in other studies [36–41].

In the compounds $(CH_3)SiXSi(CH_3)_3$, the SSCC increase in the series O < S < Se (in opposition to the variation of the electronegativities of the X), which indicates a decrease of $d_\pi-p_\pi$ interaction on passing from oxygen to selenium derivatives [34]. Comparison of the SSCC for methoxysilanes and their carbon analogues also confirms the occurrence of $d_\pi-p_\pi$ interaction in the Si–O bond [42]. The low values of the SSCC for compounds with Si–N bonds, despite the considerable electronegativity of the nitrogen atom have been interpreted on the basis of the $d_\pi-p_\pi$ interaction in the Si–N bond [34,43]. Analysis of the $^{13}C-1H$ SSCC for the $N-CH_3$ fragment in the compounds $(CH_3)_3MN(CH_3)_2$ and $M[N(CH_3)_2]_4$ showed [43] that the inductive effect of the $(CH_3)_3M$ group diminishes when M varies in the series Si > C ≥ Ge > Sn. Comparison of the effective electronegativities, which vary in the same sequence, with Batsanov's electronegativities [44] which do not take into account the effect of π bonding (C > Ge ≃ Sn > Si) shows that the capacity of Group IVB elements for $d_\pi-p_\pi$ interaction diminishes in the series Si > Ge > Sn. In the monohalogeno-derivatives $(CH_3)_3SiX$ with X varying in the series F–Cl–Br–I, the SSCC increase correspondingly (118.8, 120.5, 121.0, and 121.5) in a sequence opposite to that in the variation of the I effect of the halogen atom. According to Schmidbaur [34], this indicates a decrease of the capacity of the halogens for $d_\pi-p_\pi$ interaction in the series F > Cl > Br > I. However, this conclusion is not entirely correct, since in methyl halides the SSCC also increase from the fluoride to the iodide derivative [45].

The effect of the $d_\pi-p_\pi$ interaction in the Si–N bond was investigated by Zuckerman and coworkers [46–48], who showed that the $J(^{15}N-^{1}H)$ SSCC for the compounds $(CH_3)_3M^{15}NHC_6H_5$, where M = Si, Ge, or Sn, and for aniline are similar but differ from the SSCC for the pyridinium ion, the orbitals of the nitrogen atom of which are sp^2 hybridised. On this basis, it was concluded that there is no stereochemical evidence for $d_\pi-p_\pi$ interaction in M–N bonds. However, according to other data [13,49], sp^3 hybridisation of the orbitals of the nitrogen atom by no means rules out its $d_\pi-p_\pi$ interaction with the silicon atom.

2. Analysis of Chemical Shifts in ^1H NMR Spectra

^1H NMR is mainly employed to investigate organic derivatives of Group IVB elements (however, ^{19}F NMR also yields information about the $d_\pi-p_\pi$ interaction [50]). The attempts to isolate the contributions to chemical shifts associated with the $d_\pi-p_\pi$ interaction encountered considerable difficulties. This is because the chemical shift is a function of a large number of intramolecular factors [51] the most important of which are the inductive effects of the substituents and the effects of the anisotropy of the magnetic susceptibility and of the intramolecular electric field [52]. Therefore experimental chemical shifts must be treated with much caution in attempts to obtain information about $d_\pi-p_\pi$ interaction. We shall consider certain data obtained after approximate allowance for the above factors.

The idea of the first series of studies [53–55] consisted in a comparison of the relations in the ^1H NMR spectra of organic derivatives of silicon, germanium, and tin with the similar relations for carbon compounds. It was shown that in the series $(CH_3)_4-nMR_n$, where M = Si, Ge, or Sn and R = Cl, Br, I, OAlk, C_6H_5, or $CH=CH_2$, there is a linear correlation between the chemical shifts and the inductive constants σ^* of the substituents R for each R and M. Similar relations hold also for carbon compounds. Therefore the points corresponding to different R for carbon compounds on the plot of τCH_3 against $\Sigma\sigma_R^*$ were transferred onto the chloride straight line in the direction parallel to the $\Sigma\sigma^*$ axis. The values of σ_{eff}^* were then obtained for each R. When the σ_{eff}^* were used for correlation with the τCH_3 for silicon, germanium, and tin derivatives, the points corresponding to certain compounds deviated from the correlation owing to $d_\pi-p_\pi$ interaction. Analysis of the deviations indicates a considerable contribution of $d_\pi-p_\pi$ interaction to the τCH_3 for R = OCH_3, OC_2H_5, and $CH=CH_2$. Bromine and iodine apparently enter into $d_\pi-p_\pi$ interaction less than does chlorine. Together with their advantages, these studies suffer from the evident disadvantages due to the assumption that the intramolecular factors influencing the chemical shifts in organic derivatives of Group IVB elements do not differ from those in carbon compounds.

Therefore in a second series of studies [56–58] an attempt was made to take into account these factors for methyl and ethyl derivatives of silicon and germanium more rigorously. The chemical shifts τ for the CH_3 and CH_2 groups in

compounds with substituents incapable of d_π–p_π interaction, in which there is almost no contribution to τ due to the anisotropy of the magnetic susceptibility and of the electric field, were considered initially. A linear correlation between the τ and the inductive constants σ^* of the substituents was found for these compounds. This made it possible to take into account accurately the changes in bond polarities in compounds with any substituents and hence to calculate the values of τ due solely to the I effect. Subsequently corrections were applied to these chemical shifts, taking into account approximately, on the basis of the appropriate formulae, the magnetic anisotropy and the electric field of the substituents, and the τ_{calc} were obtained. The discrepancies between the τ_{calc} and τ_{exp} were attributed to the effect of d_π–p_π interaction, decreasing in the series F > OCH_3 > Cl > C_6H_5 > Br and Si > Ge.

Because data concerning the involvement of the vinyl group in π bonding with elements of the silicon subgroup were contradictory [28], a series of studies were undertaken to investigate this problem by ^{1}H NMR. [59-61] Analysis of the chemical shifts in the ^{1}H NMR spectra of the compounds $(CH_3)_3MCH{=}CH_2$, $(C_2H_5)_2M(CH{=}CH_2)_2$ (M = C, Si, Ge, or Sn), and $Cl_3MCH{=}CH_2$ (M = Si or Ge) taking into account the effects of the magnetic anisotropy and the electric field showed that the capacity of Group IVB elements for d_π–p_π interaction with the vinyl group diminishes in the sequence Si > Ge > Sn. This conclusion was confirmed by infrared spectroscopy [62].

In some studies conclusions concerning the d_π–p_π interaction were reached on the basis of a simple analysis of the experimental chemical shifts. Although, owing to the complex nature of the chemical shift, the results of these investigations cannot pretend to a high objectivity, we shall examine some of the most important of them. Despite the failure to take into account intramolecular factors influencing the proton chemical shifts, the data for d_π–p_π interaction obtained in these studies agree qualitatively with the results of the investigation of this effect by other physical and chemical methods. The reason for this is probably as follows. It has been shown [58] for the compounds R_nMX_{4-n} (where R = CH_3 or C_2H_5, M = Si or Ge, and X = F, Cl, Br, OCH_3, or C_6H_5) that the principal factors affecting the proton chemical shift in the Group R are the inductive I effect of X and the intramolecular electric field of X (except for the case where X = C_6H_5, the effect of the anisotropy of the magnetic susceptibility of the M–X bond is extremely small). Both factors lead to a decrease of proton screening in the groups R. d_π–p_π interaction between M and X is opposed to the I effect and increases the screening of the protons in R. Therefore the conclusions concerning d_π–p_π interaction based on the anomalously high chemical shifts in certain methyl and ethyl derivatives of Group IVB elements can agree qualitatively with the results of more exact investigations. In studies of this type, a decrease of the capacity of Group VI elements for d_π–p_π interaction with Group IVB elements in the series O > S > Se > Te was established [34, 63, 64]; the occurrence of d_π–p_π interaction in bonds formed by silicon with oxygen, nitrogen, fluorine, and chlorine was discovered [65-73]; it has been shown that the amount of π character of the Sn–Cl bond is less than that of the Si–Cl bond [74] and a decrease of d_π–p_π interaction in Si–O bonds with increasing number of such bonds in the molecule was established [75, 76].

We shall now consider the results of studies in which the specific features of molecular structure make it possible to arrive at conclusions about d_π–p_π interaction without introducing corrections into the experimental chemical shifts for magnetic anisotropy and the electric field. In a study of the chemical shifts in the compounds $(CH_3)_nCl_{3-n}SiOR$, where n = 0–3 and R = alkyl group, Brune [77] demonstrated the occurrence of d_π–p_π interactions in the Si–O bond [77]. In the compounds $R'Cl_nSi(OR)_{3-n}$, d_π–p_π interaction in the Si–O fragment diminishes as chlorine atoms or alkoxy-groups accumulate; the chlorine atom is more actively involved in d_π–p_π interaction than oxygen [78-80]. Analysis of the effective electronegativities of the oxygen atoms in alkoxydisilanes showed that the delocalisation of the lone electron pairs of oxygen in the Si–Si–O fragment is accompanied by a strong d_π–d_π–p_π interaction [81]. Subsequently the characteristics of d_π–p_π interaction in organic derivatives of ethoxysilanes and also in aminoalkoxysilanes were studied by Voronkov and Pestunovich [82-85], who showed, in particular, that the conclusions [77] concerning the greater capacity of chlorine compared with oxygen for d_π–p_π interaction is erroneous. The distribution of electron density in aminoalkoxysilane molecules depends both on d_π–p_π interaction and on the effect of p, σ conjugation.

The aromatic systems of benzene, furan, and thiophen containing organometallic substituents have also been studied by ^{1}H NMR. It has been established both experimentally [86] and theoretically [87] that in compounds of this type the chemical shifts of certain ring protons are almost independent of the magnetic anisotropy and the electric field of the substituents. Therefore in many cases it is possible to relate these chemical shifts to the electronic effects of the substituents and to obtain information about the d_π–p_π interaction in the bond between the Group IVB element and the ring. Analysis of the ^{1}H NMR and ^{19}F NMR spectra of the compounds $XC_6H_4M(CH_3)_3$ (where M = Si, Ge, or Sn [88]) and $(FC_6H_4)_nSn_{4-n}$ (where R = CH_3, C_2H_5, [89] or C_6H_5 [90]) established that d_π–p_π interaction occurs in the M–ring bond, the interaction being a minimum for M = Sn and almost absent in lead derivatives [90].

As in other investigations [91-95], Angelelli et al. [96] concluded on the basis of the dipole moments of aryl derivatives of elements of the silicon subgroup that π bonding increases with increasing electron-donating properties of the *para*-substituent X, completely ignoring the contributions of the effects due to direct polar conjugation. The linear relation between the chemical shifts of the *para*-protons and Hammett's σ_n constants [97] showed that the d_π–p_π interaction between the phenyl ring and the atom M in the $M(C_2H_5)_3$ group diminishes in the sequence Si > Ge ≃ ≃ Sn > Pb as M is varied [98]. However, for compounds with the substituents MCl_3 the degree of d_π–p_π interaction in the M–Ph bond varies in a different sequence: Sn > > Ge > Si, which the authors explain [98] by a decrease of the capacity of silicon and germanium atoms for d_π–p_π interaction with the ring owing to their involvement in the energetically more favourable interaction with chlorine atoms. Reikhsfel'd and coworkers [99-105] showed that the d_π–p_π interaction in Si–Ph bonds competes with the intermolecular interaction involving the d orbitals of the silicon atom.

That the bonds between silicon subgroup elements and the phenyl ring are of the π type is also indicated by the ^{19}F NMR data for substituted fluorobenzenes [106] and the ^{14}N data for *p*-trimethylsilylnitrobenzene [107]. The problems of d_π–p_π interaction were examined in greater detail for organosilicon derivatives of furan and thiophen [108-110]. The trialkylsilyl group linked to the furan [108] or thiophen [108] ring behaves as a typical electron acceptor. At the same time the $(CH_2)_nSiAlk_3$ fragment is an electron donor. This demonstrates the occurrence of d_π–p_π inter-

action in furyl- and thienyl-silanes in which the silyl group is linked directly to the ring. It has been shown that the silicon atom in the $SiCl_3$ and $Si(OHAlk)_3$ groups is less strongly conjugated to the ring than the silicon atom in the $SiAlk_3$ group [110] owing to the competing $d\pi-p\pi$ interaction in the Si–Cl and Si–O bonds.

According to infrared spectroscopy [111] and electron diffraction [112] data, the lone electron pairs of the oxygen atom in compounds of the type $C_6H_5OSiH_3$ are involved in two conjugation processes—with the ring π electrons and the silicon 3*d* orbitals. This conclusion has also been confirmed by ^1H NMR. [113]

It has been shown by ^1H NMR that the $d\pi-p\pi$ character of the Si–N bond reduces the barrier to conformational transitions via an intermediate sp^2 state in *N*-trimethylsilyl derivatives of aziridine [114] and piperidine [115] compared with their carbon analogues. The $d\pi-p\pi$ interaction of silicon and germanium atoms with the nitrogen atoms of the pyrazole rings has also been established by ^1H NMR. [116]

3. The Basic and Acidic Properties of Organic Derivatives of Group IVB Elements

As already mentioned above, the chemical shift in the NMR spectra is a complex function of a large number of intramolecular and intermolecular factors. Therefore, in correlating the acid–basic properties of organic derivatives of the elements with molecular structure, correct experiments are necessary. In studies on basicity, the formation of hydrogen bonds between molecules having bonds of the type M–X (where M = Si, Ge, or Sn and X = O or N) and proton donors was investigated. Chloroform was mainly employed as the proton donor. The chemical shift of the proton in chloroform at infinite dilution or the $^{13}C-^1H$ spin–spin coupling constant of chloroform served as a measure of the strength of the hydrogen bond (and hence of the basicity of X).

It was found that the basicity of siloxanes and alkoxysilanes is much lower than that of their carbon analogues [117], which indicates, in agreement with infrared spectroscopic data [118], a strong $d\pi-p\pi$ interaction in the Si–O bond. The basicity of various compounds with M–N bonds has been investigated [43,119] and a decrease of $d\pi-p\pi$ interaction on passing from M = Si to M = Sn has been established, which in broad outline is also consistent with the results of earlier infrared spectroscopic studies [120].

The study of the acidic properties of alcohol derivatives of the elements is based on the finding [121] that alcohols form very stable [H-bonded (Ed. of Translation)] complexes with dimethyl sulphoxide. Other possible types of association are then suppressed and therefore the chemical shift of the OH proton is a measure of the acidity of the alcohol (we may note that this method has been recently criticised [122]). Organosilyl alcohols containing the $\rangle SiOH$ fragment are more acidic than their carbon and germanium analogues [123]. Comparison of the chemical shifts of the OH protons in silyl-substituted benzoic acids and phenols with their carbon analogues indicates $d\pi-p\pi$ interaction between the aromatic ring and the silicon atom, which is more pronounced in phenols [124]. The $(CH_3)_3SiSi(CH_3)_2$ group is a more powerful acceptor of π electrons from the aromatic ring than the trimethylsilyl group [125]. An appreciable $d\pi-p\pi$ interaction in the Si–O bond is also indicated by the greater strength of the hydrogen bonds in $(CH_3)_3SiOH$ than in $(CH_3)_3COH$; [122,126] for the Si–Cl bond, this follows from a comparison of the proton-donating properties of chloroform [127].

The greater capacity of silicon for $d\pi-p\pi$ intera tion compared with germanium follows from data obtained in a ^1H NMR study of the hydrogen bond in compounds of the type $(CH_3)_3M-C\equiv CH$. [128] For M = Si, the hydrogen of the $\equiv CH$ group is more mobile than for M = Ge owing to the reduced electron density in the multiple bond as a result of the interaction of the π electrons of this bond with the *d* orbitals of the silicon atom. The acidic properties of certain other acetylene derivatives of Group IVB elements have been studied by Petrov et al. [129]

The ^1H NMR study of the hydrogen bond between compounds of the type $(C_2H_5)_3MXH$ (where M = Si or Ge and X = S or Se) and proton-accepting solvents showed that silicon forms stronger $d\pi-p\pi$ bonds than germanium. The effect of the $d\pi-p\pi$ interaction in M–S bonds is more appreciable than in M–Se bonds [130].

III. STUDY OF $d\pi-p\pi$ INTERACTION BY VIBRATIONAL SPECTROSCOPIC METHODS

The effect of $d\pi-p\pi$ interaction in organic derivatives of Group IVB elements has been studied in three different ways by vibrational spectroscopic methods (infrared and Raman spectroscopy): (1) the study of the basic and acidic properties of the compounds; (2) the study of the vibration frequencies and intensities for certain bonds in organic derivatives of the elements, (3) analysis of the stretching vibration frequencies of the Si–H bond in substituted silanes.

1. The Basic and Acidic Properties of Organic Derivatives of Group IVB Elements

On formation of the hydrogen bond, organic derivatives of the elements can behave both as acids and bases. When compounds with a bond between a Group IVB element and a Group VI element form a hydrogen bond with proton donors (alcohols, pyrrole, chloroform), the compound behaves in the hydrogen bond as a base. On formation of a hydrogen bond between compounds with fragments of the type O–H, S–H, and N–H linked to a Group IVB element and hydrogen bond acceptors (dioxan, tetrahydrofuran, ethyl ether), the compound behaves as an acid. In studies of this kind it is assumed that the shift of the X–H frequency of the proton donor in the hydrogen bond on passing from the non-associated to the associated state is proportional to the hydrogen bond energy [131,132]. (In a more rigorous treatment, a linear relation was demonstrated between the νO-H frequency shift and the square of the hydrogen bond energy in phenol–base systems [133]. This is probably true also of other proton donors [133].) On the other hand, it is clear that the hydrogen bond energy is closely related to the electron density at the Group VI atom of the base or at the X atom of the X—H group of the proton donor in the hydrogen bond. The electron density at these atoms in turn depends directly on the contribution of the $d\pi-p\pi$ interaction in the M–X bond, where M is an element of the silicon subgroup. The stronger is the $d\pi-p\pi$ interaction, the lower the electron density at the atom X. Study of hydrogen bonding showed [131] that the silanols $(C_6H_5)_2SiH(OH)$ and R_3SiOH (where R = CH_3, C_2H_5, or C_6H_5) are much more acidic but only slightly less basic than the corresponding carbinols. This is evidence of $d\pi-p\pi$ interaction in silanols involving only one of the two lone electron pairs of oxygen. In the compounds $(C_6H_5)_3MOH$ (where M = C, Si, Ge, Sn, or Pb), the silanol is much more acidic

than the other hydroxy-derivatives[134,135]. In the absence of d_π–p_π interaction the acidity of the hydroxides should be determined by the electronegativity of the element M. This fact and also data for the basicity of the hydroxides leads to the following sequence in terms of capacity for d_π–p_π interaction: Si > Ge > Sn ≃ Pb. On passing to the alcohols $(C_6H_5)_3MCH_2OH$ (where M = C, Si, or Ge), one would expect that the carbinol would be the most acidic, since carbon is the most electronegative of the three elements M. However, the following acidity series was obtained experimentally: $(C_6H_5)_3GeCH_2OH > (C_6H_5)_3SiCH_2OH > > (C_6H_5)_3CCH_2OH$,[122] which according to the authors is evidence of intramolecular coordination between the oxygen and germanium atoms due to the *d* orbitals of the latter. In the silyl analogue this effect is less pronounced and in the carbinol it is absent altogether. It probably occurs in 2-substituted cyclohexanones and cyclohexanols[136] and also in the compound $H_3GeCH_2OCH_3$.[137] In the alcohols $(C_6H_5)_3MCH_2CH_2OH$ the effect is probably absent. The acidity of such alcohols is almost independent of the nature of the element M,[122] since the *I* effect of the $(C_6H_5)_3MCH_2CH_2$ group changes little as M is varied. In a study of intramolecular hydrogen bonding in the hydroperoxides $(C_6H_5)_3MOOH$ (where M = C, Si, Ge, or Sn) and their hydrogen bonding with tetrahydrofuran, it was established that the acidity of the hydroperoxides diminishes in the following sequence as M varies: Si > Ge > C > Sn.[138] This is evidence of a decrease of d_π–p_π interaction in the M–O bond in the series Si > Ge > Sn and it is consistent with the results obtained for the hydroxides $(C_6H_5)_3MOH$.[135] The effect of d_π–p_π interaction in the M–C_6H_5 bond is much less than in the M–O bond. Therefore the main factor determining the energy of the intramolecular (as well as intermolecular) hydrogen bond is the acidity of the hydroperoxides.

Studies of a series of ethers, siloxanes[118,139], alkoxysilanes, and alkoxygermanes[140-142] led to the discovery that the basicity of the oxygen atom diminishes in the series C–O–C > C–O–Si > Si–O–Si. The decrease of basicity was interpreted as a result of a shift of the oxygen *p* electron to the silicon *d* orbital. The difference between the basicities of monoethoxygermane and monoethoxysilane corresponds to a greater d_π–p_π interaction in the Si–O bond than in the Ge–O bond. On the other hand, tetraethoxygermane is only slightly more basic than tetraethoxysilane. This is because in tetraethoxysilane π-bonding with each of the oxygen atoms is weaker compared with the d_π–p_π interaction in monoethoxysilane[142]. Evidence for stronger π-bonding of oxygen to silicon than to germanium or tin was also obtained in other studies[143,144]. Thus the following series of decreasing basicity of organic derivatives of the elements with an M–O bond have been established:: SiOC > $Si(OC)_2$ > $Si(OC)_3$ > SiOSi, GeOGe > > GeOC > $Ge(OC)_2$ > $Ge(OC)_3$, and SnOSn > SnOC > > $Sn(OC)_2$.[145] It has also been shown[146] that the low basicities of compounds with the $(CH_3)_3SiO$ and $(CH_3)_3CO$ fragments is due not only to d_π–p_π interaction in the Si–O bond but also to steric hindrance to the formation of a hydrogen bond generated by the $(CH_3)_3C$ and $(CH_3)_3Si$ groups.

The force constants of the Group IVB element–Group VI element bonds have been analysed[147-149] on the basis of the vibrational spectra of compounds containing such bonds. Thus an enhanced multiplicity of the Si–O and probably Sn–S bonds has been established[147,148] but data supporting the π character of Si–S, Ge–S, Pb–S, and Sn–O bonds were not obtained[147-149]. In view of the large number of factors influencing the force constants (this is discussed in greater detail in the next section of the review), the reliability of these data[147-149] for d_π–p_π interaction is low. Studies on the basicity of organic derivatives of the elements with a Group IVB element–Group IV element bond are therefore of considerable interest. The problem of d_π–p_π interaction between elements M of the silicon subgroup and oxygen and sulphur (as well as nitrogen) atoms has been discussed[150] in a study of the basicity of compounds containing bonds involving these elements. The study showed that the capacity of M for d_π–p_π interaction with nitrogen or oxygen atoms decreases in the sequence Si > Ge > Sn. An appreciably weaker d_π–p_π interaction was observed in the Si–S bond. The authors' view that the d_π–p_π interaction of germanium with sulphur is more pronounced than with oxygen appears to be supported by insufficient evidence.

The order of the acidities of silanethiols and mercaptans, $(C_6H_5)_3SiSH \gg C_6H_5SH > (CH_3)_3SiSH > (C_6H_5)_3CSH > > (CH_3)_3CSH$,[151] proved to be similar to that obtained previously for the acidities of oxygen-containing compounds: $(C_6H_5)_3SiOH \gg C_6H_5OH > (CH_3)_3SiOH > (C_6H_5)_3COH > > (CH_3)_3COH$.[131] In the two pairs of compounds with the same structures $(C_6H_5)_3SiSH$–$(C_6H_5)_3CSH$ and $(CH_3)_3SiSH$–$(CH_3)_3CSH$ the silicon compounds are more acid. This is consistent with dative Si–S π bonding in silanethiols, which makes them stronger acids than mercaptans.

Whereas only one lone electron pair of the oxygen atom is involved in the d_π–p_π bonding in the Si–O–C group and to such pairs in the Si–O–Si group[118], the sulphur atom is probably capable of giving up only one electron pair in all cases[150].

These studies were developed further in an investigation[152] of the basicity of compounds of the type $(C_2H_5)_3MXM'(C_2H_5)_3$ (where M and M' = Si, Ge, or Sn; X = O, S, Se, or Te) and also the compounds $(C_2H_5)_3MXH$ (where M = Si or Ge; X = S or Se). The shift of the stretching vibration frequency of the C–D bond in non-associated deuterochloroform on formation of a hydrogen bond with the above compounds was studied. The shift $\Delta\nu$ was treated as a measure of the basicity of organic derivatives of the elements. Bearing in mind that (1) the basicity of organic derivatives of Group VI elements decreases in the sequence O > S > Se > Te[132] (the capacity of these elements for d_π–p_π interaction with Group IVB elements decreases in the same sequence), (2) the capacity of the elements for d_π–p_π interaction diminishes in the sequence Si > Ge > Sn,[63,111,130] and (3) the d_π–p_π interaction in the Si–Te bond (and even more so in the Ge–Te and Sn–Te bonds) is extremely weak[111,153], the authors[152] interpreted the results as follows. For all the tellurides $[(C_2H_5)_3M]_2Te$, the values of $\Delta\nu$ are similar. This shows that the steric hindrance and the d_π–p_π interaction have only a slight effect on the basicity. Nevertheless $\Delta\nu$ is a minimum for $[(C_2H_5)_3Si]_2Te$. The contribution of d_π–p_π interaction to the Si–Te bond is small, but it can be detected in the measurement of the basicity, since the latter is directly related to the electron density at the tellurium atom.

For organic derivatives of the elements with the general formula $[(C_2H_5)_3M]_2X$, the following sequences of decreasing basicity were obtained: O > Te > Se > S for M = Sn, O > Te > Se > S for M = Ge, and Te > Se > S > O for M = Si. None of them is identical with the O > S > Se > Te sequence quoted above for the series of carbon compounds. The reason for this is that the relatively small effect of d_π–p_π interaction, which, however, increases systematically in the sequence Te < Se < S, influences the basicity of the Group VI elements even in the series of organotin compounds. For the series $[(C_2H_5)_3Ge]_2X$, the

d_π–p_π interaction in the Ge–X bonds plays a more significant role. The basicity $[(C_2H_5)_3Ge]_2S$ and $[(C_2H_5)_3Ge]_2Se$ is lower than that of the corresponding tin derivatives. This is evidence of d_π–p_π interaction in the Ge–Se bond, which becomes even more pronounced in the Ge–S bond. In the series of compounds $[(C_2H_5)_3Si]_2X$, the values of $\Delta\nu$ are much lower than in the organogermanium and organotin series. This shows that the d_π–p_π interaction with silicon is stronger than with germanium or tin. From this point of view, examination of the series of compounds $[(C_2H_5)_3M]_2O$, $[(C_2H_5)_3M]_2S$, and $[(C_2H_5)_3M]_2Se$ yields striking results. In each of these series the basicity falls on passing from M = Sn to M = Ge and Si, which is also evidence of a decrease of the capacity of Group IVB elements for d_π–p_π interaction in the sequence Si > Ge > Sn. The degree of d_π–p_π interaction in the Si–O, Si–S, and Si–Se fragments varies approximately in the proportions 4 : 2 : 1, as shown by the analysis of the infrared spectra of substituted silanes containing these fragments[111]. Therefore the extremely low basicity of hexaethyldisiloxane is a result of a more pronounced effect of d_π–p_π interaction in silicon derivatives in general and in the Si–O bonds in particular. Moreover, as already mentioned[146], $\Delta\nu$ for $[(C_2H_5)_3Si]_2O$ is low also because of steric hindrance to the formation of a hydrogen bond due to triethylsilyl groups.

A strong d_π–p_π interaction in the Si–N groups was established in a study of the basicity of a series of organosilicon amines[120]. It was shown that the shift $\Delta\nu_{C-D}$ of the stretching vibration frequency of the C–D bond in mixtures of Cl_3CD with silylamines, characterising the basicity of the nitrogen atom, is in the range 50–80 cm^{-1} for compounds of the type $(CH_3)_3SiNR_2$, 30–35 cm^{-1} for the cyclic compounds $[(CH_3)_2SiNR]_3$, and 15 cm^{-1} for $(CH_3)_3SiNHPh$, $(CH_3)_3SiNPh_2$, and $[(CH_3)_3Si]_2NPh$. If one assumes that with decrease of basicity the effect of d_π–p_π interaction increases, then in the last of compounds the effect is a maximum. In trisilylamines the $\Delta\nu_{C-D}$ effect was not observed, which is evidence of an extremely low basicity of the nitrogen atom. However, the basicity data conflict with the conclusion of Randall and Zuckerman[46] that there is no stereochemical evidence for d_π–p_π conjugation in the Si–N bond, which was based on a study of the infrared and NMR spectra of *N*-trimethylsilyl-, *N*-trimethylgermyl, and *N*-trimethylstannyl-derivatives of aniline. This apparent contradiction can be resolved if one remembers that the lone electron pair of the nitrogen atom can interact both with *nd* orbitals and with the phenyl ring. While the data of Abel et al.[120] indicate conjugation of the lone pair of the nitrogen atom and those of Randall and Zuckerman[46] demonstrate the absence of d_π–p_π interaction, a common conclusion of both investigations is that the interaction of the lone electron pair of the nitrogen with the phenyl ring is much stronger than with *nd* orbitals.

The results obtained in the determination of the basicities of two series of compounds, $(CH_3)_3MN(CH_3)_2$ and $M[N(CH_3)_2]_4$ (where M = C, Si, Ge, or Sn), show that the silicon derivatives form weak hydrogen bonds: this is due to the delocalisation of the *p* electrons in the Si–N bond. According to Mack and Yoder[43], d_π–p_π interaction is more pronounced in silicon derivatives, is much weaker in germanium derivatives, and is probably absent in tin derivatives. The study of the basicity of ethyl(dimethylamino)germanes also indicates a smaller contribution of d_π–p_π interaction to the Ge–N bond compared with Si–N.[154]

Infrared spectroscopic data for silylamines[155] and trimethylsilyldiazomethane[156] as well as the results obtained in a study of the relative basicities of disilazanes[157] have been interpreted on the basis of the d_π–p_π interaction in the Si–N bond.

It was established by infrared spectroscopy[158,159] that the basicities of arylsilanes and organosilicon derivatives of thiophen are much lower than those of their carbon analogues. This is a consequence of d_π–p_π interaction, as a result of which the SiR_3 (R = alkyl or H) substituents in the benzene or thiophen rings become less effective electron donors than the corresponding substituent CR_3. The basicity of the vinyl derivatives of Group IVB elements is much lower than that of the corresponding carbon analogues; with increase of the atomic number of the Group IVB element, the basicity increases[160]. This is caused by the effect of d_π–p_π interaction, which decreases in the sequence Si > Ge > Sn.

The infrared spectra of compounds of the type $(CH_3)_3M$–C≡CH, where M = C, Si, Ge, Sn, or Pb, have been studied in various electron-donating solvents. It has been noted[161–162] that all the compounds except carbon derivatives form hydrogen bonds with the solvent, which is evidence of a considerable acidity of the hydrogen atom in the –C≡CH fragment. The acidity of organic derivatives of the elements increases as a result of intramolecular interaction of the π electrons of the triple bond with the *nd* orbitals of the Group IVB element. Thus the presence of d_π–p_π interaction in ethynyl derivatives of the elements has been convincingly confirmed by NMR[128,129] and infrared spectroscopic[161,162] methods.

2. Vibration Frequencies and Absorption Band Intensities of Certain Bonds in Organic Derivatives of Group IV Elements

Since the contribution of the effect of d_π–p_π conjugation in the M–X fragment to the total MX bond energy is comparatively small, considerable caution must be exercised in drawing conclusions concerning d_π–p_π interaction on the basis of an analysis of the force constants. For such conclusions to be valid, it is necessary to have rigorous proof that the changes in force constants (including the changes under the influence of the d_π–p_π conjugation) are caused by electronic effects. As a rule it is necessary to carry out a theoretical analysis of the vibrations of the molecules investigated and to obtain proof that the vibration, on the basis of the changes in frequency of which conclusions concerning intramolecular effects of the type of d_π–p_π interaction are arrived at, is characteristic. Unfortunately the latter requirement has not been fulfilled in all the studies dealing with this problem.

It has been established that the bonds formed by silicon with elements such as N, O, F, and Cl have relatively high force constants[147,163]. On this basis, Kriegsman[147,164] concluded that d_π–p_π interaction must play an important role in compounds containing such bonds. According to Kriegsmann[165], the order of the Si–N bond in hexamethyldisilazane is 0.18. The Ge–N and Sn–N bonds also have partial double bond character, which is indicated by the M–N force constants in the compounds $M[N(CH_3)_2]_4$.[166]

Subsequently the vibrational spectra of compounds of the type $(H_3Si)_nX$ and $[(CH_3)_3Si]_nX$, where X is an element in Groups IV–VI and *n* is the valence, were studied systematically by Bürger (see Bürger's review[167] and the paper summarising his results[168]). In the analysis of the force constants of the Si–X bonds of these compounds, account was taken of the contribution of the d_π–p_π interaction in the bonds between silicon and elements in Groups V–VII. The effect of d_π–p_π interaction was studied on the basis of the

vibration spectra of the compounds SiX_4 and Si_2X_6,[169] where X = Cl, Br, or I. Detailed studies of the d_π–p_π interaction in compounds with Si–O–Si and Si–O bonds and related germanium derivatives were made by Lazarev and coworkers[170-174].

Investigation of the stretching frequencies of the C=O bond in the compounds $R_3MOC(O)R'$ (R and R' = CH_3, C_2H_5, or C_6H_5; M = silicon subgroup elements) showed[175] that in the compounds with M = Si or Ge there is competition between πp conjugation ($R_3M-\ddot{O}-\underset{\|}{C}-R'$) and d_π–p_π interaction. As a result, the d_π–p_π conjugation in the Ge–O bonds of these compounds proved to be comparatively weak; the Si–O bond has a much greater amount of π character. In tin and lead derivatives, the amount of ionic character of the M–O bond is very high, owing to the transition of the M element to the sp^3d or sp^3d^2 valence states and the formation of M...O coordinate bonds.

The Si_3N skeleton of trisilylamines is planar, which is believed to be a result of the delocalisation of the lone electron pair of nitrogen to the silicon *d* orbitals, i.e. d_π–p_π interaction in the Si–N bond[176-178]. In contrast to trisilylamines, the heavy atoms in trigermylamines are not coplanar[179], since the d_π–p_π interaction in the Ge–N bonds is weaker than in Si–N bonds. Analysis of infrared spectroscopic and electron diffraction data for silicon and germanium compounds led to the conclusion that germanium has a smaller capacity for d_π–p_π interaction[179].

Contradictory data concerning the possibility of d_π–p_π interaction between the silicon atom and the carbonyl group were obtained in a study of silyl ketones[23-27,180]. Thus, according to Brook and coworkers[23-27], the stretching frequencies of the C=O bond indicate the presence of intramolecular coordination in α- and γ-silyl ketones. In β-silyl ketones, such interaction is prevented by steric hindrance. However, physicochemical studies on 1-trimethylsilylpropan-2-one[180] indicate the occurrence in this compound of coordination between the carbonyl oxygen and the silicon atom even in the gaseous state. The above investigations[23-27,180] are closely related to later studies[122,136,137] indicating the possibility of intramolecular coordination between the germanium (and also probably silicon) atoms and oxygen in organic derivatives of the elements with alcoholic groups of the type R_3MCH_2OH, where M = Ge or Si. However, it is noteworthy that this type of expansion of the valence shell of the silicon subgroup element as a result of the involvement of their *d* orbitals in the formation of additional bonds may differ significantly from the d_π–p_π interaction between atoms which are linked directly by a chemical bond. This is indicated also by experiment. Indeed, it has now been finally established that in the M–X fragment (where M is an element of the silicon subgroup and X an element of Groups V–VII or an α-unsaturated hydrocarbon substituent) the capacity of the atoms M for d_π–p_π interaction with X increases in the sequence Sn < Ge < Si, i.e. has a maximum for silicon. The *d* orbitals of the atoms M of the type d_ϵ (d_{xy}, d_{xz} d_{yz}) are used for π bonding[8]. The element M can also be involved in the formation of additional σ bonds on passing to the quinquevalent and hexavalent state (sp^3d and sp^3d^2). Bonds of this kind are achieved with the aid of *d* orbitals of the type d_γ (d_{z^2}, $d_{x^2-y^2}$). The capacity of the element M for σ bonding increases in the sequence Si < Ge < Sn.[1] Data on the acidic properties of the alcohols $(C_6H_5)_3MCH_2OH$ show[122] that intramolecular coordination is most characteristic of germanium (the tin derivative was not studied) and is least pronounced for the silyl analogue. These results suggest that intramolecular coordination is achieved with participation of d_γ orbitals. We may also note that, since silicon exhibits a comparatively weak capacity for coordination of the above type, the data for silyl ketones[23-27] must be interpreted with much caution. Thus, in order to isolate the contribution associated with intramolecular coordination to the stretching vibration frequency of the C=O bond in the β-silyl ketones $R_3SiCH_2\overset{O}{\overset{\|}{C}}-R'$, one must take into account rigorously not only the inductive effect of the substituent R_3SiCH_2 but also the effect of σ, π conjugation.

Infrared and NMR spectroscopic data for dialkoxydialkylstannanes were accounted for on the basis of the hypothesis of d_π–p_π interaction between the tin and oxygen atoms[181]. However, in a study of the vibrational spectra of compounds of the type $R_3Sn-O-SnR_3$, where R = alkyl or C_6H_5, the double bond character of the Sn–O fragment was not demonstrated[148]. The contradictory nature of the results of these investigations arises because the d_π–p_π bonds in tin compounds are energetically fairly weak. Therefore experimental accuracy for these compounds constitutes a particularly urgent task. Even for silicon compounds, where d_π–p_π bonds play a much more important role, allowance for all the factors influencing the force constant, necessary for the estimation of the contribution of d_π–p_π interaction, has not yet been finally achieved[167,168]. However, the literature shows that the search for a solution of this problem is being continued. A study[182] where it was established that in the absence of d_π–p_π interaction in M–X bonds the ν_{M-C} frequencies for the compounds $[(C_2H_5)_3M]_nX$ (M = Si or Ge; X = element in Groups I–VII; *n* = valence of X) are linearly related to the electronegativities of the substituents X is particularly instructive in this respect. An increase in the electronegativity of X increases the amount of *p* character of the M–X bond and the amount of *s* character of the M–C bond[183]. The ν_{M-C} frequencies in the compounds where the M–X bonds have π character are reduced compared with the values expected on the basis of the above linear relations. Analysis of the deviations leads to the following sequence in terms of the capacities of the substituents X for d_π–p_π interaction with the silicon or germanium atom: $F \geq O > Cl > Br > I \simeq S > Se > Te > Sb > Bi$. The deviations for silicon derivatives are greater than for germanium derivatives, which indicates a greater capacity of silicon for d_π–p_π interaction compared with germanium. Thus the fact that in different Groups of the Periodic System the capacity of the elements for d_π–p_π interaction decreases with increasing atomic number of the element was confirmed yet again in this investigation. This applies both to elements which behave as lone electron pair donors (elements in Groups V–VII) and to Group IVB elements with vacant *d* orbitals.

Numerous studies have been made on the effect of d_π–p_π interaction in compounds with an α-unsaturated hydrocarbon substituent linked to a Group IVB element[184-193]. It has been shown that in compounds of the type $(CH_3)_3M-C\equiv CH$ (where M = C, Si, Ge, Sn, or Pb) d_π–p_π interaction decreases on passing from silicon to lead derivatives. In compounds with several ethynyl groups, $(CH_3)_4$-nSi(C≡CH)n, one may expect that the vibrations of the individual ethynyl groups will be independent and therefore the intensities of the absorption bands of the ≡C–H and –C≡C– bonds will increase additively with increasing number of such bonds. The experimental deviations from these expectations

were accounted for by two types of intramolecular interactions—the inductive effect and the effect of the d_π–p_π interaction[185]. The conclusion that the π electrons of the acetylenic bonds interact with the 5*d* orbitals of the tin atom was based on a study of the vibrational spectra and the measurement of the integral intensities of certain absorption bands of the ethynyl compounds $(C_2H_5)_3SnC{\equiv}CX$, where X = H, CH_3, $CH{=}CH_2$, C_6H_5, or $Si(CH_3)_3$.[186] The results of these studies agree with the data obtained in the study of the acidic properties of the hydrogen atom in the ethynyl group by NMR[128,129] and infrared spectroscopy[161,162].

The conclusion that there is d_π–p_π interaction between the silicon atom and the π electrons of the triple bond was arrived at in a series of studies of Zeil and coworkers[187–190] of the vibrational and microwave spectra as well as NQR spectra of the compounds $(CH_3)_3MC{\equiv}CX$ and $(CH_3)_3MC{\equiv}CM(CH_3)_3$, where M = Group IVB element and X = H or Cl. The electron-accepting properties of the silicon atom linked directly to the triple bond are also indicated by NMR[191] and infrared spectroscopic[192] data and studies on the vertical ionisation potentials[192] of compounds of the type $R_3MC{\equiv}CH$ and $R_3M(C{\equiv}C)_nMR_3$, where M = C or Si, R = H, CH_3, or C_6H_5, and n = 1–3.

Thus in the M–C≡C system (where M = Si, Ge, or Sn) there is d_π–p_π interaction between the *d* orbitals of M and the π electrons of the triple bond, although in lead derivatives such interaction was not detected by infrared spectroscopy[193].

Many studies have been made on the d_π–p_π interaction between the *d* orbitals of Group IVB elements M and the π electrons of the ethylenic bond in compounds containing the M–C=C grouping. It has been shown that the vibration attributed to the presence of the C=C bond in the molecules has a wave-number of about 1650 cm^{-1} in alkenes, while in the corresponding vinylsilanes it is reduced by about 50 cm^{-1}. According to the authors of these investigations[20–22], this indicates the existence of a structure of the type $\bar{Si}$–$\overset{\frown}{C}$=$\overset{+}{C}$ in which the electron density in the double bond is reduced owing to d_π–p_π interaction. Subsequently Bock and Seidl[194,195] carried out a series of studies on silyl-substituted ethylenes and butadienes by physical methods among which they examined in detail the $\nu_{C=C}$ frequencies in these compounds. Comparison of these results with the vibrational spectra of alkylbutadienes enabled them[194,195] to conclude that trimethylsilyl substituents exhibit electron-accepting properties in consequence of the d_π–p_π interaction in the Si–C=C fragments. Therefore the force constants and the ν_{C-C} frequencies in silyl derivatives are reduced. Despite the agreement between the data for π bonding and the results obtained by other methods, Egorov and coworkers[28] showed that the complex mode of vibration with a wave-number of about 1600 cm^{-1} does not permit correct conclusions concerning d_π–p_π interaction on the basis of changes in the frequency of this vibration. It was noted that the intensity of the absorption bands corresponding to this vibration in the compounds $(CH_3)_3MCH{=}CH_2$ decreases in the following sequence as M is varied: Si > Ge > Sn. On the other hand, in allyl derivatives the intensity of this vibration actually increases in the same sequence. This type of variation of the intensity was tentatively interpreted[21,22,196] within the framework of the d_π–p_π interaction between the vinyl group and the Group IVB elements. However, according to Leites et al.[28] the intensity data can also be accounted for by the involvement in the above vibrations of all the coordinates of the $\diagdown C{=}C \diagup_{M}$ fragment.

Analysis of the absorption bands due to the fanwise vibrations of the $=CH_2$ group in substituted vinylsilanes led Eisch and Trainor[197] to the conclusion that there is d_π–p_π interaction in these compounds. Other workers[20–22,194,195,198] support this view. The spectra of vinyl derivatives were interpreted from a different standpoint by Leites et al.[28] The frequency shift of the $=CH_2$ fanwise vibrations of the vinyl group when the central carbon atom is replaced in succession by silicon, tin, and germanium was explained primarily by the inductive effect of the atom M. Leites et al.[28] believe that, even if a d_π–p_π interaction effect exists, it is so weak that it does not influence the parameters of the vibrational spectra. Egorov[30,199] examined the optical properties of methyl and vinyl derivatives of Group IVB elements on the hypothesis that such elements have a duel function—both electron-donating and electron-accepting ("C-effect"). Since the "C-effect" and d_π–p_π interaction act in the same direction, it is believed[200] that it is difficult to obtain information about the d_π–p_π interaction in vinyl and phenyl derivatives in Group IVB elements. The problems of the d_π–p_π interaction in vinyl derivatives of Group IVB elements were examined in greater detail by Egorochkin and coworkers[62,201]. The frequencies ωCH_2 of the out-of-plane deformation vibrations of the CH_2 group in the compounds $CH_2{=}CHX$ are known to be highly characteristic[28] and sensitive to the electronic effects of the substituents X.[202] Therefore if X is not conjugated with the vinyl group, the ωCH_2 are linearly related to the inductive constants of X.[62] The points corresponding to compounds with substituents capable of conjugation with the vinyl group deviate from this linear relation. Analysis of the deviations established[62,201] (1) an analogy between the effects of conjugation with the vinyl group and the phenyl ring, (2) a decrease of d_π–p_π interaction in the M–vinyl bonds in the sequence Si > Ge > Sn, (3) a competition between the d_π–p_π interaction in the M–vinyl and M–halogen bonds in the compounds $Hal_3MCH{=}CH_2$,[203] and (4) a decrease of the effect of σ,π conjugation in the allyl derivatives $R_3MCH_2CH{=}CH_2$ in the sequence Sn > Ge > Si and the dependence of this effect on the nature of the substituent R. These data are consistent with the results obtained by the ^1H NMR method[59–61].

Petrov and coworkers[204,205] showed that the vibrational spectra and dipole moments of silyl-substituted 1,3-dienes indicate a shift of the electron clouds of the substituent towards the silicon atom. The d_π–p_π interaction has a significant influence also on the reactivities of compounds of this class.

A number of studies[88–97,206,207] indicate the occurrence of d_π–p_π interactions between the Group IVB element and the aromatic ring. The majority of data suggest that this effect diminishes in the sequence Si > Ge > Sn. The changes in the positions and intensities of certain characteristic vibrations of the phenyl group in the phenylsilane derivatives C_6H_5SiXYZ indicate the occurrence of d_π–p_π interaction between the *d* orbitals of the silicon atom and the π electrons of the phenyl ring[31]. However, a similar study of phenylgermanes did not yield a direct answer to the question of the possibility of π bonding in the Ge–C_6H_5 fragment[32]. The reason for the contradictory nature of the results[31,32] is low sensitivity of the spectroscopic parameters of the phenyl group to the electronic effects of the substituents. The study of Egorochkin et al.[208], where conclusions concerning the electronic effects of the aryl substituents C_6H_4X were based on an analysis of the stretching vibration frequencies of the Si–H bond (these investigations are considered in greater detail below) in

compounds with the H–Si–C_6H_4X fragments, was free from this defect. The degree of $d\pi$–$p\pi$ interaction in the Si–aryl bond varies over a wide range and increases approximately linearly with increasing inductive effect of the aryl substituent at the silicon atom, i.e. with increase of the positive charge of the central element.

The linear correlation between the stretching frequency of the C=O bond in substituted acetophenones and the Brown–Okamoto σ^+ constants of the substituents[209] was used in an investigation of the electronic properties of the substituents X in the compound $CH_3CO-C_6H_4-X$, where X = $(CH_3)_3Si$, $(CH_3)_3SiSi(CH_3)_2$, $(CH_3)_3SiO$, or $(CH_3)_3SiSi(CH_3)_2O$.[125] It was established that the group $(CH_3)_3SiSi(CH_3)_2$ has a more pronounced $+I$ effect than the trimethylsilyl group but at the same time the pentamethyldisilyl group forms more stable $d\pi$–$p\pi$ bonds than does the trimethylsilyl group with both the aromatic ring and the oxygen atom. This investigation[125] was not the only one in which the enhanced electron-accepting capacity of the pentamethyldisilyl group in relation to the trimethylsilyl group was demonstrated. A similar phenomenon was observed, for example, also by Brune[81] in a study of the NMR spectra of alkoxydisilanes. Probably, in compounds with Si–Si–O or Si–Si–C_6H_5 fragments, the lone electron pairs or π electrons are probably not delocalised solely over the d orbitals of the nearest silicon atom. Both silicon atoms are involved in this process with formation of a single d_π–d_π–p_π interaction system.

3. Analysis of the Stretching Vibration Frequencies of the Si–H Bonds in Substituted Silanes

As already mentioned frequently in this review, in a spectroscopic study of the effect of $d\pi$–$p\pi$ interaction it is particularly important to select a series of compounds such that their molecular fragments are sensitive to the electronic effects of substituents; on the other hand, it is desirable that the spectroscopic parameters should depend only on electronic effects. The vibrational spectra of substituted silanes are particularly interesting from this point of view. The vibration of the Si–H bond involves almost exclusively changes in the Si–H coordinate. The mass of the substituents R in the silanes R_3SiH does not affect the Si–H stretching vibration frequency (ν_{Si-H}) and there is no mechanical interaction between the Si–H bond and the vibrations of organic substituents[210]. Thus the vibration of the Si–H bond is highly characteristic. Moreover examination of the literature data for the vibrational spectra of substituted silanes[211–214] reveals a significant dependence of ν_{Si-H} on the nature of the substituent. On the basis of the foregoing, substituents influence ν_{Si-H} only via their electronic effects. All these factors make silanes with organic substituents ideal objects for the investigation of the effect of substituents (in particular the effect of $d\pi$–$p\pi$ interaction) on the stretching frequency of Si–H bonds. However, for a long time little attention was paid to this problem in the literature.

In the first studies dealing with the effect of substituents on the ν_{Si-H} frequency in vibrational spectra, the frequency change was attributed exclusively to the inductive effect of substituents[211–214]. Thus Thompson[212] obtained the equation $\nu_{Si-H} = 17.5\,\Sigma\sigma^* + 2106$ relating the ν_{Si-H} frequency to the sum of Taft's inductive constants σ^* for the three substituents in the silanes R_3SiH. The substituents R were both alkyl groups and groups potentially capable of $d\pi$–$p\pi$ interaction with the silicon atom (for example, halogens and the phenyl group). The accumulated experimental data on the vibrational spectra of silanes revealed that inductive hypotheses alone are clearly insufficient to describe the variation of the ν_{Si-H} frequency as the substituents are varied. It was shown that the analysis of the ν_{Si-H} frequency in the silanes $R_{3-n}X_nSiH$, where X is a substituent capable of $d\pi$–$p\pi$ interaction with the silicon atom, yields information about the double-bond character of the Si–X fragment. It was established in this way that the amount of double-bond character in the linkage between the vinyl or phenyl groups and the silicon atom is considerable even in the presence of three such groups in the molecule. Another situation is observed in alkoxysilanes. The ν_{Si-H} frequency in monoalkoxysilanes differs little from the frequency in trialkylsilanes owing to the considerable contribution of $d\pi$–$p\pi$ interaction between the oxygen and silicon atoms. In di- and tri-alkoxysilanes the ν_{Si-H} frequency is higher mainly because of the inductive effect of the alkoxy-groups. The contribution of each alkoxy-group to the $d\pi$–$p\pi$ interaction with the silicon atom becomes less than in monoalkoxysilanes[198]. Attridge[215] observed that, for each series of silanes $R_{3-n}X_nSiH$ [R = alkyl; X = $N(CH_3)_2$, C_6H_5Cl, or OCH_3], the plot of $\Sigma\sigma^*$ against ν_{Si-H} is linear.

The presence of several straight line correlations was explained by the transfer of electron density from X to the silicon d orbitals. The anomalously high ν_{Si-H} frequencies in alkoxychlorosilanes, which could not be accounted for on the basis of earlier correlations[211–213], were interpreted as due to a decrease of $d\pi$–$p\pi$ electron donation caused by the competition between substituents for the silicon d orbitals. However, the series of substituents in terms of their capacities for $d\pi$–$p\pi$ interaction proposed by Attridge does not agree satisfactorily with the current hypotheses in this field.

These studies were developed further[58,111,208,216–222]. It was shown[216,217] that, for trisubstituted silanes R_3SiH with substituents R incapable of $d\pi$–$p\pi$ interaction with the silicon atoms and exerting only an inductive effect on the ν_{Si-H} frequency, we have $\nu_{Si-H} = 23.1\,\Sigma\sigma^* + 2112$. This equation relates the ν_{Si-H} frequency to the sum of Taft's inductive constants $\Sigma\sigma^*$ for three substituents. It was used to calculate the frequencies ν_{calc} in the silanes $R_{3-n}X_nSiH$ with substituents X capable of $d\pi$–$p\pi$ interaction with the silicon atom. It was found that the ν_{calc} are higher than the experimental frequencies ν_{exp}. Under the influence of the effect of $d\pi$–$p\pi$ interaction operating in a direction opposed to that of the I effect of X (this can be conventionally treated as a decrease of the inductive effect of X), the force constant and the stretching vibration frequencies of the Si–H bond decrease. The differences $\Delta\nu = \nu_{calc} - \nu_{exp}$ are a result of the $d\pi$–$p\pi$ interaction in the Si–X bonds. The values of $\Delta\nu$ in several series of compounds have been analysed: R_2XSiH, RX_2SiH, and X_3SiH, where X = F, Cl, Br, I, OAlk, SAlk, SeAlk, $NAlk_2$, PH_2, $CH{=}CH_2$, $C{\equiv}CH$, C_6H_5, C_4H_3O, C_4H_3S, OC_6H_5, SC_6H_5, $OCOCH_3$, $C{\equiv}N$, $NH(C_6H_5)$, NCS, and N_3. Next it was established[218] that the following equations are valid for di- and mono-substituted silanes R_2SiH_2 and $RSiH_3$ with substituents R incapable of $d\pi$–$p\pi$ interaction: $\nu_{Si-H} = 23.1\,\Sigma\sigma^* + 2121$ and $\nu_{Si-H} = 23.1\,\Sigma\sigma^* + 2132$, relating the ν_{Si-H} frequency to the sum of the inductive constants σ^* for the three substituents. The ν_{exp} frequencies in the silanes $RXSiH_2$, X_2SiH_2, and $XSiH_3$ with substituents X capable of $d\pi$–$p\pi$ interaction with the silicon atom differ from the ν_{calc} calculated from these equations. The differences $\Delta\nu = \nu_{calc} - \nu_{exp}$ for di- and mono-substituted

silanes agree with the corresponding $\Delta\nu$ obtained from the spectra of trisubstituted silanes[216,217]. Analysis of the values of $\Delta\nu$ in halogenosilanes[219], in compounds with silicon–Group VI element bonds[111], and silanes with Si–N and Si–P bonds[220] showed that the capacity for $d\pi$–$p\pi$ interaction with the silicon atom decreases within the Groups of the Periodic System from above downwards. It was established[203] that in silanes having only one substituent entering into the $d\pi$–$p\pi$ conjugation with the silicon atom, the values of $\Delta\nu$ are related to the constants $\sigma_n - \sigma'$, characterising the conjugation of these substituents with the phenyl ring, by the linear equation $\Delta\nu = -65.6(\sigma_n - \sigma') + 3$. These data and also the results of Egorochkin et al.[62] are evidence of a considerable analogy between the effects of conjugation with the silicon atom, the phenyl ring, and the vinyl group. In compounds of the type C_6H_5–X–SiH_3, where X = O, S, or NH, there is competition between two conjugation effects: p,π and $d\pi$–$p\pi$.[111,220] Since the dominant effect is that of p,π conjugation, the values of $\Delta\nu$ for these compounds are appreciably lower than the $\Delta\nu$ in silanes of the type Alk–X–SiH_3, where X = O, S, or NH.

It was also shown that the points corresponding to the compounds Alk_2NSiH_3 deviate markedly from the linear equation $\Delta\nu = -65.6(\sigma_n - \sigma') + 3$ towards lower values of $\Delta\nu$.[220] This is caused by the effect of p,σ conjugation in $Alk_2\overset{\curvearrowright}{N}-Si\begin{smallmatrix}H\\H\end{smallmatrix}$, which leads to a decrease of $\Delta\nu$. The effect of p,σ conjugation in this compound is associated with the unique properties of the Alk_2N group: a low-I effect and a high capacity for conjugation. The effect of p,σ conjugation is observed also in the compounds $(Alk_2N)_2ClSiH$ and $(Alk_2N)Cl_2SiH$, as shown by the deviation of the experimental $\Delta\nu$ from the values calculated assuming an additive contribution of the dialkylamino-groups and chlorine atoms to $\Delta\nu$.[220] A similar phenomenon has been observed also in chloromethoxysilanes[217]. Likewise it was established that the degree of $d\pi$–$p\pi$ interaction in the Si–N bond increases with the increasing $-I$ effect of the substituent having a nitrogen atom in the α-position relative to the silicon atom[220]. In agreement with theoretical postulates[4–8], this is caused by the increase of the capacity of the silicon atom for $d\pi$–$p\pi$ interaction when its positive charge increases. The latter relation can be clearly seen also in the study of the $d\pi$–$p\pi$ interaction in silanes having several substituents capable of such interaction[221]. A positive charge may be induced on the silicon atom by electronegative substituents. It would appear that the introduction of a second substituent X should stabilise the $d\pi$–$p\pi$ linkage between the silicon atom and the first substituent X. However, by virtue of its $-I$ effect, the second substituent X decreases the σ electron density at the silicon atom, but, being involved simultaneously in the $d\pi$–$p\pi$ conjugation, it increases the π electron density at the central atom. Thus, depending on the relative contributions of the electron-donating and electron-accepting properties of the substituents, their effect on the $d\pi$–$p\pi$ conjugation in the silane molecule can be extremely varied. This problem was investigated by Egorochkin and Vyazankin[221]. The values of $\Delta\nu$ in two series of compounds were determined: $(C_2H_5)_2XSiH$ and $(C_2H_5)X_2SiH$, where X = C_6H_5, CH_2=CH, Br, Cl, F, CH_3S, or CH_3O. The compounds $(C_2H_5)X_2SiH$ may be regarded as products of the substitution of the ethyl group in $(C_2H_5)_2XSiH$ by X. The effective charge of the silicon atom in $(C_2H_5)_2XSiH$ depends both on the $-I$ effect of X and on the electronic effect of the $d\pi$–$p\pi$ conjugation in the Si–X bond, which is opposed to it. The strength of the second $d\pi$–$p\pi$ linkage between Si and X and hence the overall effect of the $d\pi$–$p\pi$ interaction in molecules of the type $(C_2H_5)X_2SiH$ are determined by the magnitude and sign of this effective charge. These studies explain the experimental finding that the series of relative capacities for $d\pi$–$p\pi$ interaction in the silanes R_2XSiH (AlkO > F > $CH_3S \simeq$ Cl > Br > CH_2=CH > C_6H_5), RX_2SiH (Br > Cl > F > CH_3S > C_6H_5 > CH_2=CH > AlkO), and X_3SiH (Br > Cl > CH_3S > C_6H_5 > CH_2=CH > F > AlkO) are not the same. The extent of $d\pi$–$p\pi$ interaction in the molecule depends on the inductive and mesomeric effects of the substituents which alter the charge of the silicon atom. Therefore in silanes with several substituents the extent of the electron-donating properties of each substituent is determined significantly by the number and nature of its partners in $d\pi$–$p\pi$ interaction.

The equation $\nu_{Si-H} = 23.1\,\Sigma\sigma^* + 2112$, relating the ν_{Si-H} frequency to the sum of Taft's inductive constants σ^* of substituents incapable of $d\pi$–$p\pi$ conjugation was used to determine the values of σ^* for the groups C_2H_5Te (+0.4),[153] $(CH_3)_3Si$ (−0.9), $(C_2H_5)_3Si$ (−1.1), and $(C_2H_5)_3Ge$ (−0.8).[222] The higher electronegativity of germanium compared with silicon in the absence of the effects of $d\pi$–$p\pi$ conjugation involving these elements was thereby confirmed.

By taking into account rigorously the inductive effects of the substituents on the infrared spectra of substituted silanes and on the ^1H NMR spectra of alkylsilanes and alkylgermanes, it was possible to establish the effect of σ,σ conjugation in methyl derivatives of silicon and germanium[58].

The data described show that considerable advances have been achieved in the study of the effect of $d\pi$–$p\pi$ interaction in organic derivatives of Group IVB elements. Summarising the principal results of studies in this field, the following conclusions may be formulated. In compounds containing one M–X bond (M = Si, Ge, or Sn; X = element or Groups V–VII) or a group M–X–M (X = O, S, or Se), the capacity for $d\pi$–$p\pi$ interaction between the atoms M and X in a given Group of the Periodic System decreases with the atomic numbers of the elements M and X. The decrease of the capacities for $d\pi$–$p\pi$ interaction between the atoms M and X in the given Group on passing from a substituent X in the Second Period to one in the Third Period is greater the lower the number of the group to which X belongs. The mechanism of the $d\pi$–$p\pi$ interaction between the atoms Si and X is formally similar to the effects of the conjugation of the substituent X with an aromatic ring or the vinyl group. In compounds containing one Si–H bond, the relative capacity for the formation of $d\pi$–$p\pi$ linkages with the silicon atom is correlated with their Hammet resonance constants. In silane derivatives containing two or three similar substituents X capable of $d\pi$–$p\pi$ interaction, the extent of the latter is determined by the effective charge of the silicon atom, which depends on the inductive and mesomeric effects of X.

Reactivity of Organic Compounds in an Excited Electronic State

V.A.Krongauz

The review deals with the reactivities of complex organic compounds in an excited state; the characteristics of the electronic structure of the molecules, which play a fundamental rule in photochemical reactions, are discussed.
The bibliography includes 79 references.

I. INTRODUCTION

On absorption of a light quantum, the molecule passes to an excited singlet state (a direct transition to a triplet level is usually forbidden). The energy of this state is determined both by the magnitude of the absorbed quantum and by the position of the energy levels in the molecule. In the condensed phase, a series of relaxation processes takes place very rapidly (over a period $\leq 10^{-12}$–10^{-13} s). Among these, the most important is spontaneous transition from the highest to the lowest excited levels and the establishment of the equilibrium configuration of the nuclei for the given state (the excess vibrational energy is then transmitted to the medium).

At the lowest excited level, the molecule can persist for a longer period (10^{-9}–10^{-7} s at the singlet level and 10^{-6}–10^{-1} s at the triplet level). The transition to the ground state now involves both the possibility of non-radiative deactivation of the molecule and the emission of excess energy as luminescence.

Photochemical reactions can in general occur at any instant after the absorption of light by the molecule and therefore can compete with both rapid and slow deactivation processes.

As an example, we shall consider the homolytic photochemical decomposition of a molecule. On absorption of light, the molecule can easily pass to an antibonding excited level and its dissociation takes place over a period of about 10^{-12}–10^{-13} s. If there is sufficient time for the molecule to pass to a lower level, which may prove stable, its decomposition can be caused either by the fact that its vibrational energy exceeds the dissociation energy of any one bond or by pre-dissociation. Dissociation processes are also possible during the return to the ground level. In the latter case the molecule in the ground state has a much higher vibrational energy than the thermal energy of the molecules in the surrounding medium. For such a "hot" molecule to undergo a chemical transformation, the process must be very rapid, since the excess vibrational energy is dissipated over a period of about 10^{-12} s.

Naturally this approximate scheme does not exhaust all possible situations, since triplets states, $n\pi^*$ states, and charge-transfer states may play a major role in the chemical reactions of the excited molecule. Moreover, different levels can exert a mutual influence on one another, becoming mixed, which also precludes a rigorous classification.

Fortunately, in many photochemical reactions (this applies also to the majority of the reactions considered in the review) the molecules involved in them pass to the lowest excited levels which have minima on their potential surfaces, greatly facilitating the consideration of the process mechanism. We can assume that, owing to their fairly long lifetime, such excited molecules are in a thermal quasiequilibrium with the surrounding medium and the mode and rates of their reactions are determined by the energy barrier on the reaction pathway. This approach is potentially similar to that employed in the discussion of reactivities of molecules in the ground state. Therefore, in order to estimate the reactivities of excited molecules, one should consider the same parameters—the rate constant and the activation energy—as for dark processes. However, in photochemical reactions this is not a simple task, since usually it is possible to measure only the quantum yields of the processes. For a unimolecular reaction, the quantum yield $\varphi = k\tau$ and for a bimolecular process $\varphi = k\tau c$, where k is the reaction rate constant, τ the lifetime of the excited molecules of the absorbing species, and c the concentration of the second component. However, τ can be by no means always determined.

The second factor which hinders the study of the reactivities of various excited molecules is the absence of activation energy in many photochemical reactions. In particular, this casts doubt on the possibility of employing the transition state theory for the interpretation of the results, since the fundamental postulate of the theory concerning the equilibrium between the activated complex and the initial molecules breaks down. It may be that the excited molecule in such reactions should be regarded as the species which has already risen above the reaction "hump". Then the rate of the process will be determined solely by the probability factors which enter into the pre-exponential factor.

It must be emphasised that the reactivity of an excited molecule is not caused solely by the fact that it has greater energy available than the surrounding molecules. The electronic structure of the excited molecule differs from its structure in the ground state. Therefore the equilibrium positions of the nuclei must be different. We are dealing essentially with a new molecule having new properties. In other words, the excited molecule can react in a completely different manner than the molecule in the ground state.

In the present review an attempt has been made to describe the current approaches to the study of the reactivity of excited organic molecules. For this purpose, we have chosen classes of photochemical reactions which

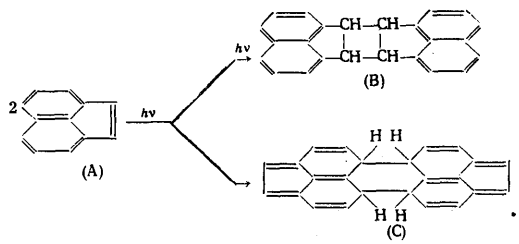
have been most thoroughly investigated in this respect. There are good reviews of many of these reactions and some are described in monographs [1-10]. Nevertheless it is desirable to consider these data in one review from a single standpoint.

II. PHOTOCHEMICAL FORMATION AND OPENING OF RINGS

1. Elementary Treatment

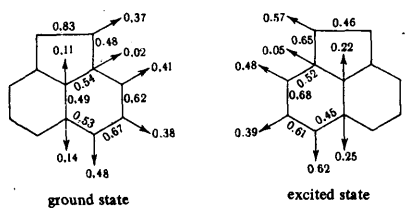
When an attempt is made to explain why the action of light on a molecule causes preferential dissociation or formation of a particular bond, the first idea that comes to mind is to examine how the reactivity indices change when the molecule passes to an excited state. The success of this simple approach may be illustrated using as an example the photocyclisation reactions of certain aromatic hydrocarbons.

This was first done by Crawford and Coulson [11] in a study of the photodimerisation of acenaphthylene [12], which might proceed in two different ways:



(I)

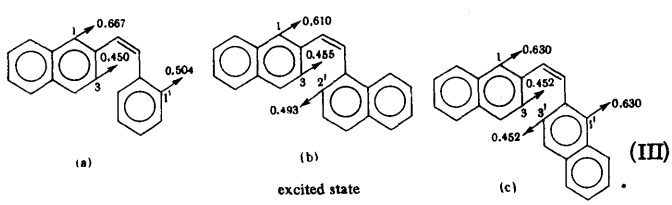
In fact the photochemical reaction leads to the formation of compound (B) only. In order to account for this finding, Crawford and Coulson compared the free valence indices and the bond orders of the molecule (A) in the ground and first excited states calculated by the simple Hückel molecular orbital method:



(II)

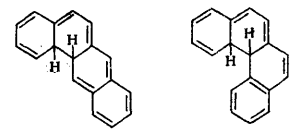
Scheme (II) shows that, on excitation of the molecule (A), the greatest decrease of bond order and increase of the free valence index of the atoms occurs in the ethylenic bond. This in fact leads to preferential dimerisation at this bond. The absence of the dimer of type (C) can probably be accounted for by the fact that this involves the formation of the energetically less favourable quinonoid structure, although the free valence indices in the para-α-positions of the naphthalene ring of substance (A) increase appreciably in the excited state.

The photocyclisation reactions of a number of naphthyl-substituted ethylenes have been interpreted similarly [13]:



(III)

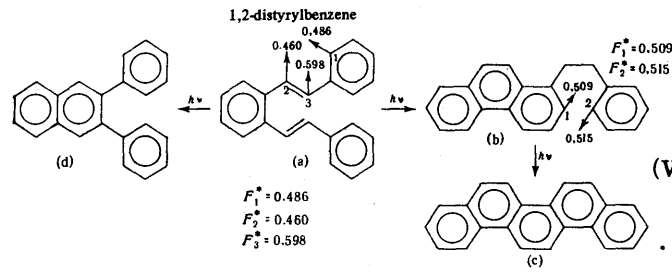
The cyclisation reaction can take place at both the α- and β-positions of the naphthalene ring. For example, with compound (a) one must consider the possibility of forming the following two isomers:



(IV)

The free valence indices for the excited molecules shown in scheme (III) suggest that the cyclisation should involve the formation of a 1,1'-bond (the sum of the F_1^* and F_8^* indices is a maximum). Indeed, experiment showed that cyclisation takes place only at the α-positions, although this mode of reaction is sterically more hindered.

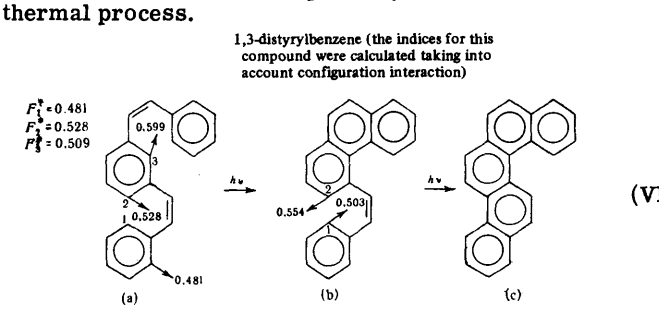
The photocyclisation reactions of distyrylbenzenes (V)-(VII) have been interpreted similarly [14]:



(V)

As in the preceding case, the cyclisation of distyrylbenzene should involve ring closure at the sites of the maximum values of $F_8^* + F_r^*$. For 1,3- and 1,4-distyrylbenzenes or their cyclisation products, this rule indeed holds. However, the reaction of 1,2-distyrylbenzene follows the (a) → (b) → (c) pathway instead of (a) → (d), probably owing to the steric hindrance in the formation of (d).

The ambiguity of the treatment of alternant hydrocarbons based on a comparison of the reactivity indices in the excited state arises because the positions in the molecule which are the most reactive in the excited state (for example have the highest free valence) are also the most reactive in the ground state. Therefore, in the absence of additional data, it is difficult to rule out the possibility that the reaction involves vibrationally excited molecules in the ground electronic level, which are formed when the electronic excitation energy is degraded. The reaction of such "hot" molecules is probably similar to the thermal process.



(VI)

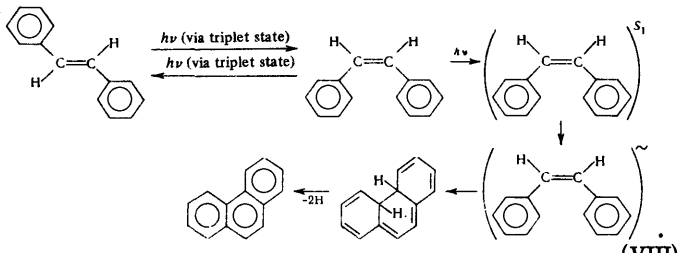
(VII)

According to Gusten and Klasing[15], the cyclisation of stilbene to 4a,4b-dihydrophenanthrene takes place in the same way (in the presence of oxidants, oxygen, air, iodine, etc., the reaction proceeds as far as the formation of phenanthrene). In a study of the photochemical cyclisation of various *m*- and *p*-substituted stilbenes, Gusten and Klasing found that for *m*-substituted stilbenes there is a satisfactory linear correlation between the sum of electron densities in the ground state at the *o*-carbon atoms involved in the new bond and the quantum yield of the reaction. For the excited electronic state of *m*-substituted stilbenes and also for the ground and excited states of *p*-substituted stilbenes, there is no correlation whatever between the electron densities and the quantum yield of the cyclisation reaction. Gusten and Klasing[15] explain this finding by postulating that the cyclisation takes place in a vibrational excited state of the molecule for stilbene and its derivatives. The absence of an effect by *p*-substituents on the rate of reaction was explained by the fact that these substituents are in the *m*-position relative to the reacting carbon atoms and therefore have little influence on the electron densities at these atoms.

On the other hand, *p*-substituents cause a significant shift of the absorption band maximum of stilbene towards longer wavelengths. There is a linear relation between the frequency of the absorption maximum and the quantum yield of the cyclisation reactions of the *p*-substituted derivatives. The authors believe that the higher the energy of the excited electronic level from which the molecule passes to the ground level, the greater its store of vibrational energy and the faster its cyclisation reaction.

A number of facts[16] indicate that the photochemical cyclisation of stilbene involves a stage in which *cis*-stilbene molecules in a singlet excited electronic state are formed. For example, on excitation to the triplet level via a triplet–triplet energy transfer, cyclisation does not occur[17,18]. Possibly the vibrational energy of the "hot" molecule formed on transfer from the triplet state is insufficient for effective cyclisation.

Thus the following scheme may be formulated for the photochemical reaction for stilbene and its derivatives.

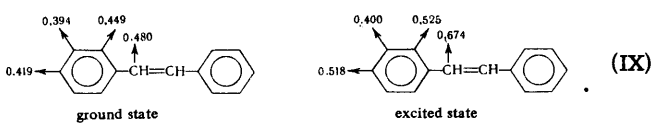


(VIII)

The symbol ~ denotes vibrational excitation.

The fact that, on pyrolysis of *cis*-stilbene, the product is also phenanthrene in a high yield[19] may be regarded as definite confirmation of the involvement of vibrationally excited stilbene molecules in the cyclisation reaction.

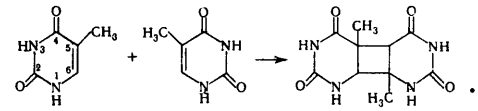
It is interesting to note that, regardless of whether electronically excited or vibrationally excited stilbene molecules are involved in the reaction, the dimerisation process which yields tetraphenylcyclobutane should compete with cyclisation to phenanthrene. The free valence indices in the ground and excited states show that the first reaction should be faster:



(IX)

Indeed, the dimerisation reaction predominates in concentrated solutions.

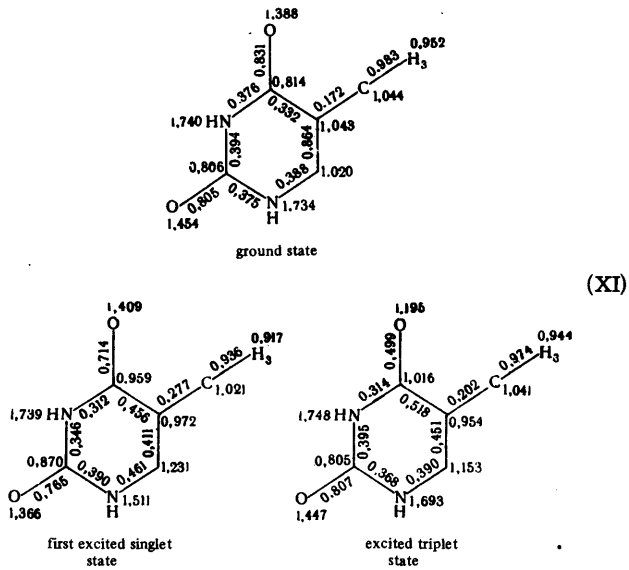
Using these simple concepts, Pullman and coworkers[20] examined the reactivities of pyrimidine rings in their photochemical dimerisation. This reaction probably plays an important role in the photochemistry of nucleic acids and in particular of DNA (nucleic acids contain pyrimidine rings as structural units). Pyrimidines are dimerised via the interaction of 5-C and 6-C atoms of two pyrimidine rings with formation of a cyclobutane ring. For example, thymine cyclises according to the mechanism:



(X)

Comparison of the electron densities and bond orders in the ground and excited states of thymine (XI) makes it clear why cyclisation takes place at the carbon atoms in the 5- and 6-positions of the thymine ring[21]†:

electron densities and bond orders of thymine



(XI)

It is noteworthy that the difference between the reactivity indices of the triplet and singlet excited states is insufficient to yield a definite conclusion about the multiplicity of the molecules involved in the reaction.

Thus simple comparison of the reactivity indices makes it possible in certain cases to obtain a definite idea about the process mechanism. However, in many instances the result is ambiguous.

A more general approach, based on the rules of conservation of orbital symmetry formulated by Woodward and Hoffmann, is possible for the interpretation of the cyclisation and cyclodecomposition reactions of symmetrical molecules.

---

†The calculation was carried out by the self-consistent field method taking into account the interaction of singly excited states.

2. Reactions with Conservation of Orbital Symmetry

It was mentioned above that one of the important problems frequently encountered in the study of reactivities in photochemical reactions is whether electronically excited molecules or hot molecules in the ground electronic level are involved in such reactions. We have seen that usually an answer to this question cannot be simply obtained. However, there are many reactions, the so called concerted reactions, for which it is possible to predict, on the basis of considerations related to orbital symmetry, whether the reaction proceeds via an excited electronic state or a ground electronic level. These considerations were first put forward by Woodward and Hoffmann [22,23] and then in a more rigorous form by Longuet-Higgins and Abrahamson [24]. They are based on the symmetry of the molecular orbitals of the starting materials and reaction products and reduce to the requirement that the symmetry be retained in the course of the reaction. This can be made clear by examples discussed in the literature [22-24]—the cyclodimerisation of ethylene to cyclobutane and the cyclisation of butadiene to cyclobutene.

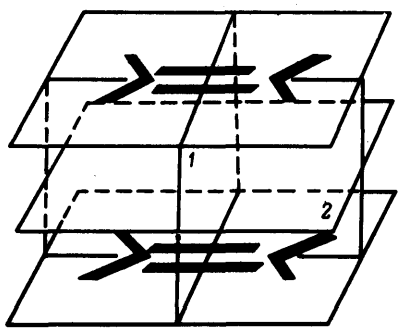


Figure 1. Mutual approach of two parallel ethylene molecules [3].

In order to form two σ bonds of cyclobutane from two π bonds of ethylene in its cyclodimerisation, it is necessary that the ethylene molecules should approach one another until the $p\pi$ electron clouds of the carbon atoms overlap. We imagine that during such approach the molecules are arranged parallel to one another and consider the symmetry of the system as a whole relative to the two planes *1* and *2* (Fig. 1).

If the ethylene molecules are in the ground state (the π bonding molecular orbital), two cases are possible: either the molecules approach one another so that components of the π-electron clouds of the same sign overlap or the approach is such that components of the π-electron clouds of opposite sign overlap (Fig. 2).

In the first case a bonding interaction takes place between the ethylene molecules—a combination of two π-electron functions of ethylene symmetrical relative to both planes *1* and *2* (such combination will be referred to as *SS*). In the second case a weak repulsion arises between the approaching molecules and the electronic combination is symmetrical relative to plane *1* and antisymmetric relative to plane *2* (*SA*). If the π-electron function of one ethylene molecule is denoted by π_1 and that of the other by π_2, the first combination may be characterised by the function $\pi_1 + \pi_2$ and the second by $\pi_1 - \pi_2$.

If we now consider what happens when two ethylene molecules in an excited electronic state (π_1^* and π_2^*) approach one another, examination of Fig. 2 readily shows that again there is a possibility of a bonding combination $\pi_1^* + \pi_2^*$ characterised by *AS* symmetry and an antibonding combination $\pi_1^* - \pi_2^*$ with *AA* symmetry.

The symmetry of the different states of cyclobutane can be treated similarly. The difference is that the carbon atoms in the cyclobutane molecule are linked by σ bonds. Here the bonding states are evidently $\sigma_1 + \sigma_2$ and $\sigma_1 - \sigma_2$ with *SS* and *AS* symmetries. The antibonding states are $\sigma_1^* + \sigma_2^*$ and $\sigma_1^* - \sigma_2^*$ with *AS* and *AA* symmetries.

We now draw lines connecting the states of cyclobutane and of the system of two ethylene molecules with the same symmetry, as in Fig. 2, and obtain a correlation diagram similar to those proposed at one time by Hund and Mulliken [25] to elucidate the relations between the molecular

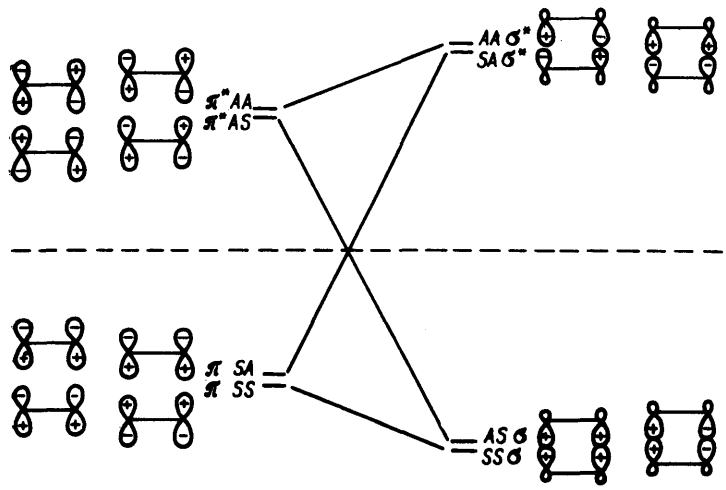

Figure 2. Correlation diagram for the formation of cyclobutane from two ethylene molecules [8].

orbitals of diatomic molecules and the atomic orbitals of their constituent atoms.

By considering the two approaching ethylene molecules as a single formation, we distribute four π electrons among its electronic orbitals in accordance with the Pauli principle. Evidently the lowest state of this system is the symmetrical (S) state $(SS)^2(SA)^2$. Similarly the lowest electronic state of isobutane should be $(SS)^2(AS)^2$ with S symmetry in which four σ electrons are located. The lowest level of a combination of two ethylene molecules should be correlated with the doubly excited cyclobutane state $(SS)^2(SA)^2$ and the lowest level of cyclobutane should be correlated with the doubly excited state $(SS)^2(AS)^2$ of the system of two ethylene molecules. However, since these states have the same symmetry, the non-crossing rule, according to which levels of the same symmetry do not intersect owing to electron repulsion, applies to them.

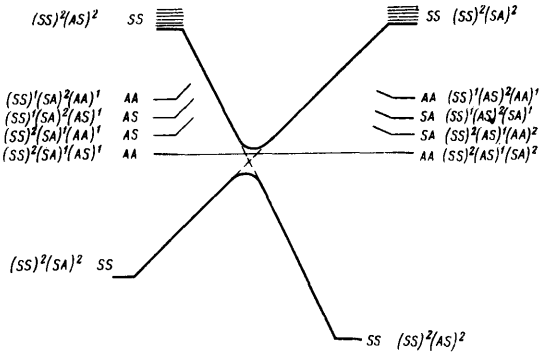

Figure 3. Diagram of electronic states for the formation of cyclobutane from two ethylene molecules. The symmetry of the states is defined by the relations[8]

$$S\times S\to S\leftarrow A\times A,$$
$$S\times A\to A\leftarrow A\times S.$$

As a result the diagram assumes the form shown in Fig. 3, where the ground level of the two ethylene molecules is seen to be correlated with the ground level of cyclobutane. The highest excited levels are also correlated with one another. It is evident from the diagram that, for the conversion of the two approaching ethylene molecules in the ground state into cyclobutane with retention of symmetry, the system must overcome an energy barrier. Therefore such a process is unlikely. In a situation where two π electrons of the ethylene molecules are promoted to excited orbitals—the state in which the conversion into cyclobutane can occur without an activation energy—is also improbable. However, the transition of one π electron of ethylene to a lower excited state yields the symmetrical function $(SS)^2(SA)^1(AS)^1$, which is correlated with the lowest excited state $(SS)^2(AS)^1(SA)^1$ of the cyclobutane molecule, corresponding to the excitation of one π electron. In other words such a transformation is allowed by symmetry and does not require an activation energy, as can be seen from the diagram. At the same time this state can be readily achieved when ethylene is subjected to the action of light [for many compounds, such an excited dimer (excimer) can be actually detected spectroscopically]. From this it follows that the dimerisation of ethylene should have a photochemical and not a thermal mechanism‡.

The correlation diagrams also make it possible to discover the relations governing the reversible cyclobutane $\rightleftharpoons$ butadiene reaction. Such reactions, which involve the formation of a σ bond from two π electrons without a change in the number of carbon atoms in the molecule, are called electrocyclic. Cyclobutene can be converted into butadiene via two pathways (Fig. 4): the dissociation of the σ bond between the C_1 and C_4 atoms in such a way that the methylene groups $H_3 \diagdown C_1 \diagup H_1$ and $C_4 \diagup H_4 \diagdown H_2$ rotate either in the same direction (Fig. 4*a*) or in the opposite directions (Fig. 4*b*). The first pathway is called conrotatory and the second disrotatory. Evidently, in conrotatory ring opening, the system retains a two-fold symmetry axis in the course of the entire reaction. In disrotatory ring opening, the system retains a plane of symmetry. This is also true of the converse reaction—the cyclisation of butadiene.

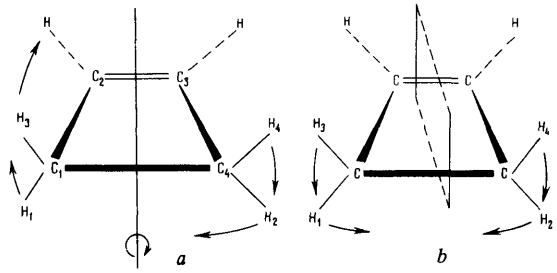

Figure 4. Symmetry of the conrotatory (*a*) and disrotatory (*b*) transformations[26].

Naturally if the polyene or the cyclic form do not contain substituents, the conrotatory and disrotatory transformations cannot be distinguished experimentally. However, if one hydrogen atom at each of the extreme carbon atoms is replaced by a substituent (as has been done in Figs. 5*a* and 5*b*), each type of rotation gives rise to different stereoisomers.

Using the same principle of the conservation of orbital symmetry, it is possible to construct correlation diagrams for these reactions[8], as was done for ethylene. The diagrams show that the conrotatory cyclobutene $\rightleftharpoons$ $\rightleftharpoons$ butadiene interconversion should have a thermal mechanism and the disrotatory interconversion should take place as a photochemical process involving the first excited states.

The same conclusions were reached in the first study by Woodward and Hoffmann[22] with the aid of simpler considerations based on the hypothesis that the nature of the electrocyclic reaction is determined by the symmetry of the highest occupied orbital of the acyclic product. For the ground state of butadiene, the ψ_2 orbital is of this kind

‡In this case thermal processes are understood as processes in which vibrationally excited molecules, formed on transition of the molecule from an excited electronic to the ground state, are involved.

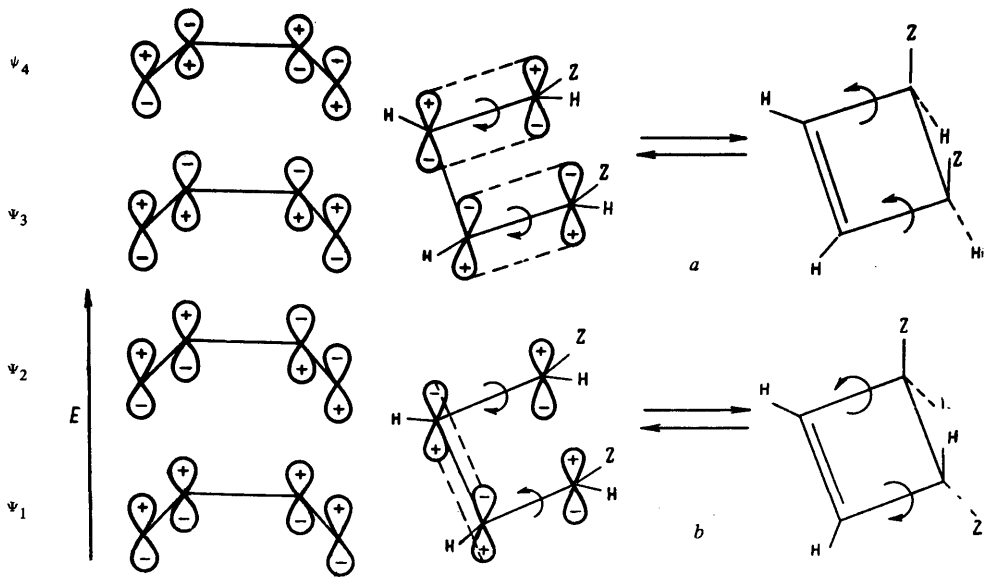

Figure 5. Schematic illustration of the butadiene ⇌ cyclobutane electrocyclic reaction[26].

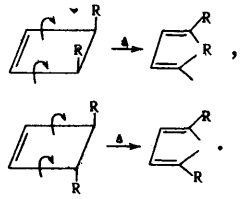
(Fig. 5). Fig. 5*a* shows that the conversion of the π bond into a bonding σ linkage in the ring as well as the reverse process require a conrotatory transformation. For the photochemical reaction, where the highest occupied butadiene level is ψ_3 (Fig. 5*b*), cyclisation and ring opening are disrotatory processes. Although these considerations do in fact give rise to certain doubts[24], nevertheless they constitute a simple and convenient procedure and lead to the same conclusions as the correlation diagrams. For example, examination of the highest occupied orbitals leads to the prediction that, for the cyclopropyl cation ⇌ ⇌ allyl cation electrocyclic reaction, the thermal process should be disrotatory and the photochemical process conrotatory[22]. This is also indicated by the correlation diagram[24]. The hexatriene ⇌ cyclohexadiene reaction should also have a thermal mechanism for the disrotatory transformation and a photochemical mechanism for the conrotatory transformation.

Generalising all these results, Woodward and Hoffmann concluded that, for all systems the acyclic components of which contain $4n$ π electrons (n = 0, 1, 2, 3, ...), electrocyclic reactions involve a conrotatory thermal mechanism and a photochemical disrotatory mechanism. For a system with an acyclic component containing $4n + 2$ π electrons, the thermal and photochemical reactions take place with rotations in the opposite sense. This relation in fact constitutes one of the familiar Woodward–Hoffmann rules.

According to the Woodward–Hoffman rules, the thermal opening of the cyclobutene ring with substituents in the 1- and 4-positions leads to the formation of isomers corresponding to the conrotatory process[27–29]:



(XII)

The symbol Δ denotes heating and R = CH_3, $COOCH_3$, CH_2OTs, or Cl.

The sequence of the transformations of the *cis-cis-cis*-cyclonona-1,3,5-triene is very instructive[30,31]:

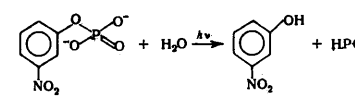
(XIII)

The principle of the retention of orbital symmetry is obeyed by all concerted organic reactions[8]. These include the Diels–Alder reaction, certain rearrangements (the Claisen, Cope, and sigmatropic rearrangements), etc. "Selection rules" have also been formulated for these reactions.

III. PHOTOCHEMICAL SUBSTITUTION REACTIONS OF AROMATIC COMPOUNDS

The scope and disadvantages of the simple molecular orbital method for the interpretation of the chemical behaviour of excited molecules can also be discovered by considering photochemical heterolytic substitution reactions involving aromatic substances.

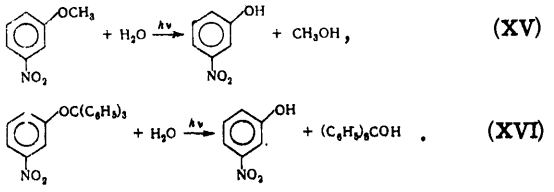
In 1956 Havinga et al.[32] observed that, when aqueous solutions of nitrophenyl phosphate and sulphate esters are illuminated, they are hydrolysed to nitrophenol and the corresponding acid. For example:



(XIV)

At the same time, in the absence of light, these substances are quite stable to water. It is particularly surprising that the photochemical hydrolysis takes place with the maximum quantum yield when the ester group is in the *meta*-position relative to the nitro-group, while the *ortho*- and *para*-derivatives are relatively inactive under the action of light. In the usual dark nucleophilic substitution reactions, the nitro-group should be *ortho*- and

para-directing regardless of whether the reaction of the substituting agent is with a fluorine (sulphur) atom or a ring carbon atom. Experiments with *m*-nitrophenyl phosphate in $H_2{}^{18}O$ showed that at pH ≤ 12 the photochemical hydrolysis involves the reaction of water with the phosphorus atom, while at pH > 12 the reaction is with a ring carbon atom[33]. Nucleophilic substitution takes place also with CH_3NH_2, CH_3OH, etc. the products being *m*-$NO_2C_6H_4NHCH_3$, *m*-$NO_2C_6H_4OCH_3$, etc. Photochemical hydrolysis has likewise been observed with *m*-nitroanisole[32,34], *m*-nitrophenyl trityl ether, and *m*-cyanophenyl trityl ether[35].

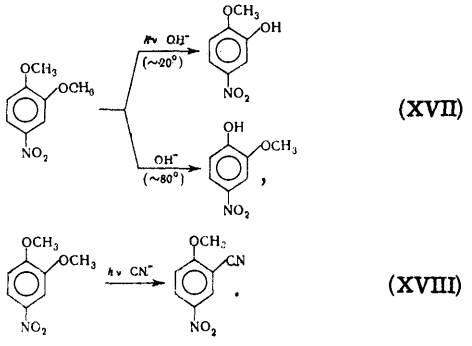


(XV)

(XVI)

The second reaction does not take place in the dark, although the corresponding *p*-isomer readily hydrolyses at 25°C.

The selectivity of the photochemical reaction is shown particularly clearly when identical substituents are present in the ring in both *m*- and *p*-positions (4-nitroveratrol)[36,37]:



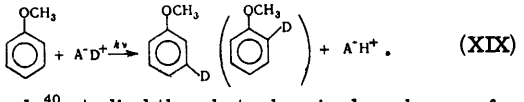
(XVII)

(XVIII)

The reaction of 4-nitroveratrol with methylamine takes place similarly[38].

Photochemical electrophilic substitution reactions include deuterium exchange in aromatic compounds, which was observed independently by de Bie and Havinga[39] and by Kuz'min, Berezin, and coworkers[40].

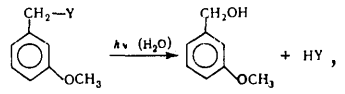
De Bie and Havinga[39] studied light-induced deuterium exchange between anisole and deuteroacetic and trifluorodeuteroacetic acid. It was found that the photochemical substitution of hydrogen in the benzene ring by deuterium takes place only in the *ortho*- and *meta*-positions, the *para*-position is almost inactive:



(XIX)

Kuz'min et al.[40] studied the photochemical exchange of deuterated naphthalene and anthracene with sulphuric acid. The rate of exchange was found to depend on the acidity of the medium, which is characteristic also of dark heterolytic substitution reactions.

Zimmerman and Sandel[41] compared the photochemical hydrolytic reactions of *m*- and *p*-methoxybenzyl acetates, 3,5-dimethoxybenzyl acetate, and *m*-methoxybenzyl chloride in aqueous dioxan solutions. In all cases when the substituted benzyl group was in the *meta*-position, photochemical hydrolysis occurred in a high yield (the presence of two methoxy-groups in the *meta*-position greatly increased the role of hydrolysis compared with homolytic radical decomposition):



(XX)

where Y = OAc or Cl. *Para*-derivatives are scarcely hydrolysed. In this case substitution takes place in the side chain although it is evident that the electron-donating substituent activates the *meta*-position with respect to the photochemical reaction, as in ring substitution.

The results have been interpreted[34,39-43], by comparing the electron densities at different atoms in the molecule. On transition of the molecule from the ground to an excited electronic state, the electron densities change, which may be illustrated for the benzyl cation and anion as examples[41]. Here the $-CH_2^+$ and $-CH_2^-$ groups play the role of electron-accepting and electron-donating substituents (Fig. 6).

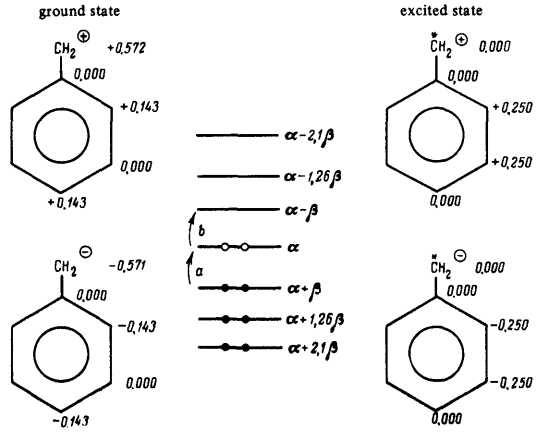


Figure 6. Charge distribution in the benzyl cation and anion[41].

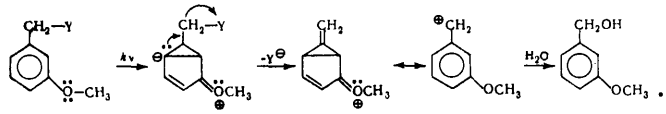
Fig. 6 shows that in the ground state positive and negative charges in the cation and anion are localised in the *ortho*- and *para*-positions, while in the first excited state the charges are localised in the *ortho*- and *meta*-positions. This simple example shows that excitation of the molecule should promote both nucleophilic and electrophilic substitution in the *ortho*- and *meta*-positions. In order to account for reaction (XX) Zimmerman and Sandel[41] suggested that in the excited state of methoxybenzyl derivatives the negative charge is localised at the Y substituent with subsequent dissociation of the molecule to give the methoxybenzyl cation:



(XXI)

Similar charge distributions were obtained also by a more rigorous examination of substituted benzenes using the "molecule in molecule" method[41,43].

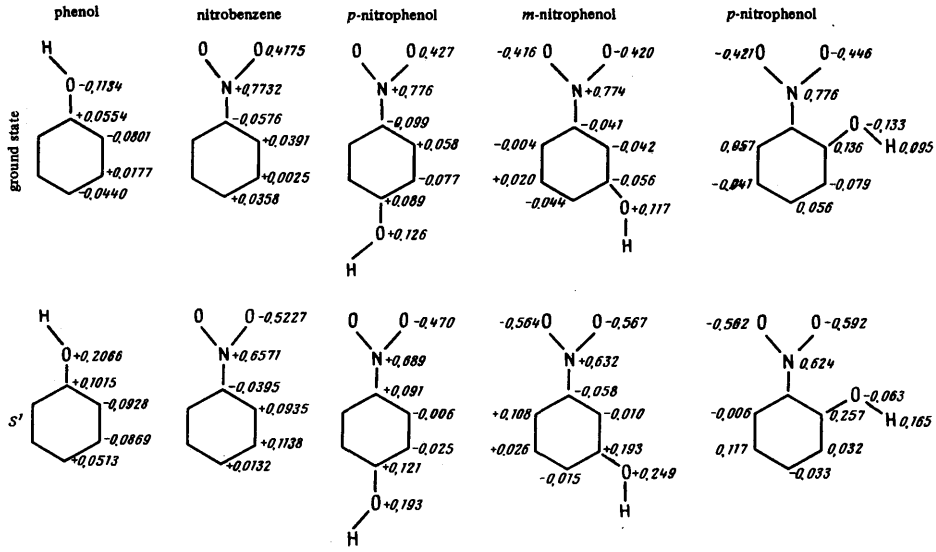


Figure 7. Charge distribution in the ground and lowest excited singlet ($\pi-\pi^*$) states of substituted benzenes[34].

Qualitatively the same redistribution of electron density on excitation of the molecule was obtained by de Bie and Havinga[39] by a calculation using the self-consistent field method for specific phenol (anisole analogue), nitrobenzene, and nitrophenol molecules (Fig. 7).

Thus the localisation of a negative or positive charge at a particular site in the excited molecule probably determines the most favourable site of attack by electrophilic or nucleophilic substituents. A number of data[34,36] clearly show that singlet molecules in the first $\pi-\pi^*$ excited state are involved in the reaction.

The above approach to the estimation of the reactivities of excited molecules in substitution reactions is quite analogous to the approaches employed for the estimation of the reactivities of molecules in the ground state in which a π complex is adopted as a model of the transition state. In this case electron density is a characteristic parameter determining the activation energy for the process. However, according to some data[34,36], the activation energy for photochemical substitution reactions is close to zero. Consequently the employment of reactivity indices such as electron density within the framework of the activated complex concept gives rise to certain doubts[44,45], as already stated. Certain qualitative considerations[34,44] reduce basically to the fact that Coulombic interaction forces arise between atoms at which positive or negative charges are located and between the substituting agents, increasing the reaction cross-section at these particular sites in the molecule. Such concepts are largely intuitive and are not related to a specific reaction model.

One can put forward also another explanation, assuming that the lower experimental activation energies for photochemical reactions are only apparent. Indeed if the substituting agent behaves as a quenching agent, it is quite likely that the quenching process follows the same pathway as the photochemical reaction[34,46]. Then both competing processes (quenching and chemical reaction) should have similar activation energies and an increase of temperature should increase the rates of both processes and should not alter their relative contributions and hence the quantum yield of the reaction. Fig. 8 illustrates a possible mechanism for the substitution reaction.

A clear representation of the intersection in space of the potential surfaces for the reactions was proposed by Kuz'min[47,48]. Like Havinga, he believes that the reaction proceeds non-adiabatically, i.e. in the course of the reaction the electronic excitation energy is degraded. In agreement with the spirit of Nagakura's idea[50], Kuz'min[47-49] believes that in the excited state too the heterolytic substitution reaction is preceded by electron transfer.

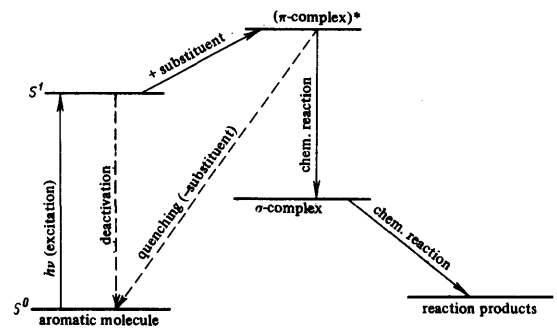

Figure 8. Schematic illustration of the elementary processes in photochemical substitution in the aromatic ring[34].

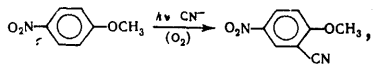
It is noteworthy that not all photochemical heterocyclic substitution reactions proceed in accordance with the distribution of electron density in the excited molecule. For example, photochemical deuteration of nitrobenzene takes place only in the *para*- and *meta*-positions[39] although the difference between the electron densities in the *meta*- and *ortho*-positions is insignificant (Fig. 7).

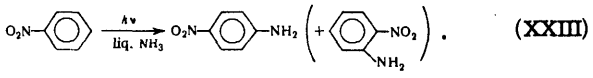
Photochemical cyanation of *p*-nitroanisole takes place in the *o*-position relative to the alkoxy-group [51]:



(XXII)

although according to Fig. 7 this position should be least favourable for nucleophilic substitution.

The position where nitrobenzene is aminated in liquid ammonia [52] is also inconsistent with charges on the ring:



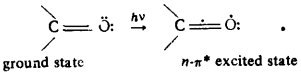
(XXIII)

Havinga and coworkers [36] explain the path of this reaction using the fact that it involves neutral ammonia molecules, and that the electron density near different carbon atoms in the ring should therefore be no longer of decisive importance. In this case a σ complex may be adopted t as a model of the transition state and the localisation energy is best employed as a reactivity index. It is also possible that reaction (XXIII) involves hot molecules (after the conversion of the molecule to the ground state). Then preferential formation of the *para*-substituted derivative is consistent with the distribution of electron density in the molecule.

IV. ABSTRACTION OF HYDROGEN BY KETONES

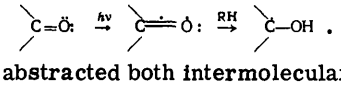
A fairly striking effect of the structure of molecules on their reactivity in the excited state is revealed by a qualitative examination of photochemical reactions of ketones. These constitute one of the most important and one of the most thoroughly investigated branches of organic photochemistry. They are considered in almost all monographs on photochemistry and in many reviews (see, for example, Refs. 1–5, 7, 53). Here we shall confine ourselves to a discussion of the relevant aspects of certain reactions involving the abstraction of hydrogen by the carbonyl group.

The specific features of the photochemical behaviour of ketones are determined by their carbonyl group C=O with an unbonded electron pair at the oxygen atom. When the molecule absorbs a light quantum, one of the electrons of this pair can pass from the non-bonding $2p_y$ orbital to the antibonding π^* orbital ($n-\pi^*$ transition).



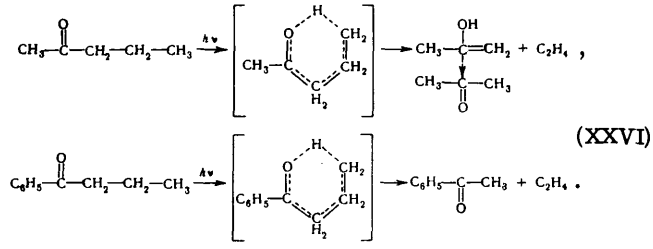
(XXIV)

This transition is forbidden by symmetry and therefore the corresponding absorption band (in the region of 300 nm) is usually weak. The $\pi-\pi^*$ and $n-\sigma^*$ transitions are of course possible, but in aliphatic and many aromatic ketones the $n-\pi^*$ state is the lowest excited electronic state of the molecule. A second important characteristic of many ketones is the comparative ease of the intercombination transition of the excited molecule from the singlet to the triplet state. Since triplet states are usually much longer-lived than singlet states, this increases the likelihood that the molecule will enter into a chemical reaction. When one of the electrons of the pair is transferred from the *n* orbital to the π^* orbital, the interaction between the electrons is weakened and a structure resembling a free radical, with a shift of the negative charge to the carbonyl carbon atom, is generated in the carbonyl group. This is probably why carbonyl compounds in the excited state readily abstract hydrogen with formation of the O–H bond:



(XXV)

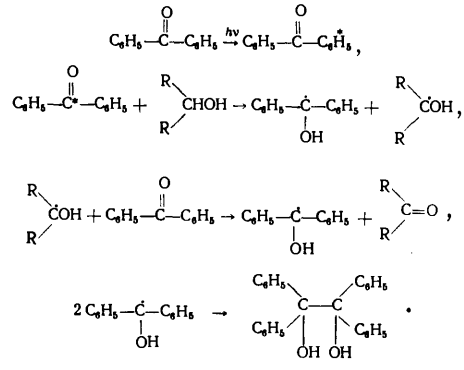
Hydrogen is abstracted both intermolecularly, for example from a solvent molecule, and intramolecularly, i.e. from a hydrogen-containing group of the ketone itself. The latter process takes place particularly readily if the ketone has an aliphatic substituent containing a hydrogen atom in the γ-position relative to the carbonyl group. Probably this proceeds via a stage involving the formation of a six-membered intermediate ring [54–56] and results in the elimination of an unsaturated compound from the ketone:



(XXVI)

Such "biting off of its own tail" by the excited ketone molecule is called Norrish type II split.

The most familiar photochemical reaction involving intermolecular abstraction of hydrogen by a ketone is the formation of benzopinacol from benzophenone, discovered by Ciamician and Silber [57] at the beginning of this century. Pitts and coworkers showed that reactions of this type involve the mechanism [58]



(XXVII)

The maximum possible quantum yield of the disappearance of the ketone in this reaction is 2.

Since the triplet $n-\pi^*$ state of benzophenone, which is the lowest excited electronic state, is involved in this reaction [59–62], it is important to consider to what extent the multiplicity and the nature of the state ($n-\pi^*$ or $\pi-\pi^*$) and the energy of excited molecules determine its capacity to enter into the hydrogen abstraction reaction.

The literature data [62] suggest that the involvement of excited singlet benzophenone molecules in the hydrogen abstraction reaction should be limited primarily by the short lifetime of these molecules [60]. This should be shown particularly clearly in cases where the rate of abstraction of hydrogen (k_r) is low compared with the rate of diffusion. Indeed the quantum yield of the abstraction of hydrogen is given in the simplest case by the expression

$$\varphi = \frac{k_r[B^*][RH]}{k_r[B^*][RH] + 1/\tau[B^*]}, \qquad \text{(XXVIII)}$$

where k_r is the rate constant for the abstraction of hydrogen, [B*] and [RH] are the concentrations of the excited benzophenone and hydrogen donor molecules and τ is the natural lifetime of B*. If it is supposed that the reactivities of excited singlet and triplet ketone molecules in the $n-\pi^*$ state are approximately the same, i.e. $k_r^{S_1} = k_r^T \simeq 10^6$ litre mole^{-1} s^{-1} [63] and $\tau_{S_1} \leq 10^{-9}$ s, then even for the reaction in pure alcohol $\{[RH] \simeq 10$ M$\}$, φ for singlet molecules should be $\leq 10^{-2}$ while for triplet molecules $\varphi \simeq 1$ ($\tau_T \simeq 10^{-5}$ s). One should remember that the quantum yield of the singlet–triplet conversion is close to unity for benzophenone. Hence it is clear that virtually only the triplet benzophenone molecules should be involved in the reaction even if their reactivity is somewhat lower than that of the excited singlet molecules. The report that excited singlet molecules can also participate in hydrogen abstraction [64] was not confirmed [65].

We shall now consider to what extent the $n-\pi^*$ state determines the reactivity of ketones. As already mentioned, owing to the weak interaction between the n and π^* orbitals, the carbonyl group excited to the $n-\pi^*$ state behaves like a free radical. Walling and Gibian [66,67] compared the reactivities of the excited benzophenone molecule and the tetrabutoxy-radical with respect to different hydrogen donors (alcohols, unsaturated hydrocarbons, alkylbenzenes) and showed that the reactivities of the alkoxy-radical and the excited benzophenone molecule vary in parallel for the series of donors investigated, although the sensitivity of the excited molecule to the strength of the C–H bond of the donor is somewhat higher than that of the radical.

Ketones usually react in the lowest excited fairly long-lived triplet state. Therefore, as a result of a decrease of the $\pi-\pi^*$ excitation energy or an increase of the $n-\pi^*$ excitation energy, the $\pi-\pi^*$ state may become the lowest excited state or its contribution to the lowest excited state increases appreciably. Comparison of the decay times and the phosphorescence spectra of acetophenone and its mono- and di-methyl derivatives in different solvents leads to the conclusion that, with increase of the number of methyl groups in the benzene ring, the triplet level of the $n-\pi^*$ state becomes higher and that of the $\pi-\pi^*$ state becomes lower [68]. Accordingly, there is a sharp decrease also in the quantum yields of the reduction of ketones in 2-propanol and cyclohexane. However, one should note that, although the lowest triplet level in dimethylacetophenone is the $\pi-\pi^*$ state, pinacol is nevertheless formed with an appreciable quantum yield.

The same behaviour is observed on passing from acetophenone to acetonaphthone, i.e. when the benzene ring is replaced by a naphthalene ring [69]. In acetonaphthone the lowest triplet state is the $\pi-\pi^*$ state, which is not sufficiently reactive to abstract hydrogen from the alcohol. However, the reaction proceeds fairly readily with a stronger reducing agent—tri-n-butyl stannate.

Thus we see that transition from the $n-\pi^*$ to the $\pi-\pi^*$ state reduces significantly the reactivity of the excited ketone molecules in the hydrogen abstraction reaction, although the latter is not fully suppressed. This finding can probably be explained by the fact that in the $\pi-\pi^*$ excited state of the ketone there is always some contribution by the $n-\pi^*$ state.

Porter and Suppan [70] believe that the $\pi-\pi^*$ state "itself" has a definite reactivity in the photochemical reduction reaction. They believe that the experiment on the sensitised photochemical reduction of α-naphthaldehyde confirms this. The lowest triplet level of this substance is the $\pi-\pi^*$ state (19 900 cm^{-1}), which lies below the triplet $n-\pi^*$ level by more than 3000 cm^{-1}. The lowest $\pi-\pi^*$ level was populated by the transfer of excitation energy from 4,4′-$[N(CH_3)_2PhCO]_2$, the lowest triplet level of which is near 21 700 cm^{-1}. It was found that with such selective population of the triplet $\pi-\pi^*$ state of α-naphthaldehyde, the quantum yield of the photochemical reduction is appreciably higher than on direct excitation of the aldehyde. However, it is then evidently difficult to assert that the lowest level is a "pure" $\pi-\pi^*$ level.

When electron-donating substituents [NH_2, $N(CH_3)_2$, OH] are introduced into the *para*-position of the benzene ring of benzophenone, the quantum yield of the photochemical reduction decreases sharply [26]. Porter and coworkers [65,70] showed that this is caused by the generation of a charge-transfer state (CTS), which leads to the disappearance of the electron density deficit at the carbonyl oxygen in the excited state. Moreover, in these excited molecules the negative charge is displaced towards the carbonyl oxygen:

(XXIX)

This leads to a sharp decrease of the reactivity of these molecules in electrophilic attack (the abstraction of the hydrogen atom may be regarded as successive removal of an electron and then a proton from the hydrogen donor [65]).

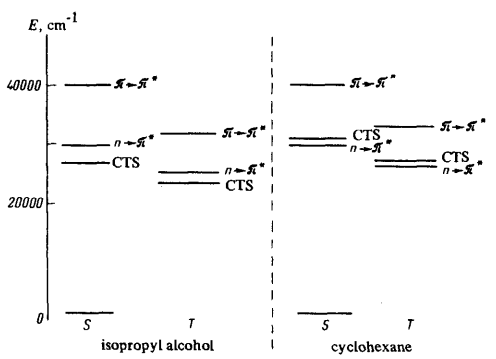


Figure 9. Energy levels of *p*-aminobenzophenone in isopropyl alcohol and cyclohexane [65].

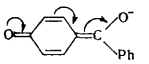
Porter [65,70] regards the $\pi-\pi^*$, $n-\pi^*$, and charge-transfer states in compounds of the type of *p*-aminobenzophenone as separate excited levels with different reactivities. On passing from a polar solvent (isopropyl alcohol) to a non-polar solvent (cyclohexane), the polarising influence of the solvent diminishes and the lowest triplet state becomes $n-\pi^*$ and not the charge-transfer state (see scheme in Fig. 9). The quantum yield of the disappearance of aminobenzophenone increases accordingly from zero in isopropyl alcohol to 0.2 in cyclohexane.

The comparison of hydroxy- and methoxy-benzophenones is extremely interesting. The complete similarity of the spectra of these compounds suggests that they have approximately the same distribution of levels and the short phosphorescence decay times in hydrocarbon and alcoholic matrices indicate that the lowest triplet level in both substances is the $n-\pi^*$ state. Nevertheless methoxybenzophenone reacts in isopropyl alcohol with a quantum yield $\varphi \simeq 1$ and hydroxybenzophenone reacts with $\varphi = 0.02$.

Porter and Suppan [70] believe that hydroxybenzophenone exhibits acidic properties in the excited state:

$$H—O—Ph_2CO \rightleftharpoons {}^{-}O—Ph_2CO + H^{+} .$$

The anion formed is unreactive in isopropyl alcohol since now the lowest triplet level is the charge-transfer state.



(XXX)

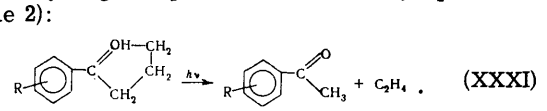
In cyclohexane, where there is no stabilisation of the charge-transfer state by the solvent, hydroxybenzophenone reacts with a quantum yield close to unity.

The properties of various excited states of the benzophenones studied by Porter and Suppan are summaried in Table 1.

Table 1. The properties of the $n-\pi^*$, $\pi-\pi^*$, and charge-transfer states of benzophenone derivatives.

States	Intensity of light absorption, lg ε	Energy range (cm^{-1} in *para*-derivatives)	Shift of absorption band by solvent, cm^{-1}	T-S splitting, cm^{-1}	Reactivity φ	Lifetime in triplet level, ms	Distribution of electrons in carbonyl group
$n-\pi^*$	2	30 000	−800	<3000	1	< 20	$C=O^{\delta+}$
$\pi-\pi^*$	4	40 000	+600	10 000	0.1	>100	C=O
CTS	3—4	30 000	+2500	>3000	0.01	>100	$C=O^{\delta-}$

Pitts and coworkers [62,71,72] believe that the unreactive state in the *para*-substituted benzophenones discussed is the triplet $\pi-\pi^*$ state (the charge-transfer state is not considered as such, as it is believed that it only makes a contribution to the $\pi-\pi^*$ state). Baum et al. [71] compared the quantum yields of the intramolecular photochemical abstraction of hydrogen in *para*-substituted butyrophenones (Table 2):



(XXXI)

Table 2. The quantum yields (φ_{II}) of the Norrish type II photochemical cleavage in benzene solutions at 25°C and 313 nm.

Butyrophenone derivatives substituted in the *para*-position	φ_{II}	Triplet level, kcal	Butyrophenone derivatives substituted in the *para*-position	φ_{II}	Triplet level, kcal
p-Cl	0.43	72.4	*p*-OH	0.00	71.0
p-$OCOCH_3$	0.42	74.3	*p*-NH_2	0.00	64.5
p-H	0.42	74.7	*p*-$NHCOCH_3$	0.00	69.9
p-CH_3	0.39	73.7	*p*-C_6H_5	0.00	not established
p-F	0.29	72.9	*p*-Br	0.00	72.9
p-OCH_3	0.10	73.3			

The data in Table 2 agree with data for the intermolecular photochemical reduction of benzophenone: as the electron-donating properties of the substituent become more pronounced, the reactivity diminishes. As before, this can be explained by a transition from the lowest $n-\pi^*$ state to the $\pi-\pi^*$ state, which involves an increase of the negative charge at the carbonyl oxygen.

It is interesting that, on passing from isopropyl alcohol to cyclohexane, there is no significant change of φ_{II}. The solvent behaves merely as a medium and its polarity evidently does not influence the rate of reaction. Clearly this result is inconsistent with Porter's data. (Pitts [71,73] notes that pinacol could not be detected at all in the photochemical reaction of *p*-aminobenzophenone in cyclohexane.)

Yang and Dusenbery [74] compared the rate constants for the photochemical abstraction of hydrogen by acetophenone and its derivatives [*p*-CH_3, *p*-CF_3, 3,4-$(CH_3)_2$] with the positions of the $[\pi-\pi^*]^1$, $[\pi-\pi^*]^3$, $[n-\pi^*]^1$, and $[n-\pi^*]^3$ levels in these compounds. It was found that the introduction of the electron accepting *p*-CF_3 group into acetophenone increases the distance between the $[\pi-\pi^*]^1$ and $[n-\pi^*]^3$ levels, which reduces the contribution of the $[\pi-\eta^*]^1$ state to the lowest state $[\pi-\eta^*]^3$ and increases the rate of photochemical abstraction of hydrogen. Introduction of the electron-donating CH_3 groups decreases the vibronic interaction of the $[\pi-\pi^*]^3$ level (which in this case is the lowest excited level) with the $[n-\pi^*]^3$ level and thereby reduces its reactivity.

In many compounds the $n-\pi^*$ and $\pi-\pi^*$ levels are so close that it is difficult to tell which of them in fact reacts.

In a study of the photochemical cleavage of substituted butyrophenones, Pitts and coworkers [75] compared the φ_{II} for these substances with their phosphorescence decay times in a solid matrix and found that for certain compounds, for example for *ortho*- and *para*-acetoxy-derivatives, the phosphorescence decay time and hence the contribution of the $[\pi-\pi^*]^3$ state to the lowest $[n-\pi^*]^3$ state increase sharply. At the same time the φ_{II} for these compounds have the same value as for the unsubstituted ketone (~ 0.4). This contradiction may arise because, for a constant quantum yield, the photochemical reaction rate constants may diminish significantly, as was shown for substituted valerophenones [76,77]. In this connection one must emphasise yet again that a simple comparison of the reaction quantum yields can lead to incorrect conclusions, since the quantum yield is not determined solely by the photochemical reaction rate constant but also by the lifetime of the excited molecule. It has been shown that in many cases [78,79] an increase of the contribution of the charge-transfer state to the excited state entails a decrease of the lifetime of the excited molecules.

In a discussion of the mechanism of hydrogen abstraction by ketones, the problem arises whether this reaction should be regarded as a two-stage process (electron and then proton transfer from the alcohol) or a single-stage process (radical abstraction of the hydrogen atom). In the first case heterolytic electrophilic substitution is evidently the rate-limiting stage, while in the second stage the reaction is homolytic. The available experimental data are insufficient to resolve this problem, which is important for the construction of a model of the transition state in the reaction.

Study of Tautomerism by Nuclear Magnetic Resonance Spectroscopy

A.I.Kol'tsov and G.M.Kheifets

The present review describes the contribution of NMR to the study of prototropic tautomerism of various types, with the exception of keto-enol tautomerism, which was dealt with in an earlier review[1]. The bibliography contains 221 references.

I. IMINE-ENAMINE TAUTOMERISM

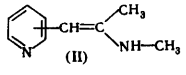
As with keto-enol tautomerism, the tautomeric change takes place slowly, and it is possible to observe separately the PMR spectra of the two forms:

(A) (B)

Ahlbrecht and coworkers[2] obtained the imine (IA) by condensing α-phenylpropionaldehyde with methylamine. Equilibrium with the enamine form (IB) is gradually established. The quantity of the enamine form increases with decrease in temperature and with increase in the polarity of the medium. The same picture is observed for non-chelate enol forms[1]. At 50° the equilibrium mixture contains 72% of the imine (IA) in chloroform and 32% in DMSO†. The amine tautomer (IB) consists of a mixture of the *cis*- and *trans*-isomers. *cis*-*trans*-Isomerisation takes place in the tautomeric change.

(IA) (IB)

The same authors[3] subsequently studied the influence of substituents on the imine-enamine equilibrium. For example, it was shown that the concentration of the enamine form (II) depends markedly on the position at which the acyclic residue is attached to the pyridine ring (100% enamine in the α- and γ-positions, and 61% in the β-position in DMSO). This result is apparently related to the deficit of electrons in the α- and γ-positions of the heterocyclic ring.



(II)

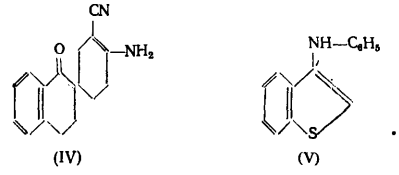
†Dimethyl sulphoxide.

Colvin and coworkers[4] observed the tautomerism of the iminourethanes (III)

(IIIA) (IIIB)

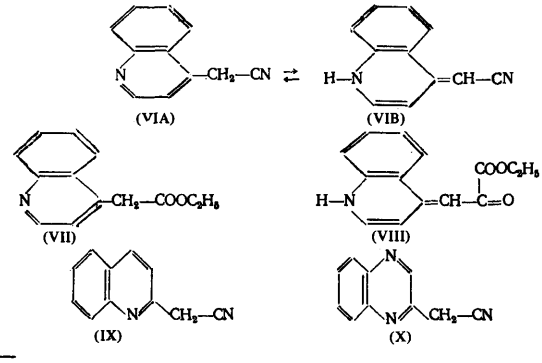
and detected forms (IIIA) and (IIIB) in comparable amounts. The broadened PMR signals of the amino-group lay in the range 3–4 p.p.m. ‡

Compound (IV) exists entirely in the enamine form[5]:



(IV) (V)

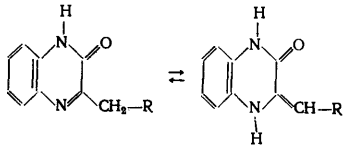
The amine form of the 3-phenylamino thianaphthene (V) predominates in neutral solvents[6]. In DMSO, 25% of 4-quinolylacetonitrile is present as the enamine form (VIB), whereas for the ester (VII) the enamine form is not observed, and for the pyruvate (VIII) the enamine form is the chief form[7]. This is apparently due to the stabilisation of the enamine as a result of conjugation between the nitrogen atom of the ring and the functional group of the side chain, which compensates the dearomatization of the heterocyclic ring. The enamine forms of 2-quinolylacetonitrile (IX) and 2-quinoxalylacetonitrile (X) are not detected[7].



(VIA) (VIB) (VII) (VIII) (IX) (X)

‡In this review the chemical shifts are given in the τ scale.

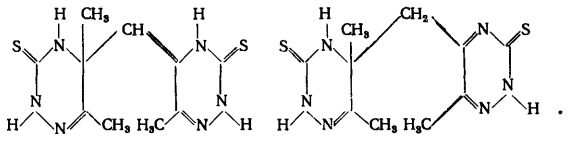
For the oxo-derivatives (XI), in which the aromaticity of the heterocyclic ring is destroyed, however, the enamine form (XIB) predominates in various solvents[7,8]:



(XIA) (XIB)

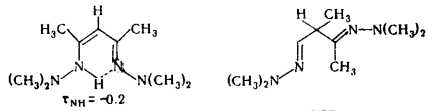
(100% for R = C_6H_5 and 70% for R = CN). The concentration of form (XIB, R = CN) decreases with increase in temperature[8].

For the dimers (XII) in DMSO, the A ⇌ B equilibrium is observed[9]:



(XIIA) (XIIB)

The tautomerism of bis-dialkylhydrazones can be regarded as imine-enamine tautomerism[10]. Acetylacetone bis-dialkylhydrazone exists entirely in the hydrazone-hydrazine form (XIII), whereas the corresponding α-methylacetylacetone derivative exists as 100% dihydrazone (XIV); this is attributed to the instability of the planar chelate structure, resulting from the spatial interaction of the methyl groups:



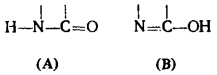
(XIII) (XIV)

For compounds of type (XIII), intra-chelate tautomerism takes place. The rapid migration of the proton between the nitrogen atoms and the consequent effective equivalence of the C–CH_3 groups is indicated by their single PMR signal in the spectrum of compound (XIII).[10]

The imine-enamine tautomerism of *o*-ethylvalerolactam[11] and *N*-isopropylideneisopropylamine[12] has been confirmed by deuteration of the protons on the carbon atoms.

II. AMIDE-IMIDOL TAUTOMERISM

The width and CS§ of the PMR signal of the mobile protons are not reliable criteria for choosing between the amide (A) and imidol (B) forms. The CS of the nitrogen and oxygen (^{17}O) nuclei and the SSCC¶ between these nuclei and the protons are more informative. The more readily available data on the CS of the stable protons of the molecule and, where possible, on the SSCC between these protons and the mobile protons are more frequently used, however.



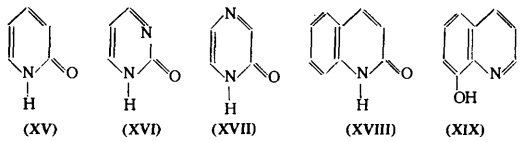
(A) (B)

§Chemical shifts.

¶Spin-spin coupling constants (J).

The absence of the imidol form (B) in simple amides† was confirmed by the PMR spectra. In all secondary amides studied, SSC between the α-protons of the substituent and the amide protons (J = 5 Hz) is observed[14,15]. The ^{15}N–H SSCC in formamide is close to 90 Hz.[16] The existence of the imidol form in the amides and hydrazides of phosphorylated carboxylic acids has been reported[17]. The imidol form is more probable for heterocyclic compounds, where it may be stabilised as a result of the formation of a heteroaromatic system. The results of NMR studies of a number of heteroaromatic compounds for which rapid tautomerism of only the amide-imidol type is possible are examined below.

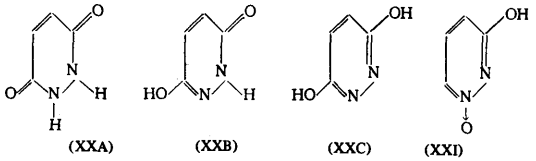
The 2-oxo-derivatives of pyridine (XV),[18] pyrimidine (XVI),[19] pyrazine (XVII),[20] and quinoline (XVIII)[21] exist in the amide form (A). For compound (XV) in non-polar media, ^{15}N–H SSC (90 Hz) is observed at low temperatures. The low values of τ_{NH} (–3.6) are attributed to the formation of dimers with strong InterMHB‡:



(XV) (XVI) (XVII) (XVIII) (XIX)

The amide structure of compounds (XVI) and (XVII) was demonstrated by comparing the CS of the stable protons of the tautomeric and fixed (O- and N-methylated) compounds. These CS were found to be sensitive to the breakdown of the aromaticity of the heterocyclic ring on production of form (A). For compound (XVIII), the ^{14}N CS was measured (235 p.p.m. relative to NO_3^-). This value is typical for amides and differs sharply from the value for 8-quinolinol (XIX) (90 p.p.m.) with sp^2-hybridisation of the nitrogen atom.

Of the three tautomeric forms of 3,6-dioxopyridazine (XX), the symmetrical form (XXA) was first proposed as the predominant form, since the spectrum shows a common signal for the protons in positions 4 and 5§.[21] These protons may also become effectively equivalent, however, if there is rapid exchange between two equivalent forms (XXB). Later, evidence in support of the oxo-hydroxy-structure (XXB) was obtained from the PMR spectra of model compounds[23,24], in agreement with the infrared and ultraviolet spectra[25-27].



(XXA) (XXB) (XXC) (XXI)

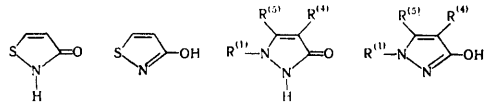
According to the PMR data, and in agreement with the infrared and ultraviolet spectra, 3-hydroxypyridazine-*N*-oxide and its methyl derivatives exist chiefly in the imidol form (XXI).[28]

†Form (B) was erroneously assumed to be present in benzoyl-α-aminoethylbenzene on the basis of optical rotatory dispersion data[13].

‡Intermolecular hydrogen bonding.

§The infrared and ultraviolet spectra indicate that the symmetric dioxo-form (XXC) is unlikely.

Of the two rapidly interconvertible tautomeric forms of 3-hydroxyisothiazole (XXII), the form (XXIIB) predominates in $CDCl_3$ (100%) and also in DMSO and methanol (~75%).[29]



(XXIIA) (XXIIB) (XXIIIA) (XXIIIB)

Tautomerism of the amide-imidol type is observed in *N*-substituted pyrazol-3-ones (XXIII, $R^{(1)} = CH_3$, C_6H_5; $R^{(4)}$, $R^{(5)} = H$, CH_3).[30,31] The PMR, infrared, and ultraviolet spectra indicate that in pyridine, these compounds exist chiefly in the hydroxy-form (XXIIIB), whereas in aqueous-alcoholic solutions, appreciable quantities of the oxo-form (XXIIIA) are observed[30,31].

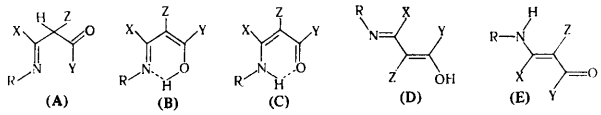
III. KETOAMINE-ENOLIMINE TAUTOMERISM

(A) (B) (C)

Like the amide form of the simple amides, the keto-amine form (C) of the vinylogous amides examined below is the most stable. The change to the enolimine form (B) generally takes place if this is accompanied by a significant gain in the energy of conjugation of the molecule as a whole (for example the formation of an aromatic ring). The keto-imine form (A) usually exists in sterically hindered systems.

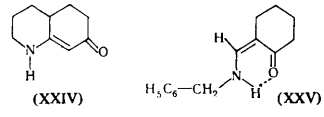
1. Schiff's Bases–Derivatives of β-Dicarbonyl Compounds

The possible tautomeric forms of the Schiff's bases (SB) (A–E) examined here are analogous to the tautomeric forms of the corresponding β-dicarbonyl compounds[1]. The SB usually exist in the stable ketoamine chelate form (C) and in some instances in the non-chelate form E¶ (Table 1).



(A) (B) (C) (D) (E)

The suggestion, based on the ultraviolet spectra[34], that the enol-imine tautomers (B) and (D) exist is refuted by PMR data[32,35]†. The PMR spectra show low-field signals due to the chelate protons ($\tau_{NH} < 1.4$), which are split in the spectra of the compounds containing ^{15}N, with SSCC 88–95 Hz. Moreover, SSC with the protons of the amino-group leads to splitting of the signals of the substituents R = Alk and X = H with SSCC 4.5–8.0 Hz and 12–14 Hz respectively. The keto-amine form also predominates in compounds (XXIV) and (XXV).[39,40]



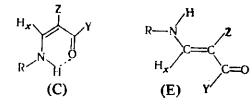
(XXIV) (XXV)

¶The presence of traces of the keto-imine form (A) in some compounds is indicated by deuterium exchange of the α-protons (Z = H) in D_2O.[36,37]

†The enol-imine structure has been assigned to the product of the monocondensation of 4,5-diaminopyrimidine with acetylacetone[38].

The *trans*-isomers (E, Z = H) of the keto-amine tautomer, detected for a number of amino-derivatives of β-aldoketones (Table 1) and acetoacetic ester[41], are characterised by high values of τ_{NH} (> 3.3) and the SSCC between the vinyl protons ($J_{HC=CH}$ = 12–13.5 Hz). For the *cis*-forms (C, Z = H) $J_{HC=CH}$ = 7–8 Hz, and the α-protons are less shielded in view of the proximity of the carbonyl oxygen atom[32] (Table 1). The SSCC with the amine protons are the same for the *cis*- and *trans*-isomers.

Table 1. *cis*-*trans* Isomerism of Schiff's base derivatives of β-ketoaldehydes[32]:



(C) (E)

Compounds			Medium	Concn., M	Concn. of tautomers, %		τ_{NH}		τ_Z		J_{H_X-Z}, Hz

[a] Pure liquids.
[b] Very broad signals.
[c] Ref. 33.

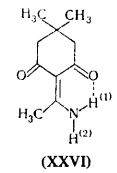
The concentration of the *trans*-isomer increases when the α-hydrogen atom (Z) is replaced by a methyl group and decreases when the methyl groups on the nitrogen atom and the carbonyl group (R and Y) are replaced by phenyl or benzyl groups (Table 1). These effects are related to the steric interactions of the substituents in the isomers (C) and (E).[32] Dilution in inert solvents decreases the proportion of the *trans*-isomer as a consequence of the rupture of the IntraMHB, which stabilises form (E).[32]

trans-Isomers were not detected in the SB derivatives of acyclic β-diketones[36,42].

The chelate amine protons of the SB are more shielded than the protons in the chelates of the corresponding β-dicarbonyl compounds, but the nature of the dependence of τ_{NH} and τ_{OH} on the substituents X and Y is the same[32,36,41,42]. τ_{NH} decreases by almost 3 p.p.m. on going from R = H to R = C_6H_5 (Table 1). Low values of τ_{NH}, indicating strong IntraMHB‡, are characteristic of the SB derivatives of the 2-acyldimedones (XXVI)[41] and (XXVII).[33] As in the β-keto-esters, the replacement of the COOAlk group in the SB by the CSSAlk group leads to a sharp decrease (by ~4 p.p.m.) in the shielding of the chelate proton of compound (XXVIII).[43] The medium and

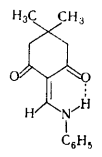
‡Intramolecular hydrogen bonding.

the temperature have little influence on τ_{NH} and the SSCC for the SB, indicating fairly strong IntraMHB and the stability of the keto-amine form (C).



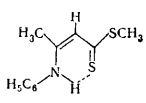
(XXVI)

$\tau_{NH}^{(1)} = -2{,}10$, $\tau_{NH}^{(2)} = +2{,}60$ $(CDCl_3)$



(XXVII)

$\tau_{NH} = -6{,}45\ (CCl_4)$

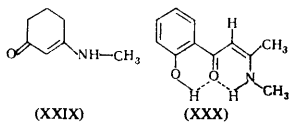


(XXVIII)

$\tau_{NH} = -4{,}88\ (CCl_4)$

A significant decrease in τ_{NH} for the chelate forms (C) is observed with increase in the electron-accepting properties of the substituent R.[36]

In the non-chelate keto-amine forms (acyclic *trans*-isomers and compounds of the type (XXIX)), an increase in τ_{NH} is observed with increase in temperature and on dilution in inert solvents. The SSCC with the amine protons remain unchanged[42].

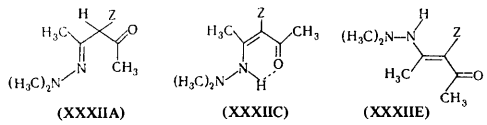


(XXIX) (XXX) (XXXI)

$\tau_{NH} = -0{,}80\ (CDCl_3)$ $\tau_{NH} = -1{,}31\ (CDCl_3)$

As in the β-dicarbonyl compounds, the IntraMHB in the corresponding SB with a carbonyl group involved in other hydrogen bonding (XXX)[45] is slightly weaker than ordinary IntraMHB (XXXI).[42]

Domnin and Yakimovich[10] demonstrated the presence of three tautomeric forms in the products of the monocondensation of β-diketones with dimethylhydrazine (XXXII, Z = Alk). The concentration of the chelate form (C) decreases with increase in the polarity of the medium and the size of the substituent Z. For compound (XXXII, Z = H), only the chelate keto-hydrazine form (C) was detected. The corresponding derivatives of 2-acetyl-2-benzoylcyclohexanones also exist in a chelate form of type (C) (τ_{NH} = –0.5).



(XXXIIA) (XXXIIC) (XXXIIE)

2. Schiff's Bases—Derivatives of *o*-Acylphenols and *o*-Acylnaphthols

In these compounds, which form condensed systems of chelate and aromatic rings, conjugation has a significant influence on the imine-amine equilibrium B ⇌ C (Table 2). The existence of the amine form, which predominates in all SB previously described, is possible in this instance only when the aromatic character of the rings is destroyed; this requires the expenditure of large quantities of energy (tens of kcal mole^{-1}).[46] Nevertheless, the existence of considerable quantities of the amine form in many instances has been demonstrated by means of the NMR spectra§ (see Table 2).

§The amine form of compounds of this type was previously detected by ultraviolet spectroscopy[47].

Measurement of the $^{15}N-H$ SSCC made it possible to determine fairly accurately the constant for the amine-imine equilibrium at various temperatures, and other thermodynamic constants (Table 2).

Table 2. Concentrations and differences in the enthalpies of the tautomers of aromatic Schiff's bases, and the CS and SSCC of the chelate protons (concentration 0.2 M):

[a]Concentration 0.02 M.
[b]0.1 in CH_3CN.

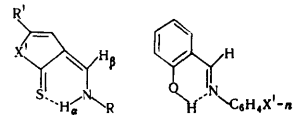
According to the results in Table 2, the concentration of the amine form (C) in α-naphthol derivatives is much greater than that in the analogous derivatives of β-naphthol and phenol. The replacement of an alkyl substituent on the nitrogen atom in α-naphthol derivatives by an aryl substituent leads to a decrease in the percentage of the amine

form. The percentage of the amine form is greater in the SB derivatives of 1-formyl-2-naphthol than in the 1-acetyl-2-naphthol derivatives.

With increase in the polarity of the medium in the order CCl_4, $CHCl_3$, and CH_3OH, the concentration of the keto-amine form increases considerably. Decrease in temperature has the same effect.

The introduction of different substituents into the benzene ring of the SB derivative of 2-hydroxyl-1-naphthaldehyde and aniline has little influence on the concentration of the intrachelate tautomers. In almost all compounds of this type, the SSCC for the chelate and aldehyde protons have values of 3–5 Hz (25–40% of the amine form) [36].

The SB derivatives of 2-thiol-3-formylfurans and 2-thiol-3-formylthiophens (XXXIII) (X′ = O, S; R, R′ = H, Alk, Ar) exist chiefly in the chelate amine form in different solvents. This is indicated by the SSCC values:



(XXXIII) (XXXIV)

$^{15}N-H_\alpha$ = 86 Hz, $H_\alpha-H_\beta$ = 13–15 Hz, and τ_{NH} has values between −2 and −5. [51]

For derivatives of salicylaldehyde (XXXIV), which exist entirely in the enol-imine form, the dependence of τ_{OH} on the substituent X′ (−3.45, −3.25, and −2.58 Ψ for X′ = OCH_3, H, and NO_2 [30]) is the opposite of that observed for τ_{NH} in aliphatic keto-amines. In the naphthol derivatives, the CS of the chelate proton is determined not only by the shielding action of the substituent R, but also by the concentration of intrachelate tautomers (XXX) (Table 2).

3. α-Azaheterocyclic Ketones, Esters, and Pyruvates

For these compounds, three tautomeric forms are possible (Table 3). The chelate forms (B) and (C), stabilised by IntraMHB, are similar to those for the SB considered above. The existence of form (C) is possible only with breakdown of the aromaticity of the heterocyclic ring. The marked tendency for the keto-amine form (C) to be produced is realised more readily in these compounds than in the SB-derivatives of phenol and naphthol, since the breakdown of the aromaticity of the heterocyclic ring takes place more readily [59].

For the esters (Y = OAlk), form (B) is not observed, and the A ⇌ C equilibrium is displaced considerably towards (A) for pyridine, quinoline, and quinoxaline, and towards (C) for cyclic amides and esters, when the aromaticity of the heterocyclic ring is decreased (see Table 3).

In the ketones (Y = Alk, Ar) and more particularly the pyruvates (Y = COOAlk), the concentration of the keto-imine form (A) is much smaller than for the corresponding esters, and the B ⇌ C equilibrium is determined by the nature of the heterocyclic ring.

For pyridine [52,53], the phenol form (B) is produced, and form (C) is not observed, since $^{15}N-H$ SSC is not observed. With increase in temperature, form (B) for a number of compounds is converted into form (A). [52,53] For the ketones and pyruvates derived from quinoline, quinoxaline, 2-oxo-1,2-dehydroquinoxaline, and other compounds, Mondelli and Merlini [7] detected form (C), in a number of instances in equilibrium with form (A). Form (B) was regarded as unlikely, because of the absence of the marked SSC of the vinyl and methyl protons (Y = CH_3), characteristic of form (B) with $J \simeq 1$ Hz. This conclusion was confirmed by the ultraviolet and infrared spectra [52,53].

Table 3. Tautomeric composition and shielding of the acidic proton for a series of α-azaheterocyclic ketones, esters, and pyruvates.

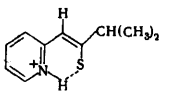
[a] Same concentration in DMSO.
[b] The analogous *para*-derivative likewise does not contain form A.

The preference for a given chelate form (B or C) is apparently determined by the energy of dearomatization of the heterocyclic ring.

The marked downfield shift of the chelate proton and the fact that it depends little on concentration [7] indicate strong IntraMHB. The CS increases in the order: esters,

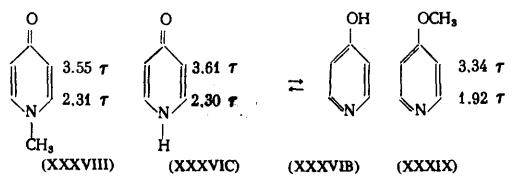
ketones, pyruvates (Table 2). The same picture is observed for the β-dicarbonyl compounds[1]. A noteworthy feature is the very strong downfield shift for 2-picolinyl isopropyl thioketone (τ = −8.60) compared with its oxygen analogue (τ = −4.0). This is attributed[60] to the participation of the bipolar form (XXXV) in the tautomeric equilibrium.



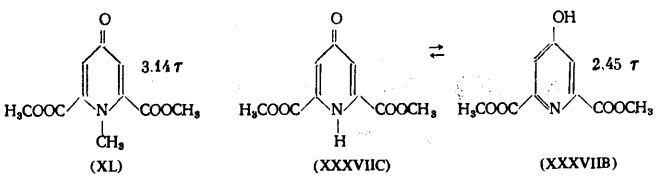
(XXXV)

4. Derivatives of 4-Hydroxypyridine

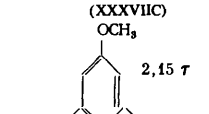
4-Hydroxypyridine (XXXVI) and its 3,5-disubstituted derivatives exist in the keto-amine form (pyridones-4) (XXXVIC),[61] whereas for various 2,6-disubstituted 4-hydroxypyridines, in particular compound (XXXVII), the enolimine hydroxy-form (XXXVIIB) predominates. These data were obtained by comparing the CS of the stable protons¶ of the tautomeric and model compounds (XXXVIII–XLI).[62,63] The pyridone-4 (XXXVI) is characterised by a low value for τ_{NH} (−3.92 in $CDCl_3$).[64]



(XXXVIII) (XXXVIC) (XXXVIB) (XXXIX)

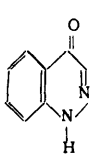


(XL) (XXXVIIC) (XXXVIIB)



(XLI)

4-Cinnolone (XLII) and its derivatives exist in the oxo-form[65,66].



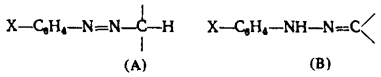
(XLII)

¶In water for 4-hydroxypyridine and in $CDCl_3$ for its 2,6-disubstituted derivatives.

IV. AZO-HYDRAZONE TAUTOMERISM

1. Arylhydrazones and Similar Compounds

For the phenylhydrazones of aldehydes and ketones, two tautomeric forms are possible:



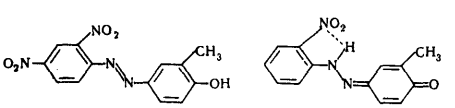
(A) (B)

The PMR spectra of freshly prepared solutions of phenylhydrazones in various solvents, and also of semicarbazones and thiosemicarbazones, contain lines due to only the hydrazone form (B).[67-69] With the passage of time, solutions of some phenylhydrazones become yellow, and the PMR spectra, instead of the signals of the –NH– (τ_{NH} = 2–3) and =CH– groups, show the signals of the protons on saturated carbon atoms, characteristic of the azo-form (A).[67] In inert media, the transformation B → A proceeds to completion in several minutes or tens of minutes, whereas in polar media the transformation is not complete even after several hours. InterMHB with the solvent molecules apparently stabilises form (B). In a number of instances the PMR spectra reveal *cis-trans*-isomerism of tautomer (B).[67,68]

2. Azophenols and Heterocyclic Azo-compounds

In contrast to the situation for the hydrazones examined above, the tautomerism of azophenols and similar compounds involves the transfer of protons between nitrogen and oxygen atoms. The PMR CS of the –NH– and –OH groups in general are not characteristic, so that information on the tautomeric composition is usually obtained from the CS of the stable protons of the ring, and also from the ^{14}N and ^{17}O CS. The *ortho*-protons of the aromatic ring of the azo-form (Ar–N=N–) absorb in lower fields (1.9–2.2 τ) than the corresponding protons of the hydrazone form (Ar–NH–N=) ($\tau > 2.5$). Moreover, the breakdown of the aromaticity on going from the phenolic to the quinone ring structure produces an upfield shift of the signals of the corresponding protons[70].

The PMR spectra of 4-hydroxy-3-methyl-2,4-dinitroazobenzene in $CDCl_3$ showed the signals of both the azophenol (XLIIIA) and quinone-hydrazone (XLIIIB) tautomers. Instead of the singlet signal of the methyl group[7,68] of form (XLIIIA), the spectrum of form (XLIIIB) shows two doublets (7.79 and 7.88 τ; $J_{HC=C-CH_3}$ = 1.4 Hz), which apparently belong to two stereo-isomers.

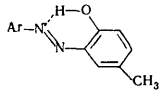


(XLIIIA) (XLIIIB)

The low value of τ_{NH} (−2.33) indicates IntraMHB for compound (XLIIIB).[70] Polar solvents bring about a marked displacement of the equilibrium towards the azo-form. In dimethylacetamide, the signals of form (XLIIIB) were not detected.

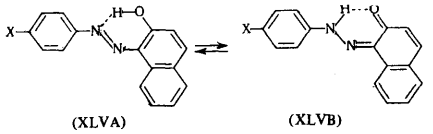
Derivatives of 2-hydroxy-5-methylazobenzene (XLIV), where Ar = nitro- and methoxy-derivatives of benzene, exist completely in the azo-form. The *ortho*-protons of

the substituent Ar absorb in the range 1.9–2.4 τ, and the values of τ_{OH} lie between −2.5 and −3.5 τ. [70,71]



(XLIV)

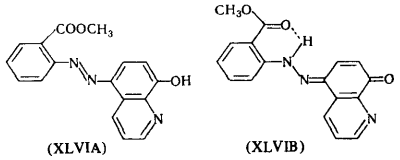
Derivatives of 1-phenylazo-2-naphthol (XLV) give an NMR spectrum which is averaged as a result of rapid intrachelate tautomeric transformations:



(XLVA) (XLVB)

Berrie and coworkers [72] compared the CS of ^{14}N in the α-position relative to the benzene ring (XLV, X = H) (111 τ) with that for compounds which are models of form (A) (−129 τ) and form (B) (175 τ) and found that $CDCl_3$ contains 21% of form (A). The concentration of form (XLV) is decreased to 3% for X = CN, and increased to 48% for X = OCH_3. This tendency was confirmed by the PMR data [70] and also by the infrared and ultraviolet spectra [70]. The *meta*-substituents have a weaker influence on the tautomeric equilibrium [72]. The percentage of the azo-form is greatest in inert media (62% for compound (XLV, X = H) in hexane) and smallest in aqueous-alcohol solution [72]. The values of τ for the chelate protons of compound (XLV) are extremely low: between −5.6 and −6.1. [71,72]

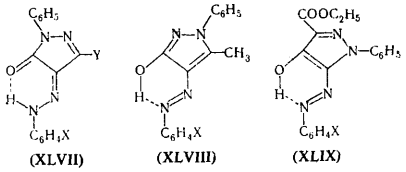
2-Phenylazo-1-naphthol exists in the hydrazone and azo-forms, and the PMR data [70] and the ^{17}O CS [73] indicate that the former predominates in $CDCl_3$. On the other hand, for 2-phenylazo-3-naphthol the equilibrium is displaced towards the azo-form [70]. The azo-form has also been assumed for 4-phenylazo-1-naphthol [70], for which, in contrast to the other phenylazonaphthols, IntraMHB is impossible. The same paper gives PMR data supporting the hydrazone structure for 1-phenylazo-2-anthrol. The spectrum of 5-*o*-carbomethoxyphenylazo-8-quinolinol in $CDCl_3$ shows the individual signals of the azophenol form (XLVIA) and the quinone hydrazone form (XLVIB) (33% and 67%). The spectra of the tautomers differ primarily in the values for the mobile protons (τ_{OH} = 4.6; τ_{NH} = −2.7).



(XLVIA) (XLVIB)

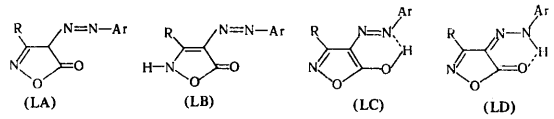
Moreover, the protons in position 4 of the quinoline ring are more shielded in form (XLVIB), in which the aromaticity is destroyed [70].

3-Substituted 1-phenyl-4-arylazopyrazol-5-ones (XLVII, Y = CH_3 or C_6H_5) in $CDCl_3$ exist in the hydrazone form, irrespective of the nature of the substituent X [70,71,74]. The spectra of the compounds with the ^{15}N isotope in the α-position relative to the benzene ring show doublet signals in weak fields (τ_{NH} lies between −3 and 3.5 τ; J_{NH} = 96 Hz). In DMSO and pyridine, compound (XLVII, Y = CH_3) apparently exists as a mixture of the hydrazone and azo-forms [74]. For the azo-derivatives of pyrazol-3-ones (XLVIII) and pyrazol-4-ones (XLIX), however, the azo-form predominates, with higher values of τ_{OH} (0–1.6) (XLVII). For compounds (XLVII–XLIX) it was impossible to detect the oxo-form, in which the mobile proton is joined to the nitrogen or carbon atoms of the ring. These results agree with the infrared spectra [71].



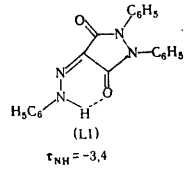
(XLVII) (XLVIII) (XLIX)

For 4-arylazoisooxazol-5-ones (L) in $CDCl_3$, the hydroxy-azo-form (C) and the hydrazone form (D) are not observed, and of the two remaining forms, form (B) predominates:



(LA) (LB) (LC) (LD)

irrespective of the substituents R (H, CH_3, C_6H_5, *p*-$NO_2C_6H_4$) and Ar (C_6H_5, CH_3O–C_6H_4). [75]



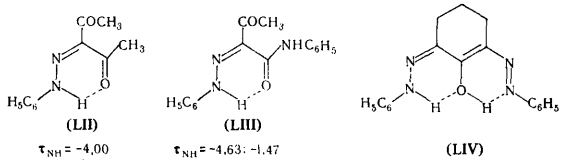
(LI)

τ_{NH} = −3,4

Of the three possible forms of 4-phenylazo-1,2-diphenyl-3,5-dioxopyrazolidine, the chelate hydrazone form (LI) is realised in various solvents [76].

3. Azoketones, Formazans, and Osazones

Phenylazo-derivatives of acetylacetone and acetoacetanilide exist in the chelate hydrazone forms (LII) and (LIII) respectively [70].



(LII) (LIII) (LIV)

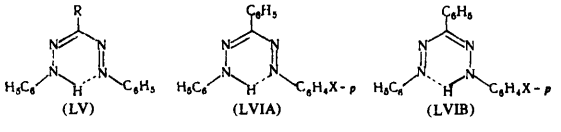
τ_{NH} = −4,00 τ_{NH} = −4,63; −1,47

Cyclohexanone-2,1,3-dihydrazone can exist in two forms: a red form, to which the chelate enol phenylhydrazone-phenylazo-structure (LIV) was assigned, and a yellow ketohydrazone form [77]. The hydrazone form, which exists as the hydrate, is converted into the red azo-form on dehydration. Two analogous forms were also found for other hydrazones of 1,2,3-tricarbonyl compounds.

The existence of tautomerism in formazans was clearly demonstrated by Mester and coworkers [78]. The PMR spectrum of the formazan of *D*-galactose penta-acetate (LV, R = monosaccharide residue) with one ^{15}N α-atom (relative to C_6H_5) (Fig. 1) shows an NH signal, split to form a doublet (J_{NH} = 46.5 Hz), expected for rapid intrachelate† migration of the proton between equivalent positions. When both α-nitrogen atoms are ^{15}N isotopes, the NH signal is split to form a triplet with component ratio 1 : 2 : 1 and J_{NH} = 46.5 Hz, since in the migration

†τ_{NH} depends little on temperature and the medium.

process the proton interacts (alternately) with two ^{15}N atoms.



(LV) (LVIA) (LVIB)

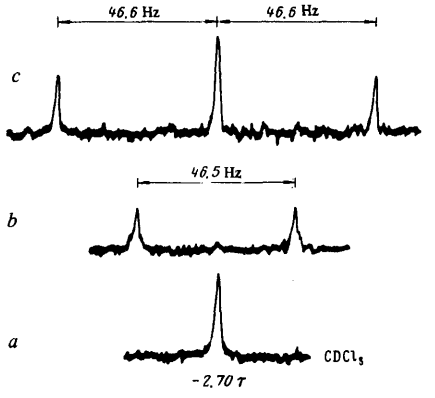


Figure 1. *a*) Low-field part of the PMR spectrum of the formazan of *D*-galactose penta-acetate in dioxan (60 MHz); *b*) the same with one ^{15}N atom; *c*) the same with two ^{15}N atoms [78].

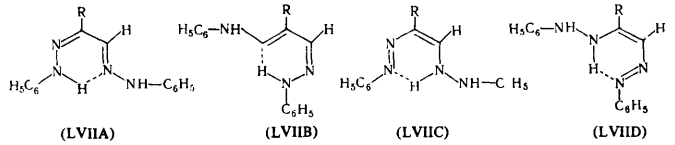
Qualitatively similar PMR spectra should also be observed for a mesomeric structure with symmetrically arranged mobile protons, but this possibility was excluded on the basis of theory [79] and the infrared spectra [80]. In the nonsymmetrical formazans (LVI) the position of the tautomeric equilibrium depends markedly on the nature of the substituent X. When X = OCH_3, the magnitude of the splitting of the (NH...N=) PMR signal is 86.5 Hz, which corresponds to 4% of form A and 86% of form B. For compound (LVI, X = NO_2), form (A) predominates (100%), since splitting is not observed. In the symmetrical structure (LVI, X = H), the splitting is equal to 45 Hz, which is half J_{NH} = 90 Hz. In compounds (LVI), τ_{NH} varies between −4.6 and −5.7 (in $CDCl_3$). [81]

The PMR spectra of the osazones of monosaccharides in dioxan (LVII, R = monosaccharide residue) with two ^{15}N atoms in the α-positions relative to C_6H_5 show two signals due to mobile protons: the chelate proton (τ_{NH} = −2.20) and the non-chelate proton (τ_{NH} = 0.79). Both signals are split to form doublets (J_{NH} = 94.5 Hz and 93 Hz). [82] Thus both protons are joined directly to ^{15}N atoms; this agrees with the previously proposed [83] bis-phenylhydrazone



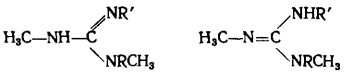
(LVIIA) (LVIIB) (LVIIC) (LVIID)

structure (LVII, A or B) and excludes the azo-form (LVII, C and D). The tautomerism of 1,2,3-tris-phenylhydrazone derivatives of propane, cyclopentane, and cyclohexane have been studied [77].

V. AMINE-IMINE TAUTOMERISM

In the amine-imine tautomeric transformation, the mobile proton moves from one nitrogen atom to another. The corresponding PMR signals are not always observed separately and usually are not characteristic. In such instances, the CS of the stable protons of tautomeric and model compounds are compared.

The splitting of the PMR signals of the methyl groups as a result of SSC with the protons on the nitrogen atoms (J = 5 Hz) made it possible to determine the structure of the predominant tautomer (A) of guanidine derivatives (LVIII, R = H, R′ = Cl, and R = Cl, R′ = H). [84]



(LVIIIA) (LVIIIB)

Of the two possible tautomeric forms of the amidoximes (LIX, R = C_6H_5, $COOC_2H_5$, $CH_2C_6H_5$, or $C(NH_2)$=NOH), the amino-oxime-form (A) is realised in various solvents [57,85].

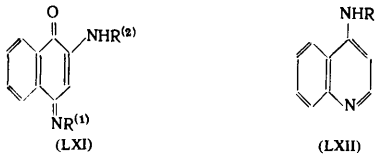
(LIXA) (LIXB)

The spectra show the signals of the amine and oxime groups (τ_{NH_2} = 4–5.5; τ_{OH} = 0–1), with intensity ratio 2:1. The PMR of the broad lines was used to determine the tautomeric form of cyanoguanidine (LX) in the crystalline state. Kotera and coworkers [86] compared with experimental value of the second moment of the PMR line with the calculated values for the two possible forms, and concluded that cyanoguanidine has the diamino-structure (LXA).

(LXA) (LXB)

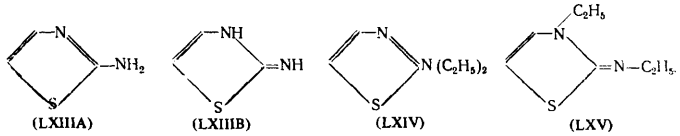
The NMR spectrum of 2-amino-1,4-naphthoquinonimine (LXI) showed that at room temperature an equilibrium between the *o*- and *p*-quinonimines is established [87].

4-Aminoquinolines exist in the amino-form (LXII) in various solvents [88,99].



(LXI) (LXII)

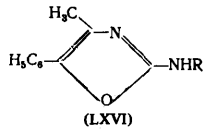
In $CDCl_3$, the CS of the vinyl protons of the potentially tautomeric 2-aminothiazole (LXIII) and the model compound (LXIV) almost coincide (2.86 and 3.52 τ) and differ sharply from the corresponding values for compound (LXV) (3.45 and 4.20 τ). This provides evidence in support of the amino-form (LXIIIA). [90]



(LXIIIA) (LXIIIB) (LXIV) (LXV)

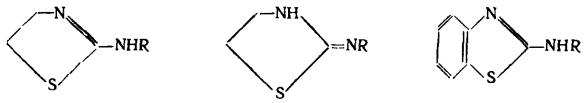
The same result was obtained for 4-phenyl-2-aminothiazole derivatives [91].

In the same way it was found [92] that 2-amino-5-phenyl-4-methyl-2-oxazolines (LXVI, R = H, CH_3, or C_6H_5) exist in the amino-form. It was pointed out [90,92] that the ultraviolet spectra do not give clear-cut information on the structure of these compounds.



(LXVI)

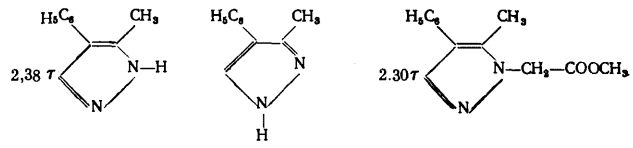
Sheinker and coworkers [93,94] showed that derivatives of 2-aminothiazoline (LXVII) exist in $CDCl_3$ in the amino-form (LXVIIA) if R = H, $CH_2C_6H_5$, or $COCH_3$, and in the imino-form (LXVIIB) if R = COC_6H_5, $COOCH_3$, or $COCCl_3$. In the derivatives with structure (A), the methylene protons in position 4 absorb in the range 6.0–6.1 τ, whereas in the tautomeric and fixed compounds with structure (B) they absorb in the range 6.3–6.5 τ. This effect is due to the deshielding influence of the neighbouring unsaturated nitrogen atom.



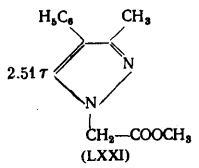
(LXVIIA) (LXVIIB) (LXVIII)

The amino-structure was also assigned to 2-aminobenzothiazoles (LXVIII) on the basis of the CS of the exocyclic nitrogen (310–320 τ). [95]

Comparison of the CS of the vinyl protons of 3-methyl-4-phenylpyrazole (LXIX) and its non-tautomeric derivatives (LXX) and (LXXI) leads to the conclusion that the form (LXIXA) predominates [96].

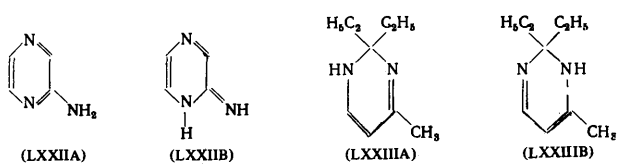


(LXIXA) (LXIXB) (LXX)



(LXXI)

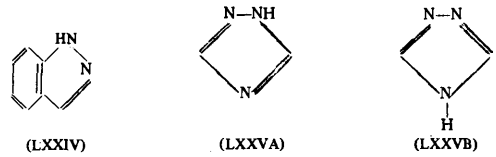
Aminopyrazine in various solvents exists in the amino-form (LXXIIA). This is indicated by the change in the CS and SSCC of the stable protons on breakdown of the aromaticity characteristic of the imino-form (LXXIIB). [20] 1,2-Dihydropyrimidine (LXXIII) in DMSO exists as a mixture of forms A and B in the ratio 2:1. [97]



(LXXIIA) (LXXIIB) (LXXIIIA) (LXXIIIB)

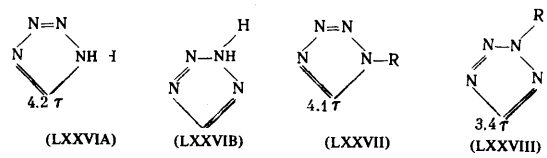
For indazole and its derivatives, the structure (LXXIV) shows best agreement with the PMR spectra [98].

The two signals of the vinyl protons in the spectrum of non-substituted 1,2,4-triazole in hexamethylphosphoramide at −34° indicate that under these conditions the unsymmetrical (1-H)-form (LXXVA) predominates [99].



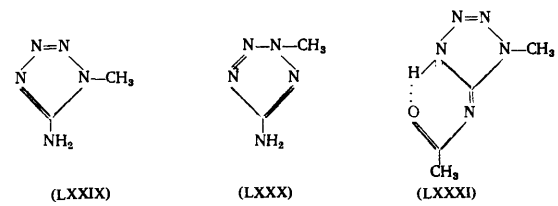
(LXXIV) (LXXVA) (LXXVB)

Benzotriazole exists in the 1-H-form. At room temperature, rapid exchange of protons between positions 1 and 3 is observed, as indicated by the symmetrical spectrum of the aromatic protons [100]. The similarity in the CS of the C–H protons of tetrazole (LXXVI) and its 1-alkyl-derivatives (LXXVII) confirms that in DMPA the tetrazole exists chiefly in the (1-H)-form [101].



(LXXVIA) (LXXVIB) (LXXVII) (LXXVIII)

5-Amino-1-methyl- and 5-amino-2-methyltetrazoles exist in the amino-forms (LXXIX) and (LXXX), but for 5-acetamido-1-methyltetrazole the imino-form (LXXXI), stabilised by IntraMHB, was detected [102].

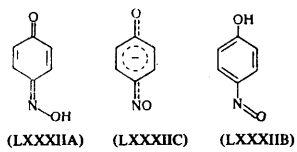


(LXXIX) (LXXX) (LXXXI)

PMR data have demonstrated the equivalence of the four pyrrole rings in various porphyrin derivatives; this is attributed to rapid tautomerism of the amine-imine type [103].

VI. NITROSO-OXIME TAUTOMERISM

Three groups of authors [104–106] have used PMR together with infrared and ultraviolet spectroscopy to study the tautomerism of *p*-nitrosophenols.



(LXXXIIA) (LXXXIIC) (LXXXIIB)

The PMR spectra of 4-nitrosophenol (LXXXII) in DMSO, D_2O acetone, tetrahydrofuran, and other organic solvents indicate that the protons in positions 2 and 6 and 3 and 5 are equivalent. On this basis, Fischer and coworkers [104] concluded that the nitroso-form (B) predominates, with rapid rotation about the C–N bond. Other workers [105,106], however, correctly point to rapid A ⇌ B transformation via the mesomeric anion (C).

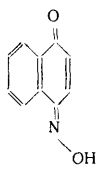
The PMR spectra of form (A), unlike those of form (B), are in fact characterised by different CS for the protons of the ring situated in the *syn*- and *anti*-positions relative

to the oxime group‡. The fact that the CS of the signals of the protons in positions 3 and 5 (and also 2 and 6) coincide, however, does not prove that form (B) predominates, since the same picture will be observed for rapid exchange of (A) with even a small quantity of (B). In the process there is rapid interconversion of equivalent stereo-isomers of form (A).

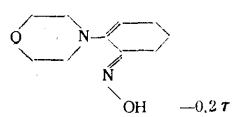
The correct conclusions[105,106] are confirmed by the fact that the values of the CS and SSCC of the nitrosophenol are intermediate between the corresponding values for the model compounds 4-nitrosoanisole and 1,4-benzoquinone-monoxime methyl ether. The addition of a small quantity of HCl or trifluoroacetic acid (TFA) suppresses the ionisation and leads to a sharp decrease in the rate of the tautomeric transformation. This is revealed by a broadening of the PMR signals in these solvents, and in dioxan containing a trace of HCl or TFA it is possible to observe separately the spectra of both tautomers, the concentrations of which correspond to 83–86% of the oxime form and 17–14% of the nitroso-form. An analogous picture is observed in pure dibutyl and dipropyl ethers, in which ionisation is unlikely. These conclusions agree with the ultraviolet spectra in the same solvents.

2-Methyl-, 3-methyl-, 2,6-dimethyl-, and 3,6-dimethyl-derivatives of 4-nitrosophenol, and also 2-chloro-4-nitrosophenol, exist to the extent of more than 95% in the benzoquinonemonoxime form. It has been shown that 3-substituted 1,4-benzoquinonemonoximes exist only in the *anti*-form[106].

Fischer and coworkers[104] compared the PMR spectra of 4-nitroso-1-naphthol and 1,4-naphthoquinonemonoxime methyl ether, and concluded that in DMSO the quinone-oxime form (LXXXIII) predominates.



(LXXXIII)

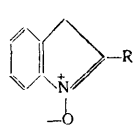


(LXXXIV)

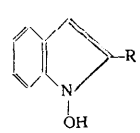
According to PMR data[107], the nitroso-derivative of 1-morpholinecyclohexane in deuterochloroform is present entirely in the form of the oxime (LXXXIV).

VII. NITRONE-HYDROXYLAMINE TAUTOMERISM

Mousseron-Canet and Boca[108,109] showed that the position of the A ⇌ B equilibrium for *N*-hydroxyindoles (LXXXV) depends markedly on the proton-donating properties of the solvent (0% of form A in pyridine and in DMSO, 33% in CCl_4, and 100% in phenol). It was suggested that in neutral solvents and in the absence of a solvent, the tautomers (A) and (B) are combined in associates by InterMHB.



(LXXXVA)

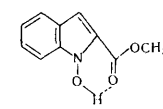


(LXXXVB)

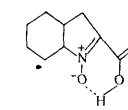
‡Moreover, form (A) should show stronger SSC through the −C=C− bond.

On dilution with proton-donating or proton-accepting solvents, the associates break down and form new InterMHB, which stabilises the corresponding tautomeric form. Since the tautomeric transformation is slow (the proton migrates between the carbon atoms and the hetero-atom[1]), the spectra of tautomers (A) and (B) are observed separately. The spectrum of the nitrone (A) contains the signal of the methylene group (6–7 τ) and the spectrum of the enhydroxylamine (B) contains the signals of the *N*-hydroxyl (3.9–4.3 τ) and vinyl protons. It should be noted that the positive charge on the nitrogen atom decreases the value of the CS of the protons of the condensed aromatic ring (by 0.2–0.3 τ) and, more particularly, of the methyl group in position 2 (by 0.8 to 1.1 τ) in the nitrone form, compared with the enhydroxylamine form.

Methyl *N*-hydroxyindolecarboxylate in chloroform is present almost entirely in the hydroxylamine form[110]. The low value of the CS of the hydroxyl proton indicates the chelate structure (LXXXVI).



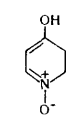
−0,03 τ
(LXXXVI)



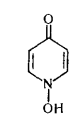
−0,40 τ
(LXXXVII)

On the other hand, with 4-bromo-1-hydroxyindole-2-carboxylic acid the chelate stabilises the nitrone form (LXXXVII).[110]

Nitrone-hydroxylamine tautomerism is observed for 4-hydroxypyridine-*N*-oxide (LXXXVIII). In contrast to the tautomerism of the *N*-hydroxyindoles, however, in this instance the proton migrates rapidly between the oxygen atoms, and the overall PMR spectrum of the two tautomeric forms is observed.



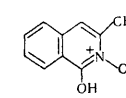
(LXXXVIIIA)



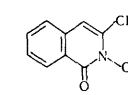
(LXXXVIIIB)

Using models of the tautomeric forms, Katritzky and coworkers[111] found that in aqueous solutions the tautomers (LXXXVIII A and B) are present in the ratio 3 : 2.

On the basis of ultraviolet and PMR spectroscopy, it was concluded[112] that the equilibrium (LXXXIXA ⇌ LXXXIXB) is displaced towards the hydroxylamine form (LXXXIXB).



(LXXXIXA)



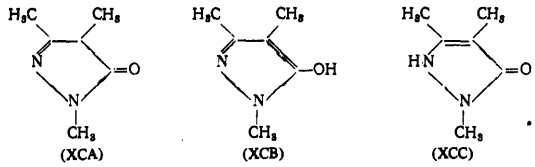
(LXXXIXB)

VIII. COMPLEX TAUTOMERISM OF HETEROCYCLIC COMPOUNDS

This section gives the results of studies of the tautomeric composition of five- and six-membered heterocyclic rings which can exist in more than the two tautomeric forms. Simpler examples were examined above.

1. Five-membered Heterocyclic Rings

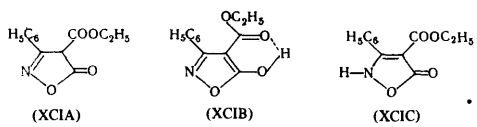
1,3,4-Trimethylpyrazolone-5 (XC), like other 1-substituted pyrazol-5-ones, may exist in three tautomeric forms:



(XCA) (XCB) (XCC)

The PMR spectrum of this compound in chloroform [113], in addition to the intense signals of form (A), shows signals characteristic of forms (B) and (C), or one of them (C(4)–CH_3 8.27; N–CH_3 6.60; NH and (or) OH 1.07 τ). These CS coincide with those for the *N*-methylated derivative, which is a model of form (XCC) and differ from those for the model of form (XCB) (C(4)–CH_3 8.06 τ; N–CH_3 6.46 τ). Thus the pyrazolone (XC) contains form (A) and a smaller quantity of form (C).

3-Phenyl-4-carbethoxyisoxazol-5-one (XCI) can also exist in three tautomeric forms:



(XCIA) (XCIB) (XCIC)

Table 4. Tautomeric composition of derivatives of pyrazol-5-one [30] and isoxazol-5-one [114].

Compound	Chloroform	Methanol	Water	Pyridine

3-Phenyl-4-methyl	40%A + 60%C	—	—	—
3,4-Tetramethylene-	80%A + 20%C	—	—	—
3-Phenyl-4-carbethoxy-	Bf	—	—	—
3,4-Dimethyl-	70%A[e]	0%A[e]	0%A[e]	30%A[e]

[a] A, B, and C represent the CH-, OH-, and NH-forms respectively (see compounds XC and XCI); [b] 10% A according to ultraviolet spectra [113]; [c] according to Ref. 112; [d] in CCl_4; [e] according to Ref. 115.

The PMR spectrum of its solution in $CHCl_3$ [114] does not contain the signal of a methine proton, and this eliminates the CH-form (A). The mobile proton absorbs in very weak fields (–2.25 τ). This value is much lower than the CS of the group in the NH-form (C) of other isoxazolones (between 0 and +1 τ) [113] and shows good agreement with the chelate structure (B). The tautomeric compositions of other pyrazol-5-ones and isoxazol-5-ones are given in Table 4.

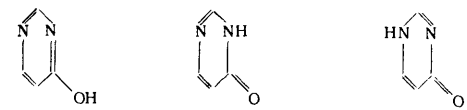
The results in Table 4, obtained by PMR spectroscopy, show that methylation of the nitrogen atom of the pyrazolones increases the concentration of the NH-form (C) at the expense of the CH- and OH-forms (A) and (B). The introduction of an alkyl group in position 4 also displaces the equilibrium considerably towards the NH-form (C) in both pyrazolones and isoxazolones. The CH-form, which predominates in CCl_4 and $CHCl_3$ (particularly in dilute solutions) is almost absent in polar media, in which the NH- and OH-forms are stabilised by InterMHB. The concentration of the OH-form increases with increase in the proton-accepting power of the solvent.

In latter work, the magnetic resonance of the protons [116] and ^{13}C nuclei [117] gave additional information on the tautomerism of 1-phenylpyrazol-5-ones. Electron-donating substituents in position 3 of the ring displace the equilibrium considerably towards the CH-form in various solvents, and electronegative substituents stabilise the OH-form. The influence of substituents and the medium on the keto-enol equilibrium of 2-phenylthiazolin-4-one [118] and 2-phenylthiazolin-5-one [119] has been studied. In the latter instance it was suggested that dilute solutions in polar solvents contain an appreciable quantity of the mesoionic form in addition to the CH- and OH-forms.

Studies of the tautomerism of five-membered heterocyclic compounds by various methods were briefly reviewed in a paper by Elguero and coworkers [30].

2. Six-membered Heterocyclic Rings

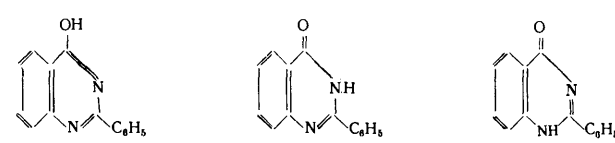
4-Hydroxypyrimidine (XCII) can exist in three tautomeric forms:



(XCIIA) (XCIIB) (XCIIC)

Comparison of the CS and SSCC for 4-hydroxypyrimidine and its methylated derivatives (Table 5), which provide models of the three tautomeric forms, indicates that the predominant form is the quasi-*o*-quinone form (B) in DMSO [120] and in water [121]§. To choose between (B) and (C) it is first of all necessary to compare the CS of the C_5–H signals, which show smaller changes than the others on *N*-methylation [121]. For the SSCC J_{56}, a linear correlation with the bond order is observed (calculation by the MO method for structures A, B, and C [121]). The same method was used to show that a form of type (B) predominates for 4-thiopyrimidine [120].

2-Phenyl-4-hydroxyquinazoline (XCIII) can exist in three analogous tautomeric forms:



(XCIIIA) (XCIIIB) (XCIIIC)

§In agreement with the infrared and Raman spectra [122,123]. According to ultraviolet spectroscopy, tautomers (B) and (C) are present in water in the ratio 2 : 1. [124]

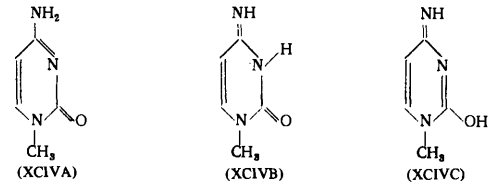
In aromatic dicyclic compounds the signal of the proton in the *peri*-position relative to a carbonyl group lies at lower fields (1.7–1.9 τ) than the other aromatic protons ($\tau > 2.0$), because of the deshielding action of the C=O bond [70,125]. The fact that the PMR spectrum of compound (XCIII) in DMSO contains a low-field doublet signal of the aromatic proton C_5–H (1.87 τ) reduces the problem to the choice between the two oxo-forms (B) and (C). In the *N*-methylated derivatives which are models of forms (B) and (C) the *peri*-proton absorbs at 1.90 τ and 1.77 τ respectively, provinding evidence in support of the amide form (B), in agreement with the infrared and ultraviolet spectra [126].

Table 5. Parameters of the PMR spectra of 4-hydroxypyrimidine and its methylated derivatives [120,121].

Compound	Medium	CSτ,			SSCC, Hz			Model form
		H_2	H_5	H_6	H_2–H_5	H_2–H_6	H_5–H_6	
4-Hydroxypyrimidine	DMSO [a]	1.80	3.63	2.05	1.0	0.5	6.3	—
	D_2O	1.63	3.49	2.02	1.0	1.2	7.15	
3-Methyl-4-pyrimidone	DMSO	1.50	3.58	2.05	0.85	—	6.0	B
	D_2O	1.58	3.45	2.01	0.80	0.6	6.8	
1-Methyl-4-pyrimidone	DMSO	1.70	3.98	2.28	0.5	2.5	7.0	C
	D_2O	1.64	3.67	2.21	0.6	2.5	7.5	
4-Methoxypyrimidine	DMSO	1.27	3.03	1.45	1.1	0.4	5.4	A
	D_2O	1.32	3.05	1.55	1.2	0.8	6.2	

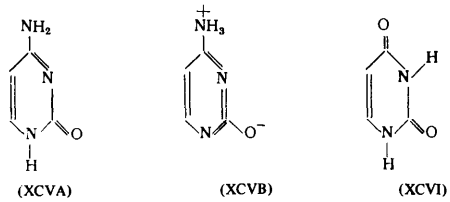
[a] The parameters of the spectra agree with earlier data [19].

The PMR spectrum of 1-methylcytosine (XCIV) with a ^{15}N atom in the amino-group shows splitting (J_{NH} = 90 Hz) of the signal, the intensity of which corresponds to two protons. This provides unambiguous evidence in support of the amino-form (A). [127]



(XCIVA) (XCIVB) (XCIVC)

Analysis of the PMR spectra of cytosine (XCV), for which seven tautomeric forms are possible, confirms the generally accepted form (XCVA) in DMSO and D_2O. [128]



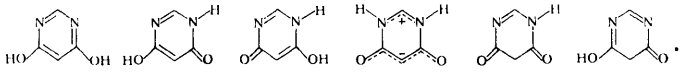
(XCVA) (XCVB) (XCVI)

The CS and SSCC (J_{56}) of cytosine and *N*-methylcytosine (XCIV) almost coincide, and the values differ considerably from those predicted for the bipolar form (XCVB), which was erroneously assumed in earlier work [129]. The tautomerism of cytosine nucleosides has been studied [127, 130,131].

PMR spectroscopy has confirmed the diamide structure of uracil (XCVI), for which six tautomeric forms are possible [19,129]. The PMR spectrum of uracil is shown in Fig. 2. The components of the C_6–H doublet (J_{56} = 7.6 Hz) are split as a result of SSC with the amide proton (J_{61} = 5.7 Hz), and the components of the C_5–H doublet are split to form a triplet, as a consequence of SSC with the two amide protons ($J_{51} = J_{53}$ = 1.4 Hz). On heating, the splitting due to the amide protons disappears as a consequence of their rapid intermolecular exchange, leaving only the splitting due to the SSC of the C_5–H and C_6–H protons. The PMR method has also been used to study many potentially tautomeric derivatives of uracil and thiouracil [132,133]. It has been concluded that the diamide form is preferred.

Figure 2. PMR spectrum of uracil in DMSO (40 MHz). [19]

For 4,6-dihydroxypyrimidine (XCVII), which is an isomer of uracil, six tautomeric forms (A–F) are possible:



(XCVIIA) (XCVIIB) (XCVIIC) (XCVIID) (XCIIE) (XCVIIF)

Table 6. Chemical shifts of the PMR of 4,6-dihydroxypyrimidine and its methylated derivatives [134].

Compound	Medium	CSτ,			Model form
		C_5–H	C_5–H	OH or H	
4,6-Dihydroxypyrimidine (XCVII)	DMSO	1.90	4.85[a]	–1.60[b]	—
	D_2O	1.60	—	—	
N-Methyl derivative (CII)	DMSO	1.76	4.75	–1.30	—
	D_2O	1.46	4.90	—	
O-Methyl derivative (CI)		2.00	2.00	4.56	–2.20	—
		2.07	2.07	4.46	—	
3-Methyl-6-methoxypyrimidone-4- (XCVIII)		1.62	1.62	4.40	—	B
		1.76	1.76	4.42	—	
4,6-Dimethoxypyrimidine (XCIX)	DMSO	1.63	3.85	—	A
Mesomeric betaine (C)	DMSO[c]	—	—	—	D
	D_2O	0.95	4.9	—	

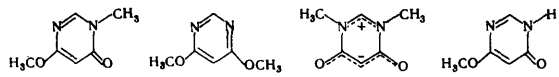
[a] Soluble on heating, C_5–H proton then replaced by deuterium; [b] overall signal of the NH and OH protons; [c] sparingly soluble in DMSO.

Comparison¶ of the CS of 4,6-dihydroxypyrimidine and its *O*- and *N*-methylated derivatives with completely (XCVIII–C) and partly† (CI and CII) fixed structures (Table 6) led to the following conclusion [134]: 1) the mono-*O*-methyl-derivative in aqueous solutions and in DMSO

¶ With allowance for the influence on the CS of the C_2–H and C_5–H protons of the neighbouring OCH_3 and N–CH_3 groups.

† For compound (CI) tautomeric forms of types A, B, C, and F are possible, and for compound (CII) forms of types B, C, D, and E are possible.

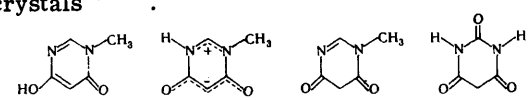
exists in the oxo-hydroxy-form (CI); 2) the mono-*N*-methyl-derivative and 4,6-dihydroxypyrimidine itself exist in DMSO in the oxo-hydroxy-form (CIIB) and (XCVIIB) respectively, whereas in water they exist chiefly in the bipolar ionic form (CIID) and (XCVIID) in equilibrium with a very small quantity of the dioxo-form‡ (CIIE) and (XCVIIE).



(XCVIII) (XCIX) (C) (CI)

The PMR data agree with the results obtained by ultraviolet [135,136] and infrared [137] spectroscopy.

NMR data indicate [134] that barbituric acid in DMSO exists in the trioxo-form (CIII), as in aqueous solutions [139] and crystals [139-141].



(CIIB) (CIID) (CIIE) (CIII)

IX. RING-CHAIN TAUTOMERISM

Ring-chain tautomerism (R-CT) of the electrophilic type (in Jones' terminology [142]) is accompanied in the great majority of examples by the migration of a proton. It can therefore undoubtedly be regarded as a form of prototropic tautomerism§.

In an examination of physical methods used to study R-CT, Jones points out that NMR is becoming one of the most valuable methods used for this purpose [142].

Because of lack of space, we cannot examine the work on R-CT carried out by means of NMR, but the following list, which illustrates Jones' prediction, may to some extent provide a useful supplement to his review.

NMR spectra have been used to study the mutarotation of sugars [144-149], aminosugars [150], and osazones of ascorbic acid [151], and the temperature dependence of the formation of hemiacetals of hydroxyketones [152] and lactones of laevulinic acid [153]. The R-CT of *o*-acylcarboxylic acids [154-159] and the similar transformation of the hemialdehydes of carboxylic acids of the benzene, pyridine, and thiophene series [157,158] have been studied. NMR has been used to study the R-CT of oxazolidines [159,160], various oxadiazines [161-165], thiazolidine- [166] and thiadiazolidine-2-thiones [167], dihydrobenzothiazoles [168], tetrahydropyrimido-4,5-*d*-pyrimidines [169], and the products of the condensation of *o*-hydroxybenzylamine with aldehydes and ketones [170]. R-CT has also been studied in alkaloids which are derivatives of indole [171].

X. DETERMINATION OF THE POINT OF PROTONATION OF UNCHARGED MOLECULES WITH TWO OR MORE PROTON-ACCEPTING CENTRES

Neutral tautomeric forms are the products of the protonation of a mesomeric anion at a given proton-accepting centre. Analogously, the protonation of neutral molecules with two or more proton-accepting centres may lead to the formation of cations with different structures in a state of dynamic equilibrium, which can be regarded as prototropic tautomerism.

The methods examined above are fully applicable to the study of tautomeric equilibrium in these systems by NMR spectroscopy.

Here, as in paragraph IX, we shall restrict ourselves to giving a list (which does not claim to be complete) of papers dealing with NMR studies of the protonation of compounds of various classes: the saturated amides of carboxylic [172-177] and sulphonic [176,178] acids, nitrosoamines [179], phenol and aromatic ethers [180-183], α-diazoketones [184], α,β-unsaturated β-aminocarbonyl compounds [185,189], guanidine [86], nitroguanidine [187], and biguanide [188], 4-dimethylaminoazobenzene [189], pyrroles [190,191] and pyrrolethiazoles [192], thiophenes [193], indoles [194], and indolizines [195,196], imidazoles [197,198] and imidazopyridines [199], pyrazolines [200], various benzazoles [201], 2- [202,203] and 4-pyridones [111,204,205] and their thio-analogues [206], aminopyridines [206], *N*-hydroxypyridine [207], and aminoquinolines [89], 4-phenylpyrimidine [208], and various amino- and hydroxypyrimidines [209], 4,6-dihydroxypyrimidine and its derivatives [134], 1-methylcytosine [127,210], caffeine [211], *s*-triazolo-(1,5*a*)-pyrimidines [212], cinnolines [213], and pteridines [214], nitro- [215,216] and acylazulenes [217] and pseudoazulenes [218], and 3-phenylsydnone [219]. NMR has also been used to study the structures of salts of heterocyclic enamines [220,221].

Study of the Location of Transition Metal Cations in Synthetic Zeolites Using Electron Paramagnetic Resonance and Optical Spectroscopy

I.D.Mikheikin, G.M.Zhidomirov, and V.B.Kazanskii

The application of EPR and optical reflection spectroscopy to the study of zeolites containing first-row transition metal cations is discussed. A qualitative theoretical analysis of the optical and magnetic properties of some ions with an unfilled $(d)^n$ electron shell is given. The most important results of EPR and reflection spectroscopic studies of the behaviour of transition metal cations in synthetic zeolites are presented. 80 references

I. INTRODUCTION

Synthetic zeolites are widely used for the separation of hydrocarbons by adsorption, for drying gases, and in petroleum refining. The last application is particularly important, because zeolites containing bi- and trivalent metal cations (introduced by cation exchange) are much more active catalysts than the amorphous aluminosilicates previously used. Most workers ascribe the catalytic properties of cation-exchanged zeolites to the polyvalent ions themselves, or to acidic centres formed by the introduction of these ions into the crystal lattice. Hence, location studies of polyvalent metal ions in synthetic zeolite structures are of fundamental importance in understanding their catalytic properties.

Because of the large volume of publications on various properties of zeolites, including a number of contradictory statements, special review articles have been written on the catalytic activity of zeolites[1-4], on the state of water and other molecules adsorbed by zeolites[5], and other similar topics. Some of these reviews discuss the location of polyvalent cations within the lattice, mainly on the basis of structural studies of zeolites containing alkali, alkaline-earth, and rare-earth metal ions.

An attempt is made here to systematise the published results of work on the structure of zeolites containing transition-metal ions. The number of such publications is not large, but it is sufficient to show that zeolites containing transition-metal cations have catalytic properties essentially different from those of zeolites containing alkali or alkaline-earth metal ions. A special feature of the present review is that conclusions regarding the sites occupied by transition-metal cations are drawn entirely from the results of optical and EPR spectral studies of the zeolites. The discussion will be largely confined to zeolites containing cations of the first transition group (ions with an unfilled $3d$ electron shell). The theory of the EPR and optical spectra of these ions is sufficiently well understood, and the spectral results can be interpreted with confidence in the light of the wealth of experimental information on homogeneous complexes. Zeolites containing cations of other transition metals have not so far been investigated by EPR and optical spectroscopy.

1. General Discussion of Synthetic Zeolites and Cation Localisation Sites in their Crystal Lattices

Zeolites, both naturally occurring and synthetic, are crystalline aluminosilicates†. The various forms of zeolites have been described in detail elsewhere, and we shall therefore only briefly consider the properties of zeolites with a three-dimensional skeletal structure, which have the highest adsorption capacity and thermal stability and therefore offer the greatest promise in the field of catalysis. Among the three-dimensional skeletal zeolites, we shall be concerned in particular with the recently developed and widely used synthetic zeolites of types A, X, and Y. The skeleton of these zeolites consists of aluminium–oxygen and silicon–oxygen tetrahedra. Twenty-four of these tetrahedra are joined to form a polyhedron (cubo-octahedron), and the cubo-octahedra are joined by oxygen bridges into the crystalline skeleton of the zeolite. Depending on the aluminium to silicon ratio, these zeolites fall into three types: A ($SiO_2/Al_2O_3 = 2$), X ($SiO_2/Al_2O_3 = 2.2-3$), and Y ($SiO_2/Al_2O_3 = 3.2-5.0$).

In type A zeolites the cubo-octahedra form a simple cubic lattice, similar to the rocksalt structure, but with each ion replaced by a cubo-octahedron. The cubo-octahedra are connected by four-membered oxygen bridges (see Fig. 1*a*). In zeolites of types X and Y the cubo-octahedra are arranged in a lattice of the diamond type, and the bridges connecting the cubo-octahedra consist of six oxygen atoms (see Fig. 1*b*).

Because of their skeletal structure, the zeolites contain holes which are interconnected by windows of well defined sizes. The holes within the cubo-octahedra are termed small holes, and their size is practically the same in zeolites A, X, and Y ($v = 150$ Å^3, $d = 6.5$ Å). The hollows bounded by the outer surfaces of the cubo-octahedra and of the oxygen bridges are termed large zeolite holes. Their diameter in A, X, and Y zeolites is ~ 11.5Å,

† Zeolites have been synthesised in which the aluminium is replaced by gallium[6,7], or chromium[8,9], and the silicon is replaced by germanium[6], beryllium, or magnesium[10].

and their volume is of the order of 800 Å^3.[11] The diameter of the six-membered oxygen windows leading from the small to the large holes is approximately 2 Å. In type-A zeolites the large holes are interconnected by 8-membered oxygen windows ($d \simeq 4.2$ Å), and in zeolites of types X and Y by 12-membered oxygen windows 8–9 Å in diameter.

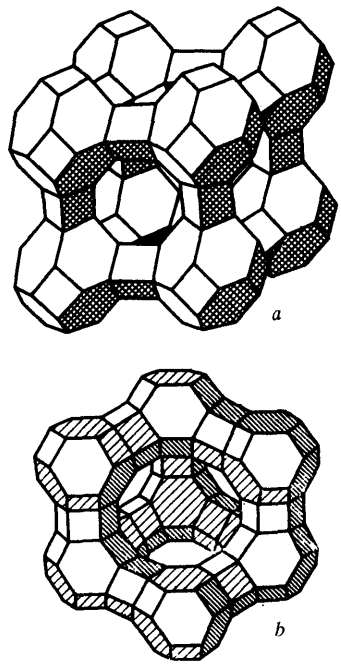

Figure 1. Three-dimensional model of the alumina–silica lattice of zeolites (*a*) of type A and (*b*) of types X and Y.

Since the aluminium–oxygen tetrahedra carry an excess of negative charge, the zeolite structure must include an equivalent amount of metal cations (usually Na^+ or Ca^{2+}). These ions can readily be exchanged[12] by other ions, and therefore a great variety of cationic forms of zeolite can be prepared. Without discussing cation exchange in detail, we note in passing that the process is determined by the nature of the metal ions, their size and charge, the pH of the medium, the temperature, and the structure of the zeolite[13–19]. The crystal lattice parameters of the zeolite are not significantly altered by cation exchange, up to the point where the crystal lattice breaks down. The stability of the zeolite structure towards exchange is determined mainly by the pH of the medium, the extent of exchange, and the zeolite type.

One of the most important problems in the structure of cationic zeolite forms concerns the sites occupied by the metal ions which compensate the charge on the aluminium–oxygen tetrahedra. In zeolites of types X and Y, three types of cation site are usually distinguished[20]: *S*I sites are the centres of the hexagonal prisms formed by the oxygen connecting links between cubo-octahedra (16 sites per unit cell); *S*II sites are the hexagonal oxygen windows which connect the large and the small holes (32 sites per unit cell); *S*III sites are the walls of the channels interconnecting the large holes (48 sites per unit cell). In type-A zeolites the *S*I sites are absent. The differences between the sites which can be occupied by cations have recently been identified in greater detail. Sites in the six-membered oxygen windows adjacent to a large hole have been designated *S*II, those adjacent to a small hole *S*II′. The location of an ion within a small zeolite hole near a six-membered oxygen window leading to the cavity of a hexagonal oxygen prism (*S*I site) is referred to as an *S*I′ site. Some characteristics of the sodium forms of synthetic type A, X, and Y zeolites are listed in Table 1.

Table 1. Some characteristics of the Na-forms of synthetic zeolites (types A, X, Y).

Zeolite type	Composition of the elementary cell of the hydrated zeolite	Size of windows, Å	Population of sites by univalent cations			Lattice parameters, Å	Adsorption capacity for water of 1 g of dehydrated zeolite
			I	II	III		
A	$Na_{12}[(AlO_2)_{12}(SiO_2)_{12}]\cdot 27H_2O$	4.2	—	8	4	12.32	0.30
X	$Na_{86}[(AlO_2)_{86}(SiO_2)_{106}]\cdot 264H_2O$	8.0	16	32	38	24.95	0.36
Y	$Na_{56}[(AlO_2)_{56}(SiO_2)_{136}]\cdot 264H_2O$	8.0	16	32	8	24.70	0.35

The sites available for cations in zeolites of types X and Y are shown schematically in Fig. 2. Depending on the symmetry of the surroundings, two types of site can be distinguished: those with C_{4v} and those with C_{3v} symmetry.

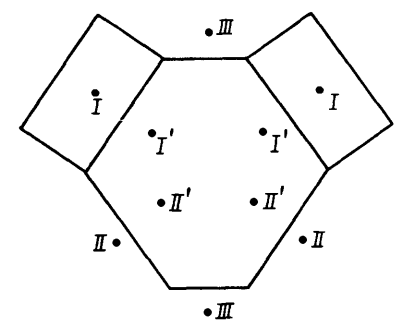

Figure 2. Structure of type X and Y zeolites (diagrammatic). The points show possible localisation sites for ions.

We know from X-ray diffraction studies of zeolites that the hexagonal oxygen windows of the cubo-octahedra are trigonally distorted. They consist of two unequal equilateral triangles, rotated by 60°, formed by the oxygen atoms of the lattice. The interplanar spacing of these triangles is several tens of angstroms.

As a result, the electrical ligand field for cations in *S*I′, *S*II′, and *S*II sites has C_{3v} symmetry (trigonal, compressed or extended along the trigonal axis of the tetrahedron depending on the conditions of the particular

system). The three planar ligands, in this case, are the oxygen atoms of the lattice, and the fourth ligand could be either a residual water molecule (or its fragments O^{2-} or OH^-), or any other adsorbate molecule. When a cation is localised in the plane of the six-membered oxygen window it experiences a ligand field with D_{3h} symmetry (special case of C_{3v}). However, an environment corresponding to a trigonally distorted octahedron can be realised also by the adsorption of three fairly small molecules on a cation in an *S*II position (see below).

The ligand field surrounding *S*I and *S*II sites has a distorted octahedral symmetry. In the former, the ligands are 6 negatively charged oxygen atoms from the zeolite lattice, which form a fairly regular octahedron. (These sites are not accessible to adsorbed molecules.) When a cation is localised on the surface of a large zeolite hole (site *S*III), one or more (up to 4) of the ligands can be provided by the lattice oxygen atoms, and the remainder may be residual water molecules, or other molecules. As will be shown below, the environment of delocalised cations ("floating" in the large holes) of fully hydrated zeolites is almost perfectly octahedral.

2. Basic Physicochemical Methods of Studying Zeolite Structure. Application of EPR and Reflection Optical Spectroscopy to the Study of Zeolites Containing Cations of the First Transition Series

Almost all the physicochemical methods used in the study of heterogeneous catalysts have been applied to the study of zeolite structures. X-ray diffraction and infrared spectroscopy are the most widely used spectroscopic methods. Other methods include chemical analysis, calorimetry, thermogravimetry, differential thermal analysis, electrical and dielectric measurements, tracer studies, measurements of static magnetism, etc. Some problems have been studied by a combination of these methods, with satisfactory results.

X-ray analysis gives the most direct indication of the sites in which metal cations are localised in zeolites, but the results are difficult to interpret because sufficiently large single crystals are not yet available, and powder patterns are exceedingly complicated. Furthermore, the method becomes unreliable at relatively low concentrations of added cations, when these do not give rise to a distinct sublattice. Adsorption and desorption phenomena on cationated zeolite forms are not easily studied by X-ray diffraction. Hence, the usefulness of the X-ray method is limited essentially to studies of the distribution of cations in zeolites.

I. r. spectroscopy is used in the main to study the nature of the acidic centres and the state of the surface hydroxyl groups in zeolites. Its relevance to studies of cation localisation sites stems from the perturbation of the vibrational spectra of adsorbed molecules (e.g. CO) by interaction with cations[21]; this provides information on the accessibility to adsorbed molecules of cations on various sites.

When the zeolite contains ions of transition metals, which are usually paramagnetic and absorb in the u.v. and visible regions of the spectrum, the combined application of EPR and reflection spectroscopy has given very promising results. The EPR and the optical spectra of transition-metal ions are very sensitive to the symmetry of their immediate environment. Hence, the localisation of ions in various crystal lattice sites can be identified, since these sites can be distinguished by the symmetry of their surroundings.

The EPR and optical spectroscopy methods are to some extent complementary, since the splitting of the electronic levels of the ions by the crystal field can easily be determined by the optical method, and the parameters of the EPR spectra are dependent on this splitting. It should be noted, however, that the EPR method gives best results with magnetically dilute samples, containing low concentrations of paramagnetic ions. On the other hand, the optical spectra of such samples tend to be insufficiently intense, owing to the low extinction coefficients of the transition-metal ions. Hence, combined EPR–optical spectral measurements is far from universally applicable.

The interpretation of optical and EPR spectra for transition-metal ions requires a knowledge of the energy levels of the ions and of the corresponding electronic wave functions in ligand fields of different symmetries. Qualitative and semi-quantitative interpretations of EPR and optical effects are usually attempted with the help of ligand-field theory, whose limitations and methods are discussed in detail elsewhere (see, for example, Refs. 22 and 23).

Most of the problems, however, concern small distortions of octahedral and tetrahedral fields, and their solution relies on the application of perturbation theory. Large distortions, e.g. the removal of an entire ligand from the coordination sphere, are not considered as a rule. Therefore, before reviewing the published data, we shall briefly summarise the results of our calculations of the electronic levels and spin-Hamiltonian constants for ions with a $(3d)^n$ electron shell in low-symmetry ligand fields. These calculations allow us to interpret more reliably the EPR and optical spectra of transition-metal cations in zeolites, and they can also be applied to the interpretation of corresponding data for oxide catalysts, on whose surface the coordination of ions may be abnormal[24]. The calculations are directly relevant, also, to the structure of "atypical" complexes of transition metals with structurally complex ligands. For example, in the bivalent copper complex $[Cu(tren)OH]^+$, studied in our laboratory[25], the ligand field has C_3 symmetry, whereas weakly distorted octahedral and tetrahedral structures are more usual for copper.

II. CALCULATIONS OF THE OPTICAL AND MAGNETIC PROPERTIES OF FIRST-ROW TRANSITION METAL IONS IN LOW-SYMMETRY LIGAND FIELDS

A full account of our qualitative evaluation of energy levels and spin-Hamiltonian constants for ions with a $(3d)^n$ electronic configuration in low-symmetry ligand fields lies beyond the scope of the present review. However, our subsequent discussion of experimental results by EPR and optical spectroscopy methods for zeolites containing first-row transition metal cations will be made more meaningful by a brief examination of the following types of ligand field distortion, which (as already stated) are found in zeolites:

1. Tetragonal distortions of a ligand field with O_h symmetry (regular octahedron), including the transition to a square planar symmetry by gradual removal of the two ligands on one of the tetrad axes, and also to axial symmetry by gradual removal of the 4 ligands in the plane perpendicular to the tetrad axis (Fig. 3*a*).

2. Distortions of a trigonal bipyramid, analogous to the above (Fig. 3*b*).

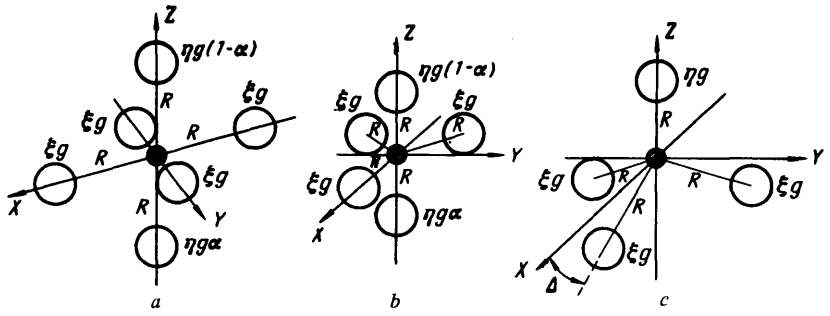

Figure 3. Models of complexes with different symmetry: (*a*) C_{4v}, (*b*) C_{3v} pyram, and (*c*) C_{3v} tetr. ξg is the effective charge on the ligands in the plane; $\eta g(1-\alpha)$ and $\eta g\alpha$ $(0 \leqslant \alpha \leqslant 1)$ are the effective charges on the ligands located on the Z axis.

3. Distortions of a tetrahedron (type C_{3v}), including the continuous transition from a planar triangular configuration to a tetrahedron compressed along the trigonal axis (Fig. 3*c*).

These distortions in the ligand field are modelled by varying the charges on the ligands located on the z-axis $[\eta q(1-\alpha)$ and $\eta q\alpha]$ or in the xy plane $[\xi q]$, and also by varying the angle Δ between the planar ligand M and the xy plane (see Fig. 3). The distances between the central ion and all the ligands are assumed to be identical and equal to R.

We shall consider only the special cases of strong and weak ligand field, because the intermediate field approximation requires electronic computation and is usually confined to specific ions in fields of known symmetry.

Ligand fields are termed weak if they split the ground state by an amount smaller than the distance to the nearest excited state but greater than the spin–orbital interaction constant λ for the corresponding ions.

Tables 2 and 3 show the angular components of the electronic wave functions, and expressions for the corresponding eigenvalues of the energy, for the strong and the weak field case respectively, calculated by the ligand field theory[22,23]. The parameters ξ, η, and $\sin^2\Delta$ have already been defined (see Fig. 3); the quantities F_2 and F_4 are the coulombic interaction integrals between an electron localised at the central ion and the spherical harmonics of a ligand field of the second and the fourth order respectively (see Ref. 23 for a more detailed discussion).

The electronic energy levels of ions in the above fields are shown in Figs. 4 and 5. The plots are constructed for $F_4/F_2 = 0.15$ because this case exemplifies nearly all possible intersections of the resulting electronic levels. Similar plots for different values of the ratio F_4/F_2 can easily be made by reference to Tables 2 and 3.

The $(3d)^n$ electron configuration (n = 2, 3, ..., 9) in a strong crystal field is obtained by progressive population of the states derived by us for a single $3d$ electron, with account being taken of Pauli's principle.

The energy levels of transition-metal ions in the free state follow Hund's rule, and therefore the following high-spin states are chosen as the initial levels in the weak field approximation of the ligand field theory:

Configuration	Ground state	Spin	Angular Momentum	Ion
d^1, d^9	^2D	$^1/_2$	2	Ti^{+3}, V^{4+}, Cr^{5+}, Cu^{2+}, Mn^{6+}
d^4, d^6	^5D	2	2	Cr^{2+}, Fe^{2+}, Co^{3+}, Mn^{3+}
d^3, d^7	^4F	$^3/_2$	3	Cr^{3+}, Co^{2+}, V^{2+}
d^2, d^8	^3F	1	3	Cr^{4+}, Ni^{2+}, Co^{+}, V^{3+}
d^5	^6S	$^5/_2$	0	Mn^{2+}, Fe^{3+}

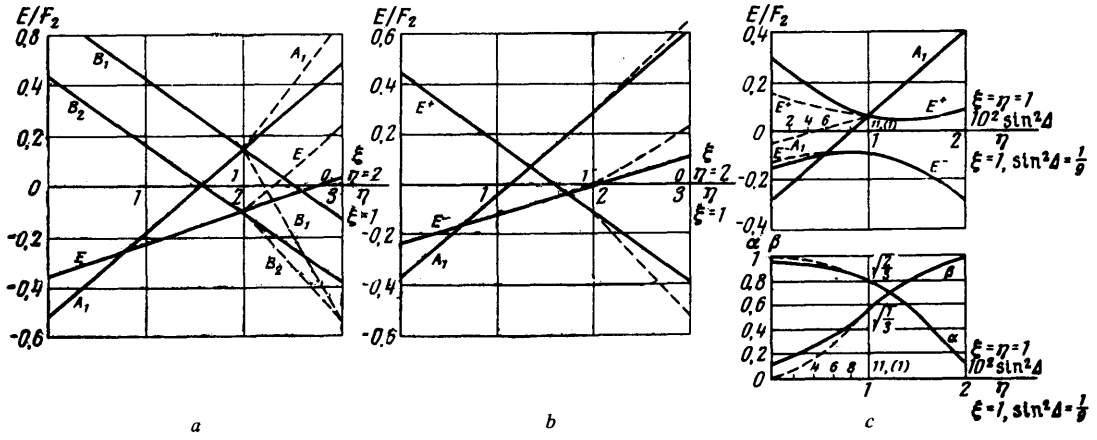

Figure 4. Energy levels of one $3d$ electron in ligand fields of symmetry (*a*) C_{4v}, (*b*) C_{3v} pyram, and (*c*) C_{3v} tetr in units of F_2 $(F_4/F_2 = 0.15)$. Plots of the coefficients in the wave functions are also shown in Fig. 4*c*. The full lines refer to changes in the parameter η at constant $\xi = 1$ (*a*, *b*) or $\xi = 1$, $\Delta = \Delta_{tetr}$; the broken lines refer to changes in the parameter ξ at constant $\eta = 2$ (*a*, *b*) or to changes in the parameter $\sin^2\Delta$ at constant $\xi = \eta = 1$ (*c*).

Since the splitting of high-spin levels which weak ligand fields induce in the $(3d)^6$ and $(3d)^4$ electronic configurations is similar to the splitting in strong ligand fields of the $(3d)^1$ and $(3d)^9$ configurations respectively, it can be discussed by reference to the results given in Table 2 and Fig. 4.[22,23]

We shall not be concerned with the behaviour of ^6S high-spin levels in weak ligand fields for $(3d)^5$ electronic configurations. The optical spectra of these ions are relatively insensitive to changes in the symmetry of the external field, and their intensity is extremely low (spin-forbidden transitions). Because of the absence of an

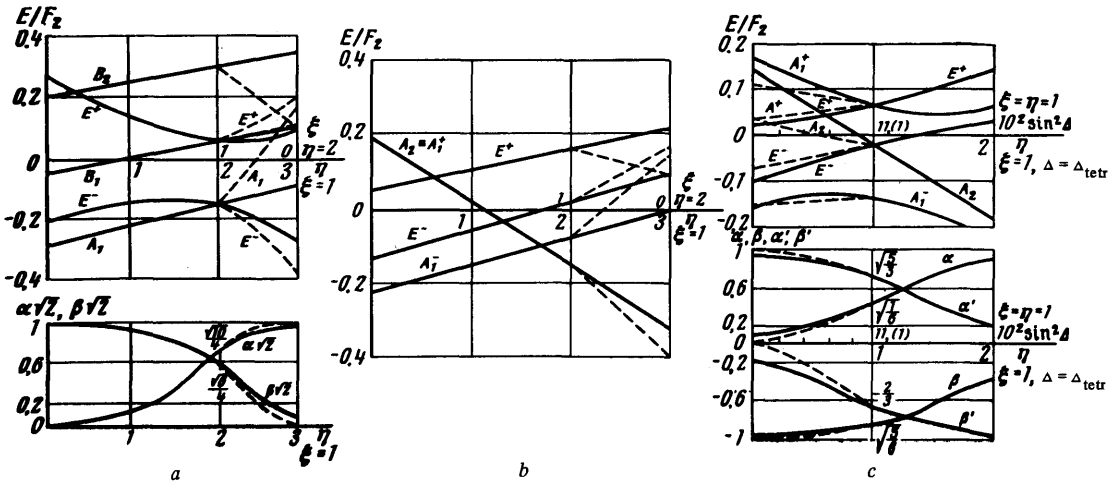

Figure 5. Splitting of the high-spin F-levels arising from the electronic configurations d^2 and d^7 in units of F_2 ($F_4/F_2 = 0.15$) in weak ligand field of symmetry (*a*) C_{4v}, (*b*) C_{3v} pyram, and (*c*) C_{3v} tetr. Figs. 5*a* and 5*b* also show plots of the coefficients in the wave functions. (The significance of the full and the broken lines is defined in the caption to Fig. 4.)

* The coefficients α and β are presented graphically in Fig. 4*c*.

** Only the analytical results are presented because the expressions are too complicated.

orbital angular momentum, the g-factor of the EPR spectrum is close to the free-electron value (*a*), and the hyperfine coupling constants are insensitive to the symmetry of the surroundings.

Table 4 lists the expressions for the spin-Hamiltonian constants of the Cu^{2+} and Co^{2+} ions in different ligand fields, needed for our subsequent discussion, and obtained from the data in Tables 2 and 3 by the method of Abragam and Pryce[26]. These expressions include the spin–orbital interaction constant (λ) of the corresponding ion and the splitting constant of its i and j electronic levels in the ligand field (Δ_{ij}).

III. RESULTS OF STUDIES ON ZEOLITES CONTAINING METAL IONS OF THE FIRST TRANSITION ROW

We shall consider the results of recent studies on zeolites containing first-row transition metal cations with a charge not greater than three, because no zeolite has yet been synthesised in which the charge of the alumina–silica lattice is compensated by cations in a still higher valency state. The results are best discussed in the order of increasing atomic number of the element introduced into the zeolite.

Scandium. The electronic configuration of the ground state of the scandium atom is $[A](3d)^1(4s)^2$, where [A] denotes the electronic structure of the argon atom. Doubly charged Sc^{2+}, with the electronic configuration $[A](3d)^1$, can be observed in principle by EPR and optical spectroscopy, but there are no references in the literature to zeolites containing bivalent scandium ions. A zeolite of type Y containing tervalent scandium ions with the [A] electronic configuration has been investigated[27] as a cumene cracking catalyst. In the same work it was shown by X-ray diffraction that extensive exchange of Na^+ ions by Sc^{3+} ions tends to disrupt the zeolite lattice.

Titanium. The electronic configuration of the ground state of the free titanium atom is $[A](3d)^2(4s)^2$. No work on zeolites containing Ti^{2+} or Ti^{3+} ions has come to our notice, probably because of the difficulty of preparing these zeolite forms.

Vanadium. The electronic configuration of the ground state of the free vanadium atom is $[A](3d)^3(4s)^2$.

Vanadium has been introduced into zeolites only as the doubly charged vanadyl cation $[VO]^{2+}$. The EPR spectra of these zeolites are reported[28] to be identical to the EPR spectrum of vanadyl in solution. No other information concerning the behaviour of vanadyl in the zeolite lattice is available. A strong internal ligand field is known to exist in the vanadyl ion: this field is mainly responsible for the optical and paramagnetic properties of the ion. The spectral parameters of the vanadyl ion are relatively insensitive to the coordination of the cation, and therefore a detailed description of the behaviour of vanadyl in zeolites cannot be expected from EPR and optical spectral studies. This conclusion, however, is not indisputable.

Zeolites containing vanadium ions in other valency states have not been prepared or investigated. An optical study of zeolites containing V^{3+} cations would be very interesting.

Chromium. The electronic configuration of the ground state of the free chromium atom is $[A](3d)^5(4s)^1$. Only zeolites containing tervalent chromium ions have so far been prepared.

We shall consider the effects which can be expected in the optical spectra of zeolites containing Cr^{3+} ions.

The spectrum of the octahedral $[Cr(H_2O)_6]^{3+}$ complex has been discussed fully[29]. The splitting diagram of the ^4F level of the ground state of the free Cr^{3+} ion in fields of C_{4v} symmetry (distorted along the four-fold octahedral axis) is shown in Fig. 5*a* with the sign of the vertical axis reversed. The optical spectra of aqueous solutions of tervalent chromium salts reveal two optical transitions within the ^4F level ($^4A_2 \rightarrow {}^4T_1$; $^4A_2 \rightarrow {}^4T_2$). It is evident from Fig. 5*a* that for a ligand field corresponding to an octahedron stretched along its four-fold axis (case of $\eta < 2$, $\xi = 1$) the absorption bands of the optical spectrum should split into two, the transitions $B_2 \rightarrow B_1$ and $B_2 \rightarrow A_1$ remaining approximately in the original positions and the transitions $B_2 \rightarrow E^-$ and $B_2 \rightarrow E^+$ undergoing a shift towards the red end of the spectrum. If the absorption bands are sufficiently broad, this effect manifests itself as a broadening of the bands accompanied by a displacement of their centre of gravity towards longer wavelengths. The same shift, but without band broadening, is produced by a weakening of the ligand field whilst retaining the octahedral symmetry.

If the octahedron surrounding the ion is compressed along its four-fold axis, the absorption bands of the Cr^{3+} ions are again broadened, but the shift is towards the blue end of the spectrum.

The optical reflectance spectra in diffuse scattered light of A, X, and Y zeolites containing tervalent chromium ions have been investigated by the present writers together with Minachev and others[30]. Since all the spectra (after cation exchange) consisted of three absorption maxima at 285, 425, and 625 nm, i.e. in the same positions as those in the optical spectra of Cr^{3+} solutions, it was concluded that the chromium ions exist as hexaquo complexes $[Cr(H_2O)_6]^{3+}$ in the zeolite structure. After vacuum heat treatment at 200–250° the samples lost most of the adsorbed water, and the absorption bands of the optical spectrum became broader and were shifted towards the red. This effect was explained by assuming that the ligand field had been weakened by the removal of the water from the second coordination sphere of the chromium ion. It follows from the above discussion that the replacement of one water molecule in the first coordination sphere of the Cr^{3+} ion by a weaker ligand (e.g. oxygen from the zeolite lattice) should lead to the same result. Both the two proposed band-broadening and band-shift mechanisms probably operate in the present system.

In zeolites of types A and X these changes in the optical spectrum were found to be irreversible, since the original spectrum of the hexaquo complex could not be reproduced by hydrating the samples at room temperature. This effect was ascribed to incipient breakdown of the zeolite lattice of CrNaX and CrNaA upon vacuum heat treatment at temperatures above 200°, which had been demonstrated independently by differential thermal analysis and thermovolumetric analysis. In contrast, with CrNaY zeolite (known to be stable up to 700°) the reflectance spectrum after water adsorption at room temperature was found to be practically identical to the spectrum recorded on the initial sample after cation exchange.

After vacuum heat treatment at 400° the optical spectrum of CrNaY zeolite showed some radical changes: the sample developed a grey colour and began to absorb over practically the whole of the visible region of the spectrum, suggesting complete breakdown of the hydration shell of the Cr^{3+} ions. The spectral changes were irreversible towards water adsorption, despite the evidence (from differential thermal and thermovolumetric analyses) that the zeolite crystal structure had survived the heat treatment. This observation was interpreted by assuming that the dehydrated Cr^{3+} ions at high temperatures can penetrate within the sodalite cells, where they experience a ligand field with a lower symmetry (probably on *SI'* sites). These holes are too small to accommodate the hexaquochromium complexes, and therefore the optical spectra after exposure to water do not revert to their original form (though some minor changes can be seen). This interpretation, which is consistent with the demonstration[31] by X-ray diffraction analysis that tervalent lanthanum cations penetrate into the small holes of LaNaY zeolite after dehydration, was further confirmed by studies of the adsorption of ethanol and diethyl ether.

Tsitsishvili and Urushadze[32] have reported an EPR study of magnetically concentrated samples of CrNaA zeolite. They observed the EPR spectra of samples, both hydrated and vacuum-dehydrated at room temperature, and found in every case a single broad line (up to 500 G) with a g-factor close to 2, which they ascribed to the octahedral hexaquocomplex $[Cr(H_2O)_6]^{3+}$. After dehydration at room temperature the lines became slightly broader.

Chromium-containing zeolites dehydrated at higher temperatures have not been studied by EPR, because the thermally stable CrNaY zeolites tend to contain iron impurities which give a broad and strong EPR signal[33], and interfere with the study of other paramagnetic ions with broad signals‡.

Before examining in detail the results of EPR measurements, we shall consider some effects which may be present in the EPR spectra of Cr^{3+} ions localised in *SI'* sites. As stated above, the ligand field in this case has the symmetry of a tetrahedron distorted along a trigonal axis. It is evident from Fig. 5*c* that the ground state of a Cr^{3+} ion in a tetrahedron extended along a trigonal axis is not orbitally degenerate, and could give rise to an EPR

‡ A sample of CrNaY zeolite in which 27% of the Na^+ had been exchanged by Cr^{3+}, and which gave no EPR signal in its sodium form, was kindly provided for our EPR measurements by No. 20 Laboratory of the Institute of Organic Chemistry of the USSR Academy of Sciences (Kh. M. Minachev's Industrial Laboratory).

signal at low enough temperatures. An analogous situation involving the Cr^{3+} ion was reported by Henning and coworkers [34]. In a tetrahedron compressed along the trigonal axis the ground state of the Cr^{3+} ion is doubly orbitally degenerate, and the spin–orbital interaction λLS splits it into four doublets which are described by the following wave functions (including the spin variables):

E (energy)	Ψ
$9/4\,\lambda$	$\Psi_1\chi(-3/2)$; $\Psi_2\chi(3/2)$;
$3/4\,\lambda$	$\Psi_1\chi(-1/2)$; $\Psi_2\chi(1/2)$;
$-3/4\,\lambda$	$\Psi_1\chi(1/2)$; $\Psi_2\chi(-1/2)$;
$-9/4\,\lambda$	$\Psi_1\chi(3/2)$; $\Psi_2\chi(-3/2)$;

$$\Psi_1 = -\sqrt{\frac{5}{6}}Y_3^{-2} + \sqrt{\frac{1}{6}}Y_3^1; \qquad \Psi_2 = -\sqrt{\frac{5}{6}}Y_3^2 - \sqrt{\frac{1}{6}}Y_3^{-1};$$

where $\chi(m)$ is the spin wave function for the spin $S = 3/2$ with a projection m on the z axis.

It can easily be shown that none of these doublets can give an EPR signal.

We have shown experimentally [35] that the EPR spectra of CrNaY samples measured at 4.2, 77, and 300°K become gradually weaker as the dehydration temperature is increased, and are practically undetectable after vacuum dehydration above 450°. This confirms our earlier conclusion [30] that after dehydration the Cr^{3+} ions penetrate into small holes and become localised at *SI'* sites. It may be argued that one water molecule (or its fragments O^{2-} or OH^-) is retained in the coordination sphere of the Cr^{3+} ion after heat treatment, and gives rise to the observed compression of the tetrahedron along its trigonal axis. This suggestion is consistent with the conclusion [31] that cation pairs of the type $M^{3+}_{SI'}...O^{2-}...M^{3+}_{SI'}$ are formed.

An effect of the zeolite crystal structure on the mechanism of cation exchange has also been reported [30]. By comparing the amount of chromium introduced into zeolites of different types under otherwise identical conditions with the amount of exchangeable sodium ions it was concluded that exchange in type A zeolites occurs only in the near-surface regions of the microcrystallites. (It should be noted that the hexaquo complexes are larger than the diameter of the windows leading into the structural pores of this type of zeolite.) Exchange does not proceed to completion even in type X zeolites, suggesting partial blocking of the windows leading into the large holes by the hexaquo complexes in the *SIII* position. This blocking effect does not take place in type Y zeolites, evidently because only a small fraction of the exchangeable Na^+ ions is in the *SIII* position (see Table 1).

Manganese. The electronic configuration of the ground state of the free manganese atom is $[A](3d)^5(4s)^2$. Only Mn^{2+} ions have been introduced into zeolites by cation exchange. The optical spectra of bivalent manganese have a very low intensity, because the transitions are spin-forbidden: this may be the reason for the lack of publications describing optical investigations of manganese zeolites.

On the other hand, a considerable volume of work on these zeolites using EPR has been published. The reason may be that in weak ligand fields the ^6S level of the Mn^{2+} ion has no closely spaced excited states, and therefore the EPR signals can be observed over a wide range of temperature and of ligand field symmetry. The experimental results are interpreted, on the whole, with the help of the theoretical concepts developed by Bleaney and Rubins [36–38]. However, the spectra of polycrystalline samples are very difficult to interpret: although the EPR spectra of Mn^{2+} ions retain their fine structure in weakly distorted octahedral and tetrahedral ligand fields, powders usually show only the ±1/2 transition because the strong angular dependence of the lines corresponding to the residual transitions give rise to fine structure. At low D values ($D/g\beta H \ll 1$), typical of the Mn^{2+} ion, the position of the lines corresponding to this transition is insensitive to the symmetry of the ligand field, and only the shape and width of some of the components of the hyperfine structure are affected (as a result of second-order effects) by changes in the surroundings of the ion. However, the hyperfine parameters, which are easily observed for the Mn^{2+} ion, are determined essentially by the degree of covalency of the bonds between the central ion and the ligands, and to a much lesser extent by the symmetry of the surroundings.

The first attempt to investigate zeolites of types X and Y containing Mn^{2+} ions by the EPR method was made by Ursu and Nicula [39] in 1964. These workers found that the resolution of the hyperfine structure of EPR spectra measured at 9 300 MHz depended on the high-temperature dehydration treatment to which the sample had been exposed. The effect was ascribed to changes in ligand-field symmetry arising from the removal of water molecules, but no attempt was made to propose a concrete model of the location of the ions in the zeolite structure.

The next series of publications, also involving EPR measurements at 9 300 MHz, was due to Barry and Lay [33,40,41]. These workers studied zeolites of types X and Y containing manganese ions in combination with the diamagnetic ions Li^+, Na^+, K^+, Cs^+, Mg^{2+}, Ca^{2+}, Zn^{2+}, and La^{3+}. Using the Mn^{2+} ions as a "paramagnetic probe", they tried to explain some features of the distribution, in zeolites, of cations devoid of paramagnetism.

The complex and poorly resolved experimental spectra, varying with sample treatment, were ascribed to Mn^{2+} ions in different states, giving rise to their individual spectra with the following parameters:

A: $g = 2.000$; $A = 97 \pm 3.5$ G;
I: $g = 2.001$; $A = 95 \pm 1.5$ G; $D = 54 \pm 18$ G;
II: $g = 2.001$; $A = 95 \pm 1.5$ G; $D = 131 \pm 3.5$ G (occasionally $D = 100$ G);
(*i*): $g = 1.996$; $A = 76.5 \pm 2$ G; $D = 65 \pm 35$ G
(*ii*): $g = 1.995$; $A = 88.5 \pm 3$G; $D < 130$G.

The states were assigned by the authors as follows: *A*—hydrated $(Mn \cdot nH_2O)^{2+}$ ions; I—Mn^{2+} ions localised on *SI* sites; II—Mn^{2+} ions localised on *SI'*, *SII'*, or *SII* sites; (*i*), (*ii*)—Mn^{2+} ions localised on *SI'* sites with a strong covalent bond to hydroxyl (OH^-) or O^{2-} ions respectively.

However, none of the spectra (with the exception of the hydrated sample) was observed in a pure form, and the spectral assignments to manganese ions in different lattice positions are not entirely convincing because they are not supported by serious arguments based on the structure of the paramagnetic centres. For example, the observed D values vary between 0.50×10^{-2} and 1.3×10^{-2} cm^{-1} and therefore correspond to a weakly distorted cubic field: they can hardly be quoted as evidence for any particular mode of stabilisation of the Mn^{2+} ion. The hyperfine coupling constants also did not vary over a wide range, with the exception of spectrum (*i*), ascribed to tetrahedral Mn^{2+} ions containing a hydroxyl group in the coordination sphere. Lastly, Barry and Lay's interpretation was not confirmed by the more recent work of Tikhomirova and coworkers [42] at a frequency of 35 000 MHz.

Because of the EPR spectrum of Mn^{2+} ions in a low-symmetry ligand field is greatly complicated by second-order effects, resulting in overlap of the hyperfine components and in the appearance of nuclear-spin-forbidden transitions, these workers carried out their measurements in an apparatus working at a shorter wave-length. They showed[42] that by working at a higher frequency ($\lambda \simeq 8$ mm, $\nu \simeq 37\,500$ MHz) the EPR spectra of Mn^{2+} ions in hydrated MnNaA, MnNaX, and MnNaY zeolites become much simpler and consist of well resolved sextets. From the intensity ratios of forbidden and allowed transitions they obtained a D value close to 106 G. They subsequently published a more detailed study of the behaviour of Mn^{2+} ions in the sodium forms of A, X, and Y zeolites during dehydration and adsorption of water vapour[43,44]. However, their conclusions rely exclusively on changes in the hyperfine coupling constants of the EPR spectra.

Since the EPR spectra of the Mn^{2+} ions in the initial samples of A, X, and Y zeolites have parameters almost identical to those of the EPR spectra of aqueous solutions ($A = 96$ G), the authors assume that the Mn^{2+} ions in this case are present in the form of aquo complexes. Dehydration at temperatures up to 150° gives EPR spectra with a hyperfine splitting constant of 87 G for all types of zeolite, which is ascribed to partially dehydrated Mn^{2+} ions. It is also pointed out that the electronic state of partially dehydrated Mn^{2+} ions is unaffected by the charge on the zeolite lattice or by the geometry of its framework.

If the dehydration temperature is raised above 150°, three types of spectrum are observed in X and Y zeolites ($A = 99$ G, $g = 2.000$; $A = 87$ G, $g = 2.000$; $A = 87$ G, $g = 2.007$), and two types of spectrum in type A zeolite ($A = 87$ G, $g = 2.000$; $A = 73$ G, $g = 2.000$). After dehydration at 300–400°, X and Y zeolites give only one EPR signal ($A = 99$ G, $g = 2.000$), and the spectra of type-A zeolites remain practically unchanged. The authors point out that the total intensity of all the spectra for a given sample remains constant.

By analogy with the interpretation of the spectra of Mn^{2+} ions in spinels[45], it is suggested that the EPR signal in a type-A zeolite with a hyperfine splitting of 73 G arises from ions localised in the neighbourhood of a six-membered oxygen ring and on the side of a small hole (site *SII'*, see Fig. 2), within which a residual water molecule is assumed to remain even after high-temperature vacuum treatment. In this case, the Mn^{2+} ion is tetrahedrally surrounded by oxygen atoms from the lattice (at 3 corners) and water (at 1 corner). This interpretation, with the Mn^{2+} ion in an *SII'* site rather than an *SII* site, is supported by the observation that water vapour adsorption must be carried out at a relatively high temperature (~ 80°) in order to reproduce the EPR spectrum with a splitting of 87 G characteristic of the partially hydrated Mn^{2+} ion.

The EPR spectra of fully dehydrated X and Y zeolites, with a hyperfine splitting of 99 G, are assigned to Mn^{2+} ions in *SI* sites, where the ligand field is octahedral. An alternative explanation is also discussed: localisation of Mn^{2+} within a small zeolite hole, since the adsorption of water and ammonia vapour gradually yields EPR spectra corresponding to the fully hydrated initial samples.

No attempt was made to interpret the EPR spectrum of Mn^{2+} ions with a splitting of 87 G and a g-factor of 2.007.

The results obtained for MnNaY zeolites by Barry and Lay are compared with those of Tikhomirova and coworkers in Table 5. Except for the data relating to the initial samples, substantial differences in experimental results and in their interpretation are evident. The discrepancy is due partly to differences in dehydration conditions, and partly to incorrect treatment of the results obtained at 9 300 MHz from poorly resolved spectra. However, the remaining doubt will not be fully removed until EPR measurements are carried out at both radio frequencies simultaneously, under standard conditions of heat treatment and with standard control of the residual water.

It may be concluded from the above review of published EPR work on synthetic zeolites containing bivalent manganese ions that the existence of Mn^{2+} in various states within the zeolite structure has been proved beyond doubt. However, because of the spectroscopic peculiarities of this ion, the detailed interpretation of the results is still tentative.

Table 5. Results obtained by different workers for type-Y zeolites containing Mn^{2+} ions.

	Initial	Partly dehydrated	Fully hydrated	References

Iron. The electronic configuration of the ground state of the free iron atom is $[A](3d)^6(4s)^2$. Tervalent iron ions can give rise to EPR spectra. However, we have been unable to find any reference to structural studies of zeolites containing ferric ions by EPR or by optical spectroscopy. Such zeolites have been synthesised, and are being intensively studied by gamma-resonance spectroscopy[46–50]. The main results, formulated by Delgass and coworkers[50], indicate that the Fe^{2+} cations in dehydrated type-Y zeolite are in a high-spin state, and occupy two types of site: *SI* (inaccessible to adsorbed molecules) and *SII* (accessible to adsorbed molecules). It is shown[44] that zeolites of types X and A are broken down by the introduction of iron ions.

The absence of EPR studies is probably due to the complexity of the EPR spectra of Fe^{2+} and Fe^{3+} ions in surroundings of low symmetry, making interpretation impossible without a special theoretical study. Not the least of the difficulties is the presence of iron impurities in the sodium forms of zeolites even before exchange, already mentioned above, which complicates the application of EPR to these systems[33]. It should not be concluded, however, that the EPR method will not be used in future to study zeolites containing iron ions.

Difficulties may arise also in the interpretation of the optical spectra of zeolites containing Fe^{3+} ions. Having an electronic structure similar to that of the Mn^{2+} ion, the Fe^{3+} ion gives strong charge-transfer bands in the near u.v. region (see Ref. 51, p. 276), with fairly strong "shoulders" in the visible region of the spectrum which tend to mask the weak, spin-forbidden d–d transitions. Optical studies of zeolites containing Fe^{2+} $(3d)^6$ ions could give very interesting results, but the d–d transitions for

the high-spin Fe^{2+} ion lie in the near i.r. region: the $^5T_{2g} \rightarrow {}^5E_g$ transition for the hexaquo Fe^{2+} ion is observed at ~ 10 000 cm^{-1} (p. 271 of Ref. 51).

Cobalt. The electronic configuration of the ground state of the free cobalt atom is $[A](3d)^7(4s)^2$. Only zeolites containing bivalent cobalt ions have so far been synthesised and investigated.

There are many references in the literature to the splitting of the energy levels of the bivalent cobalt ion, and to its magnetic properties, in the weak ligand fields corresponding to a distorted octahedron (see, for example, Ref. 52). We shall therefore confine this review to a qualitative discussion of the optical and magnetic properties of the Co^{2+} ion in weak ligand fields of symmetry C_{3v} and C_{3v} tetr. In these cases the ground state of the Co^{2+} ion ($S = 3/2$) is described by a wave function with an angular component which gives rise to an irreducible representation A_1 of the group C_{3v} (see Table 3 and Figs. 5*b* and 5*c*). Since the transitions between the levels of the split ^4F level lie in the i.r. region and are relatively weak, only the strong transition to the excited ^4P level is usually observed in the optical spectrum (see, for example, Ref. 51). Changes in ligand-field symmetry from a tetrahedron compressed along the trigonal axis to an extended tetrahedron, a trigonal pyramid, of a planar triangle should not significantly affect the spectral position of this optical transition, since the main contribution to its energy comes from the energy difference between the ground ^4F level and the excited ^4P level of the free Co^{2+} ion.

However, fairly substantial changes in the EPR spectra can be expected to result from these changes in ligand field. Table 4 shows the results of an analysis of the expressions for the g and D tensors of the Co^{2+} ion in fields of T_d, C_{3v} tetr, C_{3v} pyram, and D_{3h} symmetry, and also lists the spin ground states in a zero magnetic field.

In a tetrahedron compressed along the trigonal axis the constant D for this interaction is negative for the Co^{2+} ion (see Table 4). Since the EPR signals of Co^{2+} are usually observed at $T = 4.2°K$ ($kT \simeq 3$ cm^{-1}) because of the short relaxation times, the population of the $\pm 1/2$ spin doublet, which gives rise to the EPR signal, can be very small for $D < 0$ and $|D| \gg kT$. Hence it is obvious that the EPR signals of polycrystalline samples are difficult to observe when the surroundings of the Co^{2+} ion correspond to a tetrahedron highly compressed along the trigonal axis ($D < 0$). For example, Owen and Bowers[53] find $D = -4.5$ cm^{-1}, so that the population of the $s = \pm 1/2$ spin doublet is only $-2|D|/ekT \simeq 0.05$. Little gain in the intensity of the EPR signal can be expected from carrying out the measurement at liquid-nitrogen temperature, because the 10-fold increase in the population of the $\pm 1/2$ doublet (to 0.5) is compensated by a decrease in the difference of the populations within the doublet by a factor of $77°/2.4° = 18$. Line broadening may also appear as a result of relaxation.

On changing from compression to extension of the tetrahedron along the trigonal axis the hyperfine interaction constant changes sign, and remains positive throughout further changes in the coordination of the ion (up to the coordination of a planar triangle). Under these conditions the population of the $\pm 1/2$ spin doublet is close to 1: evidently, this should lead to a sharp increase in the strength of the EPR signal as compared with the case discussed above.

It follows that differences in the relative intensity of the EPR spectra of Co^{2+} ions in different samples can be used as a criterion of the presence of distortions in the tetrahedral ligand field, which (as stated above) do not materially affect the optical properties.

The position of the components of the fine structure of EPR spectra for a spin of 3/2 and $|D| \gg g\beta H$ has been fully discussed[54].

The most significant structural data on cobalt-containing zeolites, published up to 1970, were obtained by optical reflectance spectroscopy in the visible and near u.v. regions of the spectrum.

It has been shown[55] that the adsorption of substances such as H_2O, NH_3, CH_3OH, etc. on dehydrated CoNaA zeolites is accompanied by a colour change, which suggests that molecules of these compounds can enter the coordination sphere of Co^{2+} ions.

A recent paper by Klier[56] shows, on the basis of optical data, that the Co^{2+} ion in dehydrated type-A zeolite is localised in the plane of the six-membered oxygen window, whereas after adsorption of N_2O molecules its coordination increases to the tetrahedral configuration. Klier stresses the reversibility of this process upon outgassing the sample at 50°, but at 150° the nitrous oxide decomposes catalytically into molecular nitrogen and oxygen.

Barry and Lay[41] observed, in their study by reflection spectroscopy of CoNa13X zeolite dehydrated at 300°, that the Co^{2+} ions are located in a tetrahedral ligand field. Hence they suggested that the ions are localised in *SI'* sites in this zeolite. Three of the planar ligands are lattice oxygen atoms, and the fourth ligand is a residual water fragment (OH^- or O^{2-}). It is not clear, however, why *SI'* sites are chosen in preference to *SII'* or *SII* sites, since measurements of the specific adsorption of nitrous oxide[40] have shown that the Co^{2+} ions can be localised also in sites accessible to the molecules of adsorbate.

Until recently there were no published references to EPR studies of cobalt-containing zeolites, evidently because of the need to work at liquid-helium temperatures. We have recently reported[57] an investigation of this type on X and Y zeolites, carried out in cooperation with Brotikovskii. Since no significant difference could be found between the spectra (either optical, or ESR) of these two types, we shall confine the following discussion to the results obtained for the zeolite of type Y.

EPR and optical spectra were recorded before and after dehydration by vacuum baking. (The dehydration–rehydration cycle was found to be fully reversible.) The spectra were practically identical to those of aqueous solutions of Co^{2+} salts, suggesting that the cobalt ions after exchange (and rehydration) exist as $[Co(H_2O)_6]^{2+}$ aquo-complexes, located in large zeolite holes.

Vacuum baking at 100° removes only some of the water from the zeolite, and the Co^{2+} ions retain their hexaquo coordination. This is confirmed by the optical reflectance spectra, in which the absorption bands are only slightly displaced towards the red (from 19 000 to 17 000 cm^{-1}), with a somewhat increased intensity, after vacuum baking.

Dehydration at 200–500° produces a blue colour in the samples, characteristic of the tetrahedral compounds of bivalent cobalt, and strong, overlapping bands appear in the optical spectra at 18 500, 17 000, and 15 100 cm^{-1}. Since, as already stated, the position of these bands is relatively insensitive to distortions of the tetrahedral surroundings of Co^{2+}, it is not easy to assign the localisation of the cobalt ions to *SI'*, *SII'*, or *SII* sites.

On the other hand, we can deduce from the EPR spectra of samples dehydrated at 200–500° that after this treatment the Co^{2+} ions exist in two different states within the zeolite. For dehydration temperatures of 200–350° they

lie on SII sites, with the coordination of a tetrahedron compressed along its trigonal axis. The fourth (axial) ligand is assumed to consist of residual water molecules or water fragments (OH^- or O^{2-}). As stated above, polycrystalline samples may fail to give an EPR signal under these conditions because the ±1/2 spin doublet is lightly populated ($D < 0$). The EPR signal disappears completely[57], and reappears ($g_\parallel \simeq 2.00$; $g_\perp \simeq 2.75$) only after heating the sample at higher temperatures (400–500°). We have ascribed the spectra observed under these conditions to Co^{2+} ions localised in the plane of the six-membered oxygen window (between SII′ and SII sites). As Table 4 shows, $g_\parallel$ should be approximately 2 in this case, and $g_\perp > 2$, as observed experimentally. We have not considered the possibility of localisation of Co^{2+} ions in SI′ sites, because the adsorption of tertiary pentanol molecules on a dehydrated sample is known to alter the EPR spectrum, suggesting that quite large molecules can enter the coordination sphere of the Co^{2+} ion.

Summing up all that has been said on zeolites containing Co^{2+} ions, we stress that these cations can be introduced by exchange into zeolites of type X and Y in the form of octahedral aquo-complexes $[Co(H_2O)_6]^{2+}$, which "float" in the large holes of the zeolite lattice. As the samples are dehydrated, the cobalt ions are transferred initially to SII sites, where they retain a water molecule or fragment (OH^- or O^{2-}) in the first coordination sphere, and finally to the six-membered windows of the sodalite cells, where they remain accessible to adsorption of various molecules.

In conclusion, we note that Co^{2+} ions can be reduced if the host zeolite is dehydrated under reducing conditions. Thus, reproducible results on water adsorption at room temperature can be obtained only if the sample is carefully protected from the vapours of vacuum grease and other organic materials[57].

Nickel. The electronic configuration of the ground state of the free nickel atom is $[A](3d)^8(4s)^2$. One of the first papers describing optical and EPR studies of nickel-containing X and Y zeolites is due to Rabo and coworkers[58], who used EPR to observe the Ni^{1+} ion (electronic structure $[A](3d)^9$), obtained by reducing the samples in alkali metal vapours or in hydrogen, and also the signal from ferromagnetic metallic nickel. On the assumption that reduction of the ions does not cause them to migrate to new sites, the authors conclude that for 5–75% exchange of Na^+ by Ni^{2+} ions in dehydrated X and Y zeolites the ions occupy SII as well as SI sites. The EPR spectrum with $g_\parallel = 2.30 + 2.40$ and $g_\perp = 2.096$ is ascribed to Ni^{1+} cations localised in SI sites, and the spectrum with $g_\parallel = 2.10 + 2.13$ and $g_\perp = 2.065$ to Ni^{1+} in SII sites. Optical data were used to give a theoretical interpretation of the g-tensor values obtained from the EPR spectra. A wide absorption band at 450 nm was ascribed to Ni^{2+} ions in SII sites, and a band at 650 nm ($^2E_g \rightarrow {}^2T_g$ transition) was ascribed to Ni^{1+} ions in SII sites. The spin–orbital interaction constant found by comparing EPR and optical results was 500 cm^{-1}, in good agreement with the value for the free Ni^{1+} ion ($\lambda = 600$ cm^{-1}).

Adsorption experiments with oxygen, carbon monoxide, hydrogen, and ammonia on reduced forms of nickel zeolite have shown that Ni^{1+} ions localised on SII sites interact most strongly with adsorbed molecules, but at high temperatures the Ni^{1+} ions on SI sites also take part in the reaction $Ni^{1+} + O_2 \rightarrow Ni^{2+} + O_2^-$ during oxygen adsorption.

Olson[59] was able to confirm these conclusions by X-ray diffraction methods in his study of natural faujasite containing nickel ions ($SiO_2/Al_2O_3 = 4.6$). He found the following distribution of Ni^{2+} ions in the elementary cell of the mineral:

Site	SI	SI′	SII′	SII	SI′ + water fragment	SII′ + water fragment
Amount	10.5	3.2	2.0	6.5	5.8	2.9

From these data it was concluded that the results of X-ray diffraction analyses of zeolites in their calcium form cannot be applied automatically to zeolites containing transition-metal ions. Thus, whereas the preferred sites for alkaline-earth cations in the zeolite structure are the SI sites[60,61], and the preferred sites for rare-earth cations are the SI′ sites[31], transition-metal cations can be localised in other sites of the zeolite lattice even at low extents of exchange.

Detailed optical studies of type-A zeolite containing bivalent nickel ions have been reported by Polák and Černý[62] and Klier and Ralek[63]. The former have made computer calculations, using ligand-field theory, of the electronic spectra of ions with the $(3d)^{2,8}$ electronic configuration in a crystal field with D_{3h} symmetry. The latter workers used these theoretical calculations to analyse the diffuse reflectance spectra of NiNaA zeolites degassed at different temperatures.

They showed that in a fully hydrated zeolite the bivalent nickel ions are present as the $[Ni(H_2O)_6]^{2+}$ hexaquo complex, as shown by the almost exact correspondence of their spectra with those of aqueous solutions of nickel salts.

In partly dehydrated zeolites the Ni^{2+} ions retain approximately one molecule of water in their first coordination sphere, and they become firmly bonded to the zeolite lattice—probably in SII sites—thereby acquiring distorted tetrahedral surroundings. However, the observed optical spectra did not show the characteristic absorption maxima of tetrahedral nickel at 600–700 nm (see Ref. 51, p. 301). Further dehydration causes complete removal of the water, and the Ni^{2+} cations become localised in the plane of the six-membered oxygen window of the zeolite lattice, as shown by the good agreement between the observed and the theoretically calculated optical spectrum.

Studies were made also of the adsorption of nitric oxide, cyclopropane, ethylene, propene, and acetylene on dehydrated zeolite, and it was concluded that the process is monocentric and (with the exception of acetylene) reversible. It is assumed that the nickel cation completes its coordination sphere in the form of a trigonally distorted tetrahedron.

It has been shown by X-ray diffraction analysis[64] and by magnetostatic and ferromagnetic resonance methods[65] that Ni^{2+} ions are reduced to metallic nickel by treatment of the zeolite in a reducing atmosphere, forming microcrystals approximately 100 Å in size on the surface of zeolite single crystals.

Copper. The electronic configuration of the ground state of the free copper atom is $[A](3d)^9(4s)^2$. Many papers have been written on EPR studies of zeolites containing bivalent copper cations. Cu^{2+} ions, having the $(3d)^9$ electronic configuration (nuclear spin 3/2), give very sharp EPR spectra in magnetically dilute systems: the parameters of these spectra depend sensitively on the symmetry of the immediate surroundings of the ion. The isotropic and anisotropic hyperfine interaction constants, g-tensor components, and temperature dependence of the spectrum can often be used to determine not only the coordination of the Cu^{2+} ion, but also the percentage

covalency of the bond in the complex, and also the type of motion of the complex as a whole. Hence, zeolites containing Cu^{2+} ions are specially interesting to research workers.

We shall first of all consider some optical and magnetic properties of the Cu^{2+} ion in ligand fields with C_{3v}, C_{4v}, and D_{3h} symmetry in the light of the above calculations.

As Fig. 4*a* shows, the ground state of the Cu^{2+} ion in ligand fields with O_h symmetry is doubly degenerate, and therefore the three possible d–d transitions in the optical spectra merge into one. When the octahedron is stretched along the tetrad axis we expect (see Fig. 4*a*, $\eta < 2$, $\xi = 1$) the observed absorption band to split into two, one band remaining in its original position ($B_1 \rightarrow B_2$) and two other bands appearing at shorter wavelengths ($B_1 \rightarrow E$). In a compressed octahedron, as shown in Fig. 4*a*, the splitting of the absorption band is accompanied by a shift of all three maxima towards the short-wave end of the spectrum.

We shall now turn to the changes in the EPR spectra arising from these distortions. Octahedral complexes of Cu^{2+} ions, when subjected to a weak tetragonal distortion corresponding to stretching of the octahedron, are known to give EPR spectra whose parameters are described by the expressions

$$g_{\parallel} = 2 + \frac{8\lambda}{\Delta_{B_1B_2}}; \quad g_{\perp} = 2 + \frac{2\lambda}{\Delta_{B_1E}} \quad (\text{where: } \lambda > 0,\ \Delta_{ij} > 0).$$

Obviously, in a weakly stretched octahedron $\Delta_{B_1B_2} \simeq \Delta_{B_1E}$, and therefore $\Delta g_{\parallel}/\Delta g_{\perp} \simeq 4$. As Fig. 4*a* shows, the transition from a weakly stretched octahedron to a square pyramid or to a square plane does not affect $\Delta_{B_1B_2}$, but since Δ_{B_1E} increases, the ratio $\Delta g_{\parallel}/\Delta g_{\perp}$ must also increase.

Transition from an octahedron stretched along the tetrad axis to a compressed octahedron leads to the following expressions for the components of the g-factor: $g_{\parallel} = 2$; $g_{\perp} = 2 + 6\lambda/\Delta_{A_1E}$, and therefore the EPR spectrum should become inverted, since the perpendicular component of the spectrum now finds itself at a smaller field than the parallel component.

It is evident from Fig. 4*b* and 4*c* that the ground state of the Cu^{2+} ion is not orbitally degenerate in a compressed trigonal bipyramid or in a tetrahedron compressed along the trigonal axis (the expressions for the g-factors are given in Table 4).

We should stress that in this case, as in the case of a field with the symmetry of a compressed octahedron, the perpendicular component of the EPR spectrum experiences weaker fields ($g_{\perp} > 2$) than the parallel component ($g_{\parallel} = 2$). This is because the electronic ground level in both cases is described by a wave function with an angular component Y_2^0.

In fields with the symmetry of a stretched pyramid or of a tetrahedron stretched along the trigonal axis the ground level of the Cu^{2+} ion becomes doubly orbitally degenerate (see Figs. 4*b* and 4*c*). The angular parts of the wave functions corresponding to this doublet can be written in the following general form (see Table 4):

$$\psi_1 = \alpha Y_2^2 - \beta Y_2^{-1},$$

$$\psi_2 = \alpha Y_2^{-2} + \beta Y_2^1, \text{where: } 1 \leqslant \alpha < \sqrt{\frac{2}{3}},\ \alpha^2 + \beta^2 = 1.$$

The spin-Hamiltonian which describes the behaviour of the system allowing for spin–orbital interaction and interaction with a magnetic field can be written

$$\mathcal{H} = \lambda \mathbf{LS} + \beta(\mathbf{L} + 2\mathbf{S})\mathbf{H}, \quad S = {}^1/_2.$$

Since these interactions are much smaller than the interactions between the electrons and the ligand field, they can be calculated by perturbation theory. By applying this theory, and noting that λ is negative for the Cu^{2+} ion, it is readily shown that the orbital doublet is split into two doublets by the spin–orbital interaction, and that their behaviour in a magnetic field H is described by a spin-Hamiltonian of the form

$$\mathcal{H}_{sp} = g_{\parallel}\beta H_z S_z + g_{\perp}\beta(H_x S_x + H_y S_y)$$

where, according to first-order perturbation theory, $g_{\perp} = 0$ and $g_{\parallel} = 6\alpha^2\epsilon(6, 4)$ for the lower doublet and $g_{\perp} = 0$ and $g_{\parallel} = 4 - 6\alpha^2\epsilon(0, -2)$ for the upper doublet.

Obviously, $g_{\perp}$ will be different from zero in the higher orders of perturbation theory, but it will not be large, and since the strongest perpendicular component of the EPR spectrum occurs at very high fields for low values of $g_{\perp}$, the EPR spectra of copper ions may be impossible to observe.

We shall now review the results obtained by EPR and optical spectroscopy for zeolites containing Cu^{2+} ions.

Faber and Rogers [66] were the first to report EPR spectra from Cu^{2+} ions in zeolites. They made a theoretical analysis of the hyperfine interaction constants and the g-tensor components of the EPR spectra of fully hydrated and ammonia-saturated zeolites containing Cu^{2+} ions, and they obtained data on the degree of covalency of the bond in the complexes. However, no attempt was made to identify the structure of the zeolite, evidently because the problem had not yet been formulated at the time.

Nicula and coworkers [67] studied the hydrated, partially dehydrated, and fully dehydrated forms of CuNaY zeolite. From an analysis of the spin-Hamiltonian constants, and of the temperature dependence of the EPR spectra, they showed that the copper ions in the hydrated zeolite "float" in the large holes as the hexaquo complexes.

Unlike Polák and Cerný [62], Nicula and coworkers were able to observe hyperfine splitting in partly and fully dehydrated zeolites in perpendicular as well as in parallel orientations. Using experimental spin-Hamiltonian parameters, and theoretical expressions for a tetragonal ligand field with allowance for covalent bonding [68,69], they tried to explain the observed gradual change in the spin-Hamiltonian parameters in terms of changes in the degree of covalency of σ and π bonds in the complex upon replacing water ligands by lattice oxygen atoms. This explanation is well substantiated for tetragonally distorted, octahedral Cu^{2+} complexes, but (as will be shown later) the spin-Hamiltonian parameters do not vary smoothly in practice.

These workers point out that all the observed changes in EPR spectra are reversible only in type-Y zeolites, and hence they conclude that copper-containing zeolites of type X are decomposed by vacuum heat treatment.

In this paper, also, no attempt is made to "associate" the dehydrated copper cations with any specific site in the zeolite lattice.

Richardson [70–72] has published a series of three papers devoted to an EPR study of the localisation of copper ions in type-Y zeolites containing cations of various non-paramagnetic metals. He observed EPR spectra with parameters similar to those reported by Nicula and coworkers [67], and attempted to relate them to changes in coordination of the Cu^{2+} ion during dehydration of the zeolite. However, Richardson bases all his arguments on expressions for the spin-Hamiltonian parameters of the Cu^{2+} ion in a field with C_{4v} symmetry, and tries to assign

all the observed EPR spectra for hydrated and for dehydrated samples to copper ions localised in *SII* sites, where (as stated above) the ligand field has D_{3h} symmetry (dehydrated ion) or C_{3v} symmetry (ion in an *SII* site with 1 molecule of water of hydration). Clearly, an ion on an *SII* site can have trigonally distorted octahedral surroundings only by the adsorption of three water molecules, but Richardson ignores this possibility.

Krüerke and Jung[73] also published an EPR study of copper-containing X and Y zeolites. However, their results for type-X zeolites containing copper cations should be viewed with extreme caution, since considerable doubt exists on the stability of this zeolite lattice[67].

They studied the intensity of EPR signals from samples with a high copper content (~ 20 Cu^{2+} ions per elementary cell of the zeolite) as a function of the temperature of vacuum heat treatment, and also after adsorption of water and ammonia molecules, and they showed that the intensity of the EPR signal from a fully hydrated sample does not correspond to the analytically determined concentration of copper ions. The plot of intensity of the EPR signal against dehydration temperature had a distinct minimum at 150° (~ 50% of the initial intensity). Further increase in dehydration temperature caused the signal to increase, reaching 80% of the initial intensity at 350°, but at still higher temperatures the signal once again fell off. The dehydration process was found to be reversible.

On the incorrect assumption (see above) that these large changes in the integral intensity of the EPR signal cannot be due to changes in the configuration of the ligand field close to the site of the copper cation, Krüerke and Jung explain the decreased intensity of the EPR signals during dehydration by postulating the formation of cation pairs ($S = 0.1$) in *SI'* sites of the small holes in the sodalite cell, joined by hydrogen bridges.

The increased intensity of the EPR signal on further raising the dehydration temperature was ascribed to the removal of residual water molecules, resulting in migration of the copper cations to *SI* sites and dissociation of the cation pairs.

The subsequent decrease in the intensity of the EPR signal, at dehydration temperatures above 350°, is ascribed to irreversible changes in the zeolite structure.

The most interesting of Krüerke and Jung's results were obtained with samples containing less than 8 Cu^{2+} cations per elementary cell. By analysing the shape of the absorption line they were able to establish that the parameters of the EPR spectra change in discrete jumps rather than continuously during partial dehydration of the zeolite, and they showed that two types of copper ions are present, giving EPR spectra with the following parameters:

$$\text{I}-g_{\parallel}=2.35,\ g_{\perp}=2.06,\ A=120\ \text{Oe};$$
$$\text{II}-g_{\parallel}=2.31,\ g_{\perp}=2.06,\ A=175\ \text{Oe}.$$

The difference between the two sets of parameters is ascribed to the existence of two possible localisation sites for Cu^{2+} ions in the zeolite, with different arrangements of nearest neighbours.

Another interesting result is the gradual decrease in total intensity of the EPR signal with increase of dehydration temperature. Krüerke and Jung admit that the ideas which they had developed for zeolites with high copper concentrations cannot be applied directly to low-concentration samples, since ion-pair formation is not likely to be significant at low concentrations.

In this context it is relevant to note that Tikhomirova and Nikolaeva[74] also proposed a non-uniform distribution of cations in the zeolite and the presence of sites with a high concentration of cations from an analysis of the individual components of the EPR spectra and their temperature dependence. However, their results relate to type-A zeolites, containing low concentrations of Cu^{2+} and Mn^{2+}.

Almost at the same time as Krüerke and Jung, Slot and Verbeck published an EPR study of zeolites (type Y) containing approximately 15 Mg^{2+}, Zn^{2+}, or La^{3+} ions and 0.3 Cu^{2+} ions per elementary cell[75]. They examined only partly or fully dehydrated samples, and they also observed two types of copper cation, with EPR spectral parameters identical to those obtained elsewhere[72,73]. From measurements of relative spectral intensities for different heat treatments they concluded that dehydration is accompanied by the gradual migration of Cu^{2+} ions into the bulk of the zeolite. They propose two explanations for the constancy of the parameters of individual EPR spectra: 1) copper ions penetrate into the interior when they are replaced (by ion exchange) by hydrated ions, and they retain their coordination when the water is removed; 2) copper ions are partly or fully dehydrated at temperatures as low as 110°, and their state is unchanged when the dehydration temperature is further increased. In both cases the migrating species are thought to be copper complexes.

The former explanation does not stand up to critical examination, since heat treatment at 400° for 72 h in an oxygen atmosphere (as in Slot and Verbeck's experiments) is known to cause practically complete dehydration of the zeolite (see, for example, Ref. 70). The second explanation seems more convincing, but it can be shown by thermal analysis (see below) that the bulk of the water is removed only at temperatures of the order of 200–300°, and therefore it is hard to accept that the coordination sphere of the copper ions is broken down at a temperature as low as 110°, and that all subsequent changes in the EPR spectrum are to be ascribed only to migration of the ions.

Slot and Verbeck ascribe the difference between the parameters of their two EPR spectra to the existence of two types of localisation sites for the ions (*SI* and *SII*). They also point out that cation migration is strongly influenced by the main cation of the zeolite.

Summarising the published results, we may conclude that for copper zeolites (unlike manganese zeolites) there is acceptable agreement between the data from different laboratories. However, contradictions are apparent in the interpretation of the results. Most workers ascribe to Cu^{2+} ions in *SI'*, *SII'*, or *SII* sites (C_{3v} tetr or C_{3v} pyram symmetry) experimental EPR spectra which clearly correspond to copper ions in ligand fields with C_{4v} symmetry. In this context, we may discuss some results obtained by the writers (in collaboration with Shvets and Pecherskaya) by EPR and optical reflection spectroscopy[76,77].

The initial samples were prepared by cation exchange of Y-zeolite in the sodium form in a solution of copper acetate, and contained 2–4 Cu^{2+} ions per elementary cell.

With hydrated samples, the results were almost identical to those previously discussed. The conclusion that in fully hydrated zeolites the copper ions are accommodated in the large holes as hexaquo complexes was confirmed by optical measurements.

In partly dehydrated (100–300°) zeolites EPR signals of two types (I and II) have also been detected. Their parameters are practically identical to those reported by other workers (signal I: $g_{\parallel} = 2.38$, $g_{\perp} = 2.08$, $A = 126$ Oe; signal II: $g_{\parallel} = 2.32$, $g_{\perp} = 2.05$, $A = 162$, $B = 22$ Oe). The optical spectra of these samples showed enhanced

optical absorption in the region 400–800 nm. On raising the dehydration temperature the relative intensity of signal II (which is absent in the EPR spectra of initial or hydrated samples, where only signals of type I can be observed) increases, and the total intensity of the EPR spectrum decreases (by a factor of 10–20 for samples fully dehydrated at 500°).

These effects were interpreted as follows[72]. The type-I EPR spectrum and the optical spectrum of a fully hydrated zeolite, consisting of one broad maximum at 800 nm, are assigned to the Cu^{2+} ion surrounded by 6 water molecules. The EPR signal of the second type is assigned to Cu^{2+} ions in a square pyramidal or a plane square coordination. This is shown by the fact that, whereas the general structure of the EPR spectrum is retained, both the ratio $\Delta g_{\parallel}/\Delta g_{\perp}$ and the optical absorption at wavelengths shorter than those for the $[Cu(H_2O)_6]^{2+}$ complex are increased. Cu^{2+} ions in these coordinations are fairly strongly bound to the zeolite lattice (apparently in SIII sites), since, in contrast to hydrated samples, their EPR spectra are the same at room temperature and at liquid nitrogen temperature.

The strong reduction in the integral intensity of the EPR signals for vacuum heat-treatment temperatures of 400 to 500° can be explained in two ways: a change in the valency state of the Cu^{2+} ions (e.g. reduction to Cu^{1+}), or a very strong broadening of the EPR lines resulting from a change in coordination. The latter explanation is the more plausible, because the initial EPR spectra can be regenerated by water adsorption at room temperature but not by heating the dehydrated samples in an oxygen atmosphere. The Cu^{2+} ions in a dehydrated zeolite are assumed to occupy sites in the planar six-membered windows of the sodalite cells of the zeolite. As stated above, the ions in these sites experience an electrical ligand field with the symmetry of a planar triangle. Under these conditions it may not be possible to observe EPR signals, because $g_{\perp}$ differs very little from zero. Relaxation may also cause broadening of the EPR line, but measurements at 4.2°K failed to reveal a new signal in the EPR spectrum.

Two papers appeared while this review was in manuscript[78,79]. Gállezot and coworkers[78] showed, by an X-ray analysis of dehydrated Cu(57%)NaY zeolite, that most of the copper ions are located in SI′ sites, where they can interact with adsorbed ammonia and pyridine molecules. The second paper[79] reports an EPR study of Cu(7%)NaY zeolite. The intensity of the spectrum is found to be constant during dehydration, and the fall of intensity observed in the writers' work is ascribed to reduction of the copper ions (as discussed above) or cation-pair formation. The formation of pairs seems improbable, particularly in samples with a low copper content, but a special study of this problem seems desirable, together with a study of the effect of oxygen on the dehydration of copper-containing zeolites.

Copper ions localised in SII sites were found to be accessible to adsorption (at room temperature) of various polar molecules (methanol, ethanol, propanol, and isopropanol)[73]. The ions appear, from EPR measurements, to remain strongly bound to the zeolite lattice near the six-membered oxygen rings (SII sites), but their coordination increases to octahedral. Decomposition of the alcohol complexes of the Cu^{2+} ions in zeolite was found to set in at temperatures of the order of 200°, accompanied by dissociation of the alcohol molecules into hydrogen and acetaldehyde (in the case of ethanol). Catalytic dehydrogenation of alcohol under normal catalytic conditions (accompanied by dehydration[21]) begins at temperatures of this order. Thus, we may conclude that Cu^{2+} ions localised in SII zeolite sites act as active centres for the catalytic decomposition of alcohol into hydrogen and acetaldehyde.

The lack of catalytic activity towards the dehydrogenation of ethanol in calcium and sodium zeolites shows that the electronic structure of the zeolite cation plays an important role in determining the specificity of the catalyst.

In this context, the work of Richardson[70] has yielded some very interesting results. It describes a comparative study, by the EPR method, of the formation of cation-radicals on different forms of zeolites (including copper) on which electron-donor molecules such as anthracene, perylene, pyrene, and naphthalene had been adsorbed. Richardson points out that zeolites containing transition-metal cations, and also cadmium cations, are much more active than other zeolites towards the electron-transfer reactions leading to the formation of cation-radicals, because of the high electron affinity and strong polarising power of these cations.

These results are entirely consistent with those of Neimark and coworkers[80], who showed (from the luminescence spectra of naphthalene adsorbed on different forms of cationated zeolites) that alkali and alkaline-earth metals lead to the formation of charge-transfer complexes between naphthalene and the zeolite lattice, followed by catalytic oxidation of the naphthalene in air to α-naphthaquinone, whereas transition-metal cations produce luminescence quenching, which the authors ascribe to direct adsorption of the naphthalene on the cation (atmospheric oxidation being thus precluded).

Zinc. The electronic configuration of the ground state of the free zinc atom is $[A](3d)^{10}(4s)^2$. Bivalent zinc ions are not paramagnetic, and are inactive in the u.v. and visible regions of the spectrum. Hence, zeolites containing Zn^{2+} ions have not been examined by either of the methods discussed in this review.

---o0o---

It is clear, from this review of the recent literature, that interesting information on the behaviour of ions of the first transition row in synthetic zeolites has been obtained by EPR and optical spectroscopy. Among the specific problems examined are the coordination and valency state of the cations after exchange and after various treatments, the sites on which ions are localised in zeolites, and the mechanism of adsorption of various molecules on these ions. In many cases, catalytically active centres have been unambiguously identified. The results on the coordination state of cations in dehydrated zeolites, and on the changes in coordination resulting from the adsorption of various compounds, are particularly interesting.

For most metals it has been reliably established that the ions enter the zeolite, during cation exchange, in the form of hexaquo complexes, which "float" fairly freely in the large holes of the sodalite cells.

Upon partial removal of the adsorbed water from the zeolite, the transition-metal ions become firmly bound to the zeolite skeleton, retaining their octahedral coordination. This reaction involves the partial replacement of the water in the coordination sphere of the ion by oxygen atoms of the zeolite lattice. Further removal of water from the coordination sphere of the ion begins (depending on the ion) at temperatures in the region of 150–250°, and goes to completion at 350–450°. The coordination of the metal

ions decreases to a square pyramid, or even to a trigonal configuration, after complete dehydration.

Unlike the alkali-metal cations, the bivalent ions of the first transition series can be stabilised in *SII* and *SII'* sites even at low extents of exchange: this effect may be due to the ability of the latter ions to form groupings of the type MOH^+. These trigonally coordinated ions (e.g. copper, cobalt, and nickel) can act as specific adsorption centres for polar molecules of water, ammonia, and alcohols. Tervalent metal ions (e.g. chromium) penetrate deep into the sodalite cell upon dehydration, and become stabilised on *SI'* sites, thus acquiring a more effective screening of their excess of positive charge by virtue of the negative charges on the zeolite lattice. Hence, these ions are relatively inaccessible to large molecules such as alcohols, aldehydes, etc.

We may also conclude from this review that contemporary workers hold conflicting views on the laws which determine the distribution of cations in zeolites. The scarcity of reliable experimental data is undoubtedly responsible for this state of affairs.

The results discussed in this review also show that synthetic zeolites provide a very interesting system for the study of the anomalous coordination states of transition-metal cations introduced into the zeolite by cation exchange. These ions (particularly when doubly charged) act as adsorption centres for a number of molecules; the possibility that the molecules thus coordinated are chemically activated and that the resulting catalytic properties of transition-metal ions can be exploited is a very interesting topic, which lies beyond the scope of the present review.

Structure and Properties of Oxide Halides of Phosphorus and Certain Transition Elements

T.N.Naumova, T.S.Vvedenskaya, and B.D.Stepin

Published information is presented on the structure and the properties of phosphoryl compounds and certain others containing oxo-groups. Modern views on the structure of the phosphoryl group are related to the presence of a σ-bond and also to d_π-p_π interaction between the orbitals of the phosphorus and oxygen atoms; this type of interaction is observed also at other bonds involving phosphorus (P-Hal). Compounds containing oxo-groups exhibit donor properties, forming complexes with acceptor molecules. The general properties of donor-acceptor complex compounds are discussed. A list of 196 references is included.

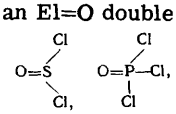
I. INTRODUCTION

Various halides containing an ElO group are of great practical value. They are widely used as non-aqueous solvents[1] and also for the separation of chlorides of different elements[2-5]. Interest is being taken at the present time in the application to laser technology of mixed-solvent solutions based on phosphoryl and other compounds containing ElO groups[6-11]. The structure of such compounds and their complexes involves several problems of theoretical inorganic chemistry, and therefore is of undoubted interest.

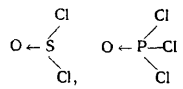
The present paper discusses certain aspects of the structure, chemical activity, and complex-forming power of halides containing an ElO group, attention being paid mainly to the phosphoryl group.

II. NATURE OF BONDING OF ATOMS IN OXIDE HALIDES OF GROUP III ELEMENTS

According to Werner the molecules NOCl, $POCl_3$, $SOCl_2$, $SeOCl_2$, etc. contain an El=O double bond:



According to the Lewis octet theory the bond between the central atom and the oxygen atom was regarded as of donor–acceptor type involving a pair of electrons on the central atom:

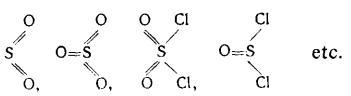


Experimental investigations of the molecular properties supported both views. The measured parachors for several compounds were lower than those calculated on the basis of Werner's formulae†, and compounds containing an El–O [type of] bond (S–O, P–O, P–S) exhibited less tendency to reactions involving addition than might have been expected for compounds containing a double bond. On the other hand, the El–O interatomic distances, the bond energies, and the dipole moments indicated the presence of a double bond[13–17].

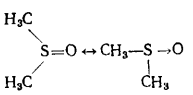
Siebert[13] characterised the ElO(S) bonds by their multiplicity, which he calculated in several oxides and oxide halides of non-metals by means of the rules that he had derived[18]. For sulphur compounds, for example, he obtained the values

SO_2	SO_3	SO_2Cl_2	$SOCl_2$	SO_2F_2	SOF_2
1.96	2.04	2.03	1.87	2.19	2.04

for the multiplicity of the SO bond. This is seen to be close to 2 in all the compounds, from which he concludes that a double bond S=O is present:



In the case of methyl derivatives, e.g. dimethyl sulphoxide, the multiplicity of the SO bond falls to 1.7, which Siebert attributes to an approach towards a donor–acceptor bond:

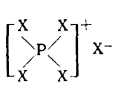


At one time Pauling regarded the resonance of two structures as the reason for the increase in the ElO bond energy‡. For phosphorus compounds the multiplicity of the PO bond is close to 2, and diminishes on passing from fluorides to bromides[20,21]; introduction of a methyl group diminishes the multiplicity considerably:

POF_3	2.34
$POCl_3$	2.09
$POBr_3$	2.02
$PO(CH_3)_3$	1.7

Discussion of the type of bond in ElO(S) groups in terms of its multiplicity is formal in character, and cannot give a complete idea of their structure.

According to modern views the nature of the (Hal)ElO bonds in Hal_3PO molecules is due to hybridisation of the atomic orbitals of the central atom, but the participation of *d*-orbitals of the central atom in bond formation is a matter of controversy[22,23]. Pauling, although the first to suggest the participation of *d*-orbitals in the formation of covalent bonds by elements in the third period, assumed for phosphorus compounds PX_5 the type of structure



in which the *d*-orbitals of phosphorus are not involved in bond formation. In the proposed formula combination of the five X atoms with the phosphorus atom can be effected by 3*s*- and 3*p*-orbitals together with electrostatic attraction between phosphorus and a unit negative charge distributed among the five X atoms. Atoms of elements in the second period—carbon, nitrogen—usually exhibit quadrivalency when they form covalent two-electron bonds. The participation of *d*-orbitals in the bond with elements in the third period may increase the coordination number of the central atom. On the other hand, the difference between the coordination numbers of elements in the second and third periods has been ascribed mainly to steric factors[24], not to the energy difference between the *d*-orbitals of the elements. The structure and the energies of the 3*d*-orbitals of isolated atoms of elements in the third period are such that their participation in bond formation is improbable[25–27].

Table 1. Energy of transition from ground state, eV.

Transition	Al	Si	P	S	Cl
One-electron					
$(s) \rightarrow (d)$	8.47	12.21	17.54	20.72	26.17
$(p) \rightarrow (d)$	3.90	5.51	7.23	7.89	11.07
Two-electron					
$(s)^2 \rightarrow (d)^2$	20.63	28.88	37.93		58.52
$(sp) \rightarrow (d)^2$	14.49	20.34	27.75	32.25	41.25
$(p)^2 \rightarrow (d)^2$		13.99	18.00		26.92

Table 1[28] shows that the $s \rightarrow d$ transition energy is rather lower in elements of the third period than in those of the second period, but is sufficiently high for the *d*-orbitals to take part in bond formation (in transition elements the energy of an $s \rightarrow d$ transition is ~ 8 eV). The radius of the 3*d*-orbitals of the phosphorus atom is 2.43 Å, considerably exceeding the radii of the 3*s*- and 3*p*-orbitals (0.47 and 0.55 Å respectively). The calculated overlap integrals of the *p*-orbitals of the ligands and the *d*-orbitals of an isolated phosphorus (sulphur) atom, e.g. the p_Z–d_{Z^2} overlap integrals, are negative, the *d*-orbitals being "smeared out" too much to form a σ-bond[28]. However the presence of ten or twelve electrons surrounding the central atom in the $POCl_3$, $SOCl_2$, etc. molecules, and the stable five- and six-coordinated compounds obtained with phosphorus, indicate the possible participation of *d*-orbitals of the central atom in the bonds. Additional interaction involving the *d*-orbitals of the central atom might explain also the high ElO, ElHal bond energies, the high vibration frequencies, and the short bond lengths between the central atom and oxygen in compounds of elements in the third period in comparison with those of elements in the second period. Quantum-mechanical calculations[29–34] have shown the possibility that *d*-orbitals of phosphorus and sulphur atoms may take part in forming σ- and π-bonds. The *d*-orbitals of the central atom undergo a considerable change of energy in the ligand field, which facilitates their participation in hybridisation.

The main factors influencing the size and energy of the *d*-orbital—(1) the spin contribution of unshared electrons, (2) the number of *d*-electrons, and (3) the formal charge on the atom—have been distinguished[22,35] according to the mode of excitation. The last factor has the greatest effect, and is explained in terms of formal concepts: electronegative substituents, by drawing electrons away from the central atom, increase its charge, which in turn leads to contraction of the *d*-orbitals.

† Sidgwick[12] showed that the parachor should decrease even with increase in the number of electrons around the atom from 8 to 10 or 12.

‡ The increase in bond energy has been discussed[19] in terms of hybridisation.

The contribution of d-orbitals to bond formation may vary. Cruickshank[36] suggested that they played an equivalent part together with s- and p-orbitals. The possibilities of sp^3d-hybridisation of the phosphorus atom have been discussed[27,37,38], and the energies of other excited states sp^2d^2, p^3d^2 have also been determined. Various energy levels have been calculated by the molecular orbital method for isolated P^0, P^+, and P^- atoms, although it is not possible to extrapolate data for individual atoms to molecules[39]. The sp^3d-hybridisation of a phosphorus atom represents the formation of five equivalent bonds.

The spatial arrangement of the hybrid orbitals may lead to various structures[40], among which a bipyramidial structure is energetically the most favourable. Phosphorus is then bound to oxygen by a σ-bond and a superimposed covalent π-bond resulting from overlapping of one of the five sp^3d-hybrid orbitals of the phosphorus atom and a p-orbital of the oxygen atom.

Molecular orbital calculations for Y_3PO molecules, taking into account the effect of substituents on the phosphorus–oxygen bond and the accompanying change in hybridisation of the phosphorus orbitals, led Wagner[41,42] to regard the σ-bond as of donor–acceptor type P → O. Two π-bonds, formed by $2p_x$- and $2p_y$-orbitals of oxygen and $3d_{xz}$- and $3d_{yz}$-orbitals of phosphorus, are superimposed on the σ-bond. This type of overlap of orbitals can be illustrated by Fig. 1[43,44], which shows the possibility of interaction between two d-orbitals of four-coordinated phosphorus and two p-orbitals of oxygen. If the molecule containing four-coordinated phosphorus is so oriented that the P=O bond lies along the x-axis, $d_\pi - p_\pi$ bonds can be formed by the binding of the phosphoryl oxygen to the phosphorus atom by a σ-bond produced by the overlapping of an sp^3-hybrid orbital of phosphorus with a p_x-orbital of oxygen and two π-bonds formed by $3d_{xy}$- and $3d_{xz}$-orbitals of phosphorus and p_y- and p_z-orbitals of the phosphoryl oxygen.

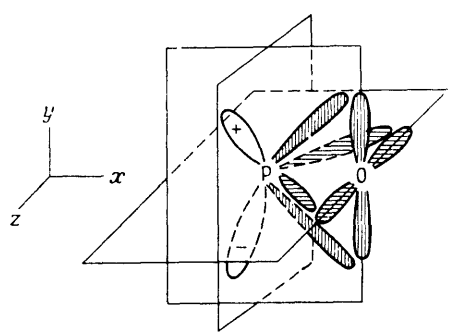


Figure 1. Scheme of $d_\pi - p_\pi$ interaction along the P–O bond.

Considering various types of substituents in the Y_3PO molecule, Wagner showed that the PO bond varies from single in trimethylphosphine oxide to almost triple in phosphoryl fluoride. The positive charge on the phosphorus atom passes through a minimum when the electronegativity of the substituent is 2.7 on Pauling's scale. In the two extreme cases—the most electronegative fluorine and the least electronegative methyl substituent—the charge distribution is

$$\underset{F_3}{-1.131} \equiv \underset{P}{+1.332} \equiv \underset{O}{-0.201} \quad \underset{(CH_3)_3}{+0.102} \equiv \underset{P}{+1.03} - \underset{O}{1.132}$$

This charge distribution shows that the dipole moment changes its direction on passing from phosphoryl fluoride to trimethylphosphine oxide. Fig. 2 illustrates the variation in the dipole moment with the electronegativity of the substituent. When the electronegativity of Y is 3.6, the dipole moment approaches zero§. Wagner's predicted variation in the dipole moment of the phosphorus–oxygen bond with the substituent has been confirmed experimentally[46,47]. It was found that the dipole moment, while depending almost solely on the electronic state of the phosphorus–oxygen (σ,π)-bond, does not vary monotonically on passing from some substituents to others, but passes through a minimum at certain substituent electronegativities. Analogous conclusions were reached from a consideration of the (σ,π)-bond of the sulphur atom in various derivatives[48].

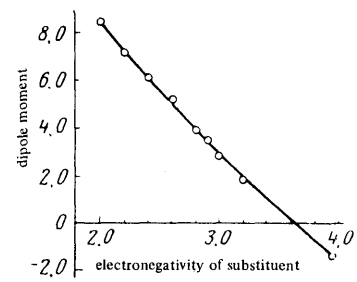

Figure 2. Variation in dipole moment of Y_3PO molecule with electronegativity of substituent Y.

In phosphoryl halides $POHal_3$ the d-orbitals of phosphorus may also interact with orbitals of the halogen atoms[49]: e.g. two $d_\pi - p_\pi$ bonds may be formed by the $d_{x^2-y^2}$ and d_{z^2} orbitals of phosphorus and the p-orbitals of the ligands[50,51]. Table 2 lists dissociation energies and bond multiplicities for several $POHal_3$ compounds[21,52]. The difference in the degree of interaction of the central atom with oxygen and with the halogen is evident. The degree of interaction diminishes in the sequence of substituents F → Br. It is apparent that $d_\pi - p_\pi$ interaction of the substituents has little effect on the P=O bond, since the presence of C_{3v} symmetry in the POX_3 system enables the orbitals of the X atoms to interact with d_π-orbitals of the phosphorus atom orthogonal to the orbitals used in the phosphorus–oxygen bond[44].

The way in which d-orbitals of the central atom are involved in the bonds has not yet been unequivocally settled. The phosphorus–oxygen and sulphur–oxygen bond lengths have been calculated[55] by the molecular orbital method for series of compounds with and without the involvement of

§ A triple phosphorus–oxygen bond has been found for the hypothetical molecule H_3PO calculated by the molecular orbital method, and the d-orbitals of the phosphorus atom are assumed to be involved in the bond[45].

d-orbitals. The results suggest that d-orbitals play a modest part in shortening these bonds, but the problem requires further consideration. The nitrogen–oxygen bond in nitrosyl trifluoride is shorter (1.15 Å) than the calculated value, as with compounds containing a P=O or an S=O bond, although the participation of d-orbitals is still less probable in this case. A possible explanation is the effect of the electronegative fluorine atom on the charge on the nitrogen.

Table 2. Energy of dissociation and multiplicity of bonds in the compounds $POHal_3$.

Hal	E, kcal mole^{-1} P–O	Multiplicity P–O	E, kcal mole^{-1} P–Hal	Multiplicity P–Hal
F	178*	2.47	90	1.35
Cl	161	2.24	61	0.91
Br	151	2.16	55	0.81

* Other numerical values have been given [53,54], but the general trend remains.

The presence of $p_\pi - d_\pi$ interactions is not indicated unambiguously by the experimental electronic, nuclear magnetic resonance, and nuclear quadrupole resonance spectra of series of compounds [56–59].

Table 3.

Compound	Force const.	Multiplicity	Compound	Force const.	Multiplicity
OPF_3	11.89	2.44	SPF_3	5.21	1.89
$OPCl_3$	10.24	2.15	$SPCl_3$	4.89	1.80
$OPBr_3$	9.74	—	$SPBr_3$	4.69	—
$OP(CH_3)_3$	9.14	1.88	$SP(CH_3)_3$	3.33	1.33

An examination has been made of the influence of the $3d_Z$-orbital component on several properties of sulphur- and phosphorus-containing molecules, including their ionisation potentials, electronic transition energies, dipole moments, and overlap integrals calculated by a semi-empirical method [60]. Introduction of this component only slightly improves the agreement between calculated and experimental values. Further investigation is required on these lines [22,23,27,39,55].

When the oxygen atom in $\rangle P{=}O$ is replaced by a sulphur atom, the multiplicity of the phosphorus–sulphur bond, the force constants, and the corresponding bond energies are smaller than in the original compound. Table 3 lists force constants and bond multiplicities for several compounds [61]. The phosphorus–chlorine bond length increases on passing from phosphoryl to thiophosphoryl chloride [62–64].

The influence of substituents on the P=O bond is probably mainly an inductive effect [65,66]. As mentioned earlier, $d_\pi - p_\pi$ interaction of the phosphorus atom with a substituent has little effect on the P=O bond. Bell et al. [67] showed that the vibration frequencies of the latter bond in the infrared and the Raman spectra vary linearly with the electronegativity of the other substituents attached to phosphorus.

Some authors regard the vibration frequencies as functions of the Taft σ^*-constants [68,69] characterising the inductive and mesomeric effect of the substituents, and also introduce into the equation constants to represent the electronic shielding of the phosphorus nucleus [70]. The force constants of the P=O bond vary linearly with the calculated π-bond energies [71]; the coefficients in the equation $K = a + bE$ depend on the nature of the substituents.

The integral intensity of the vibrational bands involving the P=O bond depends on the electronic properties of the whole POX_3 molecule, and is 80% determined [72,73] by the product

$$\left(\frac{\partial \mu_{P=O}}{\partial Q} + \frac{\partial \mu_{P-Cl}}{\partial Q}\right) Q$$

where Q is the normal coordinate of the bond and μ the dipole moment of the bond. The non-unique character of the vibrational bands of the PO bond in a series of substituted phosphoryl compounds has also been noted elsewhere [74]. No effect of the nitrogen and sulphur atoms on the vibrational frequencies and force constants of the P=O bonds was apparent in the series of compounds $(RS)_3PO$ and $(R_2N)_3PO$, and the difference found in the π-charge on nitrogen and sulphur atoms (+0.187 and −0.004) [75] was expressed in a corresponding change in the integral intensity of the P=O vibrational bands.

Table 4. Force constants of P–X bonds as function of type of hybridisation of atomic orbitals.

Force constant	pd	p	sp^3	sp^2
K_{P-H}		3.10[a]	3.30[b]	3.59[c]
K_{P-CH_3}		2.77[d]	3.05[e]	—
K_{P-F}	4.52[f]	5.19[g]	6.34[h]	6.38[f]
K_{P-Cl}	1.63[i]	2.36[j]	2.66[k]	2.78[i]

Compounds
[a] PH_3, [b] $BH_3{\cdot}PH_3$, [c] H_2PF_3, [d] $P(CH_3)_3$, [e] $SP(CH_3)_3$, $OP(CH_3)_3$, [f] PF_5, [g] PF_3, [h] OPF_3, [i] PCl_5, [j] PCl_3, [k] $SPCl_3$, [l] PBr_3, [m] $SPBr_3$, [n] $P(OCH_3)_3$, [o] $OP(OCH_3)_3$.

Examination of the effect of various factors on the force constants of the phosphorus bonds in series of compounds is of interest [61]. Table 4 lists force constants as a function of the type of hybridisation of the orbitals of the central atom. Increase in the s-character of the bond is accompanied by an increase in the force constants. A similar effect is produced by increasing the electronegativity of the substituents and also the charge on the ions.

The above regularities are less clearly exhibited by thiophosphoryl compounds [61,76,77]. In view of the diminished ionic character of the phosphorus–sulphur bond in comparison with the phosphorus–oxygen bond, it may be supposed that the mass of the atoms in the substituents and the force constants of P–X bonds—not the electronegativity—will have the decisive effect on the P–S stretching frequencies. However, Zingaro [78], in calculating the frequencies of the P–S vibrations in thiophosphoryl compounds, attributed the decisive role to the electronegativity of the substituents. These two conclusions on the effect of substituents on the phosphorus–sulphur bond are not mutually inconsistent, as might appear at first glance.

It has been proposed[79] to separate thiophosphoryl compounds into different groups containing strongly electronegative and less electronegative substituents. The regular variation in the force constant of the P–S bond within the groups is explained by mechanical interaction with P–X stretching vibrations, in agreement with conclusions reached by other workers[76]. When, however, compounds having substituents differing strongly in electronegativity are compared, this difference must be regarded as the cause of the variation in the phosphorus–sulphur vibration, in agreement with Zingaro's conclusions. Thus, similarly to phosphoryl molecules, the position of the phosphorus–sulphur band in thiophosphoryl compounds is determined by the immediate environment of the phosphorus atom[80-83].

The nuclear magnetic resonance spectra of phosphoryl compounds do not enable a similar relation to be established between the chemical shifts and the electronegativities of substituents adjacent to phosphorus. Electronic shielding of the nucleus of the central atom by substituents adjacent to the phosphoryl P–O and thiophosphoryl P–S groups increases in the sequence

$$Se < S < C_{aliph} < C_{arom} \approx P < N \approx Cl < H < O < F$$

the more electronegative the substituent element, the greater the shielding at the phosphorus atom. An explanation is provided by interaction between the substituent and the P=O or P=S electron cloud: the more electronegative the substituent, the more strongly it "draws out" the electrons of the π-bond of this group and the greater becomes the shielding of the phosphorus.

In sum the structure of molecules of the type XYZElO, containing oxo-groups, depends on the presence in the El–O group of coordinate bonds superimposed on and opposite to the σ-bond. sp^3d-Hybridisation is improbable. The $d_\pi - p_\pi$ interaction of phosphorus and halogen atoms is possible in the Hal_3PO molecule.

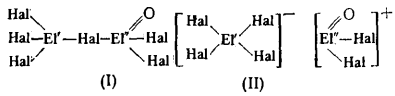
The geometrical configuration of the molecules corresponds to a distorted tetrahedron. For $POCl_3$ the P–Cl and P–O distances are 1.99 ± 0.02 and 1.45 ± 0.03 Å respectively, and the Cl–P–Cl angle is 103.6 ± 2°.[63]

III. DONOR–ACCEPTOR PROPERTIES OF OXIDE HALIDES IN CHEMICAL REACTIONS

Structural features of molecules containing oxo-groups govern their behaviour towards other compounds. The reactivity of such molecules, which is apparent in many reactions and has been discussed in detail, e.g. for organophosphorus compounds[40,44], is determined by the properties of the molecular and atomic non-bonding orbitals. Nucleophilic substitution at the phosphorus atom involves rupture of that one of the four phosphorus bonds that has the lowest electron density. Electrophilic reagents interact with the phosphoryl oxygen atom, which has the highest ME1 electrophilic superdelocalisability[84]. In the molecules XYZElO [or S] the O(S) atom and also the atoms X, Y, Z possess not only molecular orbitals but also non-bonding atomic orbitals with electron pairs, which may take part in the formation of bonds[85,86]. The possibility of their involvement in interaction with acceptor molecules depends on the factors discussed above, the interaction of hybrid molecular and atomic orbitals determining the donor properties of these molecules[87,88].

In view of the properties of the atomic orbitals of oxygen and chlorine (or other substituent) in molecules, we can in general imagine two mechanisms of interaction of molecules containing PO, SO, SeO, PS groups with various acceptors (e.g. chlorides of Groups III–V elements).

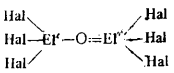
1. The donor–acceptor bond is formed by lone pairs of the halogen atom[89-96]:



(I) (II)

These structures differ in the share of the halogen Hal in the donor–acceptor bond. Case (II) involves formation of a tetrahedral ion of the type $ElHal_4^-$, which is stable with several metal chlorides.

2. The donor is the oxo-oxygen[97-109]¶:



Interaction occurs considerably more rarely according to scheme *1*, and is governed to a greater extent by the properties of the acceptor—the second component of the reaction—which is capable of forming a complex anion. The actual donor–acceptor interaction (scheme *2*) is the subject of discussion.

Substituents in XYZElO molecules, by exerting an inductive effect on the El–O bond, change its donor ability. For example, the donor power of the oxygen atom is weaker in oxide chlorides than in organic phosphoryl compounds, owing to the greater electronegativity of chlorine than of organic radicals and the stronger inductive effect of chlorine on the P=O bond. By "drawing out" the electrons from oxygen, chlorine lowers its capacity for participation in a donor–acceptor bond. The donor capacity of the compounds increases in the sequence

$$POF_3 < POCl_3 < POBr_3 < PO(CH_3)_3.$$

The electronegativity of the various organic substituents has the same effect[111].

The influence of the central atom on the properties of XYZElO molecules might be connected directly with the possibility and degree of participation of *d*-orbitals in the ElO bond: increased participation of those of the central atom should diminish the donor properties of the molecule. Phosphoryl chloride possesses donor properties; oxygen in the vanadyl(V) chloride molecule does not; while the molecules of transition elements—$TiOCl_2$, $MoOCl_2$, etc.—possess well defined acceptor properties[112,113].

On the other hand, the compound $(CH_3)_3NO$ is a poorer donor than is $(CH_3)_3PO$: the most convincing explanation here, as in the analogous case of bond shortening in the compound F_3NO, is based on the formal charge on the central atom[114].

Investigation of the complexing power of phosphoryl[89], seleninyl[115], acetyl[116-120], and thionyl[121] chlorides has made it possible to compare the donor properties of these molecules towards such acceptors as arsenic trichloride, tin tetrachloride, and titanium tetrachloride[97]. The donor properties of these molecules are found to decrease in the sequence

$$POCl_3 > SeOCl_2 > CH_3COCl > SOCl_2.$$

This donor sequence is consistent with the electronegativities of the central atoms in these molecules. It may

¶ Electrostatic interaction may be possible[110] as a consequence of the highly polar character of the phosphoryl P=O group.

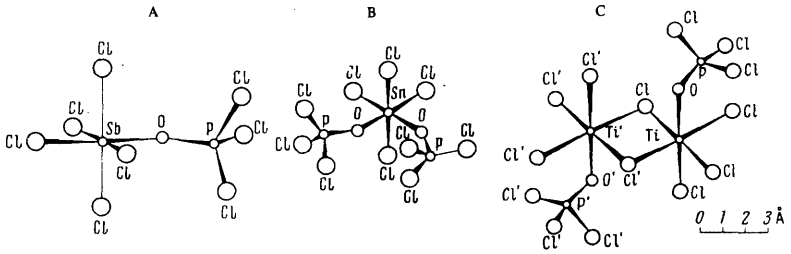


Figure 3. Structure of the compounds $SbCl_5.POCl_3$, $SnCl_4.2POCl_3$, and $(TiCl_4.POCl_3)_2$.

be supposed to a first approximation that the oxygen atom will have its maximum charge when the electronegativity of the central atom is least. The electronegativities of phosphorus, sulphur, selenium, and carbon are respectively 2.1, 2.4, 2.5, and 2.5. Increase in electronegativity increases the El–O bond order, by diminishing the donor power of the oxygen.

In view of the above mentioned inductive effect of substituents on the central atom in XYZElO(S) molecules and the appearance of a positive charge on the atom, such molecules can be assumed to possess acceptor properties. Indeed several molecules—those possessing the weakest donor properties—develop acceptor properties[97]. In this connection it is interesting that compounds are formed in mixtures of seleninyl chloride with carbon tetrachloride and of acetyl and thionyl chlorides with silicon tetrachloride, where these workers consider that the oxide chlorides are acting as acceptors, and the tetrachlorides in the uncharacteristic role of donors†. The investigation of binary mixtures with pyridine, which develops clearly defined donor properties, has established the presence of compounds when the second component of the mixture is seleninyl, acetyl, or thionyl chloride, etc.

The above considerations on the donor power of various oxo-compounds are based on experimental investigation of the complex compounds formed in mixtures and are fully valid only on the assumption of bond formation in them through oxygen.

A diminution in donor power is observed on passing from phosphoryl to thiophosphoryl chloride: thus mixtures of phosphoryl chloride with zirconium tetrachloride and niobium pentachloride are characterised by the formation of complex compounds[124–128]; no compounds are formed in the corresponding mixtures with thiophosphoryl chloride[129–131], the donor properties being determined in this case by the atomic orbitals of the sulphur atom.

IV. REACTIONS OF PHOSPHORYL CHLORIDE WITH GROUPS II–V CHLORIDES

A characteristic feature of molecules containing an oxo-group is the ability to react with valency-unsaturated chlorides of Groups III–V elements, their derivatives, and also halides of bivalent metals[132–134]. Examination of the equilibrium diagrams for systems formed by phosphoryl chloride with the chlorides $ElCl_3$ ($ElCl_4$, $ElCl_5$) by thermal analysis has established the presence of complex compounds, usually having the 1 : 1 composition, more rarely 1 : 2 and 2 : 1.[135–151] It is interesting that analogous compounds are obtained in the systems formed by two compounds containing oxo-groups—by phosphoryl chloride with molybdyl, tungstyl[112], or titanyl[113] chloride.

The resulting complexes are easily hydrolysed and are decomposed by alcohol. The melting point does not usually exceed 200°C. They are stable compounds, which can be isolated in the pure state; they dissolve in carbon tetrachloride and in nitrobenzene, while being less soluble in benzene. Dissolution in nitrobenzene is accompanied only by slight dissociation, and their stability in solution increases in the sequence

$$SbCl_5\cdot POCl_3 < NbCl_5\cdot POCl_3 < TaCl_5\cdot POCl_3 < AlCl_3\cdot POCl_3.$$

Coordination with oxygen has been found in several compounds of elements in Groups IV and V of the Periodic System[107,152–162], but the type of coordination is a matter of controversy for some double compounds with chlorides of Group III elements—boron, aluminium, gallium—and iron[94–96,104].

The main conclusions concerning the structure of these compounds were reached from a study of their infrared spectra. A shift in electron density from the El=O bond to M (scheme *2* in Section III) may be imagined to lead to an increase in the electronegativity of the phosphorus atom, influencing the displacement of electron density along the El–Cl bond: this is accompanied in the infrared spectrum by a fall in the vibrational frequency of the El=O bond and a rise in the El–Cl frequency. The newly formed M–O bond does not usually appear in the spectrum, evidently because of its low electron density[102]. On the other hand, formation of an El–Cl bond should lead to a slight shift in the El=O vibrational absorption band, but to a decrease in the El–Cl vibration frequency, as was established from investigation of complexes of nitrosyl halides[163–165]. The difficulties arising in recording the spectra of these hydrolysable substances prevent us from drawing unambiguous conclusions from the results.

X-Ray results obtained for the compounds $SbCl_5.POCl_3$,[156] $SnCl_4.2POCl_3$,[157] and $TiCl_4.POCl_3$ [158] indicate unequivocally the presence of coordination with oxygen. Fig. 3 shows the arrangement of the atoms in these compounds. The interatomic distances of the M–O donor–acceptor bond are (in Å)—TiO 2.10, SbO 2.18, $SnO_{(1)}$ 2.25, and $SnO_{(2)}$ 2.30 (for the 1 : 2 complex)—formation of an M ← O bond having hardly any effect on the P–O length, which is 1.46 Å for the compound with titanium tetrachloride, 1.46 Å for $SbCl_5.POCl_3$, and 1.41 and 1.49 Å for the tin complex (P–O bond length 1.45 Å for the $POCl_3$ molecule), and slightly increasing the ClPCl angle (by 3–4°)‡.

† The donor properties of these molecules have been noted by other workers[122,123].

‡ The mean phosphorus–oxygen distance in $POCl_3$ in the mixed complex $Mg(PO_2Cl_2)(POCl_3)$ is 1.42 Å, the molecules being slightly deformed[166].

The nuclear magnetic resonance spectra of the complex $TiCl_4.POCl_3$ (^{31}P) indicate an increase in the chemical shift δ from 2.2×10^{-6} for phosphoryl chloride to 16.6×10^{-6}, which is evidence of a decrease in the degree of shielding of the phosphorus nucleus in the complex and a diminution in the degree of π-overlap along the P=O bond[107].

Study of the chlorine-35 nuclear quadrupole resonance spectra of the complex compounds formed by antimony, iron, and titanium chlorides[167] enabled the type of chemical bond to be ascertained by comparing the state of the PCl_3 groups in the free phosphoryl chloride molecule and in the complex. The shift in the spectral bands was estimated by means of the formula

$$\Delta\rho = -\Delta I - \Delta\pi - \Delta(\alpha\sigma)$$

where I is the degree of ionic character of the bond, π is the degree of π-character, and α and σ are the degrees of s- and d-hybridisation of the bond. The state of the PCl_3 group is almost the same in the phosphoryl chloride molecule and in the complex, so that the frequency shifts obtained can be ascribed to a change ΔI in the ionic character of the bond. The frequency shifts found experimentally in the spectra of the complexes indicated that ΔI, representing the displacement of the electronic charge from chlorine to phosphorus on formation of the complex, varies in the sequence

$$SbCl_5 > FeCl_3 > SnCl_4 > TiCl_4.$$

The donor–acceptor bond M←O is stable: the compounds exist in the melt and in the vapour state. The calculated heats of dissolution of the complexes (ΔH, kcal mole^{-1})—$ZrCl_4.POCl_3$ 24.3,[131] $TiCl_4.POCl_3$ 23.3,[168] $FeCl_3.POCl_3$ 18.2,[169] $BCl_3.POCl_3$ 17.9,[151] $AlCl_3.POCl_3$ 28.4,[170] and $GaCl_3.POCl_3$ 22.6[171,172]—provide an energetic characteristic of the donor–acceptor bond.

The formation of a donor–acceptor bond can be characterised directly by a calorimetric study of reactions between donors and acceptors[111,171]. Heats of dissolution of acceptor chlorides in phosphoryl chloride have been measured according to the scheme

$$MCl_n + POCl_3 = Cl_nMOPCl_{3\,soln} \quad \Delta H_1\ n = 3\text{—}5$$
$$Cl_nMOPCl_{3\,solid} + POCl_3 = Cl_nMOPCl_{3\,soln} \quad \Delta H_2\ n = 3\text{—}5$$

The quantity $\Delta H_3 = \Delta H_1 - \Delta H_2$ is taken to be a direct measure of the donor-acceptor interaction:

$$MCl_{n\,solid\ soln} + POCl_{3\ soln} = Cl_nMOPCl_{3\,solid} \Delta H_3\ n = 3\text{—}5$$

Table 5 lists these thermal effects for a series of chlorides, among which those of Group III elements have the smallest values of ΔH_3. The nature of the coordination in them is a matter of controversy, and the general trend is due to an increase in the electronegativity of the acceptor metal atom. However, calorimetric results are only relative in character[111], since several secondary factors, e.g. changes in the structure of acceptor and donor, etc., are superimposed on the donor–acceptor interaction. Transfer of these compounds to the liquid phase involves their ionisation.

The Raman spectra of the complexes—$SnCl_4.2POCl_3$, $TiCl_4.2POCl_3$, and $SbCl_3.POCl_3$—in solution[102] indicate strong intermolecular interaction between phosphoryl chloride and the metal halide. It is usually difficult to isolate the solid adducts from solutions because of their tendency to supercooling[173] or because of the slowness of reaction between the components[89]. The composition of the solutions is complicated, and complex ions are present[174–179].

The ionisation of the complex compounds in solutions usually involves ionisation of the M–Hal bond with preservation of the MO...P donor–acceptor bond. The general scheme of ionisation is[180]

$$2\,DACl_n \rightleftarrows [D_2ACl_{n-1}]^+ + [ACl_{n+1}]^-$$

With variation in the donors the general tendency is for the degree of ionisation of the compounds in solution to increase with the donor strength[181–183].

Table 5. Heats of dissolution of acceptor chloride (ΔH_1) and of solvate (ΔH_2) in phosphoryl chloride and heats of donor–acceptor interaction [ΔH_3].

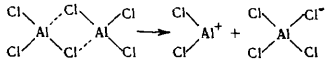
Acceptor chloride	$-\Delta H_1$	Solvate	$-\Delta H_2$	$-\Delta H_3$
$SbCl_5$	17.9	$Cl_5SbOPCl_3$	0.8	17.1
$TiCl_4$	20.7	$Cl_4Ti(OPCl_3)_2$	−1.7	22.4
		$Cl_4TiOPCl_3$	−2.7	
$SnCl_4$	20.2	$Cl_4Sn(OPCl_3)_2$	−2.1	22.3
$FeCl_3$	15.0	$Cl_3FeOPCl_3$	1.7	13.3
BCl_3	9.4	Cl_3BOPCl_3	1.5	7.9
$AlCl_3$	16.6	$Cl_3AlOPCl_3$	—	—
$GaCl_3$	11.0	$Cl_3GaOPCl_3$	0.8	10.2

Solutions of mixtures of aluminium, iron, titanium, etc. chlorides contain both cationic and anionic forms. Analysis of conductometric titration and electrical conductivity data for the solutions indicates that interaction in solution can be represented by the equation[173]

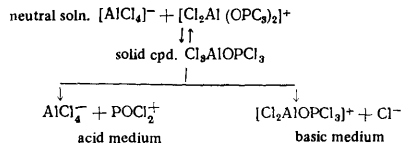
$$\text{Polymer} \rightleftarrows \text{Anion} + POCl_2^+ \rightleftarrows FeCl_4^- + POCl_2^+$$

which involves coordination with oxygen. The existence of iron in both cationic and anionic forms has been confirmed by the electrolysis of solutions of complexes of phosphoryl and thiophosphoryl chlorides with iron(III) chloride[184].

The structure of solutions of mixtures of aluminium and phosphoryl chlorides was examined in the light of possible simultaneous coordination with oxygen and chlorine[173,185]. Formation of such a complex can be pictured from a consideration of the breakdown of the dimer Al_2Cl_6:



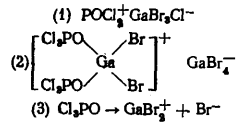
and the cation $AlCl_2^+$ combines with a donor molecule. The structure of a solution of aluminium and phosphoryl chlorides is then represented as



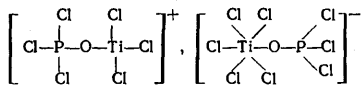
The dual character of oxygen and chlorine coordination in such solutions is supported by other work[186–188]: both a solvated O-coordinated complex and the ion $AlCl_4^-$ are present, the latter being formed in two ways:

$$1)\ AlCl_3 + POCl_3 \rightarrow AlCl_4^- + POCl_2^+$$
$$2)\ 4AlCl_3 + 6\,POCl_3 \rightarrow 3\,AlCl_4^- + [Al(POCl_3)_6]^{3+}$$

The investigation of mixed compounds in solutions of $GaBr_3.POCl_3$ suggests three possible ionisation paths with formation of the products[189]



Structure (3) is regarded[189] as the most probable; the P–O→M bond is preserved on dissociation, as in the above cases. This bond is stable also when the complex $TiCl_4.POCl_3$ dissociates in solution, and the ions



are assumed to be present[179]. A study of solutions of various donor–acceptor pairs ($GeCl_4$–acceptor) in phosphoryl chloride has established the presence of associated complexes containing the anion $[GeCl_6]^{2-}$.[190]

Binary mixtures from which individual complex compounds do not separate are of great interest. Such binary mixtures exhibit considerable departures from ideality. A positive deviation from Raoult's laws is characteristic of solutions of the mixtures $GeCl_4$–$POCl_3$, $SiCl_4$–$POCl_3$,[191,192] and $SeOCl_2$–$AsCl_3$,[193] the degree of departure from the laws of ideal solutions being proportional to the donor power of the donor (and the strength of the acceptor). Thus the $VOCl_3$–$TiCl_4$ system[194,195] can be regarded as ideal, which corresponds to the decrease in donor power in the sequence—$POCl_3 > SeOCl_2 > VOCl_3$.

We have already noted a decrease in the donor power of the P–S bond on passing from phosphoryl to thiophosphoryl chloride, but intermolecular interaction occurs between $PSCl_3$ and $SiCl_4$ in solution, producing a departure from ideal behaviour, though smaller than in the $POCl_3$–$SiCl_4$ system[196].

The Reactions of Hydrazones

Yu.P.Kitaev and B.I.Buzykin

The chemical properties of organic compounds containing an open-chain hydrazono-group are surveyed systematically. A list of 412 references is included.

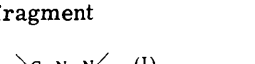
I. INTRODUCTION

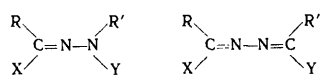
In the chemical literature hydrazones are not usually discussed as a separate class of organic compounds: most often they are regarded as derivatives of carbonyl compounds or of acids. The present review includes in the category of hydrazones all compounds whose molecules contain the triatomic fragment



(I),

not forming part of a heterocycle. However, the amino-nitrogen atom and/or the carbon atom may be included in a non-aromatic ring [1].

The close similarity of chemical and physical properties and the presence of a common functional group enable hydrazones (II) and azines (III) to be considered a single class of compounds:



(II) (III)

where R and R′ = H, Alk, Ar, Az, Ht†; Y = H, Alk, Ar, Ht, Az; X = H, Alk, Ar, Az, Ht, Hal, OR″, SR, CN, SO_2R, NO_2, NH.NR″R‴, NH.NHR″, N:NR″, COOR″, CO.NR″R‴. Several types of hydrazones have already been surveyed [2-51], and the electrochemical reduction of this class of compounds has been reviewed [52].

We have classified the numerous reactions undergone by hydrazones on the formal principle of the type of reactant.

II. REACTIONS OF HYDRAZONES WITH ELECTROPHILIC REAGENTS

Protonation

The distinguishing feature of the hydrazono-group is the presence of two nitrogen atoms—imino and amino—the valency electrons of which differ in their hybridisation (see formula II). The transition of a nitrogen atom from the sp^3 to the sp^2 state lowers its basicity. Amines possess more pronouncedly basic properties than do imines [2]. Conversion of an arylhydrazine into an arylhydrazone involves a substantial diminution in basicity [2,53-56]. Semicarbazones are less basic than semicarbazide by several orders of magnitude [56,57]. The basic character of azines (di-imines) is especially weak [2,44,49]: for example, acetone azine is 0.1% as basic as hydrazine [58]. Since the lone pair of electrons of the amino-nitrogen is delocalised in unsubstituted hydrazones as a result of conjugation with the π-system of the imino-bond [1], these compounds are also less basic than hydrazine: acetophenone hydrazone has $pK_a = 4.94$, whereas the value for hydrazine is 8.07. [59]

Increase in the electron-accepting character of R in (II) lowers the basic strength of hydrazones. This rule has been observed both with unsubstituted hydrazones [59] and with the phenyl-, [56] *p*-nitrophenyl-, [53,54] 2,4-dinitrophenyl-, [54,55] and nitroguanyl-hydrazones [60] of a large number of substituted benzaldehydes and aromatic ketones. A linear relation has been established between the Hammett constants of the substituents in the benzene ring of the carbonyl component and the pK_a value of the 2,4-dinitrophenylhydrazones [55]. The number of electron-accepting groups and their position in the benzaldehyde molecule affect the basicity of the phenylhydrazones [56].

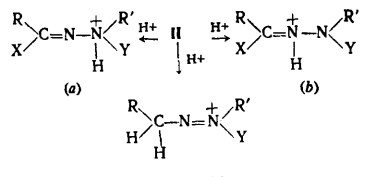
The substituent attached to the amino-nitrogen (R′ or Y in II) also has an effect. The basic character diminishes, for example, in the sequence unsubstituted hydrazones > > phenylhydrazones > *p*-nitrophenylhydrazones > 2,4-dinitrophenylhydrazones [1,2,10,45,48,53-56,59].

The introduction of electron-donor substituents into the hydrazone group will, of course, enhance the basicity, especially if the substituent is attached to the amine nitrogen. Dimethylhydrazones are stronger bases than unsubstituted hydrazones or phenylhydrazones [2]. Acetone *p*-nitrophenylhydrazone is a stronger base than the corresponding acetophenone derivative by a factor of 5. [54] The basic character of hydrazones is influenced not only by the nature of the substituents but also by the configuration of the molecule. Thus Vogel and Matter reported [61] that the *anti*-isomer of the *p*-tolylhydrazone of *p*-n-butylphenylglyoxylic acid has $pK = 6.6$, whereas the corresponding exponent for the *syn*-isomer is 5.1.

The hybridisation of the electrons of the amino-nitrogen atom varies with increase in the bulk of the substituents, depending on their nature [1], and sometimes approaches the

†Az = RCO = acyl; [Ht = heterocyclic group].

sp^2 state. As a consequence of this and the competitive influence of the substituents R, X and R', Y, hydrazones may undergo protonation either at the amine (*a*) or at the imine (*b*) nitrogen atom:



The more complicated case (*c*) is theoretically also possible, although it appears less probable.

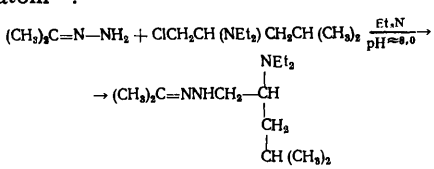
Semicarbazones are protonated at the carbamoyl group [57]. Dimethylhydrazones form quaternary salts on alkylation [62-64]; their protonation also takes place at the amino-nitrogen atom. The possibility of protonation at the imino-nitrogen is suggested by the insignificant change in basicity on passing from monoalkylhydrazones of aliphatic ketones to their *N*-acyl derivatives [65]. It is assumed that in 1,5-diarylformazans the amino-nitrogen of the hydrazone group is protonated.

Alkylation

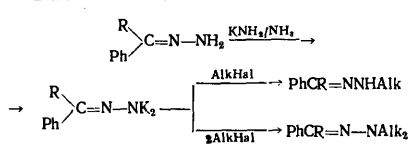
Unsubstituted hydrazones (II: R = Y = H) are converted by alkyl halides into azines of the same carbonyl compound [9,10,49]:

$$2\,PhCH{=}N{-}NH_2 + BrCH_2CH_3 \rightarrow PhCH{=}N{-}N{=}CHPh + CH_2{=}CH_2 + N_2H_4HBr$$

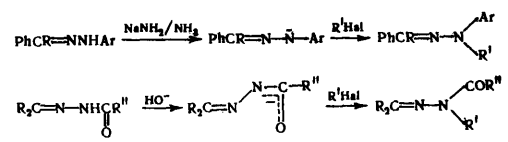
This reaction is accelerated in the presence of alcoholic alkali [66]. If, however, triethylamine in a buffer solution is used as the base, alkylation takes place at the amino-nitrogen atom [65]:



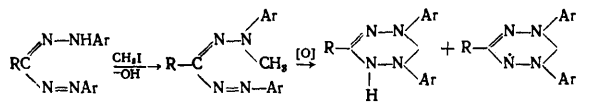
If an unsubstituted hydrazone is converted into a dianion by the action of potassamide in liquid ammonia, mono- or di-alkylhydrazones can be obtained depending on the quantity of alkyl halide taken [67]:



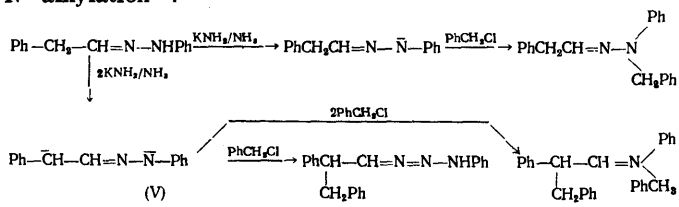
The less basic aryl- and acyl-hydrazones are usually alkylated after preliminary conversion into anions [2,9,10,45,49,68-70]. Conducting the reaction in liquid ammonia [69] generally gives high yields of alkylhydrazones:



The alkylation of formazans, like that of arylhydrazones, involves the intermediate formation of anions [47,71], although in some cases the reaction is complicated by the formation of 1,2,5,6-tetrahydro-1,2,4,5-tetrazine derivatives and then of verdazyl(IV). [72] The formation of (IV) may become the main reaction, because of the great tendency of $N_{(1)}$-methylformazans to undergo autoxidation:

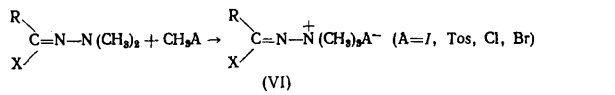


Arylhydrazones of carbonyl compounds having an α-methine group, on treatment with excess of potassamide, form the dianion (V), which is more liable to *C*- than to *N*-alkylation [70]:

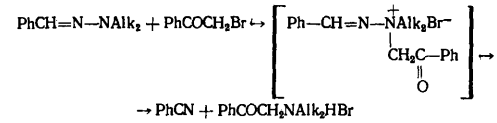


According to Grandberg et al. [73] arylhydrazones of aliphatic and alicyclic carbonyl compounds are alkylated by benzyl chloride and by dimethyl sulphate in boiling alcohol, after which they are converted into *N*-alkylindoles.

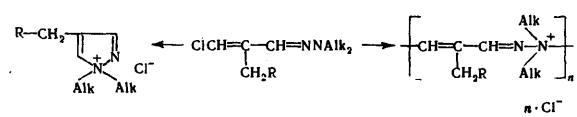
Dimethylhydrazones are easily converted into quaternary salts (VI) by the action of alkylhalides [62-64] and alkyl [arene]sulphonates [74]:



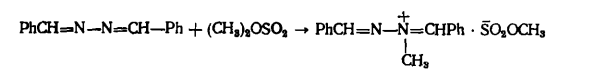
When α-bromoacetophenone is used, quaternary salts cannot be isolated from the dialkylhydrazones of aldehydes, evidently owing to their instability. In this case the products are a nitrile and an amino-ketone, resulting from rearrangement of an intermediate salt [75]:



Dialkylhydrazones of β-chlorovinyl-aldehydes are able to form polymeric quaternary salts [76]. Self-quaternisation with conversion into a 1,1-dialkylpyrazolium salt is also possible:



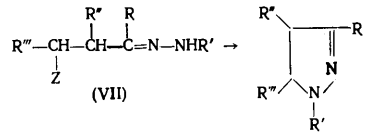
Benzaldehyde azine on treatment with dimethyl sulphate or ethyl iodide is converted into a saltlike product, whose structure is assumed [9,10,49] to correspond to a quaternary salt:



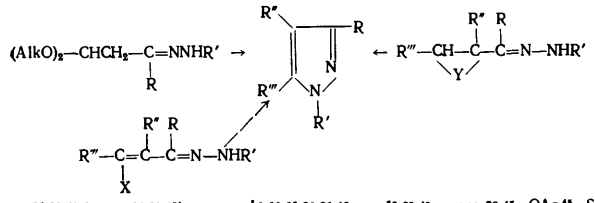
Ethyl iodide reacts similarly [9]. Diethyl sulphate and higher dialkyl sulphates do not form such salts. Aliphatic and alicyclic azines containing an α-methine group are converted by alkylating agents into a mixture of unsubstituted pyrazoline and an *N*-alkylpyrazoline [21,44,49,77].

Reactions involving the intramolecular alkylation of hydrazones with the formation of simple and fused heterocyclic systems are well known and have been widely studied [2,4,10,11,13,14,21,23,45,48,78,79]. The reaction mechanisms are largely obscure [21,23]: in parallel with an S_N

mechanism[21,23,78] the possibility is discussed of initial elimination of HZ from (VII) with formation of a hydrazone of an unsaturated oxo-compound followed by intramolecular addition of the HN fragment of the hydrazono-group at the resulting C=C bond[21,23,79]. The reactions involved in intramolecular alkylation can be represented by the schemes



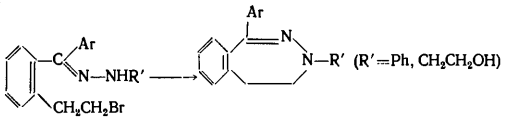
(Z=Cl[10,21,23,45], OH[10,21,45], OAlk[21], SH[23], SAr[45], NAlk$_2$[9,10,21,23,45,78,79], SeAr[23], $^+$NAlk$_3$[21])



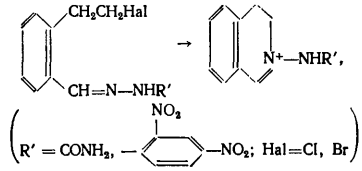
(Y=O[21,23,45,80] NH[21,23,45]) (X=OH‡[9,10,11,23,26,45], Cl[13,23,45], OAlk[23,45], OAr[45], SH[81], SAlk[82], SCN[28], Tos[23], NH$_2$[23,45], NHR[45], NAlk$_2$[23,45], NHNHR[45], —NHNH—C(=NH)—NH$_2$[83])

Here R″ and R‴ [10,84,85] and/or R and R′ [86] represent Alk, Ar, Ht, Az, a heterocyclic or a carbocylic fragment[87], a steroid residue[80], and possibly also nitroso[88] or arylazo[89,90].

Not only hydrazones of oxo-compounds having a reactive substituent in the β-position but also those in which the substituent is attached to a more remote carbon atom are capable of intramolecular alkylation. In particular, hydrazones of δ-halogeno-ketones are cyclised to diazepine derivatives by self-alkylation at the amino-nitrogen atom[91]:



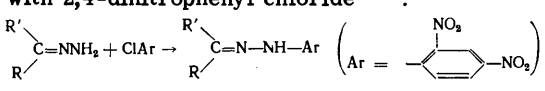
With increase in the electron-accepting properties of the substituent R′ attached to the amino-nitrogen atom the reaction centre may migrate, and self-alkylation involve the imino-nitrogen[35,45,92,93]:



The basic character of the imino-nitrogen diminishes more slowly than that of the amino-nitrogen under the influence of the acceptor substituent.

Arylation

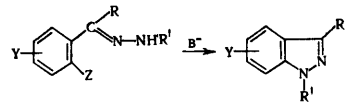
2,4-Dinitrophenylhydrazones of sterically hindered ketones are obtained by condensing unsubstituted hydrazones with 2,4-dinitrophenyl chloride[45,94]:



‡The monoenolic form of 1,3-dioxo-compounds.

This reaction was even recommended for the quantitative determination of unsaturated hydrazones[94]. Similar reactions can be used for the preparation of 2,4- and 2,6-dinitro- and the 3-R-2,4,6-trinitro-phenylhydrazones of benzophenone and fluorenone (R = H, Cl, CH_3).[95] Acetone azine reacts with picryl chloride in ethanol to form acetone 2,4,6-trinitrophenylhydrazone[45].

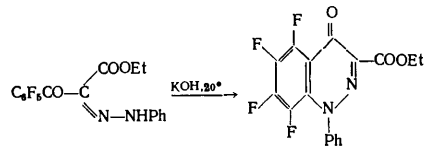
Monosubstituted and unsubstituted hydrazones of *ortho*-substituted benzaldehydes, acetophenones, and related compounds are converted by alkaline reagents into indazole derivatives (intramolecular arylation):[10,24,45,48,96-98]



(Z = Cl,[10,45] Br,[24,45] NO_2,[24,45,97] OH,[98] OAlk;[45,96] R = H, Alk, COOH, $CH_2C_6H_5$,[24,45] $COOC_2H_5$,[45] $COCH_3$,[97] R′ = H, Alk, Ph, *p*-$CH_3C_6H_4$, $Cl_XC_6H_{5-X}$,[24,45] 2,4-$C_6H_3(NO_2)_2$[45]).

Not only do hydrazones of 2,6-dinitrobenzaldehyde undergo this reaction, as assumed earlier[24], but also those of 2,4-di- and 2,4,6-tri-nitrobenzaldehydes[45] and pyridinealdehydes[98]. When Z = Hal, increasing the number of nitro-groups in the same ring increases the yield of indazole[24]. If the aryl ring contains a 2-chloro-substituent and a 6-nitro-group, the latter is the more readily replaced[45].

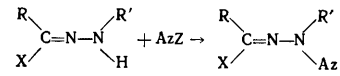
An example of intramolecular arylation with formation of a substituted cinnoline



has been reported[99].

Acylation

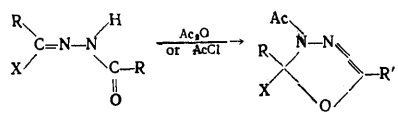
If Y = H in the hydrazone (II), acylation occurs in the usual way, and *N*-acylhydrazones (Y = Az) are formed[2,7,10,38,45,47,48,65,100-113]:



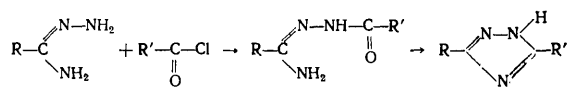
(R′ = H, Alk, Ar, Ht; Z=Cl,OEt, OAz).

Unsaturated hydrazones are converted smoothly into acylhydrazones[10,100]. Under the conditions of the Schotten-Baumann reaction many alkylhydrazones yield acetyl-, benzoyl-, and arenesulphonyl-alkylhydrazones[2,65]. Arylhydrazones are fairly easily acylated[45,48,101], but the resulting arylacylhydrazones tend to hydrolyse, and therefore the arylacylhydrazines and the oxo-compounds often separate instead of the acylated hydrazones[45]. A successful preparation requires an anhydrous solvent[45,102], and excess of the acylating agent or a catalyst (pyridine[102], zinc chloride[45,101]). 1,5-Diarylformazans are acylated with difficulty, and the yields of 1-acyl-1,5-diarylformazans are often low[47,103]. The acylation of phenylosazones is more successful[38]. Reaction between acylhydrazones

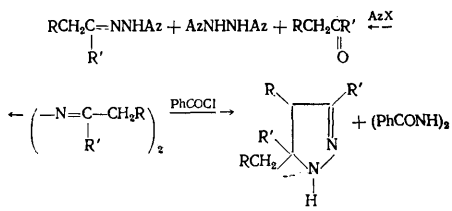
and acetic anhydride results most frequently in the formation of 1,3,4-oxadiazolines [104-107], although anomalies are observed [106]:



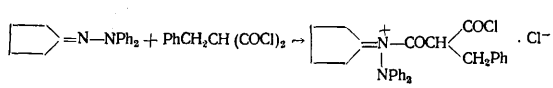
When arylhydrazones of quinones are acylated, the hydrazone form is fixed [108]. Amidrazones are acylated at the hydrazono-group [109,110], but reaction generally proceeds further with the formation of 1,2,4-triazole derivatives [45, 109-111]:



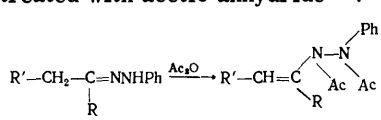
Azines, on treatment with acylating agents, are converted into acylhydrazones [49] or into mono- and di-acylhydrazines [49,112], and the methylene groups present undergo cyclisation into pyrazolines [44,113]:



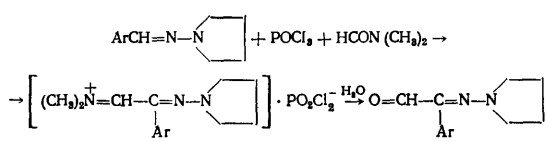
When the basicity of the amino-nitrogen atom is weakened considerably, the hydrazone may be acylated at the imino-nitrogen with the formation of a quaternary salt [114]:



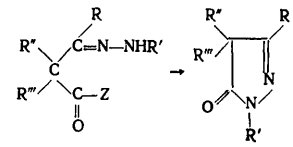
A product in which both nitrogen atoms of the hydrazone had been acylated was isolated when phenylhydrazones of aliphatic ketones, capable of conversion into alkenylhydrazines, were treated with acetic anhydride [115]:



Even disubstituted hydrazones of aldehydes do not form *C*-acyl derivatives under the usual conditions of acylation, and only in the Vilsmeier reaction are dialkylhydrazones of aromatic aldehydes converted into those of an arylglyoxal [116]:



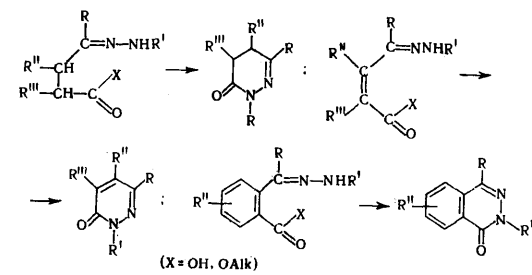
As in the case of alkylation, detailed studies have been made of intramolecular acylation with the formation of heterocyclic systems [2,9,10,23,45,83,99,114]. Hydrazones [23,45], alkylhydrazones [2,9,23,45], arylhydrazones [23,45,99], acylhydrazones [23,45], semicarbazones [23,45], thiosemicarbazones [23,45], selenocarbazones [117], and guanylhydrazones [83] of derivatives of β-keto-acids are cyclised to substituted pyrazolones:



(R′=H, Alk, Ar, Ht, —C(=O)—NH$_2$; Z=OH, OAlk, OAr, NH$_2$, NHR, NRR′, NHNHR, NHNH$_2$)

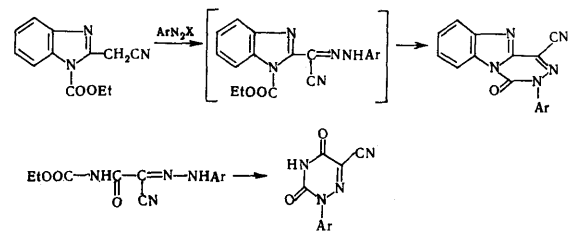
(S,Se)

Here R, R″, and R‴ may vary widely. Hydrazones of γ-keto-acids and their derivatives are cyclised to tetrahydro-3-oxopyridazines [9,10,25,26,45,46,118], and hydrazones of αβ-unsaturated γ-keto-acids to dihydro-3-oxopyridazines and tetrahydro-oxocinnolines [9,10,25,26,45,119-121]; however, hydrazones of *o*-formyl(or keto)benzoic acids are converted into dihydro-1-oxophthalazine derivatives [27,45,122]:

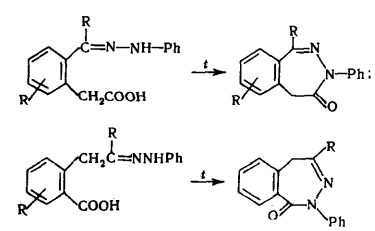


(X = OH, OAlk)

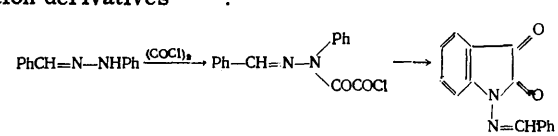
The hydrazone and carboxyl groups may be separated not only by a hydrocarbon chain but also by a fragment of a heterocycle [123] or by a carbamoyl group [124], when derivatives of tetrahydro-3,5-dioxo-1,2,4-triazine or its fused-ring analogues are formed:



Hydrazones of δ-keto-acids yield [91] substituted dihydro-3-oxoazepines:

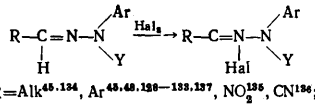


The acylation of phenylhydrazones with oxalyl chloride gives initially phenylacylhydrazones, and then *N*-aminoisation derivatives [45,125]:



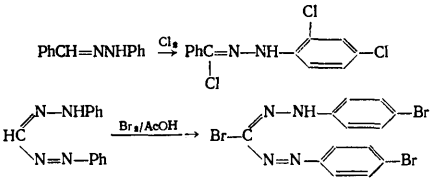
Halogenation

Halogens oxidise unsaturated hydrazones to azines [2,10,44,49] although substitutive halogenation is sometimes observed [126]. The action of halogens on arylhydrazones has been studied in greatest detail [45,48,127-137]. The hydrogen atom attached to the carbon of the hydrazone group (the methine hydrogen) in arylhydrazones of aldehydes can be replaced by a halogen atom [2,45,48,127-137]:

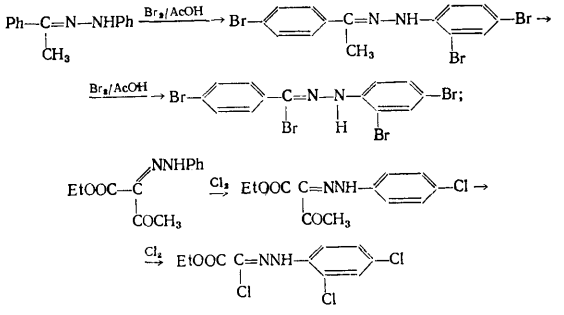


(R=Alk[45,134], Ar[45,48,128-133,137], NO_2[135], CN[136];
Y=H, CH_3; Ar=Ph, $(Hal)_nC_6H_{5-n}$, $(NO_2)_mC_6H_{5-m}$[45,48,129,130,133,134,137], Ht[128,131,133]).

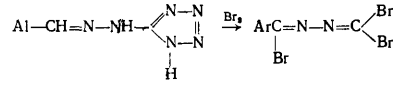
In phenylhydrazones substitution of the methine proton is accompanied by halogenation of the benzene ring attached to the amino-nitrogen atom [45,48,129], and halogens react similarly with 3*H*-formazans [43,138]:



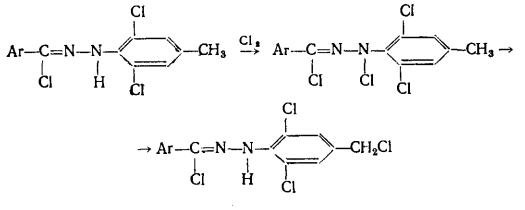
In arylhydrazones of ketones the ring is halogenated initially, after which the methyl or acetyl group may be replaced by halogen [45,48,129]:



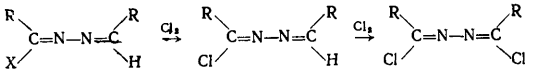
In the bromination of tetrazolylhydrazones replacement of the methine proton is accompanied by breakdown of the tetrazole ring [128]:



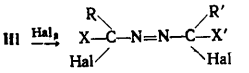
A kinetic study of the bromination of 2,4-dinitrophenylhydrazones of aliphatic aldehydes has shown that steric factors are more important than electronic factors in this series. The reason is that the *syn*-form, which does not react, must be converted into the reactive *anti*-form [134]. Arylhydrazones can undergo not only *C*- but also *N*-halogenation. The resulting derivatives are unstable, like all *N*-halogeno-compounds, and rearrange into more stable products (the Chattaway–Adamson rearrangement): [45,48,127,129]



Azines of aldehydes undergo substitution halogenation on treatment with halogens, with the stepwise replacement first of one and then the second hydrogen atom of the azine group [2,10,44,45,49,139]:

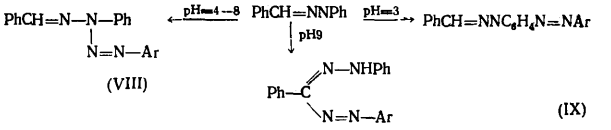


Under severe conditions of halogenation azines of the anthraquinone series undergo nitrile cleavage [139]. Azines of ketones do not undergo substitution, but add the halogen molecule at the 1,4-positions [2,10,11,44,48,140,141]:

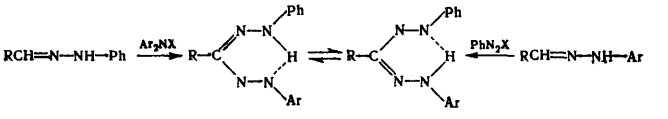


Reactions with Arenediazonium Salts

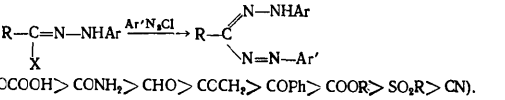
Phenylhydrazones of aldehydes react with arenediazonium salts to yield various products depending on the conditions [45,47,103,142]:



Production of the brightly coloured formazans (IX) has been the most thoroughly studied [2,11,31,38-40,47,48,71,103,137,143,144]. Arylhydrazones [47,103,117,143-146] and heterocyclic hydrazones [47,103,147-150] of aromatic [47,103,142,143,148,150], heterocyclic [47,103,143]; and aliphatic [144,147,149] aldehydes can be coupled, as well as arylhydrazones and arylosazones of sugars [38-40,47]. In general the isomeric forms of unsymmetrical formazans cannot be isolated, since they exist in equilibrium [47,103,143,145] and the two possible routes for the preparation yield the same product [145]:

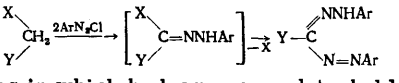


Among arylhydrazones of ketones only those in which the hydrazone carbon atom is combined with an easily eliminated group are able to undergo this reaction [47,103,144]:

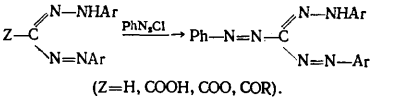


(X=COOH> H> CCCOOH> $CONH_2$> CHO> $CCCH_3$> COPh> COOR> SO_2R> CN).

Formazans are often produced by the action of diazonium salts on compounds containing an active methylene group (in the presence of a labile activating group) or a methyl group, since the rate of the second coupling (with the hydrazone formed as intermediate) far exceeds that of the first coupling [47,144]. In compounds containing an active methylene group one of the activating groups (listed above) is split off [47,144,151-155]:

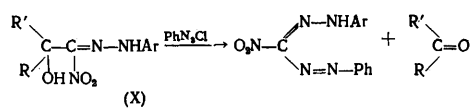


Formazans in which hydrogen or a detachable group is combined with the carbon atom react with diazonium salts analogously to arylhydrazones of aldehydes [47,108]:



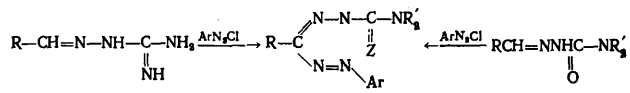
(Z=H, COOH, COO, COR).

Arylhydrazones of general formula (X) also yield formazans by eliminating a molecule of a carbonyl compound [144]:



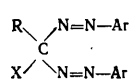
(X)

It has been reported [83,103] that analogues of formazans, the so called guanazyls, have been prepared from guanylhydrazones; among semicarbazones only $N_{(4)}N_{(4)}$-disubstituted derivatives yield such products, whereas acyl- and thioacyl-hydrazones do not react with arenediazonium salts [156].



(a) Z=NH, R'=H, (b) Z=O, R'=Ar.

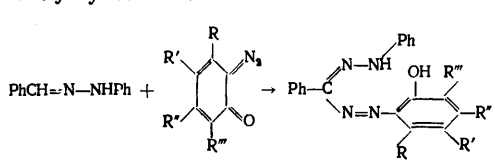
Since disubstituted hydrazones of aldehydes and $N_{(5)}$-alkylated formazans do not undergo the reaction, it was supposed that the formation of formazans involved tetrazens (VIII) as intermediates [47,103,142,148,157]. It has been shown recently, however, that the intermediate compounds are bisarylazo-derivatives (XI)



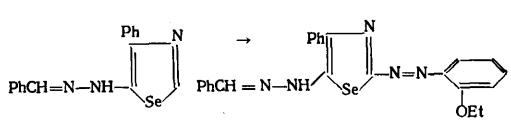
(XI)

(X=H, COOH, COOR, etc.)

In alkaline medium they isomerise rapidly into formazans (IX). [48,72,158,159] The possibility of direct substitution of the hydrogen atom in arylhydrazones of aldehydes by an arylazo-group has also been discussed [116,142]. The probability of this mechanism is supported, in our opinion, by the coupling [160] of arenediazonium salts with 1-aryl-2-pyrazolines, which are cyclic analogues of hydrazones. Diazoquinone derivatives react similarly to arenediazonium salts with arylhydrazones [161,162]:

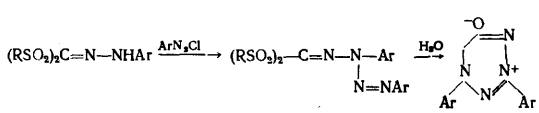


However, not all hydrazones can be converted into formazans. Thus compound (XII) is obtained from 5-benzylidenehydrazino-4-phenylselenazole and diazotised *o*-phenetidine [117]:

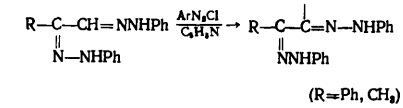


(XII)

Although arylhydrazones of bisalkylsulphonylformaldehydes split off the sulphonyl group, 1,3-diaryltetrazol-5-ones, which exist in the betaine form, are produced instead of the expected formazans [31,163,164]:



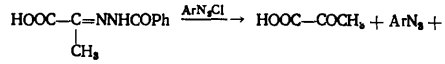
Phenylosazones of monosubstituted glyoxals are converted into phenylosazones of α-diketones [45,47,165,166], *C*-arylation occurring instead of azo-coupling:



(R=Ph, CH_3)

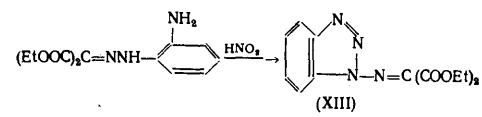
Nevertheless, formazans (azaformazans) are formed smoothly from arylosazones of sugars [38,39,47].

Acylhydrazones yield aryl azides, amides of the corresponding acids, and carbonyl compounds [167]:



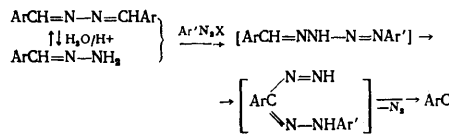
This reaction is assumed [167] to involve the intermediate formation of tetrazens, and support for this view will be found in Refs. 45 and 168.

The ability of *o*-aminophenylhydrazones to undergo intramolecular azo-coupling at the amino-nitrogen atom has been used recently by Campbell and Rees [169] to prepare derivatives of benzo-1,2,3-triazol-1-amine (XIII):



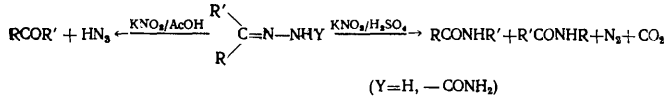
(XIII)

Azines and unsubstituted hydrazones (into which the former are initially hydrolysed under the reaction conditions) of aromatic aldehydes react with arenediazonium salts in acetic-acid solution to give arylhydrazones of the aldehydes [170]:



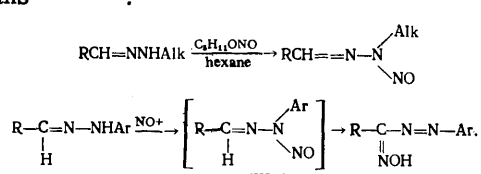
Nitrosation

In acetic-acid solution the nitrite ion decomposes hydrazones and semicarbazones with formation of an oxo-compound and an azide ion [2,171], but in concentrated sulphuric acid the Schmidt rearrangement occurs to the corresponding acid amide [2,172,173]:



(Y=H, $-CONH_2$)

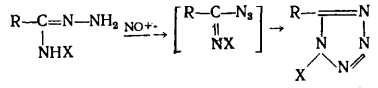
Monoalkylhydrazones of aldehydes are nitrosated by nitrous acid and its esters to relatively stable *N*-nitroso-derivatives [2], whereas the monoarylhydrazones are rapidly converted by nitrosating agents into arylazo-aldoximes (nitrosazones), which are oxime analogues of formazans [2,45,48,174]:



The formation of arylazo-aldoximes (XV) involves intermediate formation of the compound (XIV). [2,45,48,174-176].

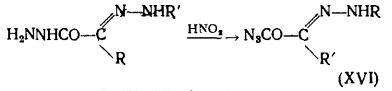
Bulky *ortho*-substituents in aromatic arylhydrazones prevent both nitrosation and the formation of arylazo-aldoximes [174].

Amidrazones, hydrazidines, and α-hydroxyamino-hydrazones, on treatment with nitrosating agents, are cyclised into tetrazoles via a stage of azido-derivatives [10,31,110,177-179]:



(X=H, NHR', OR", R'=H, Ph, 2,4-$C_6H_3(NO_2)_2$, R"=H, Alk, Ar).

When the hydrazone molecule contains an amine or a hydrazide group (not attached to the hydrazone group), attack by the nitrite ion takes place firstly at the former groups, not at the hydrazone fragment [45,170,180,181]:

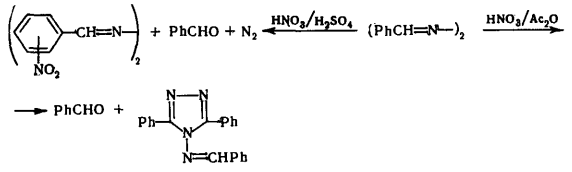


(XVI)

(R=H, Alk, Ar; R'=H, Ar).

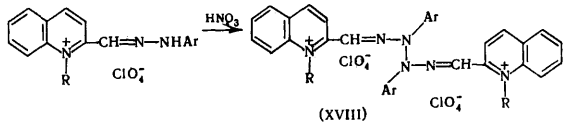
Nitration

On treatment with nitric acid in sulphuric acid, benzaldehyde azine undergoes oxidative cleavage and is partly nitrated, with formation of the azines of *p*- and *o*-nitrobenzaldehydes; when the reaction is conducted in acetic anhydride, only benzaldehyde and 4-benzylideneamino-3,5-diphenyl-1,2,4-triazole (XVII) are formed [182]:



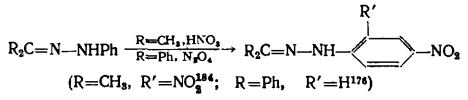
(XVII)

Aldehyde arylhydrazones are evidently more liable to be oxidised than to be nitrated by nitric acid. Thus arylhydrazones of 1-substituted 2-formylquinolinium perchlorates are easily oxidised to dimeric products (XVIII):[183]



(XVIII)

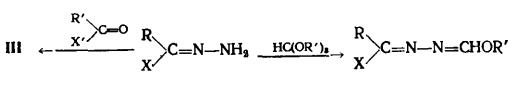
Under mild conditions phenylhydrazones of ketones are nitrated in the aniline ring by nitric acid [184] or by oxides of nitrogen [176]:



(R=CH_3, R'=NO_2 [184]; R=Ph, R'=H [176])

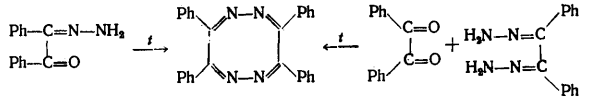
Reactions with Carbonyl Compounds

Carbonyl compounds react at the amino-nitrogen in unsubstituted hydrazones, and convert them into azines, a reaction very frequently used for the preparation of unsymmetrical azines [2,9,10,44,49,109,185,186]:

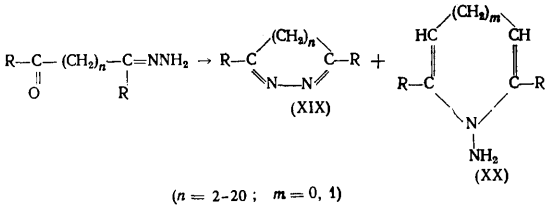


Dihydrazones of cyclohexane-1,3-dione [187] and the 1-hydrazone 2-methylphenylhydrazones of α-dicarbonyl compounds [188] react similarly. Unsubstituted amidrazones are converted into amino-azines [110]. The carbonyl compounds can be replaced by their acetals [10,44,49]. Ortho-esters give α-alkoxy-azines with hydrazones [45,189].

Monohydrazones of α-diketones when heated form an eight-membered heterocycle [190], which can be obtained also from the α-diketone together with its dihydrazone [191]:



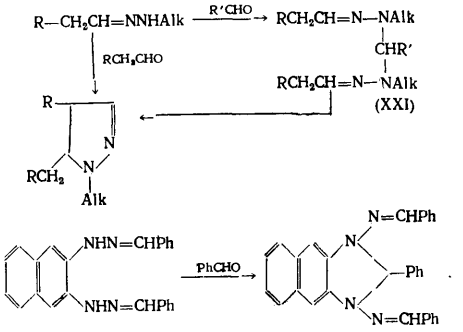
However, this reaction is not general [192]. Monohydrazones of β-dicarbonyl compounds are converted into pyrazoles (see subsection on alkylation). Monohydrazones of γ–ω-dicarbonyl compounds are able to yield either polyazines or heterocyclic compounds of the type (XIX), [2,10,25,49,193] as well as compounds of type (XX) (derivatives of *N*-aminopyrrole and *N*-aminodihydropyridine respectively) [10]:



(XIX) (XX)

(n = 2-20; m = 0, 1)

The higher electron density on the amino-nitrogen atom in monoalkylhydrazones facilitates electrophilic attack by oxo-compounds at this atom, and the reaction products are geminal dihydrazones (XXI); [2,9,10,194,195] in the aromatic series a similar reaction has been reported for a vicinal naphthylenedihydrazone of benzaldehyde [45,196]:

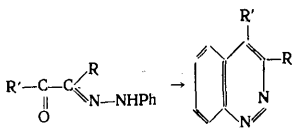


Compounds of type (XXI) are highly reactive: anhydrides of carboxylic acids acylate them to acylhydrazones [100], alkylhydrazines convert them into the corresponding hydrazones [194], and in the presence of excess of the aldehyde they are transformed into pyrazolines [194] (when Alk = H in (XXI), aldehydes yield azines [100]). It is supposed [194] that compounds (XXI) are formed as intermediates in the conversion of alkylhydrazines [194,197] or alkylhydrazones and aldehydes [194,197,198] into pyrazolines. Ioffe et al. have shown [198] that a pyrazoline is formed very easily from an aldehyde and its alkylhydrazone, but in the cross condensation of aldehydes with monoalkylhydrazones of other aldehydes and ketones the process is complicated by transhydrazonation, which occurs widely among hydrazones [199-212].

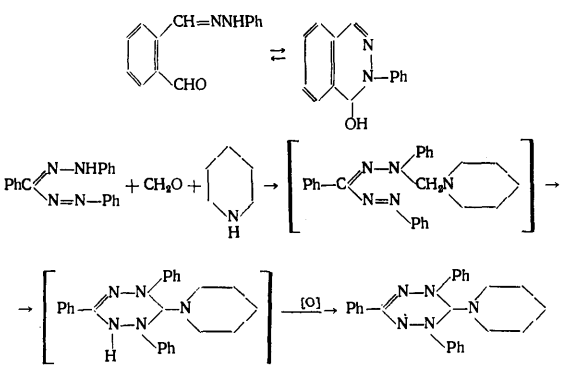
Arylhydrazones are more liable to transhydrazonation on reaction with carbonyl compounds, although phenylhydrazones form products of the triphenylmethane type,

involving condensation at the *para*-position; the reaction is catalysed by zinc chloride and by acids[45]:

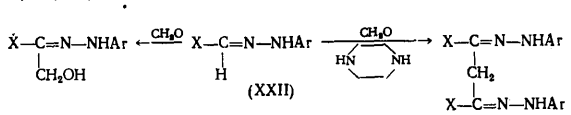
The phenyl ring is involved also in the intramolecular cyclocondensation of monophenylhydrazones of α-dicarbonyl compounds, which leads to the formation of cinnoline derivatives[26]:



The amino-group of arylhydrazones is also capable of condensation with carbonyl compounds. Phthaldehyde monophenylhydrazone exists in equilibrium with 1,2-dihydro-1-hydroxy-2-phenylphthalazine[27]; and 1,3,5-triphenylformazan reacts with formaldehyde and piperidine to give 1,3,5-triphenyl-5-piperidinomethylformazan, which under the reaction conditions cyclises into a 1,2,3,4-tetrahydrotetrazine derivative, and this oxidises spontaneously to verdazyl[213]:

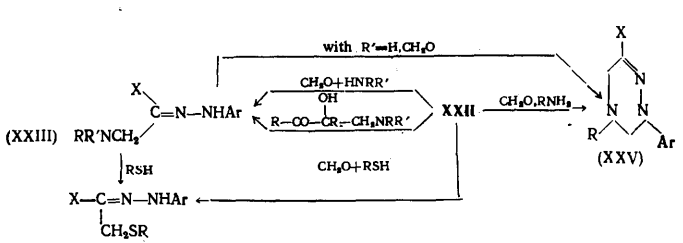


Oxo-compound arylhydrazones of type (XXII) (X = Az, NO_2, N:NAr, Ht, sometimes Ar) behave as if they contain a mobile hydrogen atom, and form arylhydrazones of α-hydroxy-ketones or bisarylhydrazones of 1,3-diketones[2, 10, 26, 45, 157, 214, 215]:



If the phenyl group in (XXII) contains an *ortho*-carbonyl group, intramolecular cyclocondensation may occur, leading ultimately to cinnoline derivatives[26].

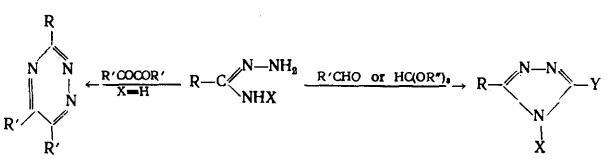
As compounds (XXII) (including 3*H*-formazans[157]) contain a mobile hydrogen atom, they undergo the Mannich reaction[45, 215-219], being converted into (XXIII), and with formaldehyde in the presence of thiols they yield (XXIV):[219]



A case of detachment of an acetyl group has been reported in the preparation of Mannich bases of the type (XXIII) from 2,3,4-trioxopentane 3-phenylhydrazone, formaldehyde, and piperidine[220]. The dialkylamino-group in (XXIII) is quite mobile, and can be substituted by the action of secondary amines, compounds containing a reactive hydrogen atom[218], and thiols[219] (including benzenethiols[220]), which helps to explain certain anomalies observed when these reactions are carried out[215]. The activity of (XXII) in the Mannich reaction is extremely high: they displace the dialkylaminomethyl group from Mannich acyloin bases[217].

When R′ = H in (XXIII), the *syn*-forms are able to condense with a further aldehyde molecule to 2,4,6-trisubstituted 2,3,4,5-tetrahydro-1,2,4-triazines (XXV).[221] Hahn showed[222-225] that the same products are formed by the reaction of hydrazones of type (XXII) with formaldehyde and primary amines. The formation of 1,2,4-triazine derivatives (XXV) from hydrazones of type (XXII) is a variety of the Mannich reaction, is quite general in character[222-226], and can be termed the Mannich–Hahn reaction.

Amidrazones and hydrazidines are also cyclised to 1,2,4-triazine derivatives on reaction with α-dioxo-compounds[110, 227-230], and into 1,2,4-triazole derivatives on treatment with aldehydes, acetals, or orthoesters[28, 45, 110, 231-233]:



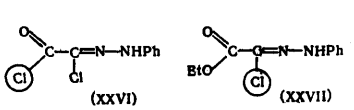
(X=H, Alk, Ar, NHR; Y=R′ or OR″).

III. REACTIONS OF HYDRAZONES WITH NUCLEOPHILIC REAGENTS

1. Substitutions at the Carbon Atom of the Hydrazone Group

Substitution occurs readily at the carbon atom attached to the hydrazono-group if the substituent X in the general formula (II) for a hydrazone is chlorine, hydroxyl, nitrile, an *NN*-dialkylaminoarylazo-group, etc.[2, 31, 32, 45-47, 123, 130, 134, 138, 143, 179, 187, 189, 234-251] (see Table):

A chlorine atom attached to the hydrazone carbon atom is less reactive than one attached to a carbonyl carbon but more reactive than an ethoxy-group; and the circled chlorine atoms in (XXVI) and (XXVII)



are replaced by the action of the azide ion[237, 239, 243].

There are also cases in which the products of nucleophilic substitution of hydrazones then undergo cyclisation[23, 31, 45, 131, 243-248]. Azines also undergo S_N reactions readily if X = Hal, CN, NO_2, etc. in (III),[22, 29, 31, 128, 138, 167, 189, 249-251] but cyclisation is then observed considerably more frequently[22, 29, 31, 32, 45, 133, 250, 251].

2. Reactions of Halogenated Hydrazones with Tertiary Amines

Halogeno-hydrazones (XXVIII) are able to react with tertiary amines by the usual mechanism of nucleophilic substitution to give a quaternary salt (XXIX),[45] but more frequently XH is eliminated with the formation of the extremely reactive "nitrilimine" (XXX), one of the most thoroughly studied 1,3-dipolar reagents[2,31-35,45,252,253]:

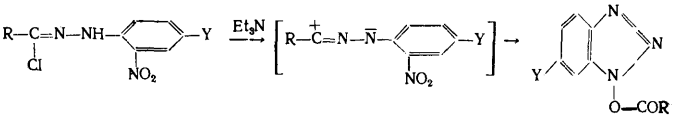
[a] Under the reaction conditions rearranges into a hydrazide (thiohydrazide).
[b] Very easily oxidised to formazan[47,143].
[c] The hydrazide of the acid is used.

A nitrilimine cannot be isolated in individual form, since it either dimerises to a dihydrotetrazine (XXXI)[31-35,45,252-255] or, in the presence of an unsaturated compound in the reaction medium, undergoes 1,3-dipolar cycloaddition with the formation of various five-membered heterocyclic systems. The mechanism of the latter type of reaction has been discussed many times in the literature[253,256,257], and a multicentre cyclic transition state is the most probable. 3-Halogenated formazans can also serve as source of nitrilimines[31-35,45,252,253]. Various types of ethylenic compounds (including cyclic and heterocyclic), alkenylamines, alkynes, nitriles, azomethines, isocyanates, aldehydes, thioaldehydes, carbon disulphide, and carbodi-imines have been used as dipolar reagents[31-35, 45,252-263]. The enhancement of the electron-accepting properties of the substituents R and Ar in (XXX) diminishes its reactivity towards addition at the double bond and increases the probability of dimerisation[268].

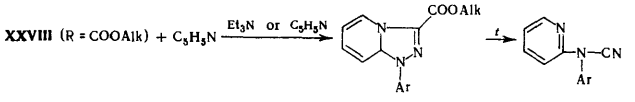
A nitrilimine adds more easily at a C=C than at a C≡N[264] or a C≡C[259] bond, but reacts less actively with a >C=N fragment[260]. In pent-1-en-4-yn-3-ones the nitrilimine reacts with the multiple bond having fewer substituents[261]. Cycloaddition is a stereospecific reaction: the most highly substituted carbon atom of the ethylenic or acetylenic group becomes position 5 of the pyrazoline or pyrazole ring[262].

The cyclic products formed by the reaction of (XXX) with aldehyde oximes and azines rapidly undergo further reaction, splitting off a molecule of water in the first case and cleaving at the N–N bond in the second, to give substituted triazoles as final products[268]. Vinyl derivatives of quinquevalent phosphorus, containing the group

undergo the usual type of 1,3-dipolar cycloaddition with nitrilimine[264], whereas $\alpha\beta$-unsaturated phosphonites and phosphines react by a mechanism of 3 + 3 addition[265]. Acylhydrazones, as well as semicarbazones and α-halogeno-aldehydes, are converted by tertiary amines into oxadiazole derivatives[2,266]. If the aryl ring in (XXVIII) contains an *o*-nitro-group, the resulting nitrilimine rearranges rapidly into a 1-acyloxybenzotriazole[267,268]:



Pyridine, quinoline, and isoquinoline can also act as dipolarophilic agents in reactions with hydrazones of type (XXVIII) in which R = COOAlk, but at high temperatures the products rearrange into heterocyclic *N*-arylcyanamides[269,270]:

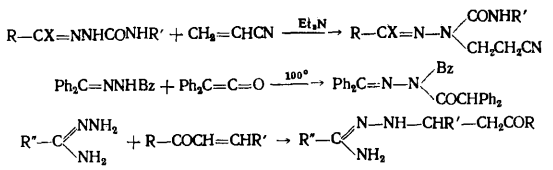


IV. ADDITION REACTIONS

1. Addition of Hydrazones at Multiple Bonds

Unsubstituted and monosubstituted hydrazones of aldehydes and ketones, as well as disubstituted hydrazones of aldehydes, contain a mobile hydrogen atom, and therefore are able to undergo the Michaelis reaction[2-7,9-12,21,23,24,25, 271-281]. Addition can take place at azo[45,282-284], ethylenic[2-7,9-12,21,23,45,271,272,285,287], acetylenic[9,10,23,24,45,286], azomethine[45,100,103,180,181,209,273-277], nitrile[2-7,9-12,23,45, 278-281], and carbonyl[27] groups, the amino-proton being more mobile than the hydrogen atom attached to carbon.

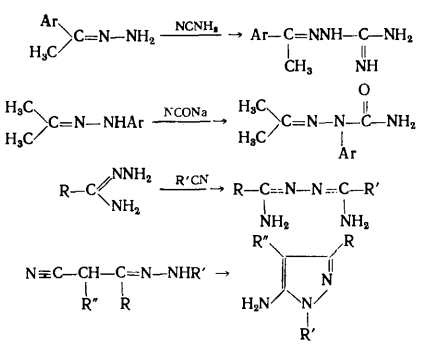
The reaction between semicarbazones and acrylonitrile is catalysed by tertiary amines[271]; benzophenone benzoylhydrazone reacts with diphenylketen in hot (100°C) xylene[287]; whereas amidrazones (amino-hydrazones) add to the ethylenic bond in vinyl ketones already at room temperature[272]:



The cyclisation of hydrazones of $\alpha\beta$-unsaturated carbonyl compounds, which occurs by a mechanism of intramolecular nucleophilic addition[23], is the most widely developed method for obtaining pyrazolines. The ease of ring closure depends on the nature of the substituents in carbonyl and hydrazine residues, and it occurs either when the hydrazones are formed or when they are heated in solution, often in the presence of acids[21,23]. The capacity for cyclisation diminishes with increase in the electron-accepting character of R′. Addition of the N–H group of hydrazones to an acetylenic bond has been observed mainly in cases of intramolecular cyclisation with the formation of pyrazoles[2-7,9-12,23,45]. Unsubstituted hydrazones[273], alkyl-, aryl-, and acyl-hydrazones[45,273,274], 1,5-diarylformazans[47,103], and substituted amidrazones[275,276] are easily added at the C=N bond of alkyl, aryl, and acyl isocyanates and isothiocyanates to give *N*-substituted semicarbazones and thiosemicarbazones respectively.

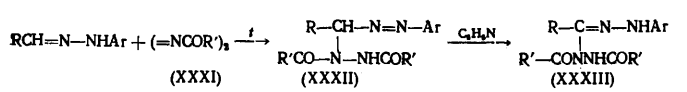
An example has also been reported of the preparation of a pyrazoline by the intramolecular nucleophilic addition of a hydrazone at the C=N bond of an azomethine[277], and an example of the addition of an unsubstituted hydrazone at a C=N bond of an azine[100].

The NH group of a hydrazone adds also to a C≡N bond, although with greater difficulty than at an ethylenic bond[271]. Acetophenone hydrazone and cyanamide in boiling alcohol yield the guanylhydrazone of this ketone[278], and $N_{(2)}$-arylsemicarbazones are obtained from sodium cyanate and arylhydrazones[45]:



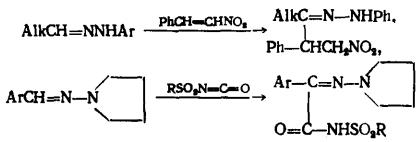
Amidrazones add to mono- and di-nitriles in the presence of triethylaluminium[279]. The intramolecular addition characteristic of hydrazones of α-cyano-carbonyl compounds provides a method for preparing aminopyrazoles[2-7,9-12,23,45,280,281].

The nature of the reaction products obtained from arylhydrazones and azo-acyls (XXXI) has been discussed many times. It is now considered that an azo-hydrazine (XXXII) is formed, which under the reaction conditions sometimes—and then only partly—rearranges into the hydrazidine (XXXIII); but (XXXII) easily passes into (XXXIII) on dissolution in pyridine[45,282-285]:

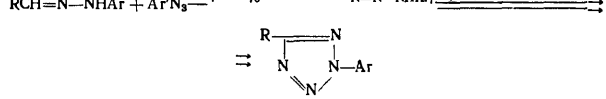


The ability of hydrazones to add to a C=O bond has been discussed above (Section II, subsection on reactions with carbonyl compounds).

Hydrazones are able to add to ethylenic[286], acetylenic[287], and azomethine[209] bonds by means of the =C–H fragment, but few examples of these reactions have been reported hitherto:



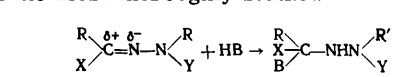
The reaction of aldehyde hydrazones with azides in the presence of sodium alkoxides leads to the formation of 2,5-diaryltetrazoles[31,45,288,289]. If the reaction is conducted under milder conditions, however, it is possible to isolate intermediate addition products—1,4,6-trisubstituted 1,2,3,5,6-penta-azahexa-2,4-dienes—which on further heating are cyclised to the tetrazoles[45,167,288]. Hence the first stage involves addition to the 1,3-dipolar reagent, and the second stage intramolecular azo-coupling:



Unsubstituted hydrazones, in the form of an anion, add to toluene-*p*-sulphonyl azide, but the products are unstable, and decompose into a diazo-compound, nitrogen, and toluene-*p*-sulphonamide[290,291].

2. Addition at the C=N Bond of the Hydrazone Group

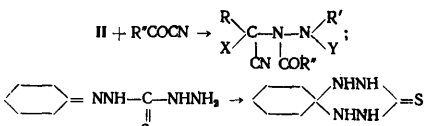
Reactions involving the addition of nucleophilic reagents have been the most thoroughly studied[1,2,9,10,32,44,45,48,49,292-314]:



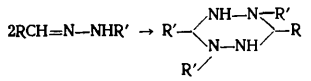
(B=—CN [2,10,32,44,45,48,49,292—294], —NHN=CRX [100], —NHNHR″ [295], —OR″ [1,296], —SR″ [297], —P(O)(R″)$_2$ [298—300], —HCR′NO$_2$ [301,302], —R″ (R″MgX, R″Li) [2,9,10,44,45,292,303—308]).

In azines both azomethine fragments are capable of addition[2,9,10,44,49].

Hydrocyanic acid adds relatively easily to unsaturated hydrazones[10,45], alkylhydrazones[292], arylhydrazones[2,45,48], semicarbazones[2,10,45,292], and azines[2,32,44,49,292] of aliphatic and alicyclic aldehydes and ketones, which are converted into α-cyano-substituted hydrazines. Acetone cyanohydrin can be used instead of hydrocyanic acid[293]. α-Ketonitriles behave similarly to hydrocyanic acid, adding at the azomethine bond of arylhydrazones of aliphatic aldehydes and ketones to form acylated α-cyano-substituted hydrazines[45,294]:

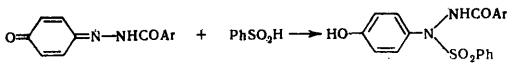


Hydrazines[295] and hydrazones[100] are able to add to the C=N bond of hydrazones. The transhydrazonation of hydrazones by hydrazines evidently also involves an intermediate stage of addition. The dimerisation of unsaturated hydrazones of aliphatic aldehydes[45,309] and of monoalkylhydrazones[32,310,311] and phenylhydrazones[312] of formaldehyde to 1,3,4,6-tetrasubstituted hexahydro-1,2,4,5-tetrazines is due to the addition of the NH group of one hydrazone molecule at the C=N bond of another molecule:



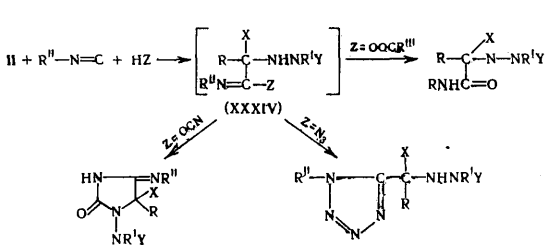
(R=H, Alk; R'=H, Alk, Ph)

The hydroxy-groups of cellulose react with the thiosemicarbazone of formaldehyde[296], and hydrogen sulphide with its azine[297]. Ring–chain tautomerism of 2'-hydroxyethylhydrazones also involves addition of a hydroxyl at the azomethine bond (Ioffe and Potekhin, Dorman—see Ref. 1 for literature). Dialkyl(and aryl)phosphines[298,299], dialkyl hydrogen phosphines[300], and nitroalkanes[301,302] add normally to hydrazones. Arenesulphinic acids and to mono(benzoylhydrazones) of *p*-benzoquinone at the 1,6-substituents[45]:

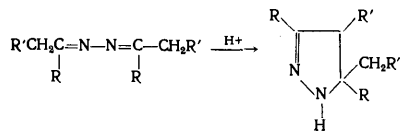


Mixed organomagnesium compounds react with unsaturated hydrazones, alkyl-, aryl-, and dialkyl-hydrazones, and azines of aldehydes to form hydrazines. This involves alkylation (or arylation) of the carbon atom in the hydrazone group[2,9,10,44,45,292,303–305]. The reaction is complicated by several secondary and consecutive processes, such as cleavage of the N–N bond, reduction, and rearrangements[2,45,304–308]. Organolithium compounds add somewhat more readily at the azomethine bond of hydrazones, and the yields of hydrazines are higher[304]. Strengthening the electron-accepting properties of the aryl group in dimethylhydrazones of substituted benzaldehydes favours the addition of an organolithium compound.

In the presence of acids isocyanides react with acetylhydrazones and azines to form an addition product (XXXIV),[2,31,313,314] which tends to rearrange or cyclise (Ugi's reaction):

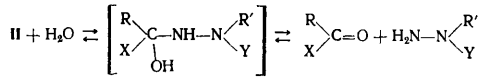


Less study has been made of reactions in which electrophilic addition takes place at the C=N bond in hydrazones. The aldol type of condensation in the presence of acid catalysts must be included among such reactions. Thus azines of carbonyl compounds containing an α-methine group cyclise to pyrazolines under the influence of acidic reagents[2,9,10,21,23,44,49,105,113,315,316]:



A kinetic study of the formation of 1-*cis*-3'-phenylpropenyl-5-phenylpyrazole in the pyrolysis of the azine of cinnamaldehyde has shown that this reaction is intramolecular[317], and so can indeed be included in the present type.

Hydrolysis. Being a weak nucleophilic reagent, the water molecule adds with difficulty at the C=N bond of hydrazones. The resulting *gem*-hydrazino-alcohols are unstable and decompose into the hydrazine and the carbonyl compound, or else lose the molecule of water and are converted back to the hydrazone, so that a dynamic equilibrium is established that under normal conditions is almost entirely displaced to the left:



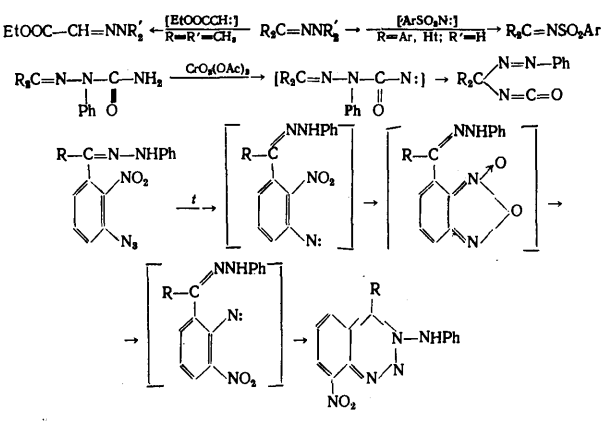
Alkaline[2,45,48] and especially acid catalysis[2,9,10,41,45,48,101,209,292] facilitates considerably the hydrolytic cleavage of hydrazones. The hydrolytic stability of these compounds is very greatly dependent on the nature of the substituents[2,45,48]: quaternary salts of hydrazones are most easily hydrolysed[9,10,49], followed by unsubstituted hydrazones[45] and alkyl- and acyl-hydrazones[2,9,10,49,292]. Arylhydrazones are more difficult to hydrolyse than are semicarbazones. Increasing the number of electron-accepting groups in the phenylhydrazone molecule improves its stability to acid hydrolysis[45,48]: for example, acetone 2,4-dinitrophenylhydrazone remains unchanged under conditions such that the phenylhydrazone is completely hydrolysed[45]. Arylhydrazones of α-keto-acids and α-dicarbonyl compounds possess improved stability. Arylosazones of sugars readily eliminate an arylhydrazine when boiled in acid medium[35,45]. Whereas the rates of hydrolysis of stereoisomeric oximes differ substantially, those of the stereoisomeric hydrazones of *p*-methoxybenzophenone differ insignificantly[318]. Almost all types of hydrazones and azines can be cleaved hydrolytically to the carbonyl compound, but if in (II) the substituent X = Hal, AlkO, ArO, NO_2, CN (see Section III, 2), ArN:N (formazans)[319], a hydrazide (a tautomeric form of a hydroxy-hydrazone: X = OH) is formed initially, and is then hydrolysed to the carboxylic acid and the hydrazine.

The hydrazone group is hydrolysed with greater difficulty than ester[10,38,45] and acylamino[10,45] groups. If these are present in a hydrazone molecule (X = COOR, OAr, NHAz, CONHR), they can be hydrolysed without the hydrazone fragment being affected.

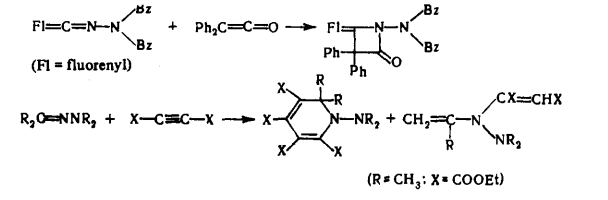
3. Cycloaddition

In contrast to alkenes and azomethines, which form three-membered rings with carbenes and nitrens[11,320], hydrazones are cleaved by these reagents. A carbene displaces the residue of the carbonyl compound[321,322],

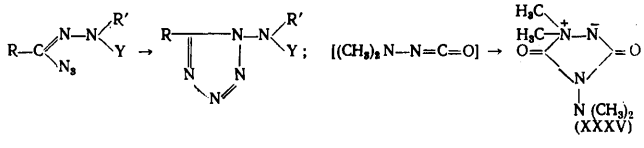
and a nitren the hydrazone fragment[323]; examples of 1,1-cycloaddition to hydrazones are not yet known. If a nitren is formed directly in the hydrazone molecule, the reaction is complicated by rearrangement[324,325]:



The possibility of 1,2-cycloaddition with hydrazones is shown by the reaction of aromatic diacylhydrazones with ketens[282]. Hydrazones do not react by 1,2-cycloaddition with acetylenic derivatives, perhaps owing to the instability of the ring: either linear 1 : 1 adducts are formed, or a second acetylenic molecule is involved to yield a cyclic 1 : 2 adduct[326]:

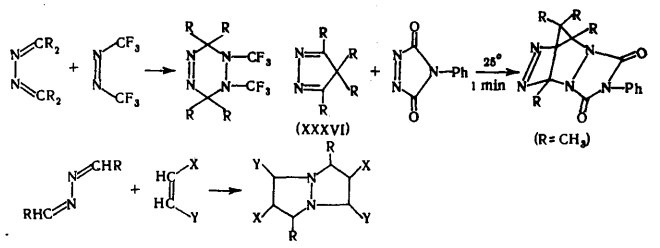


Reactions involving the 1,3-cycloaddition of hydrazones and azines to nitrilimine have been discussed above (Section III, 2). The formation of tetrazole derivatives from azido-hydrazones and azido-azines (very often at the instant of formation)[31,174] and the dimerisation of the dimethylhydrazone of carbon dioxide (dimethylamine isocyanate) into an ylid (XXXV)[327]



must be included in this type of reactions.

Examples of hydrazones functioning as dienophiles in the Diels–Alder reaction could not be found. A very attractive idea was to use azines as dienes, but the investigations showed[28,44,49,328] that only in very rare cases[329] could azines undergo 1,4-cycloaddition: usually they behave as "criss-cross" bis-1,3-dipolar reagents and form 1 : 2 adducts that are derivatives of tetrahydropyrazolo[1,2-*a*]pyrazole[28,44,328,330–333]. Aromatic and aliphatic aldazines and ketazines, and azines of perfluorinated carbonyl compounds react with alkylated alkene derivatives of acrylic, maleic, hydrocyanic, cyanic, and thiocyanic acids, and with alkyl, aryl, and acyl isocyanates, in conformity with this scheme of "criss-cross" addition[28,44,49,328,330–333]:

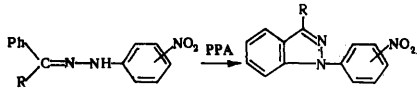


Such behaviour of azines towards dienophiles must evidently be explained by the non-coplanarity of azine molecules[1,334] and by steric hindrance to formation of the S-*cis*-form. The cyclic azine (XXXVI) very readily undergoes the Diels–Alder reaction[335].

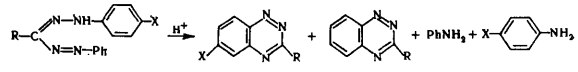
V. CATALYTIC CONVERSIONS

Action of Acids

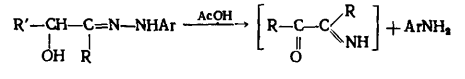
Several reactions of hydrazones in the presence of acids have already been discussed. The conversion of arylhydrazones of carbonyl compounds into indoles, known as the Fischer–Arbuzov reaction, also takes place under the influence of acids and acidic reagents[2,15–19,45,336]. Information on the catalysts used in this reaction will be found in Refs. 16–19. The formation of pyrroles from azines (the Piloty reaction) is a form of the Fischer–Arbuzov reaction[2,16–19,49]. The process involved in the formation of products of non-indole type under conditions for the synthesis of indoles has been termed an "anomalous Fischer–Arbuzov reaction".[16–19,337–341] Nitrophenylhydrazones of acetophenones, benzaldehyde, and aromatic ketones are cyclised into indazoles under the influence of polyphosphoric acid (PPA):[24,342–344]



Formazans are converted by strong acids into benzo-1,2,4-triazines and anilines[45,47,103,143,345]. Phenazine derivatives have been isolated as secondary products. Unsymmetrical formazans yield two benzo-1,2,4-triazines:

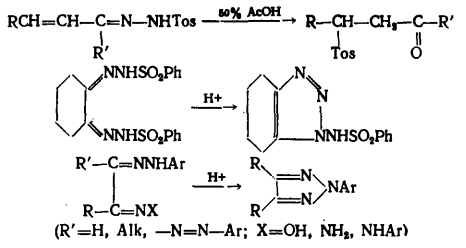


Heating arylhydrazones of α-hydroxy-carbonyl compounds in acetic acid results in fission of the nitrogen–nitrogen bond with formation of an unstable α-iminoketone, formed as intermediate in the preparation of osazones from α-hydroxy-carbonyl compounds and hydrazines[346,347]:

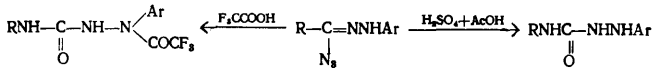


Toluene-*p*-sulphonylhydrazones of αβ-unsaturated ketones are converted in hot 50% acetic acid into good

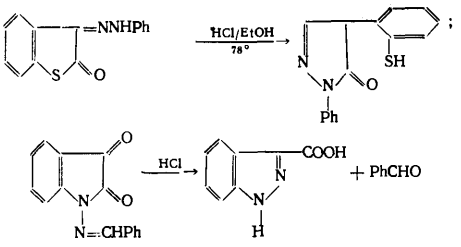
yields of β-tosylated ketones[348], whereas bisbenzenesulphonylhydrazones of α-diketones in acid medium form 1-substituted 1,2,3-triazoles[349]:



Formazan osazones[38,39], bisarylhydrazones, and hydrazone oximes of α-dicarbonyl compounds cyclise under these conditions to give 2-substituted 1,2,3-triazoles[20,28,88,350]. α-Azido-hydrazones in acid medium undergo rearrangement into 1,4-disubstituted semicarbazides (Curtius type of rearrangement)[236]:

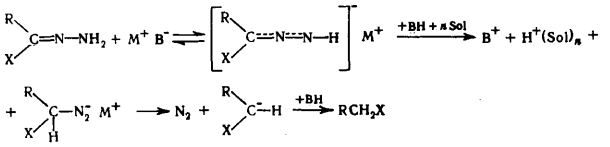


Several hydrazones of heterocyclic aldehydes and ketones, as well as hydrazones containing a heterocyclic radical, are able to rearrange under the influence of acids to form a new heterocyclic system, most often a pyrazole ring[25,45,351] (recyclisation):



Action of Bases

Strong alkalis (potassium hydroxide and alkoxides) convert unsubstituted hydrazones and semicarbazones into saturated hydrocarbons (Wolff–Kishner reductions)[2,10,11,36,37,352–354]:

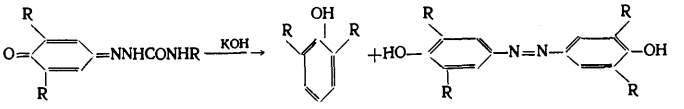


(B=OH⁻, RO⁻, $CH_3SOCH_2^-$; Sol = ROH, dimethyl sulphoxide)

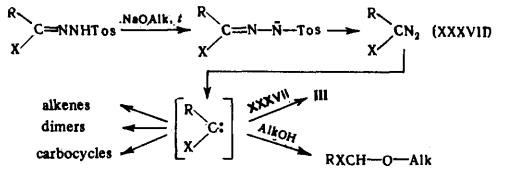
Azines undergo complicated changes in the presence of strong bases, evidently through an intermediate stage of nitrile cleavage. Thus under the influence of potassium *t*-butoxide in boiling xylene benzaldehyde azine gives a mixture of products, mainly 3,5-diphenyl- and 1-benzyl-3,5-diphenyl-1,2,4-triazoles together with benzoic acid[355]. Boiling arylhydrazones of aromatic aldehydes in the presence of potassamide or sodamide in xylene or benzene leads to the formation of amides[11,45,50,356–358] (the Robev rearrangement), which under the reaction conditions may decompose into an arylamine and a nitrile. This reaction involves an intermediate stage of homolytic cleavage of the nitrogen–nitrogen bond[357,358]:

Such cleavage produced by alkalis occurs also in benzoylphenylhydrazones of quinones[359] or aromatic ketones[360]:

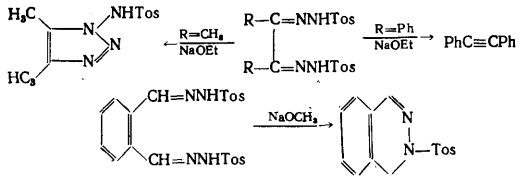
Semicarbazones of quinones decompose in hot alkali into phenols[361,362], and azophenols have been isolated as by-products[362]:



Diazo-compounds are formed by the hot alkaline cleavage of toluene-*p*-sulphonylhydrazones of aliphatic, mono-, di-, and tri-cyclic, aromatic, and steroid aldehydes and ketones[11,320,363]. They are not usually separated from the hydrazones, but are converted *in situ* into carbenes[10,11,321,363–372]. Decomposition of the dry sodium salts of toluene-*p*-sulphonylhydrazones gives similar results[365,370,371]:

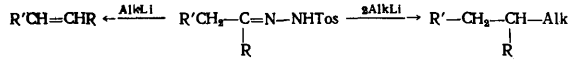


Toluene-*p*-sulphonylhydrazones of $\alpha\beta$-unsaturated ketones behave similarly on alkaline decomposition in protic solvents[372], whereas in an aprotic medium cyclopropenes are formed[373]. Depending on the nature of the groups in the carbonyl component, bistoluene-*p*-sulphonylhydrazones of α-dicarbonyl compounds form either alkynes or 1,2,3-triazole derivatives[363]:



The alkaline cleavage of the corresponding dihydrazone of phthaldehyde also yields a heterocycle, not a dicarbene[374].

The action of a lithium alkyl on toluene-*p*-sulphonylhydrazones of carbonyl compounds containing an α-methine group provides a convenient method for obtaining alkenes[375,376] and dienes[377] that are particularly inaccessible, e.g. in the terpene or steroid series. The abnormally high content of *cis*-alkenes in the products is evidently due to the fact that intermediate formation of a carbene is not involved[378]. Toluene-*p*-sulphonylhydrazones of $\alpha\beta$-unsaturated ketones are converted by butyllithium or sodium hydride into pyrazoles[372]. The use of excess of a lithium alkyl yields the alkylated hydrocarbon without the formation of alkenes[379]:



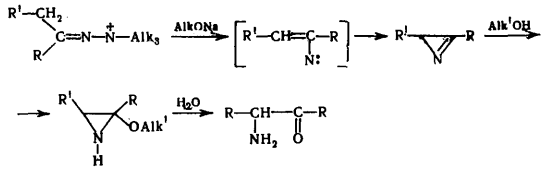
Under the influence of alkalis quaternary hydrazonium salts of aldehydes undergo amino–nitrile cleavage with rupture of the nitrogen–nitrogen bond [2,11,49,51,63,74–76,380–383]:

$$RCH{=}N{-}\overset{+}{N}Alk_3 \xrightarrow{OH^-} RCN + Alk_3N$$

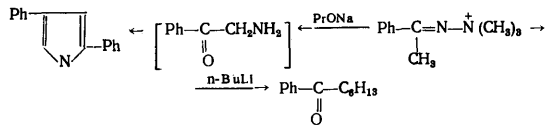
This is a general reaction for cyclic and acyclic hydrazonium salts [51] containing the fragment

$$-CH{=}N{-}\overset{+}{N}\lessgtr .$$

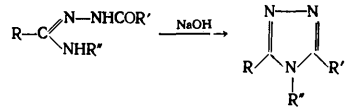
Quaternary salts of disubstituted hydrazones of ketones containing an α-methine group are cleaved by alkalis to α-amino-ketones [2,8,62,384–386]. The intermediate nitren isomerises into an azirine, which adds a molecule of an alcohol to form the alkoxyaziridine, and this is converted by water into the amino-ketone [62,384–386]:



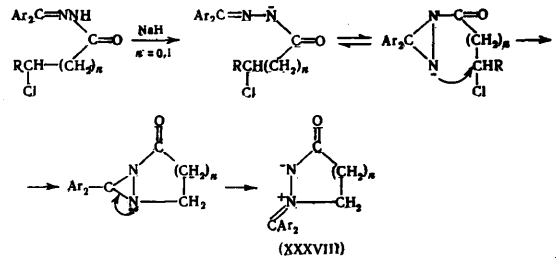
Acetophenone trimethylhydrazonium iodide is converted by an alkoxide into 2,4-diphenylpyrrole [386], and n-butyllithium yields 1-phenylheptanone [387]:



In the presence of alkalis or acids dihydrazones and oxime hydrazones of α-dicarbonyl compounds are cyclised to 1,2,3-triazole derivatives [28,45], whereas acylated amidrazones in alkaline medium are cyclised to 1,2,4-triazole derivatives [22,28,388]:



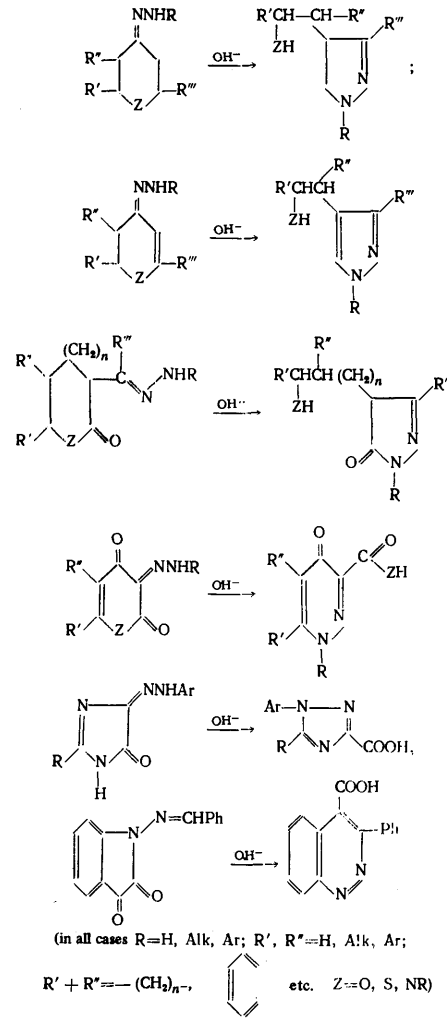
Acylhydrazones of aromatic ketones, obtained from hydrazides of α- and β-chloro-carboxylic acids by the action of bases such as sodium hydride, form cyclic ylides (XXXVIII), [389] most probably by the following series of reactions:



(XXXVIII)

Hydrazones of certain heterocyclic ketones undergo rearrangement with formation of a different heterocyclic system [9,10,23,25–27,45,49,390–396], more often in alkaline than in acid solutions. Monosubstituted and unsubstituted hydrazones of flavanones [45,390,391] chromones and thiochromones [45], 3-acylchromones [392], pyrones [23,45,49], α-acyl-γ-lactones [23,45] and thiolactones [45,393], and 3-acylindoles [49,394] when heated in alkaline medium rearrange to derivatives of pyrazole, pyrazoline, or pyrazolone.

Hydrazones of α-acyl- and α-oxo-δ-lactones [26,27,45,395] are converted into pyridazones (cinnolines), and 5-arylhydrazones of unsubstituted, 2-alkylated, and 2-arylated imidazoline-4,5-diones into 1-aryl-5-R-1,2,4-triazole-3-carboxylic acids [396]. Hydrazones that are derivatives of *N*-amines of nitrogenous heterocycles also tend to undergo such rearrangements [26,45,125]. A common feature of these reactions is rupture of the Z–C bond in the heterocycle with nucleophilic attack on the amino-nitrogen atom of the hydrazono-group and formation of a carbon–nitrogen bond in a new heterocycle:



(in all cases R=H, Alk, Ar; R′, R″=H, Alk, Ar; R′ + R″=—(CH$_2$)$_n$—, etc. Z=O, S, NR)

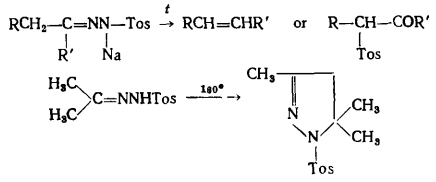
Pyrolysis

Heating to 200–300°C aryl-, diaryl-, and acyl-arylhydrazones of aldehydes, sometimes also of ketones [397], often in the presence of transition-metal chlorides, leads to heterolytic cleavage of the nitrogen–nitrogen bond with formation of a nitrile and an arylamine [2,10,45,50,101]:

$$RCH{=}NNHR'Y \xrightarrow{200-300^\circ} RCN + R'NHY$$

Alkylhydrazones of aldehydes are also capable of nitrile cleavage, but the reaction occurs with greater difficulty [50,197]. Trialkylhydrazonium salts of aldehydes of type (VI) are cleaved considerably more easily [50,51].

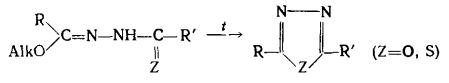
In the case of bisarylhydrazones of 1,4-diketones heating leads to the formation of *N*-arylpyrroles[17]. Pyrolysis of the sodium derivatives of toluene-*p*-sulphonylhydrazones is one method for generating carbenes[320,398,399], whose further transformation depends on the structure of the carbonyl component, mostly yielding alkenes[398], sometimes ketones containing a *p*-tolylsulphonyl group[399]:



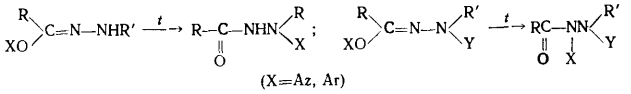
Pyrolysis of acetone toluene-*p*-sulphonylhydrazone is "anomalous" and leads to the formation of 3,5,5-trimethyl-1-*p*-tolylsulphonyl-Δ^2-pyrazoline[400]. Thus the products are analogous in structure to those obtained by the catalytic decomposition of acetone phenylhydrazone[339]. Derivatives of Δ^2-pyrazoline are formed also by pyrolysis of the perchlorate of acetophenone dimethylhydrazone[101].

When acylhydrazones, including semicarbazones and thiosemicarbazones, are boiled in solvents or are heated above their melting points, azines are formed[44]. The pyrolysis of aromatic azines at temperatures around 300°C passes through a stage in which diazo-compounds are formed[2,11] and then carbenes[338,401], yielding stilbene derivatives[2,10,44,49,402], but cyclopropane derivatives when alkenes are present[332]. Aliphatic azines decompose analogously, but the possibility of isomerisation into azo-compounds produces conditions under which various alkanes can be formed[44,49,403].

Amidrazones, acylamidrazones, and hydrazidines are cyclised at 150–200°C to 1,2,4-triazole derivatives[2,28,110,404], but dihydrazones and oxime hydrazones of α-diketones form 1,2,3-triazole derivatives[20,28,405]. Acyl- and thioacyl-hydrazones, including semi- and thiosemi-carbazones, of α-alkoxy-carbonyl compounds (acylhydrazones of esters) are cyclised at high temperature to oxadiazoles or thiadiazoles[10,316,406]:



Arylhydrazones and disubstituted hydrazones of α-acyloxy- and sometimes α-aryloxy-carbonyl compounds (arylhydrazones of acid anhydrides or esters), however, undergo a Chapman rearrangement under these conditions[31,45,407]:



(X=Az, Ar)

Photolysis

When benzaldehyde phenylhydrazone is illuminated, the nitrogen–nitrogen bond is broken with the formation of benzonitrile, aniline, and benzaldehyde, the last produced from its imine[408]. Diazo-compounds[409] and then carbenes[369] are intermediates in the photolysis of toluene-*p*-sulphonylhydrazones, but the products obtained are different from those from the alkaline or thermal decomposition of this group of hydrazones[369,409,410]. Thus photolysis of the sodium salt of the toluene-*p*-sulphonylhydrazone of nortricyclanone yields 3-nortricyclyl *p*-tolyl sulphone, whereas its pyrolysis gives 4-ethynylcyclopentene[410]. The photolysis of aromatic azines involves rupture of both nitrogen–nitrogen and carbon–nitrogen bonds with the formation of aryl cyanides, *cis*- and *trans*-stilbenes, and aromatic imines, which are hydrolysed to aldehydes[2,44,411]. In aliphatic azines the cleavage of carbon–carbon bonds in the carbonyl component is also observed[44,49,412]:

Stereochemistry of Free-radical Additions in the Bicyclo[2.2.1] heptene and Bicyclo[2.2.1]heptadiene Series

V.A.Azovskaya and E.N.Prilezhaeva

The stereochemistry of free-radical additions to norbornene and norbornadiene systems is examined. The dependence of the direction of radical attack on the degree of substitution of the bicyclene, and on the position and steric and electronic effects of the substituents is discussed. A mechanism of radical rearrangement of the corresponding norbornene radicals is considered. 109 references.

1. INTRODUCTION

Among the various bridged cyclic hydrocarbons the system containing a norbornene skeleton is one of the most interesting and also closest to important natural compounds of the terpene type. The rigid fixed geometry of bicyclo[2.2.1]heptane and its derivatives leads to distortion of the valence angles and hence to the establishment of a different type of strain. This in turn brings about an unusual interaction of the electronic and steric effects of the substituents and the reactivity of the latter is closely connected with their position in the molecule.

Owing to the extensive development and use of modern methods of separation and identification of compounds it has recently become possible to find more precisely the structure of intermediate products and also the stereochemical results of the behaviour of these systems under various conditions. Exceptions to the stereochemical rules previously thought to be firmly established are now being found. For example, there is now very extensive discussion of the nature of norbornyl cations, instances of non-stereospecific addition of polar reagents are being reported, and the question of the possible existence of non-classical 7-norbornyl radicals is being discussed.

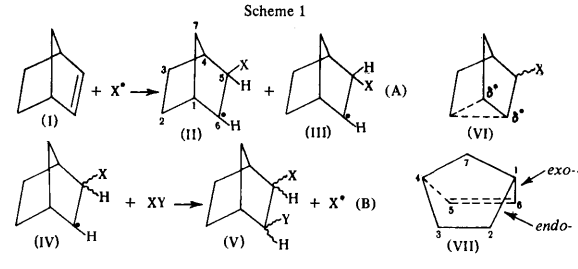
Davies and Cristol [1] have already reviewed the addition of free radicals to norbornene and norbornadiene systems but only dealt with the literature up to 1963. The relatively extensive investigation of such reactions and especially of their stereochemical aspect began again after 1963 and a critical appraisal of the new results is very desirable†. This is all the more important in that in this field new methods of investigation (especially NMR spectroscopy and gas–liquid chromatography, or GLC) have disclosed significant departures from the known stereochemical rules, and also to the observation of interesting free-radical rearrangements. In the present review we used the results of investigations in which the radical nature of the process has been rigorously proved and the stereochemistry of the products reliably established.

† When the present review had almost been completed, we learnt that a review by Davies [2] dealing with free-radical reactions in the bicycloheptane series had appeared in 1970 in a Chemical Society Special Publication. However, it examines the published information from a somewhat different aspect.

2. FREE RADICAL ADDITION TO NORBORNENES

Since it is known that most of the reagents concerned react with alkenes by a free-radical chain mechanism [3,4], the stereochemistry of the products of addition to norbornene (NB) (I) will be determined mainly by the stereochemistry of two stages: (A) the addition of the free radical X·, and (B) chain transfer (scheme 1).

Scheme 1



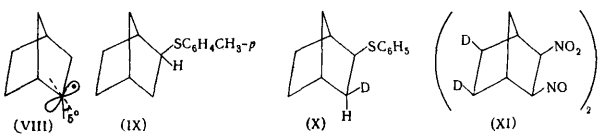
Even the first investigations in this field led to the conclusion of the participation in the reaction of classical free radicals of type (II) as opposed to a non-classical radical of type (VI), analogous to a non-classical carbocation [5]. The absence of addition products of the Wagner–Meerwein rearrangement type during the course of the free radical reactions also evidently agreed with this conclusion.

The *exo*-direction is evidently the most accessible for attack by a free radical in the NB molecule and therefore *exo*-radical attack was considered the rule until recently [6]. The greater accessibility of the *exo*-side of molecule (VII) is evidently due to its lesser steric blocking by the methylene bridge in comparison with the obstacles at the side of the dimethylene bridge in the *endo*-approach of the radical. A second factor favouring the formation of radical (II), and not (III), is the absence in transition state (II) of shielding of the $C_{(5)}$ and $C_{(4)}$ hydrogens, shown in an increase in the torsional strain effect [7].

A theoretical calculation of the structure of the 6-norbornyl radical appeared recently [8]. It was shown

that its most stable configuration has the deformed sp^2 planar structure (VIII) ($H_{(6)}$ emerges from the $C_{(1)}-C_{(6)}-C_{(5)}$ plane at an angle of ~5°), and the orbital with an unpaired electron has maximum extension in the *exo*-direction from $C_{(6)}$. This should also be apparent on assuming the *exo*-approach of the reagent to the norbornyl radical.

Hence both at the stage of initial attack and also at the stage of chain transfer with participation of the norbornyl radical *exo*-approach of the reagents, leading to *cis*-*exo*-addition, is postulated.

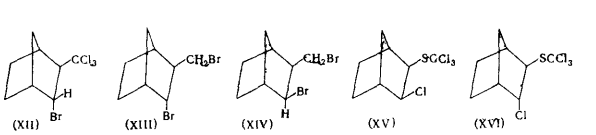


Actually, stereospecific *exo*-addition was observed in the reaction of NB with thiols [*p*-thiocresol[5], methanethiol, 2-methylpropane-2-thiol, thioacetic acid (TAA), and thiophenol[9]], acetone and acetaldehyde[10,11], formamide[12,13], in the free-radical chloroalkylation by chloroalkanes of the RCH_2Cl type[14]. In every instance exclusively *exo*-products of type (IX) were formed. The nature of the addition products did not allow any differences between the *cis*- and *trans*-addition to be distinguished. However, in an investigation specially made for this purpose, Davies and coworkers showed[9] that *S*-deuteriothiophenol adds to NB with the formation exclusively of the *cis*-*exo*-addition product (X). The reaction of N_2O_3 with *exo*-*exo*-2,3-dideuterionorbornene (XI) proceeds in an analogous manner[15].

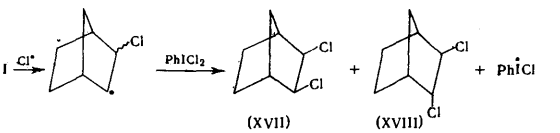
When an attacking radical has a sufficiently large steric volume, the initial addition from the less inconvenient *exo*-side in every instance (with participation of NB) without exception. However, chain transfer can be effected from various sides of the intermediate radical (II), depending on the nature of the reagent and substituent already present in the NB molecule. In this instance the stereoelectronic interaction between group X of Scheme 1, p. 516, and the molecule of the carrier can bring about *trans*-addition, despite the unfavourable effect of the torsion strain. Thus bromotrichloromethane[16-19], *p*-toluenesulphonyl chloride[20], and perfluoroiodopropane[21] give products of the *trans*-addition type (XII) with NB. CCl_4 adds similarly[16]. True, a recent repeat investigation[22] showed that for CCl_4 the ratio of *cis*-*exo*- and *trans*-addition products is 1 : 18.2.

In addition to the above reagents, which give predominantly *cis*-*exo*- or *trans*-products, there are also others for which the stereoelectronic interaction is intermediate. Then a mixture of *cis*-*exo*- and *trans*-addition products is obtained.

Thus a mixture of products of type (XIII) and (XIV) was obtained on the addition to NB of methylene dibromide, methyl bromoacetate[9], t-butyl hypochlorite[23], *N*-chlorourethane[24], N_2O_4,[25] ethyl chloroglyoxalate[26], and bromodicyanomethane[27].



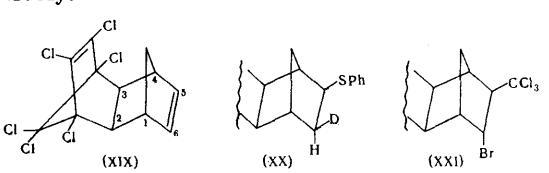
A similar intermediate example is evidently the addition to NB of trichloromethanesulphenyl chloride with the formation of a mixture of the products (XV) and (XVI) in 40 : 60 ratio[28].



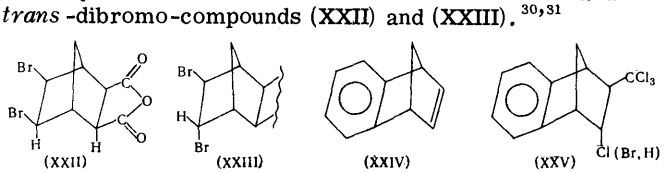
The radical chlorination of NB is yet another example. In the thermal or photochemical generation of chlorine radicals from phenyl iododichloride at 0–80°C, a mixture of the *cis*-*exo*- and *trans*-dichloro-compounds is formed; (XVIII) : (XVII) = 2.4.[29]

During photoinitiated halogenation‡ with chlorine[29], when a less bulky reagent participates in chain transfer, approximately equal amounts of the *cis*-*exo*- and *trans*-dichloro-compounds are formed.

Chain transfer from the endo-side of the intermediately formed radical can probably favour the electronic interactions of group X with the end of the carrier molecule. For example, with CCl_3Br and CCl_4 the repulsive forces that arise act together with the steric factors, leading exceptionally to *trans*-addition. How does the presence of substituents in the norbornene ring affect the stereochemistry of the addition? Evidently, 2,3-*exo*-substituents do not affect the direction of either the initial attack by the radical, or the chain transfer stage. Actually, the reactions of aldrin (XIX) and NB take place analogously: *S*-deuteriothiophenol[1] adds in the *cis*-*exo*-position but bromotrichloromethane, CCl_4,[17] *p*-toluenesulphonyl chloride[20], and perfluoroiodopropane[21] in the *trans*-position with the formation of products of type (XX) or (XXI) respectively:

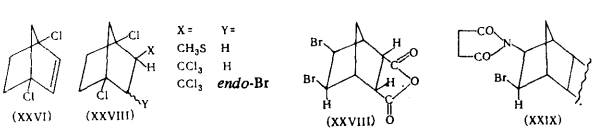


Bromination of the *exo*-anhydride of norbornenedicarboxylic acid leads to a mixture of the *cis*-*exo*- and *trans*-dibromo-compounds (XXII) and (XXIII).[30,31]



The addition of chloroform, CCl_4, or CCl_3Br, to benzonorbornadiene (XXIV),[32] just as for NB itself, leads to *trans*-products of the (XXV) type.

Evidently, 1,4-substituents also do not affect the stereochemistry of the process. The addition of methanethiol, bromotrichloromethane, and chloroform to 1,4-dichloronorborn-5-ene (XXVI) leads to products (XXVII) analogous to those obtained from NB itself[33]:

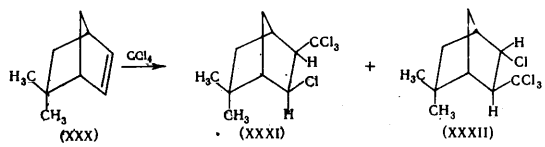


‡ In parallel with the homolytic processes in the above reaction ionic addition also occurs, but the investigators were able to extrapolate the "pure" radical halogenation from the experimental results for the products.

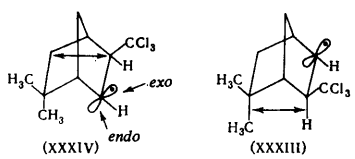
When the substituent occupies the 2- and/or 3-*endo*-positions or is at the double bond of the norbornenyl ring then when *exo*-selectivity is retained in the first stage this can significantly affect the stereochemical results of the reaction.

The exclusive formation of *cis*-*exo*-products occurs in the bromination [30,31] and reaction with *N*-bromosuccinimide [34] of the *endo*-anhydride of norbornenedicarboxylic acid, compounds (XXVIII) and (XXIX). Screening of the *endo*-side of the norbornene ring by the anhydride ring makes *cis*-*exo*-addition the only possibility.

In the reaction of CCl_4 with 2,2-dimethylnorborn-5-ene (XXX) a mixture of the *cis*- and *trans*-products (XXXI) and (XXXII) in the ratio 1.2 : 1 is formed [22]:



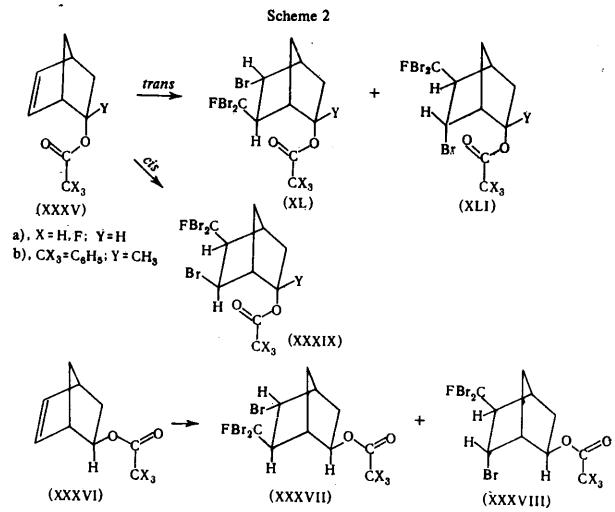
Since the quantities of *cis*- and *trans*-products are approximately equal, clearly the 2-methyl groups have an insignificant effect on the entering CCl_3 radical. As follows from the structure of the products obtained, the influence of the 2-*endo*-methyl group is especially pronounced at the chain transfer stage. Whereas for the radical (XXXIII) *trans*-addition takes place (as for unsubstituted NB), in the radical (XXXIV) the *endo*-methyl group exerts a greater steric barrier than the *exo*-CCl_3 group, which leads to the *cis*-product (XXXI):



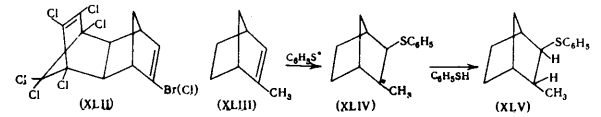
Osborn and coworkers assume [22] that the 2-*endo*-methyl group is situated closer to the line of formation of the new bond than the CCl_3 group and this is evidently also connected with the more rigid steric control of the 2-*endo*-substituent. It is noteworthy that the decrease in steric strain in *exo*-attack at the radical (XXXIV) evidently here plays a more important part than electronic interactions (the forces of repulsion of the two electron-withdrawing substituents in *exo*-attack, and conversely, the attraction of two different substituents in *endo*-attack at the chain transfer stage).

An analogous conclusion about the influence of 2,3-*endo*-substituents was drawn by Ludwick and Martin [35]. In studying the addition of tribromofluoromethane to norborn-5-ene-*endo*-2,3-dicarboxylic anhydride and to norborn-5-ene-2-*endo*- and 2-*exo*-acetate (or -benzoate) (XXXV) or (XXXVI), they found that the ratio of *exo*-*cis*- and -*trans*-addition products is determined by steric requirements produced by the 2-*endo*-substituent. Thus whereas the reaction with NB itself or with the 2-*exo*-acetate (XXXVI) leads to the formation of only the *trans*-products (XXXVII) and (XXXVIII), the 2-*endo*-substituted compounds (XXXV) always form a mixture of the *cis*-*exo*- and *trans*-addition products (XXXIX)–(XLV), and on going from the acetate (XXXVa) to the benzoate (XXXVb) the *trans*-product of type (XLI) almost disappears from the reaction mixture (see Scheme 2):

Scheme 2

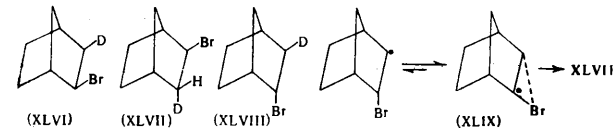


The addition of chloroform to 6-bromoaldrin (XLII) [17] or *p*-thiocresol to 6-chloroaldrin [36], and also of thiophenol to 6-methylnorbornene (XLIII) [9] proceeds by a *cis*-*exo*-process with the formation of products of the type (XLV):



This is evidently connected with the decrease in the torsion strain in the transition state during chain transfer from the *exo*-direction, and also the existence of a steric barrier for *cis*-distribution of two bulky substituents.

Hence in the norbornene series the rule of initial *exo*-radical attack would seem to be strictly obeyed. However, in 1964, in studying the deuteriobromination of NB, Kwart and Nyce [37] obtained a mixture of three bromo-compounds containing 60% of the product of *exo*-*cis*-addition (XLVI) together with 40% of a mixture of approximately equal amounts of the *trans*-bromo-compounds (XLVII) and (XLVIII)§:



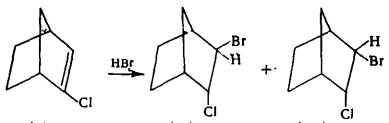
Here *exo*-attack is no longer exceptional, although it remains preferential (4 : 1). Kwart and Nyce assume the possibility of the formation of *trans*-bromo-compounds

§ Kwart and Nyce did not isolate the bromo-compounds (XLVII) and (XLVIII) and the assignment of the corresponding structures was made on the basis of a degradation analysis of the dehydrobromination products. In this it was assumed that in every instance *cis*-elimination takes place preferentially. Later investigations showed that in a series of norbornene halogeno-derivatives *trans*-elimination is six times more preferable than *endo*-*cis*-elimination [30]. Hence the true ratio of the bromides in the complementary investigation may be different.

through a bridged radical of type (XLIX). The greater stability of the latter also evidently brings about a decrease in the steric barrier for *endo*-attack.

The intermediate formation of bridged radicals owing to the possible extension of the valence cloud of the sulphur and halogen atoms was demonstrated earlier in additions to alkenes [39,40] and suggested to explain the comparatively ready 1,2-radical migration of halogen and alkanethio- or arylthio-groups [41]. The existence of such radicals was also confirmed by the EPR method [42].

The hydrobromination of 6-bromo- or 6-chloro-norbornene (L) also leads to a mixture of dihalogeno-compounds owing to both *exo*-attack (LI) and *endo*-attack (LII) by the bromine atom (ratio ≃ 7 : 3). [42-45]



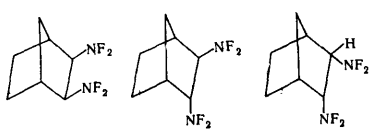
(L) (LI) (LII)

However, the assumption of the possibility of the existence of bridged radicals cannot explain the hypothetical formation of *cis*-*exo*-halogeno-compounds in all the above examples.

The observed instances of *endo*-attack can evidently also be explained without involving the concept of bridged radicals.

For this we must consider the other side of the question: the steric compactness of the attacking radical, which evidently markedly reduces the steric interactions of the entering substituent with the 2,3-*endo*-hydrogen atoms of the NB molecule.

Thus it was recently observed that a mixture of *cis*-*exo*-, *trans*-, and *cis*-*endo*-5,6-difluoroamines, (LIII)–(LV), is formed in the radical addition of tetrafluorohydrazine to NB. [46] In this instance the addition is no longer *exo*-stereospecific, although it still remains *cis*-*exo*-stereoselective.



(L II) (LIV) (LV)

Evidently this also applies to the radical halogenation of NB (see p. 522) in which the formation of *trans*-dihalogeno-compounds is probably partly linked with the initial *endo*-attack.

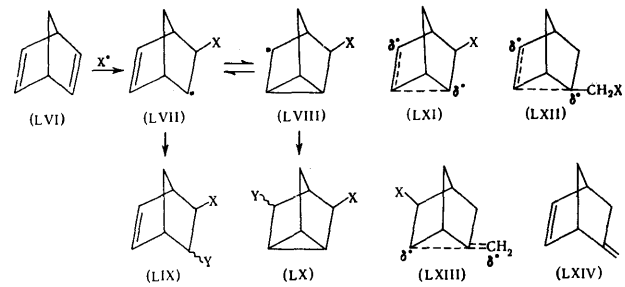
Even more significant changes in the stereochemical rules of radical attack are observed for norbornadienes with 7,7-substituents, especially well screened at the *exo*-side of the molecule. Examples of this series will be examined below.

3. FREE RADICAL ADDITION TO NORBORNADIENE (NBD)

The main feature of the reactions of NBD (LVI) is participation of the second double bond in the process, with the formation of substituted nortricyclene compounds of type (LX) owing to homoallyl interaction (see Scheme 3).

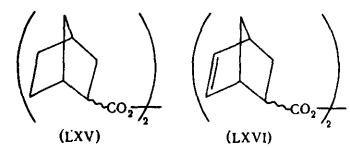
Just as in the NB series, the many investigators have not presented convincing arguments in support of the successive formation of classical intermediate radicals of type (LVII) and (LVIII) and against the existence of a non-classical radical to the type (LXI).

Scheme 3



It is now certain that neither the $C_{(1)}-C_{(2)}$ σ-bond in NB, nor the $C_{(2)}-C_{(3)}$ π-bond in NBD participates significantly in the delocalisation of the radical centre in these systems¶. The investigation of the competing addition of the trichloromethyl radical to a mixture of NB and NBD showed [48] that the effect of the second double bond is strictly additive: NBD is twice as reactive as NB. There is therefore no basis for assuming the existence of a transition state with lower energy, leading to a non-classical radical of type (LXI). The relative rates of addition of the methyl radical† to NB and NBD are 50 and 115 respectively [49]. The ratio of these quantities for NB and NBD probably also shows the absence of significant homoallyl strain. Similar results against the non-classical radicals of the (LXII) and (LXIII) type were obtained in studies [50,51] of the reactions of 5-methyl-norborn-2-ene (LXIV).

The activation parameters for the homolysis of *endo*- and *exo*-bonds of t-butylnorbornyl- and norbornenyl percarboxylates have been compared [52]. The results also rule out the probability of the formation of non-classical radicals at the rate-determining stage of the reaction. Similar results were also obtained in studying the thermal decomposition of diacyl peroxides of the (LXV) and (LXVI) type [53]. The participation of classical free radicals has also been confirmed in many other studies [5,6,36,37,51,54].



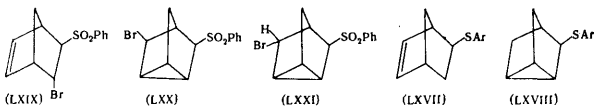
(LXV) (LXVI)

A convincing proof in support of the existence of discrete radicals (LVII) and (LVIII) is, for example, the change in the ratio of the reaction products (Scheme 3) with the concentration of the ligand and its reactivity. For example, *p*-toluenesulphonyl chloride [20], mercapto-acetic acid [55], perfluoroiodopropane [21], chloroform, butanal, heptanal, diethyl phosphite [48], and CCl_4 [56]—reagents with a relatively low transport constant—lead only to the corresponding nortricyclenes. On the other hand *p*-thiocresol and thiophenol [57] give a mixture of 5-*exo*-arylthionorborn-2-enes of type (LXVII) and the nortricyclene thioethers of type (LXVIII). An analogous

¶ True, the participation of the $C_{(2)}-C_{(3)}$ π-bond in the delocalisation of the radical centre at $C_{(7)}$ in the generation of C–7-radicals by the decarbonylation of the corresponding aldehydes is accepted [47], but this is not an addition reaction.

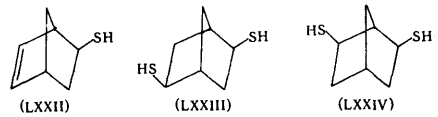
† In relation to the rate of withdrawal of hydrogen from iso-octane by the methyl radical.

mixture of products is formed in the reaction of NBD with CCl_3Br.[56] Phenylsulphonyl bromide forms the *trans*-addition compound (LXIX) and a mixture of the nortricyclene bromides (LXX) and (LXXI) in the ratio 4 : 3:[58]



(LXIX) (LXX) (LXXI) (LXVII) (LXVIII)

However, under the action of ultraviolet radiation H_2S gives only 5-mercaptonorborn-2-ene (LXXII) and the 2,5- and 3,5-dimercaptonorbornanes (LXXIII) and (LXXIV):[59]

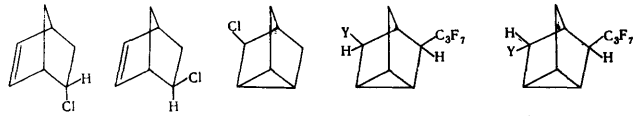


(LXXII) (LXXIII) (LXXIV)

In the reaction of phenylsulphonyl halides with NBD the relative amounts of nortricyclene products of type (LXX) and (LXXI) increase as the ligand activity in halogen transfer is reduced in the sequence: sulphonyl chloride > bromide > chloride[60].

The results of a series of recently published investigations can be explained satisfactorily by considering not only the existence of discrete radicals of structures (LVII) and (LVIII), but also the mobile equilibrium between them. For example, in the reduction of norbornenyl and nortricyclyl bromides and chlorides by tri-n-butyltin hydride the composition of the resulting mixture of NB and nortricyclene did not depend on the initial bromide (or chloride)[61]. In other words, the equilibrium between the norbornene and nortricyclene radicals was established more rapidly than their stabilisation. In the reduction of nortricyclyl bromide with triphenyltin hydride the relative amount of nortricyclene hydrocarbon was increased when the hydride concentration was raised, which agreed completely with the existence of an equilibrium pair of classical radicals. Similar results were also obtained in other methods of regenerating the radicals: by heating di-t-butylpercarboxylates of NB,[52] by decarboxylation of the corresponding aldehydes in chlorobenzene in the presence of peroxides[47], from the corresponding bromides in the presence of cobalt chloride and Grignard reagent in ether[61].

Other interesting examples of homoallyl–cyclopropylcarbinyl rearrangement have been published. For example, Cristol and Glason[62] found that in the reduction of *endo*- and *exo*-norbornenyl and nortricyclyl chlorides (LXXV)–(LXXVII) with sodium diphenyl at room temperature the composition of the reaction products (NB : nortricyclene = 1 : 3) did not depend on the initial chloride, that is, the equilibrium of the radicals was established more rapidly than the capture of an electron from the diphenyl radical-anion. However, at −58°C (LXXV) and (LXXVI) gave a mixture in which there was only 30% nortricyclene, but (LXXVII) a mixture in which there was up to 90% of the latter. Hence the reaction proceeds through classical radicals and the activation energy for their rearrangement is greater than for the capture of electrons from the radical-anion.



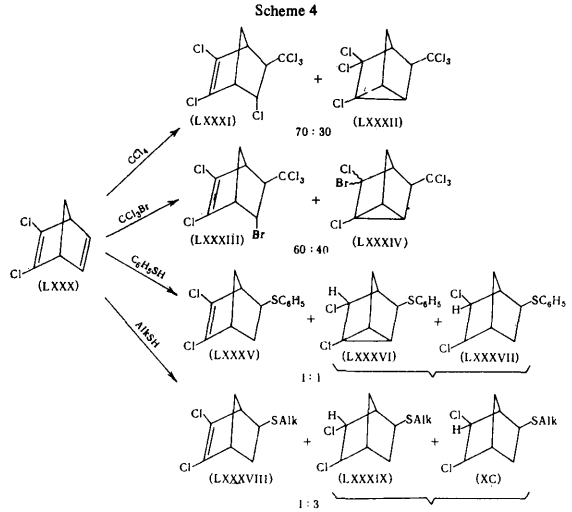
(LXXV) (LXXVI) (LXXVII) (LXXVIII) (LXXIX)

As regards the stereochemistry of addition to unsubstituted NBD, until recently it was always observed that initially there is *exo*-attack by the radical. Chain transfer for the nortricyclene radical (LVIII) evidently proceeds equally readily from both sides of the molecule, as a result of which in every instance mixtures of products of the type (LXXVIII) and (LXXIX) are formed[48,56,58].

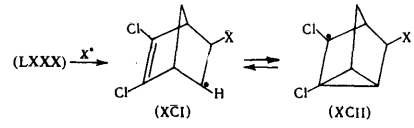
Just as in the NB series, substituents can significantly affect the stereochemical result of additions to NBD and the position of the nortricyclyl–norbornenyl equilibrium.

Thus it has been shown that free-radical addition to 2,3-dichloronorborna-2,5-diene (LXXX)[63] gives products represented in Scheme 4:

Scheme 4



In comparison with the corresponding reactions for unsubstituted NBD, the quantity of nortricyclene derivatives is less in the present instance. Actually, a norbornene derivative of type (LXXXV) is completely absent in the reactions of NBD with, for example, CCl_4, and with thiophenol only 19% of the norbornene addition product (LXXXV) is formed in comparison with 50% of the thioether (LXVII). This is shown by the decrease in reactivity of the 2,3-chloro-substituted double bond of the intermediate radical (XCI) towards intramolecular radical attack, leading to the formation of (XCII), which extends the lifetime of (XCI) in the non-isomerised state:

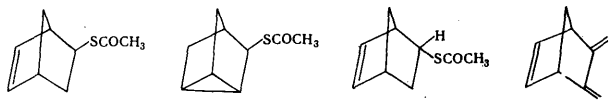


(XCI) (XCII)

The product ratios (LXXXI) : (LXXXII) and (LXXXIII) : (LXXXIV) are evidently regulated in this instance not only by the rate with which the molecule of the attacking agent transfers the chain (dissociation energy of the C–Br bond in $CBrCl_3$ 49.5 kcal mole^{-1}, compared with 67.9 kcal mole^{-1} for C–Cl in CCl_4), but also by steric factors at the chain transfer stage. Finally, we note the formation of *trans*-products with bulky ligands and the absence of appreciable steric differences for chain transfer by the radical (XCII) with *endo*- and *exo*-sides of the molecules.

In all the above examples in the NBD series, *exo*-radical attack is observed initially. However, exceptions have been observed very recently. It has been found that *endo*-addition products are formed in this instance not only with

large addends (for example, N_2F_2 [46]), but also in the addition of thiols [64]. Thus in the reaction with thioacetic acid in addition to 35% *exo*- (XCIII) and 37% nortricyclene (XCIV) thioacetates, 17% of the *endo*-thioacetate (XCV) was observed:



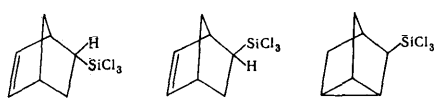
(XCIII) (XCIV) (XCV) (XCVI)

Interestingly, when thiophenol is used the proportion of the *endo*-isomer is reduced‡.

Another example is that of the *endo*-attack by the SPh radical on the intracyclic double bond of the triene (XCVI). [65]

Evidently, the absence of 2,3-*endo*-substituents in the NBD series allows even large ligands to overcome the relatively less availability of the *endo*-side of the diene molecule than is observed in the NB series.

The *endo*-isomer (XCVII) was also observed, together with *exo*- and nortricyclene derivatives (XCVIII) and (XCIX), in the reaction of NBD with trichlorosilane (in 7 : 28 : 53 ratio respectively), which was explained by the coordination of the system of double bonds of NBD with the *d*-orbitals of the silyl radicals participating in the reaction [66]:



(XCVII) (XCVIII) (XCIX)

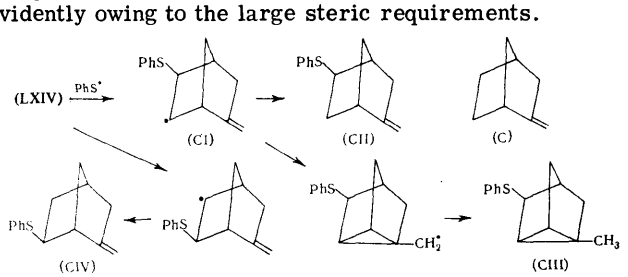
In the radical chlorination of benzonorbornadiene (XXIV) with nitrile chloride, *trans*-dichlorides, formed as a result of initial *endo*-attack by the chlorine atoms, were also isolated [67].

4. ADDITION TO NORBORNANE AND NORBORNENE SYSTEMS WITH HEPTACYCLIC (EXOCYCLIC) DOUBLE BONDS

The presence of a heptacyclic bond significantly affects the reactivity of the bicycloheptene system in homolytic reactions and the stereochemistry of the addition products.

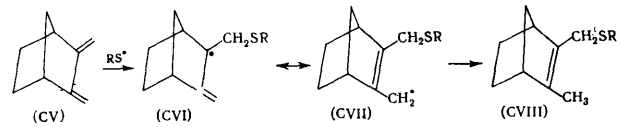
It must first be noted that the heptacyclic double bond is less reactive than an intracyclic one, which follows, for example, from the results on the competitive addition of thiols to NB and methylenenorbornane (C) [65,68] (ratio of reaction rates C/NB = 0.027 for thiophenol [65]).

From the reaction of 6-methylenenorbornene (LXIV) with thiophenol [69], three thioethers, (CII)–(CIV), were isolated, formed by the addition to the more reactive intracyclic double bond. The existence of three discrete radicals—precursors of the thioethers which are formed—was proved. However, the trichloromethyl radical is thought to be added at the heptacyclic double bond [50], evidently owing to the large steric requirements.



‡ In earlier studies the *endo*-thioether was never observed in this instance [57].

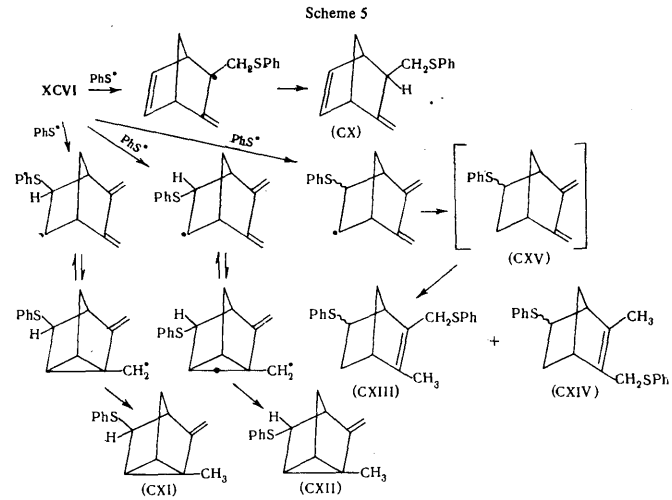
The reaction of *p*-thiocresol [70] and thiophenol [65] with 5,6-dimethylenenorbornane (CV) leads to a 1,4-addition product (CVIII). The formation of the latter is evidently favoured by the greater steric accessibility of the radical centre in (CVII) in comparison with that in (CVI):



(CV) (CVI) (CVII) (CVIII)

On reaction with thiophenol the triene (XCVI) gives a mixture of five thioethers (CX)–(CXIV), see Scheme 5.

Scheme 5



Here, judging from the ratio of the products, attack at the intracyclic double bond—thioethers (CXI)–(CXIV)—and at the 5,6-diene system—thioether (CX)—proceed to approximately the same extent. The diene (CXV) is more active and under the reaction conditions only the products of the addition to it of a second thiol molecule could be isolated. Interestingly, in this instance *endo*-attack by the thiyl radical on the *endo*-cyclic double bond occurred—ratio of thioethers (CXI) : (CXII) = 7 : 3.

In studying the reactions in the competing addition of thiophenol, methyl mercaptoacetate [65], and methyl and trichloromethyl radicals [48] to alkenes with various combinations of intra- and hepta-cyclic double bonds, results were obtained which mainly agreed with the order of reactivity of these systems. For example, the relative rates of addition for methyl mercaptoacetate are:

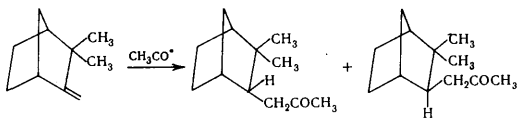
(I)	(LXIV)	(CV)	(XCVI)	(LVI)
1.00	1.44	3.55	1.72	1.83

The slight increase in the reactivity of (LXIV) in comparison with that of NB can be attributed to the somewhat greater strain of the molecule owing to the introduction of the heptacyclic double bond. The diene (CV) is the most active, that is, the intracyclic double bond in the triene (XCVI) decreases the activity of its diene system. According to Trecker and Henry [48] the reason for this is that the transition state for the sterically more favourable 1,4-addition leads to a strained NBD system. In the transition state itself, 1,2-addition evidently destroys the allyl stabilisation of the radical centre owing to conjugation with the π-electrons of the 2,3-double bond and consequently a general reduction in the reactivity of the

triene is observed. Furthermore, from these results it is clear that the intracyclic double bond and the diene system have comparable activities in homolytic reactions.

5. ADDITION TO 1,4,7-SUBSTITUTED NORBORNENES AND NORBORNADIENES

The above examples of *endo*-radical attack with participation mainly of comparatively small addends would appear to be only a few exceptions to the general rule of *exo*-addition. However, even the direction of approach of the addend in stage B (Scheme 1, p. 516) depends on the nature of the substituent present in the alkene molecule or introduced into it in the attack stage. In a recent paper [11] on the addition of various carbonyl compounds to camphene (CXVII) it was shown that even with acetaldehyde 7% of the product formed (CXIX) is due to chain transfer from the *endo*-side of the intermediate radical:



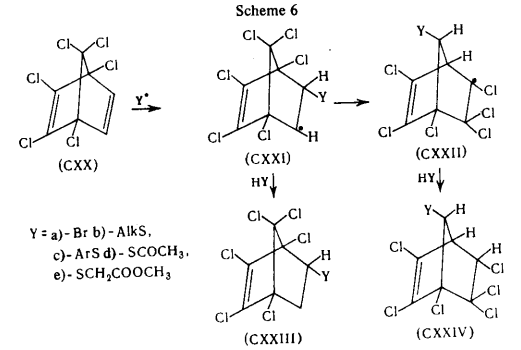
(CXVII) (CXVIII) (CXIX)

It can therefore be assumed that the accumulation of bulky substituents, especially in position 7, can significantly affect the stereochemical results of the reaction. Actually, in studying the addition of ethanethiol to 1,2,3,4-7,7-hexachloronorborna-2,5-diene (HCNBD) (CXX), we observed for the first time the formation of considerable amounts (up to 50%) of an *endo*-addition product (CXXIII).[71]

Subsequent study of the reactions of polysubstituted NBD, undertaken in parallel by Soviet and English chemists (Davies and coworkers, King's College, London), also led to extremely interesting results.

Thus, it was found that the hydrobromination [72-81] and thiylation of HCNBD by various thiols [72,82,83] (alkylthiols, arylthiols, thioacetic acid, methyl thioglycollate) proceed with a high degree of *endo*-stereoselectivity (Scheme 6):

Scheme 6

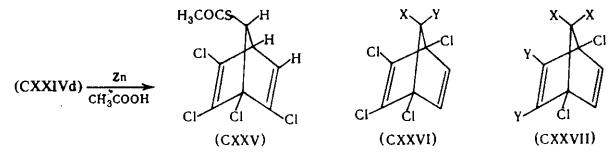


(CXX) (CXXI) (CXXII) (CXXIII) (CXXIV)

In addition to the *endo*-addition products (CXXIII), their isomers with substituents in the 7-*syn*-position (CXXIV) were observed, which showed that the reaction was accompanied by a free radical isomerisation which takes place under mild conditions and which is analogous formally to the well known Wagner–Meerwein cationic rearrangement (the mechanism of this rearrangement is discussed in more detail below). The 7-*syn*-structure of the isomers (CXXIV) was proved by the *endo*-position of the substituent in the corresponding intermediate radical (CXXI), and consequently by the *endo*-stereospecificality of the initial radical attack.

For some time the structure of products of type (CXXIV) was questioned§ in view of the fact that there is some difficulty in proving it rigorously. However, the *syn*-configuration of the substituent was established reliably on the basis of an analysis of the NMR spectrum of the dechlorination products from the 7-*syn*-thioacetate (CXXV) [73,75-78] and by a comparison of the NMR spectra of corresponding sulphides of the HCNBD and 1,2,3,4,7-*anti*-pentachloronorbornadiene (CXXVIb) series [84].

The complete reversal of the direction of radical attack observable in additions to HCNBD was explained [73,74,82,83] mainly by steric screening of the *exo*-side of the molecule of the diene by bulky electronegative 1,4,7-substituents:



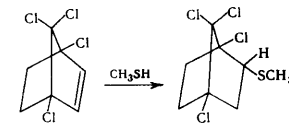
(CXXV) (CXXVI) (CXXVII)

a), X = Cl; Y = H
b), X = H; Y = Cl

a), X = Cl; Y = SMe
b), X = OCH3; Y = Cl

Actually, 1,4,7,7-tetrachloro-2,3-methylthionorborna-2,5-diene (CXXVIIa) and 1,2,3,4-tetrachloro-7,7-dimethoxynorborna-2,5-diene (CXXVIIb), which also contain bulky electronegative substituents at the bridge and alkylthiols mainly in the same manner as HCNBD.[85]

Even in the presence of 2,3-*endo*-hydrogen atoms, 1,4,7,7-tetrachloronorborn-3-ene (CXXVIII) adds ethanethiol *endo*-stereospecifically [86]:



(CXXVIII) (CXXIX)

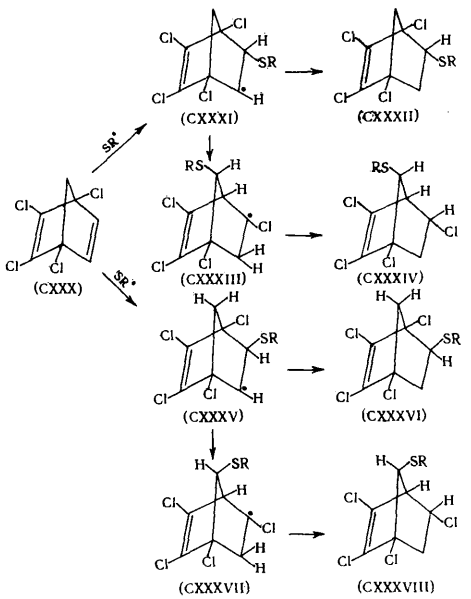
However, the substituent at the bridge is not the only steric barrier against *exo*-attack by a radical. The thiylation of 1,2,3,4-tetrachloronorborna-2,5-diene (TCNBD) (CXXX) with thioacetic acid [72-74] or ethanethiol [84] proceeds nonstereospecifically with the formation of a mixture of *endo*- and *exo*-epimers (CXXXII) and (CXXXVI) and the corresponding products of their rearrangement—7-*syn*- and 7-*anti*-epimers (CXXXIV) and (CXXXVIII) (Scheme 7). About 30% of the products are due to *endo*-radical attack.

Evidently, the absence of bridging chlorine atoms in TCNBD, as compared with HCNBD, greatly facilitates the *exo*-approach of the radical to the multiple bond. The latter also appears in the experimental conditions under which the reaction is effected: heating for 48 h at 60°C for HCNBD and by an exothermic reaction for TCNBD.[73]

Hence the direction of radical attack on the polychloro-substituted NB and NBD is controlled both by the bridge $C_{(7)}$ and also, although to a lesser degree, by the bridge-terminal $C_{(1)}$ and $C_{(4)}$ chlorine atoms. However, the introduction of 1,4-substituents in itself is probably not sufficient condition for the *endo*-approach of a radical, since it has been proved that 1,4-dichloronorbornene (XXVI) forms only *exo*-products with CH_3SH, CCl_3Br, and $CHCl_3$.[33] The absence of 2,3-*endo*-hydrogen atoms in the substituted NBD greatly facilitates *endo*-attack by the

§ Davies and coworkers [82,83] accepted the *cis*-configuration of the substituent on the basis of the absence of the corresponding *exo*-product; the *anti*-configuration has been proposed [72,74] on the basis of analogy with additions to tetrachloronorbornadiene.

Scheme 7



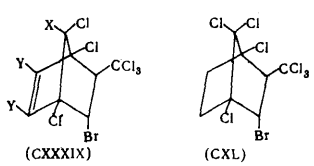
radical. In this the screening effect of the 2,3-*endo*-hydrogen atoms in NB is probably comparable in magnitude with the similar but oppositely directed effect of the 1,4-chlorine atoms in TCNBD: in the addition of thioacetic acid to NBD 17% of an *endo*-thioacetate of type (XCV) is isolated[64], but for TCNBD under comparable conditions the amount of *endo*-epimer (CXXXII) is doubled[73].

Evidently, of the two bridging substituents it is the 7-*anti*-chlorine atom that acts as a steric barrier against *exo*-attack. Thus, it has been proved[84] that in reaction with ethanethiol and thiophenol 1,2,3,4-*syn*-7-pentachloronorborna-2,5-diene (CXXVIa) behaves like TCNBD, and its 7-*anti*-isomer (CXXVIb) like HCNBD.

Even now it can be stated that the "*exo*-addition" rule cannot be considered all-embracing and the direction of attack by the free radical is a function of the degree of substitution of the diene and of the position and nature of the substituents.

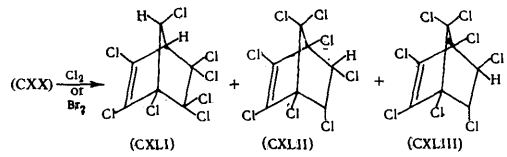
However, all the bicyclic alkenes investigated above contained substituents of similar inductive effect (OCH_3, Cl). It remained uncertain whether the effect of the bulky substituents on the direction of radical attack in polysubstituted NB and NBD is a purely steric effect or whether in this instance an electronic effect is also apparent.

From this point of view it is interesting that the addition of CCl_3Br to HCNBD, TCNBD, 7-*anti*-pentachloronorbornadiene (CXXVIb), 1,4,7,7-tetrachloronorbornene (CXXVIII), and 2,3-dimethylthio-1,4,7,7-tetrachloronorbornadiene (CXXVIIa) leads, just as for NB itself, solely to products of *trans*-addition with the *exo*-disposed trichloromethyl group of the type of (CXXXIX) and (CXL):[86]



where X = Cl or H, Y = Cl; or X = Cl, Y = SCH_3.

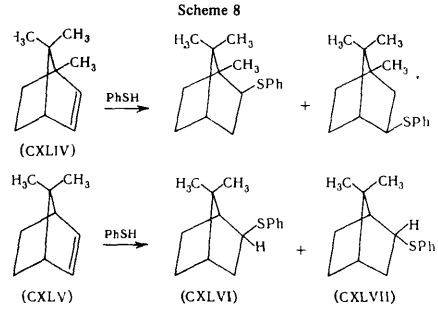
In studying the bromination and chlorination of HCNBD, although they were not able to inhibit the ionic processes, Davies and Parrot[87] also showed that *exo*-radical attack by halogen atoms takes place and a large proportion of the 7-*anti*-isomer (CXLI) is formed as a result of isomerisation of the product of radical *exo*-addition[87]:



Purely radical chlorination of HCNBD was effected by the same investigators by the action of sulphuryl chloride with the formation of the same three isomers but in another ratio. It is notable that whereas the *cis*-*endo*-product (CXLII) is almost absent in the reaction with Cl_2, it amounts to 11% of the isomeric mixture when SO_2Cl_2 is used, which is evidently associated with the greater size of the carrier-addend.

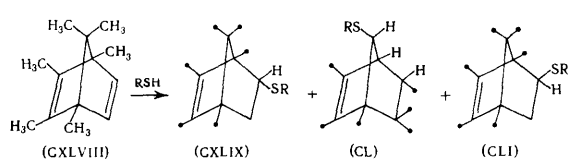
On the basis of the exceptional *exo*-attack by the bulky CCl_3 radical and the analogous behaviour of halogen atoms, Davies and coworkers[9,86] concluded that the direction of radical attack in the series of substituted NB and NBD is controlled mainly by electronic, and not steric, factors. In this, the relatively more electron-deficient $CCl_3^{\cdot}$ and $Br^{\cdot}$ radicals will experience some attraction at the side of the bridge chlorine atoms and the less electrophilic thioradicals $CH_3S^{\cdot}$ are repelled by the same substituents, which facilitates *endo*-radical attack. Davies and Rowley[109] think that this assumption agrees with the exclusive *exo*-addition of thiophenol to bornylene (CXLIV) and apobornylene (CXLV)[109] (Scheme 8).

Scheme 8



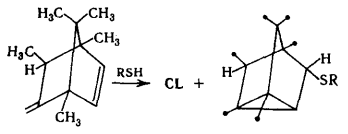
Brown and Kawakami's reinvestigation of the last reaction confirmed the high degree of *exo*-stereoselectivity, but it was found that in this instance up to 5% of the *endo*-thioether (CXLVII) is formed in comparison with 0.5% for NB itself.

On the other hand, it was shown recently[89,90] that the addition of 2-methylpropane-2-thiol to hexamethylnorbornadiene (HMNBD) (CXLVIII) proceeds with a high degree of *endo*-stereoselectivity with the formation of the 5-*endo*-, 7-*syn*-, and 5-*exo*-sulphides (CXLIX)–(CLI) in the ratio 51 : 45 : 4, respectively:



where R = t-C_4H_9.

Stereospecific *endo*-radical attack was also observed in the reaction of 2-methylpropane-2-thiol with methylenepentamethylnorbornene (CLII).[89,90] As a result, nortricyclene and 7-*syn*-sulphides (CL) and (CLIII) were obtained—both by addition of the thiol to the intracyclic double bond of the diene¶:



(CLII) (CLIII)

where R = t-C_4H_9.

Of the two dienes, (CXLVIII) and (CLII), the first was much more reactive in thiylation, but the intracyclic double bond of the diene (CLII) was much more reactive than the heptacyclic, just as was found earlier for unsubstituted alkenes[48,65] (see p. 521).

Taking into account the results of the thiylation of the polymethylated bicyclenes it must be assumed that the stereochemistry of the free radical addition to norbornene and diene systems is probably determined by a complex combination of electronic and steric factors. It seems that there is a definite lower limit for most of the steric and electronic factors under discussion produced by the substituents present either in the norbornyl system or in the molecule of attacking agent. Agents with not very demanding steric requirements (halogens, hydrogen halides, certain thiols, tetrafluorohydrazine, and nitryl chloride) can attack the molecule of unsubstituted NB and NBD from the *exo*- and the *endo*-directions, with preferred *exo*-attack. For 2-*endo*-substituted NB and NBD the ratio of the products depends on the stereoelectronic interrelations of the 2-*endo*-substituent and addend at both stages of the addition. For NB and NBD with 1,4,7-substituents, the 7-substituent, located above the plane of the double bond, and to a lesser extent the under-bridge substituents exhibit considerable steric control. However, the latter cannot appear for addends with low steric requirements (as evidently occurs in the reaction of thiophenol with bornylene and apobornylene).

An analogous proposal was recently made by Brown and Kawakami[88], who investigated the addition of various reagents under polar and radical conditions to NB and apobornene (CXLV) (including radical thiylation). They concluded that the breakdown of *exo*-stereospecificity in the reactions of apobornylene is the consequence of the appearance of steric control at the side of the 7-methyl substituents. However, the latter may not appear, depending on the mechanism of addition of the addend and the steric requirements of the latter.

In this connection it is also relevant to mention two recent papers[91,92], in which it was noted that the relative reactivity of the alkene under radical additions depends mainly on the induction effect of the alkyl substituent for the addition of small radicals, and is determined by the steric requirements in attack by large radicals.

In speaking about the electronic effects of the substituents evidently discussion must not be limited to consideration of only their electrostatic interaction with the attacking radical. This point of view, adopted by Davies and Rowley[86] to explain the exclusive *exo*-addition of CCl_3 radicals to polychloro-substituted NB and NBD ascribes relative nucleophilic properties to thiyl radicals, which clearly contradicts known results[93,94]. Evidently, in addition to the electrostatic interaction of the substituents their effect on the double bond of the bicyclene must be considered to a lesser extent. For example, it is known that whereas NB and NBD add various electrophilic reagents very readily[95,96], in the HCNBD molecule the 5,6-double bond has almost lost its nucleophilic nature and the corresponding reactions occur under much more severe conditions and with very small yields[73,83].

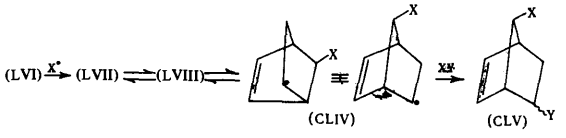
Bearing in mind the magnetic anisotropy of the double bond (for example, the shift of the signals of the 2,3-vinyl protons under the action of 7-*syn*-CH_3 groups[97]) it seems most probable that in these systems the direction of radical attack will be determined by the complex stereoelectronic effects of the substituents in addition to the steric factors.

Undoubtedly further accumulation of experimental results in this field will allow the influence of steric and electronic effects on the stereochemical results of the reactions to be distinguished more sharply.

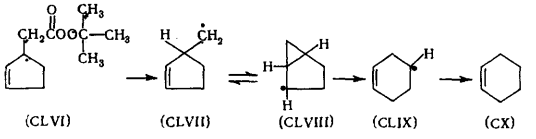
6. MECHANISM OF ISOMERISATION OF NORBORNENYL RADICALS

The results described in the preceding section show that addition to NBD is usually accompanied by the rearrangement of intermediate radicals with the formation of nortricyclene structures or compounds with 7-*syn*- or 7-*anti*-substituents. Usually the formation of both isomerised products is not observed in a single reaction. However, it was extremely strange, that the nortricyclyl (cyclopropylcarbinyl) radical (LVIII) found in equilibrium with the norbornyl radical (LVII)[61,62] does not exist in equilibrium with radical (CLIV), apparently because the breaking of the 2,6-bond is equally probable (Scheme 9),

Scheme 9



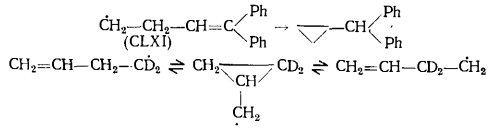
particularly as in several recent papers the formation of the cyclopropylcarbinyl radical is taken as the intermediate stage of the 1,2-migration of the vinyl groups. Such a mechanism was, for example, proposed for the thermal rearrangement of t-butyl cyclopent-2-enylperoxoacetate (CLVI):[96]



We note that during the rearrangement of ester (CLVI) rearrangement of the primary radical centre (CLVII) into the secondary (CLIX) takes place. Although Slaugh[98] also does not consider this sufficient driving force, nevertheless the reverse isomerisation (from the corresponding cyclohexenyl derivative) does not occur under these conditions.

¶ In this instance, in addition to free-radical isomerisation of the Wagner–Meerwein type already mentioned, 1,3-migration of hydrogen in the intermediate radical was observed, this will be considered in more detail below, p. 525.

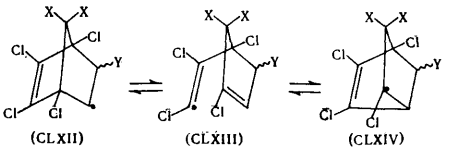
Confirmation of the proposed mechanism is given by the formation of cyclopropyldiphenylmethane in the generation of 4,4-diphenyl-3-butenyl radicals (CLXI) from the corresponding per-esters [98] or the formation of a mixture of but-1-ene-3,3-d_2 and but-1-ene-4,4-d_2, by the radical decarbonylation of 4-pentenal [99]:



Taking into account all the above information, it would be expected that the nortricyclyl radical (LVIII) can also play the part of an intermediate product in the process of 1,2-vinyl migration with the formation of 7-substituted NB (CLV).

Alden and Davies [100] also proposed just such a scheme for the mechanism of the above-mentioned radical rearrangement of the Wagner–Meerwein type, and then confirmed it reliably by a series of experimental facts, and it has now been adopted in the studies of other investigators. It was first assumed that the rearrangement proceeds according to a scheme [10,72,101] analogous to that proposed earlier for the high-temperature isomerisation of bornyl radicals [32]. However, in none of the instances investigated was a substituted allylcyclopentene corresponding to the radical (CLXIV) observed. The formation of an isomerised radical (CLXIV) both directly from (CLXII) and also through the stage of formation of (CLXIII) requires the (relatively unfavourable from the energy point of view) breaking of the $C_{(1)}-C_{(2)}$ vinyl bond (the dissociation energy of this bond is 10 kcal mole^{-1} above the dissociation energy of the C–C bond in alkanes) [102].

Scheme 10

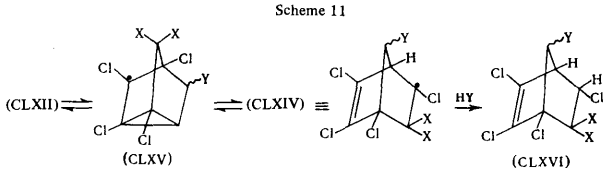


(CLXII) (CLXIII) (CLXIV)

Since until recently in reactions involving NBD itself only the formation of substituted nortricyclenes was observed, evidently an important factor for the occurrence of homolytic isomerisation according to Scheme 9 is the introduction into the molecule of the diene of substituents favourable to β-breaking with the shift of the equilibrium towards the side of formation of the radical (CLIV). This agrees completely with the known general position of free-radical chemistry [103,104].

The driving force for the observed rearrangement is evidently the greater stability of radical (CLXIV) in comparison with radical (CLXII), brought about by stabilisation of the radical centre by the neighbouring chlorine atom. The latter is consistent with the results of Nesmeyanov and coworkers on the isomerisation of acyclic halogen-containing radicals [41,105,106]. In a similar manner, the change from secondary to tertiary radical centre is probably the driving force for rearrangement in reactions involving HMNBD (Scheme 12, p. 526).

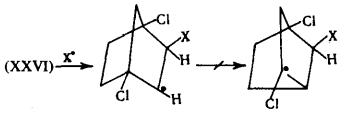
Scheme 11



(CLXV) (CLXVI)

Here in the reaction with HCNBD the *syn/endo* ratio of the sulphides (CXXIV)/(CXXIII) (Scheme 6, p. 522) was ~3 : 1, [73] and under similar conditions with HMNBD it becomes only ~1 : 1. [90] This is in good agreement with the known greater stabilising effect of the chlorine atom standing at the radical centre in comparison with the corresponding effect of the methyl group [41].

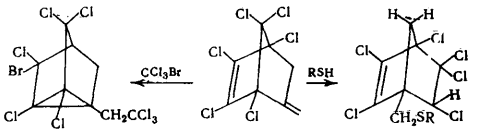
Characteristically, in the absence of a second double bond in the molecule of 1,4-dichloronorbornene (XXVI) even in the presence of a chlorine atom, which should be favourable to the stabilisation of a new radical centre, isomerisation products were not observed [33]:



In accordance with the proposed mechanism, the structure and ratio of the final products of addition to saturated NBD should be determined by the action of steric and electronic factors on the position of the equilibrium (CLXII) ⇌ (CLXV) ⇌ (CLXIV) and the rate of chain transfer of the radicals formed intermediately.

Actually, in the addition of thioacetic acid to TCNBD [73] the decrease of steric strain at the chain transfer stage from the *exo*-radical (CXXXV) to the *endo*-radical (CXXXI) (Scheme 7), evidently leads to an increase in the lifetime of the first. This, in turn, significantly alters the ratio of the products: *exo/anti* (CXXXVI)/(CXXXVIII) ≃ 1 : 1, whereas *endo/syn* (CXXXII)/(CXXXIV) ≃ 18 : 1. The screening of the 7-*anti*-chlorine atom of the *exo*-side of the HCNBD molecule in comparison with TCNBD also appears in the ratio of the thioacetates obtained: *endo/syn* (CXXIIId)/(CXXIVd) ≃ 0.7 : 1, but for *endo/syn* (CXXXII)/(CXXXIV) ≃ 18 : 1.

In studying the reaction of HCNBD with methanethiol and ethanethiol at various temperatures and addend concentrations and also under comparable conditions but with different thiols [73], it was shown that the ratio of the products, and consequently also the position of the equilibrium of the corresponding radicals (Scheme 11, X = Cl), depends significantly on the experimental conditions and rate constants of chain transfer to the addend participating in the reaction. The latter is also confirmed by the example of reactions with participation of hexachloromethylenenorbornene (CLXVII): only the corresponding nortricyclene (CLXVIII) was isolated in the reaction of this diene with CCl_3Br whereas addends with a lesser transfer constant (alkanethiols, thioacetic acid, methyl thioglycollate) give only products of rearrangements of the type (CLXIX): [97]

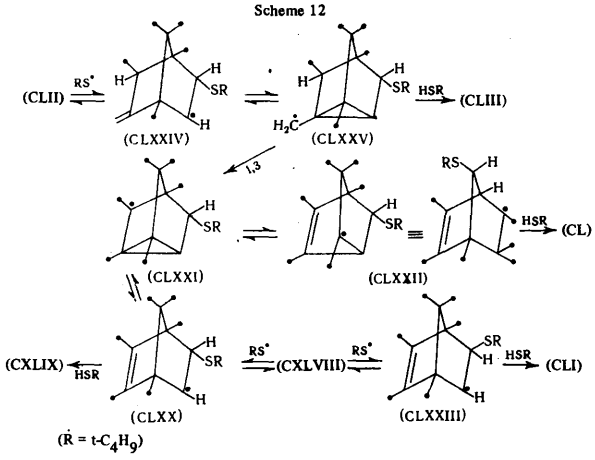


(CLXVIII) (CLXVII) (CLXIX)

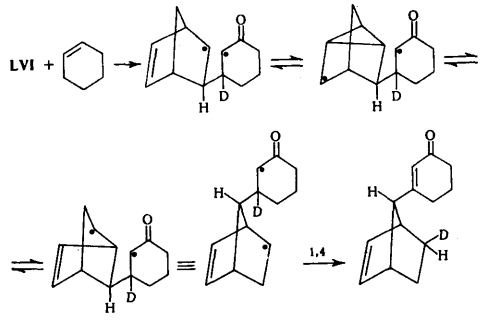
Confirmation of the proposed scheme of rearrangement is also the formation of the same 7-*syn*-sulphide (CL) in the thiylation of HMNBD and methylenepentamethylnorbornene (CLII), which can evidently proceed solely through the

formation of a common intermediate nortricyclene radical (CLXXI) (Scheme 12).[89,90] The presence in the reaction mixture of a nortricyclene product corresponding to radical (CLXXV) and the absence of a sulphide corresponding to the radical (CLXXI) is evidently connected with steric hindrance at the chain transfer stage, with participation of the latter:

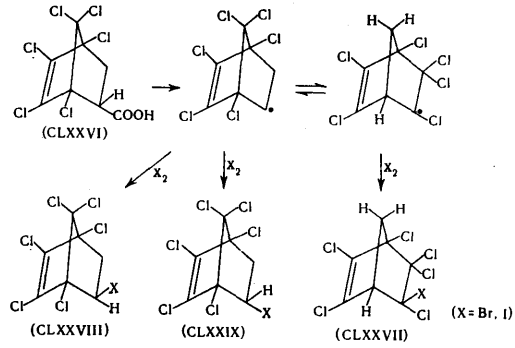
Scheme 12



Interestingly, for the formation of 7-*syn*-sulphide (CL) from the diene (CLII) 1,3-migration of the hydrogen with a corresponding shift of the radical centre in the radical (CLXXV) is postulated. The possibility of such a migration is confirmed, for example, by results obtained by McCullough and Rasmussen[107], who describe the *exo*-stereospecific 1,4-migration of hydrogen in the photochemical reaction of NBD with cyclohexen-2-one or 3-methylcyclohexen-2-one.



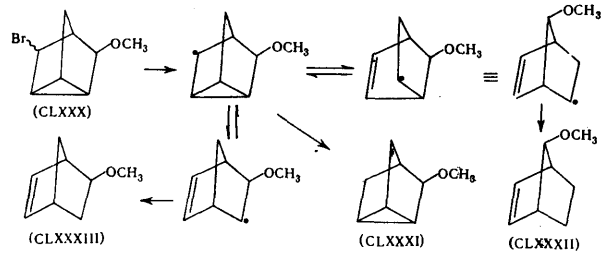
Hence in radical reactions of addition to polysubstituted NBD equilibrium is established between the intermediately formed radicals according to Scheme 9. The position of the equilibrium is determined by the competition between the steric and electronic interactions of the substituents of the reagents and also by the experimental conditions. Another example of this is Davies and Mason's modified Hunsdiecker reaction[2] for 1,4,5,6,7,7-hexachloronorborn-2-ene-5-carboxylic acid (CLXXVI) and its methyl analogue. In both instances when bromine is used the corresponding rearranged products (CLXXVII) are formed. Evidently, participation in the reaction of a slower chain carrier (in comparison with iodine) ensures the possibility of isomerisation:



Interestingly, the ratio of *exo*- to *endo*-halides (CLXXVIII) : (CLXXIX) when iodine is used is higher than for bromine, which also evidently confirms the importance of the electronic factor in this instance.

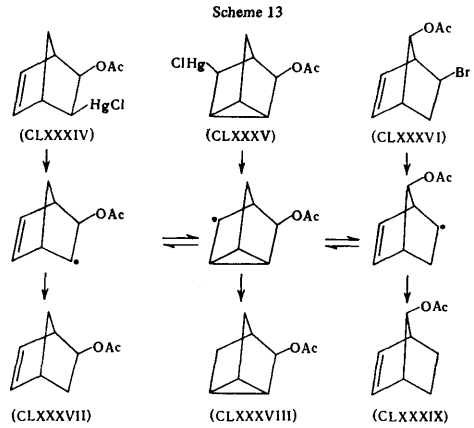
A rearrangement of the Wagner–Meerwein type has been reported very recently in the reaction of unsubstituted NBD with tetrafluorohydrazine[46] and cyclohexen-2-one[107].

In investigating the reaction of Grignard reagents with methoxy-substituted nortricyclyl bromide (CLXXX)†, Davies and coworkers observed both the norbornene ethers (CLXXXII) and (CLXXXIII) in the reaction mixture as well as the corresponding nortricyclene (CLXXXI):[2]



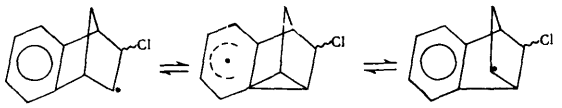
Similar results were obtained in the reduction of acetoxy-substituted mercury chlorides (CLXXXIV), (CLXXXV) or bromides (CLXXXVI) with sodium tetrahydroborate, or tri-n-butyl- or triphenyl-tin hydride or deuteride[108]. Irrespective of the initial acetate an equilibrium mixture of the three products (CLXXXVII)–(CLXXXIX) was obtained (see Scheme 13):

Scheme 13



The radical rearrangement with 1,2-shift of the phenyl group was observed in the reaction of benzonorbornadiene (XXIV) with nitryl chloride[67]:

† $CoCl_2$ catalyst.



Interestingly, in this instance the isomers ratio *endo/syn* ≃ 20 : 1, and *exo/anti* ≃ 1.3 : 1, which also clearly shows steric control in the radicals formed as intermediates.

From the above examples, it becomes evident that under different experimental conditions, in particular when addenda with a low transfer constant participate in the reaction, the lifetime of the intermediate radicals can be sufficient for the establishment of equilibrium according to Scheme 9 (p. 524).

---o0o---

Hence a rather complex and still extremely contradictory interrelation of the steric and electronic effects of the substituents, which determine the direction of both stages of 1,2-addition and also the position of the equilibrium between the radicals formed, is observed in the reactions examined. Therefore the continuation of investigations in this field using modern methods of characterisation is extremely interesting and useful for finding both general and particular rules in free radical chemistry.

Chemical Effects of Laser Radiation

Yu.P.Yampol'skii

This review deals with the chemical effects observed under the influence of laser light. The operating principle of the laser, the main types of laser, and the properties of laser radiation are briefly described. The application of laser techniques to the production and investigation of short-lived excited states is discussed. One-photon and multi-photon processes induced by laser radiation are considered. Several examples of the specificity of the reactions initiated by laser light are given. 140 references.

I. INTRODUCTION

In the hands of scientists and engineers, lasers have proved an important new tool to study interactions with matter. The physical principles of laser action were formulated as a result of the fundamental researches on quantum electronics carried out in the USSR (by Basov and Prokhorov's team) and in the USA (by Townes and Schawlow's team). In 1958 Schawlow and Townes [1] drew attention to the possibility of producing an optical quantum generator (laser) based on stimulated (or induced) radiation processes†. The first solid-state laser, using ruby, was constructed by Maiman [2] in 1960, and one year later Javan, Bennett, and Herriott assembled the first gas (helium–neon) laser [3]. At about this time, suggestions that laser light could be used to study chemical processes began to appear in the literature [4,5]. The most attractive properties of laser light for this purpose are its high intensity and monochromaticity, and also its accurate collimation, which enables the laser energy to be transmitted over long distances or concentrated into small, isolated regions of matter. The radiation of many lasers lies in the i.r. region of the spectrum, i.e. in a region where absorption is accompanied by the excitation of intramolecular vibrations. The availability of high-intensity, monochromatic light sources for this spectral region gave a new impetus to infrared photochemistry, i.e. to the excitation of specific molecular vibrations, and to the selective initiation and control of chemical reactions.

Many papers (both theoretical and experimental) have been written in recent years on the effect of laser radiation on matter and on the chemical reactions induced by laser light. Some overall trends are becoming apparent, and we can attempt to generalise some of the published results.

II. PROPERTIES OF LASER LIGHT. VARIOUS TYPES OF LASER

Lasers are devices for the generation or amplification of light by stimulated emission. Consider a vessel exposed to a flux of incident light. The atoms and molecules in the vessel will absorb light and undergo transitions. The transition from an excited level to the ground level can occur either spontaneously or by induced (stimulated) processes (see Fig. 1). The number of absorbtions and of induced emissions per unit time in unit volume is given by

$$\Delta N_{ik} = B_{ik}u_\nu N_i \quad (1)$$

$$\Delta N_{ki} = B_{ki}u_\nu N_k \quad (2)$$

where, as shown by Einstein in 1917,

$$B_{ik} = B_{ki} \quad (3)$$

(u_ν is the photon flux; N_i and N_k are the numbers of atoms in the i-th and the k-th level per unit volume; B_{ik} and B_{ki} are the Einstein coefficients).

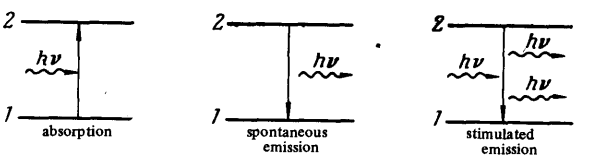

Figure 1. Model of absorption, spontaneous emission, and stimulated emission processes: *1*) ground level, *2*) excited level.

The fall in intensity of the light beam per unit volume along the direction of the incident beam is given by the formula

$$-\Delta U = B_{ik}N_i u_\nu \Delta E - B_{ki}N_k u_\nu \Delta E \quad (4)$$

where $\Delta E = h\nu = E_k - E_i$ (E_k and E_i are the energies of the k-th and the i-th level; ν is the frequency corresponding to the transition).

Using Eqn. (3),

$$-\Delta U = u_\nu B_{ik}N_i \Delta E\left(1 - \frac{N_k}{N_i}\right) \quad (5)$$

Under conditions of thermodynamic equilibrium

$$\frac{N_k}{N_i} = e^{-\frac{\Delta E}{kT}} \quad (6)$$

† This principle for the amplification of light had been suggested earlier (in 1940) by V.A. Fabrikant.

and, since $\Delta E > 0$, the exponential factor in the expression

$$-\Delta U = u_\nu B_{ik} N_i \Delta E \left(1 - e^{-\frac{\Delta E}{kT}}\right) \quad (7)$$

is always less than unity and therefore the stream of radiation must lose energy at any finite temperature (in the limit of $T \to \infty$, $\Delta U \to 0$). The condition for light amplification (or "negative absorption") is

$$\frac{N_k}{N_i} > 1 \quad (8)$$

This condition can be satisfied only by non-equilibrium processes. A population of energy levels corresponding to the inequality (8) is termed a population inversion. The more substantial the population inversion, the greater is the amplification of the light beam. Let us consider the ways in which population inversion can be induced. Assume that the atomic or molecular system can exist in three energy levels *0*, *1*, and *2* (see Fig. 2). Population inversion arises when the probability of a $1 \to 0$ transition is less than the probability of a $2 \to 1$ transition under conditions such that the rate of the $2 \to 0$ transition is sufficiently low.

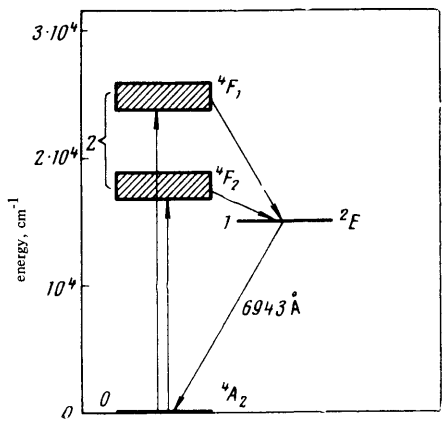

Figure 2. Energy levels of ruby ($Cr^{3+} \cdot Al_2O_3$).

Lasers consist of an active medium (i.e. the substance whose optical transitions are used to generate light), a pump (to excite the system), and suitable resonators (mirrors) to cause excitation of specific vibrations in the active medium. The active medium can be solid, gaseous, or liquid. Pumping, i.e. the production of a population inversion, is achieved in a variety of ways, depending on the type of laser: solid-state lasers are pumped optically, semiconductor lasers by electrical impulses, and gas lasers are usually pumped by electrical discharges. The resonator usually consists of a system of two plane-parallel mirrors.

Fig. 2 represents the system of energy levels for the ruby laser. Irradiation of the ruby crystal from a xenon flash tube causes inversion of the population of the ^2E level. The radiation density u_ν increases as a result of multiple reflections from the silvered end-faces of the crystal, and stimulated emission appears. The intensity of emission increases very rapidly until level *1* becomes depleted. The duration of the light pulse ("spike") is 10^{-6} s, and the total duration of the stream of separate spikes is of the order of 10^{-3} s. This operating regime for a pulsed laser is termed free generation.

Lasers can also be operated in a different regime: the so-called modulated Q-factor or giant pulse regime, or in English terminology the Q-switched regime[6]. By inserting a shutter between the crystal and one of the mirrors, the photon flux in the active medium of the laser is decreased, thus decreasing the number of stimulated transitions per unit time and hence enhancing the population inversion. A very powerful light pulse is obtained when the optical shutter is momentarily opened. Although the total energy of the giant pulse is about an order of magnitude lower than that obtained in the free generation regime, the length of the pulse can be as small as 10^{-8} s, and therefore power levels of hundreds of megawatts can be obtained. The optical shutter usually consists of a solution of a dye, which is decolorised by a very intense light beam (see Section III).

Even shorter (10^{-11}–10^{-12} s) and more powerful pulses have been generated as a result of recent advances in the Q-switching method. Picosecond pulses of laser light have been produced by the mode-locking method. The radiation from a solid-state laser consists of many modes or frequencies of vibration, close to the fundamental frequency. Some dyestuffs behave as amplitude modulators when irradiated: they amplify the frequencies of highest amplitude and they attenuate all the other frequencies. As a result, the many frequencies generated by the laser become phase-locked, and a series of narrow pulses (of length inversely proportional to the width of the corresponding frequency component) is produced[7,8] as a result of constructive and destructive interference.

The main types of laser are listed in Table 1 together with some properties of their radiation. The light emitted by lasers has some unique properties, not found in ordinary light sources (coherence, high monochromaticity, intensity, etc.). Not all of these are equally important from the point of view of initiating chemical reactions: the most valuable property of laser light in this respect is the intensity of the radiant energy available over a narrow range of frequencies. As Table 1 shows, the generated band-width in any laser is much narrower than the absorption band of the molecules. It is also possible to increase the density of laser radiation by focussing the beam. A monochromatic, low-divergence laser beam can be focussed into a spot 10^{-6}–10^{-4} cm^2 in area. Because of the coherence of laser radiation, interference can take place in the focal region: the amplitude of the radiation field will vanish, or increase by a factor of two, between points half a wavelength apart. Since many of the effects of laser radiation are non-linear, i.e. they vary as the square (or some higher power) of the intensity of radiation, interference can be expected to enhance some of the high-intensity effects of laser radiation. Such giant intensities of radiation are accompanied by substantial values of the electric and magnetic vector of the light wave. Thus, an electric field strength of 10^6 V cm^{-1} is set up when a pulse from a 1 MW ruby laser is focussed into a spot 0.2 mm in diameter. This level of field strength is comparable with the electric fields present within molecules. It follows that the electric field associated with the light waves can induce strong perturbations, leading to polarisation (and, in the limit, ionisation or dissociation) of the molecules.

When laser radiation is used to initiate chemical reactions, it would be desirable to have a smooth control over the wave length of the light (to suit the particular system)

Table 1. Main types of laser.

Active medium	Operating regime	Pump	Wave length	Monochromaticity, Δλ	Duration of emission, s	Power	Light flux[a] photons/cm^2 s	Comments	Ref.

while retaining its high power and monochromaticity. Laser emission consists of discrete lines, usually in the i.r. region of the spectrum or close to the red end of the visible region. However, radiation in the u.v. region or close to the u.v. limit of the visible region would be much more appropriate in chemical applications (photon energy 4—7 eV). Only two gas lasers emit in this region of the spectrum: the N_2 pulsed laser[13], which has a relatively low power, and the recently discovered helium—cadmium laser, which can be operated in the continuous wave regime[14]. Laser radiation in the u.v. region can be obtained also by frequency doubling, which involves transmitting strong laser pulses through certain crystals (KH_2PO_4, $NH_4H_2PO_4$). In this way we can obtain light with λ = 3471 Å (by doubling the frequency of the ruby laser) or λ = 2650 Å (by twice doubling the frequency of the Nd^{3+} laser). Thus, by using the harmonics of laser light, we can increase the number of available discrete wave length and produce powers of the order of 0.1 MW in the short-wave region. Lasers based on organic dyes[15,16] offer an even better choice of wave lengths in the region of interest. The emission from these lasers can be controlled over fairly wide wavelength limits (several hundreds of Ångstroms). Dye lasers were discovered quite recently (in 1967), but the number of dyes in which laser action has been observed already exceeds the number of active media used in all other types of laser. In principle, the number of dyes capable of laser action is almost infinite, and it should be possible to synthesise dyes having the required properties (frequency, amplification coefficient) and to use a special laser for each of a large number of narrow frequency ranges. Thus, with the help of lasers based on solutions of organic dyes we expect to progress from a discrete and limited choice of frequencies (obtained from solid-state lasers) to a practically free choice of frequencies in the visible and near infrared regions of the spectrum. Generation from a 4-methylumbelliferone laser beginning at 3850 Å, i.e. in the u.v. region, has recently been reported[17].

III. MECHANISM OF THE EFFECT OF LASER RADIATION

1. Effects Associated with Electronic Excitation

a. One-photon effects

Direct excitation to the triplet state. When a substance having a singlet ground state is irradiated with light of relatively low frequency, direct excitation of triplet levels is not observed, because the extinction coefficients of light with a frequency corresponding to these transitions are 10^5—10^6 times smaller than the extinction coefficients for allowed transitions. Although the lowest triplet level of most molecules is located between the ground and the first excited singlet level (Fig. 3), the electronic spectra of molecules show their first absorption at frequencies corresponding to the $S_1 \leftarrow S_0$ transition. With ordinary photochemical excitation by light of low intensity, triplet states can arise only by $T_0 \leftarrow S_1$ transitions from excited singlet states (Fig. 3).

However, direct population of triplet levels can be induced by using laser light. In spite of the low probability of $T_0 \leftarrow S_0$ transitions, sufficiently intense radiation can make these transitions observable. Direct triplet excitation has been observed in a number of aromatic hydrocarbons and dyes with low-lying excited states[18-21] (see also a discussion[22] of the criteria for the direct formation of triplet states). The most convenient material for a study of this effect is anthracene, because the frequency of the transition to the triplet state in this material (14 750 cm^{-1}) is close to the frequency of radiation from the ruby laser (14 400 cm^{-1}). Phosphorescence has been observed in anthracene irradiated with light from a ruby laser[23] operated in the *Q*-switched mode. Since the quantum energy of the ruby laser is lower (by 350 cm^{-1}) than the excitation energy of anthracene, direct absorption can occur with a small activation energy, which may even

exceed 350 cm^{-1}, if a vibrationally excited triplet of anthracene is formed during absorption.

In molecular oxygen the ground level is triplet. However, transitions to the singlet, vibrationally excited $O_2(^1\Delta_g + v)$ level can be induced [24] by Nd^{3+} laser light

$$O_2(^3\Sigma_g^-) \rightarrow O_2(^1\Delta_{g+v})$$

and in this way the reactions of singlet oxygen can be initiated.

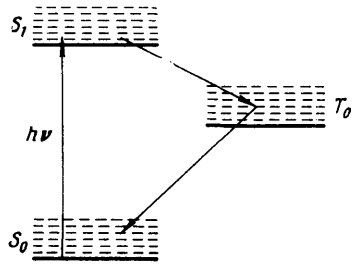

Figure 3. Energy levels of an organic molecule (the broken lines denote vibrational sublevels).

The one-photon mechanism of transition to a triplet state acting as an intermediate in a chemical reaction has been convincingly demonstrated [25] in one system only: the gas-phase photochemical bromination of perfluoro-olefins, initiated by light from a ruby laser. (The rate of the dark reaction is very low for these compounds.) During normal photobromination with light of wavelength below 6800 Å the Br_2 molecule dissociates into atoms and the reaction proceeds by a radical-chain mechanism. The energy of a light quantum corresponding to $\lambda = 6940$ Å is not sufficient for direct photodissociation of Br_2, but this quantum can excite a transition from the ground to the lowest excited state ($^3\Pi_{1u} \leftarrow {}^1\Sigma_{g^+}$). The vibrational energy of this state of the Br_2 molecule can be altered also by varying the radiation frequency [26] within several cm^{-1}. In this way, the addition to a double bond of bromine molecules in the triplet state and in exactly known vibrational states has been investigated. It has been shown that the reaction rate is very sensitive to the wavelength (within the absorption band) and is directly proportional to the intensity of the incident light at constant wavelength. Thus, the reaction is not caused by direct dissociation of the Br_2 molecules, corresponding to the appearance of a continuum in the spectrum. At the same time, participation of atomic bromine is suggested by the inhibiting effect of traces of NO. Mass spectrometric analysis of the products obtained in bromination experiments with labelled $^{79}Br-{}^{79}Br$ and $^{81}Br-{}^{81}Br$ molecules confirmed the absence of isotopic enrichment of the reaction products, which would be expected if the addition of Br_2 occurred by a molecular mechanism. The primary photobromination product, $Br_2(^3\Pi_{1u})$, has a closely spaced set of vibrational levels, the difference in energy between successive levels being less than kT at room temperature. Hence, the probability of vibrational energy transfer is high. Since the dissociation energy of this state of the Br_2 molecule is only 6 kcal $mole^{-1}$, the $Br_2(^3\Pi_{1u})$ molecule can acquire, by collision, the vibrational energy necessary for dissociation into Br atoms, which then enter into the chain reaction leading to the brominated product. The contribution to the reaction from the molecular mechanism is negligibly small.

Excitation into singlet states. The main feature of the excitation of singlet levels by giant laser pulses is the fact that the pulses are very intense and of short duration (shorter than, or comparable with, the mean life time of the singlet excited states). Because of the high intensity, excited levels can be highly populated. As a result, the spectral properties of the material are changed, and observation of the absorption spectra of excited singlets becomes possible. The short duration of the laser pulse enables us to monitor processes occurring in nanoseconds [27], and even picoseconds, provided that the reaction is accompanied by fast emission [28]. The frequencies of transitions into excited singlet states of organic molecules lie in the u.v. region. Since lasers which emit at these frequencies are not powerful enough, one-photon excitation to singlet states is usually carried out by utilising the higher harmonics of the light from very powerful pulsed lasers. Excited singlets, and their reactions, have been investigated by an extension of Norrish and Porter's [29] flash photolysis and spectroscopy method. An intense flash of light creates macroscopic concentrations of the primary photochemical dissociation product in the irradiated material: free atoms, radicals, or molecules in excited states. The excited system can be investigated either spectroscopically or kinetically. In the former case a second (test) pulse of light is transmitted through the system after a predetermined interval, and the absorption spectrum of the short-lived products is recorded. In the kinetic method, light of wavelength corresponding to the absorption maximum of the short-lived product is continuously passed through the cell, and changes in transmission are monitored for a predetermined period following excitation. The classical flash photolysis method uses pulses of 10^{-6} s duration, obtained from a discharge tube, which limits the application of the method to processes with rates $<10^6$ s^{-1}. Processes 100–1000 times faster can be studied by using laser-pulse excitation. The apparatus used by Porter and Topp [30,31] to record the absorption spectra of the excited singlets of aromatic compounds is shown in Fig. 4. The spectra were measured a known time after excitation by a giant pulse of the first harmonic of a ruby laser (3470Å). Part of the light, selected by a beam splitter, was focussed on a cell containing the solution of the experimental compound. The other part of the beam passed through the splitter, was reflected by a mirror back to the splitter, and to a cell containing the scintillator intended to generate a continuum in the spectral region of interest. The test pulse passed through the cell into the spectrograph, where the spectrum of the singlet excited states produced by the laser pulse was recorded. The time delay is determined by the distance between the beam splitter and the mirror: for example, a distance of ~3.5 m will produce a delay of 25 ns. For kinetic measurements, the test source of light can be a flash from a discharge tube of duration (several milliseconds) large compared to that of the excitation pulse from the laser. In practice, it is possible to use a small part of the light output of the lamp used for optically pumping the laser. It is important that the intensity of this light source remains practically constant during the measurement.

Novak and Windsor [32] used a slightly different method to generate their test pulse. They used a prism to isolate the beam of primary laser radiation, which is usually lost when a crystal of KH_2PO_4 is used for frequency doubling, and focussed it on to a cell containing an inert gas. The luminescence produced by the dielectric breakdown of this gas, having a continuous spectrum, could be used as the test pulse. Time resolution was obtained by directing the test radiation to a fast-response photocathode after it had passed through the cell. Obviously, the time delay can be controlled, as in the previous apparatus [31], by varying the distance between the prism and the inert gas cell with the help of a mirror. Lastly, by using a monochromator, the absorption spectra of excited singlets can be investigated from the time-resolved absorbance curves for several different wavelengths. This method has been used by a number of workers [33-38].

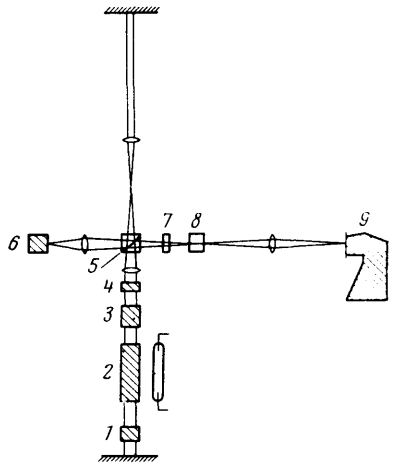

Figure 4. Apparatus for spectral measurements on short-lived products in the nanosecond region: *1*) Q-switch; *2*) ruby laser; *3*) $NH_4H_2PO_4$ crystal; *4*) filter; *5*) beam splitter; *6*) source of test pulses; *7*) attenuator; *8*) cell containing experimental compound; *9*) spectrograph.

Using this method, Porter and Topp [31] obtained the $S_X \leftarrow S_1$ absorption spectra for many aromatic hydrocarbons, and they were able to measure the mean life time of the first excited singlet. The latter quantity can also be measured independently from the rate of decay of fluorescence: in most cases the results obtained by the two methods were practically identical. The interpretation of singlet–singlet absorption spectra is complicated by the accumulation of the T_0 triplet in solution as the excited S_1 singlet disappears, so that the observed spectrum is not a simple one. With some hydrocarbons (pyrene, coronene) the apparent lifetime of the excited singlet is found to be much greater than the duration of the laser pulse, and therefore the spectra observed at very short delay times are characteristic of the excited singlet only. The isolation of the $S_X \leftarrow S_1$ absorption spectrum from the $T_X \leftarrow T_0$ background, which increases with time, is further complicated [33,34] by the great similarity between these spectra. This similarity has been reported for many hydrocarbons: naphthalene and benzanthracene [33,34], anthracene [36], biphenyl [39], pyrene, and coronene [31], and therefore it must be a general phenomenon, as theoretically predicted [40]. However, absorption from S_1 and T_0 levels has different polarisations [36,41]. The absorption spectra of excited singlets have been observed also for halogenated hydrocarbons [35,42].

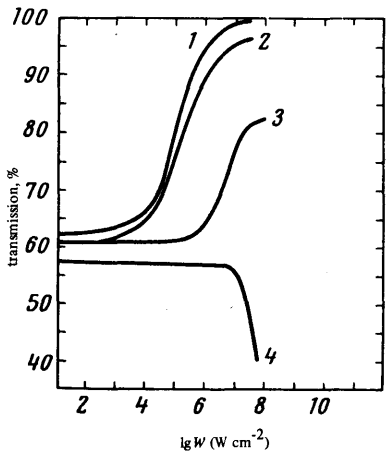

Figure 5. Transmission of dye solutions against intensity of laser radiation [30]: *1*) phthalocyanine in chloronaphthalene solution; *2*) vanadyl phthalocyanine in toluene; *3*) cryptocyanine in isopropanol; *4*) Sudan Black in acetic acid.

With dyes, whose electronic absorption spectra lie in the visible region, one-photon excitation of singlet levels can be induced by the radiation of the ruby laser. These processes are involved in the bleaching of the dyes used as passive optical shutters in Q-switching. Under the influence of a high-intensity beam the population of ground state dye molecules decreases, and as a result deviations from Beer's law are observed and the transmittance of the solution increases with light intensity. This behaviour is shown by solutions of phthalocyanine and cryptocyanine (see Fig. 5). At least two different mechanisms for this process can be suggested. According to the first [43,44], the dye acts as a two-level system, and the transition saturates when the populations of the ground and the excited state are equalised and the rates of absorption and stimulated emission are also equalised. However, it has been shown [45] that for most dyes at experimentally accessible photon fluxes the rate of stimulated radiative transitions from an excited level is smaller than the rate of intersystem crossing, as a result of which the triplet levels become populated. Thus, the dye should be treated as a multilevel system. The condition necessary for bleaching is that the cross-section for absorption of light of the laser generation frequency by molecules raised to the excited level should be less than the absorption cross-section for the ground state. In the opposite case—as with the dye Sudan Black, see Fig. 5—an increase in absorbance is observed. However, these phenomena can be explained only by assuming multi-photon excitation.

b. Multi-photon processes

Many of the effects of laser radiation are produced by multi-photon processes. Such processes are important in two respects. When laser radiation gives rise to excitation, ionisation, or chemical reaction, the process usually involves the absorption of more than one quantum, since the quantum energy of currently available lasers is several times smaller than bond dissociation energies, electronic excitation energies, or ionisation potentials. The rate of a multi-photon process is proportional to I^n, where $n > 1$. Hence, the larger n, the faster does the relative importance of multi-photon processes increase with intensity of illumination. Cross-sections for n-photon absorption are listed in Table 2: it can be seen that even at a flux of 10^{30} photons cm^{-2} s^{-1} the probability of two-photon excitation is less than the probability of one-photon excitation. However, the role of multi-photon processes may be enhanced by the non-linear self-focussing effect [47].

Table 2. Cross-sections for n-photon absorption.

n	Cross-section
1	10^{-17}–10^{-18} cm^2 $molecule^{-1}$
2	10^{-48}–10^{-54} cm^4 s $photon^{-1}$ $molecule^{-1}$
3	10^{-75}–10^{-85} cm^6 s^2 $photon^{-2}$ $molecule^{-1}$
4	10^{-115} cm^8 s^3 $photon^{-3}$ $molecule^{-1}$

Multi-photon (in particular, two-photon) processes were first observed in classical photochemistry, i.e. at relatively low light intensities [48]. In this case multi-photon processes can be favoured by producing high concentrations of metastable triplet states: the necessary increase in the life time of the triplet states is achieved by freezing the irradiated compound in a solid matrix. Two-photon excitation includes intersystem crossing and triplet–triplet absorption. Several reactions of the excited T_1 triplet have been observed: solvent interactions, decomposition, and photoionisation. The rate of a two-photon process is $r \propto I^2$, or more precisely $r \propto I_{\nu_1} I_{\nu_2}$. It is an interesting peculiarity of two-photon photochemical reactions that they require simultaneous irradiation with light of frequencies ν_1 and ν_2. The quantum yields of multi-photon processes are small: for two-photon processes, they are of the order of 10^{-2} for light intensities of 10^{14}–10^{17} photons cm^{-2} s^{-1}. However, at higher light intensities their yield (and therefore also the relative importance of multi-photon processes in competition with one-photon processes) is expected to increase. By using pulsed incoherent light sources, or better still lasers, multi-photon processes can be induced without special precautions to ensure long life times of the metastable states. In this case densely populated triplet levels are obtained not by lowering the probability of transitions from the triplet level, but by a high rate of generation of triplets under the influence of intense light. We shall now examine in detail some multi-photon processes induced by laser radiation.

Multi-photon excitation. Multi-photon (mostly, two-photon) excitation of aromatic molecules by a giant laser pulse has been observed by many workers [23,49–52]. In most cases, the excitation was detected by fluorescence or absorption, which depend (for two-photon processes) on the square of the intensity of the exciting light. A fluorescence yield proportional to the square of the intensity of a ruby laser has been reported [53] for benzoquinone, naphthaquinone, anthraquinone, N-ethylacridone, and many other aromatic molecules. All these molecules do not absorb (by the normal one-photon mechanism) light of wavelength 6490 Å, but they can be excited by u.v. light of wavelength close to one-half that of the radiation from the ruby laser. If a two-photon transition takes place, the experimental compound contains excitation levels of energy double that of the quantum. Hence, we may think of two-photon and multi-photon spectroscopy as a method of determining electronic excitation levels [54]. Resonance conditions are fairly easy to satisfy, because the electronic absorption bands of organic molecules usually contain vibrational fine structure and therefore are relatively broad. Hence, two-photon transitions will give rise to a vibrationally excited singlet state, as for example in the excitation of anthracene by light from a ruby laser [23]. An important feature of two-photon transitions is the fact that they obey quantum-mechanical selection rules different from those of ordinary one-photon transitions. Transitions involving a change in the parity of the initial and the final states are allowed in the one-photon excitation of molecules with a centre of symmetry, whereas in two-photon excitation transitions without parity changes are allowed [55,56]. Thus, states which are not accessible to ordinary optical excitation can be excited by using two-photon transitions. These transitions have been observed, for example, in coronene, 1,2-benzanthracene, and other aromatic hydrocarbons [32].

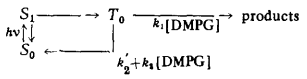
Since two-photon transitions have been observed with ordinary incoherent light sources as well as with lasers, the role of the coherence and monochromaticity of laser light has been questioned. Weiss and coworkers [57] compared the two-photon excitation cross-sections of naphthalene and anthracene with a laser and a xenon flash tube respectively. They found very similar values. A theoretical analysis [58] also led to the conclusion that the effect of coherence is negligible.

The degree of polarisation of the exciting light may have a stronger influence on the cross-section for two-photon absorption [59]. It has been shown [60] that the transition probabilities in anthracene and in 9,10-dichloroanthracene are several times greater in linearly polarised than in circularly polarised exciting light. The vibrational sub-level of the final excited state also depends on the polarisation of the light.

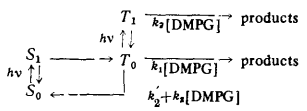
Multi-photon ionisation. Multi-photon ionisation in gases under the influence of laser radiation has been studied in detail [60–63]. Much less is known about multi-photon ionisation (photoconductivity) in the liquid phase. It has been shown [64] that light pulses from a nitrogen laser can generate photoconductivity, by a two-step mechanism, in solutions of N,N,N',N'-tetramethyl-p-phenylenediamine in non-polar solvents. The intermediate products may consist of triplet and singlet excited states, and possibly also charge-transfer complexes (CTC). Another paper [65] deals with the role of the solvent in the photoionisation of the same compound. The reaction $Fe^{2+} \rightarrow Fe^{3+}$ also appears to involve a metastable intermediate produced by a two-photon mechanism [66].

Chemical reactions induced by multi-photon excitation. The excitation which precedes

two-photon chemical reactions can occur either with formation of metastable (triplet) states or by the simultaneous absorption of two photons. It is suggested[56] that the latter process includes the formation of an intermediate virtual state. The mechanism of two-photon chemical reactions of the first type is similar to that of ordinary two-photon photochemical processes[48]. The photolysis of Methylene Blue by giant pulses from a ruby laser, studied by Tanaka and coworkers[67], is a good example of reactions of this type. The photo-reduction of Methylene Blue by ordinary light involves interaction between the reducing agent and the lowest triplet state of the dye. α-Dimethylphenylglycine (DMPG) was the reducing agent used. At low intensities of laser radiation the reaction follows the scheme



where the ratio $\frac{k_1 + k_2}{k_2'}$ is identical to the values found in ordinary photolysis. However, an increase in light intensity is accompanied by an apparent increase in the value of k_1. This increase was ascribed to the onset of triplet–triplet absorption in Methylene Blue, producing an excited triplet which takes part in the reaction and increases the rate of photo-reduction:

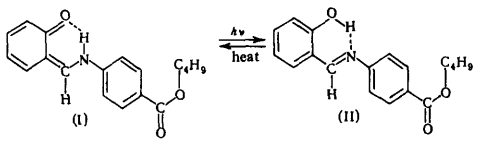


The above scheme is identical to two-photon excitation in ordinary photolysis‡. In the present case two-photon excitation arises because of the high rate of population of S_1 under conditions leading to sufficiently fast $T_0 \leftarrow S_1$ intersystem crossing, and also because the levels T_0–T_1 and S_0–S_1 are equidistant. The fact that in laser photolysis the metastable level can be excited only by a photon of energy equal to that used to excite the ground level limits the number of systems capable of undergoing chemical change under the influence of laser radiation. In this sense, the initiation of two-photon processes with two ordinary light sources of different wavelengths is a more flexible procedure. In principle, chemical reactions can be induced by using two laser lines of different wavelength (for example, with a gas laser, which radiates at different frequencies), or with a laser synchronised to a flash tube[70]. However, no system has yet been investigated by these methods.

Very high populations of triplet levels have been observed in studies of the *cis–trans*-isomerisation of substituted indigo dyes initiated by laser light[71]. A sharp decrease in transmission occurs at a radiation intensity of 10^{26} photons cm^{-2} s^{-1}: it is ascribed to the high population of a level with a higher absorption at 6940 Å than the ground level. The authors estimate that 62% of the molecules of *N,N*-dimethylindigo pass into the triplet state, whereas only 6% are present in the form of excited singlets.

‡ It should be noted that the mechanism of excitation of Methylene Blue by giant pulses from a ruby laser is much more complicated. In aqueous solutions, the dye exists in a partly associated form, as dimers[68]. Laser radiation gives rise[69] to a triplet of the monomer and a triplet of the dimer, which forms an additional excited state (probably a charge-transfer complex).

Prokhorov and coworkers[53] studied a number of multiphoton chemical reactions induced by laser radiation. Some azomethine dyes can undergo tunnelling hydrogen transfer under the influence of u.v. light:



accompanied by a change in the electronic configuration of the molecule and detected by a shift in the maximum of the fluorescence band. Fluorescence characteristic of compound (II) was observed by irradiating (I) with light from a ruby laser operated in the *Q*-switched mode. Since $I_{fluor.} \sim I^2_{exc.}$, the hydrogen transfer process must involve two-photon excitation. Free radicals produced by giant pulses from a ruby laser in triphenylmethane, α-nitronaphthalene, and other aromatic compounds frozen at 77°K have been detected by ESR. The triphenylmethyl radical $(C_6H_5)_3C^{\cdot}$, formed when $(C_6H_5)_3CH$ is irradiated with ordinary light with a quantum energy of 5.5 eV, was detected during irradiation of $(C_6H_5)_3CH$ with ruby laser light. It is evident that a three-photon mechanism must be involved, since $I_{fluor.} \sim I^3_{exc.}$, and the energy of three quanta of ruby radiation is close to 5.5 eV.

Porter and Steinfeld[72] studied the photolysis of phthalocyanine vapour at 420–430°C, a temperature at which the compound is stable. A pulse from a ruby laser with an energy of 40 J (equivalent to a power of 50 kW) did not cause decomposition, whereas a giant pulse of energy ~2 J but corresponding to a power of 100 MW produced decomposition of approximately 50% of the material in the path of the beam. The steep variation of reaction yield with intensity is evidence for a multi-photon mechanism. A reaction product with an absorption maximum in the u.v. region, characteristic of indole derivatives, was observed. The existence of a metastable or resonance level, excited by laser light, seemed probable in all the reactions considered.

Two-photon reactions have been observed also in systems where the electronic excitation of the reactants involved the simultaneous absorption of two quanta. Porter[73] exploited the two-photon initiation of the hydrogen–chlorine reaction in a lecture demonstration. When a mixture of $Cl_2 + H_2$ was illuminated with light from a ruby laser in the free generation regime (30 J) no reaction was observed, since both hydrogen and chlorine are transparent to red light, but an explosive reaction was induced by introducing a solution of cryptocyanine dye in the laser cell (even though the energy of the laser pulse had been decreased by a factor of 10). The explosion was initiated by the two-photon dissociation of chlorine, since the energy of two quanta of ruby laser light (3.57 eV) falls within the range of electronic absorption of chlorine (3.0–5.2 eV). The reaction $Cl_2 + CH_4$ involves a similar mechanism[74]. All possible chloro-substituted methanes are found among the reaction products, which points to a radical mechanism. Rousseau and coworkers[75] observed two-photon excitation and decomposition of AgCl under the influence of ruby laser light. AgCl is transparent to light of λ = 693 nm, but it absorbs at 347 nm. The reaction produces colloidal silver, identified by its absorption spectrum; it is accompanied by luminescence ($\tau = 10^{-4}$ s), with $I_{lum.} \sim I^2_{exc.}$ Light from a He–Ne laser (633 nm) of much lower intensity produced no reaction at the same (fully absorbed) energy.

2. Effects Associated With Vibrational Excitation

Lasers are powerful sources of radiation in the near and medium i.r. region. The absorption of radiation of frequency 10^2-10^4 cm^{-1} produces vibrational excitation in molecules. If the irradiated material is a sufficiently strong absorber at the frequency generated by the laser, it will display high, non-equilibrium occupancies of its vibrational levels. Deactivation of these excited states can occur either radiatively (by i.r. fluorescence), or by a non-radiative mechanism involving various relaxation processes. As long as the radiated power of the laser is not too high, very high vibrational temperatures can be reached without raising the translational temperature, i.e. without heating the material. With the most powerful lasers, infrared heating of the material can occur. The difference between this process and normal heating is that the whole of the absorbed energy is transferred to vibrations in the first instance, before being redistributed among other degrees of freedom. Ultimately, excitation of all the vibrational, rotational, and translational degrees of freedom can be expected, with the possibility of decomposition of the molecule. If the system can equilibrate between all degrees of freedom before decomposition sets in, the laser-induced reaction will not differ in any way from normal thermal decomposition at moderately high temperatures. However, if the chemical reaction begins before all the relaxation processes have gone to completion it may exhibit entirely different kinetic parameters (rate constants, activation energies). This is particularly true when absorption of a quantum raises the molecule to an excited vibrational level close to the dissociation threshold, and there is a finite probability of further thermal activation leading to dissociation (see, for example, Ref. 25). An alternative path to non-equilibrium chemical reactions involves multi-photon vibrational excitation. Examples of both types of process are discussed below.

Vibrational excitation by laser radiation. Measurement of the time dependence of the i.r. fluorescence from molecules which have been excited by laser radiation is a powerful new method of studying energy transfer processes in gases. Upwards of 20 compounds have been examined by this method, including methane, ethane, ethylene, and CO_2. The main results are discussed in recent reviews [76,77]. Recent developments in laser technology, by making available picosecond pulses, have enabled intramolecular vibrational relaxation to be studied [78] in complex molecules over times of the order of 7.5×10^{-12} s, i.e. over a few tens of vibrations.

Decomposition under the influence of laser radiation. As we have already pointed out, vibrational excitation can lead to decomposition of the irradiated compound at sufficiently high radiated powers. This type of decomposition has been observed by irradiating various hydrocarbons with light from a CO_2 laser [79,80]. Further work [81] showed that the decomposition of ethylene, propene, allene, and divinyl becomes appreciable only at pressures above a definite threshold. Thus, the decomposition of ethylene begins at pressures above 120 mmHg, and at pressures above 220 mmHg it is accompanied by strong self-heating, formation of carbon and resins, and visible luminescence. This steep pressure dependence arises from the pressure-induced broadening of the absorption bands. The greater the broadening, the more fully is the laser radiation absorbed by the compound. The distribution of reaction products is almost the same as in the thermal reactions of the hydrocarbons.

Decomposition of CO_2 is responsible for the relatively low power available from the sealed gas laser (in which circulation of the gas mixture is not provided) [82,83]. It has been shown [82] that the extent of conversion of CO_2 is large because the equilibrium $CO_2 \rightleftharpoons CO + \frac{1}{2}O_2$ in the system is displaced towards the right by adsorption or chemical reaction of the products (O_2 or O) with the electrodes or the walls of the discharge tube.

Multi-photon vibrational excitation and dissociation. With powerful modern lasers,

$$(2-3)\hbar\omega \approx D \text{ and } \omega \approx 10\omega_e$$

where $\hbar\omega$ is the quantum energy, and D and ω_e are "typical" values of the dissociation energy and natural vibration frequency of a chemical bond. It follows that direct photodissociation (without a predissociation step) can occur by a multi-photon mechanism with resonance transitions through several vibrational levels. The theory of "oscillating" molecular vibrations and photodissociation in a powerful field of laser radiation has been discussed by Askar'yan [84,85] and by Bunkin and coworkers [86].

There are two possible regimes of vibrational excitation and dissociation of molecules under the influence of laser light. The first occurs when the force acting on a molecule in an intense light field is linearly related to the field and has a frequency equal to that of the light field. This state of affairs is usually found with polar molecules. The molecules are set oscillating in the field when their mean dipole moment interacts with the electric component of the radiation field. The probability of two- and three-photon purely vibrational transitions (i.e. not involving a change in the electronic state) has been evaluated [86] for diatomic molecules in the anharmonic oscillator approximation. Molecular vibrations can interact with the field only as a result of their anharmonicity, which ensures that transitions with $|\Delta n| > 1$ are allowed. The probability of the process depends essentially on whether the discrete vibrational spectrum includes resonant transitions defined by the condition

$$(\omega - \omega_{n,0})^2 \ll \left(\frac{\mu\varepsilon}{\hbar}\right)^2$$

where $\omega_{n,0} = \frac{1}{\hbar}(E_n - E_0)$; ϵ is the electric field strength of the electromagnetic wave; μ is the dipole moment. It is evident from this formula that the resonance conditions is most easily satisfied by highly polar molecules in a field of high intensity. With a field of 3×10^7 V cm^{-1}, resonant transitions are more probable than non-resonant transition by a factor of 10^3. The difference is even greater at higher fields. Three-photon transitions without resonance are improbable at 10^7 V cm^{-1}, but at $\epsilon = 3 \times 10^8$ V cm^{-1} their probability is quite large.

The second excitation regime describes the situation when the force for excitation has a frequency different from that of the light wave. A force of this type may arise from atom polarisability, i.e. from the excitation of homopolar as well as heteropolar molecules. This force is proportional to the square of the field, and therefore it can only give rise to new spectral absorption lines in very strong light fields [84,85].

Evidence of initiation of a chemical reaction by the above mechanism is given in two papers only. Eisenthal and coworkers [87] studied the effect of ruby laser pulses (0.1–5 MW cm^{-2}) on biphenyl. The power density of

these pulses corresponded to a peak field strength of $10^{-4}-10^{5}$ V cm^{-1}. The observed fast luminescence spectrum was different from the fluorescence and the phosphorescence spectrum of the compound, and its intensity was proportional to the cube of the light intensity. Hence it was concluded that three-photon vibrational excitation and dissociation into two phenyl radicals can take place in laser light. The luminescence is produced by dissociation products with an excess of energy of ~30 kcal mole^{-1}. A similar mechanism is probably involved also in the photodissociation of dibenzofuran, dibenzthiophen, and also dibenzyl, for which a two-photon mechanism has been proposed.

Prokhorov and coworkers[53] observed the decomposition of α-nitronaphthalene irradiated with light from a dysprosium laser ($h\nu$ = 0.5 eV). This reaction probably involves stepwise excitation to vibrational sublevels of the electronic ground state, followed by dissociation of the bond (~1.1 eV bond strength).

IV. HIGH-TEMPERATURE REACTIONS

When solids are irradiated with laser pulses, instantaneous heating and evaporation occur, accompanied by plasma formation at the highest powers. Hence, lasers have been used for the mass-spectrometric[88] and emission-spectrometric[89] analysis of solids, and also in pyrolytic gas chromatography[90].

Hydrocarbons have been synthesised[74] from carbon (heated by a giant laser pulse) and hydrogen: the products included acetylene (90%), methane, ethylene, allene, methylacetylene, and diacetylene. Subsequent work[91,92] showed that the formation of acetylene (which can be observed also with normal laser pulses) is the result of interaction between C_2 and hydrogen or hydrocarbons in the gas phase. Some other reactions can also be ascribed to the diatomic C_2 radical[93]. Laser heating of silicon and germanium in a hydrogen atmosphere, and of carbon in an atmosphere of chlorine, has yielded SiH_4, GeH_4, and CCl_4 respectively[74]. A method for producing diamond from graphite in a laser beam has been patented[94].

The gas phase formed when solids are impulsively heated with laser radiation often differs in composition from the vapour evolved on slow heating. This type of phenomenon has been observed[95] with the oxides, sulphides, selenides, and tellurides of arsenic, antimony, and bismuth. The gas phase obtained by laser vaporisation is characterised by particles of the type Bi_3X: a probable explanation is that critical conditions are approached in the region subjected to instantaneous heating.

As already pointed out, dielectric breakdown can occur in transparent liquids and gases exposed to strong optical fields. Multi-photon processes play an important role in dielectric breakdown[60]. However, once a plasma has been formed, the medium becomes opaque to the laser radiation, and thereafter it can be heated to very high temperatures by the laser beam. Breakdown can initiate the fixation of atmospheric nitrogen[74] and the formation of acetylene from methane[96], but attempts to prepare ammonia by this method from a stoichiometric mixture of nitrogen and hydrogen have been unsuccessful[74]. Breakdown due to pulses from a ruby laser was shown[97] to produce C_2, C, C^+, C^{2+}, Cl, and O^+ in organic vapours (CCl_4, $CHCl_3$, CH_3COCH_3, CH_3OH, and n-C_6H_{14}). The vibrational state of C_2 was different in CCl_4 and $CHCl_3$ vapours. Chloroform and carbon tetrachloride gave C_2Cl_4, C_2Cl_6, C_6Cl_6, and octachloronaphthalene. Methanol gave only high-molecular products.

V. CHEMICAL EFFECTS OF LASER LIGHT IN VARIOUS SYSTEMS

We have considered the various types of excitation produced by laser radiation, and the corresponding mechanisms by which chemical reactions can be induced by laser light. Often the mechanism of a particular reaction is not known, and in some cases the observed changes can be ascribed to more than one factor. Systems of this type are best described without attempting to associate them with any particular mechanism.

1. Decomposition of Organic Compounds

Wiley and Weeravagu[98] studied the chemical effects of focussed light from a ruby laser operated in the free generation regime (pulse energy 3.5 J) on various solid or frozen aromatic compounds. According to the distribution of reaction products, all the compounds examined can be classified into three types (see Table 3). The first is characterised by the formation of acetylene in much larger amounts than methane. Compounds of the second group give comparable yields of methane and acetylene.

Table 3. Decomposition products of organic compounds[98].

Compound	Products, vol.%				
	CH_4	C_2H_2	C_2H_4	C_4H_2	$C_4H_4+C_4H_6$
Biphenyl	7	84	6	Tr*	3
Naphthalene	4	87	4	Tr	5
Anthracene	4	85	3	Tr	8
Phenanthrene	2	91	1	Tr	6
Benzoic acid	3	85	1	Tr	11
Benzil	15	65	19	1	—
Anthraquinone	3	86	2	Tr	9
Methyl Yellow	28	57	8	7	Tr
Toluene	38	51	10	1	—
p-Xylene	42	48	9	1	—
Mesitylene	46	40	13	1	—
Methylene Blue	44	43	8	3	2
Benzene	56	16	21	1.5	—
N,N-Dimethylaniline	77	2	12	5	—
N,N-Diethylaniline	51	9	26	7	—

*Traces.

Lastly, irradiation of some compounds (benzene, *N,N*-dimethylalanine, and *N,N*-diethylalanine) yields much larger amounts of methane than of acetylene. In addition to CH_4 and C_2H_2, appreciable amounts of ethylene, vinylacetylene, and diacetylene are produced in many cases.

The unexpected distribution of reaction products, summarised in Table 3, allows us to exclude a purely thermal decomposition mechanism at the focus of the laser beam. On the other hand, the high yields of methane from compounds such as benzene and benzil, which do not contain methyl or methylene groups, and also the CH_4/C_2H_2 ratios for pairs of compounds such as benzene–biphenyl and benzene–benzoic acid, make it very difficult to interpret the results. As Table 3 shows, chemically and structurally very different compounds fall in the same group.

The authors suggest that the reactions of hot atoms or radicals (CH, CH_2 or CH_3) formed "under specific focussing conditions of the laser beam" may be responsible for the formation of large amounts of methane and acetylene. Although reactions of atomic carbon sometimes give the same products[98] as the decomposition of aromatic compounds under the influence of laser light, the formation of particles like C or CH requires such large energy expenditure as to be inadmissible, except by a multi-photon mechanism, whose probability is low, however, at the relatively low intensities of a laser beam in the free generation regime. Whereas the above results suggest some measure of specificity in the effect of ruby laser light on solid aromatic compounds—in particular on frozen benzene—other results by Bragin and coworkers[100,101] show that laser radiation can initiate non-specific pyrolysis reactions in liquid benzene (and other aromatic compounds), with hydrogen and carbon as the only products. Liquid benzene was irradiated with unmodulated pulses of laser radiation, of energy in the range 1–8 J (i.e. of the same order of magnitude as the luminous fluxes used by Wiley and Weeravagu[98]). The wavelength of the laser light did not appear to play any part, but a sharp energy threshold of the laser pulses was identified below which no decomposition occurred. Above the energy threshold the formation of solid reaction products was accompanied by generation of shock waves. The threshold energy depended on whether a finely divided suspension was present in the liquid benzene, but not on its chemical nature. These observations, together with the anomalously high quantum yield (0.33), forced the authors to the conclusion[101] that the reaction is initiated by the temperature rise of the microscopic solid particles always present in a liquid, and proceeds by a chain mechanism. However, this mechanism fails to explain why the reaction follows an entirely different course in solid benzene irradiated with laser light, with a specific rather than thermal mechanism (as shown by the nature of the products). On the other hand, if laser radiation can initiate the pyrolysis of benzene, it is not clear why acetylene was not detected among the products although it is the commonest product of high-temperature decompositions of hydrocarbons. Studies of the laser photolysis of benzene[38,102] (λ = 3471 and 2645 Å) have revealed an intermediate with an absorption maximum close to 5000 Å and a life time of 2×10^{-8} s. This absorption was originally ascribed to the $^1E_{1u} \leftarrow {}^1B_{2u}$ singlet–singlet transition, but a more careful comparison with pulse radiolysis data[103] led to the conclusion that the particle responsible for this absorption is an excimer of benzene, formed by a two-photon mechanism. The excimer is formed from highly excited states of benzene with an energy of ~7 eV. At the same time, stable products are formed, and they accumulate in solution after prolonged irradiation (trienes, and fulvene derivatives). It is probable that laser radiation causes opening of the aromatic ring, which may explain the formation of CH_4 in Wiley's experiments[98]. The benzene biradical may be an intermediate in this reaction[103].

The data reviewed by Wolfgang[99], and also some recent experimental results[104,105] on the effect of laser radiation on a number of gaseous unsaturated hydrocarbons, suggest that hydrogen transfer reactions may be involved. We have detected[104] ethylene and ethane in acetylene irradiated with light from a Nd^{3+} laser (10^{-3} s, 1–10 J). As Table 4 shows, C_2 hydrocarbons are predominant among the products of this reaction.

We were unable to detect any higher hydrocarbons, in particular benzene—a familiar product of the photolysis of acetylene. Significant amounts of hydrogen, carbon black, and pyrolytic carbon were also absent. It is evident, from the composition of the products, that the radiation from a neodymium laser has a specific effect on acetylene, quite unrelated either to pyrolysis or to ordinary photolysis. The vibrational spectrum of acetylene includes a strong $3\nu_3$ overtone whose frequency (9640 cm^{-1}) is close to that of neodymium laser light (9400 cm^{-1}).[106] If this fortuitous agreement between the frequency of the laser radiation and the natural vibration frequency of the irradiated compound is responsible for the chemical reaction, we may expect both the absorption and the reaction to disappear if an isotopic frequency shift is introduced by replacing C_2H_2 by C_2D_2. However, we find that C_2D_2 also undergoes chemical reaction when irradiated with neodymium laser light, but in this case the product consists mainly of ethane. Irradiation of an equimolar mixture of C_2H_2 and C_2D_2 leads to isotope exchange with formation of C_2HD. The products obtained by irradiating ethylene with neodymium laser light included methane, acetylene, and divinyl in the ratio 3 : 1 : 1. The high relative yield of methane is remarkable, since neither pyrolysis nor ordinary photolysis of ethylene gives significant amounts of methane. Wiley and Reich[105] also obtained unexpectedly high yields of methane in their work on the irradiation of acetylene with light from a ruby laser in the free generation regime (Table 5).

Table 4. Products obtained from acetylene by the action of radiation from a neodymium laser in the free generation regime[104].

Starting material	Gaseous products, vol.%				
	ethane	ethylene	divinyl	vinylacetylene	diacetylene
C_2H_2	—	71.7	0.5	13.7	13.2
C_2D_2	71	2.0	5.5	21.3	—

Table 5. Products obtained from gaseous hydrocarbons by the action of radiation from a ruby laser in the free generation regime[105].

Hydrocarbon	Products				
	CH_4	C_2H_2	C_2H_4	C_2H_6	Higher
Cyclopropane	26.5	none	11.5	62	none
Ethylene	4.3	none	—	95.7	none
Acetylene	59.3	none	40.7	—	none
Ethane	32.1	—	not measured	67.9	none
Butane	25.4	1.2	26.9	43.4	3.6*

*Propene.

The material balance of these reactions suggests that in some cases (C_2H_4) large amounts of hydrogen must have been formed, in others (C_3H_6, C_2H_2) carbon must have been formed, or polymers with a low hydrogen content.

2. Polymerisation

Pulses of laser light can initiate polymerisation reactions. In the earliest experiments[107] polymerisation was

obtained in the presence of a dye sensitiser. When acrylamide was irradiated with argon laser light (4880 Å) in the presence of a sensitiser (4,5-dibromofluorescein + *N*,*N*,*N*′,*N*′-tetramethylethylenediamine) the polymerisation yield was 10^3 per absorbed photon[108]. The polymerisation of vinyl acetate, initiated by giant laser pulses (λ = 3472 Å) in the presence of 2-azo-bis-isobutyronitrile, is described in the Patent literature[109]. Polymerisation without sensitisers was first reported by Pao and Rentzepis[110], who irradiated styrene frozen at 77°K with light from a ruby laser (0.3 MW). A two-photon mechanism was suggested. The yield of polymer was 0.01% per pulse. The i.r. spectrum of the polymer was indistinguishable from that of polystyrene, and its molecular weight was 3.6×10^5. Because styrene does not absorb strongly at 3470 Å, it can only be polymerised in a rigid matrix (not in the liquid phase). Other monomers which are better absorbers at this frequency (e.g. *p*-isopropylstyrene) were successfully polymerised at room temperature. Polymerisation of the chloro-derivatives of styrene was easier still.

The possibility of polymerising styrene with giant ruby laser pulses was later confirmed by Apletalin and coworkers[111]. However, these workers described the process not in terms of two-photon excitation of the lower electronic levels, but in terms of multi-photon dissociation (probably by Bunkin's mechanism[86]) and ionisation, giving rise to a breakdown phenomenon accompanied by visible luminescence with a continuous spectrum.

3. Disintegration and Degradation of High-molecular Compounds

In opaque polymers, the energy of laser pulses is absorbed in a very small volume, and therefore the material is locally heated to very high temperatures (see Section IV). The mechanical degradation processes observed when powerful laser pulses are focussed within transparent polymers are very much harder to interpret[60]. Mechanical disintegration is evidently associated with chemical degradation of the polymer, which may result in the appearance of paramagnetic centres in the polymer[112]. These changes are sometimes preceded by phase transformations (melting and recrystallisation of some of the structural elements of the polymer)[113]. A study[114] of the decomposition of poly(methyl methacrylate), PMMA, under the influence of ruby and neodymium laser pulses has shown that gases are formed by a two-photon or a three-photon process, depending on the photon energy. The composition of the gaseous decomposition products of PMMA included CO, CO_2, and CH_4, whereas normal thermal degradation of PMMA yields only the monomer (at low temperatures) or a complex mixture of secondary reaction products—mainly acetylene and ethylene—at higher temperatures[115]. Hence, we can dismiss the purely thermal mechanism of degradation of transparent polymers exposed to laser radiation.

Many investigations[116-120] have been devoted to the action of laser radiation on opaque polymers (phenolic resins, elastomers) and on coal. The gaseous degradation products were found to consist predominantly of acetylene and hydrogen. The composition of the reaction products was quite different from the composition of the products of low-temperature (500–900°) degradation of these materials, and also from the composition of the products obtained by the action of a xenon flash tube[119]. A study of the laser degradation of coal in a time-of-flight mass spectrometer has shown that the primary products are H atoms and methyl radicals. The strongest peak in the mass spectrum was due to acetylene[121].

(Added in proof)

Several relevant papers have appeared since this review was submitted for publication. The most interesting results relate to the possibility of selectively initiating chemical reactions by monochromatic laser light, using resonant excitation of selected intramolecular vibrations. It has been shown[122] that the dissociation of BCl_3 under the influence of CO_2 laser light occurs by a cascade mechanism (i.e. by an *n*-photon mechanism with $n \gg 1$), and high vibrationally excited states, close to the dissociation threshold, have been observed spectroscopically. Mixtures of BCl_3 and H_2 react explosively when irradiated. The initiation of chemical reactions by excitation of molecular vibrations has been demonstrated in a number of other systems[124-126], including N_2F_4 in mixtures with N_2, H_2, and CH_4, and also CH_3OH mixed with CD_3OD. This work has shown that in many cases the anharmonicity of vibrations is not an insuperable obstacle to selective bond breaking. Two-stage excitation is proposed[127] for systems in which the vibrational–translational relaxation processes can compete with resonant excitation processes at levels not high enough to reach the dissociation threshold. Using this method, the photodissociation of HCl and the photoionisation of rubidium vapour have been demonstrated[128].

Barashev and Tal'roze[129] have developed a criterion for distinguishing photochemical from purely thermal effects of laser radiation on matter. A group of papers[130-132] deals with a theoretical analysis of the initiation of chemical reactions by laser light. Several reviews of the properties and applications of various types of laser have appeared: dye lasers[133], lasers based on compounds of the rare-earth elements[134], and pulsed gas lasers[135]. Further work on the laser photolysis of benzene has been reported[136]. Lastly, the laser photolysis of acetophenone[137], thiocyclobutanes and thiocyclopentanes[138], the two-photon gas-phase decomposition of azoethane[139], and the photoionisation of water[140] have been described.

Use of Reversed Gas Chromatography in the Investigation of Polymeric Compounds

V.G.Berezkin and A.N.Genkin

The principal aspects of the use of gas chromatography for investigating polymers when they are employed as a stationary phase (the reversed gas chromatographic method) are considered: the identification of polymers, the determination of their molecular weights, the study of the thermodynamics of the dissolution of low-molecular-weight substances in polymers, the determination of the temperatures of the phase transformations, degrees of crystallinity, kinetics of crystallisation processes, and the chemical changes taking place in the polymers.
The theoretical principles of the use of reversed gas chromatography and the peculiarities of the gas-chromatographic behaviour of polymers determined by the structure and their phase and physical states are discussed. 67 References.

I. INTRODUCTION

The classical version of the gas-chromatographic method cannot be used directly for investigating involatile high-molecular-weight compounds. Destructive gas chromatography is an indirect method, since it is based upon the correlation between the characteristics of the polymeric system being studied and the spectrum of products for its pyrolysis or from other chemical changes.

Another, qualitatively different, approach to the investigation of high-molecular-weight compounds is possible—the use of reversed gas chromatography (RGC). In RGC the system being studied is, unlike the classical version, the stationary phase, on which known volatile compounds (standards) are separated. RGC is based on the use of the direct interaction of the standard chromatographable compounds with the polymeric system being studied and the establishment of a definite connection between the chromatographic characteristics of the standard compounds and the composition, structure, and other properties of the polymeric system used as the stationary phase. Therefore the RGC method can be regarded as a direct method of investigation of high-molecular-weight compounds.

Martin[1] was the first to report the value of gas–liquid chromatography (GLC) in the study of the thermodynamics of the interaction of volatile substances with an involatile phase. The terminology "reversed gas chromatography" was proposed in 1966.[2,3]

Initially RGC was regarded as a method of solving separate, rather general problems: identification[4,5], determination of phase transformations[6,7], study of kinetics[8,9], etc. The wider concept of RGC as a physicochemical and analytical method of investigation of involatile systems was proposed by one of us[2,3].

The possibility in principle of using RGC as an independent analytical method for identification was first stated by Zhukovitskii and Turkel'taub[4]: "In individual instances the test substance can be used as a stationary phase, with the aim of identifying the components and finding the presence of impurities of a definite nature. For example, the presence of polar impurities in a non-polar solvent has a marked effect on the retention time for polar impurities".

The RGC method can be used for investigating both liquid and solid substances. In the investigation of polymers as stationary phases in each specific instance preliminary consideration must be given to the mechanism of the chromatographic process (absorption, adsorption, mixed), which is determined by the possibility of using recently developed theories of gas–liquid or gas–adsorption chromatography to obtain the physicochemical characteristics of polymeric specimens.

Owing to the widespread use of polymers in the practice of modern gas chromatography as liquid stationary phases (silicone oils, polyglycols, polyethers, rubber) and as solid adsorbents and carriers (porapaks of various grades, polyurethanes, polyalkenes, etc.) much material has accumulated on the retention volumes of various volatile compounds on polymeric phases. An analysis of these results can give valuable information in the study of many specific problems. The aim of the present review, however, is to find the main regions and prospective uses of RGC in the investigation of polymeric compounds.

II. IDENTIFICATION OF POLYMERS

Experimental verification of the applicability of reversed chromatography for identification purposes showed that this method permits group identification of the compounds used as stationary phase[5]. As an example, Fig. 1 gives the relative retention times for substances of different polarities (methanol, heptane, toluene) in a triangular coordinate system, when normal alkanes, aliphatic alcohols, and acids are used as stationary liquid phase. It was found that each of these homologous series is characterised by a sharply defined range of values of the retention times of standard compounds. We note that this method makes it possible even to distinguish some isomeric compounds. Thus the spectra of standard

volatile compounds are different for 1,3-butylene glycol and 1,4-butylene glycol, and also for primary and secondary octyl alcohols. The results given show the rather high sensitivity of the method of reversed chromatography. Similar results can also be obtained for polymeric systems.

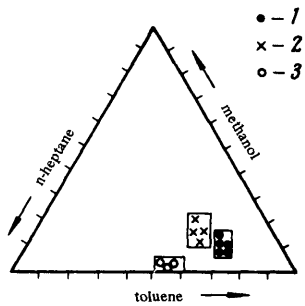

Figure 1. Diagram for group identification by three standard components: *1*) aliphatic acids; *2*) normal aliphatic alcohols; *3*) n-alkanes.

The large body of information that has accumulated in gas chromatography on the use of polymers as stationary liquid phases for separating mixtures of volatile compounds (for example, see McReynolds [10] and Lewis [11]) suggests that polymers can also be identified by RGC. Thus according to Devyatykh and coworkers [12] the retention volume for phosphine on a column with silicone oil 702 is 1.75 cm^3, with silicone oil VKZh-94 B it is 1.58 cm^3, and with silicone oil PFMS-4 it is 2.52 cm^3. Another example is of two polymeric compounds of the same type—poly(propylene glycol) with $\bar{M}_n$ = 1760 and poly(ethylene glycol) with $\bar{M}_n$ = 1540, which are characterised by markedly different retention values [10], which allows the RGC method to be used for their identification (see Table 1). RGC results for the identification of compounds are presented more conveniently on a logarithmic scale as spectra of relative retention volumes (or times) for volatile standard compounds (see Fig. 2). As Fig. 2 shows, polymers of rather similar structure are characterised by markedly different spectra. This form of presenting experimental results can be used in the future for compiling an atlas of spectra of standard volatile compounds on polymeric substances.

The RGC method has been developed in most detail for the characterisation (identification) of the asphaltenes (molecular weight 500–1000).[5] The so-called specific coefficients of interaction of volatile standard compounds with the stationary liquid phase I_g were used as characteristics of the asphaltenes:

$$I_g = 100 \lg (V_R^0/V_{RA}^0) = 100 \lg (V_g/V_{gA}) \quad (1)$$

where V_R^0 or V_g are the retention volumes of volatile standard on a column with asphalt, V_{RA} or V_{gA} the retention volumes of a hypothetical alkane, having the same molecular weight as the volatile standard being used. Recent investigation [13] showed the adequate constancy of I_g with respect to the principal parameters of the experiment.

Dorrence and Petersen [14] showed the advisability of using chemical reactions with the stationary liquid phase being investigated by RGC. To study the functional groups in the asphaltenes the specimen being studied in the column was subjected to silylation, as a result of which the active hydrogen atoms in the hydroxyl and carboxyl groups were replaced by trimethylsilyl radicals. Treatment of the asphaltene with *NN*-bis(trimethylsilyl)acetamide at 160°C led to a marked decrease in the specific interaction coefficients with selected volatile standards (phenol and propionic acid). This method can be used to characterise the functional groups of various polymeric compounds.

Table 1. Specific retention volumes of volatile compounds on polyglycols being used as stationary liquid phases (120°C; solid carrier: Celite 545).[10]

Polymeric stationary liquid phase	Specific retention volumes of the volatile compounds, ml g^{-1}								
	methanol	furan	hexane	ethyl acetate	cyclohexane	benzene	butanol	water	heptanol
Poly(propylene glycol) 1760	7.6	7.8	8.0	15.3	14.5	24.3	44.9	9.8	321
Poly(ethylene glycol) 1540	15.1	9.0	2.9	15.5	6.6	23.7	60.2	35.0	316

In conclusion, we note that when a packed column is used for the RGC method ~0.4 g of the test compound is required, but the amount is reduced to 3–4 mg when a capillary column is employed [5]. The use of the microversion of reversed chromatography is especially important for polymers which are difficult to prepare and in general for difficultly accessible compounds.

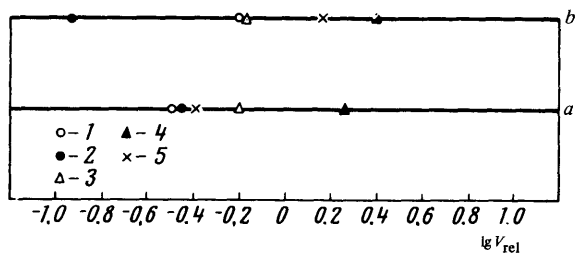

Figure 2. Chromatographic spectra of standard compounds on identifiable polymers: *a*) poly(propylene glycol) 1760; *b*) poly(ethylene glycol) 1540; *1*) methanol; *2*) hexane; *3*) ethyl acetate; *4*) butanol; *5*) water.

In view of the fact that the task of identification of the polymers sometimes reduces to the determination of their molecular weights, which is of interest in itself, we will examine how the retention of volatile compounds varies with the molecular weight of the polymer.

III. DETERMINATION OF THE MOLECULAR WEIGHT OF POLYMERS

A change in the molecular weight of a polymer leads to a change in many of its properties, and in particular in its chromatographic properties.

Evidently, the retention volume can be regarded as a colligative property of solutions, since its value is determined ultimately by the vapour pressure of the substances dissolved in the stationary liquid phase.

Like the other colligative properties of solutions (vapour pressure, freezing point depression, etc.), the retention volume of a dissolved substance depends upon the number of particles per unit volume of solution, and consequently on the molecular weight of the solvent [15] (the number-average molecular weight for a polydisperse polymeric liquid phase):

$$V_g^{(i)} = \frac{RT}{\overline{M}_n f_i^0 \gamma_i^\infty} \qquad (2)$$

where $V_g^{(i)}$ is the specific retention volume of the ith substance at column temperature T; f_i^0 and γ_i^∞ are the fugacity of the pure ith substance and its activity coefficient at infinite dilution in the stationary phase; $\overline{M}_n$ is the molecular weight of the stationary liquid, and R the gas constant.

However, as a strict analysis of the theory of dilute solutions [16] shows, only the molecular weight of the dissolved substance can be determined from the colligative properties of solutions, but not that of the solvent. This also applies to the retention volume. Actually, from the quantity Vg, which is readily determinable by experiment, only the product $\gamma_i^\infty \overline{M}_n$ can be calculated from Eqn. (1), and in all independent methods of determining γ_i^∞ a knowledge of the molecular weight of the solvent is always necessary.

Hence Eqn. (2) cannot be used for calculating the molecular weight of the stationary liquid. Nevertheless this equation is often used to determine γ_i^∞ and here $\overline{M}_n$ is usually taken as equal to the molecular weight of the monomeric form of the solvent, even when the latter is a strongly associated liquid.

Generally speaking, the values of γ_i^∞ or their variation with M_n needed for evaluating the molecular weight of the solvent by Eqn. (2), can be calculated theoretically. However, current theory of solutions does not in many instances yet permit the thermodynamic functions of the solution to be calculated with sufficient accuracy just from the molecular characteristics of the initial pure components, especially for polar associated substances. Usually, the theoretical expressions for the activity coefficients include parameters, the a priori evaluation of which is extremely difficult [17].

Consequently, semiempirical methods are often used for evaluating the quantities γ_i^∞ needed for the calculation of M_n by Eqn. (2).

Martire and Purnell [18] started from the well known Flory–Huggins [19] equation for the activity coefficient of the solvent in solutions of polymers and postulated its validity for limitingly concentrated (in relation to polymers) solutions:

$$\ln \gamma_i^\infty = \ln \frac{V_i^0}{V_p} + 1 - \frac{V_i^0}{V_p} + \chi, \qquad (3)$$

where V_P and V_i^0 are the molar volumes of the solvent (polymer) and of a low-molecular-weight solute respectively and χ is the Flory–Huggins interaction parameter. Then by assuming that within a polymer-homologous series the parameter χ is almost independent of $\overline{M}_n$ of its members, it is easy to use Eqns. (2) and (3) to calculate the molecular weight of the polymeric phase, if the retention volumes of a standard substance on this phase (index b) and on the same polymer with a known molecular weight (index a) are determined:

$$\frac{1}{\overline{M}_n^{(a)}} = \frac{\rho_a}{\rho_b \overline{M}_n^{(a)}} + \frac{\ln [(V_g^{(i)})_b / (V_g^{(i)})_a] + \ln (\rho_b / \rho_a)}{\rho_b V_i^0}, \qquad (4)$$

where ρ_a and ρ_b are the densities of phases a and b, and $\overline{M}_n^{(a)}$ and $\overline{M}_n^{(b)}$ are the number-average molecular weights of the polymers of phases a and b. Another, more convenient, modification of this method is the determination of the molecular weight of the polymeric stationary phase from the relative retention volumes of two substances of similar nature (often neighbouring members of a single homologous series), measured on phases a and b:

$$\frac{1}{\overline{M}_n^{(b)}} = \frac{\rho_b}{\rho_b \overline{M}_n^{(a)}} + \frac{\ln (R_a / R_b)}{\rho_b \Delta V_i^0}, \qquad (5)$$

where R_a and R_b are the relative retention volumes of two selected standard dissolved substances X and Y ($V_g^{(Y)} = 1$) on phases a and b:

$$\Delta V_i^0 = (V_i^0)_Y - (V_i^0)_X.$$

This method is usable for comparatively low-molecular-weight polymers—liquid silicones, polyglycols, and hydrocarbon oils with $\overline{M}_n \leqslant 1500$. The accuracy of the proposed method decreases as the molecular weight is raised.

The Flory–Huggins equation (3) and the assumption that χ is independent of the molecular weight of the polymer at a sufficiently high value are valid only in the absence of a specific interaction of the dissolved substance with the solvent. Hence the volatile compounds (solutes) used should preferably be saturated hydrocarbons.

Martire and Purnell [18] gave as an example the determination of the molecular weight of poly(propylene glycol) 1200 with the use of n-heptane and n-octane as volatile compounds and poly(propylene glycol) 400 as liquid phase of known molecular weight. The molecular weight of the poly(propylene glycol) calculated by Eqn. (5), was 1220 (according to the cryoscopic method, $\overline{M}_n = 1260$).

The use of the chromatographic method for determining the molecular weight of the stationary phase can naturally also be effected on a purely empirical basis by a preliminary calibration, that is, obtaining the graphical dependences of the retention volume on the molecular weight of the members of the polymer homologous series being studied.

The possibility of using this method was considered in several papers, for example, that of Kogan and Fedotova [20]. In this it was noted that with increase in the molecular weight of the oligomers containing –OH and –SH terminal polar groups and employed as the stationary phase the retention volumes of the non-polar compounds increase somewhat, whereas those of polar compounds (water, alcohols, ketones, ethers, etc.) fall considerably.

The effect of the molecular weight of poly(ethylene glycols) of the general formula $HO[CH_2CH_2O]_nCH_2CH_2OH$ on the retention indices of compounds of various types was also examined by Evans and Smith [21]. The most pronounced dependence of the retention volumes on the molecular weight of the polymeric stationary phases is observed for compounds capable of specific interaction with the terminal polar groups of polymers, for example, with the formation of hydrogen bonds. It was found that the retention volumes of such compounds depend linearly on the concentration of terminal functional groups in the polymeric molecule, that is, on the quantity $1/\overline{M}_n$, [22,23] where $\overline{M}_n$ is the molecular weight of the polymer.

The observed relations can be explained on the basis of the lattice theory of polymer solutions [19], which postulates

that long polymeric chains can be regarded as consisting of a set of segments—sections of the chain which are capable, because of the flexibility of the chain, of exchanging sites with the molecules of the second component of the solution and which occupy one cell of the quasicrystalline lattice of the liquid.

If we have a polymer with terminal polar functional groups the latter can, in accordance with the above ideas, be regarded as molecules of another component of the solution, since in their chemical behaviour (specific interaction with polar dissolved substances) they differ from all the other segments of the polymeric chains.

These predictions are justified, for example, by the fact that the reactivity of the terminal functional groups of macromolecules is often close to that of the same group in small molecules and does not depend on the size of the molecule [24].

In this instance a polymer with terminal functional groups, capable of reacting specifically with certain volatile compounds, can be regarded as a binary solution consisting of functional groups (solute) and of the remaining segments of the polymeric chains (solvent).

On the other hand, it is well known that when the stationary phase is a solution of a dissolved substance B, which reacts specifically with compound A, which is being passed through the column, then the distribution coefficient of compound A (K_A) depends on the concentration of substance B in the following manner [25]:

$$K_A = K_A^0(1 + K_x x_B), \qquad (6)$$

where K_X is the thermodynamic characteristic of the interaction of substances A and B, equal to the equilibrium constant of the reaction of complex formation A + B $\rightleftharpoons$ A.B, x_B the mole fraction of substance B in the stationary phase, and K_A^0 the distribution coefficient when $x_B \to 0$.

In the example being considered the functional groups play the part of the complex-forming agent B, and their mole fraction is $2m/\bar{M}_n$, where m is the molecular weight of the segment.

Hence

$$K_A = K_A^0\left(1 + K_x\frac{2m}{\bar{M}_n}\right) \qquad (7)$$

It is noteworthy that K_A^0 is in general also a function of the molecular weight owing to the contribution of the configuration term to the activity coefficient of the dissolved low-molecular-weight substance:

$$\left(\ln \gamma_{\text{config.}}^{\infty} = \ln\frac{V_i^0}{V_p} + 1 - \frac{V^0}{V_p}\right).$$

In this connection the relative retention volumes of the volatile compounds which react specifically with the functional groups of the polymers compared to the compounds incapable of such reaction (for example, saturated hydrocarbons) with approximately the same molar volume, will take into account to a considerable extent the change in the configuration entropy:

$$V_{\text{rel.}} = \frac{V_g^{(A)}}{V_g^{(\text{hyd})}} = \frac{K_A}{K_{\text{hyd}}} = \frac{K_A^0}{K_{\text{hyd}}}\left(1 + K_x\frac{2m}{\bar{M}_n}\right) \qquad (8)$$

Here K_{hyd} is the distribution coefficient of a hydrocarbon with a molar volume close to that of substance A.

Hence the relative retention volume for the standard volatile compounds which interact specifically with the terminal functional groups of the polymer is itself a more accurate linear function of $1/\bar{M}_n$.

On the basis of such ideas, a linear relation between V_{rel} and $1/\bar{M}_n$ was found earlier [23], but use of this equation did not reflect a specific interaction in the systems being considered. However, an equation of type (8) is valid only for such systems. Actually, as various investigations [18-20] have shown, V_g for saturated hydrocarbons varies with the molecular weight of the stationary phases by a different law.

It is interesting to note that Evans and Smith [21] observed a linear relation between the Kovačs retention indices (I) of polar compounds passing through a column and $1/\bar{M}_n$ for poly(ethylene glycols). The Kovačs index is known to depend linearly on the logarithm of the relative retention volume of the substance. Evidently, the linear dependence of I on $1/\bar{M}_n$ is the result of the fact that the quantity $K_X x_B$ in Eqn.(8) is rather low in comparison with 1 [$x_B < 0.2$; at a comparatively high temperature (100°C) the probability of the formation of hydrogen bonds becomes very slight and consequently K_X is small and probably even less than 1]. Then $\ln(1 + K_X x_B) \simeq K_X x_B$. A detailed experimental study of relations of the type of Eqn.(8) was made [22] in which specimens of poly(diethylene glycol maleate adipate) of various molecular weights were used as stationary phase and the chromatographed mixture contained ethanol, propanol, and benzene (internal standard).

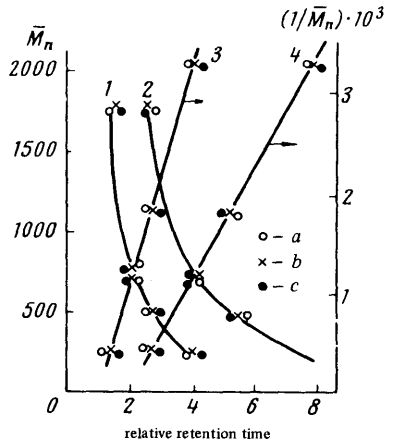

Figure 3. Variation of the relative retention times of ethanol (*1*, *3*) and propanol (*2*, *4*) (standard: benzene) with the molecular weight ($\bar{M}_n$) and the quantity $1/\bar{M}_n$ for poly(ethylene glycol maleate adipate): *a*), *b*), and *c*) series of experiments.

To reduce the adsorption effect of the carrier on the retention of polar alcohols the polyether being tested was carried on sodium chloride (0.25–0.5 mm fraction), proportion 1% of the carrier weight (column 200 × 0.4 cm, temperature of investigation 30°C). Fig. 3 shows the results for three series of experiments on the form of the variation of the relative retention time for ethanol and propanol with the molecular weight $\bar{M}_n$ and with $1/\bar{M}_n$. As Fig. 3 shows, the relative retention time of the volatile compounds which interact specifically with the terminal groups of the polymer depend linearly on the reciprocal

of its molecular weight. Naturally, to increase the sensitivity of the method the standard compounds used must be those having a strong specific interaction with the polar terminal groups of the polymer, that is, be characterised by very high values of K_X.

It was interesting to examine the effect of temperature on the parameters of Eqn.(8). It was to be expected that the first term of this equation should not depend significantly upon temperature, since it is linked with the non-specific interaction of the molecules of the volatile substances with the central fragments of the polymer molecule. For example, the second term of Eqn.(8), which reflects the specific interaction of a polar compound with the terminal groups of the polymer should depend on the temperature. To check these qualitative ideas, published results [10] were used to calculate the relative retention volumes of methanol (internal standard: decane) on poly(ethylene glycols) with molecular masses in the range from 300 to 6000 at 100° and 120°C. Fig.4 shows the variation of the relative retention volume with the reciprocal of the molecular mass. In accordance with Eqn.(8), this relation is linear, with the first terms being almost the same for the two temperatures, but the second term decreasing as the temperature is raised.

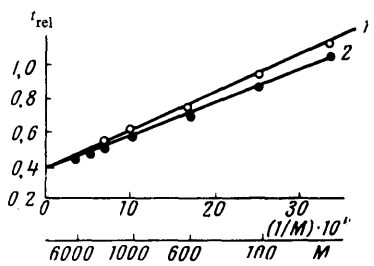

Figure 4. Variation of the relative retention volume of methyl alcohol with the reciprocal of the molecular weight of poly(ethylene glycol). Temperature, °C: *1*) 100; *2*) 120.

The relations found between the retention quantities for polymers with terminal functional groups which differ markedly from the main chain of the macromolecule can be used for polymers with number-average molecular weights up to 30 000–50 000.

The practical use of the chromatographic method is connected with the use of polymers of known molecular weight for a preliminary calibration. Several essentially positive features of the method are noteworthy. The carrying out of the experiment in a stream of carrier gas, the possibility of pre-heating the specimen, and performing the experiment at elevated temperatures considerably reduce the number of possible low-molecular-weight impurities, which usually impede the determination of the number-average molecular weight. Furthermore, the method is sensitive mainly to impurities which are capable of specific interactions with volatile substances of the standard mixture. We note that the possibility of determining the molecular weight of a series of oligomers with polar functional groups—poly(propylene glycols), poly(diethylene glycol adipates,) and thiokols—has been confirmed [20].

Kogan and Fedotova [20] have demonstrated another possible practical use of the variation of the retention of volatile substances with the molecular mass of oligomers. They showed that this relation can be used to select effective solvents for the fractionation of oligomers, since the solubility of the polymers and the retention volumes of the solvents are symbathically interconnected. For fractionation of oligomers a solvent must be chosen, the solubility in which of the members of the polymer homologous series shows the greatest dependence upon molecular weight. The use for this purpose of solvents and precipitants chosen on the basis of RGC results has given good results.

IV. INVESTIGATION OF THE THERMODYNAMICS OF THE INTERACTION OF VOLATILE COMPOUNDS WITH POLYMERIC COMPOUNDS

Even in the very beginning of the development of gas–liquid chromatography, one of its originators (Martin) noted the wide prospects of the use of the method for determining thermodynamic characteristics. He wrote [1]: "The method [of gas chromatography] provided perhaps the easiest of all means of studying the thermodynamics of the interaction of a volatile solute with a non-volatile solvent, and its potential value for providing this type of data should be very great". Thus position is also valid for polymeric compounds used as stationary phases.

An investigation by the gas-chromatographic method of the thermodynamic parameters for the interaction of low-molecular-weight compounds with polymers requires the calculation of a series of specific features for the behaviour of high-molecular-weight substances.

First of all it is necessary to note that the complexity of the molecular structure of polymeric materials leads to a variety of states in which the stationary polymeric phases can be found. Thus the polymers can be in two phase states—crystalline and amorphous, distinguished by differing degrees of ordering: long-range order in the arrangement of the links and chains for crystalline polymers and short-range order characteristic for liquid and amorphous solid polymers.

Solid polymers can also be partly crystalline, when crystalline and amorphous regions coexist in the polymer. In certain respects such a polymer can be regarded as an ordinary mixture of impermeable crystals and quasi-liquid amorphous medium [26].

Depending upon the temperature, amorphous polymers can be found in three physical states: vitreous, highly elastic, and visco-fluid distinguished by different degree of mobility of the structural elements of the macromolecules. The vitreous state is characterised solely by vibrational motion of the atoms which form the chain, in consequence of which the polymeric chain acquires the ability to buckle; the visco-fluid state by the mobility of all the macromolecules as a whole [27].

The mechanism of the retention (sorption) by polymeric molecules of low-molecular-weight compounds is determined by the phase and physical state of the polymers.

When the polymeric stationary phase is at a temperature below the glass temperature (T_g) the molecules of the specimen are not able to penetrate through the entire mass of the polymeric phase, and the retention here is determined by absorption on the polymeric surface, that is, gas-adsorption chromatography is involved. A similar situation is observed for crystalline polymers in the temperature range below the melting point.

Amorphous polymers at temperatures above T_g are capable both of dissolving low-molecular-weight compounds and of adsorbing them at the polymer–gas and polymer–solid carrier interfaces. When the high-molecular-weight phase is a partly crystalline polymer, then in the temperature range $T_g < T < T_f$ there is also the possibility of adsorption of the vapours of substances at the interfaces between the crystalline and amorphous regions.

In gas chromatography experimental methods for the determination of the contributions of each of the retention mechanisms to the total retention volume have been developed, and particularly methods of calculating retention due to dissolution of the substances in the stationary phase [28–30].

A knowledge of the retention volume due to dissolution of a substance permits the most important thermodynamic characteristics of the dissolution process to be calculated, namely, the distribution coefficient $k = V_g\rho$ (where ρ is the density of the stationary liquid phase), the activity coefficient γ_i [at infinite dilution, according to Eqn.(2)], and the changes in the excess partial molar thermodynamic functions of the solute [25]:

$$\Delta\bar{H} = R\frac{\partial \ln \gamma_i}{\partial\left(\frac{1}{T}\right)},\quad \Delta\bar{S} = -R\frac{\partial (T\ln\gamma_i)}{\partial T},\quad \Delta\bar{G} = -RT\ln\gamma_i.$$

Even the first studies of the thermodynamics of dissolution showed completely satisfactory agreement between the distribution coefficients for polymeric stationary phases determined by static and chromatographic methods. As an example, Table 2 gives results obtained by Anderson and Napier [31] for the distribution coefficients of benzene and cyclohexane in the gas–cresyl ester of poly(ethylene glycol) system.

Table 2. Distribution coefficients determined by static and gas-chromatographic methods for cresyl poly-(ethylene glycol) ether [31].

Compound	conditions					
	80°		100°		131°	
	GLC	static method	GLC	static method	GLC	static method
Benzene	71.6	73.0	43.4	44.1	23.4	20.1
Cyclohexane	18.9	19.9	13.5	15.0	9.3	7.8

The thermodynamic functions for the dissolution of volatile organic compounds were determined for several polymeric phases: Reopleks 400, poly(ethylene glycol) 600, Ftorsilikon FS-16, Silikon DS-550, [32] polyglycols [33,34], silicones [35], and solutions of magnesium chloride in poly-(ethylene glycol)-400. [36]

Problems in the use of gas chromatography for studying the thermodynamics of the interaction of a volatile substance with a polymeric phase were examined specially by Smidsrød and Guillet [37], who used Eqn.(2) to calculate from chromatographic results the coefficients γ_i^∞ for acetic acid, butanol, *o*-chloronaphthalene, naphthalene, and hexadecane in poly(*N*-isopropylacrylamide).

The excess thermodynamic functions for mixing at temperatures above the flow points of the polymer (Table 3) were calculated from the temperature dependences of γ_i^∞.

In calculating the activity coefficient from the chromatographic results by Eqn.(2), Smidsrød and Guillet [37] use the number-average molecular weight of the polymer; however, they note that for polymers some parameter determined by the size of the segment of the polymeric chain should be introduced instead of M_n. This indeterminacy disappears for the relative activity coefficients, which can also give valuable information in investigations of interactions of low-molecular-weight compounds with polymers [38].

Table 3. Excess thermodynamic functions for the mixing of volatile compounds of various types in poly(*N*-isopropylacrylamide), [38] temperature 200°C.

Compound	$\Delta\bar{G}$, cal mole^{-1}	$\Delta\bar{H}$, cal mole^{-1}	$\Delta\bar{S}$, cal deg^{-1} mole^{-1}
Acetic acid	−6740	−2400	+ 9.2
Butanol	−5390	+1100	+13.7
Naphthalene	−4360	+3900	+17.5
1-Chloronaphthalene	−4010	+3606	+11.3
n-Hexadecane	−1760	+2200	+ 8.4

The determination of the activity coefficients of low-molecular-weight compounds in polymers, especially under conditions of infinite dilution, is of considerable interest, especially for the theory of polymer solutions.

Thus the Flory–Huggins theory of regular solutions of polymers [19], which is based on a lattice model of liquids, allows the free energy of mixing in the dissolution of a long-chain polymeric molecule in a low-molecular-weight solvent to be calculated; for the case where the volume fraction of the polymer tends to 1 it yields Eqn.(3) for the activity coefficient of the substance dissolved in the polymer.

The first three terms on the right-hand side of Eqn.(3) are determined by the contribution from the changes in configurational or combinatorial entropy of mixing, due to the structure of the macromolecule (a flexible long chain, the segments of which are mobile and can exchange lattice sites with molecules of low-molecular-weight substances). Such a structure leads to large positive changes in entropy on the formation of polymer solutions and explains the characteristic negative departure from Raoult's law for the vapour pressure of the low-molecular-weight component of the solution.

The interaction parameter χ entering into Eqn.(3) reflects, in accordance with the theory of regular solutions, the contribution to the change in total free energy of dissolution of the change in free energy due to contact between the molecules of the components of the system. In the earlier stage of development of the theory of polymer solutions the interaction parameter χ was given the value of the van Laar enthalpy of mixing [19]:

$$\chi = \frac{V_i^0(\delta_i - \delta_p)^2}{RT}, \qquad (9)$$

where δ_p and δ_i are parameters of the solubility of the polymer and low-molecular-weight components of the solution respectively, in which δ_i is connected with the cohesion energy density $\Delta E_i^v/V_i^0$ by the relation

$$\delta_i = \left(\frac{\Delta E_i^v}{V_i^0}\right)^{1/2},$$

where ΔE_i^v is the heat of vaporisation of the pure ith component, and V_i^0 the molar volume of the ith component. However, the parameter χ is now regarded as a reduced

residual chemical potential consisting of enthalpy and entropy terms[39]:

$$\chi = \chi_H + \chi_S, \tag{10}$$

$$\chi_H = -T\left(\frac{\partial \chi}{\partial T}\right), \quad \chi_S = \frac{\partial(\chi T)}{\partial T}. \tag{11}$$

From the theory of regular solutions, the parameter χ is independent of the concentration of the solution. However, for many systems χ is a function of the composition of the solution and usually increases with the polymer concentration. Thus for the polyisobutylene–benzene system at 25°C the parameter χ rises from 0.50 in the range of infinitely dilute solutions to 1.1 for $v_p \to 1$ (v_p is the volume fraction of the polymer)[39]. χ is exceptionally important in investigating solutions of polymers: it determines the solubility of the polymer, the critical compositions and temperature of the solutions as a function of the length of the molecule. Gas chromatographic measurements and application of Eqn.(2) enable the activity coefficient γ_i^∞ of the solute to be determined, and consequently the parameter χ for $v_p \to 1$:

$$\chi_{v_p \to 1} = \ln \gamma_i^\infty - \left(\ln \frac{V_i^0}{V_p} + 1 - \frac{V_i^0}{V_p}\right). \tag{12}$$

Values of χ_H and χ_S can be estimated from the temperature dependence of χ and Eqn.(11). Gas chromatography also allows the value of χ at finite concentrations of a low-molecular-weight solute to be calculated[40]. If the solution can be regarded as regular, it is easy to use Eqn.(9) and the values of χ to find the density of the energy of cohesion, an important characteristic of polymers. The change in χ with concentration and also the high value of the entropy constituent χ_S cannot be explained by the simple theory of regular solutions. There are now several other theories of solutions of polymers: Prigogine's theory of corresponding states[41] which takes account of the change in volume during dissolution; a theory using ideas of the theory of corresponding states and employing the equations of state of the pure components in the calculation of the characteristics (Flory theory)[39,42]; and various others.

Gas chromatography exhibits wide possibilities for the experimental verification of these theories.

A recent paper by Patterson and coworkers[43] examined the possibility of evaluating the interaction parameter χ as the most important thermodynamic characteristic of solutions of polymers directly from the retention volumes and not from γ_i^∞ to determine which it is necessary to know the number-average molecular weight of the polymeric liquid phase ($\overline{M}_n$). In this paper it was shown that:

$$\ln\left(\gamma_i^\infty \frac{\overline{M}_n}{M_i}\right) = \ln\left(\frac{a_i}{w_i}\right)^\infty = \ln\frac{v_i}{v_p} + \left(1 - \frac{V_i}{\overline{M}_p v_p}\right) + \chi =$$

$$= \ln\left[\frac{RT}{p_i^0 v_g^{(i)} M_i}\right] - \frac{p_i^0}{RT}(B_{ii} - V_i), \tag{13}$$

where v_i and v_p are the specific volumes of solute and polymer respectively; a_i and w_i the activity and weight fraction of solute; M_i is the molecular weight of the solute, p_i^0 the vapour pressure of the pure solute at temperature T; $p_i^0/RT(B_{ii} - V_i)$ a term allowing for the non-ideality of the gas phase, and B_{ii} the second virial coefficient of the pure ith solute. Consequently,

$$\chi = \ln\left[\frac{RTv_p}{p_i^0 V_g^{(i)} V_i}\right] - \left(1 - \frac{V_i}{\overline{M}_n v_p}\right) - \frac{p_i^0(B_{ii} - V_i)}{RT}. \tag{14}$$

At sufficiently large $\overline{M}_n$ the term $V_i/\overline{M}_n V_p$ can be neglected and then χ can be calculated without knowledge of the molecular weight of the polymer or its dispersion.

It was shown[45] that the change in the excess partial molar enthalpy of dissolution ($\Delta\overline{H}_i^\infty$) can be recalculated from the temperature dependence of χ after allowing for the temperature dependence of the molar volumes of the solute and polymer:

$$\Delta\overline{H}_i^\infty = RT^2(\alpha_p - \alpha_i) + R\left[\frac{\partial \chi}{\partial\left(\frac{1}{T}\right)}\right], \tag{15}$$

where α_i and α_p are the coefficients of thermal expansion of the components of the solution in the liquid state. The first term in $\Delta\overline{H}_i^\infty$, determined by the difference in the thermal expansion of the low-molecular-weight solute and the polymer, is ~100 cal at 300°K.

Use of the Flory theory of solutions of polymers[42] leads to values of χ which differ greatly from the corresponding values calculated from the Flory–Huggins equation within the framework of the theory of regular solutions. It was found that the combinatorial part of the free energy of mixing is independent of the temperature and consequently

$$\Delta\overline{H}_i^\infty = R\left[\frac{\partial \chi^*}{\partial\left(\frac{1}{T}\right)}\right], \tag{16}$$

where χ^* is the interaction parameter calculated on the basis of the Flory theory.

Gas chromatography can be used extensively in the investigation of cross-linked polymers. From the statistical theory of the swelling of cross-linked polymers[19], at $v_p \to 1$,

$$\ln \gamma_i^\infty = \ln\frac{V_i^0}{V_p} + 1 - \frac{V_i^0}{V_p} + \chi + \frac{\rho_p V_i^0}{2M_c} \tag{17}$$

where V_p is the molar volume of the polymer before cross-linking, ρ_p the density of the polymer, M_c the molecular weight of the segment of the chain between the nodes of the lattice.

The parameter M_c, which is a characteristic of the density of the lattice and determines its strength, can thus be calculated from results of the chromatographic determination of γ_i^∞.

An investigation of the thermodynamics of the interaction of cross-linked polymers with low-molecular-weight compounds is of great interest in connection with the extensive use in chromatographic analysis of polymeric sorbents such as, for example, Porapak[44–46].

However, the use of gas chromatography for investigating solutions of polymers requires the investigation of a series of specific problems.

Primarily this is a problem of finding the gas–polymeric phase equilibrium under dynamic chromatographic conditions. The very high viscosity of the polymers, from 10^3 to 10^{13} P, should, at first glance, lead to the very slow diffusion of small molecules in the polymeric film, much slower than through a film of ordinary liquid.

However, only relatively non-coordinated movements of small segments of the polymeric chain are necessary for the diffusion of small molecules in a polymeric mass. In this connection the diffusion coefficients of low-molecular-weight substances are determined by the mobility of the segments and the packing density of the chains; here the molecular weight of the polymer is almost without effect on the rate of diffusion and the permeability through a film of polymer[26]. As a result, despite the enormous viscosity of the polymers the diffusion coefficients of small molecules in them are only one or two orders of

magnitude less than in ordinary liquids. Thus the diffusion coefficient of benzene in natural rubber is $D_{50^\circ} = 3 \times 10^{-7}$ cm^2 s^{-1},[26] and for CO_2 in poly(methylsiloxane) rubber $D_{20^\circ} = 3.8 \times 10^{-5}$ cm^2 s^{-1}.[27]

The high efficiency of the widely used chromatographic columns with polymeric liquid phases, for example, with silicone rubbers or poly(ethylene glycols) also shows that gas–polymer equilibrium is established rather rapidly under gas chromatographic conditions. However, in each instance of the study of the thermodynamics of polymer solutions by gas chromatography it is evidently necessary to prove that the measured retention volumes correspond to gas–polymer equilibrium. For example, it can be shown that the distribution coefficients K are independent of the carrier gas velocity.

An investigation of the rate of mass transfer in polymeric films is also of independent interest, since the permeability of the polymeric films for small molecules provides the basis of the technique of membrane separation of mixtures of substances[47].

Gas chromatography can be used to investigate the rate of mass transfer in liquid or amorphous films, from the variation of the height of the equivalent theoretical plate (HETP) with the velocity of the carrier gas[48].

The HETP equation allows the quantity d_L^2/D_L to be determined (where d_L is the thickness of the film of stationary liquid phase, and D_L the diffusion coefficient of the substance in the film); it is proportional to the so-called permeability lag time[26]. When d_L can be evaluated independently, the diffusion coefficient of the substance D_L can readily be determined from the lag time. The permeability P can be estimated from measurements of the distribution coefficients (K), which can be found from the retention volumes, and from the diffusion coefficients[26]:

$$P \equiv D_L \frac{K}{RT} . \qquad (18)$$

Incidentally, the parameter P can also be obtained directly from the component HETP, characterised by the erosion of the peak as a result of the resistance to mass exchange in the liquid phase (C_L):[48]

$$C_L \simeq \frac{K\frac{q_s}{q_m}}{\left(1+K\frac{q_s}{q_m}\right)^2}\frac{d_L^2}{D_L} \approx \frac{d_L^2}{K\frac{q_s}{q_m}D_L} \qquad (19)$$

for

$$K\frac{q_s}{q_m} \gg 1,$$

where q_S and q_m are the sections of the stationary and gas phases in the column respectively.

The use of gas chromatography in investigating diffusion in polymers and their permeability has a number of definite advantages over the usual methods of determining these quantities. These advantages are mainly connected with the rapidity and ease of the experiment, the availability of standard apparatus, and evidently, the adequate accuracy.

Another important feature is the above-mentioned variety of mechanisms of retention by polymeric phases, which act simultaneously in a chromatographic column.

As is known, important information about the retention mechanisms and the possibility of estimating the contribution of each mechanism to the total retention are given by the variation of the specific retention volumes with the amount of stationary phase in the column[28,29].

In the determination of retention volumes on polymeric phases an appreciable dependence of the retention volume on the size of the specimen even for very small specimens is often observed. Thus, Lavoie and Guillet[49] observed a dependence of V_g on the size of the specimen in the range 0.1–1 μl and evidently only for specimens of ~0.01 μl does Henry's law cease to be obeyed, from which the independence of V_g and the size of the specimen also follows.

The non-linearity of the distribution isotherms even in the range of very small concentrations (low volume fraction of the low-molecular-weight component, but nevertheless the mole fraction can be very large) can in many instances be explained by the sorbed molecules (especially the vapours of poor solvents) having a tendency to form aggregates inside the polymers[26]. It is therefore to be expected that the worse the dissolving ability of the sorbate, the narrower the range of concentrations where the distribution isotherm is close to linear. This conclusion is confirmed, for example, by results[37] where the greatest dependence of the retention volume on the size of the specimen was observed for the peaks of hexadecane, which is a very bad solvent for the polymeric phase, poly(*N*-isopropylacrylamide).

The values of V_g used to calculate the thermodynamic characteristics of the distribution, have been obtained by extrapolating to zero size the experimental relations between V_g and the size of the specimen.

Methods have now been developed for the chromatographic investigation of the thermodynamic parameters for the distribution at the terminal concentrations of sorbed substances and in particular methods of determining distribution isotherms[40] and the specific surfaces of the stationary phase[25], which can undoubtedly be also used for polymeric phases.

These methods are undoubtedly widely used in studying the permeability, swelling, and plasticising of polymers.

V. STUDY OF PHASE TRANSFORMATIONS

A phase transformation converts the initial stationary phase into a new non-stationary phase (new sorbent), which is in general characterised by physicochemical properties different from those of the initial phase. This should be reflected by a change in the chromatographic characteristics of volatile standard substances in the range of the phase transformation of the stationary phase. Therefore the RGC method can be used for studying phase transformations in polymers. In studying phase transformations it is desirable to use as chromatographic characteristics not only the retention volume or time, but also the width of the peak of a volatile standard compound[7].

The marked dependence of the retention parameters on temperature in the range of fusion of the stationary liquid phase was noted long ago[50–55]. However, usually the investigators were interested not in studying the phase transformation phenomenon but in its effect or use in analytical chromatography. Thus the pronounced decrease in the retention of the compounds being analysed on eicosane when the column is cooled to a temperature below its melting point has been used[50] as a method of rapid elution from the column of heavy hydrocarbons after the analysis of the lighter components.

Evidently the first studies in which the chromatographic properties of stationary phases were specially investigated in the range of their phase transformations were those of liquid crystals (as stationary liquid phases)[6,56,57]. The stationary liquid phases found in a liquid-crystalline state are very selective for the separation of the isomers of organic compounds (for example, *o*-, *m*-, and *p*-cresols).

At the temperatures of the phase transformations from the crystalline state to the mesomorphic liquid-crystal, and also in going from the mesomorphic to the isotropic liquid state sharp anomalous changes in the specific retention volume are observed.

As shown by Alishoev and coworkers [7] the RGC method can also be used successfully in studying the phase transformations on going from one crystalline modification to another by the example of carbon tetrachloride. Subsequently this method was used successfully by Guran and Rodgers for investigating phase transformations in crystals of thallium nitrate [58], Cu_2HgI_4, and Ag_2HgI_4. [59] In all the above instances the results of the gas-chromatographic experiment agree well with those on phase transformations obtained by other methods.

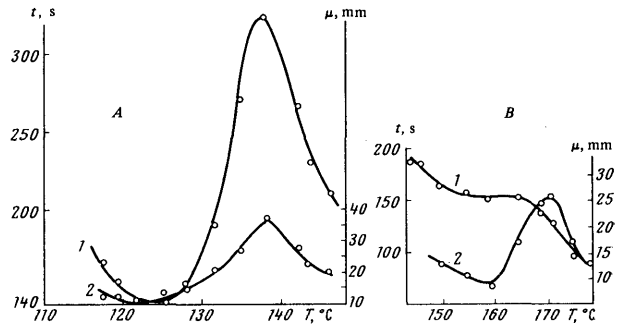

Figure 5. Variation of the retention time (*1*) and peak width (*2*) with the column temperature: *A*) the n-tetradecane–polyethylene system; *B*) the cetene–polypropene system.

According to Berezkin and coworkers [60], the RGC method was first used specially for studying phase transformations in polymers by Alishoev and coworkers [7], who investigated stereoregular polymers with a high degree of crystallinity: polyethylene and polypropylene. A mechanical mixture of powders of the test polymer (1%) with glass spheres was put in a column (100 × 0.4 cm) which was connected to a chromatograph and heated at a rate of 0.2–0.5 deg min^{-1}. Periodically a specimen of standard substance was introduced into the column and its chromatogram recorded. The results of the experiments were presented as graphs of the retention time and peak width of the standard substance (for polyethylene–tetradecane and polypropylene–cetene) against column temperature (Fig. 5). [7] In the instances investigated the retention time and peak width curves show a maximum (a plateau on the cetene retention time curve for polypropylene) in the temperature range of the phase transformation. The appearance of maxima is due to a change in the distribution constant and diffusion coefficients of the standard volatile substance as a result of the phase transformation. In the deposition of polypropylene on glass spheres from its solution in decalin at 110°C or from a melt in an inert atmosphere the plateau on the curve in this coordinate system associated with the phase transformation almost disappears. Similar behaviour is noted in studying phase transformations of thallium(I) nitrate crystals [58].

Guillet and coworkers [37,49,61–63] have made a large contribution to the development of the RGC method in studying phase transformations in high-molecular-weight compounds and their quantitative interpretation.

In these studies the variation of $\lg V_g$ with the reciprocal of the temperature was examined for polymeric stationary phases. Fig. 6 shows the most general type of this relation for the semicrystalline polymer [64]. Such behaviour is characteristic, for example, of polypropylene and crystalline polystyrene when hydrocarbons (n-alkanes) are used as solutes.

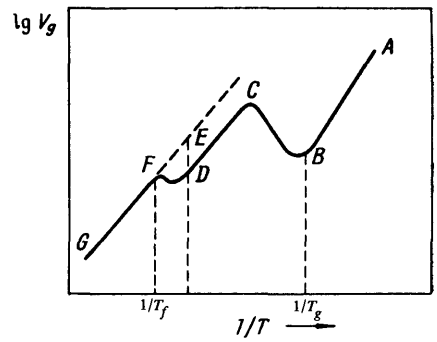

Figure 6. Variation of the retention volume with the reciprocal of the absolute temperature of the column for semicrystalline polymers.

In the range corresponding to the part *AB* of the curve the polymer is at temperatures below the glass point. The retention is here determined by adsorption on the surface of the vitreous polymer, since the molecules of the specimen cannot penetrate into the body of the polymeric film.

The linear dependence of $\lg V_g$ on $1/T$ is observed up to the glass point (T_g) (point *B*). An increase in the retention volume at the phase transformation point, also observed for phase transformations of the first type [55], is, as already noted, due to a fundamental change in the structure of the stationary phase. A further rise in temperature leads to passage of the curve through a minimum and to an increase in $\lg V_g$ along the part *BC*. Guillet [62] explains this increase as follows. The region *BC* corresponds to non-equilibrium adsorption of the vapour on the polymeric phase. The molecules start to penetrate into the body of the phase but the diffusion rate is so small that only at point *C* does the adsorption of vapour reach the entire thickness of the film in the contact time. This prediction could readily be checked from results on the variation of V_g with gas velocity. However, the studies of the behaviour of stationary phases close to the transformation point do not include such results.

The possibility of chain flexibility (progressive movement of the segments) in the amorphous ranges of polymers is known to increase with the temperature. In addition, an increase in the temperature leads to breakdown of ordered supermolecular structures (blocks) and the molecules acquire the conformation of disordered convoluted and tangled balls [64]. In other words, raising the temperature leads to a decrease in the mean cohesion energy of the molecules of amorphous polymers, which should, in turn,

lead to a decrease in the activity coefficient of the solutes—compare, for example, Eqns.(9) and (3). It seems that these changes in the cohesion energy are most pronounced in the region BC of the curve (Fig. 6).

Thus the increase in V_g with temperature is explained by the fact that in the range BC as the temperature is raised the activity coefficients γ^{∞} of the solutes decrease more sharply than the vapour pressure of the vapour of the pure solutes p_1^0 or f_1^0 of Eqn.(2) increases.

The definition and depth of the minimum on the curve (Fig. 6) depend on the nature and dimensions of the molecules of the volatile solutes. Thus it has been shown [38] that for butanol and acetic acid the graph of $\lg V_g$ against $1/T$ for the stationary phase poly(*N*-isopropylacrylamide) is a straight line over the entire temperature range. Possibly the formation of strong hydrogen bonds by the molecules of the alcohol and acid with the amide group of the polymer makes the mechanism of their dissolution in the polymer differ from that for hydrocarbons.

Nevertheless it should be noted that the nature of the inflection on the graph of $\lg V_g$ against $1/T$ close to the glass temperature and the dependence of its form on the nature and size of the sorbate molecules are still far from explained.

At point C, an amorphous polymer or an amorphous part of a semicrystalline polymer evidently reaches a state which is identical with that of ordinary liquids. Thus, for poly(*N*-isopropylacrylamide) point C is close to its flow point. Thus along the segment CD in addition to possible adsorption at the surface and at the boundaries of the amorphous and crystalline regions, dissolution of the vapours of the volatile compounds takes place over the entire volume of the amorphous part of the polymer. In this region the thermodynamic functions of the dissolution can be determined.

Close to point F the crystalline part of the polymer melts. In this region a characteristic maximum is usually observed on the curve (Fig. 6). [55,63] The range FG corresponds to the state when the entire mass of the polymer participates in the dissolution of the molecules of the specimen. Since it is thought that on the segment CD the crystalline regions of the polymer do not participate in the retention of the solute molecules, it is possible to estimate the degree of crystallinity of the specimen in the temperature range CD. Actually, extrapolation of the line FG in the range of temperatures below T_f allow the retention volume which would correspond to a hypothetical amorphous state of the entire polymer at $T < T_f$ to be estimated. Then the degree of crystallinity can be calculated from the formula:

$$\text{degree of crystallinity} = \frac{(V_g)_E - (V_g)_D}{(V_g)_E} \cdot 100 \qquad (20)$$

(see Fig. 6).

In this the possibility of adsorption of the volatile standards at the boundary between the crystalline and amorphous parts or at the gas–polymer and polymer–solid carrier surfaces is not taken into account.

Guillet has termed the method of investigating the structure and physical state of polymers from the temperature dependence of the retention volumes the method of "molecular specimens" [62].

This method has been used for determining the degree of crystallinity of high-density polyethylene at various temperatures [63]. Fig. 7 shows the variation of its degree of crystallinity with temperature obtained gas-chromatographically and by differential thermal analysis. As Fig. 7 shows, the agreement between the two methods is completely satisfactory.

As the form of the curve in Fig. 6 shows, the variation of $\lg V_g$ with $1/T$ can be used to determine the glass point of the polymers.

Table 4 [49] shows values of T_g obtained by differential thermal analysis and by reversed chromatography. The agreement between the two methods is completely satisfactory and evidently in determining T_g of the polymer by gas-chromatography it is desirable to use as characteristic quantity the temperature (T_1) of the first departure from linearity on the curve of the logarithm of the retention volume against the reciprocal of the temperature.

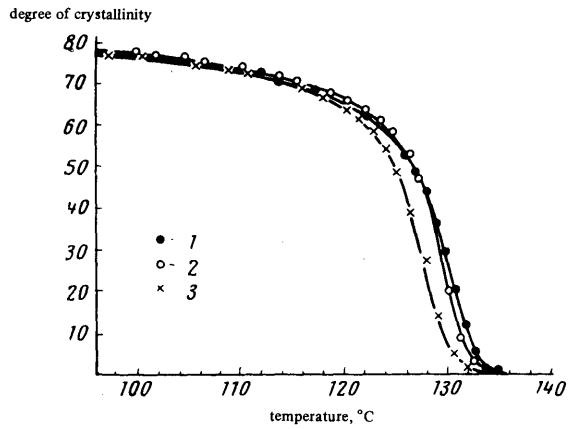

Figure 7. Variation of the degree of crystallinity of high-density polyethylene with the temperature: *1*) Calorimetric results; *2*) and *3*) results obtained by the method of molecular specimens; *2*) on cooling at a rate of 1.0 deg min^{-1} and heating at 0.5 deg min^{-1}; *3*) on cooling according to the ballistic rule and heating at 0.5 deg min^{-1}.

Table 4. Determination of the glass temperature by the reverse gas chromatographic method [49].

Characteristic	Poly (vinyl chloride)		Polystyrene	Poly(methyl methacrylate)
	A	B		
Molecular weight	68 000	35 500	31 000	48 000
Standard volatile component	dodecane	dodecane	dodecane	hexadecane
Glass temperature, °C (DTA)	75±2	75±2	95±2	100±2
Temperature for the first departure from linearity, T_1, °C	81	81	88	97
Temperature of first minimum, T_2, °C	91	91	100	105

The RGC method has also been used successfully for studying the kinetics of the crystallisation of organic substances from the melt. The use of this method for polymeric compounds has been described by Guillet and

coworkers[63], and for monomeric compounds by Andreev and coworkers[65].

The features of the reversed chromatography method in the study of phase transformations are the relative simplicity of the apparatus and experimental procedure, the possibility of rapid measurement of the chromatographic characteristics for volatile standard substances of various types and the use of small amounts of the polymers being tested. Another advantage of the RGC method in comparison with widely used methods based on measuring the heat of phase transformation is the possibility of studying slow phase transformations.

VI. INVESTIGATION OF THE KINETICS OF THE REACTIONS OF POLYMERS

In studying the kinetics of chemical reactions by the RGC method the reaction is effected in a chromatographic column where the reaction mixture is used as stationary phase for a standard mixture of volatile non-reacting compounds. The change in the composition of the reaction mixture with time is determined by periodic measurement of the elution characteristics of the volatile standards. The determination of the composition of the reacting system with time is based on the use of a relation of the type

$$c_i = f(V_j), \qquad (21)$$

where c_i is the concentration of one of the components in the reaction mixture, V_j the retention volume of one of the standards. The concept of "component" also embraces the functional groups of the polymer being tested.

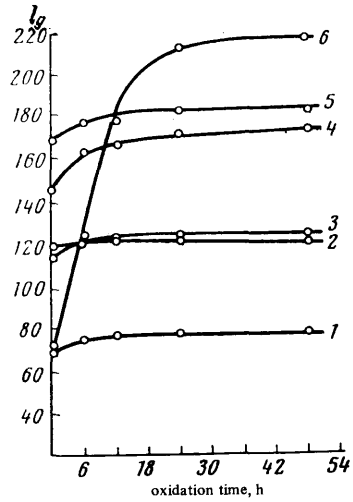

Figure 8. Change in the interaction coefficients during the oxidation of asphaltene: *1*) butanol; *2*) propionic acid; *3*) pyrrole; *4*) phenol; *5*) formamide; *6*) 1-methylpyrrolidone.

This method requires small amounts of the test substances and is characterised by the following advantages: a thin film of the phase allows the kinetic regime to be realised readily, an investigation of the kinetics of the reaction can be made without removal of specimens, and it is possible to investigate the kinetics of reaction systems which cannot be analysed chromatographically. The method was proposed by Berezkin and coworkers[60] and used for studying the kinetics of oxidation of benzaldehyde into benzoic acid[66]. It was shown that the oxidation of benzaldehyde by atmospheric oxygen (air is a carrier gas) proceeds formally by a first-order reaction, and the rate constant obtained in a chromatographic experiment differs from that obtained in a bubbling reactor by no more than 3%.

This method was subsequently used by Davis and Petersen for studying the oxidation of asphaltene[67]. Fig. 8 shows the change in the specific interaction coefficient — see Eqn. (1) —for various volatile standards as a function of the time of oxidation of the asphaltene with air at 130°C.

Undoubtedly, the RGC method is extremely convenient for studying the kinetics of the reactions of polymeric compounds.

In conclusion, we wish to emphasise that although the development of the RGC method is far from ended the experience that has already been accumulated is sufficient for the wide use of this method in polymer chemistry for solving the most diverse problems.

Reactions of RȮ, RṠ, and RȮ$_2$ Radicals with Phosphites and Phosphines

D.G.Pobedimskii, N.A.Mukmeneva, and P.A.Kirpichnikov

The review deals with studies designed to elucidate the detailed mechanism and quantitative relations in the kinetics of the reactions of RȮ, RṠ, and RȮ$_2$ radicals with phosphites and phosphines. It is shown how the isotope tracer method has been used to prove the irreversible formation of the phosphoranyl radical—the primary intermediate in these radical reactions. The results of the study of the competition between the addition of RȮ and RṠ radicals to phosphites and phosphines on the one hand and their other reaction pathways (abstraction of a hydrogen atom from hydrocarbons, addition to a double bond, and monomolecular decomposition) on the other have been analysed. The last section discusses the mechanism of the inhibiting effect of aromatic phosphites in the thermo-oxidative degradation of polyolefins within the framework of the hypothesis that they terminate kinetic oxidation chains by radical exchange.
The bibliography includes 49 references.

I. INTRODUCTION

Organophosphorus compounds are involved in many free radical reactions[1-6]. The autoxidation of compounds such as phosphites and phosphines has a radical chain mechanism and constitutes a large and important class of organic reactions. The aim of the present review is to examine and analyse the kinetics and mechanisms of the elementary steps of the interaction of RȮ, RṠ, and RȮ$_2$ radicals with phosphites and phosphines, i.e. to examine all the reactions constituting the basis for the autoxidation processes of these compounds. There is in addition a practical aspect of the studies of these elementary radical reactions associated with the participation of phosphites in polymer stabilisation processes.

II. REACTIONS OF RȮ AND RṠ RADICALS

The reactions of RȮ radicals play an important role in the transfer of kinetic chains in the autoxidation of phosphites and phosphines. Before discussing the kinetics, we shall first examine the mechanism of the transfer reaction.

Trialkyl phosphites $(R'O)_3P$ readily interact with t-BuȮ radicals, forming the corresponding derivatives containing the phosphoryl group $\rangle P=O$:

$$(R'O)_3P + t\text{-}BuO^{\cdot} \rightarrow (R'O)_3P{=}O + t\text{-}Bu^{\cdot}.$$

These reactions take place with a high enthalpy change (the P=O bond energies are in the range 120 — 150 kcal mole^{-1} [5]). For example, the heats of reaction t-BuȮ

radicals with ethyl and butyl phosphites, which we estimated as the differences between the heats of formation of the final products and the initial reactants, are respectively 74 and 46.5 kcal mole^{-1}; the known values of ΔH_f^0 were employed[7-10].

Walling and Rabinowitz[11] studied by gas – liquid chromatography (GLC) and mass spectrometry the products of the interaction of triethyl phosphite with various oxy-radicals: in all cases triethyl phosphate and hydrocarbons were detected. The results of the quantitative analysis of the products are presented in Table 1.

Table 1. Products of the reactions of RȮ radicals with triethyl phosphite (in the absence of oxygen)[11].

Source of RȮ radicals	Type of RȮ radicals	Conditions of radical generation	No. of moles of phosphite per mole of peroxide	No. of moles of phosphate per mole of peroxide	No. of moles of hydrocarbon per mole of peroxide
Dicumenyl peroxide	$PhC(CH_3)_2\dot{O}$	Ultraviolet irradiation, 25°, 125°	5.4	2.16	0.46 (dicumene)
Ditto	ditto	ditto	5.4	1.87	0.71 (dicumene)
Di-t-butyl peroxide	$(CH_3)_3C\dot{O}$	Ultraviolet irradiation, 25°	3.6	2.08	0.31 (isobutane); 0.20 (isobutene); 0.035 (2,2,4-trimethylpentane); 0.080 (tetramethylbutane); 0.020 (2,2,4-trimethylpentane)
ditto	ditto	120°	3.4	2.2	Isobutane, isobutene tetramethylbutane (not determined quantitatively)

Table 1 shows that, firstly, the yield of phosphate is on average 2.0 moles per mole of peroxide and, secondly, the yield is independent of the source and type of RȮ radicals, the conditions of their generation, and also of phosphite concentration when the rates of thermal initiation by di-t-butyl and dicumenyl peroxides are almost equal (1.7×10^{15} and 2.2×10^{15} cm^{-3} s^{-1})†. This implies that phosphite molecules fully accept all the peroxy-radicals formed from the peroxide.

The following mechanism for the interaction of triethyl phosphite with RȮ radicals has been proposed on the basis of the composition of the reaction mixture[11]:

$$ROOR \rightarrow 2R\dot{O}, \quad (1)$$

$$R\dot{O} + R(OEt)_3 \rightarrow RO\dot{P}(OEt)_3, \quad (2)$$

$$RO\dot{P}(OEt)_3 \rightarrow \dot{R} + O{=}P(OEt)_3, \quad (3)$$

$$\dot{R} + \dot{R} \rightarrow \text{disproportionation products}, \quad (4)$$

$$\dot{R} + \dot{R} \rightarrow \text{recombination products}. \quad (5)$$

One may suppose that a similar mechanism will probably hold also for the reactions of tributyl phosphite with t-BuȮ radicals, where tributyl phosphate was detected as the main product by the ^{31}P NMR method[14].

Bentrude's data[15] derived from an analysis of the reaction product of another (aromatic) phosphite (triphenyl phosphite) conflict with this mechanism to some extent. Thus, in the stages involving the transfer of an oxygen atom [stages (2) and (3)], one should expect the formation of triphenyl phosphate; moreover, such a pathway is thermodynamically favourable (according to our estimate, the formation of the phosphate is exothermic to the extent of about 41 kcal mole^{-1}). However, in the experiment (130°C, di-t-butyl peroxide, chlorobenzene, no oxygen) only diphenyl phosphite, isobutene (1.0 and 0.5 mole per mole of triphenyl phosphite respectively), and phenol were detected[15]. This is because in the presence of triphenyl phosphite the elementary steps involving the substitution (exchange) of radicals mainly occur:

$$t\text{-}Bu\dot{O} + (PhO)_3P \rightarrow t\text{-}BuOP(OPh)_2 + Ph\dot{O}.$$

Furthermore, by hypothesis, the mixed phosphite, which is unstable under the experimental conditions, decomposes fully with formation of an olefin and diphenyl phosphite. This mechanism is confirmed also by the observation of the ESR spectrum of the phenoxy-radical under the conditions of the photolysis of di-t-butyl peroxide in the presence of triphenyl phosphite (–85°C, cyclopropane)[16].

The substitution of t-BuȮ radicals, accompanied by the dissociation of the P – C bond in the phosphoranyl radicals and less probable from the thermodynamic point of view, was also observed when these radicals were allowed to act on tri-n-butylphosphine (130°C, no oxygen)[17]. Quantitative study of the reaction products of the phosphine yielded an estimate of the probability of this reaction: the yield of t-butyl di-n-butylphosphinite, which can only be obtained in the substitution step

$$t\text{-}Bu\dot{O} + n\text{-}Bu_3P \rightarrow t\text{-}BuOP(n\text{-}Bu)_2 + n\text{-}B\dot{u},$$

amounts to about 80%; the fraction of phosphine oxide, formed in the step involving the transfer of an oxygen atom, is significantly lower (20%).

Thus there is a definite kinetic control of the relative amounts of the products of addition to phosphines and aromatic phosphites. At the present time it is difficult to interpret this phenomenon unambiguously; its possible causes may be different distributions of unpaired electron density in the P – O and P – C bonds of phosphoranyl radical and also the differences between the energies of the bonds undergoing dissociation.

In an interesting recent study[16], where the intermediate radical products of the oxidation by t-BuȮ radicals of a large class of trialkyl phosphines and trialkyl phosphites were investigated by ESR, showed that in all cases alkyl radicals are present. The authors demonstrated by special experiments that, in the absence of organophosphorus compounds, in the photolysis of di-t-butyl peroxide (between –70° and –90°C, cyclopropane), only t-BuȮ radicals are formed, while in the presence of such substances alkyl radicals are detected immediately; the ratio of the line intensities in the hyperfine structure and the proton hyperfine coupling constants (HCC) are consistent with this interpretation of the ESR spectra. Thus, in the reactions of triethyl-, tri-isopropyl-, tri-isobutyl-, and tricyclohexyl-phosphines, the observed ESR spectra were assigned respectively to $CH_3\dot{C}H_2$, $(CH_3)_2\dot{C}H$, $(CH_3)_2CH\dot{C}H_2$ and $\dot{C}_6H_{11}$ radicals, probably formed by a substitution mechanism‡:

$$R'_3P + \dot{O}C(CH_3)_3 \rightarrow R'_2P{-}OC(CH_3)_3 + \dot{R}'. \quad (6)$$

† According to the literature[12,13], the rate constants for the decomposition of the peroxides are $k = 10^{15.1} \exp(-36\,000/RT)$ for di-t-butyl peroxide and $k = 10^{14.6} \exp(-34\,500/RT)$ (s^{-1}) for dicumenyl peroxide.

‡ Adams and Ingersoll[18] succeeded in detecting by the ESR method the alkyl radicals $CH_3\dot{C}H_2$, $CH_3(CH_2)_2\dot{C}H_2$, and $CH_3(CH_2)_6\dot{C}H_2$ formed under simpler conditions: in the photolysis of iso-octane solutions of the same peroxide in a flow system (20°C, trialkylphosphines).

The behaviour of trialkyl phosphites (trimethyl, triethyl, and tri-isopropyl phosphites) in relation to t-BuO· radicals is fundamentally different from that of the trialkylphosphines: in all cases only the t-Bu· radicals were detected; they are probably formed by a mechanism in which an oxygen atom is transferred:

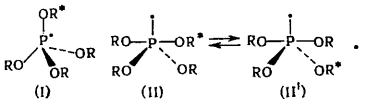
$$(R'O)_3P + \dot{O}C(CH_3)_3 \rightarrow (R'O)_3P{=}O + \dot{C}(CH_3)_3 \ . \qquad (7)$$

This result (see also Hudson and Hussain[19]) may be regarded as confirmation of the mechanism of the interaction of trialkyl phosphites with t-BuO· radicals proposed[11] on the basis of chemical analysis of non-radical products.

The problem arises whether the phosphoranyl radical [$R'_3\dot{P}OR$ or $(R'O)_3\dot{P}OR$] is a kinetically independent species or whether it is a form of transition state for the transfer of an oxygen atom or for substitution via mechanisms (6) and (7). Other experimental data, which allow a choice to be made, will be considered next.

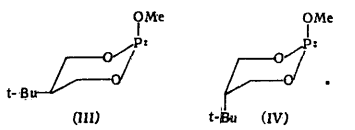
Bentrude and Wielesek[20], who studied the decomposition of di-t-butyl hyponitrite, labelled with the ^{14}C isotope in the methyl groups, in deoxygenated benzene solution at 65°C in the presence of tri-t-butyl phosphite, showed that the phosphite is quantitatively converted into phosphate. It was demonstrated that, firstly, the fraction of labelled phosphate is independent of the concentration of phosphite and of the phosphite/hyponitrite ratio, secondly, the ^{14}C label is hardly incorporated into the unreacted phosphite or phosphate added before the reaction, and, finally, the fraction of labelled phosphate is constant (about 75%).

These results are important; they imply that all t-Bu*O· radicals, which have emerged from the [Bu*-O· O· — Bu-t] cage, are entirely captured by acceptor (phosphite) molecules and that the formation of the phosphoranyl radical $[(t\text{-}BuO)_4\dot{P}]^*$ as an intermediate is irreversible. Bentrude and Wielesek[20] suggested that a statistical distribution of the ^{14}C label in the phosphoranyl radical becomes possible if the radical has the structure of an equilateral pyrimid (I) where all four alkoxy-groups are configurationally equivalent or it can obtain in a trigonal-bipyramidal structure (II) as a result of the pseudorotation of configurationally non-equivalent groups; by hypothesis, such rotation takes place at a frequency higher than that of the decomposition of radical (II):



(I) (II) (II')

However, it has been shown[21] that stereospecific transfer of an oxygen atom from t-BuO· radicals to a mixture of geometrical isomers—six-membered cyclic *cis*(III)- and *trans*-(IV)-phosphites—and also to the optically active methylphenyl-n-propylphosphine $\{[-\alpha]_D\}$ takes place with retention of the configuration at the phosphorus atom. The results of a stereochemical study of the free-radical oxidation at the tervalent phosphorus atom are presented in Table 2.



(III) (IV)

The retention of the configuration at the phosphorus atom in a radical reaction (stereospecificity, retention of the sign of optical rotation) implies that the pseudorotation of the substituents at the phosphorus atom in the radical with structure (II) is impossible, since it should lead to the inversion of the sign of optical rotation or to the isomerisation of the phosphite.

Thus a reasonable explanation of both the statistical distribution of the ^{14}C label and the retention of the configuration at the phosphorus atom in the oxidation by t-BuO· radicals can be obtained only within the framework of the model where the phosphoranyl radical has structure (I).

Table 2. Oxidation of an optically active phosphine and a mixture of isomeric phosphites by t-BuO· radicals.

Source of t-BuO· radicals	Optical activity of phosphine oxide	(III):(IV) ratio	(III)-oxide:(IV)-oxide ratio
t-BuO—N=N—OBu-t-	−16.7±0.2	15:85	21:79
(65°, CH_3CN, without O_2)		91:9	96:4

The formation of phosphoranyl radicals was first observed directly by Kochi and Krusik[16] and by Davies et al.[22] Thus, Kochi and Krusik[16] observed in the oxidation of trimethylphosphine by t-BuO· radicals (photolysis of di-t-butyl peroxide, cyclopropane, temperature between −70° and 90°C) an ESR spectrum with a doublet splitting of 619 G, which was assigned to hyperfine interaction involving the ^{31}P nuclei in the $t\text{-}BuO\dot{P}(CH_3)_3$ radical. According to Davies et al.[22], the addition of t-BuO· radicals to triethyl phosphite (photolysis of di-t-butyl peroxide, cyclopentane, −85°C) is accompanied by the appearance of the ESR spectrum of the phosphoranyl radical $t\text{-}BuO\dot{P}(OC_2H_5)_3$ with an HCC constant a_P = 891 G and g = 2.008; it is noteworthy that this was the first determination of the g-factor of the phosphoranyl radical.

Another striking example illustrating the possibility, in principle, of the formation of the phosphoranyl radical as a kinetically independent species is the observation[14] of the chemically induced nuclear polarisation of ^{31}P (CINP-31P), which arises in the thermal decomposition of di-t-butyl and dibenzoyl peroxides in the presence of triethyl, tributyl, or triphenyl phosphite (110 — 190°). Since the appearance of CINP in chemical reactions implies that they take place with formation of radical pairs[23,24], the negative sign of the chemically induced nuclear polarisation of ^{31}P suggests that the CINP in phosphate molecules is solely a result of the elementary step involving the disproportionation of the radical

(1) (2)

in singlet radical pairs [$a_P > 0$; $\Delta g = (g_1 - g_2) > 0$; the g_2-factor of the majority of hydrocarbon radicals is 2.0024 — 2.0025,[25] while according to the literature[22] the g_1-factor of the phosphoranyl radical $t\text{-}BuO\dot{P}(OC_2H_5)_3$ is 2.008]§; previously this type of disproportionation of phosphoranyl radicals was examined by Davidson[26] on the basis of the chemical analysis of the non-radical products.

§ Disproportionation in triplet pairs is unlikely since it leads to the formation of a phosphate molecule in an electronically excited triplet state.

Thus the study of the chemically induced nuclear polarisation of ^{31}P is extremely promising from the standpoint of the identification or refining of the mechanism of the elementary radical reactions of organophosphorus compounds.

For example, analysis[27] of the sign of the CINP involving ^{31}P nuclei (emission) in the dicyclohexyl peroxydicarbonate (or dilauryl peroxide) — dimethyl phosphite systems (75 — 110°C, tetrachloroethane) led us to the conclusion that of the two kinetically equivalent mechanisms of the formation of the polarised product (phosphate)—via the abstraction of a hydrogen atom and the recombination of the $(MeO)_2\dot{P}{=}O$ and $R\dot{O}$ radicals ($a_P > 0$ $\Delta g > 0$; absorption by ^{31}P expected in "random" pairs) or via the "adhesion" of the $R\dot{O}$ radicals to the double bond of the phosphite with subsequent disproportionation of the radicals  and $O\dot{R}$ ($a_P > 0$, $\Delta g > 0$; emission expected in singlet pairs)—the second mechanism actually obtains.

The above analysis shows that the composition of the intermediate and final products of the reactions of $R\dot{O}$ radicals with phosphites and phosphines has been investigated fairly completely; only one other aspect of the mechanism needs to be refined, namely the reaction kinetics. However, so far there are no experimental data obtained by direct determination of the elementary rate constants; the only source of information on this problem is kinetic analysis of the competition between the reactions involving the abstraction of a hydrogen atom from the hydrocarbon by $R\dot{O}$ radicals and their addition to phosphites and phosphines.

Table 3. Ratios of the rate constants for the reactions of t-Bu$\dot{O}$ radicals with triethyl phosphite and triphenylphosphine (130°C, hydrocarbon).

Hydrocarbon	k_{ph}/k_{RH}	
	$(EtO)_3P$	Ph_3P
Cyclohexane	610±10	7.0±0.2
Cyclohexene	440±10	7.4±0.2
Cyclopentene	610±10	7.4±0.2
Cumene	730±10	10.3±0.5
2,3-Dimethylbutane	1100±100	9.8±0.7

Thus Walling and Pearson[28] investigated the competition between the addition to triethyl phosphite or triphenylphosphine of t-Bu$\dot{O}$ radicals (the radicals were generated by the thermal decomposition of di-t-butyl peroxide at 130°C in sealed tubes) and the abstraction by them of a hydrogen atom from various hydrocarbons (cyclohexane, cyclohexene, cyclopentene, cumene, and 2,3-dimethylbutane). The results of the kinetic analysis are presented in Table 3; the ratios of the rate constants for the reaction of the phosphite k_{ph} to that for the reaction of the hydrocarbon k_{RH} were estimated from the composition of the products—a phosphate and an alcohol).

Table 3 shows that triethyl phosphite reacts 82 ± 20 times faster with t-Bu$\dot{O}$ radicals than does triphenylphosphine and that even the abstraction of a hydrogen atom from hydrocarbons cannot compete effectively with these two reactions.

Since the study under consideration[28] is unique as regards the quantitative kinetics of the reactions of $R\dot{O}$ radicals with phosphines, we believe it is useful to supplement its results with an approximate calculation of the activation energy for the reaction of t-Bu$\dot{O}$ radicals with triethyl phosphite on the basis of the quantitative data of Walling and Pearson.

The activation energy for the competing reaction with cyclohexene is approximately 3 kcal mole^{-1}.[29] The main reaction (the addition to the phosphite) can occur at a rate comparable to that of the competing reaction only if its activation energy is equal to or somewhat less than 3 kcal mole^{-1}. The activation energy for the reaction of $(EtO)_3P$ with t-Bu$\dot{O}$ radicals can be estimated approximately in the following way. In Walling and Pearson's experiments[28], the concentration of peroxide molecules was 6×10^{23} cm^{-3} and the rate constant for the decomposition of the peroxide at 130°C was $k_{decomp} = 4.0 \times 10^{-5}$ s^{-1} (we obtained this value from other literature data[12,13]). Therefore the rate of initiation under these conditions is

$$W_i = 2 \cdot 4.0 \cdot 10^{-5} \cdot 6 \cdot 10^{23} = 4.8 \cdot 10^{19} \text{ cm}^{-3}\text{ s}^{-1},$$

so that the steady-state concentration of t-Bu$\dot{O}$ radicals may be determined as follows:

$$[\text{t-Bu}\dot{O}]_{st} = \frac{4.8 \cdot 10^{19}}{k_{RH}[RH] + k_{ph}[(EtO)_3P]} = \frac{4.8 \cdot 10^{19}}{A} \text{cm}^{-3}.$$

Next the rate constant k_{RH} for the abstraction of a hydrogen atom from cyclohexane, which we estimated from Walling's data[29], is

$$10^{-13}\exp\left(\frac{-3000}{RT}\right) = 2.4 \cdot 10^{-15} \text{ cm}^{-3}\text{ s}^{-1}$$

then the rate of abstraction becomes

$$W_{RH} = 2.4 \cdot 10^{-15}\frac{4.8 \cdot 10^{19}}{A} 12 \cdot 10^{23} = \frac{13.8}{A} \cdot 10^{28} \text{ cm}^{-3}\text{ s}^{-1},$$

where 12×10^{23} is the concentration of hydrocarbon molecules.

Since the concentration of phosphite molecules was 12×10^{23} cm^{-3}, then, in terms of the activation energy for the reaction of the phosphite E_{ph}, its rate at 130°C should be

$$W_{ph} = 10^{-13} \cdot 10^{-E_{ph}/4.57 \cdot 403} \cdot 12 \cdot 10^{23}\frac{4.8 \cdot 10^{19}}{A} =$$

$$= \frac{5.76}{A} 10^{30} \cdot 10^{-E_{ph}/4.57 \cdot 403} \text{ cm}^{-3}\text{ s}^{-1}.$$

For the reaction of the phosphite with t-Bu$\dot{O}$ radicals to proceed at an inappreciable rate, it must amount to not more than 1% of W_{RH}, i.e.

$$\frac{5.76}{A} 10^{30} \cdot 10^{-E_{ph}/4.57 \cdot 403} \leqslant \frac{13.8}{A} 10^{26}$$

or

$$10^{30} \cdot 10^{-E_{ph}/4.57 \cdot 403} \leqslant 2.4 \cdot 10^{26}.$$

Hence it follows that the activation energy for the reaction of triethyl phosphite with t-Bu$\dot{O}$ radicals is $E_{ph} \geqslant 3.62 \times 4.57 \times 403 = 6.7$ kcal mole^{-1}¶. Evidently this value of E_{ph} is higher than the activation energy for

¶ In the calculation of E_{ph} a typical value was adopted for the pre-exponential factor for the reaction of t-Bu$\dot{O}$ radicals with molecules, namely 10^{-13} cm^3 s^{-1};[30] it can be easily shown that with the pre-exponential factor equal to the bimolecular collision frequency ($10^{-10} - 10^{-11}$ cm^3 s^{-1}), E_{ph} should be even higher.

the reaction of the active hydrocarbon. Using it, it is possible to show that only in the presence of a 100-fold excess of the phosphite can the competing reaction with the hydrocarbon be supressed. This conclusion, albeit in fact inconsistent with the conclusions of Walling and Pearson, makes it necessary to treat with a certain amount of caution the earlier estimate of the relative reactivity of triethyl phosphite[28].

Walling and Pearson employed the method of competing reactions also for the determination of the relative reactivities of the triethyl phosphite — triphenyl phosphite, tri-n-butylphosphine — triphenylphosphine, and triethyl phosphite — tri-n-butylphosphine pairs in relation to t-BuȮ radicals. Kinetic analysis (the reactivities were estimated from the degree of consumption of the reactant) led to the following relative reactivity series for the compounds investigated (at 130°C):

$$Bu_3P : (EtO)_3P : (PhO)_3P : Ph_3P = 1.9 : 1.6 : 1 : 0.78\dagger .$$

It is useful to estimate the ratio of the rate constants for the reactions of triethyl and triphenyl phosphites (k_1/k_2) from an approximate calculation of the activation energies for the two reactions. Thus, for the overall decomposition of di-t-butyl peroxide in the presence of triphenyl phosphite, one can postulate a competition between the decomposition of the t-BuȮ radical:

$$(CH_3)_3C\dot{O} \xrightarrow{k_d} \dot{C}H_3 + CH_3COCH_3$$

and its addition to the phosphite:

$$(CH_3)_3C\dot{O} + (PhO)_3P \xrightarrow{k'_{ph}} (CH_3)_2C{=}CH_2 + HOP(OPh)_2 + Ph\dot{O} .$$

In Bentrude's experiments[15] (in this investigation a detailed study was made of the reaction products of triphenyl phosphite), the concentration of t-BuȮ radicals was (130°C, in chlorobenzene)

$$[t\text{-}Bu\dot{O}]_{st} = \frac{2 \cdot 4 \cdot 10^{-5} \cdot 2.4 \cdot 10^{20}}{k'_{ph}[(PhO)_3P] + k_d} = \frac{2 \cdot 10^{16}}{B} \quad cm^{-3}$$

where 4×10^{-5} s^{-1} is the rate constant for the decomposition of the peroxide and 2.4×10^{20} cm^{-3} is the concentration of peroxide molecules, while the rate constant for the decomposition of the radicals $k_d = 10^{11.5} \exp(-10\,600/RT) = 5.6 \times 10^5$ s^{-1}.[31] Therefore the rate of decomposition of t-BuȮ radicals is

$$W_d = 5.6 \cdot 10^5 \cdot \frac{2 \cdot 10^{16}}{B} = 1.1 \cdot \frac{10^{22}}{B} \quad cm^{-3}\,s^{-1}.$$

Since the concentration of triphenyl phosphite molecules was 5×10^{20} cm^{-3}, the rate of reaction of triphenyl phosphite with t-BuȮ radicals at 130°C should be

$$W'_{ph} = 10^{-13} \cdot 10^{-E'_{ph}/4.57 \cdot 403} \frac{2 \cdot 10^{16}}{B} \cdot 5 \cdot 10^{20} = \frac{1}{B} 10^{24} \cdot 10^{-E'_{ph}/4.57 \cdot 403} \quad cm^{-3}\,s^{-1}$$

Using the kinetic condition for the supression of competition by the phosphite which we derived above, one can show that

$$\frac{10^{24}}{B} \cdot 10^{-E'_{ph}/4.57 \cdot 403} \leqslant 1.1 \cdot \frac{10^{20}}{B} .$$

Hence it follows that the activation energy for the reaction of triphenyl phosphite $E'_{ph} \geqslant 3.96 \times 4.57 \times 403 = 7.3$ kcal mole^{-1}.

† It follows from the data in Table 3 that the relative reactivity of triphenylphosphine should be 0.020; this finding confirms yet again the contradictory nature of the results in Table 3.

Since this is lower than the activation energy for the decomposition of t-BuȮ radicals, triphenyl phosphite can accept these radicals to an appreciable extent‡. Next, assuming that the reactions of triethyl and triphenyl phosphites have the same pre-exponential factor (about 10^{-13} cm^3 s^{-1}), it is possible to estimate the ratio of the rate constants for these reactions; k_1/k_2 is found to be 2.1. This is close to the value of 1.6 found by Walling and Pearson[28] from experimental kinetic data for the joint consumption of triethyl and triphenyl phosphites in the decomposition of di-t-butyl peroxide, which illustrates the internal consistency of the estimates of activation energy quoted here.

In conclusion of the discussion of the kinetics of the reaction of RȮ radicals with phosphite and phosphines, one should also point out that the level of the quantitative kinetics of these radical reactions is fairly low. For the majority of elementary reactions, there are no quantitative data and treatment has to be restricted to approximate estimates of activation energies and rate constants. For example, by studying the rate of consumption of reactants under various experimental conditions (different rates of initiation, temperatures, radical sources, relative amounts of the reactants, etc.) and using the kinetic procedures of the method of competing reactions, it is possible to determine, in principle, the rate constants for elementary radical reactions. So far no experimental studies on these lines have been made.

We shall now consider the experimental data on the mechanism and kinetics of the reactions of RṠ radicals with phosphites and phosphines. Like those of the RȮ radicals, these reactions are of interest from the standpoint of the determination of the mechanism of the formation of phosphoranyl radicals; moreover, they are suitable for the generation of alkyl radicals of known structure from mercaptans and disulphides.

Walling et al.[11,32] established by gas — liquid chromatography that the main molecular products of such interaction are the phosphorothionates $(R'O)_3P{=}S$ and phosphine sulphides $R'_3P{=}S$ as well as hydrocarbons or sulphides; their formation is greatly accelerated by ultraviolet irradiation, azobisisobutyronitrile (AIBN), and di-t-butyl peroxide; this implies that the reaction involves kinetic chains. The following mechanism has been proposed on the basis of the composition of the reaction products of triethyl phosphite, for example:

$$R\dot{S} + P(OEt)_3 \rightarrow RS\dot{P}(OEt)_3 \rightarrow \dot{R} + S{=}P(OEt)_3 ,$$
$$\dot{R} + RSH \rightarrow RH + R\dot{S}$$

or

$$\dot{R} + RSSR \rightarrow RSR + R\dot{S} .$$

Many facts support the above mechanism of the interaction of RṠ radicals with phosphites or phosphines[11,32]. For example, Kochi and Krusik[16] detected by the ESR method the $(CH_3)_3\dot{C}$ radical, which is formed in the photolysis of di-t-butyl disulphide in the presence of tri-isopropylphosphine (−90°C, cyclopropane) probably by the reaction

$$(CH_3)_3C\dot{S} + [(CH_3)_2CH]_3P \rightarrow (CH_3)_3\dot{C} + [(CH_3)_2CH]_3P{=}S.$$

Subsequently Kavun et al.[33] demonstrated by the ESR method that the alkyl radicals formed in thermal decomposition of di(trichlorophenyl) disulphide (60 — 100°C, benzene, no oxygen) in the presence of triphenylphosphine combine with stable nitroxide radicals as acceptors; the

‡ Indeed hardly any acetone was detected in the mixture of products[15].

kinetic behaviour of the acceptor then reflects accurately the kinetics of the rate-limiting stage—monomolecular decomposition of the disulphide bond. The following mechanism has been proposed for the decomposition of a disulphide in the presence of a phosphine:

$$RSSR \rightarrow 2R\dot{S};$$
$$R\dot{S} + R'_3P \rightarrow RS\dot{P}R'_3 \rightarrow \dot{R} + S{=}PR'_3;$$
$$\dot{R} + \text{acceptor} \rightarrow \text{stable product}.$$

This mechanism is confirmed by the kinetics of reactions in which radicals combine with acceptors.

Finally Bentrude et al.[21] established that the stereospecific transfer of the sulphur atom from BuS· radicals to a mixture of geometrical isomers (III) and (IV) (see p. 557) takes place, as for t-BuO· radicals, with retention of the configuration at the phosphorus atom.

This result and also the direct detection of alkyl radicals and their combination with stable nitroxide radicals as acceptors illustrate the common features of the interaction of RO· and RS· radicals with phosphites and phosphines, which take place via the formation of an intermediate phosphoranyl radical; in this sense the reactions of RO· and RS· radicals have common properties and features.

Only one study has been made[28] on the kinetics of the reactions of RS· radicals, in which the ratio of the rate constants for the interaction of n-BuS· radicals (from n-BuSH) with triethyl phosphite and styrene, initiated by AIBN at 70°C, was measured. By hypothesis, the following reactions occur under experimental conditions:

$$\text{AIBN} \xrightarrow{k_0} \overbrace{\dot{r} + N_2 + \dot{r}} \begin{cases} \xrightarrow{fk_0} \dot{r} + N_2 + \dot{r} \\ \xrightarrow{(1-f)k_0} r{-}r + N_2 \end{cases},$$
$$\dot{r} + RSH \xrightarrow{k_1} rH + R\dot{S},$$
$$R\dot{S} + P(OEt)_3 \xrightarrow{k_2} \dot{R} + S{=}P(OEt)_3,$$
$$\dot{R} + RSH \xrightarrow{k_3} RH + R\dot{S},$$
$$R\dot{S} + CH_2{=}CHPh \xrightarrow{k_4} RSCH_2{-}\dot{C}HPh,$$
$$RSCH_2{-}\dot{C}HPh + RSH \xrightarrow{k_5} RSCH_2{-}CH_2Ph + R\dot{S},$$

where f is the probability of the emergence of the radicals from the "cage".

Since the sulphide $RSCH_2CH_2Ph$ was obtained only by the reaction with styrene and the phosphorothionate $S{=}P(OEt)_3$ by the reaction with a phosphite, the rate constant ratio k_4/k_2 is determined by analysing the products for an olefin and phosphite:

$$\frac{d[\text{olefin}]}{d[\text{phosphite}]} = \frac{d[\text{sulphide}]}{d[\text{phosphorothionate}]} = \frac{k_4[\text{olefin}]}{k_2[\text{phosphate}]}.$$

The average value of this ratio was found to be 3.2. On the basis of a study by Sivertz[34], who showed that RS· radicals add to the styrene molecule with a diffusional rate constant of 1.3×10^{-12} cm^3·s^{-1}, Walling and Pearson[28] determined the absolute rate constant $k_2 = 0.4 \times 10^{-12}$ cm^3 s^{-1}; this value implies that the reaction of RS· radicals with triethyl phosphite should occur with an almost zero activation energy.

It is noteworthy that there are no serious grounds for regarding this conclusion as unambiguous; this follows from the following considerations. Firstly, analysis of the experimental results of Walling and Pearson[28] in Table 4 showed that, with an approximately constant $[\text{styrene}]_0/[\text{phosphite}]_0$ ratio, the rate constant ratio k_4/k_2 varies in parallel with the increase of the concentration of the mercaptan (by a factor of 2); such an increase can probably be explained either by the fact that at the concentrations indicated in Table 4 there is not sufficient time for the mercaptan to accept all the cyanoisopropyl radicals ṙ emerging from the initiator "cage" into the bulk of the solvent or by the occurrence of side reactions where the olefin is alkylated, which were disregarded by the authors in the kinetic treatment of the experimental results.

Table 4. Ratios of the rate constants for the addition of n-BuS· radicals to triethyl phosphite (AIBN, 70°C, n-BuSH, styrene, no oxygen).

$10^3[\text{n-BuSH}]_0$, M	$\frac{k_4}{k_2}$	$\frac{[\text{olefin}]_0}{[\text{phosphite}]_0}$	$10^3[S{=}P(OEt)_3]$, M	$10^3[\text{sulphide}]$, M	$\frac{k_4}{k_2}\left(\frac{[\text{olefin}]}{[\text{phosphite}]}\right)_{av}$
4.1	1.9	1.0	1.6	2.5	1.71
4.3	2.3	0.8 av 0.9	1.3	1.9	2.07
9.5	4.9	0.9	0.43	1.02	4.4
4.5	2.3	0.47	1.9	1.5	1.22
9.5	4.4	0.6 av 0.53	0.52	1.37	2.33

Secondly, according to the same authors' estimate, the difference between the reactivities of n-BuS· and t-BuO· radicals in relation to various phosphites and phosphines is almost independent of the structure of the radicals and lies in the range 0.1 — 1.0; this means that the reaction of n-BuO· radicals, like that of t-BuO·, with phosphites probably involves an appreciable activation energy.

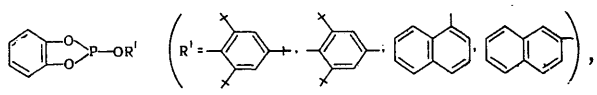
III. REACTIONS OF RO_2· RADICALS

In the previous section evidence was presented demonstrating that RO· and RS· radicals interact effectively with phosphites and phosphines under any conditions either by a radical exchange (substitution) mechanism or via a sulphur or oxygen atom transfer.

At first sight this has the consequence that the kinetics of the reactions of RO· and RO_2· radicals should be determined only by the reactivity of the phosphites (phosphines) and should not be sensitive to the type of the oxygen-containing radical. However, many facts contradict this conclusion.

In liquid-phase chain oxidation of hydrocarbons, the intensity of the chemiluminescence associated with the exothermic elementary step (recombination of peroxy-radicals) decreases appreciably in the presence of certain phenolic and amine inhibitors[35]; this is explained by postulating that the rate of linear chain termination by the inhibitor becomes higher than the rate of quadratic termination (via the recombination of RO_2· radicals). However, Khloplyankina et al.[36], who studied the AIBN-initiated oxidation of ethylbenzene at 60°C by a chemiluminescence method, showed that the introduction of tri-isopentyl phosphite, tri-isopentyl phosphate, and diethylphosphorous acid has almost no effect on the luminescence intensity I: their relative reactivities in the reaction with RO_2· were found to be respectively 1×10^{-5}, 2×10^{-3}, and 1×10^{-5}, i.e. the rate of this reaction is zero or very low.

When an aromatic phosphite,



is introduced into the reaction mixture, the chemiluminescence intensity decreases slightly. It was then found that the rates of consumption of these phosphites, calculated from the kinetic luminescence data, are on average higher by one- two powers of 10 than the specified rate of initiation, while the quantity $[d(I/I_0)/dt]_{max}$ (the maximum slope of the kinetic curve), which characterises the capacity of the inhibitor molecules to react with peroxy-radicals[35], remained almost constant and was usually equal to the corresponding quantity measured in experiments with free phenols (catechol and substituted phenols), which may be obtained by the hydrolysis of phosphites, i.e. may be present as impurities.

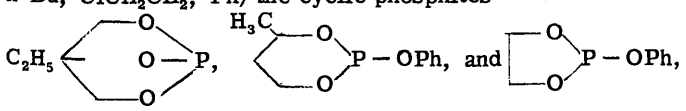
All these characteristics of the quenching of chemiluminescence by aromatic phosphites may be accounted for by adopting a mechanism in which a single kinetic oxidation chain is terminated either by 10 — 100 phosphite molecules or by a single phenol molecule (for an impurity/phosphite ratio of 0.1 — 0.01). The agreement between the slopes of the kinetic luminescence curves for the consumption of the phosphite and its hydrolysis products is evidence that the second mechanism obtains, i.e. aromatic phosphites, like aliphatic phosphites, hardly react with RO_2 radicals at 60°C.

Walling and Rabinowitz[11] were the first to draw attention to the fact that at higher temperatures (about 130°C) the oxidation of aliphatic phosphites by alkoxy-radicals in the presence of O_2 becomes autocatalytic (an excess super-stoichiometric amount of phosphate is formed). They also explained the autocatalysis on the hypothesis that at 130°C the peroxy-radicals, into which the alkyl radicals $\dot{R}$ (t-Bu$\dot{O}$) were converted at 130°C under the influence of molecular oxygen (see p. 556 for the mechanism of the formation of $\dot{R}$), rapidly oxidise new phosphite molecules, regenerating at the same time the active centres of the kinetic chains—the $R\dot{O}$ radicals:

$$\dot{R} + O_2 \rightarrow R\dot{O}_2,$$
$$R\dot{O}_2 + P(OR')_3 \rightarrow RO_2\dot{P}(OR')_3,$$
$$RO_2\dot{P}(OR')_3 \rightarrow O{=}P(OR')_3 + R\dot{O},$$
$$R\dot{O} \rightarrow \text{stages (2) and (3).}$$

It should be noted that this mechanism does not include the termination of the kinetic chains; the oxidation continues until the complete consumption of the phosphite.

An illustration of the mechanism of the autoxidation of phosphites with AIBN as an initiator is provided by the data of Bentrude[15], who measured the yields of trialkyl and triallyl phosphates in the oxidation by RO_2 radicals (benzene, 80°C, O_2) of phosphites $(R'O)_3P$ (where R' = Et, n-Bu, $ClCH_2CH_2$, Ph) the cyclic phosphites



and the mixed phosphite $(EtO)_2P(OPh)$: in all cases the yield was found to be close to 80 — 90% for the molar ratio phosphite/initiator = 10. It is noteworthy that, when di-t-butyl peroxide was employed as an initiator, the rate of initiation decreased under the experimental conditions (130°C, chlorobenzene) only by a factor of 2 (relative to AIBN), while the yield of cyclic and aromatic phosphates was less than 2.5 moles per mole of the peroxide; this can probably be accounted for by the occurrence of the competitive radical exchange reaction (see Section II).

The above example shows that, in order to conclude that a particular reaction is impossible (such a conclusion was arrived at by Neiman and Miller[37] for the reaction of RO_2 with phosphites on the basis of the results of Khloplyankina et al.[36]), it is insufficient to investigate this reaction at only one temperature; a comprehensive kinetic investigation is required.

Clearly the results of only one study[15] do not yield a complete picture of the kinetics of the reactions of $R\dot{O}_2$ with phosphites; in addition, it is necessary to have data which would make it possible to identify the oxidation conditions and to find the rate-limiting stage (from the effect of O_2 pressure, rate of initiation, phosphite concentration, etc. on the rate of formation of phosphates).

Buckler[17] observed the autocatalytic oxidation of tri-n-butylphosphine under the influence of O_2 to phosphine oxide and n-butyl di-n-butylphosphinite at 26°C in hexane solution in the absence of initiators. It was found that the catalysis is possible when the diffusion of oxygen is retarded and chain propagation

$$R\dot{O}_2 + PR_3 \rightarrow R\dot{O} + O{=}PR_3$$

is much faster than chain transfer

$$R\dot{O} + PR_3 \rightarrow \dot{R} + O{=}PR_3$$
$$R\dot{O} + PR_3 \rightarrow \dot{R} + ROPR_2.$$

Next it was discovered that the relative yields of phosphine oxide varies in parallel with the increasing polarity of the solvent. This finding implies that the polarisation of the P — O bond in the phosphoranyl radical $R - O\dot{P}R_3$ is probably the main cause of the formation of phosphine oxide (see also p. 556). Since in this investigation an initiator was not employed, the nature of the elementary chain initiation step remains obscure.

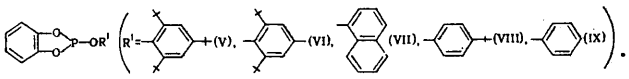
The above brief analysis shows that there are almost no quantitative data for the reactions of $R\dot{O}_2$ radicals with phosphites and phosphines although these reactions, like those of the $R\dot{O}$ and $R\dot{S}$ radicals, are important in the autoxidation of phosphites and phosphines and, as will be shown below, in polymer stabilisation processes. Quantitative kinetic criteria for such reactions are very necessary for practical purposes.

IV. THE ROLE OF RADICAL MECHANISMS IN THE OXIDATION OF POLYMERS INHIBITED BY PHOSPHITES

Hitherto the kinetics and mechanisms of the reactions of low-molecular-weight radicals $R\dot{O}$ and $R\dot{O}_2$ with phosphites and phosphines in the liquid phase were considered. The kinetics of the reactions of $R\dot{O}$ and $R\dot{O}_2$ macroradicals with phosphites are of exceptional interest for the theory of polymer stabilisation. Unfortunately, there are almost no quantitative data for the rates of these reactions in polymer melts and in the solid phase. Nevertheless, such data would be extremely significant. The point is that the idea of the involvement of aromatic phosphites in the termination of kinetic chains in the oxidation of polymers (in the melts) and the associated theory of the action of organophosphorus inhibitors (critical concentrations, linear relation between the induction period and phosphite concentration, etc.) are based on hypotheses concerning the reactions of low-molecular-weight $R\dot{O}$ and $R\dot{O}_2$ radicals (see Sections II and III); these hypotheses were developed by Levin[38,39] and confirmed by a number of investigators

in studies on the high-temperature (180 — 220°C) oxidation of polypropylene[38-43]. Initially we shall examine the available data in this field and then interpret them from the kinetic standpoint.

Levin and coworkers[39,40,43], who studied the oxidation of polypropylene at 200°C (i.e. in the melt) and at an oxygen pressure of 200 mmHg, observed a linear relation between the induction period in the oxidation process τ and the concentration of aromatic phosphites with the general formula



Comparison of several mechanisms for the inhibited oxidation of polypropylene in the presence of these phosphites shows that formally they all reduce to a linear relation between τ and the phosphite concentration.

Firstly, phosphites may inhibit degenerate branching:

$$\mathrm{RH} + \mathrm{O_2} \xrightarrow{W_0} \dot{\mathrm{R}} + \mathrm{H\dot{O}_2},$$

$$\dot{\mathrm{R}} + \mathrm{O_2} \xrightarrow{k_1} \mathrm{R\dot{O}_2},$$

$$\mathrm{R\dot{O}_2} + \mathrm{RH} \xrightarrow{k_2} \mathrm{ROOH} + \dot{\mathrm{R}},$$

$$\mathrm{R\dot{O}_2} + \mathrm{R\dot{O}_2} \xrightarrow{k_3} \text{stable products},$$

$$\mathrm{ROOH} + \mathrm{RH} \xrightarrow{\frac{O_2}{k_4}} \delta\mathrm{R\dot{O}_2},$$

$$\mathrm{ROOH} + \mathrm{P(OR')_3} \xrightarrow{k_5} \text{stable products}.$$

Kinetic analysis of this mechanism (where δ is the probability of degenerate chain branching) in the steady state (with respect to $\dot{R}$, $R\dot{O}_2$, and ROOH) leads to the following relation between the rate of consumption of the phosphite and its concentration:

$$-\frac{d[\mathrm{P(OR')_3}]}{dt} = \frac{k_2 k_5 [\mathrm{RH}]\, W_0^{1/2} [\mathrm{P(OR')_3}]}{k_3^{1/2}(k_4[\mathrm{RH}] + k_5[\mathrm{P(OR')_3}])}.$$

At fairly high phosphite concentrations, we obtain

$$-\frac{d[\mathrm{P(OR')_3}]}{dt} = \frac{k_2[\mathrm{RH}]\, W_0^{1/2}}{k_3^{1/2}}.$$

and

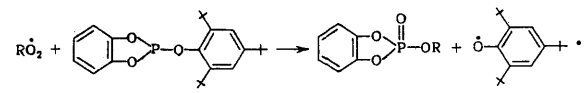
$$\tau = \frac{k_3^{1/2}}{k_2[\mathrm{RH}]\, W_0^{1/2}} [\mathrm{P(OR')_3}]_0.$$

i.e. τ varies linearly with $[P(OR')_3]_0$. In addition, it is possible to show that, under the experimental conditions (200°C, typical inhibitor concentration $10^{-1} - 10^{-2}$ mole kg^{-1}), the phosphite (V) is in fact capable of suppressing degenerate branching, since

$$\frac{W_5[\mathrm{ROOH}]}{W_4[\mathrm{ROOH}]} = \frac{0.4 \cdot 10^{-13} \exp(-14\,000/RT)(10^{-1} - 10^{-2})}{1.6 \cdot 10^{-13} \exp(-25\,000/RT) \cdot 23} = 1.2(10^3 - 10^4).$$

The rate constant for the bimolecular decomposition of polypropylene hydroperoxide was obtained by ourselves from the results of Pudov and Neiman[44] and the "liquid-phase" rate constant for the reaction of tri-t-butylphenyl *o*-phenylene phosphite with 1,1-diphenylethyl hydroperoxide (this hydroperoxide can serve as a model of polypropylene hydroperoxide) extrapolated to 200°C was taken from Mukmeneva[45]; the inhibitor and polymer concentrations were $10^{-1} - 10^{-2}$ and 23 mole kg^{-1}. However, the finding that the effectiveness of the phosphites (V) — (IX) investigated is not correlated with the rates at which they decompose 1,1-diphenylethyl hydroperoxide in the liquid phase at 25°C cannot be accounted for within the framework of this mechanism[39,45,46].

Secondly, phosphites can terminate kinetic oxidation chains probably by replacing the active macroradicals $R\dot{O}_2$ by relatively inactive resonance-stabilised phenoxy-radicals[38] (see also Section II):



In this case the general mechanism of the inhibited oxidation can be represented as follows:

$$\mathrm{RH} + \mathrm{O_2} \xrightarrow{W_0} \dot{\mathrm{R}} + \mathrm{H\dot{O}_2},$$

$$\dot{\mathrm{R}} + \mathrm{O_2} \xrightarrow{k_1} \mathrm{R\dot{O}_2},$$

$$\mathrm{R\dot{O}_2} + \mathrm{RH} \xrightarrow{k_2} \mathrm{ROOH} + \dot{\mathrm{R}},$$

$$\mathrm{R\dot{O}_2} + \mathrm{P(OR')_3} \xrightarrow{k_p} \mathrm{O{=}P(OR')_3(OR)} + \mathrm{Ar\dot{O}},$$

$$\mathrm{ROOH} + \mathrm{RH} \xrightarrow{\frac{O_2}{k_4}} \delta\mathrm{R\dot{O}_2}.$$

Assuming steady-state concentrations of $\dot{R}$, $R\dot{O}_2$, and ROOH, it is possible to obtain the following expression for the rate of consumption of phosphite:

$$-\frac{d[\mathrm{P(OR')_3}]}{dt} = \frac{k_p[\mathrm{P(OR')_3}]\, W_0}{\delta k_2[\mathrm{RH}] + k_p[\mathrm{P(OR')_3}]}.$$

At fairly low values of δ (it has been shown in a review[47] that, at oxygen pressures ranging from 0 to 200 mmHg, δ varies in the range $17 \times 10^{-3} - 0.8$, i.e. is less than unity), this expression simplifies:

$$-\frac{d[\mathrm{P(OR')_3}]}{dt} = W_0 \text{ and } \tau = \frac{1}{W_0}[\mathrm{P(OR')_3}]_0;$$

i.e. in this case τ depends linearly on $[P(OR')_3]_0$. This mechanism is confirmed by the critical concentrations of the phosphites investigated[40-42] (observed in kinetic experiments), i.e. concentrations above which the oxidation process passes from a non-steady state to a steady state (hypotheses concerning the critical concentrations of inhibitors of different types have been developed by Neiman and Shlyapnikov[48,49]). Evidently an unambiguous and direct demonstration of the elementary kinetic chain termination stage in oxidation by aromatic phosphites in the polymer melt and in the solid phase would be of fundamental importance for the theory of the stabilisation of polymers by these compounds; hitherto such a demonstration has not been achieved in any of the experimental studies.

Thirdly, a linear relation of the type $\tau \cong [P(OR')_3]_0/W_0$ may be obtained on the hypothesis[37] that aromatic phosphites inhibit the oxidation of polypropylene via their hydrolysis products, which are formed in the course of the oxidation process. Indeed, the formation of water molecules in the induction period of the oxidation reaction becomes the rate-limiting stage in this case and therefore the hydrolysis of the phosphite is of zero order with respect to the phosphite. However, from the standpoint of these hypotheses about phosphites as sources of catechol and other stabilisers, one cannot explain the finding that the phosphites investigated (except phosphites with the substituents and) have a critical concentration, while all theoretically conceivable products of their hydrolysis (phenols, catechol, *o*-phenylenephosphorous acid, phosphorous acid, and others) do not exhibit such a concentration[41].

Thus the existence of a linear relation between the induction period and the concentration of aromatic phosphites can be explained unambiguously by adopting the mechanism in which the kinetic oxidation chains are

terminated by radical exchange. This mechanism probably obtains in polymer melts; on the other hand, the presence of critical phosphite concentrations can serve as a kinetic criterion of its validity. Moreover, such a mechanism makes it possible to deal more rigorously and on a sounder basis with the selection of phosphites for which an inhibiting effect may be predicted.

It is noteworthy that the extensive data on the effectiveness of aromatic phosphites in polymer oxidation products in melts can be hardly used for solid-phase reactions of $R\dot{O}_2$ radicals with phosphites; this follows from the kinetic characteristics of solid-phase radical reactions (see the review on radical polymer degradation and stabilisation reactions[47]). We may note that, in order to determine the effectiveness of the phosphites in the termination of kinetic chains in the oxidation of a solid polymer (100 – 130°C), it is necessary to know not only the rate constant and the elementary mechanism of the interaction of the $R\dot{O}_2$ macroradical with the phosphite (which characterises the kinetic stage) but also the diffusion coefficient of the phosphite in the solid polymer (the macrodiffusion stage).

---o0o---

This review has dealt with the most important radical reactions of phosphites and phosphines, their role in autoxidation processes in the liquid phase and in the inhibited oxidation of polymers in melts has been assessed, and their quantitative kinetic characteristics have been given.

It is noteworthy that the quantitative data for many reactions are extremely contradictory; frequently this applies not only to kinetic constants but even to the mechanisms. For example, the mechanism of the termination of kinetic chains in the oxidation of polypropylene by aromatic phosphites via radical exchange is valid provided that the phenoxy-radical is not involved in the propagation of the $Ph\dot{O} + RH \rightarrow PhOH + \dot{R}$ chains but recombines with a second peroxy-radical. Calculation shows that 200°C the rate via the first pathway for the disappearance of phenoxy-radicals is comparable with the rate via the second pathway; one can only suppose that phenoxy-radicals disappear via disproportionation to low-molecular-weight products. The solution of these problems constitutes an important step in the creation of a theoretical basis for the stabilisation of polymers by organophosphorus compounds.

Association of Hydrocarbon Hydroperoxides

O.P.Yablonskii, V.A.Belyaev, and A.N.Vinogradov

The results of studies on the association of hydrocarbon hydroperoxides and the formation of their complexes with alcohols and aromatic, dienic, and olefinic hydrocarbons are reviewed. The role of the intermolecular hydrogen bond in the decomposition of hydrocarbon hydroperoxides is demonstrated.
The bibliography includes 53 references.

CONTENTS

1. Introduction
2. Self association of hydrocarbon hydroperoxides
3. Intramolecular hydrogen bonds in hydroperoxides
4. Intermolecular hydrogen bonds in "hydrocarbon hydroperoxide-proton acceptor" complexes
5. The role of the intermolecular hydrogen bond in the decomposition of hydrocarbon hydroperoxides

1. INTRODUCTION

The oxidation of hydrocarbons by molecular oxygen (autoxidation) constitutes an important method for the industrial preparation of valuable oxygen-containing compounds. Numerous studies on the liquid-phase oxidation of various hydrocarbons have now firmly established that hydroperoxides are the first stable products of their oxidation[1-5]. The molecules of organic substances with a hydroxy-group (alcohols, phenols, hydroperoxides, etc.) are known[6,7] to be capable of associating with one another and with the molecules of other compounds by hydrogen bonding, the presence of which has a significant effect on the reaction kinetics. The study of the association processes of hydroperoxides and their derivatives makes it possible to assess more fully the results obtained in the liquid-phase oxidation of hydrocarbons and also to suggest radical improvements to the process. Hydroperoxides play a fundamental role in polymer oxidation and degradation processes, promoting chain branching. A very important factor here is that the branching efficiency, i.e. the decomposition rate constants and the number of radicals formed per decomposition step, depends on the physicochemical state of the hydroperoxide. The association equilibrium constants enter into all the kinetic equations and therefore the knowledge of these constants and of the coordination numbers is always essential. In the present paper an attempt is made to review data obtained in the study of the association of hydrocarbon hydroperoxides by ^{1}H NMR and infrared spectroscopy.

2. SELF ASSOCIATION OF HYDROCARBON HYDROPEROXIDES

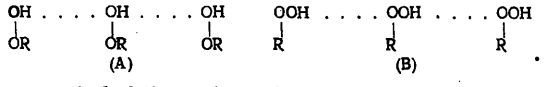
Up to 1950 only the infrared spectra of hydrogen and deuterium peroxides were investigated, the 870 cm^{-1} band being attributed to the O — O bond[8].

The infrared spectra of isopropylphenyl, tetralyl, cyclohexyl, and t-butyl hydroperoxides were recorded in 1951. Sherve et al.[9] attribute three frequencies to the vibrations of the C — O — O — H group: 840, 880 (OOH), and 3600 cm^{-1} ($OH_{stretch}$). The shift of the absorption maximum towards shorter wavelengths on dilution with carbon disulphide indicates the presence of hydrogen bonds in the system. Karyakin et al.[10] established that the vibrations of the hydroperoxy-group C — O — O — H are fairly active in the infrared and have the following characteristic frequencies (mean values):

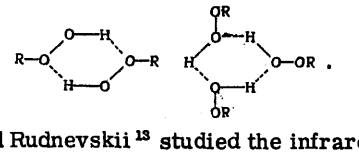
C—O—O—H_{def}	840	cm^{-1}
O—$O_{stretch}$	880	»
C—$O_{stretch}$	1151	»
O—H_{def}	1300	»
O—$H_{stretch}$	3450	»
First overtone	6800	» .

The presence of these frequencies in the infrared spectrum of any compound (primarily two of them: 840 and 3450 cm^{-1}) may serve as an indication that the given compound is a hydroperoxide.

Table 1 lists the vibration frequencies of the C — O — O — H group in various hydroperoxides. A number of studies have been made on the structure of hydroperoxide association complexes. Thus Minkoff[11] suggested on the basis of the stretching vibration frequencies of the OOH group that there are two types of association (A and B) in hydroperoxides (3.01 and 2.92 μm bands):



It was concluded that, depending on the nature of the monomer (free hydroperoxide molecules) and the concentration of the hydroperoxide in heptane solution, the isomers of the hydroperoxide exist in dimeric and trimeric forms[12]:



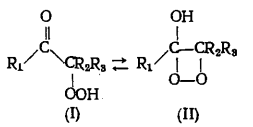
Zharkov and Rudnevskii[13] studied the infrared spectra of t-butyl hydroperoxide solutions in carbon tetrachloride in the range 3200 — 3600 cm^{-1}. They were the first to calculate for hydrocarbon hydroperoxides two association constants from the change in the intensity of the absorption band due to the OH group at 3540 cm^{-1}: the dimerisation constant and the constant for a higher degree of association, together with the dimerisation energy (6.3 ± 1.0 kcal $mole^{-1}$) and the energy of further association (2.8 ± 0.7 kcal $mole^{-1}$). The authors put forward a mechanism for the association of t-butyl hydroperoxide which includes the formation of a cyclic dimer via two hydrogen bonds

with subsequent linear association which probably takes place via the oxygen atoms of the hydroperoxy-groups in the cyclic dimer not involved in hydrogen bonding.

Table 1. C—O—O—H vibration frequencies in the infrared spectra of various hydroperoxides[10].

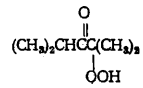
Hydroperoxide	Structural formula	Wave number, cm^{-1}					
		C—O—O—H def.	O—O stretch	C—O stretch.	O—H def.	O—H stretch	O—H first overtone
Isopropylphenyl hydroperoxide		837	881	1155	1325	3450	6740
Tetralyl hydroperoxide		833	885	1150	1300	3380	6840
Decalyl hydroperoxide		837	873	1155	1310	3400	6900
Hydroxymethyl hydroperoxide		840	880	no data	no data	3400	6800 6450
Heptyl hydroperoxide		862		1135	1300	3450	no data
t-Butyl hydroperoxide		846	888	1194	1365	3520	ditto
Cyclohexenyl hydroperoxide		838	856	1160	1305	3450	»
Hydrogen peroxide	H—O—O—H		870	—	1370	3417	»

In recent years the proton magnetic resonance method (^{1}H NMR) has been widely used in the study of hydrogen bonds[14-20]. The ^{1}H NMR chemical shifts of a number of alkyl hydroperoxides were first measured by Japanese investigators[7]. The proton resonance in the OOH group occurs at a lower field than the proton resonance in the CH_3 group approximately by 9.06 p.p.m. (at a working frequency of 27 030 MHz and H_0 = 6300 G). The signal of the hydroperoxy-proton is close to that of the carboxy-group in aliphatic acids (9.9 — 10.3 p.p.m.), occurring in a lower field than the OH proton signal in alcohols (3.7 — 4.44 p.p.m.). The shift of the signal due to the OOH proton as a function of concentration is attributed to the formation of a hydrogen bond. Richardson and Steed[18] studied the structure of α-ketohydroperoxides and also the intermolecular and intramolecular hydrogen bonds in these compounds. They established that the equilibrium in reaction (1) is fully displaced to the left:



(I) (II) (1)

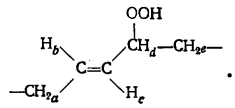
The proton magnetic resonance spectrum of the compound



shows that the proton linked to oxygen gives rise to a signal at low field (9.39 p.p.m. for an 11% solution in carbon tetrachloride), characteristic of the hydroperoxy-group. This finding led to the conclusion that the compound is most likely to exist in the hydroperoxy-form (I) [Eqn. (1)]. On the basis of the infrared spectra, the authors calculated the enthalpy (−1.45 kcal mole^{-1}), free energy (−0.12 kcal mole^{-1}), and entropy (−4.3 e.u.) of the monomer — dimer equilibrium for form (I). The low enthalpy for form (I) can be explained by the formation of a strong intermolecular hydrogen bond according to the following scheme:

 (2)

According to the infrared spectroscopic data, the energy of this bond is −1.86 kcal mole^{-1}. In the ^{1}H NMR spectra of the monohydroperoxides of oleic and linoleic acid esters[19], the hydroperoxy-group gives rise to a broad signal at 8.92 p.p.m. (30 — 40% solution in carbon tetrachloride) and the infrared spectrum shows a band due to the vibrations of the OH group at 3440 cm^{-1}. These hydroperoxides probably have the following structure:



The chemical shifts of the individual groups of protons and the spin — spin coupling constants are listed below:

δ_a, p.p.m.	δ_b, p.p.m.	δ_c, p.p.m.	δ_d, p.p.m.	δ_e, p.p.m.	J_{ab}, Hz	J_{bc}, Hz	J_{cd}, Hz	J_{ac}, Hz	J_{bd}, Hz
2.10	5.60	5.30	4.11	1.44	±6.25	±15.59	±8.04	±0.96	±1.17

The splitting constant (15.6 Hz) confirms that the (*b*) and (*c*) protons are in the *trans*-position. In the spectrum of 1-tetralyl hydroperoxide the signal due to the hydroperoxy-proton is at 8.65 p.p.m., while in the spectrum of the monohydroperoxide of methyl-linoleic acid prepared in different ways the signal is at 9.0 and 8.8 p.p.m. Kucher et al.[20] studied the dependence of the chemical shifts of the proton in the OOH group of isopropylphenyl hydroperoxide on its concentration in various solvents: carbon tetrachloride, isopropylbenzene, and nitrobenzene. Extrapolation of the concentration curve (in carbon tetrachloride) to infinite dilution yields the chemical shift δ = 6.55 p.p.m., while in the pure hydroperoxide δ = 8.62 p.p.m. The authors estimated the dimer ⇌ monomer equilibrium constants from the slope of the $\delta = f(c)$ concentration curve at infinite dilution and obtained a value of 19.5.

The self-association processes of isopropylphenyl, t-butyl, and t-pentyl hydroperoxides have been analysed on the basis of ^{1}H NMR data[21-23].

The thermodynamic parameters of the hydrogen bonds have been calculated from the temperature and concentration variation of the chemical shift of the proton in the

OOH group of hydroperoxides in an inert solvent (Table 2). It has been shown (see also Zharkov and Rudnevskii[13]) that the self-association of hydroperoxides takes place via the formation of cyclic dimers with subsequent linear association of the dimer with hydroperoxide molecules. The calculated enthalpies of formation of the hydrogen bond in hydroperoxides makes it possible to compare them in terms of the strength of the hydrogen bond with other classes of compounds and to devise a general mechanism of the self-association of hydroperoxide molecules. The hydrogen bond in hydroperoxides is weaker than in other compounds containing hydroxy-groups (alcohols, phenols, and acids).

Table 2. Thermodynamic parameters for the formation of hydrogen bonds by hydroperoxides[21,22].

Hydroperoxide	K_{dim} at 21°C (p.p.m.)$^{-1}$	$K_{subs.\ assn.}$ at 21°C, (p.p.m.)$^{-1}$	$-\Delta H_{dim}$, kcal mole^{-1}	$\Delta H_{subs.\ assn.}$ kcal mole^{-1}	$-\Delta S_{dim}$, cal mole^{-1} deg^{-1}	$-\Delta S_{subs.\ assn.}$, cal mole^{-1} deg^{-1}
t-Butyl hydroperoxide	19±2	180±20	6.6±1	3±1	17±2	0±3
t-Pentyl hydroperoxide	18±2	180±15	6.5±1	3±1	17±2	0±2
Isopropylphenyl hydroperoxide	15±2	146±15	7.7±1	2.2±1	21±3	2±3

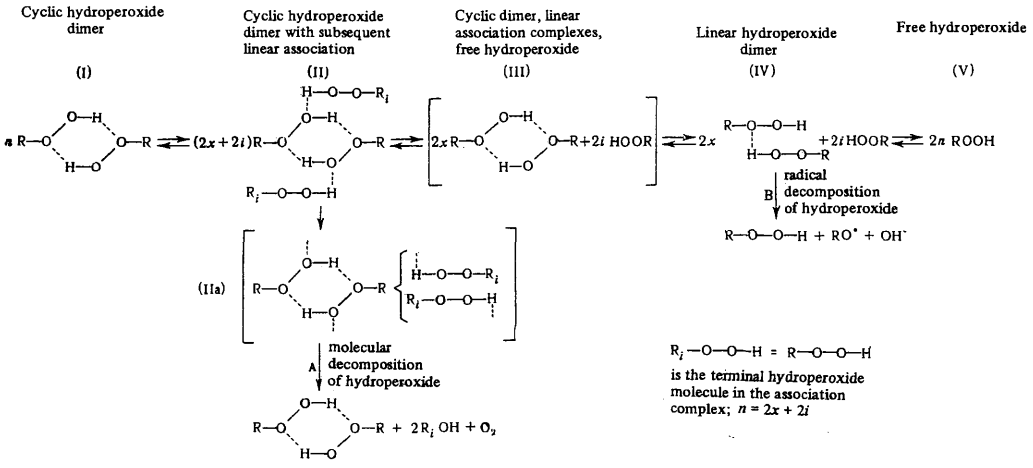
The mechanism of the self-association of hydroperoxide molecules devised by the authors is given below[23]. Generally speaking, one can suggest that at comparatively low temperatures the hydroperoxide exists in forms (I) — (V). However, examination of the relative equilibrium constants K_{12} for the monomer ⇌ cyclic dimer equilibrium [forms (V) and (I)] and the equilibrium constants for the subsequent linear association [forms (I) and (II)] at different temperatures showed that, with decrease of temperature, K_{12} increases faster than does K.[21,22] One should then expect that under certain conditions the constants will become equal (for example, near −40°C for isopropylphenyl hydroperoxide) and that at lower temperatures dimerisation will predominate [form (I)].[23]

With increase of temperature, one of the dimers of form (I) decomposes with formation of form (II). It was found that the enthalpy of formation of the overall hydrogen bond in the cyclic dimer is 6 — 8 kcal mole^{-1}, while that for the hydrogen bond formed in subsequent association is only 2 — 3 kcal mole^{-1}. In its turn form (II) can dissociate into a cyclic dimer and the linear association complex [forms (III) and (IV)]. The cyclic dimer decomposes further into form (IV) and then into form (V).

The formation of a hydrogen bond is known[24] to weaken the H — O and O — O covalent bonds in the molecule of the proton donor and to strengthen the bonds adjoining the oxygen atom in the acceptor molecule. Thus in the hydroperoxide molecule, which is a donor in form (IV), the weakest O — O bond is weakened further by the formation of an intermolecular hydrogen bond. This leads to a cleavage of only one hydroperoxide molecule in form (IV) via the familiar mechanism (see the above mechanism, reaction B) of the unimolecular decomposition of the hydroperoxide with formation of free radicals.

In the association complex comprising the cyclic hydroperoxide dimer with subsequent linear associations [form (II)], the terminal hydroperoxide molecules may be in the immediate vicinity of one another owing to their polar interaction. Moreover, in these molecules, as in form (IV), the O — O bonds are weakened. All these factors suggest that both hydroperoxide molecules decompose simultaneously without the formation of free radicals (reaction A), in agreement with the usually observed second order of the thermal decomposition reaction of hydroperoxides[26]. The second order decomposition reaction of hydroperoxides is observed at high hydroperoxide concentrations, i.e. when association complexes of type (II) predominate in solution. The main products of reaction A are an alcohol and molecular oxygen. The only products of the thermal decomposition of t-butyl hydroperoxide (95 — 100°C) are trimethylmethanol and oxygen[27]. Dimethylphenylmethanol and oxygen were also found in the products of the thermal decomposition of isopropylphenyl hydroperoxide[28].

The mechanisms of the unimolecular and bimolecular thermal decomposition of hydroperoxides discussed above lead to the conclusion that the hydroperoxide molecules, which behave as proton acceptors in forms (II) and (IV),



Mechanism of the self association and the uni- and the bi-molecular decomposition of hydrocarbon hydroperoxides in inert solvents.

function as reaction catalysts ("autocatalysis"). In the cyclic dimer the hydrogen bonds are stabilised in the six-membered ring where the covalent bonds are not weakened, since the effects of the hydrogen bonds cancel out. This leads to the conclusion that the cyclic hydroperoxide dimer is the most stable association complex from the standpoint of the thermal stability of hydroperoxides. The thermal stability of the hydroperoxide in form (I) is close to that of the free hydroperoxide [form (V)].

The relative stabilities of the cyclic dimers of various hydrocarbon hydroperoxides are determined by the energy of the hydrogen bonds in the hydroperoxide molecules involved in their formation. The higher the hydrogen bond energy, the more stable the ring. Thus the equilibrium between forms (I) and (IV) of the hydroperoxides forming stable rings is displaced to the left and in this case the probability of the formation of form (IV) is lower than for hydroperoxides forming less stable rings.

On this hypothesis, isopropylphenyl hydroperoxide (ΔH = 7.7 kcal mole^{-1}) should have a higher thermal stability than t-butyl hydroperoxide (ΔH_{12} = 6.6 kcal mole^{-1}) and t-pentyl hydroperoxide (ΔH_{12} = 6.5 kcal mole^{-1}). On the other hand, the higher the hydrogen bond strength in linear association complexes of form (II) ($\Delta\bar{H}$ = 3.0 kcal mole^{-1} for t-pentyl and t-butyl hydroperoxides and $\Delta\bar{H}$ = 2.2 kcal mole^{-1} for isopropylphenyl hydroperoxide), the greater the shift, other conditions being equal, of the equilibrium between forms (II) and (III) towards form (II), in which two $R_i-O-O-H$ molecules are in a position energetically favourable for decomposition and where in addition the O — O bonds are weakened owing to the stronger hydrogen bond.

From this standpoint, isopropylphenyl hydroperoxide should also have a higher thermal stability than t-pentyl and t-butyl hydroperoxides.

Conclusions concerning the different thermal stabilities of hydroperoxides based on the properties of the hydrogen bond are consistent with thermal stability data. Thus pure isopropylphenyl hydroperoxide is stable in saturated hydrocarbon solutions at 130 — 140°C,[28] while t-butyl hydroperoxide is cleaved at an appreciable rate at a temperature as low as 90°C.[29] It is also known[30] that t-pentyl hydroperoxide decomposes in octane at 110°C.

3. INTRAMOLECULAR HYDROGEN BONDS IN HYDROPEROXIDES

Hydroperoxides can form intramolecular hydrogen bonds in addition to addition to intermolecular complexes. The intramolecular hydrogen bond in isopropylphenyl hydroperoxide between the OOH group and the π electrons of the aromatic ring has been investigated by infrared spectroscopy[31]. In the infrared spectrum the OH absorption band consists of a doublet with maxima at 3497 and 3530 cm^{-1}. The 3530 cm^{-1} band was assigned to the vibrations of the free OH group and the 3497 cm^{-1} band to the vibrations of the bound OH group. The authors calculated from the temperature variation of the intensities of these bands that the energy of the intramolecular hydrogen bond was 0.9 ± 0.10 kcal mole^{-1}. The presence of an intramolecular hydrogen bond between the OOH group in isopropylphenyl hydroperoxide and the aromatic π electrons was confirmed[32].

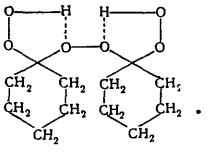
Terent'ev and Antanovskii studied the intramolecular hydrogen bonds in a number of hydroperoxides[33,34]. Table 3 lists the shifts $\Delta\nu$ of the band due to the C — O — O — H group on formation of an intramolecular hydrogen bond and the bond energies E_H. The authors calculated E_H for di-(1-hydroperoxycyclohexyl) peroxide from the intensity of the single absorption band at 3435 cm^{-1}, characteristic of its C — O — O — H group.

Table 3. The shifts $\Delta\nu$ of the bands due to the C — O — O — H group on formation of an intramolecular hydrogen bond and the intramolecular hydrogen bond energies[34] E_H.

Hydroperoxide	$\Delta\nu$, cm^{-1}	E_H, kcal mole^{-1}
Isopropylphenyl hydroperoxide	33 28	0.9±0.1[31]
Tetralyl hydroperoxide	28	0.9±0.1
Diphenylethyl hydroperoxide	30	0.96±0.11
	107	7.0±0.5
	172	11.2±0.8
	112	7.3±0.5

The occurrence of a strong intramolecular hydrogen bond in α-keto hydroperoxides was pointed out earlier[18].

Di-(1-hydroperoxycyclohexyl) peroxide was investigated by NMR[35]:



The chemical shift of the hydroperoxy-proton does not change in the concentration range 0.2 — 0.01 p.p.m. in carbon tetrachloride solution at 15 — 80°C (9.3 p.p.m.). This value agrees satisfactorily with the δ_a obtained for other hydroperoxides[21,22]. The constancy of the chemical shift of the proton signal of the OOH group in the concentration and temperature range investigated suggests a strong intramolecular hydrogen bond in this compound.

4. INTERMOLECULAR HYDROGEN BONDS IN "HYDROCARBON HYDROPEROXIDE — PROTON ACCEPTOR" COMPLEXES

Like other substances with hydroxy-groups (phenols, alcohols, and acids), hydrocarbon hydroperoxides react with proton acceptors to form hydrogen-bonded association complexes[26]. The formation of the latter may influence the kinetics and mechanisms of reactions involving hydroperoxides which occur in the liquid phase[36]. In this connection the study and experimental determinations of the energy of the hydrogen bonds between hydroperoxides and various proton acceptors is of both theoretical and practical interest.

Systematic studies on the formation of complexes by hydroperoxides with various proton acceptors by spectroscopic methods were begun in 1968. The only earlier study[37] on this problem dealt with the formation of complexes by t-butyl hydroperoxide with different acceptors: styrene, benzene, *o*-dichlorobenzene, and chlorobenzene.

Table 4. The frequencies, integral intensities, and association constants of the hydrogen-bonded complexes of isopropylphenyl hydroperoxide[38].

Acceptor	ν_{OH}, cm^{-1}	$\Delta\nu_{OH}$, cm^{-1}	$\Delta\nu_{1/2}$, cm^{-1}	$10^{-3}A$, litre mole^{-1}cm^{-2}	K, litre mole^{-1}

Isopropyl ether	3326	225	122	51.2	1.78

Shabalin and Kiva[38] examined the proton-donating capacity of isopropyl hydroperoxide and established that it is intermediate between those of alcohols and phenols. They investigated by infrared spectroscopy the complexes of isopropylphenyl hydroperoxide formed via hydrogen bonding with different proton acceptors. Table 4 lists the frequencies and integral intensities for the infrared spectra of the isopropylphenyl hydroperoxide complexes. Assuming that in all cases the interaction of isopropylphenyl hydroperoxide with a proton acceptor yields a 1 : 1 complex, the authors calculated the association constants K for certain systems (Table 4) using the equation

$$K=\frac{1-\frac{D}{D_0}}{\frac{D}{D_0}\left[C_a-C_{hp}\left(1-\frac{D}{D_0}\right)\right]}, \qquad (3)$$

where D_0 and D are the optical densities of the bands due to the free OH groups before and after the addition of the acceptor, C_{hp} is the initial molar concentration of the hydroperoxide, and C_a the molar concentration of the acceptor.

The same workers[39] used infrared spectra to calculate the energies of the hydrogen bonds between isopropylphenyl hydroperoxide and different acceptors. Shabalin et al.[32] also showed that an intermolecular hydrogen bond is formed between the isopropylphenyl hydroperoxide proton and the π electrons in the rings of aromatic solvents. The shift of the band due to bound OH groups is linearly related to the ionisation potential of the aromatic solvent.

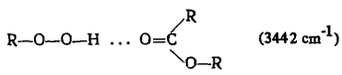
The intermolecular hydrogen bonds have been investigated and the bond energies for the t-butyl hydroperoxide — isopropyl ether and t-butyl hydroperoxide — pentyl acetate systems in carbon tetrachloride have been calculated in the range 20 — 50°C (Table 5)[34].

Table 5. The shifts $\Delta\nu$ of the band due to the C — O — O — H group on formation of the hydrogen bond and the hydrogen bond energy E_H (ROOH = t-butyl hydroperoxide)[34].

Complex	$\Delta\nu$, cm^{-1}	E_H, kcal mole^{-1}
	220	3.7±0.4
	120	3.3±0.3
	172	*
	60	—

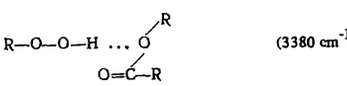
*E_H could not be determined experimentally, since in this system there is a chemical reaction between the donor and the acceptor[40].

On the basis of the infrared spectra, the authors suggest that in the system with the ester, apart from complexes of the type



(3442 cm^{-1})

the complexes



(3380 cm^{-1}),

are formed to a very small extent.

The energy of the hydrogen bond was calculated from the van't Hoff equation:

$$\ln\frac{D_1^H D_2^{bound}}{D_2^H D_1^{bound}}=\frac{E_H(T_2-T_1)}{R\ T_2\ T_1}, \qquad (4)$$

where D^H and D^{bound} are the optical densities of the absorption bands due to the "free" and bound (by hydrogen bonding) C — O — O — H groups at two temperatures.

The possibility of association via hydrogen bonding with aromatic amines was pointed out by Ivanov[41], who established by infrared spectroscopy that in the interaction between aniline and hydroperoxides, which are intermediates in the autoxidation of hydrocarbons, in particular with isopropylphenyl hydroperoxide, these substances undergo association at low temperatures with formation of the following molecular compound:

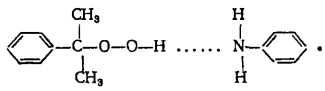


Table 6. Frequencies and half-widths of the infrared absorption band of the OH group and the energies of the intermolecular hydrogen bonds between hydrocarbon hydroperoxides and aromatic solvents.

Solvent	Isopropylphenyl hydroperoxide			t-Butyl hydroperoxide			t-Pentyl hydroperoxide

Recently the authors of the review used NMR and infrared spectroscopy to study the formation of hydrogen bonds in complexes of hydroperoxides with various proton acceptors. Thus more detailed studies were made of the complexes of hydrocarbon hydroperoxides with aromatic solvents[42]. The data in Table 6 shows that the stability of the complexes of hydroperoxides with aromatic solvents increases with the degree of substitution of the protons in the benzene ring by alkyl groups (CH_3). The chemical shifts of the proton involved in hydrogen bonding in the complexes of hydroperoxides with aromatic solvents are satisfactorily correlated with the ionisation potentials of the latter and also with the frequency shifts of the OOH group in the complexes. The higher thermal stability of hydrocarbon hydroperoxides in aromatic solvents (in the presence of an excess of the solvent) compared with aliphatic solvents can be accounted for by the formation of weak intermolecular complexes via hydrogen bonds between the hydroperoxide and the aromatic solvent.

Since the energy of the hydrogen bond in these complexes is lower (Table 6) than in the self-association of hydroperoxides (Table 2), the O — O bond in the hydroperoxide molecule in the complex is weakened less than in the linear hydroperoxide dimer, in consequence of which the hydroperoxide molecule in the complex is more stable than in the linear dimer.

The hypothesis that "aromatic hydrocarbon–hydroperoxide" complexes exist also explains the higher thermal stability of aliphatic-aromatic hydroperoxides compared with aliphatic hydroperoxides dissolved in an inert solvent, for example a saturated aliphatic hydrocarbon.

The formation of complexes of hydrocarbon hydroperoxides with amines has been discussed[43]. The interest in systems comprising hydroperoxides and amines is due to a number of factors. In most cases such systems are used as initiators of polymerisation processes. They are studied in order to find ways of preventing the oxidative degradation of polymers; in many cases amines are employed as inhibitors of the thermal polymerisation of monomers.

NMR data have led to a mechanism of the association of hydrocarbon hydroperoxides with amines using triethylamine as an example. At low triethylamine concentrations, association of the type OH...O (hydroperoxide — hydroperoxide) predominates, at high triethylamine concentrations the N...HO association is dominant, and in the intermediate region the dominant form is

$$R_3NH^+ \ldots {}^-OOR_1$$
$$\vdots$$
$$HOOR_1 .$$

The existence of dimers formed via a polar interaction may be expected in solution, the screening decreasing in the sequence

$$\sigma(OH \ldots O) \simeq \sigma(N \ldots HO) > \sigma(NH^+ \ldots {}^-O).$$

The low thermal stability of hydrocarbon hydroperoxides in the presence of amines and the lower activation energy for their decomposition can be explained by the formation of a strong hydrogen bond between the hydroperoxide and the amine or its salt, which facilitates the cleavage of the hydroperoxide molecule at the weak O — O bond.

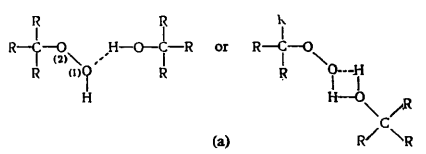
One of the final products of the decomposition of hydrocarbon hydroperoxides is an alcohol. Their interaction with hydroperoxides via hydrogen bonding may influence the rate of decomposition of the hydroperoxide. The formation of complexes by tertiary hydrocarbon hydroperoxides with a number of alcohols has been studied[35] by ^1H NMR. In all the complexes investigated, the energy of the "alcohol — hydroperoxide" hydrogen bond

$$R{-}O{-}O{-}H$$
$$\vdots$$
$$H{-}O{-}R$$

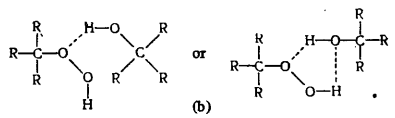
(calculated from the signal of the proton in the alcoholic OH group) is 3.5 — 4.5 kcal $mole^{-1}$ and the energy of the "hydroperoxide — alcohol" bond (ROOH...$\overset{H}{\underset{|}{O}}$ — R) (calculated from the signal of the proton in the hydroperoxide OOH group) is about 2.5 kcal $mole^{-1}$. Using the thermodynamic data obtained for the association of hydrocarbon hydroperoxides, alcohols, and their complexes, the following sequence may be established in terms of the strength of the hydrogen bond:

$$\left[\begin{matrix}\text{Hydroperoxide}\\ \text{Alcohol}\end{matrix}\right] \simeq \left[\begin{matrix}\text{Hydroperoxide}\\ \text{Hydroperoxide}\end{matrix}\right] < \left[\begin{matrix}\text{Alcohol}\\ \text{Hydroperoxide}\end{matrix}\right] < \left[\begin{matrix}\text{Alcohol}\\ \text{Alcohol}\end{matrix}\right]$$

The dependence of the chemical shifts of the OOH and OH protons in the hydroperoxide — alcohol mixture on the alcohol concentration leads to the possibility of identifying the oxygen atom of the hydroperoxide involved in the association with the alcohol. Generally speaking, one can suppose that the hydrogen bond between the alcohol and the hydroperoxide involves both the first oxygen atom of the hydroperoxide:



and its second oxygen atom:



(b)

The "alcohol — hydroperoxide" hydrogen bond is approximately equally strong for all alcohols. This conclusion is consistent with the finding that

$$\delta^{OH}_{[alcohol]\to 0} \simeq const.$$

It is extremely likely that the hydrogen bond between the alcohol and the hydrogen peroxide involves the first oxygen atom of the latter, since in this case the steric factor is less important. This is confirmed indirectly by the finding that at low hydroperoxide concentrations the "alcohol — hydroperoxide" hydrogen bonds (ROOH...$\overset{H}{O}$—R) depend on the structure of the alcohol (Table 7).

Table 7.

Alcohol	$\Delta\delta_{OOH}$, p.p.m.
C_2H_5OH	2.02
$(CH_3)_2CHOH$	2.00
$(CH_3)_3COH$	1.90
$CH_3(CH_2)_4OH$	1.80
$C_6H_5(CH_3)_2COH$	1.50

$\Delta\delta_{OOH}$ decreases with increasing importance of the steric factor in the alcohol. If the "alcohol — hydroperoxide ("σ") bond involves the second oxygen atom (the position of which is analogous to that of the oxygen atom in the alcohol), a similar relation between $\delta^{OH}_{[alcohol]\to 0}$ and the steric factor of the hydroperoxide would be expected.

The formation of complexes via hydrogen bonds between tertiary hydroperoxides and a ketone and an ether was investigated[43] and the composition of the complexes and their influence on the decomposition of the hydroperoxides were discussed. A study was also made of the complexes of t-butyl hydroperoxide with a number of olefins and dienes formed by hydrogen bonding between the hydroperoxy-proton and the π electrons of the double bond[35]. It has been shown by infrared spectroscopy that the stability of the complexes formed increases with the basicity of the olefins, i.e. with the number of alkyl substituents at the double bond.

The decomposition and dissociation of the complex ROONa.ROOH via the mechanisms[44]

$$\text{(decomposition)} \qquad ROONa \cdot ROOH \to ROONa + ROH + {}^1/_3O_2, \qquad (5)$$

$$\text{(dissociation)} \qquad \left[\begin{matrix} ROONa \\ \vdots \\ HOOR \end{matrix}\right] \rightleftarrows ROONa + ROH, \qquad (6)$$

where R = $(CH_3)_2CC_6H_5$, were investigated by ^1H NMR. In the decomposition of the complex via reaction (5), the ^1H NMR spectrum shows a combined signal due to the hydroperoxide OOH and alcoholic OH groups. The rate constants for the decomposition of the hydroperoxide in the complex and the activation energy for the decomposition process (E = 16.5 ± 1.0 kcal mole^{-1}) were calculated from the variation of the overall chemical shift due to the hydroxyl protons with reaction time and temperature. The reaction was found to be of first order with respect to the hydroperoxide in dilute solutions of the complex.

In dilute solutions the monomer of the complex may dissociate via mechanism (6). The dissociation constant of the complex $K_{30°} = 4.93 \times 10^{-2}$) and its enthalpy of dissociation (ΔH = −12.7 ± 1 kcal mole^{-1}) were calculated from the temperature variation of the chemical shift of the OOH proton in the complex at its different concentrations. The hydrogen bond in the complex of isopropylphenyl hydroperoxide and its sodium salt is much stronger than that formed in the self dissociation of isopropylphenyl hydroperoxide. The low thermal stability of the hydroperoxide in the ROONa.ROOH complex compared with the "pure" hydroperoxide can be accounted for by the effect of the stronger hydrogen bond and hence by the greater weakening of the O — O bond. "Pure" isopropylphenyl hydroperoxide is stable in solution in saturated hydrocarbons up to 130°C, while the hydroperoxide in the ROONa.ROOH complex decomposes at an appreciable rate already at 30°C.

5. THE ROLE OF THE INTERMOLECULAR HYDROGEN BOND IN THE DECOMPOSITION OF HYDROCARBON HYDROPEROXIDES

The study of the kinetics of the liquid-phase oxidation of hydrocarbons showed[45,46] that hydroperoxides, which are formed as intermediates, are cleaved by a unimolecular mechanism under certain conditions and by a bimolecular mechanism under others. The decomposition of the hydroperoxide via two mechanisms has been explained by the formation of a hydrogen bond in hydroperoxide solutions[23]. The addition to the hydrocarbon undergoing oxidation of substances capable of associating with hydroperoxides and thereby rupturing the hydrogen bonds between hydroperoxide molecules leads to a change from bimolecular to unimolecular decomposition[47].

Since hydroperoxides form hydrogen bonds with other oxygen-containing compounds, one may expect that certain oxidation products will influence the decomposition of hydroperoxides and the rate of formation of radicals (by forming various complexes with the hydroperoxide). This hypothesis is confirmed by the finding that the decomposition of hydroperoxides is facilitated in the presence of alcohols[29], organic acids[48], and other compounds capable of forming association complexes with hydroperoxides via intermolecular hydrogen bonds.

A study of the oxidation of decane showed[48] that the linear relation between the rate of branching of the radical chains and the hydroperoxide concentration obtains only in the early stages of the reaction, where the decomposition products still have almost no influence on the reaction. The further non-proportional increase of the concentration of radicals is related to the formation of oxidation products, for example acids. This phenomenon has been studied[49] in the decomposition of n-decyl hydroperoxide in the presence of caproic acid. The authors suggest that the decomposition of the hydroperoxide into radicals takes place via the intermediate formation of the complex

$$ROOH + n\,R'COOH \overset{k}{\rightleftarrows} ROOH \ldots R'COOH \overset{k'}{\to} RO^{\cdot} + \dot{O}H + R'COOH. \qquad (7)$$

Owing to the formation of hydrogen bonds in this complex, the dissociation of the O — O bond in the hydroperoxide molecule is facilitated, which leads to the formation of radicals. The activation energy for the decomposition of

the hydroperoxide in the ROOH...RCOOH complex is 16.1 kcal mole^{-1}, which is much less than the activation energy for the decomposition of the hydroperoxide in the absence of an acid (23.8 kcal mole^{-1}).

It has also been noted in the literature that the kinetics of the oxidation of hydrocarbons are influenced by solvents in which the oxidation is carried out[50]. The presence in the reaction mass of solvents capable of forming hydrogen bonds with the hydroperoxide leads to a rearrangement of the structure of the association complexes formed with participation of the hydroperoxide which in turn alters the rate of initiation of the oxidation of hydrocarbons. Similar views were also put forward before. For example, it was suggested[51] that pyridine be employed as a kind of catalyst for the oxidation of hydrocarbons, since it forms a hydroperoxide — pyridine complex the decomposition of which at the O — O bond is fairly rapid. The rate constant for the decomposition of t-butyl hydroperoxide into radicals is a factor of 200 higher in the presence of pyridine compared with the pure hydroperoxide. A study of the decomposition of t-butyl hydroperoxide in cyclohexanone showed that the presence of cyclohexanone in the reaction mass greatly accelerates (by a factor of 7 — 10) the decomposition of the hydroperoxide into radicals. The infrared spectra indicate the formation of a complex[52].

The thermodynamic data obtained for complexes of hydrocarbon hydroperoxides with various compounds and the literature data on the activation energies for the decomposition of hydroperoxides have led to a general correlation between the strength of the hydrogen bond in the complex and the activation energy for the hydroperoxide decomposition reaction[53]. With increase of the enthalpy of the hydrogen bond in the hydrocarbon hydroperoxide complexes with various compounds, the activation energy for the decomposition of the hydroperoxide falls. Thus the activation energy for the decomposition of hydroperoxides in aromatic hydrocarbons amounts to 25 — 40 kcal mole^{-1}, while in the presence of amines or in the alkali-catalysed decomposition of hydroperoxides it is 14 — 18 kcal mole^{-1}. A correlation between the chemical shift and the displacement of the stretching vibration frequency of the hydrogen-bonded complexes of hydrocarbon hydroperoxides on the one hand and the activation energy for the decomposition of the hydroperoxides on the other has also been observed.

Reactivities of Alloxazines and Isoalloxazines

V.M.Berezovskii, L.S.Tul'chinskaya, and N.A.Polyakova

The advances in the chemistry of alloxazines and isoalloxazines in the last 10-12 years have been reflected particularly in the study of their reactivities. The review deals with the reduction, oxidation, and nucleophilic and electrophilic substitution reactions, the reactions of exocyclic amino-groups, the methyl group in the 8-position of the flavine nucleus, and others. The reactivities of alloxazines and isoalloxazines are discussed with reference to quantum-chemical parameters. The bibliography includes 245 references.

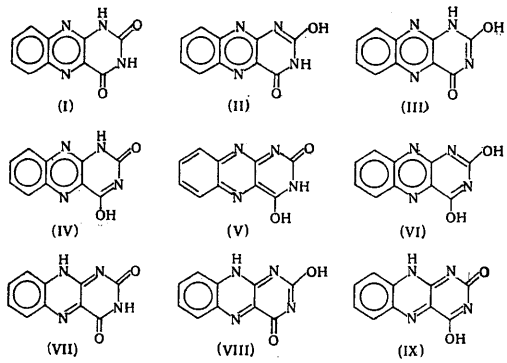
1. INTRODUCTION

Alloxazines and isoalloxazines—2,4-dioxo-1,2,3,4-tetrahydrobenzo[*g*]pteridines—constitute a heterocyclic series of compounds the natural representatives of which [riboflavin (vitamin B_2) and its coenzymes—riboflavin 5′-phosphate or flavin mononucleotide (FMN) and P^1-(riboflavin-5′)-P^2-(adenosine-5′)diphosphate or flavin-adenine dinucleotide (FAD)] combine with a specific protein and fulfil key electron transfer functions in metabolic processes.

However, for a long time after the discovery of riboflavin (1932), which proved to be the basic structural unit of the cofactors of flavin oxidation-reduction enzymatic systems, mainly the synthetic pathways of alloxazines and isoalloxazines and their analogues were investigated[1,2] using the complete flavin system as a basis for the discovery of its essential biological properties. The entire wide variety of the chemical characteristics of compounds of the alloxazine and isoalloxazine series has been demonstrated only in the last 10–12 years. Thus the electronic structures and steric configurations of the riboflavin molecule and of related compounds, the reactivities of ring nitrogen atoms, the capacity of the carbon atoms in the benzene ring for electrophilic substitution, the oxidation of alloxazines to *N*-oxides, the reactions of exocyclic amino-groups and of the methyl group in the 8-position of the flavin nucleus, photochemical reactions, spectroscopic properties of alloxazines and isoalloxazine molecules, etc. have been investigated; the results of the studies of the chemical properties have been interpreted in relation to the principal biochemical function of flavins. The combined studies on the reactivity and its dependence on the π-electronic parameters of the molecule led logically to the determination of the structure of a new flavin cofactor of succinate dehydrogenase—an enzyme which catalyses the dehydrogenation of succinic acid to fumaric acid in the key tricarboxylic acid metabolic energy cycle (the Krebs cycle)—and a new flavin cofactor of another enzyme—monoamine oxidase.

2. TAUTOMERIC FORMS OF ALLOXAZINE AND ISOALLOXAZINE

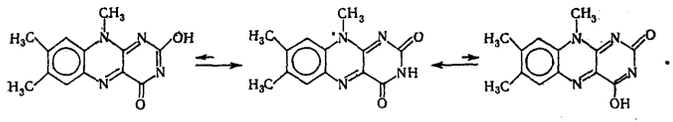
Alloxazine can have 6 possible lactam-lactim tautomeric forms (I)–(VI), while isoalloxazine has only 3 tautomeric forms (VII)–(IX) as a result of the fixation of the electronic configuration by the substitution of the hydrogen atom in the 10-position by an alkyl group:



The problem of the tautomeric forms of heterocyclic compounds is frequently solved by comparing their electronic spectra with those of model compounds having a known structure[3]. However, experimental studies of *N*- and *O*-alkyl derivatives of flavins[4-6] have shown that, owing to the insignificant differences between the absorption spectra, the study of the lactam–lactim tautomerism of such flavins by ultraviolet spectroscopy is impossible[7]. Calculation of the transition energies and oscillator strengths for the tautomeric forms (I)–(IX) by the Pariser–Parr–Pople self-consistent field (PPP SCF)

method also led to the conclusion that the transition from the lactam to the lactim form has little influence on the absorption spectra[8,9].

O-Alkyl, *S*-methyl, and deoxy-derivatives of lumiflavin differ markedly from lumiflavin itself in their basicity: they are fully protonated even in dilute acetic acid[5]. These compounds are relatively unstable and are readily hydrolysed, being easily converted into lumiflavin in the presence of weak oxidants. On this basis, it has been concluded that flavins exist in the lactam form[7] and have virtually no admixture of the hydroxyimino-forms[7,10]; the prototropic equilibrium is apparently fully displaced towards the lactam form[7]:



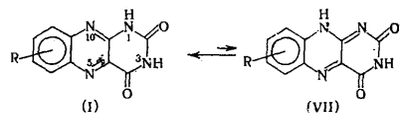
The infrared spectra of a large number of substituted alloxazines and isoalloxazines and their comparison with the spectra of compounds with fixed structures established that both alloxazines and isoalloxazines have the lactam structure in the solid state[11].

By comparing the calculated energies of the upper bonding and lower antibonding orbitals for all possible tautomeric forms of alloxazines and isoalloxazines, Nishimoto[9] showed that the electron affinity of the dioxo-forms is fairly high and that such compounds are effective oxidants. It has been suggested that in biological systems isoalloxazines are capable of tautomeric conversion into the enolic forms as a result of the formation of hydrogen bonds with proteins and thus behave as both electron donors and acceptors in biochemical reactions[9].

It is noteworthy that the π-electron energy of the 4-*C*-enolic form (IX) is higher by 4–5 eV than for the tautomeric 2-*C*-enolic form (VIII), i.e. form (IX) is energetically more favourable[12].

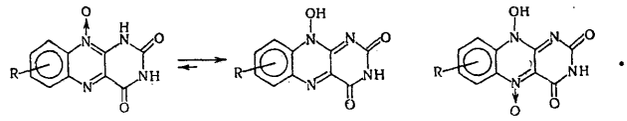
Berezovskii and Aksel'rod studied the possibility of the alloxazine and isoalloxazine tautomerism in many alloxazines[13,14], their 5-*N*-oxides[15], 10-*N*-oxides[13,14], and 5,10-di-*N*-oxides[15]. It was shown[13,14] that the difference between the structure of alloxazines and isoalloxazines, which depends on the $-N_{(5)}=C-C=N_{(10)}-$ (I) and $-N_{(5)}=C-C=N_{(1)}-$ (VII) chromophoric groups, can be established with reasonable certainty by ultraviolet and fluorescence spectroscopic methods.

Comparison of the ultraviolet, infrared, and fluorescence emission spectra of a number of substituted alloxazines with thoes of substances having fixed structures showed[11,13,16] that alloxazines as well as their 5-*N*-oxides (with the N→O bond)[15] have the alloxazine tautomeric structure of type (I). These data are consistent with the results of quantum-chemical calculations by the LCAO-MO method for a number of 7- and 8-substituted alloxazines and isoalloxazines, which indicate that the alloxazine structure (I) is energetically somewhate more favourable than the isoalloxazine structure (VII):[17]

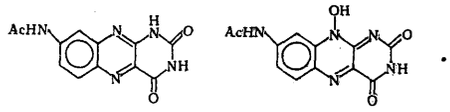


(I) (VII)

On the other hand, the *N*-hydroxy(isoalloxazine)-structure of type (VII) should be assigned to alloxazine 10-*N*-oxides and 5,10-di-*N*-oxides which lack substitutents at the 1-*N* atoms[13,15], in view of the similarity of the fluorescence and absorption spectra of such *N*-oxides with those of isoalloxazines (riboflavin and others):



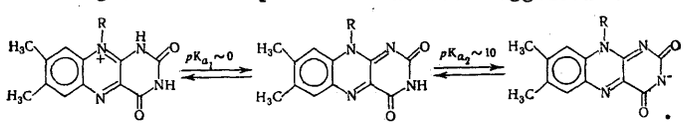
Comparison of the infrared spectra of 8-amino- and 8-dimethylaminoalloxazines established that amino-alloxazines exist in the amino- and not in the imino-form[11]. On the basis of a comparison of the absorption and fluorescence spectra with those of the 8-amino-1,3-dimethyl-alloxazine, which has a fixed structure, one may postulate that in alcoholic solutions 8-aminoalloxazines and their *N*-oxides have the alloxazine structure[14]. 8-Acylamino-alloxazines have the alloxazine structure of type (I) in alcoholic solutions and 8-acylaminoalloxazines *N*-oxides have the isoalloxazine structure of type (VII) with an N–OH group[14]:



Despite the existing extensive experimental results, hitherto no data are available on the interconversion of the tautomers and on the simultaneous presence of different tautomeric forms in solutions .

3. ACID–BASE PROPERTIES

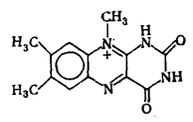
In the oxidised state flavin is weakly amphoteric; the following acid–base equilibrium has been suggested[18]:



The ionisation constants of riboflavin, 2′,3′,4′,5′-tetra-acetylriboflavin, riboflavin 5′-phosphate, and FAD have been determined from measurements of oxidation–reduction potentials[19], fluorescence[20,21] and absorption[19,22] intensities, and also by acid–base titration[23–25]. The following values have been obtained for riboflavin: pK_{a1} = 0,[26] −0.2,[19] and 0.1;[22] pK_{a2} = 9.5,[19] 10.2,[20] 9.95,[24] and 10.[23] The acid dissociation constants of alloxazine and its derivatives with substitutents in the benzene ring have been determined spectrophotometrically (by the method of Geissman and Davis); it was found that the pK_a for these compounds are satisfactorily consistent with the inductive effects of the substituents, the pK_a increasing in the following sequence[22]:

$$8\text{-Cl} < \text{H} < 7.8\text{-di-CH}_3 < 8\text{-NH}_2 .$$

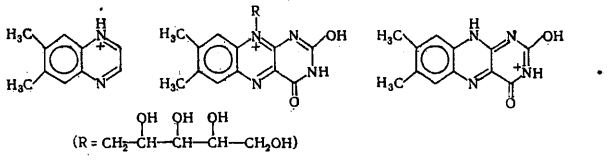
X-Ray diffraction analysis of the structures of riboflavin hydrobromide[27,28] and 10-methylisoalloxazine[29–32] established that in the crystalline state the flavin is protonated at 1-N and the cation has the following structure:



Protonation of the flavin in sulphuric acid results in a considerable hypsochromic shift of the long-wavelength

absorption band and a bathochromic shift of the band in the near ultraviolet, so that they merge into a single band at 390 nm.[7] Comparison of the ultraviolet spectrum of the unsubstituted flavinium cation with those of model alkylflavinium derivatives led Dudley et al.[7] to the conclusion that in aqueous solutions flavins are protonated at 1-N. This agrees with calculations[8,33] according to which the maximum π-electron density is localised at 1-N.

However, later calculations by the self-consistent field (SCF) method[12,34-37], the extended Hückel method[36,38], and also by the simple LCAO-MO method[17] of the distribution of electron density in substituted alloxazines and isoalloxazines established that the highest electron density is concentrated at the oxygen atoms of the carbonyl groups. It is noteworthy that the basicity of atoms of different chemical types is determined not only by electron density but also by the energy of formation of the X—H bond[38]. The similarity of the magnetic circular dichroism spectra of flavinium and 6,7-dimethylquinoxalinium cations has also been used as an argument in support of the proposed structure of the cation[39]; this structure does not conflict with the protonation of riboflavin at the oxygen of the $C_{(2)}$—O carbonyl group:

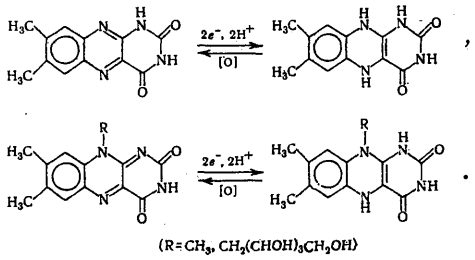


The structure of the monocations of alloxazines and isoalloxazines protonated at the oxygen atom in the 2-position has been proposed on the basis of the disappearance of one of the carbonyl absorption bands (1650 cm^{-1}) in 50% sulphuric acid[40]. The conclusion that alloxazines and isoalloxazines are *O*-protonated agrees with the available data on the protonation of lumazines—substances which are very similar to flavins[41].

Infrared spectroscopy established that, regardless of the nature of the cations, metal salts of flavins have the lactim structure in the solid state[11].

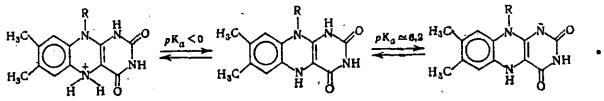
4. REDUCTION

Under aerobic conditions, both alloxazines and isoalloxazines exist in the fully oxidised form, since their oxidation-reduction potentials (for example, −0.21 V for riboflavin) are much lower than the potential of atmospheric oxygen (+0.82 V).[42] Certain reducing agents (sodium hydrosulphite, zinc in acetic or hydrochloric acid, hydrogen in the presence of the palladium or platinum catalyst, etc.) are capable of reducing these compounds under anaerobic conditions to the non-fluourscent 5,10- and 1,5-dihydro-forms[43-47]. In the presence of oxygen, the fully or partly reduced alloxazines and isoalloxazines are reoxidised:



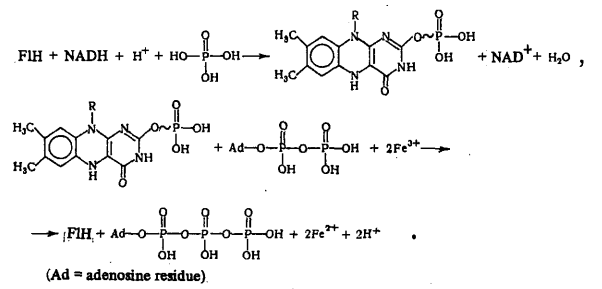
(R = CH_3, $CH_2(CHOH)_3CH_2OH$)

In dilute aqueous solutions the reduced flavins are colourless and in concentrated solutions they are orange-brown[48]. An equation has been formulated for the acid–base equilibria of flavins in the reduced form[18]:



Comparison of the ultraviolet spectra of 1,5-dihydrolumiflavin and its *NN*- and *OO*-dialkyl derivatives established that 1,5-dihydroflavins have the lactam structure, which has also been confirmed by the infrared spectra of a 5-acyl-1,5-dihydrolumiflavin and 1,5-dihydroriboflavin in chloroform[4,7]. However, in contrast to flavins, the conversion of 1,5-dihydroflavins into the lactim form does not involve a considerable energy increase, in agreement with the ease of alkylation at the oxygen atom[7].

It has been suggested that oxidative phosphorylation processes involving flavins (FlH) yield phosphate esters of the lactim form of 1,5-dihydroflavin, which transfer the phosphate group to ADP with formation of ATP:[49,50]

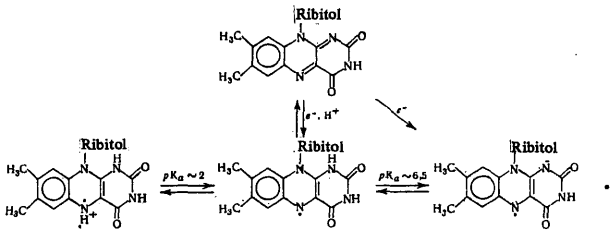


(Ad = adenosine residue)

Since alkylation at 3-N does not affect the acidity of 1,5-dihydroflavin (pK_a = 6,[18] 7.2 [51]), it is believed that the dissociable proton is at 1-N.

On the basis of the analysis of the absorption spectra at different pH, a non-polar molecular structure folded along the $N_{(5)}$—$N_{(10)}$ axis and having the "butterfly wings" conformation has been proposed for 1,5-dihydroflavin[7,10,18]. This non-planar structure of 1,5-dihydroflavins agrees satisfactorily with calculations by the Hückel[52] and self-consistent field[34] methods and has been reliably established by the X-ray diffraction analysis of 5-acetyl-3,7,8,10-tetramethyl-5,10-dihydroisoalloxazine[53] and also 5-acetyl-9-bromo-1,3,7,8,10-pentamethyl-1,5-dihydroisoalloxazine[54,55]; the planes of the benzene and pyrimidine rings are inclined at an angle of 140–160°.[53,56]

In contrast to the two-electron reduction of alloxazines and isoalloxazines discussed above, one-electron reduction of flavins, for example riboflavin, leads to the formation of free radicals—flavosemiquinones[19]:



However, one cannot be certain whether the flavosemiquinones are intermediates[57] in the two-electron reduction or whether they are formed in the interaction between the oxidised and reduced forms of flavins[58]:

$FlH + FlH_3 \rightleftharpoons FlH_2$ (green chloroflavin),

which is more likely, since flavosemiquinones exist in solution in equilibrium with other forms [7,59,60]; at pH 8–9 the concentration of radicals is minimal and the equilibrium is displaced towards the oxidised and reduced forms [61,62]. Fairly stable dimeric complexes are formed from products corresponding to different degrees of reduction [63,64]:

$FlH + Fl\dot{H}_2$ (green verdoflavin),

$Fl\dot{H}_2 + FlH_3$ (carmine red rhodoflavin hydrochloride).

Numerous studies have been made on the one- and two-electron reduction reactions of flavins and on the determination of the structure of flavin radicals [51,65–70].

The reduction of flavins in the dark takes place with only a few electron-donating substrates: NADH, NADPH, and their analogues [71–73], dihydrolipoic acid [74,75]; *cis*- and *trans*-dihydrophthalic acids and their esters [76], and mercaptans [77]. The reaction of flavins (FlH) with NADH and NADPH and with their analogues is of second order and that with dihydrolipoic acid is of first order; the reduction proceeds via a two-electron mechanism [73], rapid dissociation of one of the thiol groups preceding the reduction process. The reduction by dihydrophthalic acids and their esters is a second order reaction of pH > 9. [76] Flavins react with mercaptans according to the mechanism [73,77]

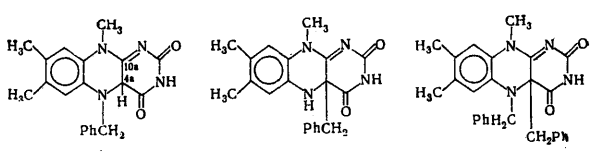
$$2RSH + FlH \rightarrow RSSR + FlH_3 .$$

Under anaerobic conditions, flavins are readily reduced photochemically by many substances which behave as electron donors: ethylenediaminetetra-acetic acid (EDTA) and aminoacids—cysteine, methionine, proline, histidine, etc. [78–83]

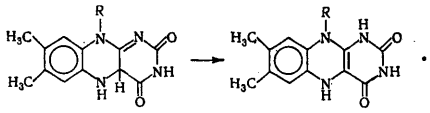
The hypothesis that water may function as the electron donor in the electrochemical reduction of flavins [84–87] appeared to be controversial [88,89], but certain experimental data obtained in recent years by manometric and mass-spectrometric methods indicate that water is decomposed in photochemical reactions involving riboflavin or lumiflavin [90–92]. Probably photoexcited flavin reacts with an external electron donor in the triplet state [93–95]. The ribityl side chain promotes the transition from the first excited singlet state of flavin to the triplet state [96,97]. In the absence of an external electron donor, its role is assumed by the ribityl side chain (in riboflavin), which is cleaved in this process [95].

It has been suggested that the direct cleavage of riboflavin to lumichrome can also proceed via the singlet excited state [98]. Different aspects of the nature of the first excited triplet and singlet states have been investigated [99–106].

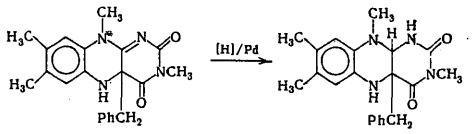
Apart from the reduction of alloxazines and isoalloxazines involving the nitrogen atom in the 1- and 5-positions, other types of reduction have been studied. Hemmerich and coworkers carried out the photochemical reduction of lumiflavin by phenylacetate ions and isolated mono- and di-benzyl derivatives of 4a,5-dihydrolumiflavin [82,107]:



It is possible that 4a,5-dihydroflavins of this kind are formed in biochemical reactions under the influence of hydride ions, for example, in the dehydrogenation of succinic acid to fumaric acid in the presence of succinate dehydrogenase [108]. It is also possible that in biochemical reactions the 4a,5-dihydroflavin is subsequently converted into the 1,5-dihydroflavin as a result of an intramolecular proton shift [108]:

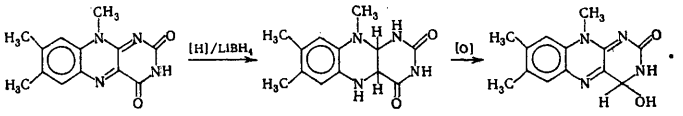


Catalytic hydrogenation of 4a-benzyl-3-methyl-4a,5-dihydrolumiflavin leads to further reduction and the formation of 4a-benzyl-3-methyl-1,4a,5,10a-tetrahydrolumiflavin [82]:



On reduction with sodium borohydride, flavinium salts are also converted into 1,4a,5,10a-tetrahydro-derivatives [109].

The reduction of isoalloxazines, for example, lumiflavins with lithium borohydride takes place via two pathways: under anaerobic conditions, 1,5-dihydrolumiflavin is formed (see above), i.e. the usual reduction product, while in the presence of atmospheric oxygen the reaction leads to the formation of 3,4-dihydrolumiflavin, which is resistant to reoxidation in the crystalline state and in solution in organic solvents, but undergoes photochemical oxidation to lumiflavin [110]. Possibly the initial product of this reaction is 1,4a,5,10a-tetrahydrolumiflavin, which is then partly oxidised and rearranges to 3,4-dihydrolumiflavin [110]:



The reduction by lithium borohydride involving the carbonyl group in the 4-position has also been observed for alloxazines, for example 1,3,7,8-tetramethylalloxazine, which is converted into the 3,4-dihydro-derivative [111].

It is remarkable that D- and L-aminoacid oxidases reduced with lithium borohydride do not lose their biocatalytic activity, which suggests that the dehydrogenation of the substrate does not involve the 4-position of the flavin prosthetic group [112].

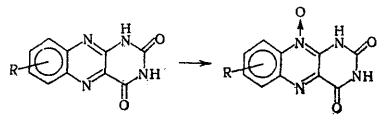
Under severe catalytic hydrogenation conditions, the benzene ring in the isoalloxazine molecule is reduced with formation of an octahydroisoalloxazine [113].

5. OXIDATION

Isoalloxazines, including riboflavin, are resistant to oxidising agents, even when these are as strong as nitric acid, hydrogen peroxide, and bromine, but are oxidised by chromic acid and potassium permanganate [1,2]. When riboflavin is oxidised with lead tetra-acetate or periodic acid, the side chain between adjacent hydroxy-groups is cleaved and 7,8-dimethyl-10-formylmethylisoalloxazine is formed [114,115]; the same compound is obtained on photolysis.

Petering and Giessen [116,117] oxidised 8-chloroalloxazine with 30% hydrogen peroxide in 88% formic acid and ascribed the structure of 8-chloroalloxazine 5,10-di-*N*-oxide to the product [116]. Later Berezovskii and Aksel'rod

showed[118,119] that in the oxidation of the 8-chloroalloxazine, alloxazine, 7-methylalloxazine, 7,8-dimethylalloxazine (lumichrome), 1,3-dimethylalloxazine, and others with 30% hydrogen peroxide in 88% formic acid, peracetic acid, and monopersulphuric acid, only the corresponding alloxazine mono-*N*-oxides can be identified unambiguously at the instant of formation:



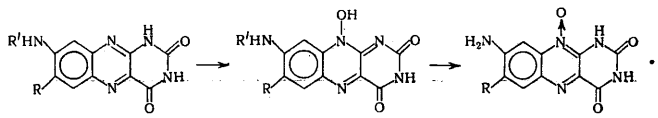
Alloxazine *N*-oxides have the 10-*N*-oxide structure[118], since the oxidation of the nitrogen atoms in the 1- and 3-positions of the pyrimidine ring and in the 5-position of the pyrazine ring in the molecule is hindered by the oxo-groups in the 2- and 4-positions.

It is noteworthy that the unambiguous course of the oxidation of the pyrazine ring of 8-chloroalloxazine agrees with the fact that the pyrazine ring of 6-chloroquinoxaline also yields mainly the mono-*N*-oxide on oxidation[120]. Alkaline cleavage of 8-chloroalloxazine *N*-oxide followed by decarboxylation yielded the corresponding 7-chloro-2-hydroquinoline 1-*N*-oxide[118].

The formation of 10-mono-*N*-oxides is consistent with calculations according to which the excess electronic charge at the nitrogen atom in the 5-position of the alloxazine rings is much lower than at the nitrogen atom in the 10-position[17,121].

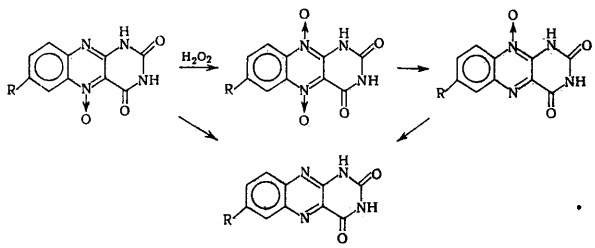
It is striking that derivatives with a nitro-group in the 9-position (for example 7,9-dinitroalloxazine and 6,9-dinitrolumichrome) are not oxidised with hydrogen peroxide and do not give rise to *N*-oxides[122]. On the other hand, 7-methyl-6-nitroalloxazine is oxidised with formation of the 10-*N*-oxide[122].

Aminoalloxazines could not be oxidised unambiguously with hydrogen peroxide to give the corresponding 10-*N*-oxides. This was achieved via the acyl derivatives of 8-aminoalloxazines. The corresponding *N*-oxides of amino- and acylamino-alloxazines were synthesised in this way[14]:



(R = H, CH_3; R' = CH_3CO, C_6H_5CO, $CH_3C_6H_4SO_2$)

The 5-*N*-oxides of alloxazine, 7-chloro-, 7-methyl-, and 1,3-dimethylalloxazine, obtained by Goldner's method[123-125] in which the corresponding nitrosouracils are cyclised, were oxidised with hydrogen peroxide in formic acid at 40°C to the corresponding alloxazine 5,10-di-*N*-oxides[15]:

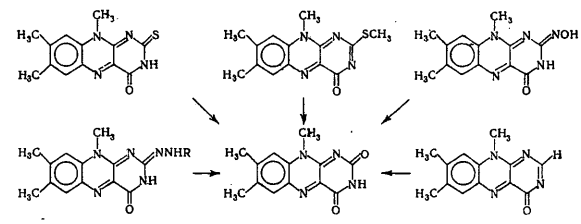


A characteristic feature of alloxazine 5,10-di-*N*-oxides is the non-equivalent stabilities of the *N*-oxide groups, which corresponds to the different basicities of the nitrogen atoms in the 5- and 10-positions of the alloxazine rings.

Thus, on heating 7-methylalloxazine 5,10-di-*N*-oxide in formic acid, the oxygen atom and the hydrogen atom in the 5-position are split off and 7-methylalloxazine 10-*N*-oxide is formed[15]. Under the same conditions, alloxazine 5-*N*-oxides are deoxygenated with formation of non-oxidised alloxazines.

The $N_{(10)} \rightarrow O$ bond is much stronger than $N_{(5)} \rightarrow O$, but prolonged boiling of alloxazine 10-mono-*N*-oxides in formic acid leads to complete deoxygenation with formation of alloxazines[15].

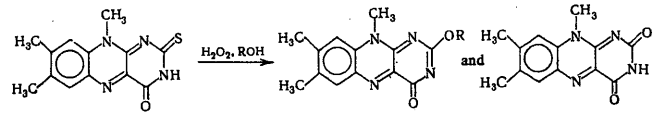
Whereas isoalloxazines, for example lumiflavin, are resistant to the action of hydrogen peroxide and other oxidants, the 2- and 4-derivatives (2- and 4-thiolumiflavins, thio- and imino-ethers, oximes, hydrazones, semicarbazones, and also 2- and 4-deoxy-derivatives) can be readily oxidised with atmospheric oxygen or dilute hydrogen peroxide to the flavin oxo-form[5,6,126-130]:



(R = H, COC_5H_4N, $CSNH_2$, $C_6H_4NO_2$)

2-Iminolumiflavin, which is not oxidsed by weak oxidising agents, is an exception[126].

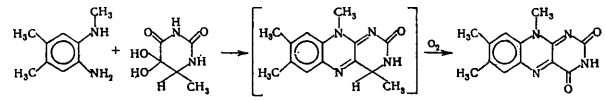
It is noteworthy that, when hydrogen peroxide is allowed to react with 2-thiolumiflavin in alcohol, the product is not 2-deoxylumiflavin, postulated previously[128], but a mixture of 2-*O*-alkyllumiflavin and lumiflavin, which can be readily separated[6]:



2- and 4-Deoxylumiflavins are unstable and are oxidised to lumiflavin at the instant of formation[127]. However, when nitrous acid, which behaves as a "radical-scavenger",[131] is employed, it is possible to obtain a stable 2-deoxylumiflavin in the form of the perchlorate[6]. It can be converted into lumiflavin by photochemical oxidation[6].

4-Deoxyalloxazine and 4-deoxylumiflavin, obtained by the condensation of the corresponding diamines with isodialuric acid, are even less stable than the 2-deoxy-isomers; they exist in the form of hydrates and at the instant of formation are oxidised by atmospheric oxygen to alloxazine and lumiflavin respectively[132].

In exactly the same way the condensation of *o*-diamines with 6-methylisodialuric acid yields lumiflavin as the sole reaction product. It is interesting to note that in this case the C–C bond is readily cleaved (at room temperature)[132]:



The introduction of nucleophilic substitutents into the benzene ring of the isoalloxazine molecule enhances the resistance of 2-deoxyisoalloxazines and 2-thioisoalloxazines to oxidation. Thus 8-acetamide-2-deoxynorlumiflavin is not oxidised by atmospheric oxygen or even weak oxidising agents[133].

In contrast to 2-thiolumiflavin, 8-amino-2-thionorlumiflavin is not appreciably susceptible to the action of atmospheric oxygen. Only the reaction with hydrogen peroxide results in a slow formation of the 2-oxo-group and the liberation of sulphur [133].

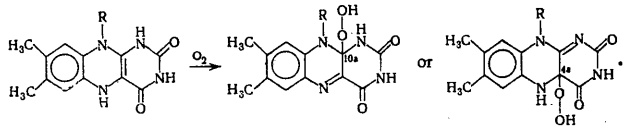
In contrast to flavins (FlH), 1,5-dihydroflavin (FlH_3) are readily oxidised even by atmospheric oxygen with the possible involvement in the reaction with oxygen of the free radicals $F\dot{I}H_2$ which are always present in a small amount in the reduced flavin [134]:

$$FlH + FlH_3 \rightleftharpoons 2F\dot{l}H_2,$$
$$2F\dot{l}H_2 + O_2 \rightleftharpoons 2FlH + H_2O_2.$$

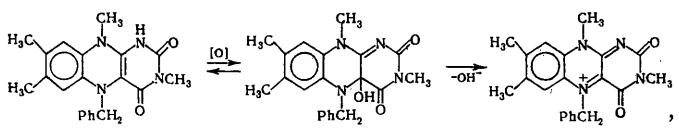
However, it is more likely that 1,5-dihydroflavins rather than the free radicals (flavosemiquinones) react with oxygen [56,135]. A spectrophotometric study of the kinetics of their oxidation established that the rate of reaction increases with the formation of the oxidised flavin and therefore the reaction may be regarded as autocatalytic [134]. Since 1,5-dihydroflavin is usually present in a non-coplanar conformation [7], it probably reacts with oxygen after transition to a planar vibrationally excited state as a result of the formation of a π-complex between the oxidised and reduced flavins [56]. Alkylation of 1,5-dihydroflavin at the nitrogen atom in the 1-position stabilises the 1-coplanar state, hinders the conformational transition of the molecule to the planar state, and sharply increases its resistance to oxidation by atmospheric oxygen [7,136].

In flavoproteins the coplanar structure of the dihydroflavin may arise as a result of the formation of a complex with adenine or tryptophan [56].

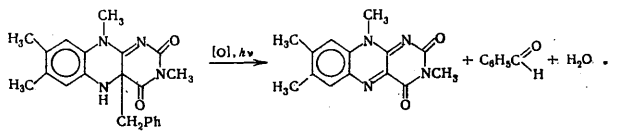
In the oxidation of 1,5-dihydroflavins and 5,10-dihydroalloxazines, the intermediates are hydroperoxides with the hydroperoxy-group in the 10a- [137-140] or 4a-position [140], the 4a-position being apparently more reactive [82,107,141]:



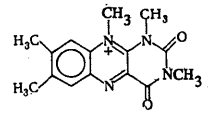
5,10-Dihydroalloxazines react with their hydroperoxides to form 10a-hydroxy-1,10a-dihydroalloxazines [142]. Whereas 5-benzyl-3-methyl-1,5-dihydrolumiflavin is reversibly oxidised in the dark via the intermediate formation of a free radical to a carbinol base, which at pH < 4 splits off a hydroxide ion and is converted into a quaternary 5-benzyl-3-methyl-lumiflavinium salt:



its isomer, 4a-benzyl-3-methyl-4a-5-dihydrolumiflavin, undergoes an irreversible photochemical oxidation with simultaneous cleavage of the C–C bond and the formation of 3-methyl-lumiflavin [82,107]:

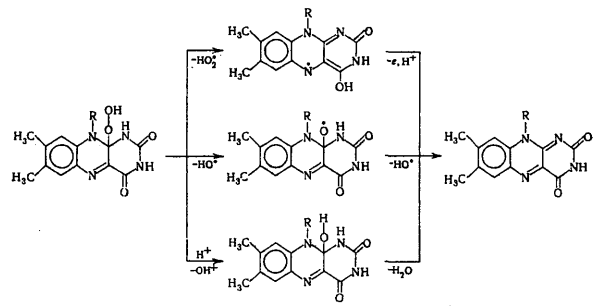


Quaternary flavinium salts are formed by the oxidation of 1,3-dialkyl-1,5-dihydrolumiflavins and their 5-acetyl derivatives with nitrous acid [136]:



O-Alkyl derivatives of 5-acetyl-1,5-dihydrolumiflavin react in the same way. The planarity of the dihydroflavin molecule in the oxidation reaction may be achieved by the intermediate formation of a free radical [136].

The prosthetic group of flavoproteins of various types has a specific protein environment and this probably determines the nature of electron transfer from the reduced form of the flavin either directly to oxygen (oxidases) or to an intermediate one-electron acceptor (dehydrogenases) and is reflected in their behaviour in the reaction with sulphite [140]. Thus oxidases form with sulphite an adduct via the nitrogen atom in the 5-position in the flavin, while dehydrogenases do not react with sulphite [140,143]. The differences between the reactions of flavoproteins of different types (dehydrogenases and oxidases) may be related also to the subsequent behaviour of dihydroflavin hydroperoxides, which can be cleaved in different ways [140]:



A similar series of reactions may be expected for the adduct inolving the 4a-position [140].

In accordance with the mode of cleavage of dihydroflavin hydroperoxides, dehydrogenases react predominantly with formation of HO_2 and an intermediate flavin radical [140]; it has been established that the majority of enzymes of this type form free Flavin radicals on reaction with oxygen, which then rapidly interact with one-electron acceptors [144,145]. A characteristic feature of the dihydro-forms of oxidases is reaction involving the formation of flavins and hydrogen peroxide [146].

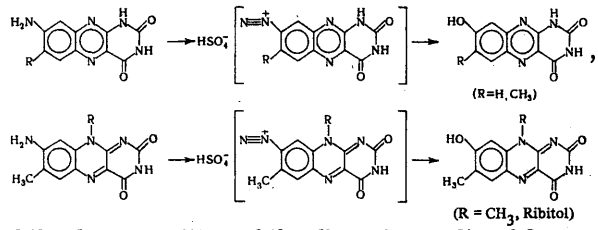
6. NUCLEOPHILIC SUBSTITUTION

8-Chloroalloxazine does not react with aliphatic and aromatic amines, pyridine, and morpholine on heating [147]. 8-Halogeno-substituted isoalloxazines behave differently—they readily react with nucleophilic agents such as monoethanolamine, diethanolamine, piperidine, and morpholine on heating in the presence of their excess or on carrying out the reaction in dimethylformamide (DMF) solution [147,148]. 8-Hydroxyethylaminonorlumiflavin was obtained in this way from 8-chloronorlumiflavin [148].

The lesser reactivity of 8-chloro-7,10-dimethylisoalloxazine compared with 8-chloro-10-phenylisoalloxazine can be accounted for by the influence of the electron-donating CH_3 group in the 7-position [147]. The chlorine atom in the 8-position of the isoalloxazine ring is also substituted

by a methoxy-group. Thus 8-chloronorlumiflavin reacts with sodium methoxide to form 8-methoxynorlumiflavin[148].

8-Hydroxyalloxazines and hydroxy-analogues of natural flavins—8-hydroxynorlumiflavin and 8-hydroxynor-riboflavin[149,150]—have been synthesised by the diazotisation of sulphuric acid solutions of 8-aminoalloxazines, their 9-azo-derivatives, and also 8-aminoisoalloxazines with subsequent hydrolytic decomposition of the diazonium salts[149,150]:



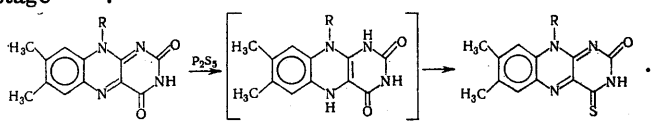
(R=H, CH_3)

(R = CH_3, Ribitol)

If the decomposition of the diazonium salts of 8-aminoisoalloxazines is carried out under the conditions of the Sandmeyer reaction, the corresponding 8-halogenoisoalloxazines are formed. 8-Chloronorlumiflavin[133], 8-chloronor-riboflavin, and 8-bromonorlumiflavin were obtained in this way[151]. It was shown that dimethyl sulphoxide promotes the nucleophilic substitution of the diazo-group in the 8-position of isoalloxazine by a halogen[151].

The reaction of alloxazines and isoalloxazines with nucleophilic agents usually does not entail substitution at the 2-C and 4-C carbon atoms of the pryimidine ring.

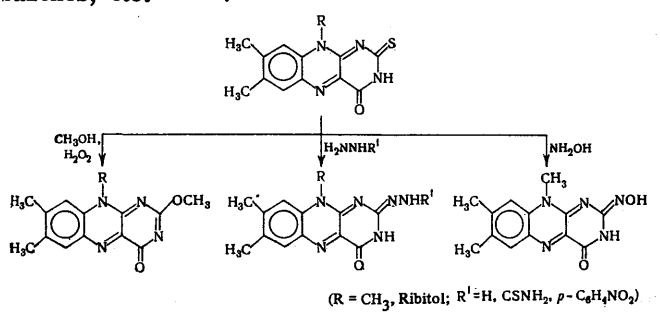
The introduction of sulphur into the 4-position of the isoalloxazine rings in the reaction of lumiflavin and 2′, 3′, 4′, 5′-tetra-acetylriboflavin with phosphorus pentasulphide in pyridine with formation of 4-thiolumiflavin[127] and 2′, 3′, 4′, 5′-tetra-acetyl-4-thioriboflavin[152] constitutes an exception. In this case there is probably initial reduction by sulphide and then substitution in the 1,5-dihydroflavin stage[10,127]:



(R = CH_3, $CH_2(CHOAc)_3CH_2OAc$)

A similar selective substitution for sulphur takes place also in the purine series[153]. The 2-oxogroup is resistant to the action of phosphorus pentasulphide.

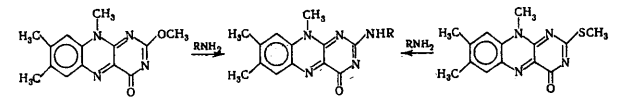
Nucleophilic substitution in the 2- and 4-positions of flavins occurs only with their derivatives: 2- and 4-thioflavins and *O*- and *S*-alkyl derivatives. 2-Thiolumiflavin and 2-thioriboflavin readily react with nucleophilic agents (the alkoxy-group, hydrazine hydrate, *p*-nitrophenylhydrazine, semicarbazide, thiosemicarbazide, and hydroxylamine) with formation of *O*-alkyl derivatives of oximes, hydrazones, semicarbazones, thiosemicarbazones, etc.[5,10,128]:



(R = CH_3, Ribitol; R′=H, $CSNH_2$, *p*-$C_6H_4NO_2$)

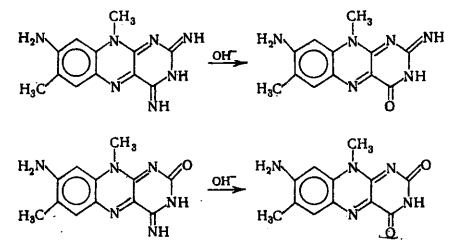
Similar reactions have also been described for 4-thiolumiflavin[5].

2-*O*-Alkyl derivatives and also 2- and 4-thioethers react with ammonia and amines (aniline, monoethanolamine, morpholine, and others) with formation of imines and iminoethers[5,10]:

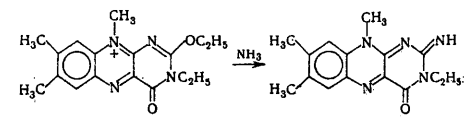


(R=H, C_6H_5, CH_2CH_2OH, $(CH_2)_5N(CH_3)_2$)

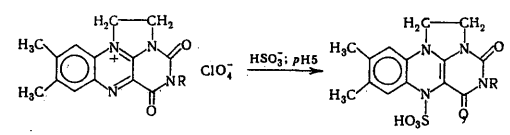
The imino-group in the 4-position is hydrolysed selectively under mild conditions. Thus 8-aminonorlumiflavin-2,4-di-imine is converted after only a brief treatment with warm alkali into the 3-monoimine, which is much more resistant to alkali; the 4-monoimine readily gives rise to the dioxo-compound under similar conditions[133]:



When nitrogen-containing heterocycles are converted into quaternary salts, the attack by nucleophilic agents is facilitated, as happens for nucleophilic substitution of pyridinium, pyrylium, thiapyrylium, and other cations[154]. Dudley and Hemmerich showed that 2-*O*,3-*N*-dialkyllumiflavinium salts react with ammonia via a simple addition–elimination mechanism with formation of lumiflavinimine[136]:



When sodium bisulphite is allowed to react with flavinium salts having substituted nitrogen atoms in the 1- and 3-positions, the nucleophilic bisulphite ion adds to the 5-position with formation of a dihydroflavin-sulphite adduct[155]:



The sulphite adduct of the 1,3,7,8,10-pentamethylisoalloxazinium salt is less stable and was not obtained in a pure form, but in this case too the sulphite anion probably adds to the 5-position[155].

It has been established that sulphite ions form adducts with the flavin prosthetic groups of many flavoproteins: glucose oxidase[143], D- and L-aminoacid oxidases, hydroxynitrile lyase, lactate oxidase, and glycolate oxidase[140], i.e. with enzymes of the oxidase type which transfer hydrogen directly to molecular oxygen. Flavin dehydrogenases, which transfer hydrogen to a specific acceptor, do not react with the sulphite anion[140]. This is an interesting case of correlation between the chemical reactivity of the flavin prosthetic group of flavoproteins of different types and their biochemical functions.

7. ELECTROPHILIC SUBSTITUTION IN THE BENZENE RING

Electrophilic substitution of the benzene ring in compounds of the alloxazine and isoalloxazine series was unknown until recently. Direct introduction of various substitutents gives rise to many possibilities for the structural modification of the molecules of riboflavin and related compounds, since the possibility of obtaining benzene ring-substituted alloxazines and isoalloxazines is greatly restricted by the limitations of the direct syntheses[1,2].

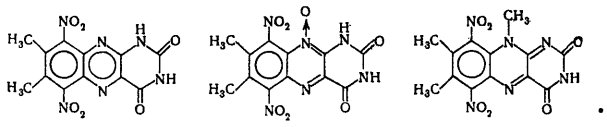
It has been established by LCAO-MO calculations[17] that the introduction of electron-donating substituents (CH_3, Cl, OH, NH_2, etc.) into the 7- and 8-positions of the alloxazine and isoalloxazine rings give rise to changes in the distribution of electron density (q_π) and peripheral electron density (f_π) mainly in the benzene component of the molecule, the type of distribution of q_π and f_π being largely similar for alloxazines and isoalloxazines.

Quantum-chemical calculations show that when either the static "isolated molecule" approximation (active centre characterised by the maximum value of q_π) or the dynamic approximation assuming localisation (the localisation energy LE is a minimum at the active centre) is employed[156] for alloxazine, lumichrome, riboflavin, and 8-amino- and 8-hydroxy-alloxazines, the electrophilic attack may be directed primarily to the carbon atom in the 9-position or to the 6-position in 7-methylalloxazine. Apart from the 9-position, the 7-position is reactive in alloxazine, 8-aminoalloxazine, and 8-hydroxyalloxazine and the 6-position is reactive in lumichrome and riboflavin[17] (see Table). These conclusions are fully consistent with the experimental data.

Berezovskii and Aksel'rod studied the nitration of alloxazines[122,157], their 10-*N*-oxides[122], and isoalloxazines[122] under conditions such that the reaction was known to have an electrophilic mechanism[158].

In the nitration of alloxazine with fuming nitric acid in the presence of concentrated sulphuric acid at 20°C, the product is a mixture of 7- and 9-mononitro-derivatives in proportions of 2:3. Nitration of alloxazine under severe conditions—with fuming nitric acid in 25% oleum at 70°C—leads to 7,9-dinitroalloxazine, which is formed also when the 7- and 9-mononitro-compounds are nitrated under the same conditions. In accordance with the directing effect of the first nitro-group, the second nitro-group substitutes the hydrogen atom in the benzene ring in the meta-position[157]. Nitration of 7-methylalloxazine and its 10-*N*-oxide with nitrating mixture at 20°C yields only the 6-nitro-derivatives[122]. Selective nitration in the 6-position is consistent with the lower localisation energy for 7-methylalloxazine (see Table) compared with the 8-position.

Nitration of 7,8-dimethylalloxazine, its *N*-oxide, and lumiflavin with fuming nitric acid in the presence of concentrated sulphuric acid leads unambiguously to the formation of the 6,9-dinitro-compounds[122]:



Under these conditions, mononitro-derivatives could not be obtained. Possibly the methyl groups in the 7- and 8-positions greatly enhance the nucleophilic properties of the 6- and 9-positions, which become equivalent and the nitration involves them both at the same rate. Otherwise the reaction would have terminated at the stage corresponding to the formation of the mononitro-compound (the 6- or 9-nitro-derivative) which is incapable of undergoing further nitration. Indeed it was found that 7,8,10-trimethyl-9-nitroisoalloxazine (obtained by direct synthesis) remains unchanged under the conditions of the nitration reaction[122].

McCormick[159] achieved the bromination and chlorination of lumiflavin and 2′,3′,4′,5′-tetra-acetylriboflavin in the 9-position by treatment with *N*-halogenosuccinimide in trichloroacetic acid in the presence of catalytic amounts

The activity indices of the 7- and 8-substituted alloxazines and isoalloxazines.

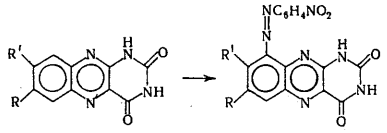
of benzoyl peroxide. Possibly the flavin reacts with the halogen in a protonated form via an electrophilic mechanism [159], but, since benzoyl peroxide is used as a catalyst, the possibility of a radical mechanism cannot be ruled out.

Berezovskii and Tul'chinskaya and coworkers studied the azo-coupling of 8-amino- and 8-hydroxy-alloxazines with diazotised aromatic amines [150]. When 8-amino-alloxazines were coupled with phenyl- and *p*-nitrophenyl-diazonium chlorides in aqueous DMF at pH 2–3, 8-amino-9-arylazoalloxazines were obtained and in the azo-coupling of 8-hydroxyalloxazines in a weakly alkaline medium the products were 9-arylazo-8-hydroxyalloxazines:



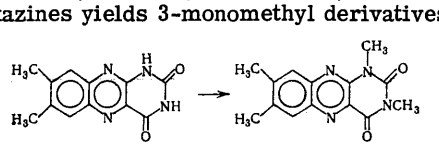
(R = H, CH_3; R' = OH, NH_2)

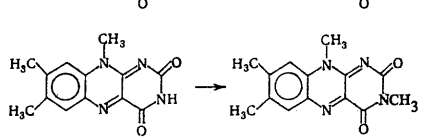
The finding that the azo-coupling of 8-amino and 8-hydroxy-alloxazines involves the 9-position of the alloxazine ring and not the 7-position is consistent with the calculated reactivity indices (q_π, f_π, LE; Table).

The attempt to carry out the azo-coupling of 8-amino-norlumiflavin and 8-aminonor-riboflavin with *p*-nitrophenyldiazonium chloride was unsuccessful, which, apart from steric factors, may be accounted for also by a reduced reactivity of the 9-position compared with 8-aminoalloxazine (a decrease of the peripheral electron density and a higher localisation energy; Table).

8. ALKYLATION

Alloxazines and isoalloxazines are alkylated in both oxidised and reduced forms. Alkylation of alloxazines with methyl iodide [44,160], diazomethane [161], or dimethyl sulphate [162] in DMF in the presence of potassium carbonate [4] involves the ring nitrogen atoms of the pyrimidine ring and leads to 1,3-dimethyl derivatives, while methylation of isoalloxazines yields 3-monomethyl derivatives [4,160,161]:



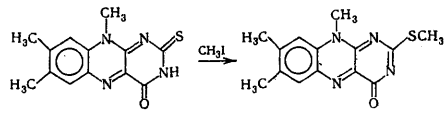


2′,3′,4′,5′-Tetra-acetylriboflavin is alkylated similarly with formation of, for example, the 3-methyl, 3-ethyl, and 3-benzyl tetra-*O*-acetylriboflavins [44]. 8-Aminonor-lumiflavin is methylated by methyl iodide in an alkaline medium in the 3-position with 8-amino-3-methylnorlumi-flavin as the product [133].

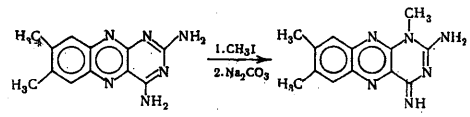
Like isoalloxazines, alloxazine *N*-oxides are not alkylated at the nitrogen atom in the 1-position. When alloxazine 10-*N*-oxide was methylated with methyl iodide or dimethyl sulphate in an alkaline medium, only 3-methyl-alloxazine 10-*N*-oxide was obtained [13].

Compounds with various substituents at 1-N and 3-N can be obtained by further alkylation of monoalkyl-substituted alloxazines [111,160].

When 2- and 4-thiolumiflavins are treated with alkylating agents (methyl iodide in chloroform), they are alkylated to the corresponding thioethers and the reaction with the 2-thio-derivative takes place also without a basic catalyst [5], for example:



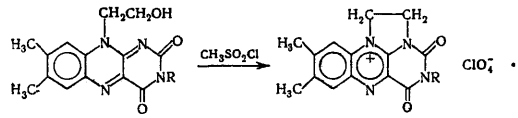
On the other hand, 2,4-diamino-7,8-dimethylbenzo[*g*]-pteridine is methylated by methyl iodide in boiling cellosolve with formation of a quaternary salt, which on treatment with aqueous sodium carbonate solution is converted into the 1-*N*-methyl derivative [163]:



Berezovskii and coworkers studied the alkylation of 8-aminoalloxazine and 8-aminoisoalloxazine with ethylene oxide [164]. Hydroxyethylation of an aqueous suspension of sodium derivatives of 8-aminoalloxazine, 8-aminonorlumi-chrome, and 8-dimethylaminoalloxazine yielded on heating 3-(2′-hydroxyethyl)-8-(2′-hydroxyethylamino)alloxazine, 3-(2′-hydroxyethyl)-8-(2′-hydroxyethylamino)norlumi-chrome, and 3-(2′-hydroxyethyl)-8-dimethylaminoallox-azine respectively, the product obtained from 8-aminonor-lumiflavin being 3-(2′-hydroxyethyl)-8-aminonorlumiflavin.

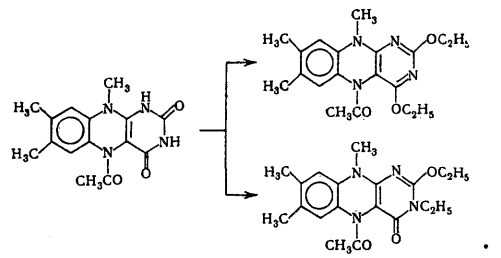
3-(2′-Hydroxyethyl)-8-(2′-hydroxyethylamino)alloxazine is readily dealkylated by 70% sulphuric acid with formation of 8-aminoalloxazine [164].

It has been established for 10-(2′-hydroxyethyl)-7,8-dimethylalloxazine [155] that isoalloxazines can undergo intramolecular alkylation in the 1-position in the presence of methanesulphonyl chloride, DMF, and potassium carbonate with formation of quaternary flavinium salts:



A similar intramolecular alkylation at the 1-N-position has been observed also for 10-formylmethyl-7,8-dimethyl-isoalloxazine [7,26].

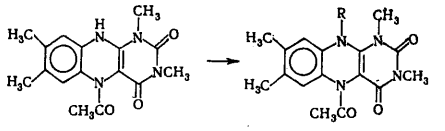
In contrast to flavins, 1,5-dihydroflavin reacts with electrophilic agents at 2-O, 4-O, 3-N, and 5-N. Owing to the high sensitivity of the dihydro-form to oxygen, stabilised 5-acetyl-1,5-dihydro-compounds were employed [4]; they are readily alkylated with formation of a mixture of 2-O, 4-O, and 2-O, 3-N-dialkyl derivatives; the nitrogen atom in the 1-position of dihydroalloxazines is not alkylated [4]:



The finding that 5-acetyl-1,5-dihydrolumiflavin is not alkylated at the 1-nitrogen atom can be accounted for by the enhanced electron density at the carbonyl oxygen in the $C_{(2)}$—O^{136} group and not by the steric hindrance due to the substituent in the 10-position [4].

5,10-Dihydroalloxazines behave differently. Thus alkylation of 5-acetyl-5,10-dihydroalloxazine in DMF in the presence of potassium carbonate yields a complex mixture of products of alkylation at 1-N, 3-N, or 10-N which contains, after acid hydrolysis and oxidation, 1- and 3-monomethylalloxazines, 1,3-dimethylalloxazine, and a small amount of 3,10-dimethylisoalloxazine [4].

If one begins with 5-acetyl-1,3-dimethyl-5,10-dihydroalloxazine, 10-alkylation takes place with formation of 5-acetyl-10-alkyl-1,3-dimethyl-1,5-dihydroisoalloxazines [136]:

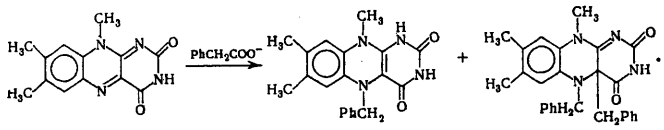


(R = CH_3, C_2H_5, $CH(CH_3)_2$, $CH_2COOC_2H_5$, $CH_2C_6H_5$)

The course of the further conversion of this compound into an oxidised form of isoalloxazine is unknown.

1,3,10-Trialkyl-1,5-dihydroflavins are alkylated in the 5-position by alkyl halides in DMF in the presence of potassium carbonate [136].

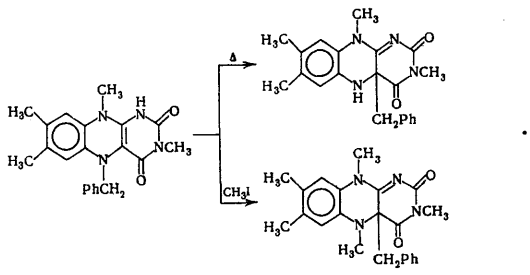
Hemmerich and coworkers studied the reductive photochemical alkylation of flavins on treatment with phenylacetate ions which are decarboxylated in this process [141], the residue formed entering into the 5- or 4a-position with formation of mono- and di-benzyldihydro-derivatives [82,107,141]:



Isolumiflavin (6,7,10-trimethylisoalloxazine) gives only the 4a-benzyldihydro-derivatives, evidently owing to steric hindrance [82].

The reductive photochemical alkylation of 5-benzyl-lumiflavin on treatment with cyclopentadiene, thiolane, and dialkyl sulphides also involves the 4a- or 5-position [165,166].

On fusion (without access of air), 5-benzyl-1,5-dihydrolumiflavin rearranges to 4a-benzyl-4a,5-dihydro-lumiflavin [82]. A similar rearrangement occurs also in the methylation of 5-benzyl-1,5-dihydrolumiflavin with methyl iodide, the rearrangement being accompanied by methylation in the 5-position [82]. Under the same conditions, the isomeric 4a-benzyl-4a,5-dihydrolumiflavin is not alkylated in the 5-position:

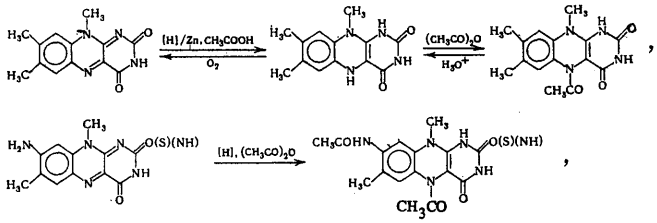


Flavin radicals alkylated in the 5-position were obtained by alkylating a mixture of oxidised and reduced flavin with alkyl halides in the presence of triethylamine [70].

9. ACYLATION

In contrast to alkylation, acylation of alloxazines and isoalloxazines takes place selectively only with their dihydro-derivatives at the 5-nitrogen atom and leads to the formation of 5-acyl-5,10-dihydroalloxazines and 5-acyl-1,5-dihydroisoalloxazines and their derivatives [127]. 5,10-Dihydroalloxazines and 1,5-dihydroisoalloxazines, which are unstable and sensitive to atmospheric oxygen, are thereby stabilised [4].

The acylation reaction is carried out simultaneously with reduction by adding zinc dust to a suspension of the alloxazine or isoalloxazine in a 1:1 mixture of acetic acid and an organic acid anhydride. Hemmerich and coworkers obtained in this way 5-acetyl-1,5-dihydrolumiflavin [127,133], 8-acetamido-5-acetyl-1,5-dihydronorlumiflavin, and its 2-thio- and 2-imino-analogues:



as well as 5-acetyl-5,10-dihydroalloxazine, its 1,3-dimethyl derivative [4], 5-acetyl-1,5-dihydro-2-thiolumiflavin [127], 2′,3′,4′,5′,5-penta-acetyl-1,5-dihydroriboflavin [4,167], etc.

On reductive acetylation, quaternary flavinium salts can be converted into the corresponding 5-acetyl-1,5-dihydro-derivatives [155].

The acetyl group in the 5-position inhibits reoxidation but at 50°C and in the presence of atmospheric oxygen it is readily hydrolysed by hydrochloric acid [4,127,133]. Simultaneous reduction and formylation with zinc dust and formic acid are achieved similarly and result in the formation of 5-formyl-5,10-dihydroalloxazine, 5-formyl-1,5-dihydrolumiflavin [4], and 4a-benzyl-5-formyl-4a,5-dihydrolumiflavin [82].

When riboflavin is treated with chlorocarbonic ester in an alkaline solution and is simultaneously reduced with sodium hydrosulphite, only the 5-position is acylated, the primary and secondary hydroxyls in the ribityl chain not being involved; the reaction leads to the formation of 5-ethoxycarbonyl-1,5-dihydroriboflavin [167]. However, when riboflavin is treated with benzoyl chloride in alkaline solution with simultaneous reduction, the product is 2′,3′,4′,5′,5-pentabenzoyl-1,5-dihydroriboflavin [167].

Brustein and Hemmerich showed that, when 3-methyl-lumiflavin reacts with pyruvic acid under aerobic conditions under illumination, reductive acetylation takes place with formation of 5-acetyl-3-methyl-1,5-dihydrolumiflavin [168]. Under anaerobic conditions, photochemical reduction predominates, leading to the formation of 3-methyl-1,5-dihydrolumiflavin [168].

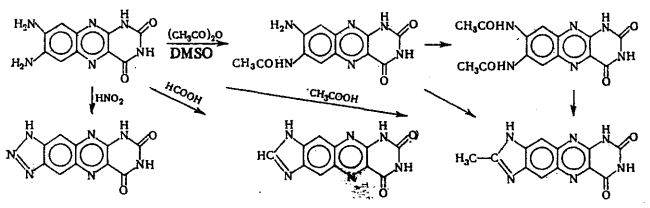
A similar reductive acylation reaction is observed in biological catalysis by flavoproteins, which are reduced by pyruvate with formation of the corresponding adduct [169]. Possibly the first stage of the flavin-dependent dehydrogenation is such "group transfer", in contrast to "species transfer" (hydride ion transfer) known previously [168]. This hypothesis is confirmed by the finding that certain flavoproteins do not exhibit oxidation-reduction properties [170], for example hydroxynitrile lyase.

10. REACTION OF AMINO-SUBSTITUENTS

The amino-groups in the benzene component of the alloxazine and isoalloxazine systems are nucleophilic centres and can react with electrophilic agents. Beresovskii and coworkers studied the acylation of 8-amino-alloxazines [14]. This showed that the weakly basic amino-group of 8-aminoalloxazines does not react with an excess of acetyl chloride under mild conditions. However, after these compounds had been heated for 20 h with acetic anhydride in pyridine at 60°C, their acetyl derivatives were obtained. 8-Benzoyl- and 8-tosyl-aminoalloxazines were synthesised by acylating 8-aminoalloxazine and 8-amino-7-methylalloxazine with benzoyl chloride and toluene-*p*-sulphonyl chloride [14].

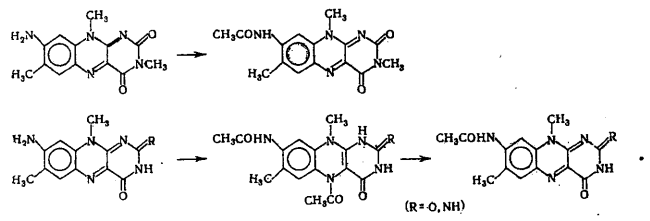
In a study of the acetylation of 7,8-diaminoalloxazine, it was shown that the reaction proceeds in steps owing to the different reactivities of the exocyclic amino-groups [171].

It proved possible to select conditions ensuring the monoacylation of 7,8-diaminoalloxazine with acetic anhydride in dimethyl sulphoxide (DMSO) at 20°C; the structure of 7-acetamido-8-aminoalloxazine was attributed to the monoacyl derivative [171]. Further acetylation yields 7,8-diacetamidoalloxazine:

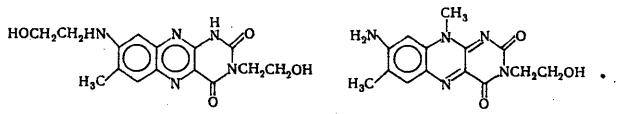


On heating, the acetyl derivatives of 7,8-diamino-alloxazine show a marked tendency to undergo the imidazole cyclisation. The corresponding imidazo-alloxazines are also obtained on refluxing 7,8-diamino-alloxazine with acetic and formic acids: interaction with nitrous acid gives rise to the triazolo[4,5-i]-alloxazine system [171].

On refluxing with a mixture of acetic anhydride and acetic acid, 8-aminoisoalloxazines are acetylated to the 8-acetamido-derivatives [133], which can also be obtained under the conditions of reductive acetylation with subsequent selective hydrolysis of the acetyl group at the 5-N nitrogen atom of the 1,5-dihydro-compound. Hemmerich and coworkers obtained in this way 8-acetamidonorlumiflavin and its 2-imino- and 2-deoxy-analogues [133]:



It has been shown that there is a difference between the reactivities of the amino-groups in the 8-positions of alloxazines and isoalloxazines with respect to hydroxyethylation [164]. Whereas on treatment with ethylene oxide and heating, the 8-amino-group in the sodio-derivatives of alloxazine and 8-norlumichrome is hydroxyethylated together with the cyclic 3-imino-group, in isoalloxazines the amino-group remains inert.



The higher reactivity of the 8-amino-group in the alloxazines ring system compared with isoalloxazine has been confirmed by calculations [17], which established that the electron density (1.830) and the peripheral electron density (0.618) at the amino-group of 8-aminoalloxazine are higher than for 8-iminoisoalloxazine (1.817 and 0.254 respectively).

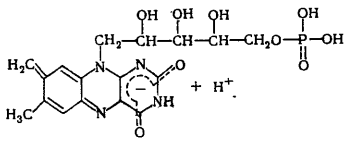
The 9-amino-group in the isoalloxazine ring system is readily diazotised by nitrous acid; the diazonium salt enters into the azo-coupling reaction and is deaminated. Lumiflavin is obtained in this way from 9-aminolumiflavin as a result of diazotisation and decomposition of the diazonium salt [172]. However, the diazo-group in this compound could not be replaced by bromine in the Sandmeyer reaction, possibly owing to steric hindrance [172].

8-Aminoalloxazines and 8-aminoisoalloxazines [133,173] are also diazotised by nitrous acid [133,149-151,174]; the diazonium salts formed are coupled in an alkaline medium to β-naphthol [164,174] and in dilute formic acid to certain aromatic amines (diethylaniline, *NN*-bis-β-chloroethyl-aniline) [175] with formation of azo-compounds.

11. REACTIONS OF THE METHYL GROUP IN THE 8-POSITION

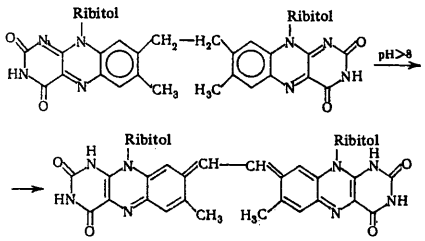
Until recently the biological importance of the two *ortho*-methyl groups in the benzene part of the molecule of riboflavin and its coenzymes (FMN and FAD) was not clear. Although the removal of the methyl groups from the flavin involves relatively small steric and electronic changes in the molecule, it nevertheless entails a sharp decrease or total loss of biocatalytic activity [176]. The replacement of these groups by other substituents (NH_2, NHRibitol, OH, Cl, etc.) yields inhibitors of certain metabolic reactions [177-179].

The 8-methyl group in the isoalloxazine ring system exhibits acidic properties, resembling those of nitrotoluene or methylbenzoquinone [18]. At pH 6.8–6.9 and 90–95°C in D_2O the protons of the 8-methyl group of FMN are exchanged for deuterium [180], which has been explained by the possible formation of an anion with a strongly delocalised charge; the formation of such an anion, which would compensate the loss of aromaticity in the benzene ring, is impossible in the deprotonation of the 7-methyl group, for example:

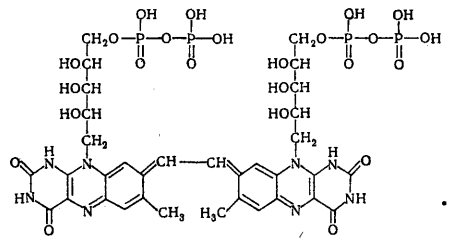


The mobility of the hydrogen atom of the 8-methyl group is shown in flavin dimerisation reactions. Hemmerich et al. established that, under non-aqueous alkaline conditions (BaO in methanol, K_2CO_3 in DMF), flavins are irreversibly dimerised [148] in a manner analogous to the oxidation of nitrotoluenes to stilbenes [18]. The 8-methyl groups in the two molecules are then oxidised and dimerised with the formation of the CH_2-CH_2 group and flavin compounds are

reduced—a diflavin biradical is formed[18] and reacts with a further flavin molecule to form the flavosemiquinone anion and the "diflavin radical"[69]. In the presence of atmospheric oxygen, this radical is oxidised to the stable benzoquinonoid bisriboflavin[148]:

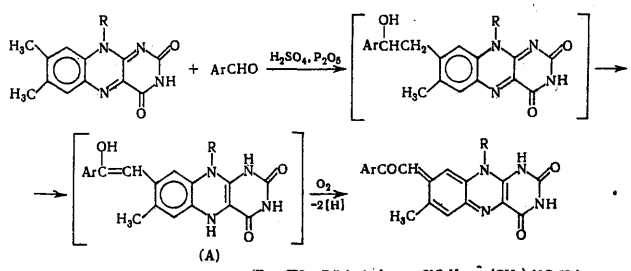


It is noteworthy that, in the phosphorylation of riboflavin under extremely dehydrating conditions (orthophosphoric acid and phosphorus pentoxide), the formation of phosphate esters of flavins with the usual structure is also accompanied to some extent by an analogous oxidative dimerisation involving the 8-methyl group with formation of the benzoquinonoid bisriboflavin 5′-diphosphate[181]:



The ^{1}H NMR spectra of the benzoquinonoid bisriboflavin 5′-diphosphate and the benzoquinonoid bisriboflavin lack the resonance signal due to the protons of the 8-methyl groups, while the signal of the 7-methyl protons is retained[181], which is evidence of a change in molecular structure involving the 8-methyl groups. The benzoquinonoid bisriboflavin 5′-diphosphate and the benzoquinonoid bisriboflavin were found to inhibit oxidative phosphorylation processes in rat liver mitochondria.

The 8-methyl group in the flavin molecule may be regarded as a nucleophilic centre. The enhanced reactivity of the 8-methyl group of flavins compared with the 7-methyl group is reflected in its capacity to interact with electrophilic agents (active carbonyl, nitrosyl, etc. groups). Thus under anhydrous conditions (concentrated sulphuric acid and phosphorus pentoxide) flavins enter into the Knoevenagel reaction with *p*-chlorobenzaldehyde and *p*-dimethylbenzaldehyde, forming the corresponding 8-α-derivatives[148,182]:

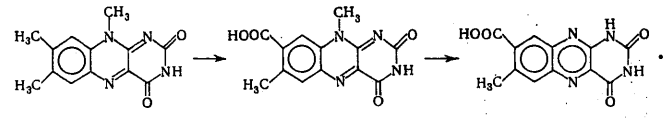


(A)

(R = CH_3, Ribitol; Ar = *p*-ClC_6H_4; *p*-$(CH_3)_2NC_6H_4$)

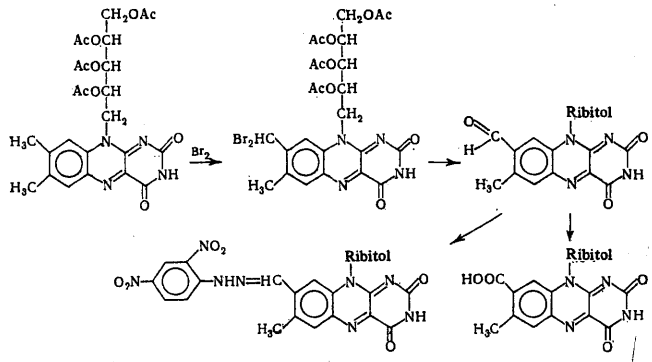
Possibly this reaction proceeds via the intermediate formation of an aldol, which is converted as a result of an intramolecular oxidation-reduction reaction into a compound of type (A) which on oxidation in air gives rise to the corresponding 8-α-derivative of the flavin[182].

The reactivity of the 8-methyl group of flavins is also shown in the reaction of lumiflavin with nitrous acid in boiling acetic acid with formation of 8-carboxynorlumiflavin[148]:



This acid is unstable and is readily converted into 8-carboxy-7-methylalloxazine in a warm alkaline solution.

McCormick achieved the bromination of the 8-methyl group of 2′,3′,4′,5′-tetra-acetylriboflavin with an excess of bromine in pyridine and dioxan; the reaction led to the formation of 2′,3′,4′,5′-tetra-acetyl-8-α-dibromoriboflavin, which was hydrolysed to 8-formylnor-riboflavin on refluxing in 6 *N* hydrochloric acid. This compound is oxidised by dilute aqueous potassium permanganate or periodic acid solution to 8-carboxynor-riboflavin. The condensation of 8-formyl nor-riboflavin with 2,4-dinitrophenylhydrazine led to the formation of the corresponding hydrazone[183]:



Hemmerich and coworkers achieved the monobromination of 2′,3′,4′,5′-tetra-acetylriboflavin at the 8-methyl group by brief treatment with molecular bromine in dioxan in the presence of catalytic amounts of dibenzoyl peroxide and obtained 2′,3′,4′,5′-tetra-acetyl-8-α-monobromoriboflavin[184].

The study of the reactivity of the substituents in the benzene ring of isoalloxazines, in particular the 8-methyl group in riboflavin[148,183], played a decisive role in the determination in 1970 of the structure of a new flavin coenzyme of succinate dehydrogenase (SD) by two groups of investigators: Ghisla et al.[184] in West Germany and Walker and Singer[185] in the USA.

Earlier Kearney, Singer, and Wang established that the flavin present as the prosthetic group in succinate dehyrogenase from ox heart[186] and pig heart[187] is not identical with FMN or FAD[188,189] and, in contrast to these coenzynes, is linked by a covalent bond to one of the protein aminoacids[190].

The flavin of succinate dehydrogenase could not be separated by the usual methods (treatment with strong acids in the cold, boiling in water and 50% ethanol) and only treatment with proteolytic enzymes (trypsin, chymotrypsin) led to the isolation of a flavin peptide derivative, called SD-FAD and containing one mole of 5-adenylic acid, one mole of D-ribose, and two phosphorus atoms joined by the pyrophosphate linkage[190]. The dinucleotide differed from FAD by a hypsochromic shift of the ultraviolet absorption band (from 375 to 350 nm) and certain other properties[190].

SD-FAD was converted into AMP and SD-FMN by brief hydrolysis in 1 *N* hydrochloric acid at 100°C or by treatment with nucleotide pyrophosphatase.

Hydrolysis of SD-FAD (6 *N* HCl, 95°C, 18 h) leads to a riboflavin derivative (SD-riboflavin) and 6–7 aminoacids: alanine, serine, glutamic acid, valine, and threonine with a second serine molecule as the terminal aminoacid residue[190]. The ribityl structure of the substituent in the 10-position was established by periodate oxidation[190].

It was shown that the covalent linkage between the flavin and the aminoacid cannot involve the 1-, 2-, 3-, 4-, and 5-, and 10-positions in the isoalloxazine ring for the following reasons. On alkaline hydrolysis of SD-FAD, urea is formed, which rules out substitution in the 1- and 3-positions[18]. Since the removal of the ribityl side chain by alkaline photolysis[191] does not rupture the bond with the aminoacid in the residual substance, the 10-position was also eliminated[18]. All possible substitutions by alkyl, aryl, acyl, alkoxy-, amino-, and mercapto-groups in the 2-, 4-, and 5-positions are reversible under the conditions of hydrolysis or weak oxidation[5,128].

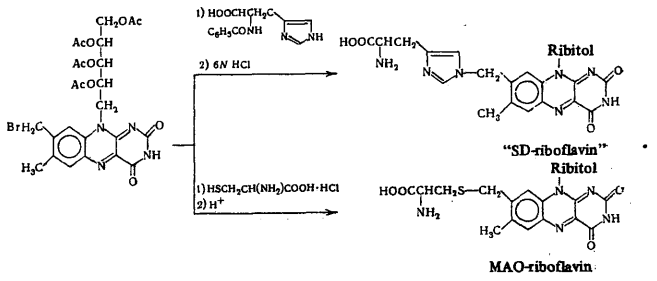
It was also shown that the hyperfine structure of the ESR spectrum of the "SD-flavin" radical differs from that of the riboflavin radical, which made it possible to eliminate the 7- and 9-positions characterised by low spin densities[189]. It was suggested that the addition to aminoacids takes place via the 8-methyl group[191], which is also consistent with the results from double resonance electron spin spectra[192].

On acid hydrolysis of "SD-riboflavin" under severe conditions in an atmosphere of helium, histidine was isolated in 80% yield. The same aminoacid is isolated on neutral photolysis and reductive cleavage of SD-FAD by hydrogen over palladium, i.e. under conditions where 3-benzylhistidine is cleaved[185].

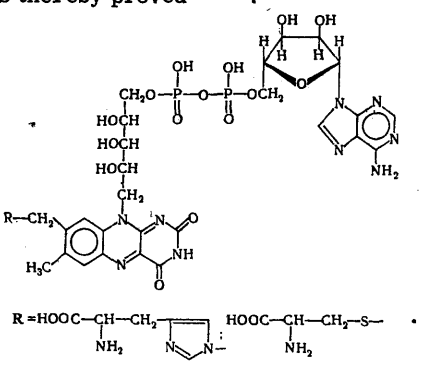
By analogy with the benzylation of histidine at 3-N and also on the basis of steric considerations, it was suggested that the flavin is linked to histidine via the 3-N atom[185].

The results led to the conclusion that "SD-riboflavin" has the structure of 8-α-(1- or 3-L-histidyl)riboflavin[183]. 8-α-(*N*-L-Histidyl)riboflavin, obtained by direct synthesis (heating of 2′,3′,4′,5′-tetra-acetyl-8-α-bromoriboflavin with benzoylhistidine in anhydrous dimethylformamide with subsequent hydrolysis by 6 *N* hydrochloric acid) prove to be spectroscopically and chromatographically identical with "SD-riboflavin"[184].

Next it was shown that the non-dissociating cofactor of monoamine oxidase (MAO) is not FAD but its derivative[193,194]. Stepwise hydrolysis of monoamino-oxidase yielded a mononucleotide and "MAO-flavin"—a riboflavin oligopeptide containing cysteine, serine, tyrosine, and two molecules of glycine. Further hydrolysis of the compound led to the isolation of 8-α-(*S*-cysteinyl)riboflavin[195,196], which Ghisla and Hemmerich also obtained synthetically by the reaction of tetra-acetyl-8-α-bromoriboflavin with cysteine hydrochloride and subsequent deacylation[197]:



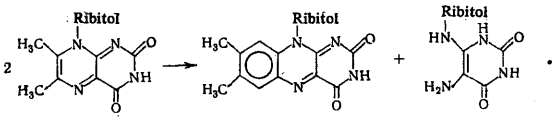
Thus detailed and far-reaching studies of the chemical behaviour of alloxazine and isoalloxazine compounds led to the determination of the unusual structures of new non-dissociating flavin coenzymes of succinate dehydrogenase [8-α-(*N*-L-histidyl)FAD][184,185] and monoamino-oxidase [8-α-(*S*-cysteinyl)FAD],[196,197] the flavin moiety of which is linked covalently to the aminoacid via the 8-methyl group; the earlier suggestion of the possibility of such a linkage was thereby proved[198,199]:



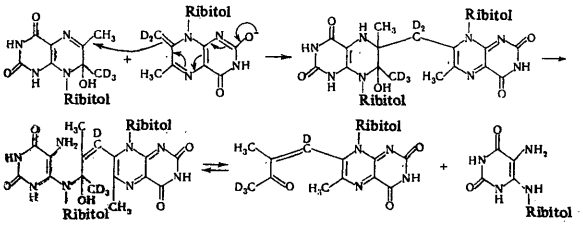
Thus the non-equivalent reactivities of the 7- and 8-methyl groups in the flavin molecule are used in nature as a fine-control factor for the construction with participation of a specific enzyme of the flavin prosthetic groups of succinate dehydrogenase and monoamino-oxidase.

It is interesting to note that the methyl groups of riboflavin are genetically related to the methyl groups of 6,7-dimethyl-8-(1′-D-ribityl)lumazine in the biosynthetic process.

The mobility of the hydrogen atoms of the methyl groups of lumazine, two molecules of which have been shown by Plaut[201,202] to be converted into one riboflavin molecule, is employed in the biosynthesis of riboflavin by the microorganisms *Eremothecium ashbyii* and *Ashbya gossypii*[200]. The same reaction was achieved *in vitro* by Cresswell et al., who showed that in a buffer solution at pH 7.3 6,7-dimethyl-8-(1′-D-ribityl)lumazine condenses into riboflavin in 55% yield on heating under nitrogen in the absence of an enzyme or an external carbon source[203]:



The study of the condensation of deuterated lumazine into riboflavin led to a possible mechanism of this reaction in which there is an initial attack by the carbanion on the 6-position of hydrated pteridine with formation of a carbinolamine in equilibrium with the ketone and finally the formation of the corresponding deuteroriboflavin[204,205]:



Plaut and coworkers propose a different mechanism for the non-enzymatic and enzymatic syntheses of riboflavin from lumazine[206–208].

12. OTHER REACTIONS

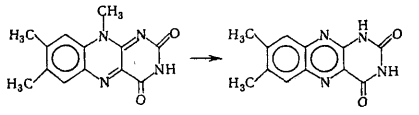
It was shown recently that, on photoexcitation with visible light under anaerobic conditions in an acid medium (pH < 5), lumichrome is hydroxylated in the aromatic ring, possibly in the 9-position, with formation of 9(6)-hydroxylumichrome [142].

An important reaction—the photolysis of riboflavin and other flavins—takes place with partial or complete removal of the side chain in the 10-position depending on the conditions; complete dealkylation leads to the conversion of isoalloxazines into alloxazines.

The studies on the photolysis of riboflavin have been reviewed [1,2,88,209].

Investigations in recent years have been devoted mainly to the identification of the intermediates in the photolysis of flavins and the study of its mechanism [210-217].

It is noteworthy that light is not a specific catalyst of the cleavage of isoalloxazines to alloxazines [4]. This reaction is catalysed also by metal ions such as Fe^{2+}, Sn^{2+}, Co^{2+}, [218,219] and in certain cases by bases [220] and reagents for the carbonyl group [4], quaternary amines, thioethers [87], etc. Thus, when lumiflavin was heated in acetic acid containing hydroxylamine for 120 h, lumichrome was obtained [4]:



The reverse transition, from alloxazines to isoalloxazines, is unknown.

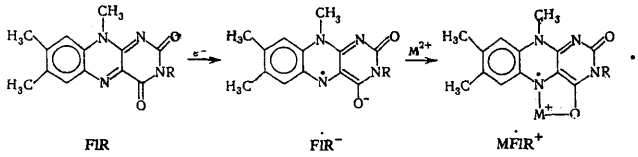
Alkaline or acid degradative cleavage of alloxazines and isoalloxazines with their conversion into quinoxalines has been investigated in fair detail and discussed in earlier papers [1,2,209]. This reaction is widely used to establish the structures of various derivatives of alloxazine and isoalloxazine [118,119,221-223].

Flavins are capable of forming complexes with different organic compounds, as a rule in 1:1 proportions [224]. Such compounds include phenols [225], indoles [226,227], purines [228,229], benzoic acid [230], aminoacids [231,232], etc. There are data showing that the tyrosine aminoacid residue in certain flavoproteins is involved in complex formation with the flavin [233]. Possibly this complex formation between flavin and aromatic aminoacids is in fact the main link between the prosthetic group and the apoenzyme in many flavoproteins [230].

In order to investigate the nature of the bond between flavins and aromatic aminoacids, McCormick and coworkers [234-237] employed as model compounds flavinylpeptides obtained by the interaction of methyl esters of aromatic aminoacids (L-tryptophan, L-tyrosine, and others), with 3- and 10-carboxyalkyl derivatives of flavins.

Riboflavin forms with certain metal salts insoluble intensely coloured chelate complexes, probably via the 5-nitrogen atom and the oxygen of the 4-carbonyl group. The metal ions involved in such complexes are Ag^+, Hg^+, Cu^+, Fe^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, and Mn^{2+}. [238,239] The chelate complexes with univalent metals are more stable than those with bivalent metals. It is noteworthy that the biocatalytic activity of many flavin enzymes is associated with the metal cations they contain, such as those of iron, molybdenum, copper, or manganese [240].

Flavins do not show an appreciable affinity for transition metal cations with a constant valence [238,241], probably owing to the low basicity of the 5-nitrogen atom and the high energy of the enolisation of the 4-carbonyl group [23]. However, in the form of flavosemiquinones, in particular radical-anions, they acquire a specific affinity for metal cations [242]. Under physiological conditions, the half-reduced flavin contains a small amount of radical-anions in consequence of disproportionation. However, in the presence of transition metal cations the equilibrium is displaced towards the formation of radicals owing to complex formation [243]. Under the experimental conditions (in dry DMF) in the presence of a stoichiometric amount of a strong base, for example potassium t-butoxide) 100% of the flavin radical-anions is formed [244]. The formation of the chelate complex can be represented by the following scheme [245]:



FlR FlR⁻ MFlR⁺

Further study of the reactions of alloxazines and isoalloxazines and of their reactivities, the elucidation of the relation between the parameters of the electronic structures in difference positions of the flavin molecule and its interaction with the apoenzyme, the study of the biochemical role of flavin radicals and flavin complexes with aminoacids and metals, as well as investigations of other types will undoubtedly promote a far reaching development of the chemistry of alloxazine and isoalloxazine derivatives and the discovery of the essential features of flavoprotein catalysis.

Resolution of Racemic Alcohols into Optical Isomers

B.A.Klyashchitskii and V.I.Shvets

The review analyses two classes of methods for the resolution of racemic alcohols into optical isomers: resolution by the synthesis and separation of diastereoisomeric derivatives and resolution without the formation or isolation of diastereoisomers. The fundamental classical studies on the resolution of racemic alcohols are noted. Attention has been concentrated on modern trends and modifications based on the latest advances in organic chemistry. It has been shown that the application of physicochemical methods leads to fundamentally new possibilities for the resolution of racemic alcohols. The bibliography includes 128 references.

I. Introduction 592
II. Resolution of racemic alcohols by the synthesis and separation of diastereoisomers 592
III. Resolution of racemic alcohols without the synthesis or isolation of diastereoisomers 598

I. INTRODUCTION

The problem of the resolution of racemic alcohols arose in the past century in connection with the development of stereochemical hypotheses and a series of fundamental studies by Pasteur[1]. Pasteur's work determined the trend in studies in this field of organic chemistry for many decades. The list of racemic alcohols resolved hitherto is extremely impressive. The advances achieved in this field have been described in detail in a series of reviews[2,3] and monographs[4,5]. Modern studies on the resolution of racemic compounds differ qualitatively from earlier investigations as regards the aims of the investigators and the methods employed.

In connection with the vigorous development of biochemistry, it has become evident that the optical activity of natural compounds has a deep significance. The stereochemical characteristics of structure have a great influence on the biological activity of organic compounds. It is not fortuitous that all substances entering into the composition of cells and involved in fundamental vital processes (proteins, nucleic acids, lipids, polysaccharides, etc.) are optically active. Therefore the aim of the resolution of a racemate is frequently to obtain the optical isomer with the natural configuration. The principal task of the chemist is the creation and the preservation in the substances which he synthesises of the structures and configurations of the natural compounds.

A second feature of modern investigations is the improvement and modification of classical methods for resolution and, what is most important, the introduction into this field of modern physicochemical methods: gas–liquid chromatography (GLC), paper chromatography (PC), adsorption and ion-exchange chromatography, etc., which would make it possible to develop fundamentally new procedures for the resolution of racemates. The attempts at theoretical generalisations concerning resolution processes are important, since the available data for these processes still have more empirical features than any others in organic chemistry. The creation of a theory of resolution will make it possible both to predict the possibility of the resolution of a racemate by a particular process and to select the optimum method.

Together with the fundamental classical studies, this review describes the modern trends in the field of resolution of racemic alcohols based on the latest advances in organic chemistry. The methods of resolution have been divided into two main groups: (1) resolution by the synthesis and separation of diastereoisomeric compounds and (2) resolution without the synthesis or isolation of diastereoisomers.

II. RESOLUTION OF RACEMIC ALCOHOLS BY THE SYNTHESIS AND SEPARATION OF DIASTEREOISOMERS

The entire resolution process may be reduced to three consecutive operations (the so called "Pasteur's second method"): (1) the formation of a pair of diastereoisomers; (2) the separation of this pair using the differences between the properties of the diastereoisomers; (3) decomposition of the individual diastereoisomers with isolation of the optically pure enantiomorphs. For the first operation, it is necessary that the reaction of the racemic alcohol with the asymmetric agent should have a fairly high yield. The possibility of the second operation has been greatly improved recently when effective physicochemical methods have become available together with the crystallisation procedure. The third stage should be quantitative and should occur under mild conditions excluding the possibility of racemisation.

The two principal versions of resolution via diastereoisomeric compounds are discussed below.

1. INTRODUCTION INTO THE RACEMIC ALCOHOL MOLECULE OF A FUNCTIONAL GROUP CAPABLE OF FORMING DIASTEREOISOMERIC SALTS WITH OPTICALLY ACTIVE BASES

Historically this is one of the first and widely used methods. Salt formation is convenient because the resulting diastereoisomeric crystalline salt can be separated by fractional crystallisation. The first mention of the theoretical possibility of a large-scale employment of this type of resolution occurs in an early communication by Erlenmeyer and Arnold[6]. The fundamental idea of this method consists in the introduction into the alcohol molecule of the so called "connecting link" containing a functional group (carboxy-group) capable of forming a salt with an optically active base, for example:

$$R{-}OH + HOOCR_1COOH \rightarrow ROOCR_1COOH \xrightarrow{R^*} ROOCR_1COOH \cdot R^*,$$

where R–OH is the racemic alcohol, $HOOCR_1COOH$ the "connecting link", and R* the optically active base.

Evidently in this case the "connecting link" is a dibasic acid. Phthalic acid has been most frequently employed. The work of Pickard and Kenyon [7] was one of the earliest. Subsequently this acid was employed in many cases for the resolution of various racemic alcohols [8-10]. There is no necessity to enumerate all the resolutions achieved via acid phthalates—only a few need be considered. The classical method of Pickard and Kenyon (acid phthalate → brucine salt) has been used to resolve a number of diols, for example 3-(2-methylphenoxy)propane-1,2-diol [11] and butane-2,3-diol [12], and acetylenic alcohols, for example 3-methylpent-1-yn-3-ol [13] and 3,5-dimethylhex-1-yn-3-ol [14], difficulties arising in the last case in the fractional crystallisation of the brucine salts owing to a possible adsorption of the more soluble salt on the crystals of the less soluble salt. Recently the same method was employed to resolve 2-octanols (crystallisation of the salts with phenylethylamine, employed for the first time instead of the usual brucine) [15] and 2-butanols (salts with brucine) [16]. It is also possible to achieve the optical resolution of steroids containing a hydroxy-group via cinchonine salts of acid phthalates [17].

An interesting modification of this method was proposed in 1969, [18] consisting in the simultaneous application of the processes of Pope and Peachey [19] and Kantor and Hauser [20]. Pope and Peachey [19] showed that the resolution, which depends on relatively small differences between the solubilities of diastereoisomeric salts, can be made more effective when it involves an optically inactive reactant (A) competing with an optically active resolving agent (B) in the reaction with the racemic substance (±C). In successful cases the inactive reactant interacts completely with one enantiomorph while the optically active reactant interacts with the other.

(1) Classical resolution:

$$2(\pm C) + 2B_{act} \rightarrow (+)\text{-C.B.} + (-)\text{-C.B.}$$

(2) Pope and Peachey process:

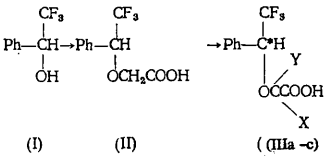
$$2(\pm C) + B_{act} + A_{inact} \rightarrow \begin{matrix}(+)\text{-C.B} + (-)\text{-C.A} \\ \text{or} \\ (-)\text{-C.B.} + (+)\text{-C.A}\end{matrix}.$$

Owing to the slight differences between the solubilities of the diastereoisomers, in process (1) their separation requires repeated recrystallisations. In process (2), where the products are not diastereoisomers, with a successful choice of A the separation could be achieved more readily and with a smaller number of recrystallisations. The process of Pope and Peachey was applied in the classical procedure [7] for the resolution of various secondary alcohols using triethylamine as A, brucine as B and acid phthalates derived from secondary alcohols as ±C. The optical purity of the alcohols isolated was high even without additional recrystallisation. The resolutions of 2-butanols, 2-octanols, and 1-phenylethanols were achieved. An additional advantage of this modification consists in a decrease of the consumption of the asymmetric reactants (B) which are usually expensive. In 1953 Kantor and Hauser [20] modified process (1) in the resolution of acid phthalates derived from 2-butanol by using a deficiency of the solvent for the reactants. After prolonged refluxing, the salts formed are effectively recrystallised before their isolation, which leads to higher optical yields in a single stage than in the usual procedure (82% optical purity in the case of 2-butanol). The simultaneous use of the process of Pope and Peachey and the modification of Kantor and Hauser leads to secondary alcohols with a higher optical purity than can be obtained by processes (1) and (2), [18] albeit at the expense of the yield.

In 1951 Zeiss showed [21] that tertiary alcohols, for example ethylmethylphenylmethanols, can be resolved by the method of Pickard and Kenyon (via the acid phthalate with subsequent formation of a brucine salt). Later Kenyon and coworkers carried out a similar resolution of 2-(1-naphthyl)butan-2-ol [22], 2-phenylbutan-2-ol [23], and 2-methyl-3-phenylpropane-1,2-diol [24]. Admittedly in the last case the resolution via the acid phthalate was unsuccessful since neither the phthalate nor its salts with various alkaloids were crystalline. The resolution was achieved by the reaction of 3-nitrophthalic acid followed by the formation of its strychnine salt. The diastereoisomeric salts were separated by crystallisation and decomposed with ammonia. Subsequent treatment of the 3-nitrophthalate with alkali yielded the optically active 2-methyl-3-phenylpropane-1,2-diol [24]. 3-Nitrophthalic acid was used in a number of other cases, for example by Holding et al. [25]

Succinic acid has also been used as a "connecting link" in the resolution of alcohols [26]. The optical isomers of cyclopent-2-en-1-ol were separated via the formation of salts of the acid esters of succinic acid and (+)-α-(1-naphthyl)ethylamine [27]. A number of resolutions have been carried out using phthalamic [28] and sulphuric [29] acids. Sulphates may be suitable for the resolution of certain glycols although as a rule acid alkyl sulphates are unstable and difficult to prepare.

It should be noted that the method under consideration does not always lead to the desired results. For example, the attempt to resolve the acid phthalates derived from 2,2,2-trifluoro-1-phenylethanols (I) via diastereoisomeric salts with optically active bases [30] was unsuccessful, since the ester of this alcohol proved to be readily hydrolysable even on treatment with brucine. This is because of the acidity of the alcoholic hydroxyl group. In 1968 the separation of the optical isomers of compound (I) was achieved [31] with a low yield by the fractional crystallisation of its esters with acetoxyandrost-5-ene-17β-carboxylic acid by a method which is discussed in detail in the next section. The high interest in 2,2,2-trifluoro-1-phenylethanol is due to the fact that in many cases the optically pure enantiomorph of this alcohol is a suitable solvent for NMR spectroscopic studies. Recently Pirkle et al. [32] achieved a new and novel resolution of compound (I) using a monobasic acid (substituted acetic acid) as the "connecting link":

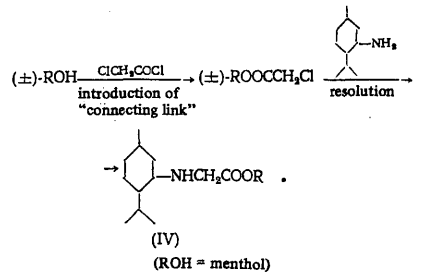


(I) (II) (IIIa-c)

(a, X=H, Y=Br; b, X=Br, Y=H; c, X=Y=Br)

The interaction of the alcohol (I) with ethyl bromoacetate led to 2-trifluoro(phenyl)ethoxyacetic acid (II), the optical isomers of which were then separated via salts with amphetamine [$PhCH_2CH(CH_3)NH_2$]. The α-bromoesters (III, a – c), readily hydrolysable to the optical isomers of the alcohol (I), were obtained by regenerating the optical isomers of the acid (II) from the diastereoisomeric salts and by treating them with bromosuccinimide. The introduction of bromine is necessary to facilitate the subsequent hydrolysis. 2,2,2-Trifluoro(1-naphthyl)ethanol optical isomers were separated similarly [32]. This method can be used for the resolution of other acids and similar alcohols when the classical process does not lead to the desired result.

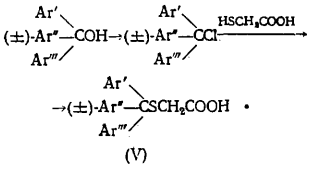
The formation of an ester with chloroacetic acid has been used to separate menthol isomers[33]. Here the asymmetric agent is (−)-menthylglycine formed by the reaction:



(IV)
(ROH = menthol)

The diastereoisomeric esters (IV) obtained were separated by crystallisation. The addition of acrylic acid has been used[34] to introduce a carboxy-group into the molecule. The reaction of (±)-1-trifluoromethylethanol with acrylic acid led to the adduct (±)-β-(1-trifluoromethylethoxy)-propionic acid the optical isomers of which were separated via diastereoisomeric salts with strychnine. The alcohol isolated from the separated adduct racemate was optically active.

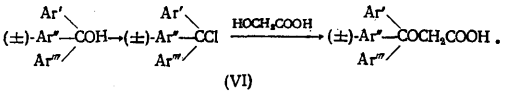
The separation of the isomers of trityl alcohols presents considerable difficulties. The separation of the isomers of biphenylyl-α-napthylphenylmethanol and 12-phenyl-12-benzoxanthenol, a trityl alcohol in which two aryl groups are linked together to form a heterocyclic ring, via the diastereoisomeric salts of substituted thioglycolic acid and alkaloids was reported by Wallis and Adams as late as 1933:[35]



(V)

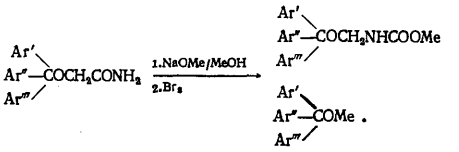
The isomers of the acid (V) were separated via their brucine salts. Treatment of the separated acids with silver nitrate in aqueous acetone yielded the optically active alcohols. Later this method was recognised as unsatisfactory[2] but Murr[36] showed that the optical yield amounts to 60% and may be increased.

The difficulty of separating the optical isomers of trityl alcohols is due to the lability of the trityl ester bond formed on introduction of a carboxy-group via the esters of dibasic acids. Although the separation of the isomers of α-naphthylphenyl-*p*-tolylmethanol by the classical method of Pickard and Kenyon[7] has been reported[37], it was not reproducible[38,39]. It was therefore suggested that the carboxy-group be introduced into the trityl alcohol molecule via an ether linkage[36,38]. The formation of an ether with glycolic acid was employed:

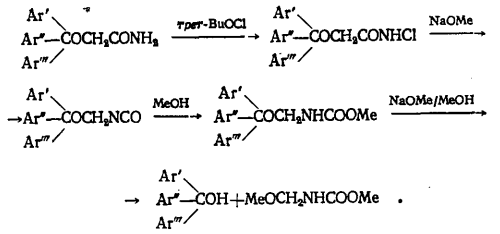


(VI)

The isomers of the acid (VI) were separated via salts with brucine [for the (−)-form] and cinchonidine [for the (+)-form]. The attempt to regenerate the optically active alcohol from the acid (VI) via the formation of an amide with subsequent Hofmann degradation did not yield the desired result owing to the dissociation of the ether linkage:

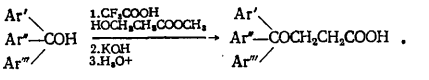


The yield of the ethyl ether of the tritylmethanol was 85%. The regeneration was achieved via the chloramide according to the following scheme:



The isomers of biphenylyl-α-naphthylphenylmethanol were separated in this way[38] but the attempt to separate those of biphenylyl-*p*-chlorophenylphenylmethanol were unsuccessful.

Derivatives of hydracrylic acids were used in 1969 to separate the isomers of α-naphthylphenyl-*p*-tolylmethanol[39]:



(±)-β-(α-Naphthylphenyl-*p*-tolylmethoxy)propionic acid was resolved via the diastereoisomeric salts with brucine. The alcohols were regenerated from the methyl esters of the separated acids by the reverse Michael reaction.

In conclusion mention should be made of a study[40] which proved to be useful in the isolation of the acid ester of an alcohol with a dibasic acid from the separated diastereoisomeric salts. The authors suggest that ion-exchange chromatography be used for this purpose, which makes it possible to isolate the acid ester in almost quantitative yield.

Summarising this method for the resolution of alcohols (using a "connecting link"), we should note that it made it possible to obtain a large number of optically active alcohols. The numerous dibasic acids and optically active bases (among which alkaloids are frequently employed) permit an extensive variation of their combinations in cases of failure. Nevertheless the investigator cannot be absolutely certain that the differences between the solubilities of the diastereoisomeric salts and their chemical stabilities will be sufficient for a successful resolution. A serious disadvantage of the method is associated with the isolation in a pure form and a sufficiently large amount of only one of the enantiomorphs (from the less soluble salt), while the other is isolated in only a small amount and with an inadequate optical yield. In view of the salt-like nature of the diastereoisomers, crystallisation is perhaps the only process suitable for their separation. The next modification of the resolution procedure via diastereoisomeric compounds does not suffer from this disadvantage.

2. DIRECT INTERACTION OF THE RACEMIC ALCOHOL WITH THE OPTICALLY ACTIVE RESOLVING AGENT AND THE FORMATION OF DIASTEREOISOMERIC DERIVATIVES

This method has the advantage that the stage involving the introduction of the "connecting link" is eliminated and the diastereoisomeric products are obtained by the direct interaction with a particular asymmetric agent. However, until recently this method had not been used quite so widely as the preceding one, since the diastereoisomeric compounds obtained (usually esters of an optically active acid) are normally difficult to crystallise. Nevertheless the use of modern physicochemical methods and of new asymmetric agents for the resolution (such as carbohydrate derivatives) has greatly extended the scope of this method.

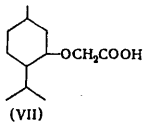
a. The Formation of Diastereoisomeric Esters of Optically Active Acids

Many optically active acids have been employed in classical resolution of this kind.

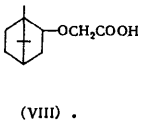
Mandelic acids [41]. This expensive reagent, which is used, in particular, for the resolution of (±)-menthol, is fully racemised in the alkaline hydrolysis of the diastereoisomers, which constitutes a serious disadvantage. The resolution of *erythro*-1-(4-hydroxyphenyl)-2-(1-methyl-2-phenoxyethylamino)propan-1-ol isomers [42] may serve as an example of resolutions with the aid of mandelic acid. The isomers of synthomycin were separated via esters with D-(−)-acetylmandelic acid, which yielded laevomycetin [43].

Camphoric acid. The majority of the diastereoisomeric esters of camphoric acid could not be separated by crystallisation, so that resolution with the aid of this agent is usually only partial [44]. Camphorsulphonic acids have also been used [45].

The employment of menthoxyacetic acid (VII) and bornylacetic acid (VIII) as asymmetric agents is promising for the resolution of phenols, glycols, and alcohols with a high molecular weight:



(VII)



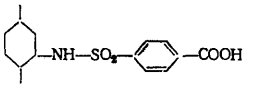
(VIII).

This version resembles the previous method, since an optically active alcohol is in fact employed for the resolution and the acetic acid residue constitutes a "connecting link". The acids (VII) and (VIII) are readily obtained from chloroacetic acid and the sodium derivatives of the corresponding alcohols. The resulting esters of the racemic alcohols have a fairly high specific optical rotation and are readily crystallised. Hydrolysis of the separated esters leads to an optically active alcohol, while the asymmetric agent is regenerated. The isomers of *trans*-cyclohexane-1,2-diol were separated in this way [46]. With the aid of the chloride of the acid (VII), Taub et al. [47] separated the isomers of the 4-*O*-methyl ester of the macrolide zearalenone and obtained the product with the natural configuration.

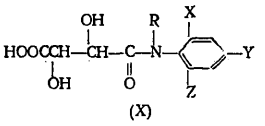
Recently the range of acids suitable for the resolution of alcohols via the diastereoisomeric esters have been greatly extended. Thus the reaction of (+)-*threo*-2-amino-1-(*p*-nitrophenyl)propane-1,3-diol hydrochloride or hydrogen sulphate with dibenzoyl-D-tartaric acid readily yields the crystalline neutral ester only with the D-isomer, which permitted a ready separation of the optical isomers [48]. (±)-2-Dimethylaminocyclohexanol was resolved with the aid of dibenzoyl-L-tartaric acid [49]. 3β-Acetoxyandrost-5-ene-17β-carboxylic acid was used in the resolution [31] of trifluoromethylphenylmethanol mentioned above. On the other hand, certain racemic steroids (the 3-methyl ether of oestradiol and 19-nortestosterone) were resolved via the formation of esters with the monomethyl ester of diacetyl-D-tartaric acid [50].

Aminoacids have been used in a number of cases for the resolution of alcohols. Halpern and Westley [51] proposed a method for the chemical resolution of racemic secondary alcohols into optical isomers, consisting in the esterification of the alcohol with an L-aminoacid in the presence of toluene-*p*-sulphonic acid with subsequent separation of the resulting ester sulphonates by fractional crystallisation and isolation of the optically pure (98 to 100%) (+)-isomer of the alcohol. Valine and alanine, with the aid of which it was possible to separate the isomers of 2-butanol, 2-methylcyclohexanol, menthol, and other alcohols, were employed as the L-aminoacids. In 1967 Germyn [52] extended the Halpern–Westley method to primary alcohols having obtained the enantiomorphs of 2-methylpentan-1-ol by the crystallisation of the tosyl derivatives of their esters with D- and L-valine; the use of alanine, tyrosine, leucine was unsuccessful. Probably a successful choice of aminoacid would make it possible to resolve also other racemic alcohols by the Halpern–Westley method, which can therefore be regarded as fairly general.

Campholic acid (1,2,2,3-tetramethylcyclopentanecarboxylic acid) has been proposed as a new convenient asymmetric agent for the resolution of menthol isomers [53], since only one of the diastereoisomeric esters [the (−)-menthyl ester of (+)-campholic acid] is crystalline, while the other is a liquid. This method is unsuitable for the resolution of the neo- and iso-forms of menthol, because neither diastereoisomeric ester is crystalline. Other agents which may serve for the resolution of alcohols are (−)-menthyl-*p*-sulphamoylbenzoic acid (IX), proposed by Everard and Mills [54], and also substituted tartranilic acids (X) suggested recently [55] for the resolution of racemic bases, since tartranilic acid itself has been used for the resolution of alcohols [56]:



(IX)



(X)

(R=H, Me; X=NO_2, Cl, Br, Me, H; Y=H, Cl, Br; Z=H, Cl, Br.).

So far we have considered studies in which diastereoisomeric esters of racemic alcohols and an optically active acid were separated by crystallisation processes. As mentioned above, the development of physicochemical methods has made it possible to achieve the separation of many diastereoisomers, including those which are not crystalline. This has occurred mainly owing to advances in adsorption, ion-exchange, gas–liquid, and paper chromatography. Small differences between the physical properties of diastereoisomeric esters proved sufficient to separate small amounts of substances both for preparative and for analytical purposes. As a rule the use of physicochemical methods yields both enantiomorphs with a high optical purity.

Thus optically active secondary alcohols can be separated with about 100% optical purity via the chromatography of their esters with optically active acids on an optically inactive ion exchanger. The enantiomorphs of (±)-2-butanol were separated via the esters with

(−)-mandelic acid by chromatography on Dowex-50W-X2.[57] The resolution by analogous chromatography of 3-methylbut-2-yl lactate was even easier, 26 millimoles of a mixture of diastereoisomeric esters yielding 1.2 millimoles of the optically pure (+)-3-methylbutan-2-ol.[58] The separation of esters formed by (±)-2-methylbutan-1-ol with mandelic acid was not achieved by ion-exchange chromatography[58] but by gas–liquid chromatography (g.l.c.)[59]; the authors suggested that, for the successful chromatographic separation of the esters, it is necessary that the hydroxy-group should be linked to the asymmetric carbon atom.

Until recently the separation of diastereoisomeric esters by g.l.c. was used mainly for analytical purposes (for tests of the optical purity of the specimen, the determination of the absolute configuration, etc.)[60]. The optical purity of asymmetric alcohols was determined by g.l.c. in 1963.[61] Subsequently the formation of R-(−)-menthyloxycarbonyl derivatives of asymmetric alcohols (in particular α-phenylalkylmethanols) was used for this purpose[62]. Gil-Av et al. showed[60] that many gas–liquid chromatographic resolutions are possible also on a preparative scale. They separated[63] the esters formed by 2-alkanols containing between 4 and 19 carbon atoms with hydroxypropionic acids with the aid of g.l.c. on columns containing squalene, poly(propylene glycol), and other phases. The DL-(or LD-) derivatives have longer retention times than the LL-(or DD-) derivatives. Carbonic acid esters of the type ROCOOR' are particularly convenient for the preparative separation by g.l.c. of the enantiomorphs of racemic alcohols[64] in view of the ease of their synthesis and subsequent hydrolysis. The structural features of diastereoisomeric esters which favour their separation by g.l.c. have been investigated[65]. Such attempts at theoretical generalisation based on the accumulated factural data are particularly valuable, since they allow a well founded choice of a particular resolving agent for the racemic mixture, the prediction of the necessary chromatographic conditions (such as temperature, solvent, etc.), and an understanding of the reasons for the differences between the physicochemical properties of diastereoisomers. The authors deduced a number of relations: (1) the higher the conformational stability of the groups linked to both asymmetric centres, the better the separation; (2) in view of the small free energy differences, slight structural changes in diastereoisomeric esters can lead to a great improvement in separation; (3) in the study of the mechanism of the separation of esters by g.l.c., both steric and electronic factors can be taken into account.

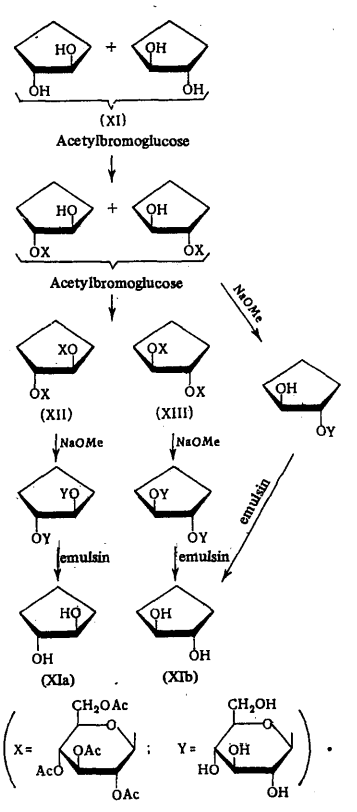
Among other modifications of this method, mention should be made of the possibility of separating the diastereoisomeric esters of lower alcohols and optically active acids by distillation through a sufficiently effective fractionating column using the slight differences between the vapour pressures of the diastereoisomers. This has been demonstrated in the separation of the optical isomers of 2-butanol via esters with L-lactic, L-2-acetoxypropionic, and D-2-propyloxypropionic acid by [fractional] distillation.

b. Formation of Diastereoisomeric Urethanes

The formation and separation of diastereoisomeric urethanes obtained by treating the racemic alcohol with L-menthyl isocyanate is one of the earliest methods of resolution[67]. However, the low availability of the asymmetric agent, the difficulty of hydrolysing the urethanes and also the conversion of L-menthyl isocyanate into an amine by hydrolysis greatly reduce its value[68]. The diastereoisomeric *N*-(1-phenylethyl)urethanes derived from certain secondary alcohols and obtained by the reaction of the aliphatic alcohol with a slight excess of (+)- or (−)-1-phenylethyl isocyanate, can be separated by thin-layer chromatography t.l.c. on silica gel G.[69] The following alcohols have been investigated: oct-1-en-3-ol, 2-octanol, 2-heptanol, 3-octanol, and 3-pentanol. It has been shown that the (++)-, and (−−)-diastereoisomers have a higher R_f than the (+−)- or (−+)-diastereoisomers, which makes it possible to establish the absolute configuration of the alcohol present in microamounts or to test its optical purity.

c. Resolution via Diastereoisomeric Carbohydrate Derivatives

Only a few cases of the use of carbohydrate derivatives as asymmetric agents for the resolution of racemic alcohols have been described in the literature. Probably this is because the glycosides employed are obtained in insufficient yields and the isolation of the optically active alcohols from the separated glycosides requires severe conditions or the use of enzymatic systems. Neuberg et al.[70] were the first to succeed in resolving pentyl alcohol, menthol, and borneol via the corresponding D-glucosides. Subsequently Helferich and Hiltmann[71] carried out a similar separation of the isomers of *trans*-cyclopentane-1,2-diol (XI):

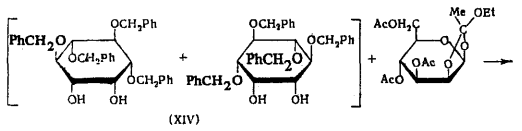


The diglucosides (XII) and (XIII) could be separated by crystallisation and enantiomorphs (XIa) $\{[\alpha]_D = -33.8°\}$ and (XIb) $\{[\alpha]_D = +33.8°\}$ were obtained after hydrolysing the

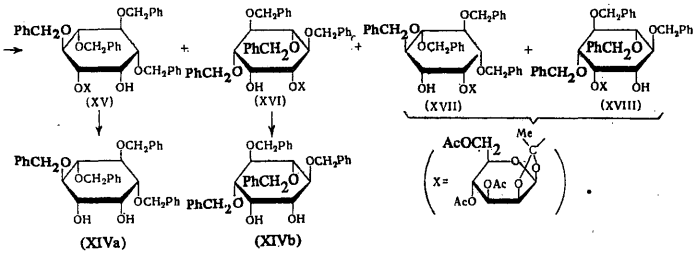
acetate groups and subsequent cleavage of the glycosidic linkage with the aid of emulsin. Hydrolysis of the monoglucoside led to a product the treatment of which with emulsin gave the dextrorotatory enantiomorph (XIb). The hydrolysis of a mixture of the diastereoisomeric menthol β-D-glucosides, as a result of which the menthol isolated after incomplete hydrolysis was optically active, shows an interesting optical selectivity [72].

The separation of the optical isomers of alcohols via diastereoisomeric glycosides has not found a wide application owing to numerous difficulties encountered in this procedure. Angyal and Shelton [73] synthesised in this way diastereoisomeric mannosylmyoinositols in a yield of about 4%. Although the diastereoisomers were readily separated by fractional crystallisation, it is impossible to employ them as the starting materials for the preparation of optically active asymmetrically substituted myoinositols owing to their small amount.

Nevertheless the use of other derivatives of monosaccharides and alcohols and different methods for the separation of diastereoisomers may greatly extend the scope of this method. This has been demonstrated for the resolution of asymmetrically disubstituted myoinositols, which have attracted attention in connection with their role in biochemical processes. The attempts at the resolution of these compounds by classical methods were unsuccessful [74]. A recently proposed method for the resolution of racemic myoinositols [75] is based on the interaction of the racemate with the orthoacetates of D-mannose and lower alcohols under the conditions of the transesterification reaction with subsequent separation of the resulting diastereoisomeric D-mannose orthoesters and myoinositol derivatives by chromatography or crystallisation and the isolation of the enantiomorph from the separated orthoesters. For example, 1,4,5,6-tetra-*O*-benzylmyoinositol (XIV) was resolved in this way [76]:

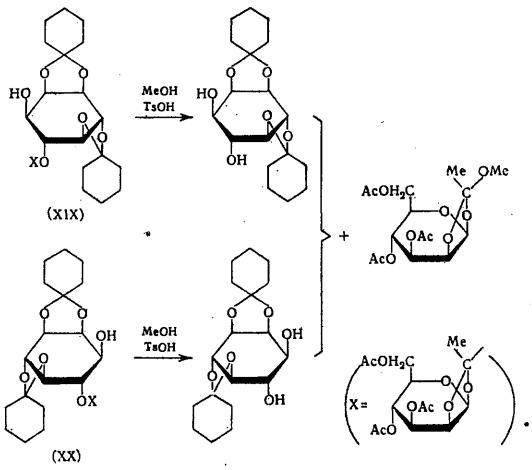


(XIV)



(XIVa) (XIVb)

The diastereoisomeric orthoesters (XV), (XVI), and the mixture of (XVII) and (XVIII) were separated by crystallisation and preparative t.l.c. The enantiomorphs (XIVa) and (XIVb) were isolated by mild acid hydrolysis of the separated orthoesters (XV) and (XVI). The isomers of 1,2,4,5,6-penta-*O*-benzylmyoinositol [77] and 1,2:5,6-di-*O*-cyclohexylidenemyoinositol [78] were separated similarly, in the latter case the enantiomorphs being isolated from the separated diastereoisomeric orthoesters (XIX) and (XX) in high yields by "reverse" transesterification with methyl alcohol, since acid hydrolysis was inapplicable owing to the lability of the *trans*-cyclohexylidene group:



(XIX)

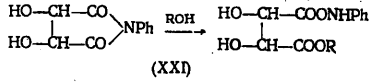
(XX)

We believe that this method may prove to be suitable for the resolution of other racemic compounds, in particular cyclic alcohols with a fixed steric configuration, with the aid of a suitably selected monosaccharide orthoester.

Mention should also be made of a study [79] where it was shown that the configuration of carbohydrates can be established by means of their diastereoisomeric derivatives with alcohols. This applies to the carbohydrates which can be readily and quantitatively oxidised to aldanic acids, the esterification of which with racemic alcohols (2-butanol, 3-methylbutan-2-ol, and 3,3-dimethylbutan-2-ol) leads to volatile diastereoisomers which can be separated by g. l. c. The peaks were identified by comparison with a specimen obtained as a result of esterification with an optically active alcohol. In all cases (lyxonic, ribonic, xylonic, arabonic, glyceric, and other acids), the separation was best with sterically hindered alcohols, in agreement with the findings of Karger and coworkers [64].

g. Other Asymmetric Agents

Of other agents proposed for the direct formation of diastereoisomeric derivatives of racemic alcohols, mention should be made of *N*-phenyl-D-tartrimide (XXI), which reacts with alcohols according to the following mechanism [56]:



(XXI)

If the alcohol molecule contains another functional group, it too can be used for the direct formation of diastereoisomeric products. Thus separation of the enantiomorphs of certain carbinols of the type RR'R"COH, where R = phenyl, R' = 2-pyridyl or 4-pyridyl, and R" = n-octyl, was achieved via salts with D-camphorsulphonic or tartaric acids [80]. Natural D-(+)-*erythro*-dihydrosphingosine was obtained by the separation of the racemic aminodiol via the salts with L-glutamic acid [81] and the enantiomorphs of 3-*O*-benzoylsphingosine were separated with the aid of D- and L-tartaric acids [82].

III. RESOLUTION OF RACEMIC ALCOHOLS WITHOUT THE SYNTHESIS OR ISOLATION OF DIASTEREOISOMERS

This large group of methods for the resolution of racemic alcohols, which includes, together with Pasteur's classical procedures, also modern methods which have been recently developed, involves a direct resolution of racemates without the formation or isolation of diastereoisomeric products. If the diastereoisomers are in fact formed, they are usually extremely unstable and cannot be isolated. An advantage of such methods is the absence of the necessity for the isolation of diastereoisomers which in many cases (for example in separation by adsorption) makes it possible to carry out the separation as a continuous process.

1. RESOLUTION OF RACEMIC ALCOHOLS BY THE CRYSTALLISATION OF ENANTIOMORPHS

The so called "Pasteur's first method" [83] is based on the mirror image differences between the enantiomorph crystals, which can therefore be separated mechanically. This method is laborious and slow and has not found a serious practical application. Very often attempts at resolution proved unsuccessful: for example, LeBel [84] could not separate the crystals of barium 2-butylsulphate; the attempt to separate mechanically the crystals of (±)-erythritol [85] was also unsuccessful. Although there is some evidence that (±)-*cis*-β-decalol can be separated by Pasteur's first method using the properties of its crystals [86], no actual resolution of this substance has been reported in the literature. The separation of the enantiomorphs of isohydrobenzoin has been quoted as a successful example [87].

The resolution of racemates by selective crystallisation is of more interest. It is usually achieved by introducing a seed of one of the enantiomorphs into a supersaturated solution of the racemate. Studies on such resolution were begun with the publication in 1866 of the report by Gernez[88], but so far few attempts have been made at a theoretical generalisation of the numerous factural data available. It is now known only that the resolution is possible if the solubility of each pure enantiomorph is higher than that of the racemic modification [89] and if the racemate consists of a mechanical mixture of the enantiomorph crystals and not a solid solution. Many substances resolved by crystallisation are known. Thus Shelomova et al. [90], who employed the method of Velluz et al. [91], elaborated the conditions for the resolution of (±)-*threo*-2-amino-1-*p*-nitrophenylpropane-1,3-diol, which involve rapid cooling of a system consisting of 86% of the racemate in the form of the hydrochloride, 14% of the free racemic aminodiol, and 10% (relative to the weight of the racemate) of the L-(+)-form. The study of the solubility curves of the racemate and the enantiomorphs of the diol showed that, if the system contains an excess of one of the enantiomorphs, its crystallisation begins. In his large review, Secor [92] quotes numerous cases of selective crystallisation, discusses the theoretical possibilities and limitations of the method, and examines the phase diagrams for systems containing optical isomers.

Powell [93] noted that the racemic substance can form crystalline molecular compounds with an optically inactive compound. This results in overcoming the van der Waals forces maintaining the enantiomorphs in the crystalline racemate and, instead of the racemate (*dl*), the *Md* and *Ml* compounds crystallise from solution, *M* being the optically inactive substance. The majority of these molecular compounds are resolved spontaneously. The advantages of such resolutions are evident: no chemical reactions are involved, there is no need to introduce additional functional groups into the racemic alcohol molecule, it is possible to resolve small amounts of substances into their enantiomorphs, etc. Powell [93] suggests that similar processes may have resulted in the appearance of the initial asymmetry in nature. A study [36] of the resolution of biphenylyl-1-(8-methylnaphthyl)phenylmethanol may be quoted as an example of the "spontaneous" resolution of racemic alcohols: the (+)-enantiomorph was isolated by crystallisation from ether and the (−)-enantiomorph was crystallised from cyclohexane.

2. CHROMATOGRAPHIC RESOLUTION

This group of methods includes the chromatographic resolutions on natural asymmetric agents (wool, polysaccharides, crystals of optically active quartz, and others [94]) and also on synthetic asymmetric agents. Examples of resolution by adsorption are discussed in detail in Klabunovskii's review [95]. The relations governing the resolution of racemic substances on starch columns have been formulated [96]. The use of brucine as an adsorbent made it possible to resolve (±)-2-octyl hydrogen phthalate [97]. Recently many resolutions have been carried out on synthetic optically active ion-exchange resins. Many such ion exchangers have been synthesised. Suda and Oda [98] prepared resins from the chloromethylated copolymer of styrene with divinylbenzene and brucine or quinone. In a recent review, Suda [99] discusses the synthesis of optically active ion-exchange resins by the polycondensation of various optically active acids or bases and the separation of racemic substances on these exchangers. Poly{[L-(1-carboxy methyl)sulphamoyl]styrene} and the D-isomer of the polymer were employed for the partial resolution of atrolactic acid [$C_6H_5(OH)C(CH_3)COOH$], mandelic acid, and other substances [100]. There is no doubt that synthetic optically active ion-exchange resins can also be employed for the resolution of various derivatives of racemic alcohols. Mixtures of racemic terpene alcohols were resolved by being brought into contact with optically active polymers under the conditions of the transesterification reaction with subsequent elution [101]. Racemic menthol in tetrahydrofuran in the presence of catalytic amounts of toluene-*p*-sulphonic acid was introduced into a column containing a granular resin obtained by the copolymerisation of a 1 : 1 mixture of (+)-s-butyl methacrylate and maleic anhydride with 2–20 wt.% of divinylbenzene and then slowly eluted with tetrahydrofuran containing alcohol and toluene-*p*-sulphonic acid, which led to the isolation of the enantiomorphs of menthol.

In 1969 resolutions with the aid of liquid ion exchangers were achieved [102]. The authors synthesised two liquid ion-exchangers: (−)-*N*-methyl-α-methylbenzyl-(1-naphthyl)amine and (−)-*N*-α-methylbenzyl(n-octadecyl)amine and determined the separation factors for the enantiomorphs of the sodium salts of (±)-mandelic acid and (±)-*N*-acetylalaline in periodic partition between aqueous solutions of the salts and the solutions of the ion exchangers in chloroform. The optical isomers of the first salt were separated by countercurrent partition; the optically pure product can be isolated even if the liquid ion exchanger is not optically pure. Although this study concerns directly only the resolution of salts of racemic

acids, the equations and principles quoted are also applicable to the resolution of other racemic substances, including alcohol derivatives, by chromatography or countercurrent partition, which yields in a single operation both enantiomorphs in equal amounts.

The development of the gas–liquid chromatographic method has led to the possibility of direct resolution of racemic alcohols and other substances by g.l.c. on an optically active stationary phase. The studies in this field were stimulated by the fact that the influence of solvents (employed in adsorption chromatography), which might have a levelling effect on the difference between the absorption properties of the enantiomorphs, is eliminated in g.l.c. Experimental conditions for the resolution of α-pipecoline, acetylmethylmethanol and other compounds have been described [103] but subsequently this study could not be reproduced [104]. Later Gil-Av et al. reported the resolution of racemates by g.l.c. on an optically active stationary phase using capillary columns equivalent to a large number of theoretical plates. Apart from its use for analytical purposes, the resolution of racemates by g.l.c. can also be of preparative value [60]. The resolution of 2-butanol, 2-pentanol, and phenylethanol by g.l.c. on an optically active quartz column has been investigated [105] and has been shown to be unsatisfactory.

The resolution of racemates by paper chromatography has been discussed by Yanovskaya [106]. The most detailed reviews of the chromatographic resolution of racemates have been published by Rogozhin and Davankov [107] and Buss and Vermeulen [108].

3. RESOLUTION WITH THE AID OF OPTICALLY ACTIVE LIQUID SUBSTANCES

A study of the resolution of racemates with liquid ion-exchangers has already been mentioned [104]. The different interfacial tensions between the enantiomorphs and an optically active liquid can also be used for the resolution of a racemic mixture [109]. If the liquid racemate is emulsified in an optically active liquid or in a solution of an optically active substance, the enantiomorphs will be deposited at different rates.

Nevertheless the most promising processes for resolution with the aid of optically active liquids are crystallisation and extraction. Although van't Hoff [110] suggested as early as the end of the last century that the solubilities of enantiomorphs in optically active substances will be different, for a long time resolution by crystallisation from optically active solvents could not be achieved. Recently examples of such resolutions have been published. 2,3-Dibromobutane-1,4-diol and di-(4-pyridyl)glycol were resolved into optical isomers by crystallisation from di-isopropyl-D-tartrate [111]; after the third recrystallisation 167 mg (!) of the optically active substance was obtained from 20 g of the racemate. The same substances were partly resolved by partitioning their racemic modifications between an aqueous medium and D-tartaric acid esters [112]. It has been suggested that there is a type of bonding between the racemate and the solvent medium and that, owing to the differences between the configurations, one enantiomorph is geometrically more suitable for the formation of such bonding than the other. If hydrogen bonds are possible, these are the most likely to be formed [113].

If each of the two enantiomorphs forms an azeotrope with a third optically active substance, the diastereoazeotropes can have boiling points differing so much that they can be separated by fractional distillation [114]. This hypothesis has not been confirmed in attempts to resolve 2-octanol with (+)-limonene as the third component under different experimental conditions. Nevertheless the study of the boiling point diagrams for systems gives rise to the hope that certain resolutions can be achieved by the distillation of diastereoazeotropes.

4. OTHER METHODS OF RESOLUTION

Sometimes the racemate is resolved by its interaction with an optically active substance which results in the formation of readily decomposed molecular complexes instead of diastereoisomers. By employing digitonin as the complex-forming agent, it proved possible to resolve the racemates of α-terpineol, tetrahydro-β-naphthol, and *i*-carvomenthol [115]. 2-Phenylbutan-1-ol was partly resolved into its optical isomers with the aid of deoxycholic acid [116]. The authors suggested that the optically selective action of lipolytic enzymes may be due to bile acids.

Numerous examples of the kinetic resolution of alcohols by selective interaction with an optically active agent have been described in the literature. Marckwald and McKenzie [117] carried out a partial esterification of (±)-2-octanol with D-tartaric acid, the unreacted part of the alcohol proving to be optically active. Here mention should also be made of stereoselective biochemical processes which consist in the selective action of various micro-organisms on one of the enantiomorphs (the so called "Pasteur's third method" [118]).

The methods enumerated in this section have been analysed in detail in special reviews and monographs [2–5].

---o0o---

A good example of classical resolution carried out recently is the separation of the enantiomorphs of 2-chloro-9-fluorenol [119]. The attempts to resolve 2-chloro-9-fluorenyl phthalate with the aid of brucine, strychnine, quinidine, and cinchonidine in various solvents were unsuccessful; also unsuccessful were the attempts at resolution with the aid of ephedrine in benzene, chloroform, and acetone. A partial resolution was achieved via the diastereoisomeric salts with ephedrine in alcohol. The acid phthalate obtained was crystallised from chloroform; the racemate was less soluble (cubic crystals) and the optically active form was subsequently isolated in the form of long needles. The isolation of the enantiomorphs of 2-chloro-9-fluorenol from the acid phthalates was achieved by treatment with methylmagnesium iodide in ether, since hydrolysis leads to racemisation. Anders and Cooper [121] isolated by g.l.c. the diastereoisomeric esters formed by racemic alcohols with 3β-acetoxy-Δ^5-etienic acid, which were separated previously [120] by fractional crystallisation. Methylphenylmethanol, ethylphenylmethanol, cyclohexylphenylmethanol, n-hexylmethylmethanol, and other alcohols were resolved in this way. Preparative separation of diastereoisomeric alcohol derivatives by g.l.c. was achieved by a number of other investigators [122,123]. For example the racemic mixture of 3,3-dimethylbutan-2-ols was resolved [123] by synthesising their esters with *N*-trifluoroacetyl-L-alanine, which were then separated by g.l.c. In a continuation of studies [79] on the resolution of racemic carbohydrates, Pollock and Jermany [124] separated by g.l.c. the diastereoisomeric esters formed by galactonic and gluconic acids with 2-butanol, 3-methylbutan-2-ol, and

3,3-dimethylbutan-2-ol. A further development of the theoretical aspects of the resolution of diastereoisomers by g.l.c. is described by Feibush [125].

Recently the present authors reported [126] the separation of the optical isomers of 1,2,4,5,6-penta-*O*-acetylmyoinositol via the diastereoisomeric D-mannose orthoacetates and of 1,4,5,6-tetra-*O*-acetylmyoinositol with subsequent deacetylation of the separated orthoacetates and the isolation of the enantiomorphs of myoinositol penta-acetate by mild acid hydrolysis. Molotkovsky and Bergelson [127] carried out a new resolution of myoinositol penta-acetates by the crystallisation of the diastereoisomeric salts of the acid oxalates of myoinositol penta-acetate with quinidine or α -phenylethylamine. The physicochemical constants of the enantiomorphs, which they isolated by treating the separated acid oxalates with lead tetra-acetate in a pyridine–dioxan mixture in an atmosphere of argon, were close to those of the optically active myoinositol penta-acetates which we obtained previously [126].

Modern methods for the resolution of alcohols are described in a recent review by Boyle [128].

Cleavage of Saturated Nitrogen-containing Heterocycles at the C-N Bond by Electrophilic Agents

E.I.Levkoeva and L.N.Yakhontov

The review deals with reactions involving the opening of saturated nitrogen-containing rings at the C-N bond under the influence of acids, their anhydrides, esters, acid halides, and a number of other electrophilic agents. The use of the reverse Ritter reaction and of the Braun reaction for the cleavage of saturated heterocycles containing a secondary nitrogen atom is discussed.
The bibliography includes 137 references.

I.	Introduction	603
II.	Cleavage of saturated heterocycles containing a tertiary nitrogen atom	604
III.	Cleavage of saturated heterocycles containing a secondary nitrogen atom	609

I. INTRODUCTION

The cleavage reactions of saturated nitrogen-containing heterocycles at the C — N bond are widely used to establish the structures of natural compounds and are of definite preparative value in organic synthesis.

Various methods for the rupture of endocyclic C — N bonds in saturated systems have been described in the literature. In the first place mention should be made of the cleavage of quaternary ammonium bases and their salts by the Hofmann and Emde methods involving heat treatment or treatment with alkalis, amalgams, and alkali metals in liquid ammonia.

These methods, which have been used successfully in the study of the structures of alkaloids and other complex heterocyclic systems, have been discussed in detail in fairly complete reviews[1-7]. Methods for the dissociation of C — N bonds in the catalytic dehydrogenation of alkaloids and on their distillation with zinc dust have been analysed in other reviews[8,9].

More specific are examples, described in various publications, of the cleavage at the C — N bonds of saturated cyclic amines in hydrogenolysis[10], the Wolff-Kishner[11-13] and Clemmensen[14-19] reduction reactions, and also as a result of oxidative[20] and electrochemical processes[21,22], in rearrangements[23-25], in transamination reactions[5,26], and in various tautomeric conversions[27-32].

In recent years attention has been increasingly drawn to a wide variety of methods for the opening of the C — N bond of saturated heterocyclic rings with a secondary or tertiary nitrogen atom by a number of electrophilic agents.

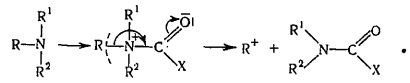
In view of the lack of reviews on reactions of this kind, it is desirable to give a general account of data from a fairly large number of publications.

The present review consists of two sections: the first deals with the cleavage reactions of saturated heterocycles containing a tertiary nitrogen atom by acids, anhydrides, acid halides, and esters and the second deals with the dissociation of C — N bonds of saturated cyclic secondary amines under the conditions of the reverse Ritter reaction and the Braun reaction.

The cleavage of tertiary cyclic amines by cyanogen bromide using the Braun method has not been included in the present paper, since the problem is dealt with in a fairly complete review[33] where the mechanism, conditions, and applications of this reaction are discussed in detail.

II. CLEAVAGE OF SATURATED HETEROCYCLES CONTAINING A TERTIARY NITROGEN ATOM

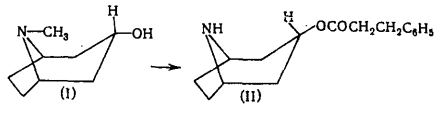
One of the methods for the dissociation of the C — N bond in tertiary amines involves their conversion into quaternary compounds by interaction with carboxylic acids or their derivatives: anhydrides, acid halides, chlorocarbonic esters, phosgene, and certain other electrophilic agents. The functional group attached to nitrogen withdraws the electron pair from the bond mainly as a result of its $-E$ effect, facilitating further dissociation:



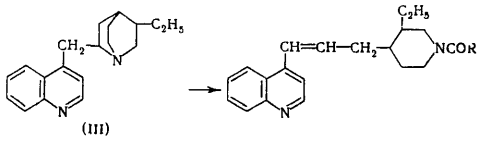
The cleavage of many tertiary cyclic amines has been achieved by this mechanism, the carbonium cation R^+ being subsequently stabilised either by the abstraction of a proton and the formation of a double bond or as a result of attack by nucleophilic agents (halide ions, water, alcohols, nitrogenous bases, etc.) with conversion into derivatives having the corresponding functional groups.

1. Dissociation of the C — N Bond by Acids

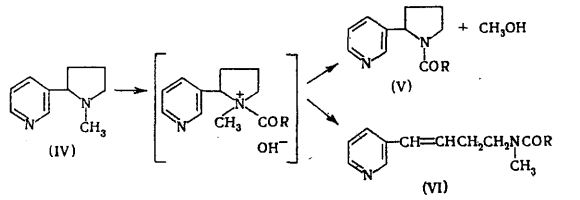
Saturated heterocyclic systems with a tertiary nitrogen atom are usually resistant to organic and inorganic acids. For example, *N*-methylpyrrolidine and *N*-methyl-1, 2, 3, 4-tetrahydroisoquinoline undergo only *N*-demethylation without ring opening on refluxing with benzoic, palmitic, acetic, or dihydrocinnamic acids[34]. When tropine(I) is heated to 200°C in the presence of dihydrocinnamic acid, the corresponding nortropine ester (II) is formed[34]:



Ring opening by acids is achieved only in compounds where the C — N bond is weakened owing to electron-accepting or bulky substituents at the carbon atom adjoining the nitrogen atom. Thus the quinuclidine ring is readily opened by acids when the α-position relative to the nitrogen atom contains a bulky substituent which is involved in addition in the formation of a conjugated bond system after ring opening. Similar cleavage takes place with dihydrodeoxycinchonine (III):[35]

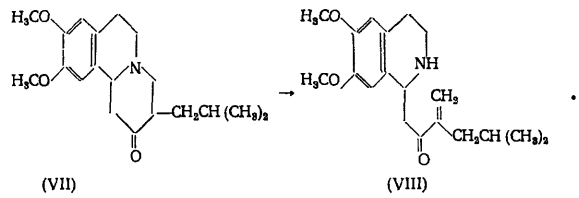


When nicotine (IV) is heated with benzoic or dihydrocinnamic acid until it starts to boil slightly, a product (VI) with an open pyrrolidine ring is formed together with *N*-acylnornicotine (V); the amount of compound (VI) increases with reaction temperature[36]:



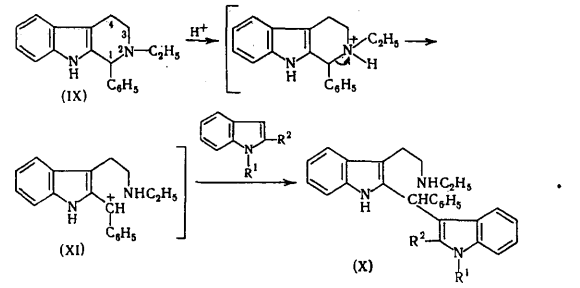
The acid cleavage of the C — N bond in saturated nitrogen-containing rings has been used to establish the structures of a number of natural compounds. Studies on the chemistry of Pereiro alkaloids containing the indoline group[37] and the *Voacanga africana* alkaloids—voacamine and voacorine, which are derivatives of 1, 2, 3, 4-tetrahydro-β-carboline[38]—may be quoted as examples.

In the course of the synthesis of emetine, Brossi et al.[39] showed that, when substituted benzoquinolizine (VII) is refluxed with acetic acid, the piperidine ring is cleaved and an unsaturated compound (VIII) is formed:



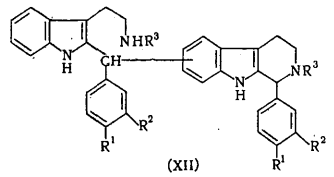
The mechanism of the opening of nitrogen-containing rings by acids has been examined in detail for the reactions of 1-aryl-1, 2, 3, 4-tetrahydro-β-carbolines[40].

When 2-ethyl-1-phenyl-1, 2, 3, 4-tetrahydro-β-carboline (IX) is heated with various indole derivatives in the presence of acetic and phosphoric acids, condensation products of type (X) are formed in high yields:



The cleavage of compound (IX) in an acid medium takes place exclusively at the $C_{(1)}$ — N bond, since only in this case is a mesomerically stabilised carbonium ion (XI) (similar to the diphenylmethyl cation) formed. The authors suggest that the $C_{(1)}$ — N bond is polarised owing to the protonation of the 2-N-nitrogen atom and attack by the nucleophilic agent (indole) at the 1-C atom, which leads ultimately to the dissociation of the ring. The carbonium cation (XI) formed interacts with the most reactive position (the 3-position) of the indole molecule. If the 3-position is occupied, the condensation involves the 2-position, which is much less reactive. In the case of 2, 3-disubstituted indoles, the reaction involves the benzene ring. Dimers of 1-aryl-1, 2, 3, 4-tetrahydro-β-carbolines (XII), which

are structural analogues of the alkaloid voacamine, were synthesised similarly[40]:

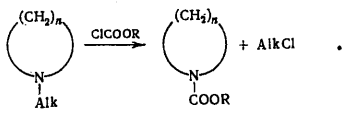


(XII)

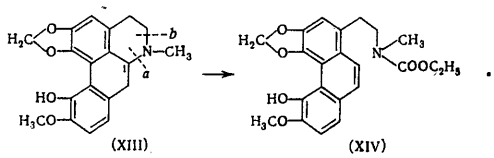
When the aryl substituent at 1-C is replaced by an alkyl substituent, the addition of indole does not take place, since the stabilisation of the carbonium cation (XI), which is essential for the reaction, cannot take place. The introduction of electron-accepting groups in the *para*-position of the phenyl substituent at 1-C enhances appreciably the reactivity of the compounds.

2. Dissociation of the C — N Bond by Chlorocarbonic Esters

Chlorocarbonic esters are regarded as "group agents" for the opening of the piperidine ring in 1,2,3,4-tetrahydroisoquinolines. The capacity of tetrahydroisoquinoline to be cleaved readily at the $C_{(1)}$ — N bond under the influence of ethyl chlorocarbonate was first observed as early as 1921 by Gadamer and Knoch[41]. Subsequently it was shown[42-44] that different quinoline, isoquinoline, pyridine, piperidine, and pyrrolidine derivatives do not undergo ring opening under these conditions. When chlorocarbonic esters are allowed to react with *N*-alkyl piperidines[43,44], tropane[44], or *N*-alkylpyrrolidines[42], only *N*-dealkylation processes take place with formation of alkyl chlorides and *N*-alkoxycarbonyl derivatives of the initial heterocycles:

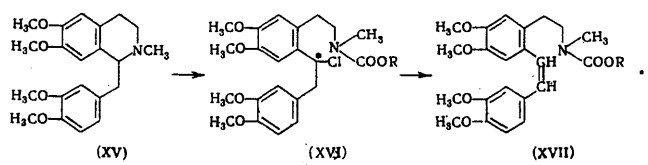


On the other hand, the majority of 1,2,3,4-tetrahydroisoquinolines readily undergoes selective dissociation at the $C_{(1)}$ — N bond on treatment with chlorocarbonic esters and are converted in quantitative yields into the corresponding open-chain urethanes. For example, the alkaloid bulbocapnine (XV), the Hofmann degradation of which is not unambiguous (it can occur via pathway *a* and *b*), gives rise only to compound (XIV) on treatment with ethyl chlorocarbonate, i.e. it is cleaved only at the $C_{(1)}$ — N bond[41]:



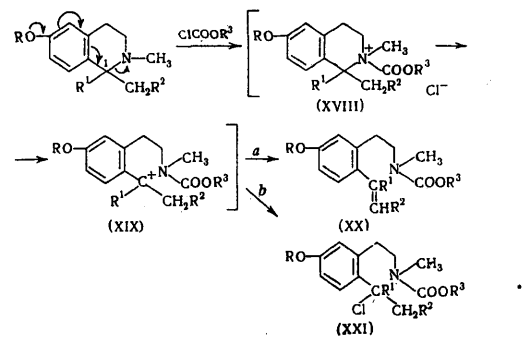
(XIII) (XIV)

When (-)-laudanosine (XV) interacts with chlorocarbonic esters, the initial product is the optically active chloroderivative (XVI), which splits off hydrogen chloride in the presence of alkali and gives rise to compound (XVII):[41,45]



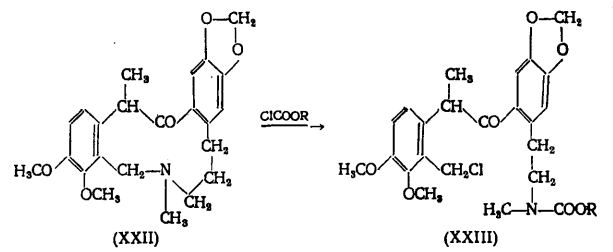
(XV) (XVI) (XVII)

Knabe and coworkers[45-49] examined the effects of substituents in the benzene ring on the ease of dissociation of the $C_{(1)}$ — N bond in 1,2,3,4-tetrahydroisoquinolines and proposed a possible reaction mechanism. They established that, on treatment with chlorocarbonic esters, the piperidine ring in *N*-methyl-1,2,3,4-tetrahydroisoquinoline cannot be cleaved, which can be accounted for by the inadequate polarity of the $C_{(1)}$ — N bond in this compound. The introduction of electron-donating groups in the *ortho*- or *para*-position of the benzene ring enhances the polarisation of the $C_{(1)}$ — N bond and facilitates the addition of the chlorocarbonic ester residue to the nitrogen atom. This results in the formation of a quaternary compound of type (XVIII) in which the $C_{(1)}$ — N bond is readily dissociated and the carbonium cation (XIX) thus obtained may be stabilised in two ways: (a) with elimination of a proton and formation of the unsaturated compound (XX); (b) via attack by a chloride ion with formation of the chloroderivative (XXI):



(XVIII) (XIX) (XX) (XXI)

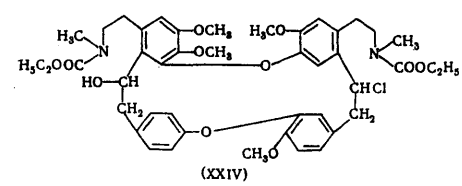
If the carbon atom adjoining 1-C does not have a proton capable of being split off, for example in the alkaloid corycavidine (XXII), a stable chlorourethane (XXIII) is formed[50]:



(XXII) (XXIII)

Otherwise, as mentioned above for (-)-laudanosine (XV), an unsaturated compound can be readily obtained.

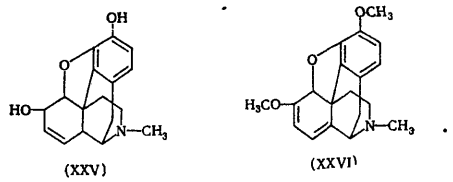
When the methyl ether of hydroxyacanthine is cleaved by chlorocarbonic ester in the presence of potassium hydroxide, the initially formed carbonium cations are stabilised by the addition of chloride and hydroxide ions with formation of compound (XXIV):[46,51]



(XXIV)

The reaction of chlorocarbonic esters with morphine (XXV) and codeine is known to result only in the acylation of the alkaloid at the hydroxy-group, while in the reaction

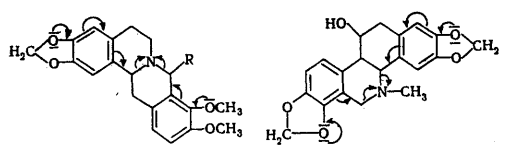
with thebaine (XXVI) the opening of the piperidine ring takes place with an almost quantitative yield[41,52]:



(XXV) (XXVI)

The example of thebaine shows that an aromatic system is not essential for ring opening. It is sufficient that the electron-donating substituent is conjugated with an allylamine residue.

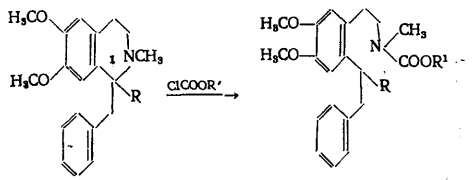
It is interesting that alkaloids of the tetrahydroberberine group (XXVII), which have, as it were, a "double benzylamine structure", do not undergo the opening of the piperidine ring when acted upon by chlorocarbonic esters[46,48]:



(R = H, $CH_2C_6H_5$) (XXVII) (XXVIII)

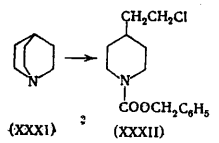
Initially it was suggested[46] that the opposed electron shifts in the two benzylamine systems in compounds of this type may reduce the polarisation of the C — N bond and prevent the reaction with chlorocarbonic ester. However, the alkaloid chelidonine (XXVIII), which also has a "double benzylamine structure", is readily cleaved at the C — N bond under these conditions[41].

Evidently not only electronic but also steric factors, primarily the degree of screening of the nitrogen atom attacked, play a major role in these processes. Indeed, whereas the yield of the urethane (XXIXa) from 1-benzyl-6,7-dimethoxy-2-methyl-1,2,3,4-tetrahydroisoquinoline (XXXa) is nearly quantitative[48], the introduction of a methyl group in the 1-position reduces the yield of compound (XXIXb) to 29% and the 1-ethyl homologue (XXXc) does not form the corresponding urethane (XXIXc) at all under standard conditions[49].



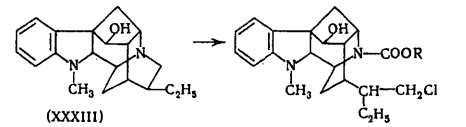
(XXX) [R = H (a), CH_3 (b), or C_2H_5 (c)] (XXIX)

Further studies showed that the cleavage of heterocycles at the $C_{(1)}$ — N bond by chlorocarbonic esters is not confined to substituted 1,2,3,4-tetrahydroisoquinolines or analogous systems in which electron-donating substituents are conjugated with the allylamine residue. It was possible to cleave the quinuclidine ring in an aprotic medium with the aid of these esters. When unsubstituted quinuclidine (XXXI) was treated with benzyl chlorocarbonate, the urethane (XXXII) was obtained in 88% yield[44]:



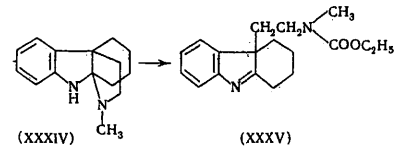
(XXXI) (XXXII)

It has been shown for 21-deoxyajmaline (XXXIII) that bicyclic systems with a nitrogen bridge are cleaved when acted upon by benzyl chlorocarbonate in a higher yield (98%) than on treatment with the corresponding ethyl ester (yield 55%)[44]:



(XXXIII)

Ethyl chlorocarbonate has been successfully used for the dissociation of the N — C bond also in *N*-methylechibolinе (XXXIV).[53] This involves the opening of the condensed pyrrolidine ring, the urethane (XXXV) being isolated in a yield of 65%:

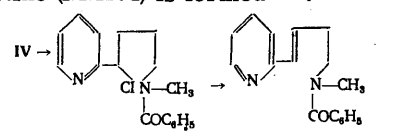


(XXXIV) (XXXV)

3. Dissociation of the C — N Bond by Acid Halides

Since acid halides are powerful electrophilic agents, they should apparently have found a wide application in reactions involving the cleavage of heterocyclic tertiary amines. However, the reaction of acid halides with tertiary amines containing even one α-hydrogen atom usually gives rise to the corresponding ketens. Therefore mainly phosgene or benzoyl halides, which are incapable of the formation of ketens, were used previously in C — N bond dissociation reactions.

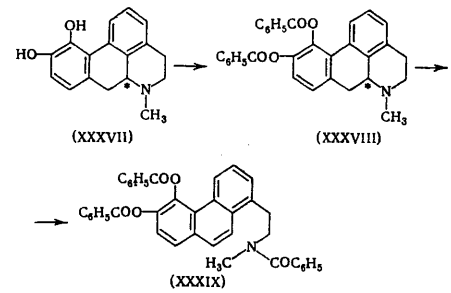
Thus, as early as 1894, a study of the reaction of benzoyl chloride with nicotine (IV) established that, when a mixture of these substances is heated to 200°C, *N*-benzoylmetanicotine (XXXVI) is formed[54,55]:



(XXXVI)

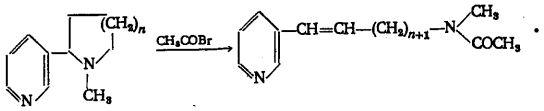
A thorough investigation of the products of this reaction led to a convincing proof of the structural formula of nicotine[54-56].

In the determination of the structure of apomorphine (XXXVII), its cleavage was also achieved with the aid of benzoyl chloride[57]. The optically active dibenzoyl derivative (XXXVIII) formed initially in this reaction reacts further with the excess benzoyl chloride, which results in the opening of the piperidine ring and the formation of an optically inactive non-basic product (XXXIX):



(XXXVII) (XXXVIII) (XXXIX)

Recently it was suggested that, with amines which are cleaved particularly readily, the amount of keten formed from the acid halide can be reduced to a minimum[58]. Indeed the reaction of acetyl bromide with nicotine (IV) yielded *N*-acetylmetanicotine (XLa) in 46 — 52% yield, while *N*-methylanabasine gave a 23% yield of the product (XLb), which is formed on opening of the piperidine ring:

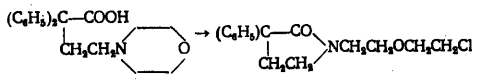


(IV) (XL) (*a*) $n=1$; (*b*) $n=2$

Appreciable amounts of keten were not detected in these reactions.

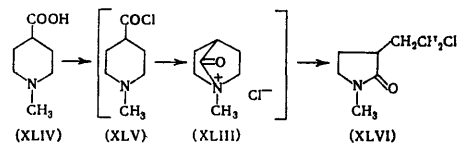
The cleavage of the piperidine ring of thebaine (XXVI) was achieved with the aid of acetyl and benzoyl chlorides in moist ethyl acetate, the corresponding codeinoacylnormethines being obtained in yields of about 90%.[52]

The intramolecular acylation of the chlorides of γ-aminoacids with a tertiary ring nitrogen atom has been the subject of a special study[59]. It was found that the reaction of γ-*N*-pyrrodinyl-, γ-*N*-piperidinyl-, and γ-*N*-morpholinyl-αα-diphenylbutyric acids (XLI) with thionyl chloride results in the opening of the heterocycle and the formation of the corresponding chloroalkyl derivatives of the *N*-substituted α-pyrrolidinone (XLII):



(XLI) (XLII)

A similar reaction occurred in the synthesis of the bicyclic lactam (XLIII) as a result of the interaction between thioonyl chloride and *N*-methylisonipecotic acid (XLIV).[59] Compound (XLIII) proved to be extremely unstable and was converted under the reaction conditions into β-chloroethyl-*N*-methyl-α-pyrrolidinone (XLVI):



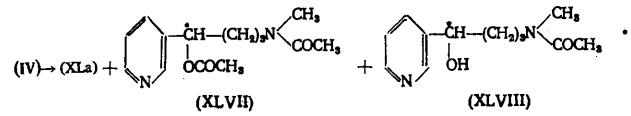
(XLIV) (XLV) (XLIII) (XLVI)

4. Dissociation of the C — N Bond by Acid Anhydrides

Acid anhydrides (mainly acetic anhydride) are fairly widely used for the cleavage of tertiary amines, including saturated nitrogen-containing heterocycles.

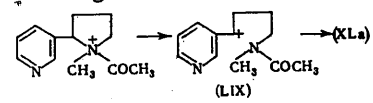
Tiffeneau's classical studies[60] showed that acid anhydrides cleave most effectively tertiary amines in which the nitrogen atom is linked to the benzyl residue and that the nature of the substituents in the benzine ring is important.

The ease of opening of the pyrrolidine ring in nicotine was also explained by its belonging to amines of the "benzyl type"[55]. In a recent study[61] of the effect of structural factors on the cleavage of tertiary amines by acetic anhydride, the interaction of the latter with nicotine (IV) was examined in detail. 1-Acetoxy-4-(*N*-methylacetamido)-1-(β-pyridyl)butane (XLVII) and 1-hydroxy-4-(*N*-methylacetamido)-1-(β-pyridyl)butane (XLVIII), which on vacuum distillation are converted into compound (XLa), were isolated from the reaction product together with *N*-acetylmetanicotine:



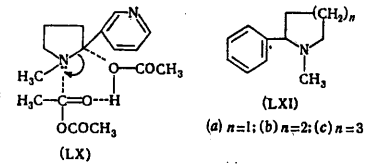
(XLVII) (XLVIII)

It is very likely that the formation of compound (XLa) from nicotine proceeds via the intermediate carbonium cation (LIX), which is stabilised subsequently by the elimination of a proton and the formation of a double bond conjugation with the pyridine ring:



(LIX)

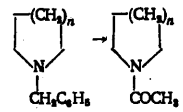
The presence of the hydroxy-derivative (XLVIII) and the acetoxy-derivative (XLVII) among the reaction products might be regarded as due to the addition of a hydroxy-group and an acetic acid residue respectively to the carbonium cation (LIX). However, the products obtained on stabilisation of the carbonium cation (LIX) should be racemates, while compounds (XLVIII) and (XLVII) proved to be optically active. Since the yield of the products of the cleavage of nicotine by acetic anhydride increases in the presence of water[62] or acetic acid[61], it was suggested[63] that the reaction proceeds simultaneously via two mechanisms: (1) via the formation of the carbonium cation (LIX), which gives rise immediately to *N*-acetylmetanicotine (XLa); (2) via a six-membered transition state of type (LX), which leads to compounds (XLVII) and (XLVIII).



(LXI) (*a*) $n=1$; (*b*) $n=2$; (*c*) $n=3$

(LX)

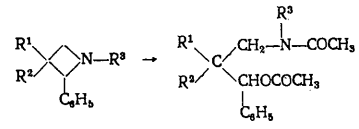
It has been shown[61] that a benzene analogue of nicotine—*N*-methyl-α-phenylpyrrolidine (LXIa)—is cleaved like nicotine on its interaction with acetic anhydride. On the other hand, the reaction of *N*-benzylpyrrolidine and *N*-benzylpiperidine, which do not contain substituents in the α-positions of the ring, with acetic anhydride in the presence of acetic acid involves the dissociation of the exocyclic C — N bond only:



It is noteworthy that the course of the above reaction is determined not only by the nature of the substituents at the nitrogen and α-carbon atoms but also by the size of the ring undergoing cleavage. Thus *N*-alkylpiperidines remain unchanged even after refluxing for 100 h with acetic anhydride and acetic acid. Under the same conditions, *N*-alkylpyrrolidines and *N*-alkylhexamethyleneimines form the corresponding acyclic amides, albeit in low yields (11 — 14%). Similarly the piperidine ring in *N*-methyl-α-phenylpiperidine (LXIb) is cleaved by acetic anhydride with much more difficulty than the five- or seven-membered ring in compounds (LXIa, c)[61].

The four-membered ring of *N*-alkylazetidines (LXII) is opened very readily on heating with acetic anhydride.

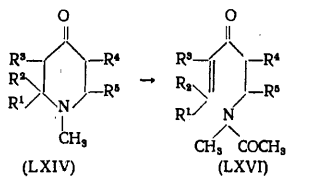
This results in the formation of quantitative yields of the corresponding γ-acetamidoacetates (LXIII):[64]



(LXII) (LXIII)

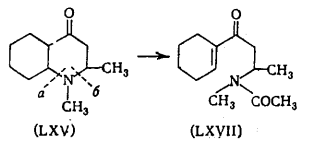
The nature of the substituents at the β-carbon atom in azetidine does not have a significant influence on the ease of ring opening and in the presence of a substituent at the α-carbon atom the C — N bond adjoining the substituent is dissociated[64,65].

A number of studies have been made[66,67] on the interaction of acetic anhydride with *N*-methylpiperidine-4-ones (LXIV) and *N*-methyldecahydro-4-quinolones (LXV) containing methyl groups in various positions in the piperidine ring. It was established that at room temperature or on heating the components to 100°C, the piperidine ring is not cleaved. The corresponding β-acylaminoketones (LXVI) are formed in maximum yields (60 — 80%) on refluxing with acetic anhydride for 2.5 — 10 h.



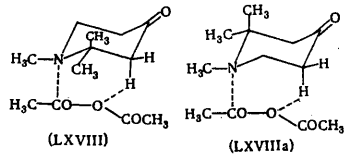
(LXIV) (LXVI)

It has been noted[66,67] that the opening of the piperidine ring always takes place with formation of "amidoketones" (LXVI) in which the vinyl group is alkylated to the maximum extent, i.e. the dissociation takes place at the most straining C — N bond. 1,2-Dimethyldecahydro-4-quinolone (LXV) is converted into a cyclohexene derivative (LXVII) on refluxing with acetic anhydride. There is no cleavage at the N — C(CH_3) bond. Consequently the effect of the cyclohexane ring, responsible for the cleavage of the piperidine fragment via pathway *a*, is much greater than that of the methyl group:



(LXV) (LXVII)

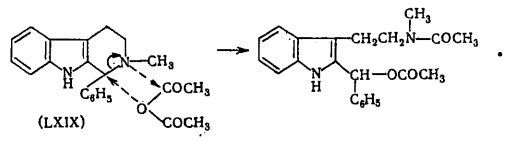
In the discussion of the possible mechanism of the opening of the γ-piperidine ring in compound (LXIV), it was suggested[67] that the reaction proceeds via a six-membered intermediate state (LXVIII):



(LXVIII) (LXVIIIa)

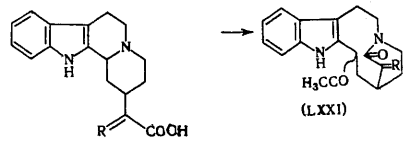
However, the formation of (LXVIII) has not been demonstrated experimentally. On the other hand, one should note that the existence of such an intermediate state does not account for the preferential dissociation of the C — N bond adjoining the most alkylated carbon atom. Indeed, it would in fact appear that the geminal substituents at the α-carbon atom should hinder the formation of the transition state (LXVIII) and should facilitate the formation of (LXVIIIa).

Therefore it appears more likely that such reactions take place via four-membered intermediate complexes of type (LXIX), proposed by Freter and coworkers[40,68] in their description of the interaction of 1-phenyl-1,2,3,4-tetrahydro-β-carboline derivatives with acetic anhydride:



(LXIX)

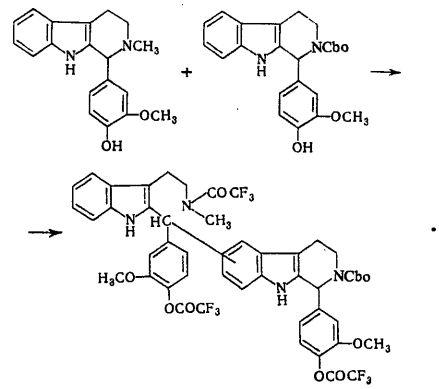
The piperidine ring of dihydrocorynantheine (LXX) was opened similarly in the presence of acetic anhydride and the cleavage products were isolated in the form of acetoxylactams (LXXI):[69]



(LXXI)

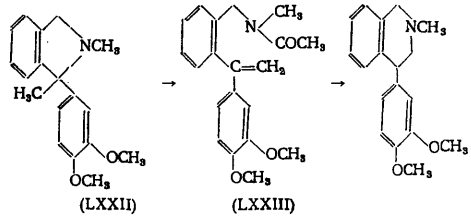
(LXX): R = H_2, CH_3OCH

Catalytic amounts of carboxylic acids may have a definite influence on the mechanism of the reactions under consideration. In order to eliminate acid catalysis, the C — N bond in 1,2,3,4-tetrahydro-β-carbolines was dissociated by trifluoroacetic anhydride in tetrahydrofuran (THF):[40]



However, the presence of phenolic hydroxyls in the initial compounds, the acylation of which involves the formation of trifluoroacetic acid, invalidates the conclusions of this investigation to some extent.

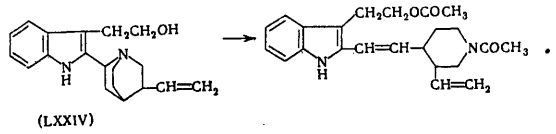
A novel method of converting the isoindoline structure into the 1,2,3,4-tetrahydroisoquinoline structure was described recently[70]. When acted upon by acetic anhydride, isoindoline (LXXII) is cleaved to the unsaturated amide (LXXIII), which then undergoes ring closure in a highly alkaline medium to a 1,2,3,4-tetrahydroisoquinoline derivative:



(LXXII) (LXXIII)

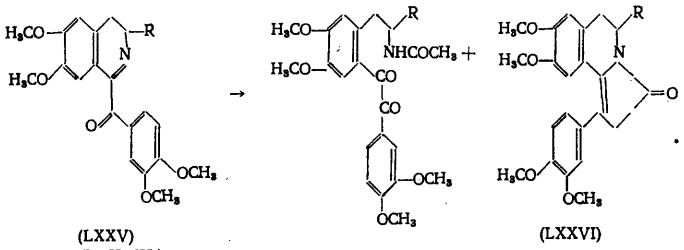
An interesting example of the use of acetic anhydride for the opening of a nitrogen-containing ring is provided by a study[71] undertaken to demonstrate the structure of

cinchonamine (LXXIV). The quinuclidine ring in this alkaloid is dissociated by acetic anhydride at the C — N bond adjoining the carbon atom linked to the indole component of the molecule:



(LXXIV)

It should be noted that unsaturated rings, such as the 3,4-dihydroisoquinoline ring in compound (LXXV), are also readily cleaved on refluxing with acetic anhydride. However, in these cases the process is complicated by the formation of side products of type (LXXVI):[72]

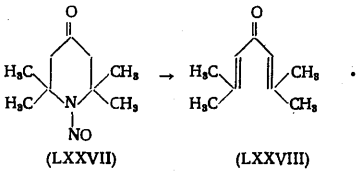


(LXXV) (R=H, CH_3) (LXXVI)

III. CLEAVAGE OF SATURATED HETEROCYCLES CONTAINING A SECONDARY NITROGEN ATOM

The C — N bond in saturated secondary amines is appreciably stable. Its thermal dissociation can be achieved only on heating to 350 — 400°C. However, the ease of dissociation of this bond may be increased by introducing certain substituents both at the nitrogen and at the α-carbon atom. For this purpose, the nitrogen atom should contain strongly electron-accepting groups, namely NO,[73] COR,[74] $SO_2C_6H_5$,[75] Br,[75,76] and others and the α-carbon atom should be linked to bulky geminal substituents which increase the strain in the C — N bond[77,78], or to allylic substituents which facilitate the stabilisation of the carbonium cation formed as a result of the dissociation of the C — N bond.

As an example one may quote 2, 2, 6, 6-tetramethyl-*N*-nitrosopiperidin-4-one (LXXVII), which on heating to 80°C yields phorone (LXXVII):[73]

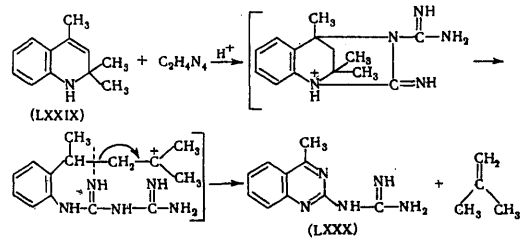


(LXXVII) (LXXVIII)

Two factors operate at once in this case: those associated with the electron-accepting nitroso-group at the nitrogen atom and the two bulky substituents at the α-carbon atom, which leads to a comparatively easy dissociation of the ring.

The introduction of electron-accepting polyfunctional groups at the nitrogen atom usually entails not only the dissociation of the C — N bond weakened thereby but also further reactions (various intramolecular condensations and rearrangements) which frequently lead to unexpected compounds.

For example, 2, 2, 4-trimethyl-1, 2-dihydroquinoline hydrochloride (LXXIX) reacts with dicyanodiamide in aqueous solution to give a 68% yield of 2-guanidino-4-methylquinazoline hydrochloride (LXXX):[79,80]

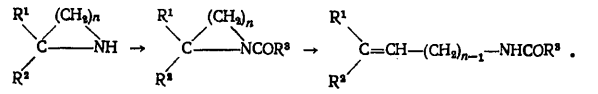


(LXXIX) (LXXX)

The most thoroughly investigated reactions involving the opening of saturated secondary cyclic amines include the reactions of their *N*-acyl derivatives with the dissociation of the endocyclic C — N bond under the conditions of acid hydrolysis on heating (the reverse Ritter reaction) and also under the influence of compounds such as phosphorus pentoxide under the conditions of the Braun reaction.

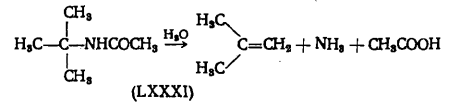
1. Dissociation of the C — N Bond under the Condition of the Reverse Ritter Reaction

In order to open the rings of saturated cyclic secondary amines containing geminal substituents at the α-carbon atom, the following method is frequently employed nowadays: the amine is converted into an *N*-acyl derivative, which is then cleaved to an unsaturated acyclic compound on heating in an acid medium:



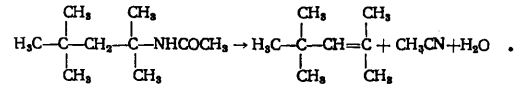
A similar cleavage of amides in which the nitrogen atom is linked to a quaternary carbon atom is known as the reverse Ritter reaction.

It has been shown[74] for t-butylacetamide (LXXXI), which is hardly hydrolysed by alkalis[81], that in an acid medium compounds of this kind readily decompose into an olefin, ammonia, and an acid via the following mechanism:



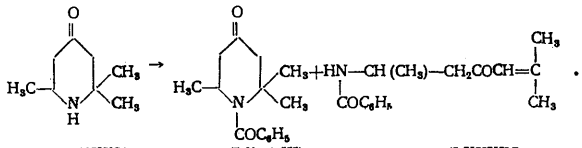
(LXXXI)

Steric hindrance at the α-carbon atom makes amides with this structure inert in relation to other substances. These compounds do not react with Grignard reagents and with acylating substances and are not reduced by hydrogen even at elevated temperatures and pressures. However, on heating to boiling, the most unstable of them decompose with formation of the corresponding nitriles and unsaturated compounds[74]:



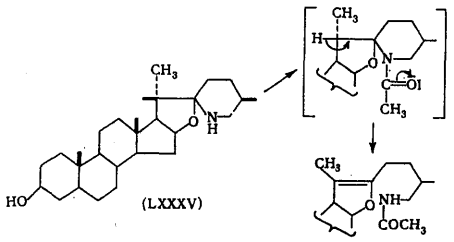
An *NN*-disubstituted amide usually yields an unsaturated monoamide. For example, the interaction of vinyl diacetoneamine [2, 2, 6-trimethyl-4-oxopyrrolidine] (LXXXII) with benzoyl chloride gives rise, together with the

expected *N*-benzoyl derivative (LXXXIII), to its cleavage product—the acyclic amide (LXXXIV):[82]



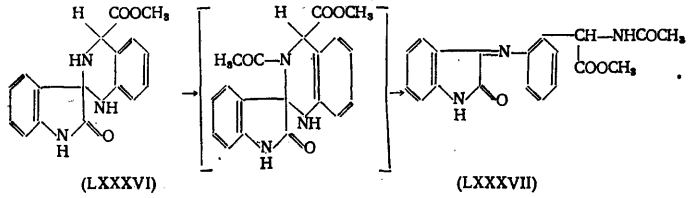
(LXXXII) (LXXXIII) (LXXXIV)

In the *N*-acetyl derivatives of the steroid alkaloids solasodine tomatidine (LXXXV), the piperidine ring is cleaved extremely readily under the conditions of the reverse Ritter reaction: after refluxing for 15 min in the presence of acetic or propionic acid and even at room temperature in the presence of hydrochloric or perchloric acid[83]:



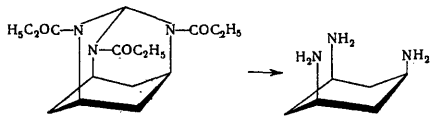
(LXXXV)

In the determination of the structures of isamic acid esters (LXXXVI), the tetrahydropyrimidine ring was opened under the influence of acetic anhydride with formation of the compound (LXXXVII), which has a highly strained system of conjugated bonds[84]:



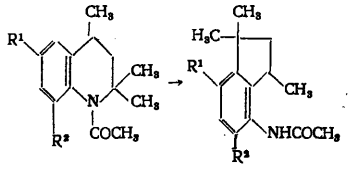
(LXXXVI) (LXXXVII)

When *NN'N"*-Tripropionyl-2,4,10-triaza-adamantane (LXXXVIII) is heated with concentrated hydrochloric acid, *cis*-1,3,5-triaminocyclohexane (LXXXIX) is formed[85]:



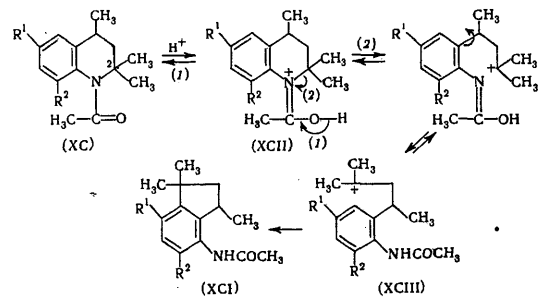
(LXXXVIII) (LXXXIX)

Electrophilic substitution reactions in an acid medium involving sterically hindered cyclic amides can be accompanied by the cleavage of the ring via the reverse Ritter reaction. Thus nitration of substituted 1-acetyl-2,2,4-trimethyl-1,2,3,4-tetrahydroquinolines (XC) (at 100°C for 1 h) in the presence of sulphuric or polyphosphoric acid led to the isolation of the corresponding indane derivatives (XCI):[86]



(XC) (XCI)
(R^1 и R^3=H, Br, NO_2)

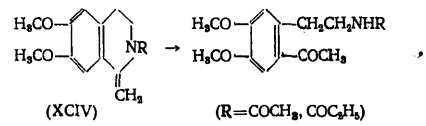
It is believed[86] that the protonation of the amide carbonyl with formation of the unstable ion (XCII) plays a decisive role in the rearrangement:



(XC) (XCII) (XCI) (XCIII)

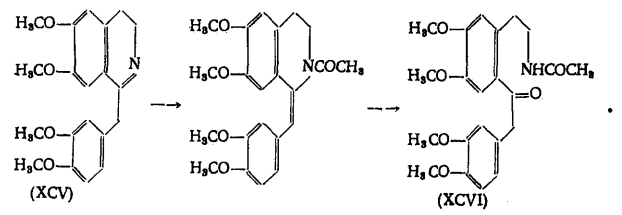
The ion (XCII) may be stabilised either by the loss of a proton (pathway *1*) or by conversion into the carbonium ion (XCIII) (pathway *2*). Then in compound (XCIII) the free *ortho*-position in the benzene ring is attacked with formation of the indane derivative (XCI). The authors[86] state that examination of atomic models demonstrates an appreciable steric interaction between the carbonyl group of the amide and the *gem*-dimethyl substituents at 2-C. After the removal of one methyl group, the strain of the $C_{(2)}-N$ bond is appreciably reduced. Thus *gem*-dimethyl groups at the α-carbon atom on the one hand facilitate the dissociation of the $C_{(2)}-N$ bond and on the other hand stabilise the intermediate ion (XCIII).

The opening of the piperidine ring in 2-acyl-1-methylene-1,2,3,4-tetrahydroisoquinolines (XCIV) in the presence of hydrochloric acid is facilitated by the electron-donating effect of the benzene ring with methoxy-groups in the 6- and 7-positions[87]:



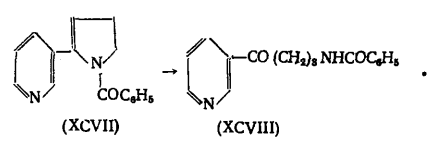
(XCIV) (R=$COCH_3$, COC_2H_5)

The dihydroisoquinoline ring of the intermediate in the synthesis of norapormorphine (XCV) is cleaved similarly to compound (XCIV); its *N*-acetyl derivative, containing the benzylidene substituent at 1-C, is converted on heating with hydrochloric acid into the corresponding deoxybenzoin (XCVI):[88]



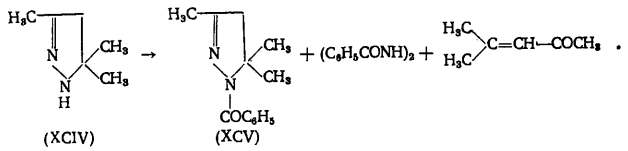
(XCV) (XCVI)

The cleavage of *N*-benzoylmyosmine (XCVII) leading to compound (XCVIII), may serve as an example of the opening of the Δ^2-pyrroline ring[89]:



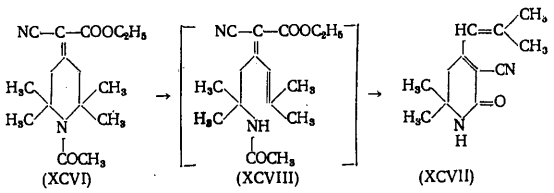
(XCVII) (XCVIII)

When pyrazolines are acylated by acid chlorides, the dissociation of C — N bonds and ring opening are also observed[90–93]. Benzoylation of 3, 5, 5-trimethylpyrazoline (XCIV) leads to the formation of dibenzoylhydrazine and mesityl oxide together with the expected amide (XCV):[93]



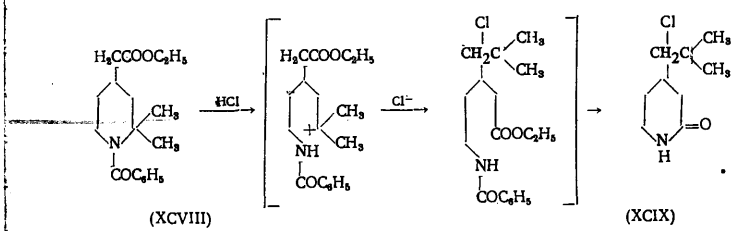
(XCIV) (XCV)

Heating of *N*-acetyl derivatives of piperidine with geminal substituents in the α-position also leads to relatively easy dissociation of the $C_{(\alpha)}$ — N bond accompanied in many cases by further reactions of the substance. For example, 1-acetyl-4-(cyanoethoxycarbonylmethylene)-2, 2, 6, 6-tetramethylpiperidine (XCVI) is converted on heating to 130°C into dehydro-2-piperidinone (XCVII)—a product of the intramolecular condensation of the unsaturated amide (XCVIII):[94]



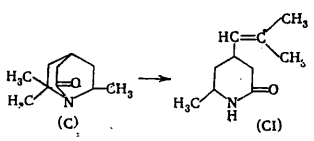
(XCVI) (XCVIII) (XCVII)

When *N*-benzoyl-4-ethoxycarbonylmethyl-2, 2-dimethylpiperidine (XCVIII) is refluxed with hydrochloric acid, a substituted 2-piperidinone (XCIX) [95] is formed, probably via the following mechanism:



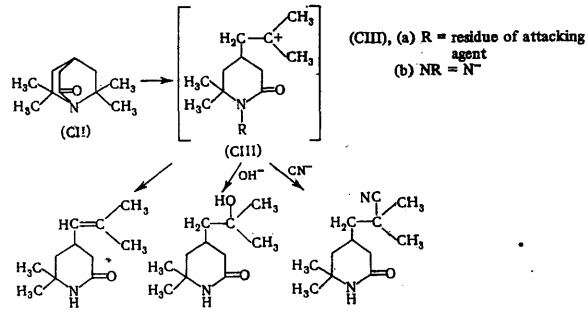
(XCVIII) (XCIX)

In many cases the products of the reverse Ritter reaction were not isolated and their formation was inferred from the change in the infrared spectrum of the reaction mass. For example, after 6, 6, 7-trimethyl-2-quinuclidone (C) ($\nu_{C=O}$ = 1750 cm^{-1}) has been allowed to stand for a long time, an absorption band appears in the infrared spectrum in the region of 1640 cm^{-1}; it was assigned to absorption by the amide carbonyl of the open-chain form (CI):[96]



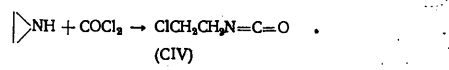
(C) (CI)

A similar cleavage of 6, 6, 7, 7-tetramethyl-2-quinuclidone (CII) takes place even more readily[97]. Here the unstable carbonium cation (CIII) is probably formed initially and then stabilised either by the addition of nucleophilic agents or as a result of the elimination of a proton with formation of an unsaturated compound:



(CI!) (CIII), (a) R = residue of attacking agent (b) NR = N^-

Evidently the cleavage of cyclic secondary amines by phosgene or sulphonyl chlorides belongs to reactions of this type. Under the influence of phosgene, aziridine readily gives rise to β-chloroethyl isocyanate (CIV):[98]

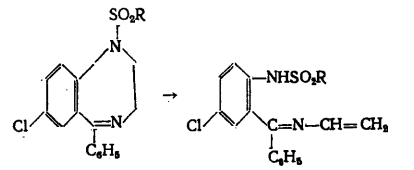


(CIV)

The introduction of the tosyl or methanesulphonyl group at the nitrogen atom also favours ring opening at the C — N bond. On refluxing in benzene, 2-phenyl-*N*-tosylazetidine (CV) is converted into the acyclic sulphonamide (CVI), which is formed as a result of the Friedel — Crafts alkylation of benzene by the cleavage product of the azetidine ring (CVII):[99]

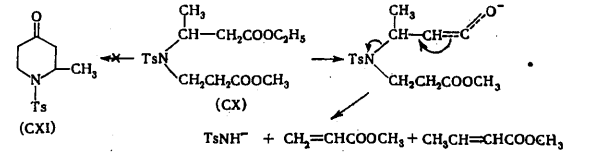
(CV) (CVII) (CVI)

When an attempt was made to remove with the aid of sodium hydride the tosyl (or methanesulphonyl) group from substituted 1, 4-benzodiazepines (CVIII), the vinylimines (CIX) were obtained, their structure being demonstrated by synthesis[100]:



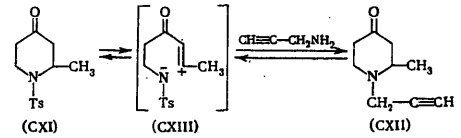
(CVIII) (CIX)

Mistryukov and Aronova[101] observed that, under the conditions of the Dieckmann reaction, the *N*-tosyl derivative (CX) does not give rise to the corresponding γ-piperidinone (CXI) but is decomposed under the influence of sodium hydride via the following mechanism:



(CXI) (CX)

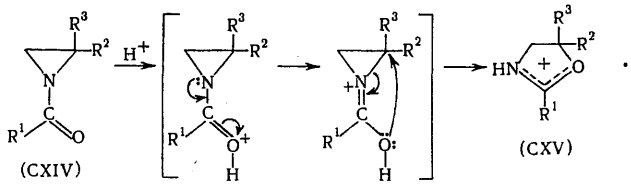
An attempt to split off in a similar way toluenesulphonamide from compound (CXI) was unsuccessful[101]. When 2-methyl-*N*-tosylpiperidin-4-one (CXI) was treated with propargylamine, only traces of the expected 2-methyl-*N*-propargylpiperidin-4-one (CXII) were detected:



(CXI) (CXIII) (CXII)

It is believed[101] that this is either due to the considerable shift of the equilibrium (CXI) ⇌ (CXIII) towards the cyclic form (CXI) or to the reduced nucleophilic properties of the open-chain form (CXIII) owing to the negative charge on the sulphonamide nitrogen.

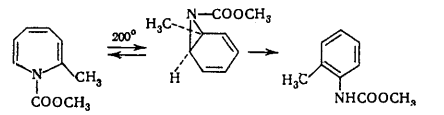
There are numerous publications on the cleavage, under the conditions reverse of the Ritter reaction, of small rings (azetidines and aziridines) with different electron-accepting residues at the nitrogen atom[102-107]. Thus, in a highly acidic medium, substituted 1-acylaziridines (CXIV) are converted quantitatively into the corresponding oxazolonium cations. The study of the ^{1}H NMR spectra at −55°C led to the hypothesis[104] that initially the amide group in compound (CXIV) is *O*-protonated with rapid opening of the aziridine ring and conversion into the *O*-protonated oxazolone, the latter being immediately converted into the oxazolonium ion (CXV):



(CXIV) (CXV)

(R^1 = CH_3, C_6H_5)

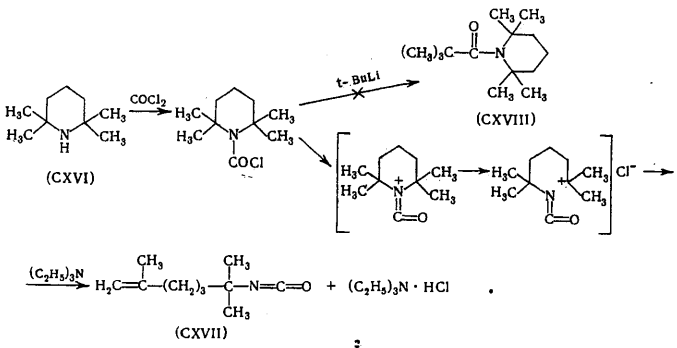
The reactions of 1-*H*-azepines accompanied by aromatisation may be regarded as of the same type. On heating to 200°C, *N*-methoxycarbonylazepines substituted in the 2-position are known to be converted[108,109] in high yields into aromatic urethanes:



In the presence of dilute acids, these processes take place much more readily, frequently at room temperature[109-111]. When the molecule contains several substituents, isomers may be formed as a result of sigmatropic migrations[109].

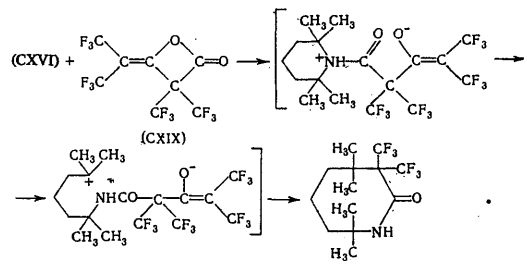
In a study dealing with amide conjugation in cyclic systems[112], it was noted that attempts at the synthesis of sterically hindered amides, where a planar disposition of the −N−C=O group is impossible, lead to molecular rearrangement already in the course of acylation. This leads to the formation of the usual conjugated amide system. An increase of steric hindrance by the branching of the alkyl substituents in the amine molecule promotes the dissociation of the C−N bond with formation of a stable t-alkyl cation.

When 2,2,6,6-tetramethylpiperidine (CXVI) reacts with phosgene in the presence of lithium t-butoxide, only the isocyanate (CXVII) is obtained and the expected cyclic amide (CXVIII) is hardly formed:



(CXVI) (CXVIII) (CXVII)

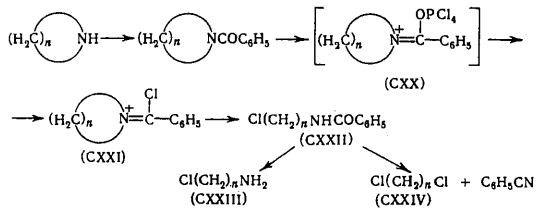
Examination of atomic models showed that the most favourable steric conditions for cleavages of this kind obtain in screen β-lactones as acylating agents. For example, on reaction with the β-lactone (CXIX), 2,2,6,6-tetramethylpiperidine (CXVI) undergoes the following transformations[112]:



(CXIX)

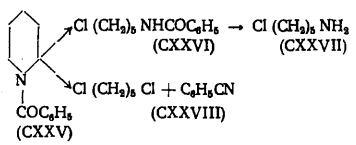
2. The Braun Reaction

The dissociation of the C−N bond in secondary cyclic amines can be achieved by a method developed by Braun[113,114]. For this purpose, the benzoyl derivative of the amine is heated with phosphorus pentachloride at 115−120°C. This results in the formation of the unstable tetrachlorophosphoranoate (CXX)† which then readily decomposes to the corresponding chloroimino-derivative (CXXI). Hydrolysis of compound (CXXI) yields a substituted benzoylamine (CXXII), the hydrolysis of which gives the monochloro-substituted amine (CXXIII). Further interaction of compound (CXXI) with phosphorus pentachloride at 180−200°C yields the dichloro-derivative (CXXIV) and benzonitrile:



(CXX) (CXXI) (CXXII) (CXXIII) (CXXIV)

For example, when *N*-benzoylpiperidine (CXXV) was allowed to react with phosphorus pentachloride at 120°C, the product was 1-(*N*-benzamido)-5-chloropentane (CXXVI), the alkaline hydrolysis of which leads to 1-amino-5-chloropentane (CXXVII). An increase of reaction temperatures to 200°C results in the formation of 1,5-dichloropentane (CXXVIII) and benzonitrile[114]:



(CXXV) (CXXVI) (CXXVII) (CXXVIII)

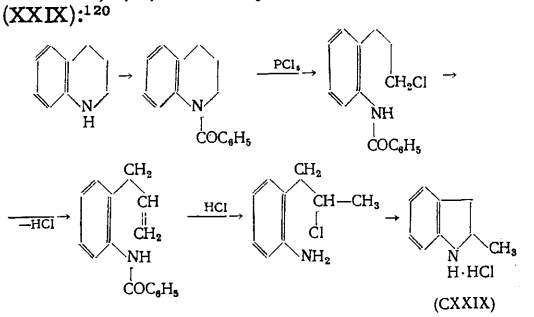
Apart from phosphorus pentachloride, phosphorus pentabromide[116], phosgene[117], and thionyl chloride[117,118] may be used in the Braun reaction. An attempt has been made to employ thionyl bromide also[117], but, on heating, the latter decomposes readily and acts as a brominating

† The lifetime of tetrachlorophosphoranoate derivatives of amides is usually very short. However, in the case of acid amides, containing powerful electron-accepting substituents, these compounds have been isolated and characterised [for example, the products of the interaction of trichloroacetamides with phosphorus pentachloride: $CCl_3C(OPCl_4)$ = NR].[115]

agent, leading to the formation of a large number of side products.

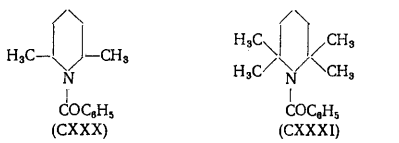
The scope of the Braun reaction is fairly wide and it has been used to open the rings of pyrrolidine[119], 1,2,3,4-tetrahydroquinoline[114,120-122] and its derivatives[123,124], indoline[125] and its derivatives[124,126,127], the alkaloids coniine[128], camphidine[129], etc.

The Braun reaction can be used also for the contraction of nitrogen-containing rings; this was demonstrated in the conversion of 1,2,3,4-tetrahydroquinoline into 2-methylindoline (XXIX):[120]



(CXXIX)

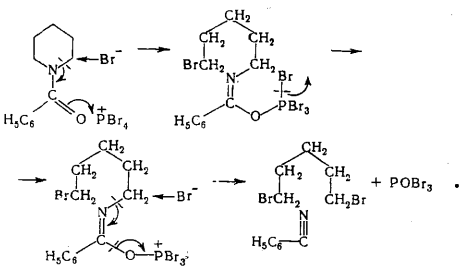
A number of studies have been made on the mechanism of the Braun reaction[130-136], in which the structure of the intermediates, the effects of substituents in the amine and acyl components of the molecule, and the kinetics of the individual stages of the process were considered. Leonard and Nommensen[134] studied several series of *N*-disubstituted benzoylamines in order to determine the effect of the screening of the α-carbon atom by alkyl substituents on the course of the Braun reaction. During this investigation, it was established that, whereas *N*-benzoylpiperidine reacts with phosphorus bromide to form 1,5-dibromopentane in 78% yield[114], the yield of the corresponding dibromide decreases with increasing steric hindrance at the α-carbon atom. With *N*-benzoyl-2,6-dimethylpiperidine (CXXX), the reaction takes place only to the extent of 19% and the tetramethyl derivative (CXXXI) does not form an aliphatic halogeno-derivative at all[134]:



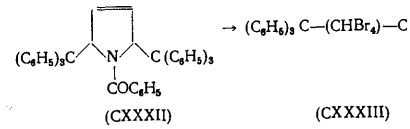
(CXXX) (CXXXI)

Similarly the yield of alkyl halides in the Braun reaction decreases with increasing screening also in the series of *N*-benzoyl derivatives of the isomeric heptyl- and butyl-amines, which supports a bimolecular reaction mechanism.

In addition, it has been shown for *N*-benzoyl-s-butylamine that, in the presence of an asymmetric carbon atom, the situation is reversed. On the basis of these findings, it has been suggested[134] that the bimolecular process in the reaction under consideration may be represented in the following way:

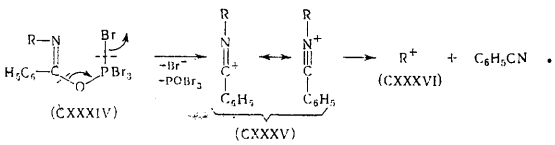


At the same time in a number of cases it has proved possible to achieve the Braun reaction with amides where the approach α-carbon atom is hindered by substituents. Thus the interaction of *N*-benzoyl-2,5-di(triphenylmethyl)-Δ^3-pyrroline (CXXXII) with phosphorus pentabromide yields 1,2,3,4-tetrabromo-1,4-di(triphenylmethyl)butane (CXXXIII) in 15% yield[137]:



(CXXXII) (CXXXIII)

Probably such sterically hindered amides react via a different mechanism involving an intermediate "carbonium-ammonium" ion. Leonard and Nommensen illustrate this mechanism by the reaction of *N*-alkylbenzoylamines with phosphorus pentabromide[134]:



(CXXXIV) (CXXXV) (CXXXVI)

The first attack by phosphorus pentabromide leads to the abstraction of a proton from the amide nitrogen and the formation of the intermediate (CXXXIV) which on decomposition can give rise to the "carbonium-ammonium" ion (CXXXV). The latter decomposes on heating into benzonitrile and the carbonium ion (CXXXVI), which, depending on its structure and the nature of the surrounding medium, can be converted into an olefin (with elimination of a proton) or can react with the available bromide ions to form an alkyl bromide.

Certain aspects of the Braun reaction have been investigated in recent years[135,136]. Various conclusions concerning the influence of the screening of the α-carbon atom in the amine part of the molecule have been confirmed and it has been shown for *N*-benzoylamine that the Braun reaction can be achieved as a rule with high yields when there are no substituents at the α-carbon atom[136].

Comparison of the yields of alkyl halides from substituted *N*-benzoylamines established that they correspond to the stability of the carbonium ion (CXXXVI). For example, the yield of benzyl chloride is 20 — 50%, while benzyl chlorides substituted in the *ortho*-position are formed in 80 — 85% yield.

New hypotheses have arisen in recent years concerning the role of the acyl residue in the Braun reaction. Earlier much importance was not attached to the nature of this part of the molecule. Braun used for acylation benzoyl chloride, which is most readily available, although he believed that any aromatic acid halide may be used for this purpose[114]. Leonard and Nommensen noted[134] that the screening of the α-carbon atom in the acyl part of the amide molecule does not affect the yield of the halogeno-derivative. However, Carlson[118,136] showed that the yields of substituted benzyl chlorides from the corresponding *N*-benzoylbenzylamines are higher than from the analogous *N*-acetylbenzylamines. This finding can also be accounted for by the fact that the phenyl group promotes the stabilisation of the intermediate ion of type (CXXXV) to a greater extent than does the methyl group.

Effects of Steric Hindrance in Molecules on the Properties and Synthesis of Hydrocarbons

V.V.Voronenkov and Yu.G.Osokin

Data on the steric hindrance in hydrocarbon molecules have been reviewed. The effect of steric hindrance on the physical properties of hydrocarbons (specific gravity, refractive index, and refraction) and on their ultraviolet and ^{1}H NMR spectra has been demonstrated. The influence of steric hindrance on the synthesis of hydrocarbons in alkylation, oligomerisation, and polymerisation reactions has been examined. A theoretical explanation has been given for a number of reactions occurring anomalously under the influence of steric hindrance.
The bibliography includes 160 references.

CONTENTS

I. Introduction 616
II. The nature of steric hindrance 616
III. Steric hindrance in the synthesis of hydrocarbons 621

I. INTRODUCTION

Hydrocarbons are a valuable starting material for the main products of large-scale organic synthesis[1]. At the same time they are convenient for the investigation of steric hindrance in molecules. This is because in hydrocarbons interactions of other types are reduced to a minimum. Therefore, when steric hindrance arises in molecules, its effect is shown most clearly in hydrocarbons. In the literature[2-10] dealing with the study of compounds of this class, the important role of steric hindrance in chemical reactions of hydrocarbons has been frequently pointed out. However, so far there have been almost no systematic descriptions of data on this problem. This review deals with the effect of steric hindrance on the physicochemical properties and synthesis of hydrocarbons.

II. THE NATURE OF STERIC HINDRANCE

Examination of numerous literature data for hydrocarbons leads to the conclusion that steric hindrance alters their molecular geometry, which entails an increase of the internal energy of such molecules, so that among the isomers of hydrocarbons, sterically hindered structures become thermodynamically less stable.

The change in molecular geometry takes place in the following three ways: rotation about the bonds with the displacement of one part of the molecule from the plane of the other, deformation of valence angles in the plane, and extension of the bonds between atoms.

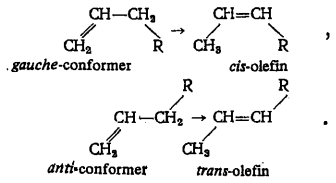
The changes undergone by the molecule under the influence of steric hindrance occur simultaneously. However, since the extension of bonds requires a much larger energy than does rotation about a single bond and the deformation of the valence angle of such a bond, it evidently follows that the first two types of geometrical changes will be mainly observed.

1. Rotational Isomerism in Hydrocarbons

When the distribution of atoms in space was considered in terms of classical stereochemistry, account was taken only of the interatomic distances and valence angles. Although this made it possible to understand many features of the structure and chemical behaviour of hydrocarbons, no less significant results in this field were achieved after the appearance of conformational concepts[9-13].

Interesting electron diffraction studies on the conformations of hydrocarbon molecules in the gas phase were carried out by Vilkov and coworkers[14]. In the determination of the energetically favourable molecular conformation, they took into account not only the repulsion between atoms not linked by valence bonds but also the interaction between the bonds in the molecule. Table 1 presents the preferred conformations of the rotational isomers of a number of hydrocarbons, taking into account the above factors.

For propene, but-1-ene, and other α-olefins, the eclipsed and *gauche*-conformations predominate. This has been demonstrated in a study of the ^{1}H NMR spectra[15] of but-1-ene, pent-1-ene, and hex-1-ene and has been confirmed by calculation[16]. In the ground state of liquid alk-1-enes the *gauche*-conformations predominate, but, on passing to olefins with a more bulky group R, the *anti*-conformations become more stable owing to a reduced steric hindrance. Such distribution of conformations accounts satisfactorily for the experimentally observed[17,18] *cis*-stereospecificity of the positional isomerism of various olefins.



Studies on a number of conjugated dienes by ultraviolet spectroscopy[19] revealed a transoid conformation of the sterically unhindered alkyl-substituted diene hydrocarbon. The *trans*-configuration of such hydrocarbons is additionally stabilised by the maximum degree of π,π conjugation.

Evidently the conjugation effect is responsible for the stable configurations of phenylcyclobutane and phenylcyclopropane, since the "banana bonds" of the latter are capable of conjugation with the aromatic ring. The rotational isomerism of alkyl derivatives of cyclic hydrocarbons is important[20-23]. Its effect on the reactions of

cyclic hydrocarbons has been examined in a review by Bragin and Liberman [10].

At the present time conformational analysis of hydrocarbons has developed so much that it has now become possible to make satisfactory predictive calculations of the energetically favourable conformations [16,28,29]. Thus, according to Kitaigorodskii [28], the potential energy which determines the conformational properties of molecules consists of the energy of interaction (repulsion) between atoms not linked by valence bonds and the elastic energy of the valence angles. The optimum conformation should correspond to an energy minimum and should arise from a compromise between the tendency of the non-bonded atoms to move apart to equilibrium distances and the tendency of the valence angles to retain the ideal values. In this connection it is of interest to quote a statement by A.A. Chugaev who wrote as early as 1904 "Chemical molecules represent [are a result of] a mechanism involving a certain energy store. In order to understand the operation of such mechanisms, it is necessary to know to an equal extent their internal structure and the distribution of energy in them" [30].

Kitaigorodskii calculated the most favourable conformations of certain hydrocarbons (bicyclic terpenes). Kitaigorodskii's method makes it possible to predict accurately the deviations of the C–C–C angles in alkanes from the tetrahedral value to 112.5°.

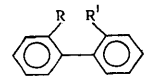
Using Kitaigorodskii's concepts, Dashevskii [29] developed a method for the calculation of the energies of formation of hydrocarbon molecules from atoms. He calculated the geometries and atomisation energies of straight-chain alkanes and their isomers.

Table 1. Stable conformations of the rotational isomers of various hydrocarbons.

Hydrocarbon	Conformation of isomer	References
Ethane		24
Butane	 *anti-* *gauche-*	12,13
Propene		14,25
α-Butene		14
Butadiene		14
Cumene		26
Phenylcyclobutane		26
Phenylcyclopropane		27

2. Atropisomerism of *oo'*-Dialkyl-substituted Biphenyls

A special case of conformational isomerism is the atropisomerism of *oo'*-disubstituted biphenyls:



As a result of the interaction of the groups R and R' in the *oo'*-positions of biphenyl, rotation of the benzene rings about the common axis becomes impossible; therefore the molecule becomes asymmetric and optical isomerism appears. Thus Meisenheimer [31] and Mills [32,33] showed by calculation that the presence of methyl groups in the *oo'*-positions is sufficient to hinder rotation. According to the Adams empirical rule, the resolution of biphenyls into optical isomers is possible when the sum of the C–R and C–R' bond lengths is greater than 2.90 Å. The steric hindrance in *oo'*-dialkylbiphenyls and their steric strain increase fairly rapidly with increasing branching of the alkyl group. Therefore the synthesis of *oo'*-di-t-butylbiphenyl is extremely difficult [34].

3. Effect of Steric Hindrance on the Physical and Chemical Properties of Hydrocarbons. The Auwers–Skita rule

The first constant widely used in organic chemistry to assess the molecular structure of hydrocarbons was molecular refraction. It was noted that the refraction of *o*-dialkylbenzenes is lower than the refractions of the corresponding *m*- and particularly *p*-isomers [35,36]. Since molecular refraction is proportional to atomic volume [37], its lower value for *o*-dialkylbenzenes is evidence of a denser packing of the atoms of the alkyl groups in their molecules compared with the *m*- and *p*-isomers. This conclusion is confirmed by the finding that *o*-dialkylbenzenes have higher densities, refractive indices, and boiling points than the *p*-substituted derivatives where there is no steric hindrance (Table 2).

Thus a kind of steric "contraction" (condensation) is observed in *o*-dialkylbenzenes, due to the interaction of adjacent alkyl groups not linked by valence bonds (the "ortho-effect"). Such "contraction" results in the appearance of repulsion forces which hinder the rotation of the alkyl groups about the single $C_{ar}-C_{alk}$ bond, leading to the deformation of the angles between these bonds and an increase of the internal energy of the molecule [38-39].

o-Dialkylbenzenes are geometrically similar to *cis*-olefins and the *p*-isomers are similar to *trans*-olefins (the Werner rule [40]). This analogy is reflected also in the

physical properties. The densities, refractive indices, and boiling points of *cis*-olefins, like those of *o*-dialkylbenzenes, are higher than for the *trans*-isomers; at the same time the molecular refractions of *cis*-olefins are lower than those of *trans*-olefins (Table 3).

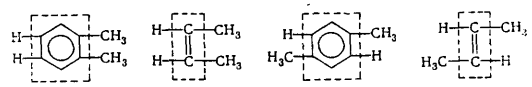


Table 2. Physical constants of *o*- and *p*-dialkylbenzenes.

Hydrocarbon	MR_D, cm^3	B.p., °C	ρ_4^{20}, g cm^{-3}	n_D^{20}
p-Xylene	36.02	138.35	0.8610	1.4958
o-Xylene	35.77	144.41	0.8802	1.5054
p-Cymene	45.34	177.25	0.8573	1.4909
o-Cymene	45.04	178.35	0.8766	1.5000
p-Diethylbenzene	48.82	183.75	0.8619	1.4948
o-Diethylbenzene	48.53	183.42	0.8799	1.5026

Thus a steric "contraction" of alkyl groups analogous to that in *o*-dialkylbenzenes is observed in *cis*-olefins. It has been shown by ^{1}H NMR [42] that in *cis*-but-2-ene there is indeed an appreciable overlapping of the van der Waals spheres of the methyl groups, which does not happen in the *trans*-isomer.

Table 3. Physical constants of *cis*- and *trans*-olefins [41].

Hydrocarbon	MR_D, cm^3	B.p., °C	ρ_4^{20}, g cm^{-3}	n_D^{20}
trans-Pent-2-ene	25.61	36.35	0.6432	1.3793
cis-Pent-2-ene	25.38	36.94	0.6555	1.3898
trans-Hex-2-ene	29.59	67.88	0.6779	1.3936
cis-Hex-2-ene	29.34	68.84	0.6872	1.3976
trans-Hex-3-ene	29.61	67.08	0.6770	1.3943
cis-Hex-3-ene	29.40	66.45	0.6799	1.3950

The overlapping of the van der Waals spheres leads to the mutual repulsion of the *cis*-alkyl groups, which in turn leads to an increase of the valence angles and of the strain in the double bond ("cisoid repulsive strain") [43]. The strain in the double bond can be estimated experimentally from thermochemical data by comparing the negative heats of hydrogenation of olefins (Table 4).

It follows from Table 4 that, with increase of the bulk of the alkyl groups in the *cis*-position of the olefin, the negative heat of hydrogenation also increases, which corresponds to a greater strain in the C=C bond and hence to a greater deviation of the C=C–C valence angle [from the ideal value], which amounts to 136° in *cis*-di-t-butylethylene. The main consequence of such strain in the double bond is an enhanced reactivity in reactions characteristic of the usual olefins. This interesting question has been discussed in detail in a review by Zefirov and Sokolov [43]. Steric hindrance is observed also in the series of monoalkylnaphthalenes [44]. α- and β-Substituted isomers are typical for these compounds, the relation between their physical properties being similar to that in *cis*- and *trans*-olefins or *o*- and *p*-dialkylbenzenes respectively. This can be inferred from the specific gravities, refractive indices, boiling points, and molecular refractions of alkylnaphthalenes (Table 5). However, one should note that, whereas the steric hindrance in *o*-dialkylbenzenes and *cis*-olefins is due to adjacent alkyl groups, in α-monoalkylnaphthalenes it arises due to "peri-hydrogen".

Table 4. Negative heats of hydrogenation of *cis*- and *trans*-olefin isomers.

Compound	ΔH_{hydr}, kcal mole^{-1}
cis-But-2-ene	28.5
trans-But-2-ene	27.5

trans-t-Butylmethylethylene	26.5
cis-Di-t-butylethylene	36.2
trans-Di-t-butylethylene	26.87

In 1,2-*cis*-isomers of cyclic compounds [45], steric "contraction" is observed as in the *cis*-derivatives of ethylene. According to the Auwers–Skita rule [46], in the series of isomeric hydroaromatic compounds the *cis*-isomer has a higher density, refractive index, and boiling point and a lower molecular refraction and hence a lower molecular volume than the *trans*-isomer. However, the studies of Kazanskii and Liberman and coworkers [47–52] showed that this rule must be used with caution. They demonstrated for a large number of examples that the *cis*-isomers of dialkylcycloalkanes can also have boiling points lower than those of the *trans*-isomers.

Table 5. Physical constants of α- and β-alkylnaphthalenes.

Hydrocarbon	MR_D, cm^3	B.p., °C	ρ_4^{20}, g cm^{-3}	n_D^{20}

β-Isopropylnaphthalene	58.89	268	0.9780	1.5861
α-Isopropylnaphthalene	58.48	272	0.9762	1.5877
β-Butylnaphthalene	63.31	275	0.9750	1.5818
α-Butylnaphthalene	62.88	280	0.9768	1.5820

The steric hindrance in hydrocarbons has a significant influence on exaltation (EM_D). Bruhl [53,54], who introduced this concept, showed that exaltation occurs on bond conjugation, i.e. in the presence of an enhanced electron mobility in the molecule. The exaltation of *p*-dialkyl-substituted benzenes, *trans*-olefins [55], and β-monoalkyl-substituted naphthalenes [56] is much higher than the corresponding values for the *o*-, *cis*-, and α-substituted isomeric hydrocarbons—compounds with steric hindrance. Thus steric hindrance in the hydrocarbon molecule leads to a decrease of exaltation, i.e. to a decrease of the mobility of its electron system.

Another example of steric hindrance in the molecule affecting exaltation and hence also conjugation in hydrocarbons is provided by the phenomenon of "central depression" [57], the essential feature of which is that substitution of the hydrogen atom by alkyl groups in the centre

of a diene molecule leads to a decrease of exaltation compared with that of the diene hydrocarbon in which the alkyl groups are present at the edges (Table 6).

Table 6. Refractions and exaltations of certain diene hydrocarbons.

The greatest steric hindrance in hydrocarbon molecules appears when t-alkyl groups are present as substituents. The mutual influence of a number of alkyl substituents in hydrocarbons has been observed by ^{1}H NMR spectroscopy (Table 7).

Table 7. Chemical shift of the protons in the t-butyl group [58].

4. Steric Hindrance to π,π- and σ,π Conjugation. Ultraviolet Absorption Spectra of Hydrocarbons

One of the main methods for the detection of steric hindrance in hydrocarbon molecules containing a π,π- or σ,π conjugated bond system consists in the investigation of their ultraviolet absorption spectra. The ultraviolet spectra of conjugated hydrocarbons depend to a considerable degree on the steric disposition of atoms in their molecules [59].

Theoretical studies by Hückel [60] and Pauling [61] and X-ray diffraction analysis established that a π,π conjugated system tends towards a distribution in one plane, since in this configuration the axes of the *p*-electronic orbitals are parallel and the orbitals overlap to the maximum extent.

The decrease of the mutual overlapping of *p* orbitals in a conjugated system when its coplanarity breaks down is shown in a change of the ultraviolet absorption spectra. These changes consist of a displacement of the *K* absorption bands towards shorter wavelengths with a simultaneous decrease of absorption intensity (ϵ_{max}). An example of this is provided by the ultraviolet absorption spectra of stilbene and dialkyl-substituted biphenyls [62]. Biphenyl, the molecule of which is coplanar owing to mesomeric forms,

absorbs much more intensely than *oo'*-dimethylbiphenyl (Fig. 1). The absorption due to the latter is very similar to that of toluene, which is evidence of a decrease of π,π conjugation via the central bond as the phenyl rings are displaced from coplanarity owing to the *oo'*-dimethyl groups. Binaphthyls [63] and 2,3-dialkyl-substituted buta-1,3-dienes [19] have similar ultraviolet spectra. The electronic spectrum of *αα'*-binaphthyl resembles that of naphthalene, while the spectrum of *ββ'*-binaphthyl reveals a strong conjugation between the naphthyl systems, that of *αβ*-binaphthyl being of an intermediate type. Thus the "peri-hydrogen atom" in naphthalene gives rise to fairly considerable steric hindrance to rotation about the

bond in *αα'*-binaphthyl.

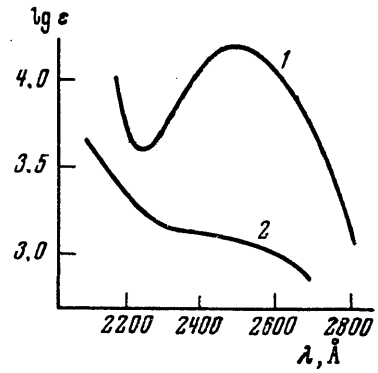

Figure 1. Ultraviolet absorption spectra (in ethanol): 1) biphenyl; 2) *oo'*-dimethylbiphenyl.

On the basis of the ultraviolet absorption spectra of methylated biphenyls, Suzuki [64] calculated the angle of φ between the planes of the benzene rings and found that the angle for the biphenyls in solution depends on the number of substituted *o*-positions. The relevant data are given in Table 8.

Koptyug et al. [65] showed that, in the ^{1}H NMR spectra of methylated biphenyls, the signals due to the protons of the methyl group in the *o*-positions are displaced to a lower field relative to the signals of the protons in the methyl groups occupying the *m*- and *p*-positions.

The steric hindrance to π,π conjugation in biphenyls promotes the stability of the corresponding free radicals [66,67]. Thus Chichibabin's hydrocarbon [68],

is a biradical only to the extent of 4%, but, when methyl groups are introduced into the *oo'*-positions of its biphenyl system, it exhibits the properties of a biradical to the extent of 100%:[69]

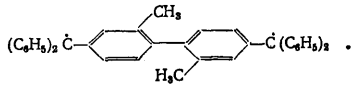

Table 8. The angle φ between the benzene rings in *o*-substituted biphenyls.

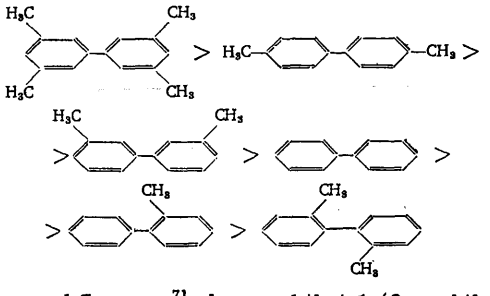
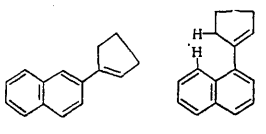
Substituents in positions				$\varphi°$
2	2'	6	6'	
H	H	H	H	20
CH_3	H	H	H	58
CH_3	CH_3	H	H	70
CH_3	CH_3	CH_3	CH_3	90

This implies that the mutually perpendicular (or nearly so) positions of the benzene rings, which arise owing to the *oo'*-dimethyl groups, are to a considerable degree responsible for the independence of the π electrons of these nuclei and of both unpaired electrons.

The steric hindrance to π,π conjugation in *oo'*-dimethyl derivatives of biphenyls has a significant influence on the stability of the molecular complexes of the methyl derivatives of biphenyl (donor) with trinitrobenzene (acceptor)[70]. It has been shown that the substitution of methyl groups in the *ortho*-positions in biphenyl, in contrast to the substitution in the *meta*- and *para*-positions, has an unfavourable effect on the stability of the complex, which diminishes in the following sequence:



Klemm and Sprague[71] observed that 1-(2-naphthyl)cycloalk-1-enes, particularly cyclopentene and cyclohexene derivatives, form with 2,4,7-trinitrofluorenone in acetic acid more stable complexes than those of 1-(1-naphthyl)-cycloalk-1-enes:



The low stability of the complexes formed by donors of the second type is due to the fact that the cycloalkene ring is displaced from the plane of the naphthalene ring system owing to steric hindrance caused by the peri-hydrogen.

Changes in the electronic absorption spectra analogous to those of alkyl-substituted biphenyls are observed for alkyl-substituted dienes and styrenes. In particular the absorption intensity of the *K* band in the spectra of dienes with the structure $R-CH=CH-CH=CH_2$ is higher than for dienes with "central depression": $CH_2=\underset{\displaystyle R}{\overset{|}{C}}-CH=CH_2$. On the other hand, it has been shown than an increase of the bulk of the group R in $CH_2=\underset{\displaystyle R}{\overset{|}{C}}-CH=CH_2$ leads to the breakdown of the coplanarity of the vinyl fragments and a decrease of the π,π conjugation (Table 9).

Table 9. Parameters of the ultraviolet absorption spectra of alkyl-substituted dienes.

Compound	$\lambda(\varepsilon)$ in iso-octane, nm	$\vartheta°$
	223 (22100)	0
	223 (12000)	45
	224 (5400)	60

Table 9 shows that an increase of the size of group R increases the angle of deviation of the vinyl fragments from coplanarity (θ) and causes a corresponding decrease of the degree of conjugation in the $CH_2=CR-CH=CH_2$ molecule, reflected in a decrease of the absorption intensity.

The hindrance to π,π conjugation in diene molecules has a significant influence on the stability of their complexes with silver. It has been shown[73] that the stability of such complexes diminishes in the sequence buta-1,3-diene > 2-methylbuta-1,3-diene > 2,3-dimethylbuta-1,3-diene.

Apart from the steric hindrance to π,π conjugation, i.e. to electronic interaction between two or more multiple bonds, there is steric inhibition of σ,π conjugation in hydrocarbons. The electronic spectra of alkylbenzenes provide an example. The changes undergone by the electronic absorption spectrum of benzene as a result of the introduction of an alkyl group into the ring are due to a displacement towards the benzene ring of the electrons of the C–H bonds involving the α-carbon atom of the alkyl group, i.e. are a result of σ,π conjugation[74]. In the presence of steric hindrance in the molecule, the conjugation of the alkyl groups with the benzene ring is weakened; the absorption intensity diminishes and the electronic spectrum is displaced towards shorter wavelengths. On the other hand, a displacement of the spectrum towards longer wavelengths with increase of absorption intensity is evidence of an increase in the degree of conjugation of the system. It is interesting to note that the bathochromic shift of the characteristic absorption band and the increase of its intensity occur in the sequences *ortho-* < *meta-* < *para*- for dialkylbenzenes (Fig. 2), *cis-* < *trans*- for

olefins, and α- < β- for monoalkylnaphthalenes, in agreement with the decrease of the steric hindrance in these molecules.

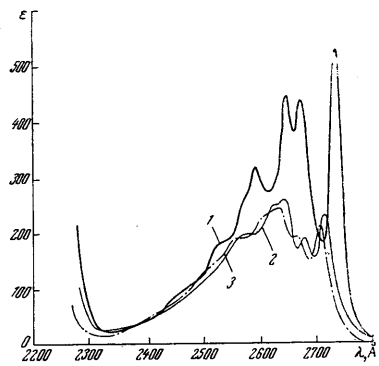


Figure 2. Ultraviolet absorption spectra of cymenes: 1) *p*-cymene; 2) *m*-cymene; 3) *o*-cymene.

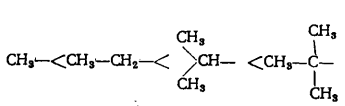
Steric hindrance, which inhibits conjugation (electron delocalisation) in hydrocarbons, affects primarily the rates of their chemical reactions. Thus, in a study of the chlorination of alkylbiphenyl ring systems with molecular chlorine, de la Mare [75] established that the methyl groups in the *para*- and *meta*-positions increase sharply the rate of reaction. The chlorination rate constant for the *oo'*-dimethyl derivative of biphenyl, where there is steric hindrance to the electron shift (conjugation), is smaller by a factor of 16 compared with that for 4,4'-dimethylbiphenyl. A similar situation is observed in hydrocarbons with steric hindrance to σ,π conjugation. It has been found that the rate of abstraction by the trichloromethyl-radical of the α-hydrogen atom in the isopropyl group of *o*-cymene, in which there is steric hindrance to σ,π conjugation, is lower than in *p*- and *m*-cymenes, where there is no steric hindrance (Table 10). The same relative reactivities of cymenes have been observed in liquid-phase autoxidation [77].

Table 10. Relative rates of reaction of cymenes with the trichloromethyl radical.

Hydrocarbon	Relative rates
o-Cymene	0.44
m-Cymene	2.3
p-Cymene	2.5

According to the literature [2,79], steric hindrance increases with the degree of branching of the alkyl groups in the sequence:



and the bulk of the alkyl group as a whole does not have a steric effect as marked as branching at its α-carbon atom. The finding that small alkyl groups with maximum branching at the α-carbon atom give rise to more pronounced steric hindrance than bulkier alkyl groups but without such branching was already pointed out in earlier investigations. Alkyl groups can be arranged in the following sequence in terms of decreasing capacity for steric repulsion:

$$(CH_3)_3C- > (CH_3)_3C-CH_2- > (CH_3)_3C-CH_2-CH_2- \quad .$$

III. STERIC HINDRANCE IN THE SYNTHESIS OF HYDROCARBONS

1. Synthesis of Alkylbenzenes and Alkylnaphthalenes

Alkylation is one of the commonest methods of synthesis of hydrocarbons [80]. The addition of alkyl groups to the aromatic ring in the presence of acid catalysts takes place in accordance with the directing rules for the benzene ring [81,82]. Thus when toluene is alkylated with primary and secondary alcohols and alkyl halides in the presence of acid catalysts, the main products are *para*- and *ortho*-alkyltoluenes. Alkylation of toluene with tertiary alcohols and t-alkyl halides leads to the formation of *para*-t-alkyltoluene with only a low content of the *meta*-isomer. *p*-Xylene is not alkylated with t-butyl alcohol and t-butyl halides.

Baur [83], who alkylated *m*-xylene with t-butyl bromide in the presence of $AlCl_3$, and Noelting [84], who butylated the same hydrocarbon with t-butyl alcohol using sulphuric acid as a catalyst, obtained the same product: 5-t-butyl-1,3-dimethylbenzene.

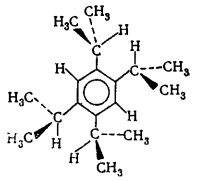
Despite the fact that the distribution of electron density in the aromatic ring of *m*-xylene (the concerted orientation of the two methyl groups) favours 1,3,4-substitution, steric hindrance to this mode of alkylation results in the formation of the symmetrical (anomalous) 1,3,5-isomer. It has been shown [85-88] that the alkylation product does not undergo subsequent isomerisation under the above conditions, i.e. it is the primary product of the addition of the t-alkyl cation. It is noteworthy that such substitution does not depend on the nature of the acid catalyst and takes place only with the t-butyl group, while the introduction of the s-butyl group into *m*-xylene under the influence of sulphuric acid and boron trifluoride gives rise to the formation of the 1,3,4-isomer.

The use of accurate modern analytical methods (capillary gas–liquid chromatography combined with infrared spectroscopy) in the study of the composition of the products of the alkylation of toluene and xylenes with various tertiary alcohols and alkyl halides in the presence of acid catalysts led to the demonstration of the absence or an extremely low content of *o*-t-alkyltoluenes and *o*-t-alkylxylenes [89-101].

It follows from the literature data [102] on this problem that the main reason for the anomalous behaviour of the t-alkyl group in alkylation reactions in the presence of acid catalysts is its bulk, which gives rise to considerable steric hindrance. However, on the basis of the bulk of the alkyl group alone, it is difficult to explain why, for example, the cyclohexyl group, which is bulkier than the t-butyl group, enters fairly readily the *ortho*-position relative to the methyl group [103].

Analysis of the structures of the *o*-dialkylbenzenes obtained by alkylation in the presence of acid catalysts showed that they contain at least one α-C–H bond in

adjacent alkyl groups. Owing to mutual repulsion, branched adjacent alkyl groups are oriented in such a way that their nearest interacting components become the protons of the α-C–H bonds, which is clearly illustrated by tetraisopropylbenzene as a model:



The minimum repulsion energy corresponds to this distribution of alkyl groups. In contrast to methyl, ethyl, and isopropyl groups, there is no similar possibility of orientation of the t-butyl group, so that its steric repulsion increases sharply [104]. A similar conclusion follows from an examination of the reaction mechanism and the geometry of the transition state.

The mechanism of the alkylation of aromatic hydrocarbons with olefins is known to involve electrophilic aromatic substitution. The mechanism of the alkylation with olefins in the presence of acid catalysts is usually treated on the basis of the hypothesis of the intermediate formation of active species: either alkyl derivatives of the acid or carbonium ions.

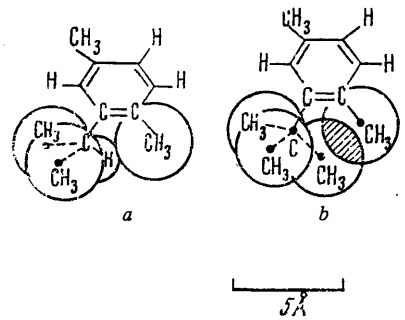


Figure 3. Molecular models: *a*) *o*-isopropyl-*p*-xylene; *b*) *o*-t-butyl-*p*-xylene.

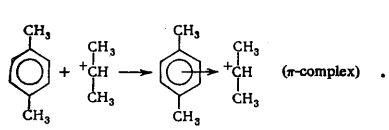
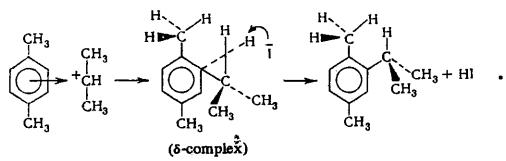
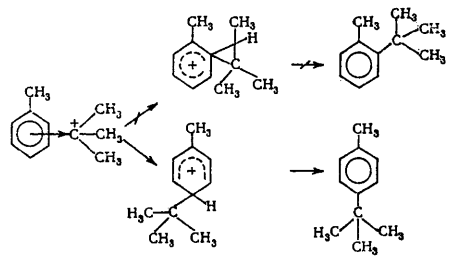
At the present time the carbonium ion theory of acid-catalysed alkylation reactions is the most popular. The existence of alkyl cations in strong acid solutions has been demonstrated by spectroscopic methods in many investigations [105,106]. Consequently alkylation of *p*-xylene takes place as follows:



The π complex rearranges to a σ complex which in the case of *ortho*-alkylation can be represented schematically as follows:



The scheme shows that the isopropyl group in the σ-complex transition state is oriented in such a way that the nearest interacting components of this group and of the methyl are the protons of the α-C–H bonds, which corresponds to the minimum repulsion energy between the *ortho*-alkyl groups. Evidently this state corresponds to the addition of any primary or secondary alkyl group. However, when a t-butyl group is introduced, then in the σ-complex transition state and in the resulting *o*-dialkylbenzene the steric repulsion effect increases sharply, as shown clearly in Fig. 3. Tending to reduce its potential energy to a minimum, the sterically strained molecule decreases the repulsive force by increasing the distance between the alkyl groups. Therefore, when the t-butyl group adds to toluene and *m*-xylene, the *ortho*-isomer is not formed:



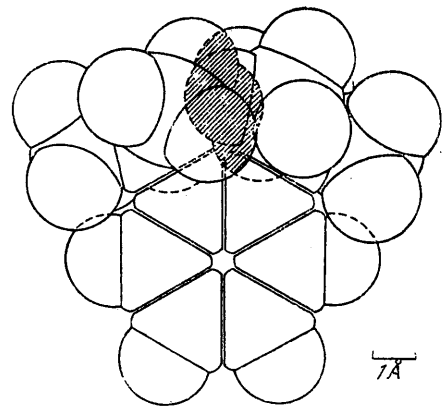


Figure 4. Molecular model of *o*-di-t-butylbenzene.

However, *o*-t-butyltoluene and 4-t-butyl-*m*-xylene were obtained by organomagnesium synthesis. Moreover, the t-butyl group was introduced into the ring by this method in the *ortho*-position relative to another t-butyl group [107]. Models for *o*-di-t-butylbenzene show marked overlapping of the van der Waals spheres of the alkyl groups (Fig. 4). The chemical properties of 1,2-di-t-butylbenzene have been investigated in detail. It is interesting to note that, on ultraviolet irradiation, it gives a mixture of the *m*- and *p*-isomers (20 and 80% respectively), which are more resistant to light; *o*-t-butyltoluene also isomerises under these conditions, but much more slowly.

Bulky adjacent groups undergoing a steric interaction with one another can actually alter the steric structure of the hydrocarbon. This has been confirmed by the finding that in 1,2,4,5-tetra-t-butylbenzene the ring is distorted so much that the boat conformation was assigned to it [108]. On irradiation with ultraviolet light, the compound isomerises to a derivative of "Dewar" benzene.

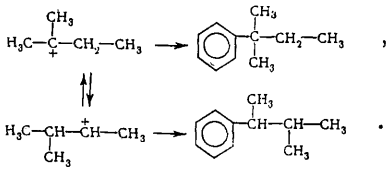
Thus in sterically hindered *o*-dialkylbenzene there is a strain in the π-electron system of the aromatic ring similar to the strain of the π-electron system of the double bond in strained *cis*-dialkylethylenes.

Steric hindrance due to t-alkyl groups arises also in the alkylation of naphthalene. However, here the hindrance is not caused by an adjacent alkyl group but by the "peri-hydrogen", which hinders the introduction of t-alkyl groups into the α-position of the naphthalene ring. Whereas t-butylmagnesium bromide reacts with bromobenzene, the reaction with α-bromonaphthalene does not occur [2]. The alkylation of naphthalene with isobutene in the presence of acid catalysts takes place anomalously, like the alkylation of toluene: only β-t-butylnaphthalene is obtained [109]. However, s-alkyl groups (isopropyl [110,111] and cyclohexyl [112,113] groups) enter the α-position of naphthalene fairly readily owing to the presence in these groups of the α-C–H bond, which permits a [favourable] orientation of the alkyl group relative to the "peri-hydrogen".

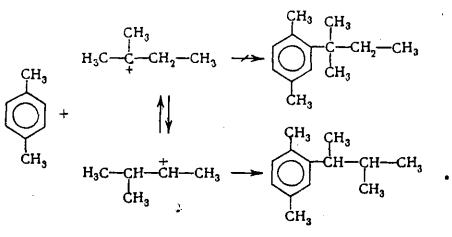
2. Anomalous Isomerisation of t-Alkyl Groups in the Alkylation of Hydrocarbons

Until recently, it was regarded as generally accepted and demonstrated that, in the alkylation of an aromatic ring with t-butyl halides, tertiary alcohols, and iso-olefins, there is no rearrangement of the resulting tertiary carbonium ions; the tertiary carbonium ion formed alkylates the aromatic ring with formation of t-alkylbenzenes [114].

However, it has been noted in a number of studies [115,116] that in the alkylation of benzenes secondary alkyl derivatives are formed together with tertiary derivatives. This is indicated, in particular, by the formation of a mixture of secondary and tertiary (main product) pentylbenzenes on alkylation of benzene with isopentyl chloride and pentenes in the presence of aluminium chloride at 0°C: [115,120]



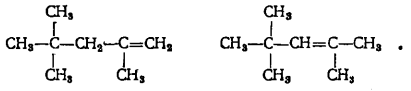
The equilibrium between the tertiary and secondary ions can be displaced towards the latter species under the influence of steric hindrance. Thus Friedman and Morritz [117], who alkylated *p*-xylene with isopentenes in the presence of BF_3 and $AlCl_3$ at 0°C, observed the formation (in yields up to 40%) of s-pentyl derivatives exclusively, which was confirmed by a careful analysis using infrared and mass spectrometry. They suggested that, when alkylation by tertiary ions (in the *ortho*-position of *p*-xylene) is hindered, the less sterically hindered secondary ions, in equilibrium with the tertiary ions, enter the ring:



3. Oligomerisation and Polymerisation of Alkyl- and Aryl-substituted Olefins

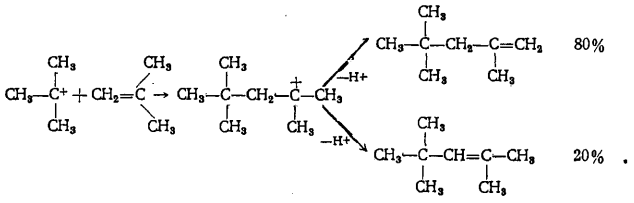
The first systematic studies on the reactivity of ethylene derivatives in the oligomerisation reaction were carried out by Lebedev and Filonenko [118], who observed that at room temperature in the presence of floridin only asymmetric di- and tri-substituted ethylene derivatives are polymerised. Further study of this problem and analysis of the accumulated experimental data enabled Korshak and coworkers [119,120] to conclude that steric effects as well as electron factors play an important role in the olefin polymerisation process.

The effect of steric hindrance is usually shown in two ways; (1) the rate of oligomerisation of olefins decreases with increasing number and bulk of substituents at the double bond and (2) the isomeric composition of the reaction products changes. In 1873 Butlerov [121] described the dimerisation of isobutene under the influence of sulphuric acid, which results in the formation of di-isobutene. The structure of di-isobutene was the subject of numerous investigations [122–125] which established accurately that this hydrocarbon is a mixture of two isomers:



The isomer with the double bond in the α-position predominates in the mixture.

On the basis of modern concepts, the dimerisation of isobutene may be represented by the following scheme:



The t-butyl cation adds to the isobutene molecule and forms a C_8 carbonium cation. The abstraction of a proton from the latter leads to the formation of two isomeric olefins in proportions of 4 : 1. The transition state in the reaction involving the abstraction of a proton from the carbonium cation contains a partial double bond (Fig. 5) stabilised by the hyperconjugation of the alkyl substituents with the electrons of the incipient π bond [126]. However, owing to steric hindrance, the formation of the β-olefin in the transition state is energetically unfavourable, as shown by the shaded part of the van der Waals spheres in the models (Fig. 5). Therefore the energetically more favourable α-olefin, in which there is no steric hindrance, is formed preferentially.

Similar steric hindrance in the transition state determines the composition of iso-olefins in the dimerisation of more complex hydrocarbons also, for example isohexenes. Thus a study of the oligomerisation of two isohexenes—2-methylpent-1-ene and 2-methylpent-2-ene [3,127]—revealed the preferential formation of isododecenes the double bond of which is remote from the quaternary carbon atom, i.e. 4,6,6-trimethylnon-3-ene and 3-ethyl-2,4,4-trimethylhept-1-ene and not 4,6,6-trimethylnon-4-ene and 3-ethyl-2,4,4-trimethylhept-2-ene (Fig. 6).

The relative contents of isododecenes with different hydrocarbon frameworks in the reaction products are determined by the concentrations of the individual hexenes in the mixture and their capacity for interaction with the

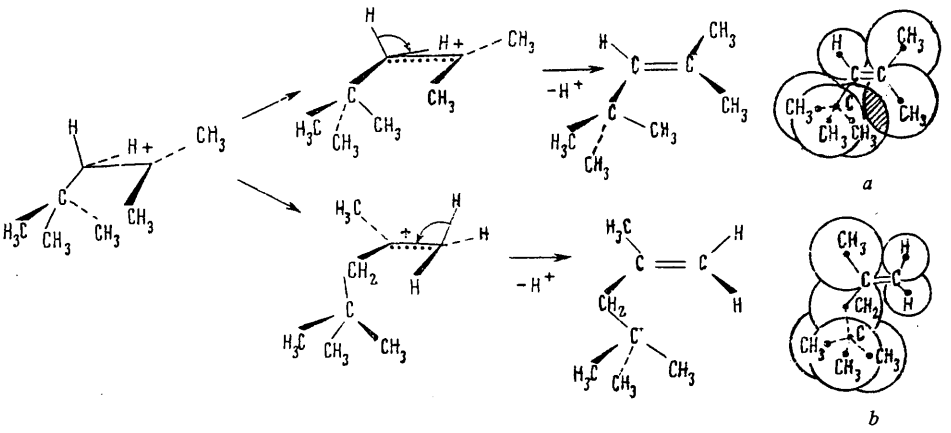


Figure 5. A three-dimensional scheme illustrating the formation of di-isobutenes and their models: *a*) 2,4,4-trimethylpent-2-ene; *b*)2,4,4-trimethylpent-1-ene.

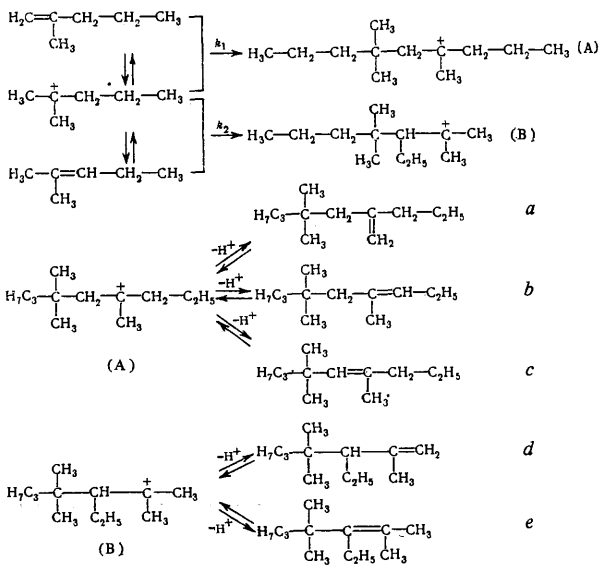

Figure 6. The mechanism of the dimerisation of isohexenes [127,128].

t-hexyl cation. It has been shown [127] that the rate of electrophilic addition of the t-hexyl cation to 2-methylpent-1-ene is five times faster than the rate of addition to 2-methylpent-2-ene, which can be explained by electronic and steric effects. The relative proportions of isododecenes with the same carbon framework but differing in the position of the double bond depend on their thermodynamic stabilities and the relative rates of abstraction of protons from different alkyl groups in the 4,6,6-trimethyl-4-nonyl cation (A) and 3-ethyl-2,4,4-trimethyl-2-heptyl cation (B).

The influence of structural factors on the rate and mode of reactions of carbonium ions has been the subject of controversy [129] and in the general case may be determined both by steric [130] and electronic effects [131,132]. A graphical representation of isododecene molecules (Fig. 7) with the bond lengths, valence angles, and actual radii of the substituents drawn to scale [59] shows that steric hindrance has a distinct effect on the structures of various isododecenes (on the basis of the overlapping of the spheres of groups not directly linked by valence bonds) (Fig. 7). Maximum steric hindrance, which occurs in the β-isododecene molecule and hence also in the transition state, results in the formation of α-isododecene as the main product of the abstraction of a proton from the 3-ethyl-2,4,4-trimethyl-2-heptyl cation (B). The insignificant formation of the β-olefin is caused by its lower thermodynamic stability owing to the marked steric hindrance arising as a result of the repulsion between the *cis*-methyl groups at the unsaturated and quaternary carbon atoms. The preferential formation of isododecene (*b*) compared with the olefin (*c*) on deprotonation of the 4,6,6-trimethyl-4-nonyl cation (A) can be explained similarly.

The literature and the present authors' experimental data [3] in Table 11 for the compositions of the oligomers should be regarded as confirmation of the hypothesis concerning the increasing role of steric effects in the formation of α-olefins on passing from the relatively low-molecular-weight C_6 hydrocarbons to the higher C_{12} hydrocarbons.

The introduction of a t-alkyl group in the β-position relative to the positively charged tertiary carbon atom increases sharply the yield of the α-olefin (Table 10). This is because, owing to the "cisoid repulsion strain" in the transition state, the formation of the β-olefin becomes energetically less favourable than that of the α-olefin, i.e. the energies of the σ,π conjugation of the alkyl substituents with the double bond of the olefin formed is no longer sufficient to overcome the steric hindrance.

The preferential formation of α-olefins, observed in the oligomerisation of olefins in the presence of acid catalysts, occurs [also] in the dehydration of alcohols and in the solvolysis of alkyl halides [139].

Thus steric factors are dominant in all elimination reactions leading to olefins if alkyl groups, at least one of which is tertiary, are present in the transition state in the *cis*-position relative to the double bond.

Molecular steric hindrance plays an important role in the polymerisation of olefins. Korshak [133] showed that the capacity for polymerisation of alkyl- and aryl-substituted olefins depends to a considerable degree on the screening of the double bond by substituents, i.e. on the steric hindrance caused by them. The influence of substituents is directly proportional to their bulk and their number.

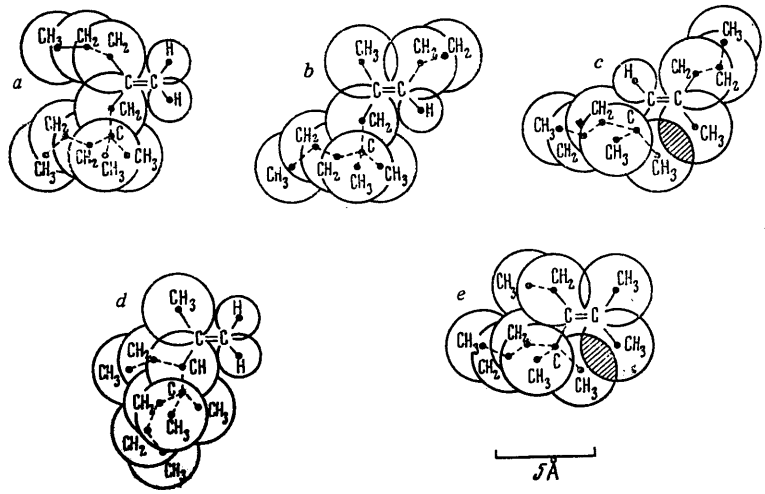

Figure 7. Molecular models of isododecenes: *a*) 4,4-dimethyl-2-propylhept-1-ene; *b*) 4,6,6-trimethylnon-3-ene; *c*) 4,6,6-trimethylnon-4-ene; *d*) 3-ethyl-2,4,4-trimethylhept-1-ene; *e*) 3-ethyl-2,4,4-trimethylhept-2-ene.

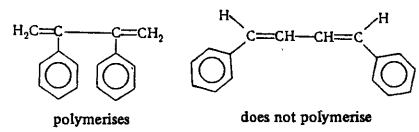
Table 11. The structures of carbonium cations and the concentrations of iso-olefins obtained from them.

α-Olefins	Wt. %	Carbonium cation	β-Olefin	Wt.%
$CH_2{=}C(CH_3){-}CH_2{-}CH_2{-}CH_3$	16	$CH_3{-}C^+(CH_3){-}CH_2{-}CH_2{-}CH_3$	$CH_3{-}C(CH_3){=}CH{-}CH_2{-}CH_3$	84
$CH_2{=}C(CH_3){-}CH_2{-}CH(CH_3){-}CH_3$	18	$CH_3{-}C^+(CH_3){-}CH_2{-}CH(CH_3){-}CH_3$	$CH_3{-}C(CH_3){=}CH{-}CH(CH_3){-}CH_3$	82
$CH_2{=}C(CH_3){-}CH_2{-}C(CH_3)_2{-}CH_3$	82	$CH_3{-}C^+(CH_3){-}CH_2{-}C(CH_3)_2{-}CH_3$	$CH_3{-}C(CH_3){=}CH{-}C(CH_3)_2{-}CH_3$	18
$CH_3{-}C(CH_3){=}CH{-}C(CH_3)_2{-}CH_3$	83	$CH_3{-}C^+(CH_3){-}CH(CH_3){-}C(CH_3)_2{-}CH_3$	$CH_3{-}C(CH_3){=}C(CH_3){-}C(CH_3)_2{-}CH_3$	17
$CH_2{=}C(CH_3){-}CH(CH_3){-}C(CH_3)(C_2H_5){-}C_3H_7$	90	$CH_3{-}C^+(CH_3){-}CH(CH_3){-}C(CH_3)(C_2H_5){-}C_3H_7$	$CH_3{-}C(CH_3){=}C(CH_3){-}C(CH_3)(C_2H_5){-}C_3H_7$	10

The concepts concerning steric hindrance developed by Korshak were confirmed also in the polymerisation of branched diene hydrocarbons. According to the mechanism established by Lebedev[134,137], butadiene polymerises with formation of carbon–carbon bonds in the 1- and 4-positions. Thus when the 1- and 4-carbon atoms are screened, polymerisation does not occur. On the other hand, if the 2- and 3-carbon atoms are screened, hindrance to polymerisation does not arise, which has been confirmed experimentally:



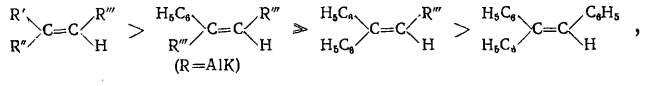
It is noteworthy that, apart from the steric factor, the conjugation effect apparently plays an important role in this case. In 1,4-diphenyl-substituted butadienes it is much more pronounced than in 2,3-diphenyl derivatives, since in the latter the phenyl groups are not included in the conjugated system of the diene.

Steric hindrance in the hydrocarbon molecule does not only retard but in some cases actually accelerates the radical polymerisation of olefins. Thus it has been established that the rate of polymerisation of α-vinylnaphthalene is higher[135] by a factor of 2.5 than the rate of polymerisation of styrene. This can be explained as follows: the vinyl group of α-vinylnaphthalene is displaced from the plane of the naphthalene ring system owing to the steric hindrance due to the "peri-hydrogen", which leads to a decrease of its conjugation with the naphthalene ring system. According to Bagdasar'yan's theory[136], a less conjugated olefin should give rise to a more reactive radical, which in fact is the reason for the higher rate of polymerisation. This leads to the following practical conclusion: in order to obtain the most reactive hydrocarbon monomers, it is necessary to synthesise hydrocarbons with a strained double bond.

4. Synthesis of Branched Alkanes

The screening of the double bonds by hydrocarbon substituents affects not only the polymerisation but also the

hydrogenation of branched olefins to alkanes. As early as the 1920's, Lebedev and coworkers[138] established that ethylene derivatives substituted to different extents are hydrogenated in different ways. The compounds R–CH=CH_2 are hydrogenated at the highest rate and CR_2=CR_2 at the lowest. This has been shown particularly convincingly by Kazanskii and coworkers[139,140], who established that in the presence of platinum black the rate of hydrogenation decreases in the following sequence:



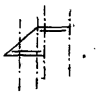
i.e. olefins with the double bond screened to a greater extent are hydrogenated at a lower rate. The rate of dehydrocyclisation of olefins is influenced more by their steric structure than by the position of the double bond[141]. The effect of the branching of the carbon framework of olefins on the yield of aromatic compounds has not in fact been investigated.

The first attempts to obtain by the Wurtz method fully methylated derivatives of higher ethane homologues were unsuccessful[142]. In general the synthesis of hexa-alkylethanes by the dimerisation of two tertiary alkyl groups is extremely difficult. The simplest analogue—hexamethylethane—was obtained from t-butyl chloride and sodium over a period of 10 days in a yield of 10%. In a number of studies[143,144], where t-alkyl halides were used in the Wurtz reaction, extremely low yields of branched alkanes were noted. Somewhat higher yields of these compounds are obtained in the organomagnesium synthesis. Therefore, for a successful synthesis of branched alkanes, it was necessary to seek ways whereby the effect of steric hindrance could be reduced to some extent[2].

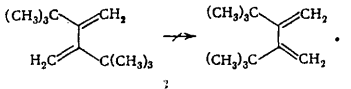
The steric hindrance in iso-olefin molecules promotes their decomposition on cracking. Thus Nazarov[142] established that the asymmetric di-t-butylethylene is readily cleaved at the site of addition of the tertiary group into lower olefins on distillation with traces of 2-bromonaphthalene-4-sulphonic acid. However, when one of the t-alkyl groups is replaced by a phenyl group, the resulting asymmetric t-alkylphenylethylenes become stable and are not cleaved even above 300°C.

5. Diels–Alder Synthesis

The Diels–Alder synthesis is a type of condensation in which a diene reacts with a dienophile in a coplanar cisoid conformation:



Naturally dienes in which such cisoid conformation of the double bonds does not arise under the experimental conditions owing to steric hindrance cannot enter into the Diels–Alder synthesis[145]. Thus Backer and Strating[146,147] showed that 2-t-butylbutadiene enters into the Diels–Alder synthesis normally, while 2,3-di-t-butylbutadiene does not react at all because it cannot assume the cisoid conformation necessary for the reaction, owing to the steric hindrance by the adjacent t-butyl groups[148]:



On the other hand, 1,3-di-t-butylbutadiene, in which the t-butyl groups are further apart and do not give rise to a steric effect, enters fairly readily[149,150] into Diels–Alder reactions. In general, if the formation of a coplanar cisoid conformation of the diene is interferred with by steric hindrance, the Diels–Alder synthesis as a rule takes place with difficulty and with low yields.

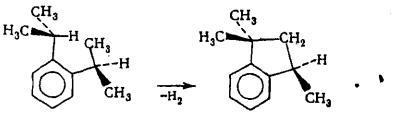
Table 12. The yield of indene in the cracking of cymenes (%).

Initial cymene	Indene
o-Cymene	3.6
m-Cymene	0
p-Cymene	0

6. The Formation of Indane–indene Structures

A characteristic feature of *o*-dialkyl derivatives of benzene is the formation of indene structures[151] (Table 12) on cracking.

The use of catalysts based on iron(III) oxide or aluminium oxide for the cracking of *o*-cymene increases the yield of indene. In the cracking of *o*-ethyltoluene, the yield of indene reaches 23%. Cyclisation of alkyl substituents as a result of their steric proximity with formation of indane derivatives was noted in the alkylation of isopropylbenzene with propene in the presence of aluminium chloride[152] according to the following mechanism:



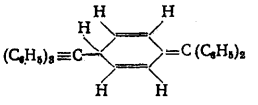
7. Dissociation of Hexa-arylethanes. The Structure of the Gomberg Hydrocarbon

In 1900 Gomberg[153] discovered the first free radical, which had an enormous influence on the further development of theory and practice in the field of organic free radicals. Gomberg obtained a free radical by treating chlorotriphenylmethane with metals (zinc, copper, and silver).

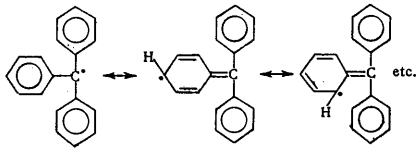
Numerous investigations led to the belief (Wieland, 1909) that chlorotriphenylmethane initially yields hexaphenylethane, which in benzene solutions consists of an equilibrium mixture of hexaphenylethane and triphenylmethyl radicals, the former predominating.

Markovnikov and Chichibabin[154] believed that the Gomberg hydrocarbon is not true hexaphenylethane but is merely identical with it [sic!].

Interesting studies on the dimer of the triphenylmethyl radical were published in 1968.[155–158] ^{1}H NMR and ultraviolet spectroscopy showed that the product of the association of the triphenylmethyl radicals obtained from chlorotriphenylmethane and silver is a hydrocarbon with the structure



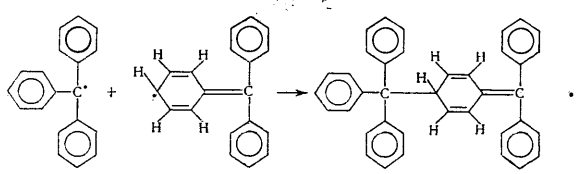
the formation of which can be understood bearing in mind that the triphenylmethyl radical can have several resonance forms:



The formation of hexaphenylethane on recombination of the classical form is difficult due to steric hindrance: under the influence of the *ortho*-hydrogen atoms, each phenyl ring is extended relative to the axis joining it to the central carbon atom which results in a propellor structure [159] in which the unpaired electron of the radical is screened by the *ortho*-hydrogen atoms.

Such radicals cannot approach one another to a distance sufficient for the formation of a C–C bond. It is interesting to note that at one time Gomberg also rejected the possibility of the dimerisation of triphenylmethyl radicals to hexaphenylethane. He wrote "...if the three valences of the carbon atom are occupied by three phenyl groups, it is difficult and probably actually impossible to introduce a complex species such as triphenylmethyl" [153]. Gomberg suggested that the association of triphenylmethyl radicals does not take place via the combination of the main (ethane) valences but in some other way.

On the basis of the above structure of the dimer of the triphenylmethyl radical, its formation actually takes place according to the following mechanism:



It should be noted that this structure of the triphenylmethyl radical dimer was proposed as early as 1905 by Jacobson [160], but, in view of the experimental difficulties involved in proving it, it remained neglected.

Thus the steric hindrance arising in the molecule play an important role here. As a result, hexaphenylmethane has still not been synthesised and [therefore] the field of triphenylmethane compounds should be thoroughly re-examined.

Biochemical Importance of Lipid Peroxides†

V.Karnojitzky

The review deals with the peroxides of unsaturated lipids; the process involving their formation is described and the catalytic action of lipoxidase and haematin compounds is illustrated. The modifying effects of various metals and their chelate complexes are discussed. The mechanism of their decomposition with formation of carbonyl, hydroxy-, epoxy-, and polymeric compounds is described.
The effect of these peroxides on haematin compounds protein thiols, enzymes, and vitamins of various types has been investigated. Various pathological changes induced by the introduction of polyunsaturated lipids and the toxicity of various oils and fats in food after heating in air have been examined. A study has been made of the damage caused by the formation of unsaturated lipid peroxides in various parts of the living cell, such as mitochondria, microsomes, lysosomes, and nuclei and of the toxicity of various types of lipid peroxides injected into living organisms, The appearance of lipid peroxides during photosynthesis and their involvement in the formation of cutin are described.
The bibliography includes 359 references.

I. INTRODUCTION

An earlier paper by the present author and Viel dealt with the biochemical role of organic peroxides and their synthesis [1] and a paper by Latarjet [2] was concerned with their radiobiology. This review is devoted exclusively to lipid peroxides and covers publications up to 1970, the majority of which appeared in print after 1965. Thus, apart from the results of quite recent studies, the review considers certain questions relating to the effect of lipid peroxides on various types of enzymes and vitamins, their role in the breakdown of certain parts of the cell, and the inhibiting effect of vitamin E in the formation of lipid peroxides *in vivo*, i.e. problems which were only touched upon or not discussed at all in earlier publications.

It is noteworthy that the biochemistry of lipid peroxides constitutes a fairly well ordered and homogeneous field. The mechanisms of their formation and decomposition are known and many of the decomposition products have been identified. There is fairly accurate information concerning the effect of peroxides on haematin compounds, protein thiols, and various enzymes and vitamins, about the inhibiting effect of vitamin E and the changes occurring as a result of the formation of lipid peroxides *in vivo*, and also about the toxicity of various oxidised oils and fats in food. In view of all the above considerations, the author thought it necessary to write the present review dealing with lipid peroxides.

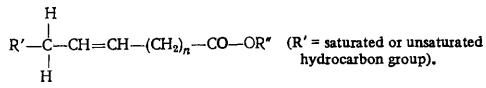
Lipid peroxides are formed as a result of the autoxidation of mono- and poly-unsaturated aliphatic acids which are present in the form of triglycerides in plant oils and animal fats. These acids can also exist in the form of phospholipids and sterol esters in various animal tissues. They are mainly oleic, linoleic, linolenic, and arachidonic acids containing respectively one, two, three, and four double bonds. Oleic acid is very common in both plants and animals and linoleic acid is particularly prevalent in plants. Linolenic acid is encountered much more rarely than the other acids but nevertheless its content is exceptionally high in linseed oil (50%) and in horse fat (16%). Arachidonic acid is present almost exclusively in animals, in which it is synthesised from linoleic acid introduced with food products. Apart from the acids enumerated above, tetra-, penta-, and hexa-enoic acids are present in animal tissues. Considerable amounts of a C_{20} acid with five double bonds and a C_{22} acid with six double bonds are present in cod liver oil‡.

At an elevated temperature and for higher degrees of unsaturation, the induction period in the autoxidation reaction becomes shorter and the rate of reaction increases. The mechanism of the autoxidation of unsaturated fatty acid derivatives has been described by Bolland [3] and Farmer [4,5] and has been discussed in detail in a number of other publications [6-9].

† The review was written originally in French specially for the journal "Uspekhi Khimii" and was translated into Russian by T. Va. Chernysheva. This is an English translation of the Russian version.

‡ Henceforth unsaturated acids will be designated by symbols such as 20 : 5 for the C_{20} acid with five double bonds, 22 : 6 for the C_{22} acids with six double bonds, etc. (Editor of Russian translation).

The first step is the abstraction of a hydrogen atom from the methylene group in the α-position relative to the double bond of the unsaturated compound:



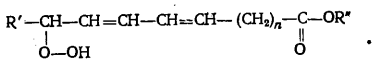
(R' = saturated or unsaturated hydrocarbon group).

The $R'-\dot{C}H-CH=CH-(CH_2)_n-CO-OR''$ radical formed in this way reacts with molecular oxygen, giving rise to the peroxy-radical $RO-O^{\cdot}$ [$R=R'-\dot{C}H-CH=CH-(CH_2)_n-CO-CR''$] which abstracts a hydrogen atom linked to the methylene carbon atom in the α-position of another lipid chain with formation of an α-methylene hydroperoxide and a radical $R^{\cdot}$:

$$RO-O^{\cdot} + HR \rightarrow ROOH + R^{\cdot} .$$

The hydroperoxide in its turn decomposes into the radicals $RO^{\cdot}$ and $HO^{\cdot}$ which initiate new reaction chains.

The formation of the hydroperoxide is accompanied by the migration of the double bonds which are conjugated in polyunsaturated systems:



In the initial stages it may be accompanied by the formation of more complex derivatives of the hydroperoxide–peroxide type:

It is interesting to note that such structures were previously proposed for polyisoprene [10-18] and squalene [17] peroxides. Thus the term "lipid peroxides" refers to a mixture of several hydroperoxides (with a large number of conjugated double bonds), glycerides, phospholipids, and sterol esters of several unsaturated fatty acids incorporating in all probability peroxy-compounds of the hydroperoxide–peroxide type.

There are two main types of effective catalysts of the autoxidation of unsaturated lipids: lipidoxidase, which is highly specific for the determination of configurations, and haematin compounds—non-specific catalysts active in relation to many compounds undergoing autoxidation which are not unsaturated lipids. The speed of their action may be greatly altered in the presence of certain metals and their chelate complexes.

II. LIPOXIDASE

Lipoxidase is absent from animal tissues [19,20] but does occur in plants, particularly in Leguminosae (soya, peas, beans, wheat, groundnuts, clover, vetch, alfalfa, kidney beans, etc.). It has also been detected in radishes and in potatoes. According to quite recent studies, the wheat and pea lipoxidases [21] as well as the soya lipoxidase [22] contain several coenzymes. The presence of lipoxidase in microorganisms is doubtful. In fact *Pseudomonas fluorescens* and *Mycobacterium phlei* are the only bacteria which rapidly oxidase unsaturated fatty acids, but this oxidation is not catalysed by lipoxidase; it has been detected in the *Aspergillus* and *Rhizopus* moulds [23] but the actual oxidation catalyst was not determined exactly.

The preparation of pure lipoxidase from soya flour has been described in detail [24,25] and a new improved method [26] based on the extraction with water of defatted soya flour at pH 4.5 and room temperature was used recently. The enzyme is isolated after successive salting-out with aqueous ammonium sulphate solutions and subsequent electrophoresis.

Pure lipoxidase consists of colourless lamellar microcrystals with molecular weight ranging from 90 000 to 100 000. [25] Since it cannot be inhibited by fluorides, cyanides, azides, pyrophosphates, and diethyl dithiocarbamate prosthetic groups must be absent [26]. Similarly the absence of inhibition by mercury chlorobenzoate demonstrates the absence of SH groups, which is confirmed by chemical determinations [27].

The catalytic activity of pure lipoxidase was studied in an aqueous 1.5×10^{-2} M solution of sodium linoleate in the temperature range from 0° to 37°C at different pH. [27] The results of this study showed that the maximum rate of oxidation occurs at pH 9.4, decreasing slightly at alkaline pH and diminishing appreciably at acid pH. Thus at pH 6.5 its activity is only one fifth of the activity at pH 9.4. The initial rate of oxidation at 37°C is higher than at 0°C but in the former case it decreases rapidly with time. Thus after 10 min the content of O_2 absorbed is identical for both temperatures, amounting to 0.15 mole mole^{-1}, but after 40 min it is only 0.4 mole mole^{-1} at 37°C and 0.6 mole mole^{-1} at 0°C.

The use of certain crude lipoxidases for the oxidation of derivatives of polyunsaturated acids at temperatures between 0° and 37°C has been described [20,28-36].

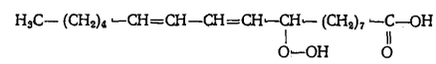
A comparative study [37] of the catalytic activities (at 20°C and pH 7) of soya, pea, groundnut, wheat, *Phaseolus mungo*, and *Phaseolus aurens* lipoxidases in the oxidation of linoleic and arachidonic acids by ammonium salts showed that none of the lipoxidases have prosthetic groups, while the *Phaseolus mungo* and *Phaseolus aurens* lipoxidases probably contain SH groups.

It follows from the above findings that lipoxidase is a highly specific catalyst in the oxidation of unsaturated lipids. Indeed it catalyses the oxidation of only penta-1,4-diene compounds $-CH=CH-CH_2-CH=CH-$ with the *cis*-configuration of the double bonds (as in natural fatty acids). It has been found that lipoxidase does not affect the rate of oxidation of mono- and di-unsaturated conjugated compounds or pentadiene compounds with the *cis-trans*- or *trans-trans*-configuration; it should be noted that the latter behave as inhibitors in oxidation reactions catalysed by *cis-cis*-pentadiene compounds. Moreover, the rate of oxidation of highly unsaturated compounds catalysed by lipoxidase is independent of the degree of their unsaturation. Thus the ammonium salts of linoleic, linolenic, and arachidonic acids are oxidised at the same rate [37]; the same can also be said concerning the esters of these acids [33,38]. Hence it follows that the catalytic action of lipoxidase diminishes with increasing degree of unsaturation of the substrate. The study [38] of the autoxidation and the oxidation catalysed by lipoxidase at 13°C of the ethyl esters of linoleic and linolenic acid showed that O_2 is absorbed (mole mole^{-1}) over a period ranging from 0.2–0.9 to 50 h in the autoxidation, while in the oxidation catalysed by lipoxidase it is absorbed over a period between 0.5 and 50 min for both esters.

A recent study [39] of the oxidation of soya, linoleic acid, and its methyl ester catalysed by lipoxidase demonstrated that O_2 attacks only the 13-C carbon atom with formation of a single conjugated hydroperoxide,

with the *cis-trans*-configuration (and not *cis-cis*), while in autoxidation and in oxidation catalysed by haematin compounds the attack is directed simultaneously to 13-C and 9-C, which leads to a mixture of two conjugated hydroperoxides:

and



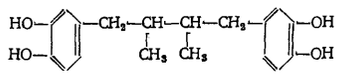
formed in equal amounts. Moreover there is a certain amount (of the order of 10%) of the non-conjugated hydroperoxide

It is noteworthy that the hydroperoxides obtained on oxidation catalysed by lipoxidase are optically active in contrast to the hydroperoxides formed on autoxidation. These results demonstrate the stereospecificity of the catalytic action of lipoxidase.

The mechanism of the oxidation catalysed by lipoxidase has been discussed in detail [37]. Probably initially a transition enzyme–substrate complex is formed and in the second stage a free radical should be generated at the α-methylene carbon atom as a result of the capture of one electron by the lipoxidase protein. In the presence of molecular oxygens, this free radical should lead to the classical autoxidation reaction (the mechanism of which is quoted above).

The inhibiting effect of various phenolic compounds on the oxidation of a 7×10^{-3} M aqueous solution of sodium linoleate at pH 9 catalysed by soya bean lipoxidase has been studied [31] at temperatures ranging from $-6°$ to 30°C. The degree of inhibition (measured as a percentage decrease of the rate of absorption of O_2) increases with temperature. For nordihydroguiaretic acid at a concentration of 10^{-4} M, it amounts to 100% at 30°C and only 32% at 0°C. At 30°C and the same concentration, the relative degrees of inhibition for α-tocopherol, hydroquinone, propyl gallate, and nordihydroguiaretic acid are respectively 27, 38, 100, and 100% . Nordihydroguiaretic acid (NDGA) also proved to be very active in oxidation reactions catalysed by various crude lipoxidases, namely the oxidation of the ammonium salts of linoleic and arachidonic acids (at 20°C and pH 7). The use of propyl gallate, hydroquinone, and α-tocopherol led to different results depending on the nature of the lipoxidase [37].

NDGA, which will be frequently mentioned from now on, is 2,3-dimethyl-1,4-bis-(3,4-dihydroxyphenylbutane):



NDGA is widely used in the USA as an inhibitor of the oxidation of many food products at a concentration of the order of 10^{-4} M.

Apart from the studies described above, the catalytic action of lipoxidase is dealt with in four extensive publications which also contain important historical data [8,40–42].

III. HAEMATIN COMPOUNDS

Haemoglobin, myoglobin, haemin, and cytochrome c are the most important biological catalysts of the autoxidation of unsaturated animal lipids. They are involved in many physiological *in vivo* reactions and also in the oxidation of food products during storage (rancidity).

In contrast to lipoxidase (which catalyses the oxidation of pentadiene systems with the *cis-cis*-configuration only), haematin compounds catalyse the oxidation not only of all the unsaturated lipids, but also of many aliphatic-aromatic and alicyclic hydrocarbons [43]. However, their catalytic activity is shown only in a colloidal medium or in an emulsion but not in a homogeneous system (lipoxidase is active in both heterogeneous and homogeneous media). Thus in the oxidation of linoleic acid catalysed by haemin, the absorption of oxygen ceases on passing from an aqueous emulsion to a homogeneous solution (as a result of the addition of acetic acid, dioxan, or pyridine) and restarts when the heterogeneous medium is restored by the addition of water [44].

The rate of oxidation increases with the degree of unsaturation of the substrate. Thus in the oxidation of the methyl esters of oleic, linoleic, and linolenic acids (at a concentration of 2×10^{-2} M) in an emulsion at 0°C catalysed by haemin (at a concentration of 2×10^{-5} M), the rates of absorption of oxygen are respectively 1.3 and 6. [45]

The rate of oxidation is proportional to the square root of the concentration of the haematin compound. This was confirmed for the oxidation of an aqueous emulsion of 0.1 M ammonium linoleate catalysed by haemoglobin [45], cytochrome c [45], and myoglobin [46] with the catalyst concentration varying from 1×10^{-6} to 7×10^{-6} M.

It is very significant that at high concentrations (ranging from values of the order of 10^{-3} M to 10^{-2} M for 1 M substrate) haematin compounds inhibit the oxidation of unsaturated lipids. A study [46] of the oxidation of an aqueous emulsion of 17×10^{-3} M linoleic acid showed that haemoglobin, which is an active catalyst at a concentration of 4×10^{-6} M, becomes an inhibitor at a concentration of 4×10^{-5} M: haemin and cytochrome c also become inhibitors at concentrations in excess of 10^{-4} M. Likewise it has been found [47] that cytochrome c has an inhibiting effect at high concentrations in the oxidation of linoleic acid.

In the oxidation process catalysed by haematin compounds, the latter decompose with the liberation of iron. This has been observed in the oxidation of aqueous 0.2 M emulsions (pH 6.8) of linoleic and linolenic acid catalysed by haemoglobin and haematin [48].

The finding that the catalytic action of haematin compounds is not inhibited by carbon monoxide and changes only slightly on formation of haemochromes with nitrogenous bases despite an appreciable change in the oxidation-reduction potential suggests that the valence of iron (in the haematin compound) is not altered during the oxidation.

The usual autoxidation inhibitors such as phenols and amines proved to be active in the oxidation of various unsaturated lipids catalysed by haematin derivatives.

α-Naphthol, catechol, p-aminophenol, and dimethylalanine are effective inhibitors in the oxidation of aqueous emulsions of oleic acid and linseed oil at 38°C catalysed by haemin [49]. The action of various enolic inhibitors, α-tocopherol, NDGA, and 2,6-di-t-butyl-4-methylanisole was examined in a study [50] of the oxidation of colloidal sodium linoleate (0.2 M) at 37°C catalysed by haemoglobin and cytochrome c. The concentration of the haematin compound was 2×10^{-5} M. It was found that α-tocopherol

is a weaker inhibitor than NDGA. Indeed in the oxidation catalysed by haemoglobin a 30 m induction period is attained at an NDGA concentration as low as 2×10^{-5} M, whereas the concentration of α-tocopherol required to produce the same effect must be higher by a factor of 10. Similar results were obtained also with cytochrome c. The action of various enolic inhibitors and synergistic agents (such as aminoacids and ascorbic acid) on the oxidation of methyl oleate, methyl linoleate, pig fat, cod liver oil, and linseed oil at 37°C, catalysed by haemin, haemoglobin, and cytochrome c, has been examined in detail [50,51].

As in the previous case, the inhibiting effect of α-tocopherol is weaker than that of NDGA, 2,6-di-t-butyl-4-methylphenol, and 2,6-di-t-butyl-4-methylanisole.

In the oxidation of pig fat at 37°C, catalysed by haemoglobin, ascorbic acid proved to be an excellent synergistic agent over a narrow range of concentrations: 10^{-4} to 10^{-3} mole kg^{-1}. The optimum concentrations of the inhibitor and the synergistic agent are as follows in moles per kilogramme:

NDGA	10^{-3}	NDGA	10^{-4}
Ascorbic acid	10^{-3}	2,6-Di-t-butyl-4-methylphenol	10^{-4}
		Ascorbic acid	10^{-4} .

These compositions increase the induction period by factors of 85 and 300 respectively. The oxidation catalysed by haematin derivatives may be inhibited also by other compounds and not only the usual inhibitors of chain autoxidation. Thus in the autoxidation of a 0.1 M emulsion of oleic acid at 37°C, leuco-Methylene Blue (at a concentration of 10^{-3} M) increases the rate of absorption of oxygen by a factor of 20, while in the oxidation catalysed by haemin (at a concentration of 10^{-5} M) the rate decreases by 20%. Probably there is a coordination between the N and O atoms with formation of a complex more resistant to oxidation.

Haematin compounds catalyse the decomposition of hydroperoxides in an inert atmosphere. The decomposition [43] of a 0.1 M emulsion of the peroxide of sodium linoleate at 40°C, catalysed by haemin (at a concentration of 2×10^{-4} M), showed that the peroxide content decreases faster in the presence of haemin than in its absence, particularly at the beginning of the reaction. Thus after 10 h the corresponding degrees of decomposition are 70 and 40% and after 60 h 96 and 84%. The initial content of hydroperoxide was 0.08 mole per mole of linoleate.

The catalytic action of various haematin compounds (catalase, haemoglobin, haematin, and cytochrome c) in the decomposition of sodium linoleate hydroperoxide has been discussed [52]. The formation of RO· radicals in the decomposition process is explained by the high yield of the corresponding carbanions in the presence of compounds (hydrogen donors) such as polyphenols [53].

Thus the corresponding alcohol is formed in 94% yield from a mixture of methyl linoleate hydroperoxide (1 M), hydroquinone (2 M), and haemoglobin (5×10^{-3} M) when it is allowed to stand in alcoholic solution at room temperature [53]. Similar results were obtained for cumenyl hydroperoxide [53] but with a lower yield (80%) of cumenyl alcohol, owing to some decomposition of the $C_6H_5(CH_3)_2CO$· radicals.

The fact that the rate of the autoxidation reaction (catalysed by haematin compounds) is proportional to the content of hydroperoxide (formed or added) and that in an inert atmosphere haematin compounds decompose the hydroperoxide ROOH with formation of RO· radicals suggests that the hydroperoxide should be formed initially without the involvement of haematin compounds. Then, evidently, the hydroperoxide may decompose with formation of RO· radicals which probably initiate the oxidation reaction, the chain mechanism of which may be inferred from the action of the usual effective autoxidation inhibitors. Nevertheless the mechanism of the decomposition of the hydroperoxide formed differs somewhat from that of the reaction catalysed by variable-valence metals:

$$ROOH + M_n \rightarrow RO\cdot + {}^{-}OH + M_{n+1} .$$

The constant valence of iron in the oxidation process suggests that an electron is abstracted from the haematin protein and not from the metal, as in the preceding case.

Apart from the classical chain termination reaction $ROO\cdot + {}^{\cdot}OOR \rightarrow ROOR + O_2$, the peroxy-radicals probably also interact with haematin compounds [45], which leads to shorter chains and a higher content of carbonyl compounds than in simple autoxidation.

The mechanism of the oxidation catalysed by haematin compounds has been discussed in detail in several earlier publications [8,43,44,52-55].

IV. VARIOUS METALS AND THEIR CHELATE COMPLEXES

The oxidation of 0.017 M aqueous emulsions of linoleic and linolenic acids at 37°C in the pH range 4.5–7.5 catalysed by various metals and their chelate complexes has been the object of serious study [56]. Among the many metals tested, very few are active. Thus Co^{2+} and Mn^{2+} are very active, while Cu^{2+}, Fe^{2+}, and Fe^{3+} are much less active; at a concentration of 10^{-3} M (one mole for ten moles of linoleate) Fe^{2+}, Fe^{3+}, Cu^{2+}, V^{2+}, Mn^{2+}, and Co^{2+} increase the absorption of O_2 by factors of 2, 3, 9, 14, 136, and 170 respectively. The catalytic activity of Fe^{2+} ions has been investigated in the oxidation of colloidal linoleic acid (0.02 M) at 30°C and pH 7 as a function of their concentration [57].

We may note that the catalytic activity of Fe^{3+} increases markedly in the presence of a reducing agent such as ascorbic acid or cysteine and depends greatly on the pH, in contrast to haematin catalysis which is very little sensitive to changes in the pH. Thus in the presence of ascorbic acid the maximum rate of oxidation (which exceeds that of autoxidation by a factor of 54) occurs at pH 5 and Fe^{3+} and ascorbic acid concentrations of 10^{-2} and 10^{-3} M respectively.

In contrast to the behaviour in the presence of Fe^{3+}, the catalytic activity of haematin compounds is weakened in the initial stage as a result of the addition of ascorbic acid, the reaction becoming autocatalytic subsequently owing to the formation of free iron by the decomposition of haematin compounds.

Thus in the oxidation of linoleic acid catalysed by haemoglobin (5×10^{-6} M) or cytochrome c (10^{-5} M) the addition of ascorbic acid (10^{-3} M) gives rise to a 30 min induction period, while in its absence absorption of O_2 begins immediately. Moreover, ascorbic acid does not affect the catalytic action of Cu^{2+} but greatly inhibits that of Co^{2+}.

At a concentration in excess of 0.1 M, phosphates inhibit the catalytic action of Co^{2+} and the Fe^{3+}–ascorbic acid system but their optimum concentrations have not yet been determined.

The rate of oxidation of linoleic acid does not change in the presence of 8-hydroxyquinoline and $\alpha\alpha'$-dipyridyl, while o-phenanthroline (2×10^{-3} M) increases it slightly;

however, the rate does not change at all in the simultaneous presence of the metals and complex-forming agents mentioned above. All the metals were used at a concentration of 10^{-3} M (except for 5×10^{-4} M Co^{2+}) with the ratio

$$K = \frac{\text{moles of complex-forming agent}}{\text{gram-atoms of metal}}$$

varying from zero to 5.

When *o*-phenanthroline is employed, with K varying from zero to 2, the rate of absorption of O_2 increases by a factor of 60 for Fe^{2+} and decreases by a factor of 170 for Co^{2+}, the increase for Cu^{2+} being only by a factor of 2.

8-Hydroxyquinoline has a less pronounced modifying effect than *o*-phenanthroline. Indeed, when K is varied from 0 to 2, the rate of absorption of O_2 increases only by a factor of 16 for Fe^{2+} and decreases by factors of 2 and 4 for Cu^{2+} and Co^{2+} respectively.

Blood serum albumin and egg albumin (at a weight concentration of 1%) increase respectively by factors of 1.9 and 3.5 the rate of O_2 uptake in the oxidation of linoleic acid catalysed by the Fe^{3+} (10^{-3} M)–ascorbic acid (10^{-3} M) system.

The catalytic activity of Cu^{2+} also increases in the presence of certain proteins. In one of the studies[58] on the oxidation of 0.1 M colloidal solution of ammonium linoleate (0°C and pH 7) catalysed by Cu^{2+} ions (10^{-3} M) it was shown that egg albumin (10^{-4} M) increases the rate of absorption of O_2 by a factor of 5. This must mean that haemocyanin catalyses the oxidation of unsaturated fatty acids.

On the other hand, horse serum, even at a dilution by a factor of 50, greatly reduces the activity of the Fe^{3+}–ascorbic acid system and completely inhibits it at a dilution of 20. It shows a similar but less marked effect on the catalytic activity of Co^{2+}, while the catalytic activity of haematin compounds changes little in its presence. Apart from weakening the action of certain catalytic systems in the oxidation of linoleic acid, it has a very pronounced inhibiting effect on the formation of lipid peroxides (pH 7) in rat brain homogenate[59]. The inhibiting effect of this serum must be a consequence of the formation of a Fe^{3+} complex of serum siderophilin.

Among numerous aminoacids, only histidine and its derivative histidylhistidine proved very effective inhibitors of the oxidation of linoleic acid catalysed by Co^{3+} (2×10^{-4} M). The inhibiting action depends greatly on the pH, becoming completely insignificant in an acidic medium. For example at pH 7 histidine (4 moles per gramme atom of Co^{2+}) decreases by a factor of 50 the rate of absorption of O_2, while at pH 5 the rate of absorption of oxygen decreases only by 1%.

At pH 7 the catalytic action of Co^{2+} is also weakened by phenylalanine but to a much less extent than by histidine.

Cysteine acts in the presence of Fe^{3+} like ascorbic acid, the maximum acceleration occurring at pH 4 and becoming zero at pH 8. At pH 5 the Fe^{3+} (10^{-3} M)–cysteine (3.3×10^{-3} M) system increases the rate of oxidation of linoleic acid by a factor of 10.

V. NATURE OF THE COMPOUNDS FORMED ON DECOMPOSITION OF LIPID PEROXIDES

The unsaturated lipid with the general formula $R-CH_2-CH=CH-R'$ (R' = saturated or unsaturated groups) initially gives rise to the hydroperoxide $R-\underset{\underset{O-OH}{|}}{CH}-CH=CH-R'$, which undergoes homolytic decomposition into the radicals $R\dot{C}H-\underset{\underset{O\cdot}{|}}{CH}=CH-R'$ and ·OH.

The ·OH radicals can interact with the initial lipid, attacking double bonds with formation of the dihydroxy-compound $R-CH_2-CHOH-CHOH-R'$, which may lead to the corresponding hydroxyketone and diketone as a result of dehydration.

The ·OH radicals can also attack the α-methylene carbon atom with formation of H_2O and the $R-\dot{C}H-CH=CH-R'$ radical (which is involved in the chain oxidation reaction).

The $R-\underset{\underset{O\cdot}{|}}{CH}-CH=CH-R'$ radicals can participate in the chain reaction, attacking the initial lipid with formation of the monohydroxy-compound $R-CHOH-CH=CH-R'$ and regeneration of the $R-\dot{C}H-CH=CH-R'$ radical. They can also decompose in two ways: (1) with dissociation of the double bond in the α-position and formation of the aldehyde RCHO and the radicals ·CH=CH–R', which combine with the ·OH radicals to give the unstable enol HO–CH=CH–R', isomerising into the aldehyde OCH–CH_2–R'; such dissociation leads to the formation of two unsaturated aldehydes (with a saturated group R'); (2) with dissociation of the double bond in the β-position and formation of the radicals R· and the aldehyde O=CH–CH=CH–R'.

The radicals R· combine with ·OH radicals to give the alcohol ROH. The greater content of carbonyl compounds compared with alcohols, particularly at low temperatures is probably due to the greater ease of dissociation in the α-position compared with the β-position.

The aldehydes thus formed undergo in turn degradative oxidation via two parallel reactions. Thus the C_n aldehyde with the general formula RCH_2CHO may be oxidised to the peroxide $R-CH_2-\underset{\underset{O}{\|}}{C}-O-OH$, which then decomposes into the C_{n-1} alcohol RCH_2OH and carbon dioxide[60–62] (or reacts with the initial aldehyde to form the acid RCH_2COOH).

The aldehyde can be also oxidised to an aldehyde hydroperoxide:

$$R-\underset{\underset{O-OH}{|}}{CH}-CHO .$$

The peroxide decomposes homolytically with subsequent elimination of hydrogen atoms from the α- or β-position relative to the carbonyl group[63]. Dissociation in the α-position leads to a C_{n-1} aldehyde and formic acid:

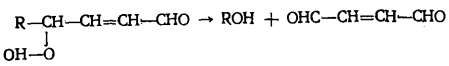
$$R-\overset{\overset{H}{|}}{\underset{\underset{O-OH}{|}}{C}}-CHO \rightarrow RCHO + HCOOH .$$

Dissociation in the β-position yields a C_{n-2} alcohol ROH and glyoxal.

With a C_n α-unsaturated aldehyde $R-CH_2CH=CH-CHO$, a hydroperoxide should be formed in the α-position relative to the double bond (i.e. in the γ-position relative to the carbonyl group), which can probably decompose owing to the dissociation in the α-position into a C_{n-3} aldehyde R–CHO and malonic dialdehyde:

$$R-\underset{\underset{O-OH}{|}}{CH}-CH=CH-CHO \rightarrow R-CHO + HO-CH=CH-CHO \rightarrow OCH-CH_2-CHO$$

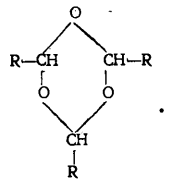
or into a C_{n-4} alcohol ROH and fumaric dialdehyde as a result of dissociation in the β-position:



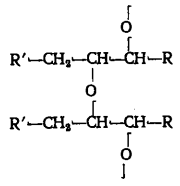
The aldehyde α-hydroperoxide $R-\underset{\underset{O-OH}{|}}{CH}-CHO$ can also decompose into H_2O and an α-ketoaldehyde RCOCHO.

The foregoing considerations account for the formation of a large number of carbonyl and hydroxy-compounds with short chains as well as formic acid in the oxidation of many unsaturated lipids. Malonic dialdehyde merits particular mention; its reaction with thiobarburic acid results in a red colour. This reaction has been frequently used for a quantitative determination of peroxides in biological media and has been discussed[64]. Mention should also be made of the formation of formates[65] which are probably produced as a result of the esterification of alcohols by formic acid.

In the presence of formic acid, aldehydes can lead to the formation of simple or mixed trioxans:

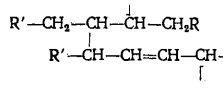


Polymers of two types may be produced. In the first case two carbon atoms are linked via an oxygen atom; the polymers correspond to the general formula



and are formed as a result of the dehydration of dihydroxy-compounds. They are produced in the presence of oxygen at a moderate temperature.

In the second case a bond is formed between carbon atoms:



In this case polymers are produced as a result of the action of dihydroxy-compounds on the olefinic compound with elimination of water. They are formed in the thermal decomposition of the hydroperoxide in an inert atmosphere. It should be noted that the polymers may contain in their chain functional groups (HO, CO) produced as a result of attack on the α-methylene carbon atom or the double bond.

At a high temperature (>250°C) and even in the absence of O_2, polymers with cyclohexene rings may be formed owing to the Diels–Alder addition of a conjugated polyolefinic compound to the initial non-conjugated polyolefinic compound. The mechanism of the formation of various types of polymers and also their determination have been the subject of a publication with 60 literature references[66].

The autoxidation of unsaturated lipids is discussed in a long paper with 192 references[67]. Another publication deals with various peroxides of unsaturated fatty acid esters[68].

Among monounsaturated lipids, the oleic acid derivatives have been most thoroughly investigated. The hydroperoxide of methyl oleate has been isolated with a purity of 85% and its properties have been described[68-70]. It is a colourless and odourless liquid readily soluble in organic solvents, decomposing slowly at room temperature, rapidly at 120°C, and in 15 min at 150°C. The autoxidation of methyl oleate has been studied[71-81] and it has been shown[78] that the *cis*-form (oleate) is converted into the *trans*-form (elaidate) during the autoxidation process.

It is clear from the above studies that the principal compounds formed in the autoxidation of methyl oleate are water, mono- and di-hydroxymethyl sterates, saturated C_7-C_9 aldehydes, C_{10} and C_{11} unsaturated aldehydes, and the hemialdehydes of suberic and azelaic acids. We may mention that α-undecenal is the main compound formed by the direct decomposition of the hydroperoxide of methyl oleate at 150°C. The formation of the above carbonyl compound can be accounted for on the basis of the considerations described in the preceding section, since the OOH group can occupy positions ranging from the 7th to the 12th as a result of double bond migration. Apart from the products mentioned above, numerous hydroxy- and carbonyl compounds are produced in consequence of the subsequent autoxidation of the aldehydes produced in the initial stage of the hydroperoxide decomposition.

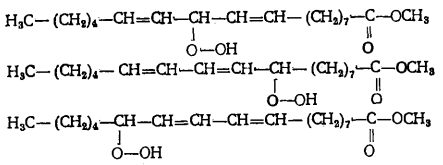
The polymer chains formed in the autoxidation of methyl oleate at 65°C [in the presence of cobalt(II) oleate] contain ester linkages[79]. The polymers obtained in the decomposition of hydrogen peroxide at 210°C[82] consist of carbon chains.

The autoxidation of oleic acid esters which are higher homologues of methyl, ethyl, and propyl oleates has also been investigated[83], but the corresponding hydroperoxides were not isolated. It is noteworthy that the maximum concentration of hydroperoxide at a given temperature decreases with increasing molecular weight of the ester. The autoxidation of oleic acid has been examined in a number of investigations[73-81,84-86]. In the latest study[86] carried out in thin layers at 60–80°C special attention was paid to the isolation and characterisation of the volatile products formed in the autoxidation.

The autoxidation of higher homologues of oleic acid and their methyl esters has also been the subject of several investigations. One fo them concerns the autoxidation of erucic acid and its methyl and propyl esters[87] and another deals with the autoxidation of brassidic acid[88]. The investigations have shown that, as with oleic and elaidic acids, the *cis*-isomer (erucic acid) undergoes autoxidation faster than the *trans*-isomer (brassidic acid). Dihydroxy-behenic acid was detected among the autoxidation products. A further investigation dealt with the autoxidation at 40°C of the methyl esters of oleic, elaidic, erucic, and α-undecenoic acids[89]; it showed that the rate of autoxidation decreases in the sequence indicated above. In a recent study[90] on the autoxidation of methyl undecenoate at 50°C, a hydroperoxide (in two stereoisomeric forms) and the corresponding epoxy-compounds were characterised.

The autoxidation of methyl linoleate has been the subject of several investigations[72,91-95]. The last study was concerned with the action of various inhibitors on the autoxidation of the *cis-cis*- and *trans-trans*-isomers. In the dark at 40–60°C there is an induction period of 15 min, while at 80°C the autoxidation begins almost at once.

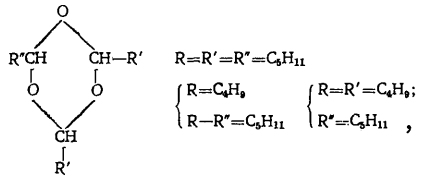
The corresponding hydroperoxide has been isolated [91-93] with purities of 84, 92, and 92% respectively. It consists of a mixture of three isomers with the following formulae:



The isomers with a conjugated diene group having the *cis-trans*-configuration constitute 90% of the total amount of hydroperoxide. Nevertheless, according to a recent investigation [94] of the autoxidation of methyl and ethyl linoleates at 60°C in chloroform solution, conjugated diene groups appear only when the hydroperoxide content is of the order of 100–200 millimoles per kilogramme of ester.

The primary decomposition products of the peroxides of methyl linoleate consist of saturated aldehydes (hexanal, pentanal), octenal, deca-2,4-dienal, and the hemialdehydes of suberic and azelaic acids.

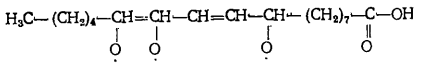
The above aldehydes were isolated also in the autoxidation at 37°C of an aqueous 2×10^{-2} M solution of ammonium linoleate [96]. The aldehydes obtained in the first stage of the decomposition of the above hydroperoxides may condense into trioxans, may be oxidised to the corresponding acids, or can undergo further oxidative degradation with formation of various carbonyl and hydroxy-compounds with lower molecular weights. The formation of 2,4,6-trialkyl-1,3,5-trixoans, simple or mixed, corresponding to the general formulae



was observed in the oxidation of methyl linoleate in a thin layer at room temperature. The trioxans were obtained as a result of the polymerisation and copolymerisation of pentanal and hexanal. Among the decomposition products of the initial aldehydes, special mention should be made of the dicarbonyl compounds consisting of glyoxals, a C_6 ketoaldehyde, fumaric dialdehyde, and hex-3-ene-1,6-dial, which were isolated in the oxidation of methyl linoleate at 45°C. [97-99].

The polymers formed as a result of the autoxidation of methyl linoleate at 4°C [82] consist of a mixture of dimers and trimers with linkages via oxygen atoms. Each chain contains C=O and O–H groups and a certain number of double bonds. The polymers obtained [100] as a result of the autoxidation of methyl linoleate at 33°C and subsequent decomposition at 100°C in an inert atmosphere also consist of a mixture of dimers and trimers but here the linkages are between carbon atoms.

The autoxidation of linoleic acid was studied recently by several investigators [101-103]. The first two studies were concerned with the identification and isolation of numerous volatile compounds and the third with the kinetic relations for autoxidation at low O_2 pressures in the presence of various inhibitors. In autoxidation in thin layers at 20° and 40°C, [101,102] saturated aldehydes ranging from C_2 to C_7, alcohols ranging from C_1 ot C_5, and esters [65] (mainly formate esters with pentyl formate predominating) were isolated. Apart from the above compounds obtained in the decomposition of the monohydroperoxide, trihydroxy-, triketo-, and hydroxyketo-compounds may also be formed as a result of the disproportionation of the radicals:



The latter are products of the homolytic cleavage of the hydroperoxide–peroxide

The autoxidation of ethyl linoleate has also been the subject of several investigations [3,104-106], in which a hydroperoxide was isolated [3]. The structure of the polymers formed in the autoxidation is similar to that of the polymers produced from methyl linoleate with linkages via oxygen atoms [106].

Two studies [107,108] have been made on the autoxidation of methyl linolenate at 37°C with isolation of the corresponding hydroperoxide having a purity of the order of 80%.

The hydroperoxide is monomeric and has three double bonds, two of which are incorporated in the conjugated group; the *cis-trans*-transfiguration predominates (the amount of the *trans-trans*-configuration is insignificant). Since the OOH group can occupy the 16-, 13-, 12-, and 9-positions, the primary decomposition products of the hydroperoxide consist of propanal, pentanal, and hepta- and octa-2,4-dienals.

The dicarbonyl compounds produced as the result of a subsequent autoxidation of the above aldehydes consist of malonic dialdehyde [109] and hex-3-ene-1,6-dial [110]. The formation of carbonyl compounds in the autoxidation of methyl linolenate (and also oleate and linoleate) is discussed in two large publications [111,112]. The structure of the polymers formed during autoxidation at 30°C is similar to that of the polymers from the linoleate hydroperoxide (linkages via oxygen atoms). Saturated C_2–C_6 aldehydes, 2,4-diethyl-6-propyltrioxan, 2,4-diethyl-6-pentyltrioxan, pentanal, acids ranging from C_1 to C_6, and their various esters were isolated quite recently in a study of the autoxidation of linolenic acid at 20° and 40°C. [113] Hydroperoxides derived from methyl linoleate, methyl linolenate, ethyl arachidonate, methyl eicosapentenoate, and ethyl esters of menhaden§ fat were obtained in 95% purity in a recent investigation [114].

The autoxidation of esters was initially carried out at 4°C over a period of 80 days and then at room temperature for 148 h until the content of hydroperoxides reached 28 moles for 100 moles of ester. The peroxides were isolated from the autoxidation product thus obtained with the aid of thin-layer chromatography.

In two important investigations [115,116] of saturated lipids, a study was made of the autoxidation at 60°, 150°, and 200°C of very pure methyl palmitate. It was found that at 60°C hydroperoxide was not formed over a period of 56 days, while at 150°C its content reached 300 millimoles per kilogramme after 3 h, and at 200°C only hydroxycarbonyl compounds and carboxylic acids formed as a result of the decomposition of the peroxide could be detected. It follows from these observations that the attack of the saturated esters by molecular oxygen at 150°C leads primarily to the formation of a double bond as a result of dehydrogenation. Although probably all the carbon atoms are attacked, the hydroperoxide is formed preferentially in the centre of the molecule. The above

§ Menhaden is a fish of the herring family (Clupeidae) (Editor of Russian translation).

two papers criticise all previous investigations and quote numerous references to studies on the autoxidation of saturated lipids.

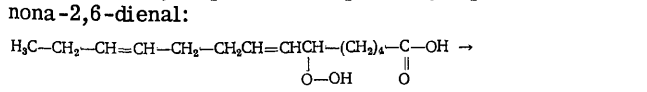
Natural fats and oils consist of triglycerides with various contents of saturated and unsaturated acids depending on their nature. Thus carbonyl compounds, formed in oxidative degradation, are of the type which would probably be formed simultaneously from oleic and linoleic acids and in some cases also from linolenic and arachidonic acids.

A lipid containing a relatively small amount of linoleic acid and in particular linolenic acid can give rise to considerable amounts of carbonyl compounds, derived from these polyunsaturated acids, in consequence of a much less extensive autoxidation of oleic acid.

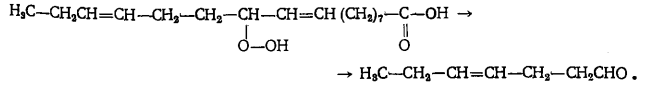
There are publications [111,112] with detailed data on saturated aldehydes, unsaturated aldehydes, and dienals formed from mutton, beef, and pork fats, cocoa oil, and also from ground nut, soya bean, and linseed oils (as well as from methyl oleate, trioleate, and linolenate and ethyl linoleate). These lipids were subjected to autoxidation at room temperature and under ultraviolet irradiation until the formation of different amounts of hydroperoxide; they were then decomposed at room temperature or at 165°C.

Hexanal, oct-2-enal, and deca-2,4-dienal were obtained by the decomposition at 100°C of autoxidised cotton seed oil (with a peroxide content of 125 millimoles per kilogramme) [117]. Numerous saturated aldehydes, unsaturated aldehydes, and dienals, as well as oct-1-en-3-ol and oct-1-en-3-one were obtained from sunflower seed oil autoxidised at 37°C. [118] Saturated aldehydes ranging from C_2 to C_9, unsaturated aldehydes from C_5 to C_9, 2,4-dienals (from C_6 to C_{10} except C_9) were isolated from the autoxidation products of soya bean oil [119]; the configuration of hexa- and octa-2,4-dienals has been discussed [120]. Hexanal, oct-2-enal, and deca-2,4-dienal have been isolated [121]; the last probably consists of a mixture of two stereoisomers—2-*trans*-4-*cis*-(28%) and 2-*trans*-4-*trans*-(72%). Numerous aldehydes, ketones, and hydroxy-compounds have been identified [122,123] as well as *cis*-hex-3-en-1-al. [124] The formation of 2,4-dienals from autoxidised pork fat has been studied [125]. The isolation of octadecadienoic acids (the 11,15-isomer and a small amount of the 10,15-isomer) from beef and mutton fat is noteworthy [126]. The autoxidation was carried out at 37°C until the attainment of a peroxide content of 2 millimoles kg^{-1} with subsequent decomposition at 140°C in an inert atmosphere.

The first hydroperoxide is probably a precursor of nona-2,6-dienal:



and the second is a precursor of hept-4-enal:



Probably the above unsaturated aldehydes are partly responsible for the odour of green cucumbers which appears in beef fat during its storage.

An attempt has been made to relate certain chemical characteristics to the organoleptic parameters of alimentary fats [127]. It was found that a very small peroxide content may be very important for the estimation of the freshness of these fats. Thus the appearance of an unpleasant taste was noted for a peroxide content of 0.10 millimole kg^{-1}.

VI. EFFECT OF LIPID PEROXIDES ON VARIOUS SUBSTRATES

The formation of epoxy-compounds and α-epoxy alcohols as a result of the decomposition of α-olefinic hydroperoxides was observed with cyclohexene [128] and many olefins [122,129]. The autoxidation of unsaturated fatty acids at the double bonds has been the subject of an intensive investigation [130–132] which established the following facts.

In the presence of haemin (weight concentration 2×10^{-5}) in a stoichiometric mixture of oleic acid and the peroxide of ethyl oleate (at room temperature and at a reduced pressure), the degree of unsaturation of the acid gradually diminishes, with an accompanying decrease of the overall content of active oxygen.

In addition the ratio

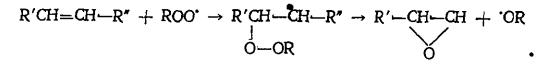
$$r=\frac{\text{unsaturated acid content}}{\text{active oxygen content}}$$

becomes close to unity.

In a mixture of unsaturated fatty acids (with an iodine number of 126) and the peroxide of oleyl alcohol, the peroxide oxygen is transferred to the double bonds of the acid. Quantitatively this phenomenon depends greatly on the nature of the haematin catalyst (weight concentration 3×10^{-3}). Thus at room temperature after 1 h the ratio $r = 0.31$ in the absence of a haematin catalyst or in the presence of oxidised cytochrome; r becomes 0.96 in the presence of reduced cytochrome [131].

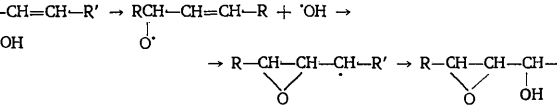
The role of reduced cytochrome in the transfer of peroxide oxygen to the double bonds of unsaturated fatty acids has been discussed in detail by Dubouloz and coworkers [133].

Epoxides may be formed immediately in the autoxidation process in consequence of the addition of ROO· radicals to the double bond:

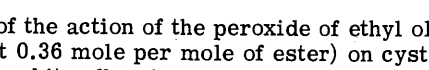


The reaction mechanism has been discussed in detail [134].

Epoxyalcohols are probably formed in the decomposition of the hydroperoxide with subsequent addition of ·OH radicals to the double bond [53]:



The epoxidation of unsaturated compounds in the presence of haematin compounds by hydroperoxides probably takes place via the addition of ROO· radicals to the double bond, since the latter are formed as a result of a series of reactions [135]:



The study [136] of the action of the peroxide of ethyl oleate (peroxide content 0.36 mole per mole of ester) on cysteine and degraded egg white albumin showed that the thiol groups of the protein enter fully into the reactions in the presence of an excess of the peroxide. The reaction products consist of disulphides and their derivatives containing oxygen. The biological importance of this reaction has been discussed in detail and the methods employed have been criticised [136].

Another study [137] dealt with the autoxidation in emulsion of linoleic acid (2×10^{-3} M) at 37°C and pH 7.4, catalysed by haemin (10^{-5} M) or haemoglobin (2×10^{-6} M) in the presence of 10^{-3} M cysteine or glutathione. The rate of

degradation of the SH groups of the last two compounds is proportional to the content of peroxide in the emulsion. The cysteine oxidation product consists of cysteine, cysteic acid, and cysteine disulphoxide.

The action of an aqueous 2×10^{-3} M emulsion of linoleic acid peroxide (37°C and pH 7.4) on various enzymes has been the subject of a major investigation[138]. It was shown that the activity of all enzymes with SH groups as well as that of cholinesterase, choline dehydrogenase, glyoxalase, β-amylase, succinate dehydrogenase, and urease is strongly inhibited. Fairly strong inhibition occurs also with other enzymes not containing SH groups, for example lipase, invertase, pepsin, trypsin, papain, and cytochrome oxidase, while xanthine oxidase, tyrosinase, catalase, and α-aminoacid oxidase are not affected. It is noteworthy that enzymes such as cholinesterase, lipase, invertase, and pepsin are also inhibited by an aqueous emulsion of palmitic acid. Here the inhibition is probably caused by the nautralisation of the positive charges of the proteins by the negative charges of the acid. Attempts have been made several times to relate the degree of inhibition of the enzymes to the content of peroxide in the emulsion. Thus an 80% degree of inhibition obtains for papain and urease at peroxide concentrations of 0.22×10^{-3} and 0.12×10^{-3} M respectively. In another study an emulsion of fatty acids from linseed oil was employed instead of the emulsion of linoleic acid. We may note that the inhibition under irradiation is more pronounced in the presence of linoleic acid than in its absence.

Thus after 2 h succinate dehydrogenase was inhibited only to the extent of 14%, while in the presence of an emulsion of linoleic acid (4×10^{-7} M) the degree of inhibition reached 63%. The degree of inhibition of succinate dehydrogenase (at a linoleic acid concentration of 4×10^{-7} M) was investigated as a function of time and it was shown that the degree of inhibition reaches 20% after 15 min, 60% after 45 min, and then tends asymptotically to 80%.

It is interesting that these enzymes can be protected from the action of peroxides by more labile enzymes containing SH groups. The protection of urease by cysteine against the action of peroxides formed in the autoxidation of linseed oil has been discussed[138]. A study has also been made[139] of the inactivation of glyceraldehyde-phosphate dehydrogenase by linoleic acid hydroperoxide and of the inactivation of ribonuclease by the same hydroperoxide[140].

A special investigation[141] of the inactivation of enzymes with SH groups by peroxy-acids has been made.

The degradation of carotene in the autoxidation of unsaturated lipids catalysed by soya bean lipoxidase has been the subject of numerous investigations[142-144]. The degradation occurs in alfalfa on storage in the field[145] as a result of the action of peroxides formed in the autoxidation of unsaturated lipids catalysed by the lipoxidase of this plant.

The study of the autoxidation[146] of colloidal methyl linoleate (3.4×10^{-2} M) initiated by X-rays in the presence of vitamin A showed that the degree of degradation of vitamin A increases with the peroxide content. Thus at a peroxide concentration of 5×10^{-5} M, only 33% of the initial vitamin A remains. The degradation of vitamin A does not occur solely under the influence of X-rays in the absence of linoleate.

The study of the autoxidation of ethyl linoleate[147] (25° and 37°C) in petroleum ether solution in the presence of carotene (weight concentration 2.5×10^{-4} in relation to linoleate) showed that the decomposition of carotene is complete over a period of 48 h. Certain autoxidation inhibitors proved effective in the stabilisation of carotene. Thus pyrogallol, hydroquinone, and α-tocopherol at a weight concentration of 3×10^{-5} relative to linoleate (at 37°C over a period of 48 h) prevent oxidation to the extent of 100, 74, and 76% respectively). A gradual breakdown of vitamin A occurs in margarine during its autoxidation at room temperature. Thus the degree of decomposition of vitamin A, reaching 6.5% for a peroxide content of 0.7×10^{-3} mole kg^{-1}, becomes 43% when the peroxide content is 10^{-2} mole kg^{-1}.[148]

The degradation of vitamin A in halibut-liver oil during its oxidation at 25°, 80°, and 98°C and also its protection by NDGA alone or NDGA in the presence of a synergistic agent have been investigated in detail[149].

The study of the degradation of vitamin A during the autoxidation of olive oil at 55°C in thin layers showed[150] that vitamin A decomposes gradually. Thus after 2 h the degree of its degradation is 69%, while in the presence of 0.048% of α-tocopherol it amounts to only 5%, reaching 36% after 10 h. Another study[151] dealt with the degradation of carotene in the autoxidation of ground nut oil at different temperatures (from 4° to 98°C) and also its protection against oxidation with the aid of α-, β-, and γ-tocopherols and gossypol.

A large publication[152] has been devoted to the degradation of carotene at 35°C under the influence of the peroxides of ethyl oleate, methyl linoleate, methyl linolenate and cotton seed, ground nut, and soya bean oils as well as to protection against oxidation with the aid of α-, β-, and γ-tocopherols and gossypol. The protective action of α-, β-, and γ-tocopherols against the degradation of carotene and bixin by the peroxide of methyl linoleate is also examined in two other papers[32,153].

In a study of the degradation of vitamin A and carotene[154] during the autoxidation at 37°C of a colloidal solution of ammonium linoleate (0.2 M, pH 7) catalysed by 2×10^{-5} M haemoglobin or cytochrome c showed that, following the absorption of 500 cm^3 of oxygen, the degree of degradation of vitamin A and carotene is respectively 88 and 53%, while in the presence of 5×10^{-3} M α-tocopherol, the degree of degradation is only 63 and 5% respectively.

Another study[50] dealt also with the question of the protection of vitamin A and carotene with the aid of α-tocopherol in the course of the autoxidation of an aqueous emulsion of oleic acid (37°C, 0.1 M, pH 7) catalysed by haemin (2×10^{-5} M). After 3 h, 1400 cm^3 of oxygen is absorbed and the degree of degradation of vitamin A is 88%, while in the presence of 6×10^{-3} M α-tocopherol the degree of degradation is only 63% and 300 cm^3 of oxygen is absorbed. The behaviour of carotene is similar to that of vitamin A. When 1400 cm^3 of oxygen has been absorbed, carotene is degraded to the extent of 63%, while in the presence of 5×10^{-3} M α-tocopherol the degree of degradation is only 5%.

Usually diets rich in unsaturated lipids but deficient in vitamin E and A cause a diminution of the vitamin A reservoir in animal livers. The addition of α-tocopherol and other antioxidants to the diet has a protective effect in relation to vitamin A, as shown by the following findings.

After seven months the vitamin A reservoir in the livers of male albino rats maintained on a diet containing 5% of pork fat and deficient in vitamins A and E is almost completely exhausted. The addition to the diet of each rat of 1 mg of α-tocopheryl acetate over a period of one week leads to a degree of degradation of vitamin A of only 71% during the same time.

The addition of α-tocopherol, leuco-Methylene Blue, phenothiazine, and tetramethylthiuram disulphide to a diet including 10% of cod liver oil and deficient in vitamin E increases the vitamin A content in chicken livers compared with the diet free from additives [155].

The addition of Methylene Blue or phenothiazine to a diet including 10–20% of cod liver oil and deficient in vitamin E increases the content of vitamin A in rat livers over a period of 14 weeks compared with the diet free from additives. The effect of the additives diminishes markedly when cod liver oil in the diet is replaced by pork fat [156,157]. The protective action of vitamin E, promoting the retention of vitamin A in rat livers, has been described in two papers [158,159].

Ethyl linoleate peroxide (250 millimole kg^{-1}) in contact with crystalline biotin leads to 96% degradation of the latter at 37°C after 12 h. As for vitamin A, α-tocopherol has a protective effect: the degree of inhibition is 44% in 48 h at a 4% concentration of this compound. Another study [160] also demonstrated the degradation of biotin at 25° and 37°C in the presence of the peroxide of corn oil (100 millimole kg^{-1}) and in the case of diets containing 5% of lipids of which 3% is cod liver oil and 2% cod liver fat; the overall peroxide content in the diet is 5 millimole kg^{-1}.

A study of the action of pyridoxine and riboflavin [161] showed that riboflavin decomposes lipid peroxides and thereby protects pyridoxine from their action.

VII. THE ROLE OF LIPID PEROXIDES IN THE DETERIORATION OF FOOD PRODUCTS

It has been already seen that carbonyl and mono- or poly-functional hydroxy-compound may be formed from lipid peroxides. The monocarbonyl compounds consist of a mixture of saturated and unsaturated aldehydoacids and in all probability are responsible for oxidative rancidity and reversion. These frequently encountered phenomena have been discussed in detail in a number of publications [11–15,162].

Cow's milk. The overall composition of the acids constituting milk lipids is as follows [163]:

Unsaturated acids (60%): 12% of acids ranging from C_4 to C_{12}, 11% of myristic acid, 28% of palmitic acid, and 9% of stearic acid.

Unsaturated acids (40%): 34% of oleic acid, 5% of linoleic acids, and 1% of others.

Acids entering into the composition of phospholipids [164]: 41% of saturated acids, 40% of mono-olefinic acids, 2.3% of conjugated and 8.8% of conjugated diolefinic acids, 3.6% of triolefinic acids, 2% of tetraolefinic acids, and 2.2% of pentaolefinic acids.

Evidently milk phospholipids have a higher content of polyunsaturated acids than glycerides.

It has been shown [165] that the content of peroxide in powdered milk allowed to stand in air increases with time. In the same study [165] it is recommended that various antioxidants (particularly of the phenolic type) be employed at a weight concentration of 10^{-4}. The formation of peroxides has been investigated in various specimens of powdered milk during storage at 2° and 38°C over periods ranging from 4 months to 1 year [13,113]. When the peroxide content is of the order of 6–10 millimoles per kilogramme of lipids, a rancid odour appears. The maximum content of peroxide formed over a period of 4 and 9 months is 5 and 14 millimoles per kilogramme of lipids.

C_2–C_{18} saturated aldehydes, C_5–C_{11} unsaturated aldehydes, C_8 and C_9 2,4-dienoic aldehydes, oct-1-en-3-one, and oct-1-en-3-ol were identified in the lipids of sour milk [166–168]. Alkyl methyl ketones $RCOCH_3$ ranging from C_1 to C_{13} are also formed [169]. Probably they are derived mainly from myristic and palmitic acids.

The nature and mechanism of the formation of various compounds in the autoxidation of milk lipids have been discussed in detail [166–174]. One of the papers [172] criticises preceding investigations.

Data on the content of peroxides and carbonyl compounds in various animal fats and edible vegetable oils as a function of storage and irradiation conditions have been published [13,175,178]. The study of the storage of raw vegetables, in particular peas [179–182], showed that the content of glucides and nitrogen remains more or less constant.

No changes occur also in blanched vegetables, i.e. those subjected to the action of boiling water which decomposes lipidoxase. On the other hand, the peroxide content and acidity of the lipid component of raw vegetables may greatly increase [181]. There is also a possibility of a decrease of the iodine number—for example, in raw peas it decreases from 98 to 89 in 5 years. We may also note that chlorophyll is degraded in peas to the extent of approximately 30% in 5 years.

Lipids, which constitute only about 0.3% of dry potato [183], contain 75% of polyunsaturated fatty acids, 53% of 18 : 2 acid, and 22.5% of 18 : 3 acid. The saturated component consists almost entirely of a C_{16} acid (17.4%). After exposure to oxygen at room temperature for 5 months, C_2–C_6 saturated aldehydes and C_1–C_5 saturated hydrocarbons were isolated. The latter are probably formed from aldehydes:

$$R{-}CHO \rightarrow RH + CO.$$

Potato chips fried at 185°C in a mixture consisting of 50% of cotton seed oil and 50% of corn oil and stored at room temperature in air were very carefully investigated [179]. 18 different carbonyl compounds were isolated from freshly fried potato chips and 19 from less fresh specimens. During ageing, the content of saturated aldehydes (particularly hexanal), α-unsaturated aldehydes (more of C_7 than C_8), and alkyl methyl ketones (more of 2-pentanone than 2-hexanone) increases. On the other hand, there is a rapid decrease of the content of deca-2,4-dienal.

On storage pork frequency becomes rancid [184]. The rancidity is accompanied by a change in colour, which becomes greyish-brown instead of pink. The rancid meat has an unpleasant odour and taste and is somewhat toxic. The rancidity is a consequence of the oxidation of oleic acid triglycerides and small amounts of polyunsaturated acids (particularly linoleic acid) and subsequent degradation of haemoglobin and myoglobin accompanied by the liberation of inorganic iron compounds. This reaction is catalysed by haematin compounds of the meat itself. The very rapid deterioration of horse meat in the presence of air is probably a consequence of an analogous phenomenon, which, however, is much more rapid owing to the higher content of linoleic acid (16%) in horse fat.

VIII. CHANGES IN LIVING ORGANISMS INDUCED BY LIPID PEROXIDES AND THEIR DECOMPOSITION PRODUCTS

The presence of peroxides at a concentration of several tens of millimoles per kilogramme of dry material was observed in the lipid component of green leaves of certain plants: sunflower, wheat, peas, beans, waterweed (Elodea) [185], and white lucerne [186]. Peroxides could not be

detected in the stalks, roots, and seeds of these plants [185]. The localisation of peroxides in the leaves and their decomposition under conditions where photosynthesis but not tissue respiration ceases suggests that photosynthesis is closely related to the formation of peroxides. This hypothesis is based on the finding that a flavin-lipoprotein compound containing iron and manganese and capable of reducing carbon dioxide was isolated from lucerne leaves [186]. The reduction was accompanied by the formation of a peroxide of the lipid component of the leaf. The role of peroxides of glycolic and glyoxylic acids in the decomposition of chlorophyll has been examined [187,188]. It is interesting that the leaves, seedlings, and seeds of certain oil-bearing plants contain substances capable of causing the decomposition of peroxides [189-191].

The polymers obtained as a result of the decomposition of lipid peroxides the formation of which is catalysed by lipoxidase, are probably components of cutin [160], an impermeable film coating part of the plants, which had been acted upon by air.

Even a balanced diet containing between 5 and 20% of highly unsaturated lipids and with a low content of vitamin E may cause the pathological changes enumerated below, which may vary depending on the type of animal [162,192,235]:

1. Yellow colour of fatty tissues.
2. The formation of the ceroid pigment in rat livers.
3. Brown colour of the rat uterus.
4. Atherosclerosis and peripheral damage of the viens in man.
5. Exudative diathesis in chickens.
6. Encephalomalacia in chickens.
7. Decrease of the capacity for egg bearing and embryo generation in hens.
8. Depigmentation of incisor teeth in rats.
9. Muscular dystrophy in ruminants.
10. Liver necrosis and pulmonary haemorrhage.

These ten pathological changes have been discussed in two large reviews [233,234]. Certain pathological changes, such as, for example, the yellow colour of the fatty tissue in certain animals, the brown colour of the rat uterus, the formation of the ceroid pigment in rats, and the appearance of exudative diathesis and encephalomalacia in chickens may be directly linked to the action of the oxidation products of unsaturated lipids on tissue proteins which results in their damage. The differences between the behaviour of chickens and rats in relation to diets with a high polyunsaturated lipid content are probably a consequence of the different structures of their capillary vessels. In other diseases, for example in muscular dystrophy or liver necrosis, which occur also in the absence of lipids from the diet, the role of polyunsaturated lipids is less clear. However, in liver necrosis the decomposition of sulphoaminoacids under the influence of lipid peroxides probably plays a considerable role. It is quite likely that muscular dystrophy is a consequence, at least partly, of the decomposition of vitamin E under the influence of these peroxides.

It is noteworthy that different antioxidants such as NDGA, Methylene Blue, diphenyl-*p*-phenylenediamine, phenothiazine, and tetraethylthiuram may be replaced in the diet by vitamin E and play a protective role against one or several of these diseases. For example, selenium compounds (at a concentration of $10^{-7}-10^{-6}$ M) can fulfil a protective role against liver necrosis and exudative diathesis but not against encephalomalacia. The action of these different antioxidants has been reviewed [233,234] and has been described in a special paper on the action of SeO_2. [235]

IX. PATHOLOGICAL CHANGES INDUCED *IN VIVO* BY A DIET CONTAINING VARIOUS LIPIDS HEATED IN THE PRESENCE OF AIR

Edible lipids consist of a mixture of triglycerides of stearic, palmitic, oleic, and linoleic acids. Animal fats contain much more of unsaturated acids (40–60%) than vegetable oils (10–30%) and much less of linoleic acid. Beef and mutton fats contain between 1 and 2% of this acid and pork fat contains 6–10%, while in many vegetable oils its content reaches 60%. Horse fat, which contains, apart from a small amount (4.5%) of stearic acid, 5.3% of linoleic acid and a considerable amount of linolenic acid (16%), is an exception.

Various fried products sold commercially are heated at 180–200°C. Under these conditions, there is usually an increase of the content of hydroxy-compounds, free acids, esters, conjugated dienes, and particularly polymers (the initial content of which is low, namely 1–2%). The content of carbonyl compounds initially increases to a maximum and then falls and that of peroxides is more or less constant. This can decrease or increase slightly but remains insignificant, its concentration rarely exceeding 10 millimole kg^{-1} (provided that the food product had not been subjected to preliminary ionising irradiation).

The degree of overall unsaturation (iodine number), and particularly the content of linoleic acid, decreases appreciably. These chemical changes are reflected in an increase of the refractive index, the dielectric constant, and particularly the viscosity [236-239].

The physicochemical changes occurring during the frying of various food products containing lipids have been discussed in a number of publications [240-244], the last of which is devoted to different types of meat.

Apart from temperature and the duration of frying, the content of the peroxides and lipids and their decomposition products is influenced by the area of contact between the lipid and air, which is determined by the shape, dimensions, and material of the frying-pan and also the duration of the preliminary heating and cooling. Indeed, peroxides are formed during the preliminary heating and then decomposed during frying and are reformed during cooling. Thus, evidently, the content of different peroxide derivatives will be higher if the heating is interrupted than when it is carried out continuously and will increase with the number of preliminary heating and cooling cycles. Nevertheless, we may note that carbonyl compounds may be partly eliminated by evaporation or can undergo further oxidative degradation: this in fact accounts for their maximum content when the heating process is of limited duration. Thus, when corn oil [236] was heated for 24 h at a constant air flow rate of 150 $cm^3\ kg^{-1}\ min^{-1}$, the content of peroxides at 120°, 160°, and 200°C was respectively 40, 3, and 1 millimole kg^{-1} (the initial content was 0.5 millimole kg^{-1}). After 24 h at 200°C (at an air flow rate varied from 0 to 2400 $cm^3\ min^{-1}$), the content of carbonyl compound changed from 86 to 116 millimole kg^{-1} (with a maximum of 122 millimole kg^{-1} for an air flow rate of 1200 $cm^3\ min^{-1}$).

When cotton seed oil was heated continuously at 175°C for 62 h [238] and with interruptions (heating for 7–8 h followed by 12–16 h of storage at room temperature), the results presented in Table 1 were obtained.

Lipid peroxides introduced into the alimentary canal by a probe gradually disappear during digestion. Thus the content of the peroxide of ethyl oleate after 5 h was only 12% of the initial value, which was 10^{-4} mole [245].

Moreover, lipids originating from various parts of the organism, particularly from the lymph (specimens of which were removed during digestion), contain no peroxides at all [245-247].

Table 1.

Substance	Content, millimole kg^{-1} heating	
	continuous	interrupted
Peroxides	2.3	3.6
Carbonyl compounds	158	155
Hydroxy-compounds	130	241
Free acids	280	560
Polymers (%)	14.8	13.8
Iodine number	103	98

Probably the peroxide of the lipid ester or triglyceride is hydrolysed by lipase with retention of the OOH functional group, which is then partly reduced by the pancreatic secretion. The above facts and also the absence of peroxides from excrement suggest that lipid peroxides are mainly decomposed on the mucous membrane of the intestine [245].

Experiments [248] performed on rats fed on a diet containing 10% of *Vernonia* oil containing 70% of 12,13-epoxyoleic acid showed the presence of this acid in adipose tissues, the liver, kidneys, and the heart and also in excrement. On the other hand, epoxides were absent from these tissues when *Vernonia* oil was replaced by corn oil. These findings suggest that epoxides are not decomposed in the digestive organs (which is surprising in view of the presence of 0.1 *N* HCl in the stomach and the sensitivity of epoxides to acid hydrolysis) and are normally stored in various tissues together with other lipids.

Hydroxy- and carbonyl compounds are readily absorbed [249]; thus the content of carbonyl compounds in the lymph may increase by a factor of 10.

A diet containing 10–20% of lipids heated in air usually causes a retardation of growth, a decrease of the degree of assimilation of food, and its efficiency, and also an increase of the amount of water required.

On such a diet, certain animal organs, particularly the liver, greatly increase in size. However, it should be noted that the restoration of a normal diet leads to the recovery of the sick animals. Vitamins (including vitamin E) ameliorate but do not eradicate these diseases. Fresh lipids as well as proteins also have a favourable effect.

The toxicity of heated lipids increases with the content of linoleic acid (with the exception of horse fat, the content of the 18 : 3 acid in normal lipids is very low), as shown by the results obtained in two studies on rats [250-252] fed on a diet containing 20% of lipids.

The toxicity increases with the number and duration of preliminary heating and cooling cycles (consequently one should avoid using the same oil in several successive frying operations) and decreases as a function of the weight of the lipid. For example, the harmfulness of various heated lipids employed in commercial frying involving large amounts of product is much less than that of lipids heated in the laboratory in much smaller amounts, as shown by studies [253-259] on rats fed on a diet containing 23% of lipids.

Since the mucous membrane of the intestine decomposes lipid peroxides, their intrinsic action must be restricted to the level of digestive enzymes. Apart from the enzymes mentioned above [138], the inhibition of xanthine oxidase by the peroxide of soya bean oil has been demonstrated [247]. Such decomposition of enzymes should be reflected in a reduced assimilability of food, which entails a retardation of growth. Thus the content of peroxides in lipids treated at 200°C is low, and consequently their role in the overall pattern of the induced diseases is very small.

However, on heating at lower temperature (60–100°C), when the content of peroxides is fairly high, their presence may be responsible for the overall toxicity of the heated lipids. Thus the inhibition of the growth of rats fed on a diet containing 20% of soya bean oil subjected to autoxidation at 60°C increases with the peroxide content [247,259]. A study on cotton seed oil autoxidised at 60°C showed that the incidence of illness increases when the maximum peroxide content is reached [240].

The relation between toxicity and the content of peroxides was observed not only with cotton seed and soya bean oils autoxidised at 60°C but also with the ethyl esters of the highly unsaturated fatty acids in the fat of the cuttle fish. The autoxidation products obtained at 30° and 100°C contained respectively 970 and 75 millimole kg^{-1} of peroxides and proved to be very toxic to rats [260].

In other studies lipid peroxides introduced via the alimentary canal proved to be non-toxic. For example the hydroperoxide of methyl oleate introduced in an amount of 5% into the diet of rats is altogether non-toxic [261,262].

Thus there is no definite relation between the degree of toxicity of the heated lipid and its peroxide content, particularly for the same lipid at low heat-treatment temperatures in the initial autoxidation stage.

It should be noted that in pathological cases, where the regeneration of the intestinal epithelium (decomposed by lipid peroxide) is slow, lipid peroxides can apparently overcome the protective effect of the intestine [263]. Studies during which methyl linoleate labelled with ^{14}C at 1-C was introduced via the digestive tract, showed that this peroxide is extensively decomposed in the intestine and the decomposition products are incorporated into various tissue lipids.

The epoxides which are deposited together with other lipids in various cell tissues are not toxic at first sight. Indeed, the introduction of 5% of methyl *cis*-epoxystearate [261,264] or 7% of epoxyoleic acid (in the form of 10% *Vernonia* oil) [248] into the diet of rats is not harmful. However, according to other investigations [265], epoxides appear to be carcinogenic.

Hydroxy-compounds, at least those with long chains, are not toxic. For example, methyl mono- and dihydroxystearates are not harmful to rats when their content is 5%. [261]

Carbonyl compounds are probably to some extent responsible for the overall toxicity of heated lipids, which decreases after their treatment with semicarbazide. They can act on digestive enzymes, since they inhibit the activity of lipase. One should examine the effect of each type of aldehydes as a function of the degree of their unsaturation; probably aldehydes with conjugated double bonds should be more toxic.

Polymers are usually toxic. Their activity evidently depends on the degree of diene conjugation or, in other words, on the content of linoleic acid in the initial lipid. This has been demonstrated for pork fat and cotton seed oil after their heat treatment in air at 95°C for 300 h and after distilling off the autoxidation products, obtained in

this way, at 300°C at a very low pressure [264]. The residue from cotton seed oil (40% of the total quantity of the oil), introduced in an amount of 20% into rat diet, caused in one week the death of all the animals, while the residue from pork fat (17% of the total quantity) does not cause death but inhibits growth [264]. We may also note that the distillation residue may contain thermal polymerisation products with cyclohexene fragments which are not formed in frying on a commercial scale [266] but the present author believes that they can be formed in the decomposition of polymers at 300°C.

On the other hand, the degree of assimilation of toxic polymers decreases with increase in molecular weight. Therefore the heaviest fractions are not always the most toxic.

Table 2. Composition of certain animal fats (%).

Fat	Acids				
	18:0	16:0	18:1	18:2	18:3
Mutton fat	34	24	44	2	traces
Beef fat	21	32	45	2	traces
Pork fat	16	30	45	7	traces
Chicken fat	7	26	38	20	traces
Horse fat	5	26	34	5	16
	(+5% 14:0)		(+7% 16:1)		

Table 3. Composition of cod liver fat (%).

Acid		% in fat	Acid		% in fat
20% of unsaturated triglycerides	18:0	3	2% of triolefinic acids	18:3	
	16:0	12		20:3	
	14:0	3		22:3	
	15:0	1	tetraolefinic acid	18:4	2
	17:0	1			
45% of mono-olefinic triglycerides	18:1	25	10% of pentaolefinic acids	20:5	9
	20:1	13		22:5	1
	22:1	6	hexaolefinic acid	22:6	9
	14:1	traces			
	16:1				

Table 4. Composition of certain vegetable oils (%).

Acid	Linseed oil	Soya bean oil	Cotton seed oil	Safflower oil	Corn oil	Groundnut oil	Olive oil
18:3	47—60	4—8	traces	traces	1.5	traces	traces
18:2	15—24	49—56	40—50	77	58	20—3	4—12
18:1	15—19	24—34	20—30	13	27	50—60	70—85
Saturated	10—15	12—17	20—30	10	12.5	10—20	7—17

In addition, one must bear in mind the existence of trioxans, particularly derivatives of 2,4-dienoic aldehydes, such as deca-2,4-dienal, in which corn oil heated at 200°C becomes enriched [237]. The importance of 1,3-conjugation has been emphasised by Holman and Greenberg [267], who discuss all compounds with two conjugated double bonds, for example the hydroperoxide of ethyl linoleate, and its reduction and decomposition products, as well as ethyl linoleate derivatives which are not involved in the normal metabolism of linoleic acid [267]. The biochemical activity of various fractions of linseed oil [266,268], herring oil [269,271], and pork fat [271] has been investigated. Several excellent papers have been devoted to the toxicity of heated lipids [249-252,256,272,273]. The compositions of various lipids are given by Hilditch and Williams [274]. The compositions of the main animal fats and vegetable oils according to the literature data [111,274] are quoted in Tables 2, 3, and 4.

X. CHANGES IN TISSUE CELLS OCCURRING ON FORMATION OF PEROXIDES

Earlier it was stated that lipid peroxides administered to rats with food are largely decomposed by the mucous membrane of the intestine and only their traces can be detected in the lymph.

Nevertheless the conditions for the formation of lipid peroxides are favourable even in the mammalian organism in consequence of the simultaneous presence in vascular endothelium also of light unsaturated lipids (in the form of an emulsion), haematin compounds, and oxygen [245]. The capacity of the tissue for the formation of lipid peroxides increases with the content of unsaturated acids and the degree of their unsaturation as well as in the presence of catalytic systems such as haematin iron or non-haematin iron together with ascorbic acid, and decreases in the presence of inhibitors, for example vitamin E.

It is noteworthy that the composition, particularly as regards polyunsaturated lipids, not only of the triglycerides of the fat reserves but also of the phospholipids in various tissues is greatly influenced by the type of lipids in the diet. Thus an increase in the content of linoleic acid in the diet increases simultaneously the content of linoleic acid in the storage lipids and the content of linoleic and arachidonic acids in various tissues. Polyunsaturated acids (other than the main acids), such as those of the 20:5 and 22:6 type, in cod liver oil are deposited in various animal tissues without change.

The correlation between the degree of unsaturation of lipids entering into the composition of tissues and the degree of unsaturation of lipids in the diet accounts for the pathological changes observed *in vivo* under the influence of a diet enriched in polyunsaturated lipids.

However, we may note that the formation of polyunsaturated 20:3 acids may occur also in tissues if the diet is deficient in linoleic acid and includes saturated lipids such as those of coconut oil. The composition of lipids in various tissues as a function of the type of lipids in the diet has been discussed in detail [275-279].

The presence of peroxides in connection with various pathological changes in tissues occurring due to a diet with a high content of polyunsaturated lipids and deficient in antioxidants has already been mentioned. Lipid peroxides were also detected after the exposure of a live animal to ionising radiation in the presence of atmospheric oxygen [280-286].

The formation of lipid peroxides under the influence of ionising radiation is in all probability initiated by $^{\cdot}OH$ and $^{\cdot}OOH$ radicals formed in the aqueous phase [13]. The analogy between the diseases caused by ionising radiation and lipid peroxides, in particular the decomposition of various enzymes, has been discussed in detail [2,287]. The detection of peroxides in the tissues of live animals has

been questioned in two publications [288,289]. Indeed, when lipids were extracted in an inert atmosphere, even traces of peroxides could not be detected in any of the organs of rats (the chromatographic method was used [290]) subjected to preliminary irradiation with X-rays in air or fed on a diet containing 20% of fresh soya bean oil or its peroxide [288]. Similar results were obtained in the study of various organs from chickens fed on a diet containing 10% of cotton seed oil. Blood lipids, which induce the formation of small amounts of a very unstable peroxide, are an exception. A study [289] based on 33 different tissues confirmed the validity of earlier results [288].

Hence it probably follows that live tissues do not contain peroxides (or at most traces in adipose tissues) and that the latter are formed *in vitro* during extraction in contact with an atmosphere from which oxygen has not been completely exhausted. A deficiency of vitamin E in the tissue probably appreciably increases the rate of formation of the peroxide *in vitro*.

Whereas the presence of lipid peroxides in live tissues is doubtful, the formation of peroxides *in vivo* is indicated by the products obtained on decomposition of lipid peroxides and the fact that such formation is prevented by vitamin E and other antioxidants. In this case lipid peroxides probably undergo gradual transformations from the instant of their formation, which lead to various physiological (decomposition of protein thiols and various enzymes) and structural changes (rupture of membranes in mitochondria and lysosomes).

When aqueous emulsions of lipid extracts from various rat organs were exposed to ionising radiation (5–100 krad), the formation of peroxides with a lipid content of several tens of millimoles per kilogramme was observed.

Peroxides are also formed during aerobic incubation of various live tissues at 37°C. However, in the majority of investigations the peroxides were determined only indirectly with the aid of a colour test for malonic dialdehyde (one of the decomposition products of lipid peroxides) with thiobarbituric acid. This very sensitive test yields interesting results in comparative studies, but does not reflect the true content of peroxides (see the discussion in Wills's paper [292]).

The considerations concerning the formation of peroxides *in vivo* and the catalysis of the oxidation of aqueous emulsions of linoleic acid by metal chelate complexes are applicable, in broad outline, to the determination of the capacity for the *in vitro* formation of endogenic peroxides in various live tissues in the presence of atmospheric oxygen, particularly when one considers the catalytic activity of various forms of iron (haematin and non-haematin) and ascorbic acid and the effect of chelating agents and of phosphate concentration. The rate of formation of peroxides in the tissue increases with its overall iron content as well as with the content and degree of unsaturation of its component lipids. In the presence of non-haematin iron, the content of ascorbic acid in the tissue is very important. Thus the onset of the formation of the peroxide on addition of ascorbic acid to homogenates of various tissues is explained by the presence in them of non-haematin iron. It has been shown [293] that in various tissues of scorbutic guinea pigs, less peroxides are formed than in the tissues of healthy guinea pigs and that the addition of ascorbic acid to tissues affected by scurvy restores their normal capacity for the formation of peroxides. It is interesting to note that tissues in a state of constant cell division, such as bone marrow, the mucous membrane of the intestine, and cancer cells, do not form peroxides.

Discussions concerning the formation of peroxides as a result of the *in vitro* aerobic incubation of various tissue homogenates have been published [292–299]. The formation of endogenic peroxides in the homogenates of various rat organs and also the catalytic effect of these homogenates in the autoxidation of linoleic acid in emulsion was discussed in detail in one of these papers.

Mitochondria usually contain considerable amounts of polyunsaturated lipids (particularly in the form of phospholipids) derived from acids with 3,4,5, and 6 double bonds, such as 18:3, 20:3, 20:4, 22:4, 22:5, and 22:6 acids. The distribution of lipid molecules in the vicinity of various cytochromes makes them particularly susceptible to autoxidation.

The composition of the liver and heart mitochrondria in various sea fish and birds and also several marine mammals has been described [301,302]. Data have also been published [302] on the composition of the mitochondria in the chicken liver and the ox heart. The composition of rat liver mitochrondria has been studied [303,304].

Suspensions of mitochrondria at 37°C in a sucrose or sodium chloride solution (with a phosphate buffer) absorb oxygen with subsequent formation of malonic dialdehyde. Ascorbic acid usually catalyses these reactions and vitamin E inhibits them.

The phenomena described below are accompanied by the degradation of enzymes such as succinate dehydrogenase, TPNH cytochrome reductase, choline oxidase, and amino-acid oxidase (on the other hand, the liver alkaline phosphatase and brain cholinesterase resist the formation of this peroxide). The degradation of the enzymes is revealed by a weakening of the oxidative phosphorylation and oxidation of α-oxoglutaric acid.

Apart from the degradation of enzymes, the mitochondrial membranes swell and are lysed with liberation of free fatty acids and soluble proteins.

Vitamin E, introduced *in vitro* into suspensions of mitochondria, decreases the absorption of oxygen and the formation of malonic dialdehyde, protecting thereby the above enzymes against oxidative degradation and the membrane against swelling and lysis. The introduction of 0.47 and 4.7% of vitamin E into mitochrondria from rabbit heat tissue decreases the rate of absorption of oxygen by factors of 7 and 28 respectively [305]. It is noteworthy that the capacity of mitochrondria for the formation of peroxides depends also on the composition of polyunsaturated lipids and antioxidants (in particular vitamin E) in the diet. Thus when a diet deficient in vitamin E and containing 3% of pork fat and 2.5% of fish fat is administered, the rate of absorption of oxygen and the amount of malonic dialdehyde formed decrease respectively by factors of 2.5 and 10 when 10 mg of α-tocopherol is added to the diet [306].

Degradation of mitochondrial enzymes has been discussed in Refs. 307 and 308 and the swelling and lysis phenomena in Refs. 309 and 310. The last two papers deal with the role which ascorbic acid plays in the occurrence of these processes.

The formation of peroxides in the mitochondria of rat liver and rabbit heart cells has been thoroughly investigated [305,306]. The inhibiting effect of vitamin E (in relation to the formation of peroxides in the mitochondria of rabbit heart cells and rat and rabbit liver cells) has been studied [311–313].

Microsomes contain 30–40% of lipids, particularly phospholipids, and twice as much of polyunsaturated lipids (in relation to nitrogenous bases) as in mitochondria. Certain molecules of these lipids are located near cyto-

chrome molecules, which gives them a particularly high capacity for the formation of peroxides [314].

Applications to rat liver cell microsomes of the same methods as for mitochondria [305] led to the discovery that the absorption of oxygen accompanied by the formation of malonic dialdehyde takes place.

The formation of peroxides in microsomes leads to a modification of the synthesis of nucleic acids and proteins and to a decrease of the synthesis of ascorbic acid and also to an inhibition of the activity of gulonolactone oxidase [315]. The microsomes themselves degenerate, their altered shape being clearly visible through an electron microscope.

As for complete homogenates and mitochondria, vitamin E plays the role of an inhibitor. Thus addition of α-tocopherol (0.25 g/gN) leads to degrees of inhibition of 72 and 69% respectively in the absorption of oxygen and the formation of malonic dialdehyde.

The formation of peroxides in the microsomes of rat liver and rabbit heart cells has been described in broad outline [314]. The inhibition of gulonolactone oxidase has been investigated [315,316], the second study [316] being concerned in addition with the dependence of the degree of inhibition of the synthesis of ascorbic acid on the content of malonic dialdehyde. The effect of TPNH and ATP on the formation of peroxides in microsomes has been studied [317].

Although lysosomes contain less lipids than mitochondria and microsomes, they nevertheless have only a simple membrane. They form peroxides with difficulty but the membrane is easily ruptured on formation of peroxide even in insignificant amounts. Thus the rupture of the membrane in rat liver cell lysosomes under the influence of ultraviolet light and γ-radiation and the product of the autoxidation of methyl linoleate is accompanied by the liberation of hydrolytic enzymes: cathepsin, glucuronidase, acid phosphatase, and aryl sulphatase. The addition of ascorbic acid increases and that of vitamin E decreases the amount of such liberated enzymes.

The formation of peroxides in lysosomes associated with the liberation of enzymes has been discussed [318-320].

The haemolysis of red blood corpuscles is associated with the rupture of membranes as a result of the formation of lipid peroxides. The haemolysis is promoted by a diet deficient in vitamin E, while the introduction of vitamin E or other antioxidants, for example reduced Methylene Blue, into the diet interferes with haemolysis. The haemolysis of red blood corpuscles has been discussed in a number of publications [321-325].

The inhibition of cell division under the influence of ultraviolet light is probably also induced, at least partly, by the action of lipid peroxides [326].

Indeed, in a study of the fertilised eggs of the worm *Chaetopterus pergamentaceus* and the sea urchin (*Lytechornus variegatus*), it was established that ultraviolet light and irradiated methyl linoleate inhibit cell division. Probably such inhibition is a consequence of the repression of the activity of the enzymes and of the depolymerisation of nucleoproteins.

Vitamin E is the usual component of the majority of living organisms. It is encountered in the tissues of all animals and is widely distributed in plants. It has also been found in unicellular organisms such as yeasts and moulds. Its antioxidant activity, which is usually shown in an increase of the duration of the induction period and in a decrease of the rate of absorption of oxygen and the rate of formation of hydroperoxides and their decomposition products, has been frequently noted in this review.

A similar situation obtains in the oxidation of linoleate catalysed by lipoxidase and haematin compounds and in the oxidation of mitochondria and microsomes.

Although α-tocopherol behaves as a weaker antioxidant *in vitro* than other tocopherols, it accumulates in the animal organism (particularly in phospholipids) and therefore under *in vivo* conditions exhibits a pronounced antioxidant activity. Its distribution in various animal fats and vegetable oils as well as in various rat organs has been discussed in two publications [16,327].

Various tocopherols do not exhibit synergism but form strongly inhibiting systems with ascorbic, citric, and phosphoric acids, which probably also play a very important role in the stabilisation of tissue lipids [326,328,329].

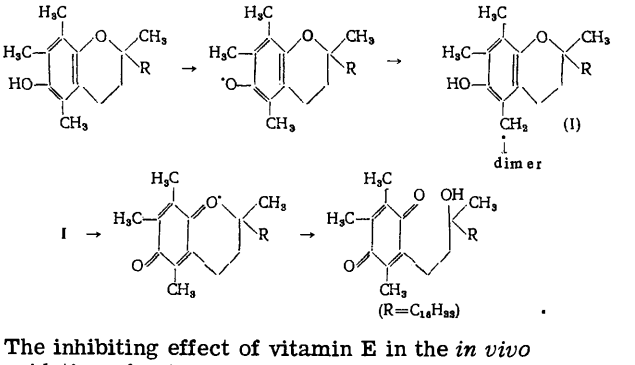
The degree of degradation of α-tocopherol in tissues usually increases with the content and degree of polyunsaturation of lipids in the diet. However, the loss of tocopherol from a tissue on a diet from which it is absent greatly depends on the nature of the tissue. We may note its very tenacious retention by the brain [330]. The decomposition products of α-tocopherol *in vivo* consist of α-tocopherylquinone (formed as a result of the opening of the pyran ring) and dimeric α-tocopherol (with an unaffected heterocyclic structure).

Indeed the presence of tocopherylquinone was established in the liver and in the muscles of mice and pigs [331] and its content in adipose tissues increases with the degree of unsaturation of lipids in the diet. (It is higher by a factor of 3 for methyl linoleate than for coconut oil [332].)

The simultaneous presence of the dimer and the quinone was also observed in the livers of mice and rats after intra-abdominal injection of α-tocopherol into animals which had been fed for a year on a diet deficient in vitamin E. [331,333] The dimer and the quinone are also formed on simultaneous oxidation (60° and 100°C) of α-tocopherol and methyl linoleate by atmospheric oxygen [334].

The effect of ROO· radicals formed as a result of the action of iron(III) salts on the hydroperoxide of methyl linoleate and the peroxides of methyl linolenate, ethyl arachidonate, and methyl eicosapentanoate on α-tocopherol has been investigated [335] and kinetic data have been published.

α-Tocopherol is converted into α-tocopherylquinone as a result of the abstraction of a hydrogen atom (from the OH group) followed by the rupture of the pyran ring, rearrangement, and fixation of the OH group [335]:



The inhibiting effect of vitamin E in the *in vivo* autoxidation of polyunsaturated lipids has been examined [16,233,234,336-338].

Ubiquinone, which is usually found in mitochondria in larger amounts than α-tocopherol, can be reduced to ubiquinol [339,340]. On the other hand, the latter can be

reoxidised by peroxides to ubiquinone. Ubiquinol proved to be an inhibitor approximately as effective as α-tocopherol in the oxidation of an emulsion of arachidonic acid catalysed by 2×10^{-6} M haemoglobin (37°C, pH 7.4) and also in the photochemical oxidation of the mitochondria in ox liver cells. These findings suggest that ubiquinol and ubiquinone can play a very important role as antioxidants for mitochondria.

Squalene [341], which is present in considerable amounts in fish lipids, can behave as an antioxidant, at least at the beginning of the reaction. In fact, a comparative study [341], of the autoxidation of methyl linoleate and methyl oleate at 63°C in the presence of 0.02% of tocopherol or squalene showed that in the first five days the content of the hydroperoxide is lower in the presence of squalene than in the presence of added α-tocopherol; after this period the formation of the peroxide in the presence of squalene is faster and after 8 days it is as rapid as in the absence of inhibitors.

We have already seen that inorganic compounds [337,338,342-344] introduced with food can prevent certain pathological changes induced by a diet with a high content of polyunsaturated lipids and deficient in vitamin E. A study [337] has shown that Na_2SeO_3 introduced into the diet gradually reduces the formation of peroxides in the liver, heart, and muscles of chickens. Selenocystine and selenomethionine were detected in the hydrolysate of liver proteins.

In addition various aminoacids containing selenium at concentrations of 10^{-4} and 2×10^{-4} play the role of inhibitors, which may be compared with α-tocopherol in the oxidation of an emulsion of methyl linoleate catalysed by haemoglobin.

These findings suggest that selenium introduced with food in the form of inorganic compounds is deposited in various tissues of the chicken as selenoproteins which *in vivo* probably behave as antioxidants. The mechanism of inhibition by selenium compounds consists mainly in the decomposition by these compounds of the hydroperoxide formed, but not via a radical mechanism. In addition, selenium compounds, which decompose peroxides, protect coenzyme A in the absence of cystine [343].

The role of selenium compounds in metabolism has been discussed in detail [338,343] and the mechanism of their interaction with hydroperoxides has been considered in another study [344].

Apart from α-tocopherol, which is widely distributed in plants [16,327], many polyhydroxy-compounds, such as simple aromatic polyphenols or heterocyclic derivatives (hydroxychromans, hydroxycoumarones [345]) can play a fairly important role in inhibition. In certain special cases their inhibiting activity may be the main function, as in the case of NDGA, the antioxidant activity of which *in vitro* has been considered in this review.

A thorough study has been made [346] of the toxic effect of various types of lipid peroxides administered intravenously and intra-abdominally to rats and chickens. It was shown that the toxicity depends to a large extent on the nature of the compound in which the lipids are bound and on the method of injection. Thus, peroxides of the triglycerides derived from olive and nut (groundnut?) oils are much less toxic than free fatty acids. Their ester and phospholipid peroxides, which are of the same type, are much more toxic when administered intravenously than intra-abdominally.

The retention of lipid peroxides by various tissues depends also on the type of peroxy-compound and the nature of the emulsifying agent. Probably it is greater the lower the toxicity of the peroxide. The peroxides of triglycerides are retained to a considerable degree by blood, lungs, the liver, the spinal column, kidneys, and the intestine. A moderate amount is retained in the heart and the muscles and a very insignificant amount in the brain, the pancreas, and in adipose tissues. The degree of retention in the blood is very considerable over a period of 1 h, is insignificant after 2 h, and becomes zero after 500 h.

Possibly the mechanism of the elimination of triglyceride peroxides differs from that for peroxides of other types. It is interesting to note that intravenous administration yields identical results with chickens and rats but after intra-abdominal administration the retention of triglyceride peroxides by various rat organs is less than by chicken organs.

We may note that in the presence of 0.5 millimole per kilogramme of the hydroperoxides of ethyl linoleate and $(CH_3)_3COOH$ [t-butyl hydroperoxide], symptoms of methaemoglobinaemia appear.

Numerous quantitative data concerning the retention of various types of peroxides by rat and chicken organs as a function of the dose administered and time and also as a function of the content of methaemoglobin in the case of ethyl linoleate and $(CH_3)_3COOH$ have been published [346].

The toxicity of certain autoxidation products of lipids and of certain organic peroxides administered to rats intra-abdominally only has been examined [2,347]. According to the data of the second study, the hydroperoxide of methyl linoleate and particularly of $(CH_3)_3COOH$ should be less toxic than was suggested in another investigation [346]. Nevertheless, it follows from the above studies [346,347] that lipid peroxides (and probably other peroxides) are much more toxic when introduced with food, which is reasonable, bearing in mind their decomposition by the mucous membrane of the intestine, which occurs in such a way that only some of their decomposition products pass into the lymph. Their toxicity when introduced by injection is undoubtedly a consequence of the combined effects resulting from attack on double bonds (which entails the degradation of the principal fatty acids, namely the 18:2 and 20:4 acids) and the degradation of haematin nuclei, protein thiols, various vitamins (particularly vitamins A and C), various enzymes, and membranes (which may lead to the haemolysis of red blood corpuscles).

Oxidation catalysed by variable-valence elements has been examined in two papers [348,349] and the general theoretical questions concerning the inhibition of autoxidation have been considered by Knorre et al. [350] Moreover, several papers and publications on synthesis after 1960 were devoted to organic peroxides in general [351-359], some of which [351-353] analyse various methods of their determination.

New Ideas Concerning the Strength of Adhesive Joints of Polymers†

J.J.Bikerman

The review was written by J.J.Bikerman specially for "Uspekhi Khimii". Bikerman is one of the leading U.S. specialists in the theory and practical aspects of surface phenomena and adhesion in polymers and solids and therefore the presentation of his views on the nature and strength of adhesive joints is of very considerable interest.
It is noteworthy that the views developed by the author depart widely from those common in the USSR and therefore his review is of special interest for the Soviet reader. Putting forward a number of interesting and well founded postulates of the rheological theory of adhesion, the author essentially ignores the molecular nature of adhesion phenomena, the chemical nature of adhesives as such, and the polymer nature of adhesives, which are not discussed in the review at all. Also ignored are the thermodynamic criteria of adhesion, the effects of the flexibility of the polymer chain and its structure on adhesion, etc. All these factors make the author's approach to adhesion somewhat one-sided and biased. However, this is compensated by a purposeful approach to the problem, a polemical presentation, and a number of postulates which are of very great practical value for all those concerned with adhesion and adhesive joints.
The bibliography includes 75 references.

I. STRENGTH OF ADHINTS AND MOLECULAR ADHESION

In 1959 a valuable review on "Modern Views on the Adhesion of High Polymers" was published[1] in "Uspekhi Khimii". In the present paper an altogether different approach to the problem is employed. The author's views on the reason for the strength of adhesive joints (or adhints as they will be called henceforth for brevity) are described in the book which has been published in two editions[2]; readers who find this review too compressed and incomplete are referred to this monograph.

The mechanical rupture of an adhint requires the application of a stress f (g cm^{-1} s^{-2} or kg m^{-1} s^{-2}) or a force F (g cm s^{-1} or kgf m s^{-2}) and the performance of a certain amount of work W (g cm^2 s^{-1} of kg cm^2 s^{-2}). The problem of the factors which determine these quantities can be expressed also in a somewhat different form. Each adhesive joint contains several components; in the simple case there are two—the adhesive and the adherend—but there may be as many as five: the first adherend, the first boundary layer, the adhesive, the second boundary layer, and the second adherend. It is necessary to find a relation between the experimental values of f, F, or W on the one hand and the properties of these components and the geometry of the adhint on the other.

The second formulation of the problem may appear strange to unprepared readers and therefore it must be justified immediately. For many years everyone believed and even now it is still frequently believed that it is necessary to overcome *adhesion* in order to rupture an adhesive joint. Theoretical or molecular adhesion is by definition the attractive force A (per unit area) between the atoms or molecules of a substance A and the atoms and molecules of a substance B along the boundary between the phases A and B. It is assumed that the mechanics of rupture is fairly unimportant. If a stress f proves to be necessary in repeated experiments for the rupture of a joint between an adherend B and an adhesive A, the implication is, according to some theoreticians, that the adhesion A between A and B is equal to f. Thus one can obtain curves relating A to, for example, the chemical composition of A and B if the breaking stress f has been measured as a function of this composition. The geometry of the adhint and the mechanics of the experiment are disregarded, since the experimenter believes that he measures molecular adhesion, which is independent of external conditions such as the kind and direction of the breaking force, the form and size of the adhesive joint, etc.

In fact the resistance to rupture (f) is never and under no conditions equal to A. One can create fairly artificially an imaginary relation between f and A, as stated in section III, 1, but it is in all cases insignificant. The identification of f with A constitutes the apex of a pyramid made up of several strata of erroneous assumptions. The principal stratum or the principal error is the hypothesis that the theoretical adhesion A may be determined by mechanical measurements on adhints. The second unjustified hypothesis is that the force responsible for rupture is equal to the external force F applied to the adhesive joint. The third error consists in the fact that the macroscopic stress is assumed to be equal to the microscopic stress. The fourth stratum involves the assumption that the microscopic stress necessary to initiate rupture is equal to molecular adhesion.

The considerations set out in the previous paragraph may be elucidated using peeling as an example. In Fig. 1, A represents a rigid adherend, R a flexible ribbon, and G a layer of glue. A force F is applied to the free end of the ribbon. Evidently the force does not act directly on the edge E of the adhesive. Thus the first task of the investigator is to calculate or measure the force and moment acting on this edge and the crack formed in it; when the crack grows, the adhint gradually disintegrates.

† Edited by Yu.S. Lipatov.

The relation between the external force F and local stresses in the adhesive and at its boundary with air depends on the thickness and nature of the ribbon, on the thickness and nature of the layer of glue, etc; a mathematical expression for this relation is given in section V, 4. If the local stresses have been determined correctly, the second of the errors enumerated above is eliminated.

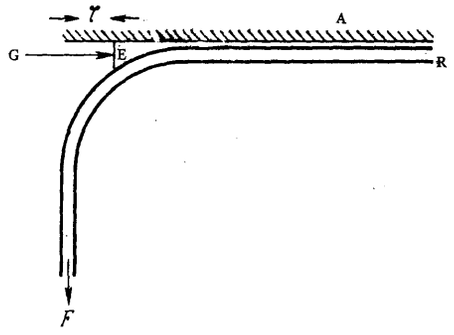

Figure 1. Peeling of a ribbon R from a rigid adherend A; G = adhesive; E = its edge.

All solids are inhomogeneous. They contain cavities, impurity inclusions, crystal lattice defects, and other flaws. Usually each flaw gives rise to a concentration of stresses in its vicinity. If the *average* stress along the cross-section of the solid is σ (g cm^{-1} s^{-2} or kgf m^{-1} s^{-2}), then the stress at the flaw may be 100 σ or even 1000 σ. The true *local* stress σ_m, which should be defined as "local at a square" [locally in a cross-section ?Ed. of Translation] is much greater than σ and a crack is initiated at the point where σ_m is particularly high. This is in fact, why for a given average stress σ, σ_m varies from point to point and solids disintegrate via a crack growth mechanism and not immediately into individual atoms or molecules. As long as the investigator bears firmly in mind the radical difference between σ and σ_m, he avoids the third error.

If the description of peeling described here is correct, then it is clear why one cannot employ the fourth stratum as a basis. The crack arises and spreads in the adhesive layer. In many systems its distance from the interface (adhesive — adherend) exceeds by a factor of hundreds and thousands the "radius of molecular action"; thus the phenomena which occur along the crack cannot depend on forces acting across its boundary.

Here one must ask the obvious question why cracks cannot originate and grow exactly between two solid phases. In this case one might expect the equality or at least a close relation between σ_m and A. The answer is that interfacial rupture is altogether unlikely. Fig. 2 illustrates the boundary between two solids; the circles represent the molecules of one solid and the crosses those of another. The [dotted] lines show that the crack spreading from left to right may be propagated in different ways. If the probabilities of all three ways are equal, the probability that the rupture will occur *between* the two phases is 1/3. The probability that the crack will occur between two phases at a distance equivalent to 11 molecules is $(\frac{1}{3})^{10}$, i.e. approximately 1 : 59 000; in other words an interfacial crack with a length equivalent to 11 molecules can be expected in only one adhint out of 59 000. The probability is even smaller if the attraction between the adhesive and the adherend (if the adherend is a material with strong cohesion) is mostly greater than the attraction between the molecules of the adhesive; this follows from the familiar general expression for van der Waals constants a: $a_{12} \simeq \sqrt{a_1 a_2}$, where a_1 is the constant for two molecules of type 1, a_2, the constant for two molecules of type 2, and a_{12} the constant for a molecule of type 1 and a molecule of type 2. If $a_1 > a_2$, then $a_{12} > a_2$. In a metal — adhesive — metal system, the numeral 1 refers to the metal and the numeral 2 to the adhesive.

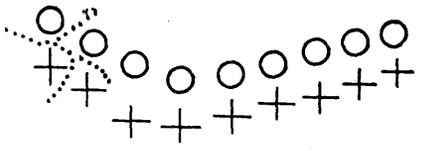

Figure 2. The growth of a crack (dotted lines) between two solid bodies.

The impossibility of rupture exactly along the interface can be proved also in a different way. Since the probability of finding a particularly weak spot in a solid is greater the larger the specimen, the breaking stress (and hence $\sigma_m : \sigma$) usually increases if the thickness of the plate undergoing rupture is reduced. The thickness of the adhesive layer is rarely below 0.01 cm and the "thickness of the slits" between different molecules in Fig. 2 may be estimated as 10^{-9} cm; evidently, for equal molecular forces, a smaller stress is needed to rupture a thicker layer.

Since material A cannot be separated from material B exactly along their boundary, the forces acting between A and B are not involved in the separation process; rupture takes place far from the boundary and the stress necessary for it cannot yield any information about the true adhesion between A and B. Thus the first postulate on which the upper part of the pyramid of errors rests is as misleading as the second. A more detailed examination of the problem of the value of A for the strength of adhints may be found in the author's book[2].

II. HOOK-TYPE ADHINTS

The main conclusion of the first section of this review is that the experimental values of f, F, and W are independent of the molecular adhesion A and cannot be used for its determination. The breaking stress is determined by the mechanical (and not chemical) properties of the components of the adhint and by the geometry of the system. The significance of this general rule can be more conveniently considered separately for each class of adhesive joint. From the standpoint of the mechanism of strength, there are three such classes. The simplest to understand and probably the oldest class is that of hook-type adhints, which occur in consequence of "mechanical adhesion". Their adherends are fibrous or porous solids (fabrics, paper, natural wood, etc.). During the formation of such joints, the liquid adhesive flows round the

fibres or filaments of the adherend and after solidification forms hook or loops around each fibre. When, say, a postage stamp is stuck to the envelope, the mechanism of joint formation differs little from the mechanism responsible for the joint between two fabrics sewn together. As in sewing, molecular contact between the adherend and the adhesive is not required in hook-type adhints, which constitutes an extremely favourable factor, since extensive purification of materials such as paper, cardboard, or wood is almost impossible even in the laboratory let alone in industry.

When a breaking force is applied to a hook-type adhint, one of the two components (the fibres of the adherend or the filaments of the adhesive) breaks because they cannot be separated in any other way; in certain systems the break occurs partly in one material and partly in the other. At any rate, f, F, and W are fully determined by the mechanical strength of the fibres which are intrinsically weak or at which the external force is concentrated; unfortunately a mathematical formulation of the strength of hook-type adhints does not as yet exist.

Generally speaking, in order to obtain satisfactory hook-type adhints, it is necessary to ensure that the adhesive penetrates the space between the adherend fibres and solidifies there. Thus the incorporation of the adhesive in the adherend is the most significant process in the life of a hook-type adhint. This process was investigated several years ago[3,4]. Two questions were investigated: (1) to what depth the adhesive should penetrate into the fibrous body in order that the strength of the adhint should reach its maximum possible value for the given system and (2) what time is necessary for such incorporation. Different types of paper and cardboard served as adherends and the extreme inhomogeneity of these materials has been the main source of the inaccuracy and the poor reproducibility of the quantitative results.

A clear answer to the first question was obtained for filter paper which is much more homogeneous than many other varieties. It was glued on one side to a thick metallic plate and on the other to an aluminium foil; the foil was peeled off after the solidification of the adhesive. For small amounts of glue (m, g m^{-2}), the resistance to peeling increased with m, but, when m exceeded 15 or 20, the resistance no longer depended on m. For this paper, 20 g per m^2 corresponded to a thickness of penetration to a depth of approximately 30 μm. The average diameter of the fibres in the paper was $8-10$ μm. Thus it was sufficient to engage by the adhesive hooks two or three fibres in the bulk of the adherend in order to attain the maximum resistance possible for the given paper.

In these experiments the adhesive employed was a melt of poly(vinyl acetate). When an aqueous solution of dextrin was employed instead, the liquid penetrated into the adherend to a considerable depth, but left behind fewer hooks after the removal of solvent, so that peeling from paper glued with dextrin was easier for all values of m than when the melt was employed.

When the foil was stripped from a laminate cardboard, the results depended on whether the foil was glued to the edge or to the centre of the cardboard rectangle. In the first case the resistance was smaller, since the external force was transmitted immediately to the loosest of the layers and the crack passed along this layer. In the second case the cleavage had to begin in an external layer, which is usually denser and stronger than the others; therefore a much greater force was required to initiate peeling. As long as the experimentor believes that he is measuring molecular adhesion between the glue and the cardboard, it will not occur to him to alter the site of the joint from the edge to the centre and vice versa.

In order to answer this question, a polyethylene vessel containing a measured amount of glue was turned upside down with the opening pointing downwards towards the paper and was then drawn along the paper at a constant velocity (u, cm s^{-1}). The depth of penetration of the glue (τ, cm) was then measured with the aid of a microscope. If the diameter of the aperture is b (cm), each point on the surface of the paper remained in contact with the glue over a period b/u seconds. During this time, the glue penetrated into the adherend to a depth τ (cm), so that the average rate of penetration was $\tau u/b$ (cm s^{-1}). The measured values confirmed the simple hydrodynamic description of the process for simple liquids.

III. IMPROPER ADHINTS

The second class of adhesive joints is also of respectable antiquity but its nature was understood only several years ago. Improper joints contain weak boundary layers. The concept of weak boundary layers is as significant for the modern ("rheological") theory of adhesive joints as the rejection of the idea that rupture takes place exactly at the interface, as stated in the first section. The adherends in improper adhints either do not contain any pores and voids capable of being filled with glue or they have at least a dense surface layer: for example, paper coated with varnish or a dyed wooden plate may be incapable of being impregnated with glue; the usual metals, glasses, and plastics are also incapable of forming hook-type adhints. The absence of voids is a general property of adherends in improper and proper adhints.

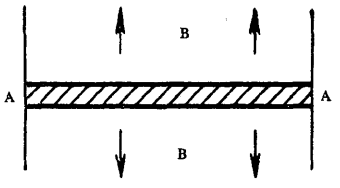

Figure 3. A proper butt joint. A = adhesive; B = adherends.

When it is said that two cylinders of a substance B are glued together with an adhesive A, only two materials are mentioned. In the schematic representation of such an adhint (Fig. 3) only two materials are indicated. In improper adhints there is at least one more substance, which is located on the boundary or along both boundaries between A and B (Fig. 4). When a breaking force is applied to the adhesive joint shown in Fig. 4, a crack arises in the boundary layer if its strength is less than that of the materials A and B. Thus the adhint is ruptured in the material which is not even mentioned in the description of the system and is determined by its properties.

According to their origin, weak boundary layers can be divided into seven groups, since three phases are involved in the formation of an adhesive joint: the medium (usually air), the adhesive, and the adherend. The material of

the weak layer can enter the adhint from the medium (air) (a), from the adhesive (b), from the adherend (c), from air and the adhesive (d), from air and the adherend (e), from the adhesive and the adherend (f) and from all three phases (g). Certain examples of these types will be described in the present section.

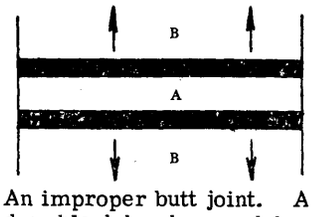

Figure 4. An improper butt joint. A = adhesive; B = adherends; black bands—weak boundary layers.

1. Weak boundary layers of the *first group* are frequently encountered. When the liquid adhesive spreads on the surface of the adherend, it must displace air from each hollow on the rough surface. If the displacement is incomplete, bubbles of air remain between the adherend and the solidified adhesive, as shown schematically in Fig. 5. Each bubble concentrates stresses in the adjoining regions of the solid; this effect was already mentioned in the first section and it is expressed by Eqn. (4) in the fifth section.

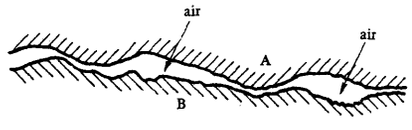

Figure 5. Air bubbles between an adherend B and an adhesive A which has not achieved complete contact with the adherend.

Air remains between the adhesive and the adherend either because the wetting of the adherend by the liquid adhesive is poor or because the adhesive joint was prepared hastily and sufficient time was not allowed for the liquid to flow into all the pits and grooves. Wetting is determined by the contact angle θ or more accurately the advancing contact angle θ_A. A modern treatment of contact angles was recently given in a book by the present author[5] but it is outside the scope of the present review. One need only point out that, when the equilibrium contact angle is zero and the advancing contact angle is negligibly small, one should employ as far as possible only adhesives giving $\theta = 0$ on the surface of the adherend.

One sometimes encounters the view that the requirement for $\theta = 0$ arises because the liquid wetting the solid has a strong affinity for it; it is believed that the liquid A displaces air from the surface of the adherend B because the molecular adhesion between A and B is high. This approach is unconvincing. The contact angle depends not only on the attraction of B to A but also on the attraction or air (or generally speaking a third phase) to A and to B. If, say, water wets poorly a solid surface, one cannot conclude that the attractive forces between these two phases are small; if the solid is heated in mercury until all the gases have volatilised and is then treated with water, the latter can readily displace mercury so that an impression will be created that the attraction of water to the adherend is high. One can appropriately mention here the mechanism of soldering. If a drop of liquid solder is deposited on what appears to be a metal the drop does not spread. Supporters of molecular adhesion have concluded that in this case the attraction between the metal and the solder is so weak that no adhesive joint is obtained. In reality liquid solvent does not displace air from the surface of the oxide but it does readily displace fused rosin from the surface of the metal.

An example resembling soldering was investigated by Nicholas and Poole[6]. Oxygen-free copper gave $\theta = 20°$ at 1200°C on tungsten and f for joints between tungsten and copper was approximately 1900 bars (1 bar = 10^6 g cm^{-1} s^{-2}). When there were 251 parts of oxygen per million parts of copper, θ reached 70° and f did not rise above 320 bars. A dark layer, the composition of which probably corresponded to the oxide WO_3, could be seen in this system as the boundary between copper and tungsten (a magnification of 450). The oxide did not behave itself as a weak boundary layer but copper did not wet it; this cavities remained between copper and the oxide after solidification.

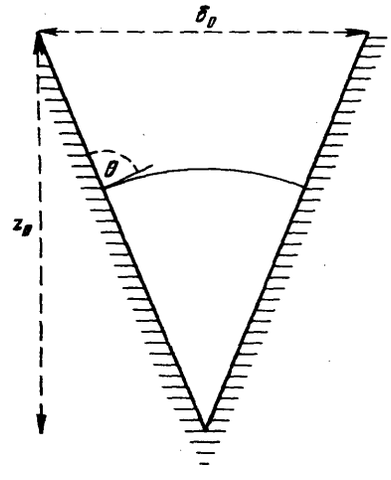

Figure 6. Displacement of air from a scratch by an adhesive flowing downwards. Maximum width of scratch—δ_0; depth—z_0; contact angle (in liquid adhesive)—θ.

In all probability the unwettability of polytetrafluoroethylene is the main reason why nothing can be glued to this polymer. There exists yet another possibility: namely that it contains impurities which act like those in polyethylene (see section III, 2), but it is difficult to reconcile this with the observation that PTFE copolymers fused and cooled on a clean metal surface (in air) form with the latter very strong adhesive joints.

The displacement of air by a liquid adhesive always requires some time and in many systems the time is very long. Hollows in solid surfaces usually have an irregular shape which is not susceptible to mathematical treatment. It is therefore necessary to resort to models. Fig. 6 shows a channel with a depth z_0 (cm) and a width at the top δ_0 (cm); a liquid fills it above and forms with the walls an advancing contact angle θ_A; the thin continuous lines indicate the position of the meniscus t seconds after the beginning of the experiment. The shortest distance between this line and the top of the channel is designated by the symbol z. If the surface tension and the viscosity of the liquid are denoted by the symbols γ (g s^{-1}) and η (g cm^{-1} s^{-1}) respectively, the following approximate formula is valid:

$$z_0 \ln \frac{z_0}{z_0 - z} - z = \frac{\delta_0 \gamma \cos \theta_A}{6\eta_m^{z_0}} t . \quad (1)$$

It is readily seen that z will equal z_0, i.e. the liquid will reach the bottom, only after an infinite time t whatever the values of γ and η. This result is obtained because the walls of the channel are assumed throughout to be ideally straight; since in reality they are rounded near the bottom, $z_0 - z$ reaches zero for finite values of t; at any rate, it is clear that haste in the preparation of adhints can result in the formation in the latter of weak boundary layers of the first group.

The flow of liquid may be accelerated by an external pressure[7], but this pressure P must be greater than the product $2\gamma\cos\theta_H/\delta_0$ (g cm^{-1} s^{-2}) in order to affect seriously the rate of flow; when θ_0 is small, i.e. the channel is a crack, the required P is much too high for practical purposes. The usual adhesives are non-Newtonian liquids, i.e. their viscosity depends on the rate of flow; estimates of this correction may be found in the literature[7,8]. The viscosity of the adhesive very often increases with the time it takes to fill the hollows in the adherend because of the evaporation of the solvent, the cooling of the melt, or a chemical reaction; if the rate of this increase is comparable to the rate of flow, the adhesive may solidify without reaching the bottom of the channel, so that air bubbles remain between the glue and the adherend[9].

2. Weak boundary layers of the *second group* consist of a substance which was previously contained in the adhesive. Industrial polyethylenes are the most thoroughly investigated representatives of this group. When the usual polyethylene is fused on a clean metal, glass, etc. support and is allowed to set, the solidified drop can be readily scraped off with a fingernail. Printing ink sticks to polyethylene but readily splits off from the latter on removal of the solvent. This lack of capacity of polyethylene for "adhesion" was previously explained, and even now continues to be explained[10], by the fact that the force field generated by the alkane chain $-CH_2-CH_2-CH_2-$ is weak; the attraction of methylene groups to solids is so weak that it can be readily overcome by a negligible external force.

The myth of the inadequate molecular adhesion of polyethylene was destroyed and the true cause of the weakness of polyethylene adhints was discovered in a series of investigations[11-15].

Firstly, technical polyethylene was purified by dissolution in boiling toluene or xylene and precipitation with acetone or butanone. The precipitate, which usually contained more than 95% of the initial polymer, did not contain polar groups (for example carbonyl groups) which can be almost always found by examining the infrared spectra of unpurified polyethylenes. The content of branched chains (for example isopropyl groups) was lower than in the initial material. Thus after purification the composition of polyethylene was closer than before to that of the ideal compound $-CH_2-CH_2-CH_2-$; nevertheless it proves to be an excellent adhesive and was used successfully to glue metals to metals, glasses to glasses, and glasses to metals[11]. All adhesive joints with purified polyethylene were made in an atmosphere of nitrogen in order to avoid oxidation.

In certain cases purification increased the tensile strength by a factor of 50. Such enormous increase of "adhesive capacity" could not be accounted for by a physical change in the material, since the density, wettability, and other measured properties did not alter appreciably as a result of purification. The author concluded that crude polyethylene contains impurities soluble in the liquid polymer and eliminated from it during solidification and crystallisation. Some of them accumulate in the surface layer. If they are almost liquid at the experimental temperature or their strength is reduced, the surface layer as a whole is characterised by a low resistance to rupture. Adhesive joints prepared with crude polyethylene must be represented by Fig. 4 and not Fig. 3; when a tearing axial force (arrows in Fig. 4) is applied, the weak boundary layer is split in two and the strength of this layer alone (and not of the polyethylene itself) determines the experimental strength of the adhint. Purified polyethylene contains almost no insoluble impurities, does not form weak boundary layers, and gives rise to strong adhesive joints.

Secondly, the resistance to rupture of the compounds just mentioned was compared[12] with the strength of polyethylene itself. If weak boundary layers are absent, the system consists of only two components: the adherend and the adhesive and rupture naturally occurs in the weaker phase. In all cases this was purified polyethylene, since the adherends were only metals (steel, copper, and aluminium) and glasses. Since the crack arose and spread in polyethylene, the rupture of the adherend — polyethylene — adherend system was largely analogous to the rupture of polyethylene itself. Fig. 7, which presents some of the results obtained by the present author and his coworkers[12,15], does indeed show that the strength of polyethylene adhesive butt joints is almost equal to the strength of polyethylene rods (the dashed line on the right-hand side of the diagram) when the layer of adhesive is fairly thick (for example 150 μm). The reason why the breaking stress f (expressed in bars in Fig. 8) increases when the thickness δ of the adhesive diminishes is explained in section V, 1. At any rate, it is clear that f is determined by the strength of the adhesive and has nothing in common with molecular adhesion between the adhesive and the adherend. Polyethylene could be seen with the naked eye or with the aid of the microscope on both rupture surfaces.

Thirdly, a low-molecular-weight substance was mixed with purified polyethylene in order to restore it to the "anti-adhesive" or non-glueing state[13]. Oleic acid, which is a typical polar compound, proved to be suitable for this purpose. On the basis of the molecular theory of adhesion, oleic acid should increase the "adhesive capacity" of non-polar polyethylene. In fact the admixture of 1 mg of the acid in 1 g of purified polyethylene reduced its resistance (Γ, g s^{-2}) to peeling (of aluminium foil glued with polyethylene to glass) and when the added concentration reached 1%, Γ fell to 10 kdyn cm^{-1} from 65 kdyn cm^{-1} for the uncontaminated polymer.

Fourthly the accumulation of oleic acid on the surface layer was confirmed by electrical measurements[14]. Purified polyethylene and its mixtures with 0.1, 0.2%, etc. of oleic acid were placed in an atmosphere of moist ammonia and the surface conductivity of the polymer was measured. The curve relating the surface conductivity $1/\chi$ to oleic acid concentration c was found to resemble very closely the $\Gamma = f(c)$ curve mentioned in the previous paragraph; when the concentration was raised from 0.1 to 0.4, $1/\chi$ fell by a factor of 6. Probably the limiting solubility of oleic acid in the solid polyethylene investigated is approximately 0.1%; when c is above this minimum, the excess acid accumulates near the surface, where it reacts with ammonia and forms ions responsible for the enhanced conductivity.

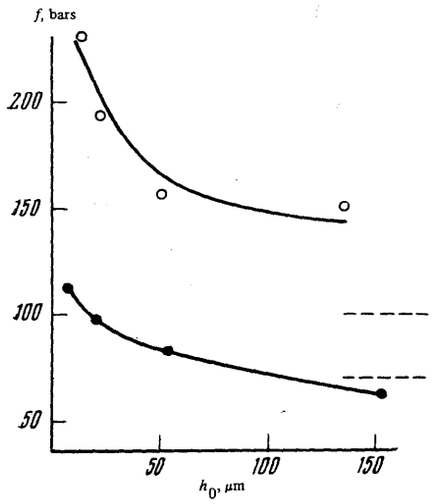

Figure 7. Resistance to rupture of "glass — purified polyethylene — glass" adhints (upper curve) and "steel — purified polyethylene wax — steel" adhints (lower curve). Abscissa—thickness of the layer of adhesive in micrometers. Ordinate—breaking strength in bars. The dotted lines indicate the tensile strength of the free polyethylenes.

Fifthly, the accumulation of the impurity near the surface and hence the formation of a weak boundary layer was eliminated by increasing the solvent power of solid polyethylene[15]. Petrol and water are almost immiscible, but their complete mixing can be achieved by adding sufficient acetone. By analogy, when polyethylene is treated with a substance soluble in solid polyethylene and capable of dissolving oleic acid, the acid will cease to accumulate in the surface layer and to reduce the strength of the adhesive joint. Ethyl palmitate $C_{15}H_{31}COOEt$ was found to be such a substance. The breaking stress for specimens with a "pin" was less than 1 bar when the adhesive was a mixture of 99 parts of polyethylene and one part of oleic acid, while the adhesive consisting of 94 parts of polyethylene, one part of oleic acid, and five parts of palmitate was ruptured following the application of a stress of 75 — 95 bars, i.e. was almost equal to the resistance of the purified polymer.

This example is particularly instructive if it is compared with the predictions of the molecular theory of adhesion. According to this theory, polar molecules increase adhesion. In fact polar oleic acid caused a catastrophic decrease of f; ethyl palmitate, the dipole moment of which is equal to that of oleic acid, does not alter f at comparable concentrations in purified polyethylene and its admixture in polyethylene contaminated with oleic acid sharply increases f. The resistance to rupture depends on solubilities and not on polarities.

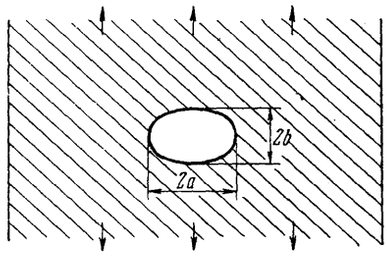

Figure 8. Concentration of stresses at an elliptical opening in the film. Axes of the ellipse—$2a$ and $2b$.

In the disintegration of systems containing weak boundary layers of the second kind, part of the layer remains on the adhesive and the remainder on the adherend. This separation has been demonstrated by simple weighing[13] and by electron microscopic observations[16].

It is clear from the foregoing that the formation of weak boundary layers of the second kind may be prevented either by removing harmful impurities from the adhesive or by increasing their solubility in the solid polymer. The third method is widely used in industry: impurities are decomposed by oxidation or by some other chemical reaction. In the fourth method they are polymerised. Polyethylene is subjected to an electric discharge in helium or another inert gas[17]. This results in the cross-linking of short molecules on the surface layer, which sometimes becomes several times stronger than the main bulk of the adhesive. Adhesive joints with such polyethylenes are ruptured in the polyethylene and for them f is determined by the strength of the polymer.

Other examples of weak boundary layers of the second group were apparently observed by Buiko and Zinchenko[18], Foster and Winn[19], etc.

3. Weak boundary layers on the adherend are also a common phenomenon. The aim of the cleaning of metallic surfaces before varnishing, enamelling, etc.[20] is to remove such layers. Since chemical contamination of the surface does not impair its mechanical properties, cleaning is unnecessary: adhesive joints with aluminium are formed daily and can be maintained indefinitely although the surface of the metal is covered by a continuous oxide film from edge to edge.

The effect of a random contamination of the metallic surface on the strength of adhints has been described in Buchan's book[21]. The attachment of rubber to brass is frequently performed in industry but is sometimes unsuccessful. Buchan studied the surface of electrolytic brass

specimens to which it was difficult to attach rubber. The complex salt $[Zn(NH_3)_6]\{Zn_3[Fe(CN)_6]_2\}$, which probably in fact formed the weak zone, was detected on some specimens. Theoretically, the cyanide electrolytes from which brass was precipitated contain no iron but sufficient iron ions entered the bath from the tubes and instruments employed in the manufacture to make possible the synthesis of the above salt.

The effect of adhesive butt joints of the type "steel — epoxy-resin — dye — tinplate — epoxy resin — steel" was investigated as a function of the purity of the tinplate[22]. Stearic acid deposited on the plate in an amount of 0.004 mg per cm^2 reduced the resistance to rupture f by 30 — 40%; when the surface concentration of the acid was raised to 0.04 mg cm^2, f was 50% below the value for the clean plate. In the presence of contaminations, the rupture surface passed along the boundary between the dye and the tinplate, i.e. in a weak boundary layer.

An example of a non-metallic surface is mentioned by Kamenskii[8]. The attachment of an unvulcanised rubber mixture to old vulcanised rubber yields adhints with low values of Γ. If the brittle and oxidised surface layer of vulcanised rubber is removed by brushing with a wire brush, the breaking stress increases, say, by a factor of 6.

A later example refers to polypropylene[23]. A double metallic plate — epoxy-resin — polypropylene film — epoxy-resin — metal adhesive lap-joint was ruptured readily and the rupture surface did not differ in any way from the initial surface of polypropylene. However, it was sufficient to treat the film with trichloroethylene vapour for several seconds to increase the resistance to rupture by a factor of 6 and to shift the rupture plane from the surface to the bulk of the film.

Industrial polycaprolactam apparently constitutes an even more striking example of weak boundary layers than polypropylene or polyethylene. It contains up to 12%, of the monomer[24], which is seen on certain films as a crystalline deposit. As long as the monomer is present on the surface of the polymer, neither polychloroprene nor polyisobutylene (deposited on a fabric ribbon) form strong adhints with polycaprolactam; however, the resistance (Γ) to rupture increases several times after the extraction of the monomer with water[25]. Unfortunately the authors did not compare the experimental Γ with the theoretical values, so that the reader finds it difficult to judge how complete the purification of polycaprolactam has been. Different elastomers form with unpurified polycaprolactams adhesive joints which have different resistances Γ. It would be instructive to compare the sequence of these elastomers in terms of increasing Γ with their sequence in terms of increasing capacity to dissolve the monomer; possibly the two series will be similar.

4. A weak boundary layer formed on interaction between the adhesive and the medium was observed when purified polyethylene was employed as the adhesive. As already stated, all polyethylene adhints described in section III, 2 were formed in an atmosphere of nitrogen. When similar adhints are prepared in air, polyethylene is oxidised (becomes yellow) at a high temperature and the oxidation products form a weak boundary layer, so that the strength of the adhint decreases.

5. Weak boundary layers of the *fifth group* are formed most often when an adhesive joint prepared in an inert medium is then introduced into a corrosive environment. Silicate glasses swell in water. Glass filaments in glass laminates also swell if the access of water to them is not prevented. Swollen glass is a weak material; in glass laminates ruptured underwater the crack usually arises in the swollen interfacial layer. Bitumen protects aluminium from corrosion simply by preventing the access of water to the metal. If water nevertheless reaches it, a phase, which may be called an aluminium hydroxide gel, gradually grows between the metal and the protective coating and bitumen is readily separated from aluminium[26].

In both examples just quoted the mechanical effects of swelling probably play a decisive role. The specific gravity of swollen glass is lower than that of dry glass and the specific gravity of aluminium hydroxide is lower than that of the metal. Thus a weak boundary layer splits the adhesive away from the adherend like a wedge. Unfortunately this mechanism has not yet been subjected to mathematical analysis.

It may be that swelling also weakened adhesive lap joints of the type "aluminium — epoxy-resin — aluminium", which were prepared in various atmospheres and were allowed to remain in the same medium for 1 h.[27] After such ageing, their f values were measured. In dry argon the resistance was only 5% lower than before ageing but in an atmosphere comprising 80% of argon and 20% of oxygen with a relative humidity of 50%, ageing reduced f by a factor of 2.

6. Weak boundary layers of the *sixth kind* are formed most frequently when the adhesive reacts chemically with the adherend. Long ago it was already noted that a highly alkaline casein glue forms weak adhesive joints of the type "wood — glue — wood". Alkali corrodes (hydrolyses) wood and gives rise to a weak zone between the adhesive and the unaffected wood. Clearly similar difficulties arise if an acid adhesive is employed to cement copper, zinc, iron, and other metals sensitive to acids. Less obvious examples are also known[28].

When rubber is vulcanised on brass, the joint will be weak in those cases where the brass surface is immaculate (see section III, 3). In many cases it is sufficient to introduce an excess of sulphur into the rubber mixture (for example 10% instead of 2%); the excess sulphur reacts with copper in the brass and forms copper sulphide, which is segregated in the form of a powder between the two main phases[21]. The excess sulphur may be harmful also in the absence of copper. A mixture of sulphur and raw natural rubber was placed on the surface of a synthetic vulcanised rubber, the entire system was heated, cooled, and the film of natural rubber (now vulcanised) was peeled off. The resistance to peeling fell when the system was heated too long; probably sulphur diffused from the mixture to vulcanised rubber and increased the brittleness of its surface layer[29].

The examples just quoted are particularly instructive, since there are still investigators[30] who believe that the chemical bond between the adhesive and the adherend may be the cause of strong adhesive joints. It is much more likely that the chemical reaction weakens the adhint instead of stabilising it.

The chemical reaction yields a new substance which is frequently insoluble in the starting materials and is independent of them; it is neither willing nor able to couple, in the words of Lucretia, the two adjacent phases.

The adhesive and the adherend do not form weak boundary layers solely via chemical reactions; sometimes diffusion is also sufficient. Two relevant examples will be quoted.

If a metal K in contact with a metal M is heated, the diffusion of the atoms of K into the lattice of M may be faster than the diffusion of M into K. Then cavities

remain in the metal K near its boundary with M; initially they are of atomic dimensions but subsequently they merge into pores, which are visible under the microscope. In other words, a weak boundary layer is produced. It was noted[31,32] on prolonged heating (25 days at 800°C) of a copper plate coated with brass or aluminium bronze (93% Cu, 7% Al). Cavities with diameters up to 0.001 cm were observed in these alloys at the very boundary with copper.

Gold filaments welded to aluminium were difficult to tear off and the rupture apparently occurred along the boundary between the two metals. In order to elucidate the mechanism of the phenomenon, the system was maintained at 450°C for 2 h and then the transition layer between aluminium and gold was investigated[33]. It was found to contain seven phases: aluminium, $AuAl_2$, AuAl, Au_2Al, Au_2Al_2 (?), Au_4Al, and gold, and numerous pores were visible along the boundary between the Au_5Al_2 (?) and Au_4Al phases. The crack spread in the region of the pores and not between the two different metals. This example too is instructive. Supporters of the molecular theory of adhesion would calculate the attraction between the ideal crystals of gold and the ideal crystals of aluminium in an ideal contact and would compare the adhesion thus calculated with the experimental strength of the weld. How remote is reality from academic theories!

7. All three phases present in the formation of the adhint participate in the creation of weak boundary layers of the *seventh group*. Such systems were studied by Black and Blomquist[34]. When the adhesive lap joint consisted of an adhesive and two aluminium plates, the breaking stress at room temperature was approximately 122 bars. The adhesive was a mixture of eight parts of phenolic resin and one part of epoxy-resin. After the system had been heated (288°C) for about 100 h, f (still at room temperature) decreased to 65 bars, so that the system may be regarded as comparatively temperature resistant. The strength of adhints of the same dimensions but with stainless steel adherends was fully comparable, before heating, with the value of f for aluminium joints, but after heating f was negligibly low. In order to reduce f almost to zero, the system had to be heated in air or oxygen; heating in nitrogen had little influence on f. The authors concluded that a component of stainless steel accelerates the oxidation of the adhesive by gaseous oxygen, i.e. catalyses the reaction. Systematic experiments showed that copper, the classical accelerating agent for the oxidation of organic compounds, is responsible.

The disintegration of the adhint began at a three-phase boundary where air, the adhesive, and the metal meet; a visible strip of oxidised adhesive gradually spread along the metal surface. All three phases were involved in the formation of a weak boundary layer: the layer did not arise when the metal contained no copper or the gas contained no oxygen and when the adhesive was a polyamide or a butadiene — acrylonitrile copolymer.

What lesson can we draw from this section? Along the boundary between the adhesive A and the adherend B, there are in many systems weak materials, different from both A and B; cleavage or rupture occur within the bulk of these materials. If the experimenter does not suspect their existence, he may decide that the disintegration was of the adhesive type, i.e. that the crack occurred exactly between A and B and that his task may be to strengthen the mutual attraction between these two substances. In fact he must discover with what kind of weak boundary layer he is dealing (the first group? the second group?...) and how the formation of such a layer can be prevented. Weak boundary layers can never be disregarded with impunity.

IV. LOCATION OF RUPTURE

The concept of weak boundary layers permits a more critical approach to the main problem of adhesive joints already discussed from the theoretical standpoint in the first section of the review. If the rupture of the adhint is seen with the naked eye to occur along the interface, the question arises of whether one is dealing with an adhesional failure or a cohesional rupture of a weak boundary layer. As just stated, the answer to this question is extremely important: the entire plan of future work on the improvement of adhints depends on it.

The conclusion that the rupture of adhesive joints hardly ever occurs exactly between the adhesive and the adherend has unfortunately been confirmed by only a few experiments undertaken to test it. It is difficult to make such experiments convincing. Generally speaking, molecular forces decrease very rapidly with distance from a given molecule or a given solid. The molecular attractive forces between two bodies A and B may be neglected compared with the forces between A and C and between C and B when the thickness of the third substance C between A and B exceeds several ångstroms; the majority of studies leading to the opposite conclusion are based on an erroneous interpretation of experimental data. Thus one can assert that experimental results confirm the above conclusion even if the residual adhesive (or one of its components) on the adherend after rupture is not thicker than several ångstroms; in other words, the monomolecular third substance on the rupture surface of the adherend already demonstrates that the failure was not adhesional. The molecular layer of the adherend (or one of its components) on the surface of the adhesive after rupture is of course also instructive.

Analytical detection of monomolecular layers on the surface of a solid is very laborious. Methods whereby it is possible to detect surface contaminations with a thickness of 100 or 1000 Å may prove to be unsufficiently precise. This remark, applies, for example, to luminescence analysis, whereby it is possible to demonstrate transition layers (at the boundary between two polymers) with a thickness of 1 μm [35] and which clearly reveals the difference between an uncontamined surface and a surface coated with a film having an average thickness of 10 μm.[36] Unfortunately the difficulties are not confined to purely analytical problems. In many cases it is not known what should be sought. If, for example, there is a weak boundary layer of the second kind, the impurities migrating onto the adherend may be chemically quite different from the main component of the adhesive. Thus, after the rupture of an aluminium — polyethylene adhint, not even a trace of polyethylene was detected on the metal but this does not imply that the rupture occurred exactly along the boundary: we may suppose that, instead of the polymer, the antioxidant added to the polymer passed onto the adherend and since the experimenter did not look for it at all he did not find it. The situation is even worse in the case of weak boundary layers of the first group. If before rupture air occupies a considerable proportion of the interface, it cannot be distinguished from the air which penetrated the space between the adhesive and the adherend at the instant of rupture. Here the presence of a weak layer must be inferred from the breaking stress f. We shall suppose that an adhesive which wets freely an adherend B_1 forms with the latter adhints the value of f for which is 100 (in terms of arbitrary units). If the same adhesive in an adhesive joint of the same type and of the same dimensions gives $f = 1$ with an adherend B_2 and no traces of the adhe-

sive can be detected on the rupture surface of B_2, one can conclude with a considerable degree of certainty that a layer of air almost separated B_2 from the adhesive even before the rupture of the adhint.

We shall consider five experimental studies on the mechanism of apparent adhesional failure. Huntsberger[37] treated ribbons of an alkyd resin (with a thickness of 4 μm) with a solution of polyisobutylene from which a film approximately 25 μm thick was obtained after evaporation of the solvent and then one ribbon was peeled from the other. The thickness of the alkyd film after rupture was the same as initially. This result is unconvincing, since it was not shown how the solvent affected the alkyd film—whether or not it became stretched during rupture, whether a certain amount of the alkyd resin remained on polyisobutylene, and what was the effect of the surface roughness on the measured thickness.

Johnson[38] rubbed the rupture surface with a potassium bromide powder and measured the infrared spectrum of the powder scraped off the surface. If the powders from the surfaces of the adhesive and the adherend were identical, then clearly the rupture occurred in a particular material and not *between* two different materials. This happened, for example, when a varnish film (of unknown composition) was deposited from solution onto an organic adherend (also insufficiently characterised). The resistance to rupture was very low and both spectra showed absorption lines due to the phthalate esters employed as plasticisers. Evidently the failure, which at first sight appeared to be typically adhesional, consisted in the splitting off of a surface phthalate film. When polymers without a plasticiser were employed, both spectra were still almost identical. They corresponded to one of the polymers slightly contaminated with the other. In a third system, a dye, i.e. plastic + pigment, was coated with the solution of another polymer. After drying and peeling, the spectra were found to be different. Unfortunately none of the above systems was investigated in detail. Four tacky plasters were clamped to five adherends, were peeled from them at two different rates, and the contact angles θ of a drop of water in air (at 50% humidity) on the adherend were determined[39]. Of the 49 results obtained, only four are quoted here; the changes in contact angle were in the same direction as in all other systems. The angle θ on glass was 11° before contact with the plaster. When the plaster was stripped off rapidly, $\theta = 36°$ was obtained; after slow peeling, θ was 44°. Water on the plaster gave $\theta = 92°$. Thus θ changed in all cases in the direction from the adherend to the adhesive and was closer to θ for the adhesive when the peeling was slow and there was more time for the adhesive to displace air from the hollows on the surface of the support. In this study measurements were made of the contact angle of water which one must suppose did not alter (or only slightly altered) the properties of the organic adhesive (polyacrylate in the preceding example). It is incorrect to employ for the estimation of wettability liquids which are good solvents of traces of the adhesive remaining on the adherend. Clearly a drop of solvent in a volume of perhaps 1 cm^3 very rapidly removes contaminations weighing 0.000001 g per square centimetre[40].

If the adhesive contains labelled atoms, its traces on the support after rupture can be comparatively readily determined[41]. Aluminium plates were covered with a solution of polyurethanes, the solvent was removed at 60°C over a period of 16 h, and the polyurethane films were peeled from the metal. When the average roughness of aluminium was 0.76 — 1.02 μm, the average thickness of the residual adhesive on it was approximately 200 Å and for a roughness of 0.38 — 0.51 and 0.13 — 0.25 μm, the average thickness of the contaminant τ was 120 and 80 Å.

In the most valuable investigation, the thickness of the residue and the resistance to rupture Γ were measured on the same specimens[42]. Radioactive polypropylene was clamped to glass at 60°C and then peeled at room temperature. When the duration of contact at 60°C was 10 min, Γ amounted to 113 kdyn cm^{-1} and the thickness τ was equivalent to 2.4 monomolecular layers; after 60 and 120 min of contact, Γ was 236 and 226 kdyn cm^{-1} and τ was equivalent to 3.4 and 5.5 monolayers. Consequently, as long as τ remained small, τ and Γ increased together. One may conclude that $\tau = 0$ only when $\Gamma = 0$; when the adhesive is separated from the support without leaving a residue, no force is required for the rupture.

The electron microscope has so far proved relatively unsuitable for the determination of τ. The reason is that usually the method of replicas has to be employed. Traces of adhesive on the adherend may dissolve in the polymer from which the replica is made or in its solvent; in all such cases the material in which the experimenter is interested becomes invisible. Even if one chooses for the replica a high-molecular-weight compound which does not mix with the adhesive, one cannot rely on the pattern obtained. The general scientific principles of adhesion are applicable to replicas as well as to any other coating. If the replica comes into true molecular contact with the adherend, it cannot be separated from it exactly along the interface. The replica can be stripped readily only if there is never any true contact. It may be that the surface of the replica which before peeling was directed towards the adherend does not reproduce its profile in all details. The differences may be insignificant in those cases where an error of 100 or 200 Å is acceptable but the method is inapplicable when monolayers are considered.

V. PROPER ADHINTS

Improper adhints are frequently encountered in the laboratory but fortunately they constitute a rare exception among adhesive joints produced industrially on a large scale. In proper joints failure occurs either in the bulk of the adherend or in the bulk of the adhesive; there is no doubt that it is "cohesional" and not "adhesional". With the exception of a negligible percentage of adhints deliberately ruptured in laboratory tests, proper joints may be said to be immortal. An old table or an old aeroplane is scrapped when the adhesive joints between the leg and the frame in the first object or between two pieces of aluminium in the second are still in an excellent state. The deterioration of other components made the whole object valueless.

If the adherends in adhesive joints are made of metal or glass and the adhesive is an organic polymer, failure occurs much more often in the bulk of the adhesive than in the bulk of the adherend. Henceforth it will be assumed that the adhesive always breaks. The adherends in proper joints have no pores in an amount sufficient to assign the adhint to the hook type described in the second section; only in rare cases is it difficult to decide to which type the given adhint belongs.

Since rupture occurs in the adhesive, the measurement of the resistance to rupture of a proper adhint reduces essentially to the measurement of the tensile strength f_M of the adhesive. This strength can be of course found quite independently of any adhesive joints. It would

appear that f_M is a characteristic property of the polymer such as its density or chemical structure; it would also appear that the resistance to rupture f of the adhint is always identical with f_M of the given adhesive. In such a case there would be no need to measure f; the strength of all adhesive joints made with a particular adhesive would be equal to the tensile strength f_M of the polymer. In fact f_M is not a very constant quantity and f usually differs appreciably from f_M. The approximate equations

$$f = \frac{1}{\alpha}\left(\frac{\xi}{\beta} - s\right) \qquad (2)$$

and

$$f_M = \frac{\xi}{\beta_M} - s_M \qquad (3)$$

probably provides the clearest illustration of the foregoing statement. Here ξ denotes the theoretical cohesion of the adhesive, β and β_M are the stress concentration factors due to the inhomogeneity of all solids, α is an analogous factor due to the difference between the mechanical properties of the adhesive and the support, and s and s_M are residual stresses. Only ξ is the same in both equations; β is not necessarily equal to β_M and s may differ from s_M. The longest section of the author's book[2] is devoted to the difference between f and f_M which, incidentally, is pointed out at the very beginning of the present review; below this difference is discussed in an abbreviated form.

1. The factors β and β_M are equal to the ratio σ_m/σ in the layer of adhesive and in the free rod of the adhesive; as in the first section, σ_m is the maximum "local stress at a square" and in the bulk of the material and σ is the stress averaged over the entire cross-section of the specimen.

If in a solid sheet or in a solid film there is a fairly wide elliptical aperture (Fig. 8) located in such a way that the major axis of the ellipse ($2a$) is perpendicular to the external force (indicated by arrows) and the minor axis ($2b$) is parallel to it, then the stress τ_m at the right-hand and left-hand edges of the ellipse is

$$\sigma_m = \sigma\left(1 + \frac{2a}{b}\right). \qquad (4)$$

Numerous formulae for apertures of more complex shapes are quoted by Savin[43]. If the ellipse is greatly extended, i.e. resembles a crack, the ratio $2a/b$ should be very large. For example, if $a = 100b$, then σ_m/σ, i.e. the stress concentration factor β is 201. In such cases, even when the average stress σ is quite inadequate to overcome the cohesion ξ of the material, the stress σ_m may prove to be greater than the cohesion and consequently can cause the growth of the crack and the rupture of the specimen.

Clearly the probability of encountering an aperture for which the ratio a/b is large enough to give $\sigma_m > \xi$ is greater the larger the specimen. This is one of the main reasons and perhaps the most important reason for the increase of f when thinner films of adhesive are employed, as shown in Fig. 7. The greater the bulk of the adhesive, the greater the maximum value of the a/b ratio.

2. Butt joints. The coefficient α depends on the geometry of the system. Adhesive joints between the end-faces of two rods or pins would appear to be most suitable for the determination of the breaking force having a general significance. If the cross-section of the rod is S (cm²) and the external force required for rupture is F (dynes or newtons), one might conclude that the stress giving rise to the growth of a crack is F/S. Such a conclusion would be erroneous.

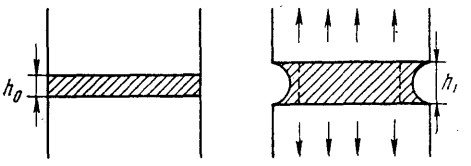

Figure 9. Concentration of stresses induced by the deformation of an adhesive "fillet". Left-hand diagram—butt joint before stretching; thickness of "fillet"—h_0. Right-hand diagram—ditto after stretching; thickness—h_1.

Fig. 9 illustrates a typical adhesive butt joint. The thickness of the adhesive layer has been increased by a factor of 20 in order to show more clearly its deformation on extension of the system. The left-hand and right-hand diagrams illustrate the system respectively before and after extension almost to rupture; the modulus elasticity of both rods is assumed to be so high that a change in their shape may be neglected. When the external force (arrows!) extends a flat cylinder of adhesive, its radius diminishes; this is Poisson compression. Fig. 9 shows that the compression cannot be homogeneous, since the adhesive is attached to adherends and its layer adjoining the adherends cannot be compressed as long as the adherends are not compressed. If this limitation did not exist, the profile of the adhesive cylinder would be as shown by the dashed line. Its true profile is indicated by the continuous curve. Clearly the cylinder is "unnaturally" extended not only along its axis but also in a perpendicular direction; it may be that both tensile and compressive stresses operate in it and the true stress σ at each point must be calculated from the theory of elasticity (or on the basis of more complex theories if the adhesive does not obey Hooke's law). This calculation has probably not as yet been performed with sufficient accuracy but the effect of the deformation of the adhesive on the distribution of stresses may be estimated roughly on the basis of the three special examples discussed below.

Suppose that the thickness of the adhesive before extension were h_0 and in the extended state h_1. We postulate that the profile of the extended cylinder is fairly close to an ellipse, the vertical half-axis of which is evidently $0.5\,h_1$; the horizontal half-axis is designated by the symbol a. We also postulate that the system was heated before deformation, so that its residual stresses s were reduced to zero. Then the volume of the adhesive will be also almost equal to the initial volume $\pi r^2 h_0$, where r is the radius of the adherend and of the initial "fillet" of the adhesive. It follows from the equality of the volumes that the half-axis a is

$$a = \frac{2r}{\pi} \cdot \frac{h_1 - h_0}{h_1}. \qquad (5)$$

On substituting this value of a in Eqn. (4) remembering that $b = 0.5\,h_1$ in this equation, we find that the stress at the

bottom of an elliptical hollow is greater than the average value by a factor α and that

$$\alpha = 1 + \frac{8r}{\pi} \cdot \frac{h_1 - h_0}{h_1^2} \quad (6)$$

Thus a purely geometrical departure of the layer of adhesive from the initial shape is sufficient to determine the stress concentration. For example, if $r/h_1 = 100$ and $(h_1 - h_0)/h_1 = 0.1$, then $\alpha = 26$. The greatest stress in the system is 26 times larger than F/S.

The above hypothesis that the layer of adhesive is free from residual stresses is invalid in the usual tests on adhesive joints. Almost always two opposed forces act along the boundary between the adherend and the adhesive. The adherend attempts to extend the adhesive in a radial direction and the adhesive attempts to reduce the radius of the adherend. If both materials obey Hooke's law and the modulus of elasticity of the adherend is many times greater than the modulus of the adhesive, the tensile stress P (g s^{-2}) acting per unity length of the boundary between the adhesive and the adherend is to a first approximation[2]

$$P \simeq \frac{h_1^{1.5} f}{2r^{0.5}} , \quad (7)$$

where h_1 and r have the previous values and $f = F/S$. Suppose that h_1/r is again 0.01; then $P \simeq 0.05\, h_1 f$. When the thickness of the adhesive layer (in the extended state) is 0.1 cm, $P \simeq 0.005\, f$ (g s^2). This tensile stress is distributed throughout the thickness of the layer, which is determined by the roughness of the interface. In this case, when the average roughness dimension is about 1 μm, the radial stress is not far from $50\, f$ (g cm^{-1} s^{-2}). In this example the maximum stress is not observed at the bottom of the elliptical hollow but at its boundary with the adherend and exceeds the average stress by a factor of 50. Its experimental estimate may be found in the paper by Mylonas[44].

Eqns. (6) and (7) are applicable, since Hooke's law holds for all parts of the system. If the adhesive is an ideal plastic material, i.e. is not deformed at all as long as the shear stress is below a characteristic value (kg cm^{-1} s^{-2}), and flows freely when the stress exceeds k, then

$$f = \frac{wk}{h_0} , \quad (8)$$

for an adhesive joint consisting of two rigid plates with a width w (cm) and a layer of adhesive with a thickness h_0 (cm). If the adherends are cylinders with a radius r, then[45]

$$f = \frac{2kr}{3h_0} . \quad (9)$$

It is remarkable that f is inversely proportional to the thickness h_0. Adhints with a very thin layer of adhesive should have an enormous strength when plastic adhesives are employed; this conclusion has been confirmed experimentally, for example by Mossatt and Wulff[46]. The effect of the thickness h on the strength of such systems is much greater than for the purely elastic adhesives discussed in section V, 1.

In principle, the critical shear stress k is a constant of the material of the same kind as the cohesion ξ. Eqns. (2), (8), and (9) show that the breaking stress f is never equal to ξ or k even when the rupture undoubtedly takes place within the bulk of the adhesive. The path from molecular forces to resistance to rupture is long and thorny.

3. Lap joints. It would appear that when the upper plate of the adhesive joint illustrated in Fig. 10 is pulled to the right and the lower plate to the left, purely tangential stresses (shear stresses) will arise in the layer of adhesive between both plates. In fact the distribution of stresses is much more complex in this case also.

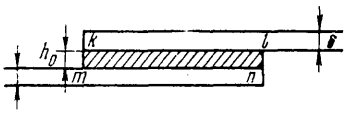

Figure 10. Concentration of stresses in a lap joint.

Firstly, the lines of force should undergo a sharp change of direction on passing from the upper plate to the adhesive and from the adhesive to the lower plate. Therefore near the points k, L, m, and n, there is a concentration of stresses analogous to that which arises at the corners of a square cut in a sheet or a film (instead of the ellipse shown in Fig. 8). The coefficient α of this concentration increases as the ratio of the thickness h_0 of the adhesive layer to the thickness δ of the solid plate diminishes; in the usual adhints α may easily reach values of 10.

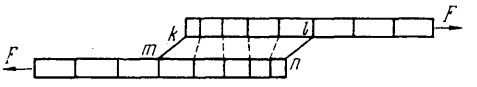

Figure 11. Differential stretching of plates in a lap joint.

Secondly, the external forces (arrows in Fig. 10) extend the plate unequally along its length, so that the film of adhesive is not only extended but also bent. This is illustrated in Fig. 11. To the right of the point l in the upper member and to the left of the point m in the lower member, the entire force F acts on the plates and their relative deformation is high. At the points k and n, i.e. at the free ends of the plates, there can be no stress. It may be that the relative deformation gradually diminishes from l to k and from m to n, as shown schematically in Fig. 11. If both the plates and the adhesive obey Hooke's law, it is possible to derive an approximation expression for the maximum coefficient α of the concentrations of tangential stresses at the ends of the layer of adhesive:

$$\alpha = \left(\frac{G_1}{2E\delta h_0}\right)^{0.5} L , \quad (10)$$

where G_1 is the modulus of shear elasticity of the adhesive, E the modulus of elasticity of the adherend on extension, δ the thickness of the plate, h_0 the thickness of the adhesive, and L the length of the overlap, i.e. the distance $\overline{kL}$ or $\overline{mn}$. Since the dimensionless ratio $L/(\delta h_0)^{0.5}$ reaches 100 in many adhints, the coefficient α due to the deformation under consideration may sometimes be actually higher than the coefficient calculated above.

Thirdly, plates are bent when an external force is applied, as shown in Fig. 12. The left-hand side shows a system subjected to a force so weak that deformation is still not observed. Clearly the force pulling one of the plates upwards does not act along the same line as the force equal in magnitude and pulling the other plate downwards. A twisting moment is generated, which leads to the deformation shown on the right-hand side of the Figure; here both forces act along the same straight line but the two plates are bent. The deformation of the plates causes the deformation of the adhesive between them. Evidently the distance between the adherends near the points m and n is greater than in the centre of the adhesive film, so that the adhesive is extended not only in the vertical direction but also its thickness near the ends is appreciably greater than before and greater than the thickness of the middle sections in the present case. The stresses in the adhesive near the ends of the film are similar to the stresses responsible for peeling (see section V, 4).

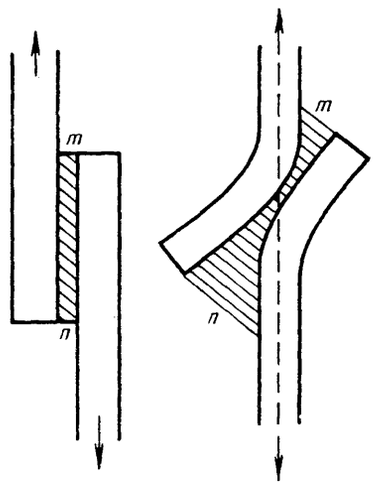

Figure 12. Bending of the plates in the stretching of a lap joint. Left-hand figure—low external force. Right-hand figure—high external force.

Their theory was developed by Goland and Reissner[47] and was tested in detail by Henning[48].

If the plates are appreciably bent, the stress in the adhesive is much greater at the ends of the film than in the centre. Therefore the middle parts of the film carry almost no load and may not be necessary. This conclusion has been confirmed experimentally[49]. When the space between two plates was filled with an adhesive along a 2.5 cm section, the resistance to rupture F was 1.3×10^9 dyn (or 1.3×10^4 newtons). When the middle half of the layer was left unfilled, i.e. the section with a length of 2.5 cm contained 0.625 cm of adhesive + 1.25 cm of void space + 0.625 cm of adhesive, F was still 1.1×10^9 dyn (or 1.1×10^4 newtons). In other words the removal of half the adhesive from the centre reduced F by only 20%. Fig. 13 presents more results[50] of the same kind. Two aluminium plates 25 mm wide and 1.5 mm thick were glued together over a section 20 mm long. The end of this section were in all cases filled with glue but in the centre there remained a void, the length of which was varied from 4 to 16 mm. This length is plotted along the abscissa in Fig. 13, the ordinate representing the stress f sufficient for rupture; it is expressed in bars. The lower curve was calculated disregarding the voids; evidently, when the length of the unfilled slit was 12 mm, i.e. 60% of the total length, f was hardly less than the resistance of a continuous film of adhesive. Calculation of the stress for the filled part of the slit yields the upper curve.

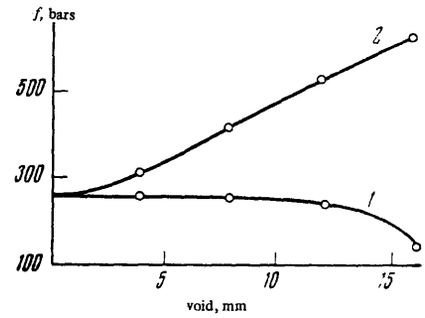

Figure 13. Effect of a cavity in the surface of the adhesive film on the strength of the lap joint. Abscissa—length of the void in millimetres. Ordinate—shear resistance in bars: 1) resistance calculated for the entire length; 2) resistance calculated for the filled section.

The coefficient α, calculated in accordance with one of the previous theories, must be introduced into the general Eqn. (2) in order to obtain some idea of the resistance to shear which may be expected from the given system. For example, α may be found from Eqn. (10), since the geometrical parameters (δ and h_0) of the system and the principal mechanical constants (G_1 and E) of the materials are known. If s_M in Eqn. (3) is low, the transient resistance of the free adhesive film (f_M) is almost equal to the ratio ξ/β. If s is also small in the given adhesive joint, then $f \simeq \xi/\alpha\beta \simeq f_M/\alpha$. For lap joints, $f = F/wL$, where F is the applied force and w and L are the width and length of the adhesive layer (which is of course continuous). We obtain finally

$$F = wLf_M/\alpha \ . \qquad (11)$$

Under favourable conditions F may be predicted, provided that w, L, δ, h_0, G_1, E, and f_M are known. If the most dangerous concentration of stresses is not a result of differential stretching but is a consequence of Eqn. (9) or the flexibility of the plates, other expressions for α must be introduced into Eqn. (2), but the equation itself remains in force; F continues to depend only on f_M and the geometry and mechanical properties of the components of the adhesive joint.

4. Peeling. An adhint subjected to peeling is illustrated in Fig. 1. The horizontal distance ζ between the point of application of the force and the edges of the adhesive "fillet" (at which the arrow from the letter G terminates) greatly influences the peeling resistance but unfortunately so far it has not been possible to calculate it convincingly on the basis of the dimensions and mechanical

constants of the components. In those cases where the flexibility of the ribbon is very high (for example, when a thin metallic foil serves as the adherend), the distance ζ can be virtually neglected. When $\zeta = 0$, there is a simple formula[51] for the minimum force F necessary for peeling:

$$F = kwf_M (E_1/E_1)^{0.25} \delta^{0.75} h_0^{0.25} . \quad (12)$$

In its derivation, it is assumed that the adhesive and the ribbon obey Hooke's law and therefore have unique values (E_1 and E) of the modulus of elasticity. As before, the width and thickness of the ribbon are denoted by the symbols w and δ, the thickness of the layer of adhesive is denoted by h_0, the transient resistance of the molecule by f_M, and the numerical factor $K = 0.38$ when the Poisson factor $\nu = 0$ for both components and $K = 0.76$ when $\nu = 0.33$ in both cases. The rigid adherend is assumed to be completely incapable of being deformed.

The accuracy of Eqn. (12) is of the same order as that of the equation $f = F/wL$ mentioned above, i.e. it disregards both the residual stresses s and the factor α. If, for example, $\alpha = 5$, the values of the force F predicted by Eqn. (12) will be five times higher than the experimental quantities. Inconsistencies of this order of magnitude were observed in the peeling of an aluminium foil glued to glass with purified polyethylene. Probably the maximum value of α is observed at the boundary between air, the adhesive, and the ribbon when the adhesive is brittle and at both ends of the adhesive film along the width w when the maximum relative extension of polyethylene is high. Incidentally, it was easy to show that considerable amounts of polyethylene were present on both rupture surfaces[13].

Equations analogous to Eqn. (12) could be derived also for the simplest cases of non-Hookean materials. Thus Fukuzawa[52] calculated Γ for peeling at an angle of 180° assuming that the adhesive is a viscoelastic substance obeying Maxwell's equation.

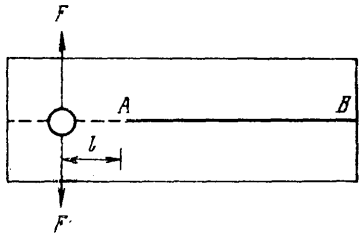

Figure 14. The splitting of two rigid bars glued along the AB plane. F = external force; L = length of crack.

Peeling theory predicts that, although the stress in the adhesive at the "leading" edge of the film (indicated by an arrow in Fig. 14) is a tensile stress, the stress somewhat to the right of the edge (in Fig. 14) changes sign so that there the ribbon is now clamped to the adhesive and compresses it. There is nothing unexpected in this phenomenon: if one end of a lever is pushed downwards, the other end tends to rise. The change in the sign of the deformation of the film was demonstrated by special measurements[53].

The direction of the external force F in Fig. 14 is perpendicular to the plane of the adhesive film. As already mentioned, the peeling angle need not be 90° (or $\pi/2$ radians). When the angle φ is altered, in certain systems [for example in poly(vinyl acetate) reinforced with silk and glued to glass], the force F is inversely proportional to $1 - \cos\varphi$, so that the work formed in peeling, which is $FL(1 - \cos\varphi)$, proves to be independent of φ; l is the length of the peeled section. In other systems the dependence of F on φ will be different for different rates of peeling. For various polyurethanes, the tension Γ for $\varphi = 90°$ was of 1.5 times or twice as high as for $\varphi = 180°$.[54]

When both adherends are rigid bars and are incapable of being bent, splitting is employed instead of peeling, as shown in Fig. 14. The work W which must be performed in the spreading of the crack within the layer of adhesive may be calculated from experiments of this kind. Usually W is proportional to the area S of the crack and the ratio W/S = "γ" is independent of S. For epoxy-resins, this "γ" was in most cases lower only by several per cent than the "γ" measured in the splitting of bars of the same epoxy-resin without any adhesive[55].

VI. DEPENDENCE OF STRENGTH ON EXTERNAL AND INTERNAL CONDITIONS

This section reviews the relations between the breaking stress f and specific resistance to peeling Γ on the one hand and the dimensions of the system, the chemical composition of the adhesive, and other conditions on the other; the results are explained from the standpoint of the author's "rheological" theory and at the same time from the standpoint of the molecular theory clearly presented in a recent review by Kardashev and Vakula[30] and in the book of Berlin and Basin[10].

1. Dependence on the method of measurement. The data in Fig. 7 were obtained for the rupture of butt joints arranged in such a way that the stress concentrations described in section V, 2 were virtually absent. When the adhesive layer was sufficiently thick, the resistance to rupture was almost equal to the tensile strength of the free adhesive in the form of a bar. The same adhesive (purified polyethylene) was employed in the peeling experiments described in section V, 4. The results were lower by a factor of 5 than expected from Eqn. (12); thus one might conclude that in the failure of geometrically different adhesive joints, different quantities are measured. As stated above, this conclusion is unjustified: experimental data do not confirm Eqn. (12) simply because it is valid only for the ideal case which departs widely from reality. So far specimens for peeling tests in which there are no lateral stress concentrations have not been found.

Instructive results were obtained on comparing butt and lap joints and joints subjected to a twisting moment[56]. Aluminium "pins" of different dimensions were attached to one another with commercial adhesives, the tensile strength f_M of which was in the range from 490 to 760 bars (in the free state). Depending on the diameter, the resistance of the adhints to rupture varied between 250 and 620 bars. We may recall that f_M is measured on specimens for which the factor α is identically equal to unity. Probably in the adhints of Winter and Krause the coefficient was about 1.2 — 2.0, i.e. their adhesive joints were designed so skilfully that the concentrations of stresses were lower than calculated in section V, 2. Lap joints in which the thickness of the aluminium plates was 0.1 cm and the length of the overlap 1 cm were ruptured at a stress F/wL = 250 bars. It is not known to what extent the

plates were bent during the measurements, but the "geometrical" concentration of stresses and the differential stretching of the adherends and the adhesive undoubtedly occurred and probably raised α to 490/250 or 760/250, i.e. 2 — 3. When two rings were glued together and a twisting moment was applied to them, the breaking stress was found to be 470 — 660 bars, i.e. α was only slightly higher than unity. The twisting of the rings was recommended many years ago as a rational method for the measurement of adhesive strength[57].

Two short steel cylinders were glued together with polysiloxane rubber and the same adhesive was employed to join two short tubes via their butt ends[58]. The systems with two cylinders were ruptured either by shearing one from the other or by turning one of them about their common axis, while the system of two tubes was ruptured only by means of a twisting moment. The stress f necessary for rupture depended little on the method of breaking employed and the plots of s as a function of the rate of rupture also proved to be almost identical for all three series of experiments. The absolute value of f increased together with the rate from 11 to 20 bars. Unfortunately the tensile strength of the polysiloxane employed was not measured; did it exceed 20 bar?

In all the experiments described in this section proper joints were employed and as far as is known the breaking stress f did not differ appreciably from the breaking stress f_M of the adhesive. The difference between f and f_M can be readily accounted for by the different values of the factors α and β. It is of course possible that the residual stress f in the adhesive layer was also not the same as in a free bar. The question arises if the molecular theory of the strength of adhesive joints can account for these results. Evidently the attractive forces usually quoted in books and papers on adhesion (dispersion forces, hydrogen bonds, etc.) in no way depend on the manner in which the adhint is broken, so that a purely molecular theory is in this case quite useless. The weakness of this theory is so evident that even its supporters had to acknowledge that the measured value of f depends on the stresses in the adhesive and on its strength. How can one estimate in this case the contribution by adhesive forces to the experimental value of f? If the type and number of functional groups on the surface of the adhesive and the adherend and their capacity to interact play a decisive role in adhesion, what part of the stress f of the tension Γ is determined by these parameters? Supporters of the molecular theory have not attempted to answer this question either; the correct answer, is, of course, none.

2. Dependence on the dimensions of the system. The effect of the thickness h_0 of the layer of adhesive on f and Γ has been frequently studied. Curves similar to those in Fig. 7 are typical for butt joints; in practice it was noted long ago that, "the thinner the adhesive layer the stronger the adhesive joint". Apparently Crow[59] obtained the earliest quantitative results. He joined together copper cylinders via their butt ends with the aid of a eutectic solder (tin + lead) and found that the thinnest layers of solder (0.02 cm) were a little less than three times stronger than thick layers (0.5 cm) and that the strength of thick layers was equal to the tensile strength (630 bars) of free rods of the same solder. The dependence of f on h_0 proved to be less pronounced but qualitatively similar for steel cylinders glued together with poly(vinyl acetate)[60] and several other systems.

In the first place it is necessary to show whether this effect of h_0 on f is real. After all, in the extension of adhints at a constant linear rate dh/dt (t is the time and h the variable thickness of the layer of adhesive), the relative deformation, i.e. $(h - h_0)/h_0 = \epsilon$ increases more slowly, the greater h_0; clearly $d\epsilon/dt = (dh/h_0)dt$. It may be that the thicker the adhesive layer, the slower its deformation for dh/dt = const. Since f decreases in many cases when the deformation is slower, the dependence of f on h_0 may be only apparent. Accurate experiments which would make it possible to dispel these doubts once and for all have not apparently been made, but the increase of f with $1/h_0$ is observed in such a wide variety of systems that it is reasonable to regard it as a real phenomenon.

Then the question arises of its causes. One of the causes, which has long been the subject of quantitative tests[61], is described in section V, 1. In those cases where the layer of polymer at the boundary with the adherend has a higher strength than the free polymer[62], one may imagine that two strengthened layers coalesce when h_0 is very low, so that f increases. The hardening and crystallisation of a polymer in thin layers generally speaking lead to a different supermolecular structure and to a different distribution of residual stresses than in thick layers. Thus β and s in Eqn. (2) also vary with h_0.

A change in the thickness h_0 undoubtedly alters also the coefficient α. According to Eqns. (8) and (9), α for ideally plastic adhesive should be inversely proportional to the thickness h_0; however, there are no examples of such a relation in the literature. The effect of h_0 on f for viscoelastic materials (rubbers) should be very remarkable. Rubbers, like gases, offer little resistance to changes in shape but tend to retain a constant volume. If h_0 is small (see Fig. 9), an appreciable increase of h is impossible without a significant increase of the volume V, since the hollows visible at the end of the adhesive film cannot alter V appreciably. If S is the area of the end-face, then $dV \simeq Sdh$. On the other hand, when h_0 is large, the adherends can move far apart without altering V, as shown on the right-hand side of Fig. 9. Therefore one may expect that the increase of f with $1/h_0$ would be particularly pronounced for rubberlike adhesives.

The data for the effect of h_0 on the strength of lap joints are contradictory. The situation is somewhat clearer for the peeling resistance $\Gamma = F/w$. According to Eqn. (12), it is postulated that this resistance increases somewhat with the thickness h_0, i.e. the dependence of Γ on h_0 should be the opposite to that of f on h_0. A qualitative confirmation of this theoretical conclusion can be seen, for example, in the numerous measurements carried out by Gardon[63] on systems consisting of two cellophane ribbons glued together with polyacrylate. Thus, for a rate of rupture of 1 mm s^{-1}, Γ was approximately 100, 250, and 600 kdyn cm^{-1} for thicknesses h_0 of 1.2, 5.1, and 258 μm. According to elementary theory, Γ should have increased by a factor of 3.8 for an increase of h_0 by a factor of 215 (258 : 1.2 = 215); experiments showed that the increase was approximately by a factor of 6.

Since the mathematical theory of peeling and rupture is still very imperfect, one cannot expect a better agreement between theory and experiment. At any rate it is difficult to doubt that the dependence of f and Γ and h_0 has a purely mechanical origin and has nothing in common with molecular adhesion. It is very gratifying to note here that Berlin and Basin[10] essentially agree with this conclusion, which follows from experimental data and from the rheological theory of the strength of adhints.

Nevertheless the increase of the strength f with $1/h_0$ has been sometimes attributed[64] to molecular attraction.

It was suggested that both adherends in the adhesive joints attract one another through the intervening layer of adhesive and that this attraction is stronger the thinner the adhesive layer. This hypothesis was apparently initiated by Smilga and Deryagin[65]. If one nevertheless concludes that f varies with h_0 for mechanical reasons, one has to ask again the supporters of the molecular hypothesis what thickness h_0 corresponds to the equality of the measured strength to A. Some investigators believe that the extrapolation of f to $h_0 = 0$ would yield a value equal or close to A. In reality such extrapolation will affect most the coefficient β, which would then become approximately equal to unity; the experimental value of f will then be almost equal to the ratio $(\xi - s)/\alpha$.

3. The strength of the adhint and the adhesive. According to the rheological theory, the strength f of proper adhints is determined primarily by the strength of the adhesive f_M, since both in the rupture of both the adhint and of a free rod made of the adhesive the crack spreads in the same material. Nevertheless, in the general case f is not equal to f_M for reasons already described in section V. The equality $f = f_M$, can only occur, if it is not fortuitous, when the adhesive joint is made up in such a way that $\alpha = 1$, when the local stress concentrations β are equal in both systems, and when the heat-treatment temperature (and other external conditions) have been chosen so that the stress s_M in the free adhesive differs little from s in the adhint. When all these factors are taken into account in the formation of adhesive joints, the equality of f (for a large thickness of the adhesive layer) and f_M can be demonstrated experimentally, as shown in Fig. 7. In the majority of experiments carried out to compare f with f_M, the values of α, β, and f were not taken into considerations, so that an exact equality of f and f_M cannot be expected. Nevertheless, there is no doubt about a close relation between these two strengths even when the above experiments are considered.

Resistance to rupture f of butt joints and the strength of free adhesive f_M (in bars).

Adhesive	Adherend			f_M	f/f_M
	steel	copper	aluminium		
	f				
Polyamide 6	720	730	660	830	0.84
Polyamide 66	680	750	670	720	0.97
Polyamide 610	530	620	570	480	1.18
Polyamide 11	390	260	410	590	0.60
Polyethylene	170	110	170	300	0.50

The Table compares the values of f and f_M for five adhesives and three adherends; adhesive pin-type butt joints were employed.

The first column indicates the composition of the adhesive, the next three give the values of f, the fifth column lists the f_M, and the sixth gives the ratio of the average values of f and f_M. Polyethylene was not specially purified, since its low f/f_M ratio probably indicates the presence of a weak boundary layer. Nothing is known about the purity of polyamide 11. The f/f_M ratio for other polyamides is so close to unity that there is no doubt about the mechanism of rupture. It is remarkable that f for adhesive joints between two copper "pins" (third column) differed appreciably from the f (was smaller) for other metals only in the case of the two adhesives where the low ratio f/f_M suggests that contaminants may be present in the interfacial layer. It may be that copper accelerates the oxidation of adhesives, as mentioned in section III, 7. In systems for which f was almost equal to f_M, f was independent of the nature of the metal: the average f was 640 bars for steel, 700 bars for copper, and 630 bars for aluminium. From the standpoint of the rheological theory, this result is obvious: since the mechanical properties of different adherends differ, it follows that the coefficients α in their adhints also depend on the nature of the adherend; but when the α nevertheless differ little from unity (as in the systems of Lewis and Tanner), the differences between three similar values of α hardly affect the resistance to stripping. It is difficult to account for the independence of f of the nature of the adherend in terms of the molecular theory; it is difficult to believe that the molecular adhesion of a polymer remains constant whatever the change in the oxide to which the polymer is attached.

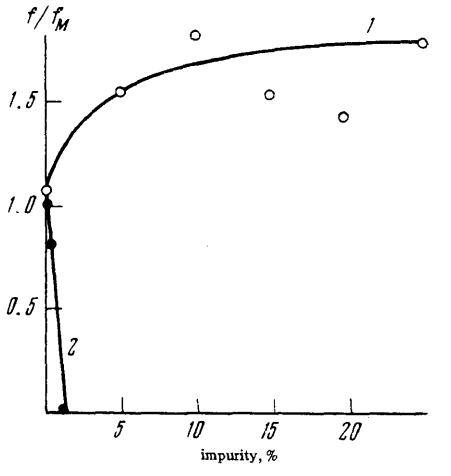

Figure 15. Difference between proper (upper curve) and improper (lower curve) adhints. Abscissa—percentage of contaminant. Ordinate—f/f_M ratio: 1) ethyl palmitate; 2) oleic acid; both in purified polyethylene.

The similarity or even equality of two values of f and f_M, which cannot be accounted for on the basis of the molecular hypothesis, has been noted many times in the literature. Some data have already been presented in section VI, 1 and VI, 2. As early as 1932, Nightingale[67] concluded on the basis of numerous observations that the strength of the soldered joints and the solder differ little however the chemical composition of the solder is varied. The resistance to rupture f in a system of two quartz cylinders with an intervening layer of solid paraffin increased from 3.3 to 14.6 bars when the thickness of the adhesive layer was diminished from 2.5 to 0.003 mm, while the tensile strength of the paraffin was 7.3 bars[68]; it may be that α in the thick adhints was 7.3 : 3.3. The f/f_M ratio varied only in the range 0.62 — 0.70 when four different adhesives consisting of an epoxy-resin cross-linked with diethylenetriamine were ruptured in the form of three bars or in the

form of layers between two aluminium cylinders. The tensile strength of ice between 0° and −10°C usually varies between 10 and 18 bars and butt joints in which copper, steel, and glass adherends were joined by a film of ice broke[69] following the application of a stress of 19 bars.

All these quantitative agreements between f and f_M are observed only because the adhesive joints are of the proper type (see section V). Fig. 15 presents certain data[15] clearly demonstrating the difference between proper and improper adhints. In Fig. 15 the fraction f/f_M is plotted against the weight ratio of the impurity (in purified polyethylene) relative to the overall weight, so that 0.05 on the abscissa axis represents a mixture comprising 0.05 g of the impurity and 0.95 g of polyethylene. The adherends consisted of stainless steel and the shape was such that α in the system was only slightly higher than unity. Curve *1* refers to mixtures of purified polyethylene and ethyl palmitate. Evidently f exceeded f_M at all impurity concentrations; one must suppose that this phenomenon was due to the factor β: on addition of palmitate, polyethylene became softened to such an extent that it was difficult to prepare from it well-formed bars for the measurement f_M. Curve *2* has been plotted for mixtures of purified polyethylene and oleic acid; here f/f_M decreases almost to zero when the concentration of the impurity is only 1%. The difference between the two curves is striking; it corresponds to a profound difference between proper (ethyl palmitate) and improper (oleic acid) adhints. The resistance to rupture of improper adhints has nothing in common with the strength of the adhesive and is much lower than the latter, since rupture does not occur in the adhesive but in a weak boundary layer.

4. The strength of adhints and the composition of the adhesive. The difference between the rheological and molecular theories of strength is shown perhaps most clearly in an examination of the dependence of strength on the molecular composition and structure of the adhesive. Unfortunately this difference remains qualitative in principle because the predictions of the molecular hypothesis are so nebulous that no quantitative or even semiquantitative conclusions can be derived from it. After repeated attempts to provide the molecular hypothesis with flesh and bones, one must conclude that essentially this theory does not exist; there are only feelings, emotions, and guesses.

What sort of theory could it be? It could relate f, for example, to the densities of cohesion energy ($\lambda\rho$) or to solubility parameters ($\sqrt{\lambda\rho}$); λ denotes the latent heat of evaporation per gramme and ρ the density (g cm^{-3}); the dimensions of the product $\lambda\rho$ are g cm^{-1} s^{-2}, i.e. the same as those of the stress. We shall designate the adhesive by the numeral 1 and the adherend by 2; then one of the possible rules of the molecular theory would be represented by the expression $f = \lambda_1\rho_1 - k(\lambda_2\rho_2 - \lambda_1\rho_1)$, where k is an unknown constant. According to this formula, when the adherend and the adhesive are very similar, $f = \lambda_1\rho_1$ and f is smaller the smaller the difference between $\lambda_1\rho_1$ and $\lambda_2\rho_2$. This rule resembles the empirical rules for the miscibility of liquids. Or f might obey the "rule of polarities": $f = a - b|n_2\mu_2 - n_1\mu_1|$, where a and b are two unknown constants, n_1 and n_2 are the numbers of dipoles per unit volume of the adhesive and the adherend, and μ_1 and μ_2 are their molecular dipole moments. When $n_2\mu_2 \simeq n_1\mu_1$, i.e. the adhesive and the adherend are both polar or both non-polar, f reaches the maximum possible value (a); if the difference $|n_2\mu_2 - n_1\mu_1|$ is large, f is much lower than a.

No rule of this kind appears to be quoted in the literature. In the formulation of the "rule of polarities" no one has even explained what meaning should be assigned to polarity: the dipole moment of the chemical bond (for example C—H), or the permanent dipole moment μ of an individual molecule (according to this criterion, even toluene is polar), or the product $n\mu$ just employed, or some other quantity. Incidentally, one cannot avoid a conflict between the "rule of polarities", however defined, and facts: non-polar polyethylene can be very effectively glued to glass and metals, while ethyl palmitate and oleic acid (the dipole moments of which are identical) have different effects on f for polyethylene adhints.

According to the rheological theory, which alone can claim to have a general significance and which alone is capable of quantitative predictions, the composition and structure of the adhesive influence the strength of the adhint via two completely different mechanisms depending on whether the proper adhint ⇌ improper adhint transition is observed. As already stated, the mechanisms of the formation of weak boundary layers are extremely varied and a change in the composition of the adhesive can readily include or exclude one of these mechanisms.

For example, we shall suppose that the chemical composition of the adhesive varies systematically in such a way that the surface tension γ of the liquid adhesive increases continuously. Since the contact angle θ usually increases with γ, at some point in the series, i.e. for a particular composition of the adhesive, the wetting will become insufficient and it will be impossible to remove air bubbles from the surface of the adherend with the liquid adhesive. In this series all the initial members (for which γ is low) will give rise to proper adhints (with high values of f), while the adhints formed by all subsequent members will break on application of weak stresses f in a weak boundary layer of the first kind.

A change in the chemical nature of the adhesive can lead to weak boundary layers of the first group, which are independent of contact angles. We shall examine a series of polymers with similar structures but with a gradually increasing molecular weight M. In many cases, when M increases, the melting point and the viscosity of the melt also increase. If the conditions governing the formation of the adhint are maintained strictly constant, for example, when the system is heated for a specific time at a specific temperature, the duration of heating may be sufficient for the removal of air bubbles when M of the liquid is low but may be too short for very viscous liquids with high molecular weights. Possibly, this is the cause (or one of the causes) of the observation that the strength of adhesive joints is sometimes a maximum for a moderate value of M of the adhesive; for example, epoxy-resins cross-linked with triethanolammonium titanate gives rise to the maximum f (shear resistance) for M = 800.

It would be easy to test this explanation. It would be necessary to measure the tensile strength f_M of the same polymers in the form of free rods and compare it with f. If f is similar to f_M for all $M < 800$ and much lower than f_M for $M > 800$, then the presence of a weak boundary layer in the second group of specimens would be very probable. Unfortunately f_M has not been measured and compared with f. This is an example of an extremely common error, which frequently lowers the level of experiments from scientific to empirical. Those who wish to understand the mechanism of the phenomenon, find the measurement of the tensile strength of adhesive joints almost useless if they are not supplemented at least by data concerning the dimensions of the specimen and the

measurements of f_M and of the thickness of the residual adhesive on the adherend. Well-founded conclusions concerning the mechanism can be reached only if the geometry of the system, the location of rupture, and the degree of similarity between f and f_M are known.

By altering the chemical nature of the adhesive, it is possible to pass from proper to improper adhints of the second group, described in section III, 2. If a liquid X is soluble in a solid adhesive A up to a concentration c_0(%), then the adhesive joints in which the adhesive has the composition $(100 - c)A + cX$ have a high strength f as long as $c < c_0$ but disintegrate readily exactly along the interface when $c > c_0$. As already stated, transitions of this kind were observed on dissolution of oleic acid in purified polyethylene. Probably they occurred also in a system comprising an epoxy-resin and tetraethylenepentamine (TEPA).[70] Butt joints between copper "pins" had a tensile strength of about 700 bars when c of the amine was 5 — 9%. When the TEPA concentration was raised to 17%, f fell approximately to 80 bars; at the same time the location of rupture migrated from the bulk of the adhesive to the interface. The strength f_M of free films of the same polymer was somewhat less than 600 bars for a ratio TEPA: epoxy-resin = 0.08 and depended little on it following further cross-linking; thus the ratio of the two strengths f/f_M was approximately 1.2 for c = 7%, 0.17 for c = 17%, and 0.07 for c = 0.33%. The curve obtained at high concentrations resembles the f/f_M curve for mixtures of polyethylene and oleic acid illustrated in Fig. 15. Probably the excess tetraethylenepentamine formed a weak boundary layer in which rupture in fact occurred. It is noteworthy that in the above investigation measurements were made of f_M and the location of rupture was determined at least qualitatively; therefore the mechanism of failure can be actually inferred and not merely discussed.

In other cases one must employ as a basis only the values of the strength and not the author's impression that the rupture was cohesional or adhesional. Films of synthetic and natural rubber were peeled from cellophane freed from glycerol[71]. The peeling resistance Γ was on average 1400 kdyn cm^{-1} for synthetic rubber and only 18 kdyn cm^{-1} for natural rubber. This difference cannot be reduced to a difference between the mechanical properties of the polymers; natural rubber, the peeling of which was "adhesional", undoubtedly formed a weak boundary layer at the junction with cellophane and probably also at the junction with other polymers[72]. Unfortunately it was impossible to find any data concerning the nature of this layer. Only on peeling natural rubber from polyisobutylene, did Γ exceed 300 kdyn cm^{-1}; one must suppose that the material of the weak boundary layer formed by natural rubber dissolved in polyisobutylene, which is very similar chemically to natural rubber. Γ for polymeric coatings on ordinary polyethylene was also very low with the exception of two butadiene rubbers; is it possible that neutral impurities present in polyethylene are soluble in polybutadienes?

Weak boundary layers of the fixed kind, formed in chemical reactions between an adhesive and an adherend, can also arise and disappear as the composition of the adhesive is varied systematically. In Berlin and Basin's book[10], where the molecular hypothesis of strength is defended, it is mentioned that the introduction of maleic acid into copolymers of vinyl chloride and vinyl acetate increases their "adhesion to metals" (i.e. f), but at the same time it accelerates corrosion and is therefore impractical. It is indeed remarkable how truth driven out of the door returns through the window; where else would one expect to find strong adhesion if not between an acid and a metal!

Possibly the TEPA — epoxy-resin system mentioned above is an example of improper adhints of the sixth and not the second kind. The point is that f for adhesive joints between titanium "pins" did not fall below 500 bar even when the ratio TEPA : resins was 0.25. One must suppose that the excess TEPA did not form weak boundary layers by itself but together with copper, which readily enters into complexes with amines. Additional examples are presented in section III, 6.

In those very numerous systems where no proper adhints $\rightleftharpoons$ improper adhints transitions occur and all the adhesive joints may be regarded as proper, the effect of composition on f and Γ may be elucidated on the basis of Eqns. (2) and (12).

According to Eqn. (12), Γ is proportional to the strength f_M. In Eqn. (2), the ratio ξ/β is close to f_M although the coefficient β is usually smaller in a thin "fillet" of adhesive than in a large bar employed for the measurement of f_M. Perhaps one may expect that both f and Γ will increase with the strength f_M of the free adhesive. This prediction of the rheological theory is fairly frequently confirmed. The variation of f and Γ with f_M is so evident that it cannot fail to be noted even by convinced supporters of the molecular hypothesis; thus one group of investigators[73] admit that the "problem of adhesional strength is inseparable... from the problem of cohesional strength"; and others[30] attribute the impairment of the "adhesive capacity" of polymeric esters (on increasing the length of the alkyl group) to the "decrease of the cohesional strength of polymers". Thus the chemical composition of a solid determines to a large extent the value of f_M and to a somewhat lesser extent also f and Γ. To a lesser extent partly because β in the adhesive layer can differ markedly from β_M in a free adhesive specimen. It is quite likely that the evaporation of the solvent from the free specimen will take place without hindrance, while evaporation from a film between two adherends will be so difficult that β_M will prove to be several times smaller than β. Since the strength of solids is equal to the strength of their weakest section, it is insufficient to state (and to note) that a substance A served as the adhesive. How was it prepared? What kind of defects remained in it? In order to understand the results of experiments on adhesive joints, it is almost necessary to have bacteriological information about them. Just as to the bacteriologist a gel containing one part by weight of tubercle bacilli per 10^{12} parts of agar is quite unlike the gel from which Koch bacilli are absent, to the investigator of strength a cubic centimetre of a solid in which a cubic micron contains a sharp crack differs decisively from another cubic centimetre in which such cracks are absent.

The composition of the adhesive can have different effects on the stripping resistance f and on f_M also because the coefficient α varies with composition. Generally speaking, α is higher the greater the difference $E - E_1$ or the ratio E/E_1; we may recall that E is the modulus of elasticity of the adherend and E_1 that of the adhesive. By varying the chemical nature of the adhesive, we also alter its E_1. Certain strength curves with a maximum may be obtained because $E = E_1$ and $\alpha = 1$ when the composition corresponds to the maximum. For example, we may suppose that two rubber "pins" are glued together with a rubber adhesive and that the composition of the adhesive is varied systematically by the introduction of increasing amounts of chlorine into the rubber. The stripping resistance f in this system may initially increase because E_1

increases with the amount of chlorine and $E - E_1$ decreases; at a certain chlorine concentration, $E_1 = E$ and f reaches its maximum value; on further introduction of chlorine, E_1 becomes greater than E, α again increases, and f again diminishes. This explanation too could be easily tested; it would be sufficient to replace rubber adherends by glass or steel adherends for which E would remain in all cases much higher than E_1; in such systems a maximum would not be observed. As a result of an incorrect hypothesis, such comparison has not been made.

The difference between the residual stresses s has already been resorted to frequently for the explanation of the incomplete agreement between the effect of composition on f and f_M. The relaxation of stresses in a free bar of adhesive takes place in many cases more readily and more completely than in a "fillet" clamped between two rigid adherends; consequently the quantity $\zeta/\beta - s$ in the bar is frequently higher than in the layer of adhesive.

In an examination of butt joints, it is usually permissible to assume that the adherends are completely undeformed during the rupture process. Such an assumption is rarely justified for lap joints and never for peeling and rupture. In such systems the values of f and Γ have no physical significance if the reader is not informed about the dimensions and the mechanical properties of the adherends or if the experimenter did not pay attention to these factors.

The foregoing can be elucidated by the example quoted in the paper of Kardashev and Vakula[30]. A hydroxylated polyester was condensed with a mixture of tri-(*p*-isocyanatophenyl)methane (TIPM) $(OCN.C_6H_4)_3CH$ and hexamethylene di-isocyanate (HMDI) $[OCN(CH_2)_6NCO]$; the greater was the amount of TIPM in the mixture, the denser was the cross-linking between the chains formed by the polyester and HMDI and, one must suppose, the higher was the modulus E_1 of the polymer. This polymer has been used as an adhesive between two unknown adherends forming a lap joint. It was found that the shear resistance decreased monotonically with increase of the relative content of TIPM in the mixture. If the adherend consisted of plates, they were bent as shown in Fig. 12; it may be that peeling and not shear occurred. The peeling resistance is generally speaking lower the more rigid the adhesive; it is evident even from Eqn. (12), which under-estimates the influence of rigidity; Γ diminishes when E_1 increases. Consequently the effect of the concentration of TIPM on strength can be understood as follows: the greater the amount of TIPM, the higher E_1; the higher E_1, the lower Γ; and the quantity Γ and not the true shear resistance determined the strength of the lap joints. Again this explanation would not be difficult to test using massive bars instead of plates but the idea of such a test apparently did not occur to the authors.

All hypotheses relating the chemical structure of the adhesive directly to the values of f or Γ are incorrect, since they do not take into account the necessary values of α, β, s, f_M, etc. let alone the possibility of the proper adhint $\rightleftharpoons$ improper adhint transition. Moreover, they are arbitrary, since they are based on an arbitrary choice of certain chemical units and the neglect of all others. We may point to the simplest example taken from the paper of Kardashev and Vakula[30]. Adhesives containing RCH_3, RCH_2Cl and RCH_2Br molecules were compared. The conclusion arrived at as a result of the observations was that the "difference between the adhesive properties of halogen-containing polymers may be accounted for by the presence of bromine and chlorine atoms". How this can be explained is not unfortunately stated. Nor is it shown that the individual properties of the halogens are significant (for example, the structure of their electronic shells); it may be that the peeling resistance depended only on the molecular weight M of the adhesive and varied in the series RCH_3, RCH_2Cl, RCH_2Br exclusively because M also varied in this series.

A more complex example may be found in the paper by De Bruyne[74]. Lap joints were formed between aluminium plates with the aid of adhesives containing epoxy-resins and phthalic anhydride. All the polymers contained 0.85 of the molecule of the anhydride per epoxy-group but also present were n groups $[-OC_6H_4C(CH_3)_2-C_6H_4OCH_2CHOH.CH_2-]$, n being varied systematically from 0.05 to 5. The shear resistance was much greater for $n > 1.5$ than for $n < 0.5$. Since the tensile strength f_M of the free polymers (bars, films, etc.) usually increases with n, this observation can be most simply accounted for by the usual similarity between f and f_M. The author preferred to point out that with increase of n there is an increase in the number of hydroxy-groups in the adhesive and that therefore f is large when the concentration of hydroxyls is high. Evidently other conclusions just as valid are possible. The shear resistance f increases with the number of benzene rings; perhaps these rings are the cause of "adhesion". The presence of isopropylidene groups $(CH_3)_2C$: also increases f; it may be that "adhesion" is caused by them. The higher the value of n, the smaller the number of carboxy-groups (from phthalic anhydride); the carboxy-groups may suppress "adhesion". This last conclusion is particularly remarkable since supporters of the molecular hypothesis of strength usually assert that carboxy-groups promote "adhesion".

The word adhesion is not placed in quotes by the above investigators but in this review the quotes are necessary in order to remind the reader that the true molecular adhesion A has nothing in common with the resistance to stripping, shear, peeling, etc. Adhesion is not the only term employed improperly (see the remarks by Raevskii and Pritykin on this matter[75]). The terms "adhesive capacity" and "adhesive properties" are used. These properties do not exist. Any substance which can exist in the liquid or plastic state so that it can fill hollows on the surface of the adherend and is capable of solidification in contact with the adherend can serve as an adhesive.

There would be no need to quarrel about words, but the danger is that the expressions "adhesion of substance A to substance B" or the "adhesive capacity of A" lead the reader to the error according to which the resistance to rupture of a single arbitrary adhint is adopted as a constant and characteristic property of the substance. Thus the resistance to rupture of films of a polyethylene and of P-118 polyisobutylene was found to be 95 kdyn cm^{-1} when the films had a particular thickness, a particular width, contained particular impurities, etc.; this resistance would be different if the amounts and nature of the impurities, the width, the thickness, etc. were altered; therefore the assertion that the "adhesion" of polybutylene to polyethylene is 95 kdyn cm^{-1} is illogical.

The main reason for the popularity of erroneous views is that organic chemists, who, of course, synthesise polymeric adhesives, continue to work on them in the field of tests and applications. Specialists in the measurement of strength and other mechanical properties of materials must be induced to undertake critical tests of the strength of adhesive joints. Since generally speaking organic chemists are unfamiliar with the science of the resistance of materials, the theory of elasticity, etc., they do not

find the evidence based on these sciences to be convincing. It is very remarkable that Berlin and Basin[10] mention the work on polyethylene briefly described in section III, 2 of the present review in a section devoted to the "morphology of the solid surface" (Ref. 10, p. 56) although polyethylene is an adhesive and not an adherend; in the description of the use of polyethylene as an adhesive on pages 196 and 197 of Ref. 10, it is written that "evidently the appearance of oxygen-containing groups in polyethylene... is the main cause" of the increase of the strength polyethylene adhints when polyethylenes are subjected to a special treatment. As mentioned in section III, 2 (and of course in the papers describing the original experiments), all the adhesive joints were formed in an atmosphere of nitrogen and the purified polyethylene contained less oxygen than the initial material.

Metallopolymers

E.M.Natanson (deceased) and M.T.Bryk

The formation of highly disperse metal particles in a polymer medium is accompanied by the chemisorption interaction of their freshly formed surfaces with the polymer macromolecules. Such systems have several advantages over ordinary filled polymers, and have been termed "metallopolymers". Several methods of obtaining such systems—electrolytic, electroflotation, thermal, and mechanochemical—are surveyed. The nature and the mechanism of interaction between the surfaces of various metals and organic (also organosilicon) polymers are described in detail. The physicochemical properties of metallopolymers and possible fields of their application are discussed. A list of 175 references is included.

I. INTRODUCTION

The development of new technology presents the chemistry of macromolecular compounds with the task of producing polymeric materials possessing several specific new properties. It has become necessary to combine the advantages inherent in polymers (low specific gravity, high elasticity and durability) with the electrical conductivity and magnetic, antifriction, catalytic, and other properties typical of metals and inorganic compounds.

Such polymeric materials can in principle be obtained in two ways: new polymers can be synthesised with several of the specified properties; and filled polymers, combining the valuable properties of their components, can be produced. Both lines of scientific research are being vigorously pursued at the present time [1-4], but polymeric materials containing various kinds of filler have already found wide practical application. The filling of polymers not only enables materials to be obtained with novel properties but also permits their physical, mechanical, and physicochemical characteristics to be varied in a controlled manner, with enhancement of the appearance and reduction in the price of goods made of plastics.

Several reviews [5-7] and monographs [8-10] have been published on the production, structure, and properties of polymeric materials containing various mineral fillers. Considerably fewer publications have appeared on the preparation and properties of polymers filled with metals of different kinds and degrees of dispersion [11]. Polymers filled with metals possess several quite specific properties (electrical, magnetic, catalytic) in addition to the above advantages inherent in polymers containing mineral fillers [12-14]. Furthermore, these two groups of filled polymers differ in the nature and the mechanism of the interaction at the solid–polymer interface [15,16].

Coarse powders, mixed mechanically with the polymer, are generally used as fillers, the particles of which form aggregates distributed non-uniformly through the polymer. During recent years systematic investigations have been made on new methods for obtaining metal-filled polymers and on the properties of the systems [17-20]. These methods consist essentially in forming highly disperse metal particles within the polymer, instead of introducing them ready made. The metal particles, having active centres on their surfaces at the instant of formation, enter into chemisorption interaction with macromolecules of the polymer within which they are formed. This leads to the production of two-phase systems having the most uniform distribution of highly disperse metal particles in the bulk of the polymer and in a stable state of aggregation. Such systems have been termed "metallopolymers". [18] Investigation of the physicochemical and mechanical properties of these systems has revealed considerable differences between metallopolymers and ordinary polymers filled with metals [21], these differences being due to the methods of preparation. The experimental results which have accumulated enable certain generalisations to be made concerning the methods of preparation, the mechanism of formation, and the properties of metallopolymers.

II. METHODS FOR THE PREPARATION OF METALLOPOLYMERS

Metallopolymers can be obtained by various methods provided that a fundamental condition is observed: highly disperse metal particles should be formed in the presence of polymers, with the appearance of chemisorption bonding between the macromolecules and the surface of the metal particles. At the present time the following methods—electrolytic, electroflotation, thermal, and mechanochemical—have been developed for the production of metallopolymers.

1. Electrolytic Method

Cathodic deposits obtained in the presence of suitable surface-active agents can be dispersed in hydrocarbon media to form stable concentrated sols.

The stability of such metal organosols is governed mainly by the degree of solvation of the metal particles by the surface-active agents. The latter compounds usually interact with the surface of colloidal metal particles, with the formation of chemically bound adsorbed films which are strongly solvated by the dispersion medium. The interaction between surface-active agents and metal particles should be limited to the formation of surface compounds firmly bound with the main mass of the metal particles. If chemical compounds of exactly stoichiometric composition are formed on the surface, and are soluble in the organic medium, the adsorbed films are unstable.

The stabilising films must be formed on the surface of the colloidal metal particles at the instant at which the latter are produced. Otherwise, the particles have time to coagulate, with the formation of coarse aggregates, which are not peptised on the subsequent addition of surface-active agents.

The above mechanism of formation of metal organosols operates also when the surface-active agents used are compounds of high molecular weight, whose macromolecules contain polar functional groups.

Examination of the structural–mechanical properties of polymer solutions showed[24] that even small additions of an active filler constitute centres for the formation of a continuous three-dimensional network, which arises from the adsorption and orientation of polymer molecules under the influence of the force field due to the filler particles. The ability of macromolecular compounds to form structures in solution and the cross-linking of a polymer on the introduction of a metal sol, together with the stability of these structures and their tendency to re-form after destruction, are the deciding factors responsible for the stability of a metal organosol.

The nature of the interaction between metal particles and macromolecules is also of substantial importance in determining the stability of the structural network of polymers in solution. Structure formation is most effective in the case of the irreversible adsorption of a polymer due to chemical interaction between the surface of the metal particle and the macromolecules.

An electrolytic method for obtaining metallopolymers in a double-layer bath with a rotating cathode[17] developed from the above investigations of the stability of concentrated metal organosols and ideas on the structural–mechanical properties of polymer solutions in the presence of fillers.

The essence of the electrolytic method is that, when aqueous solutions of appropriate salts (the lower layer of the bath) are electrolysed, metal particles deposited on a disc cathode rotating horizontally are transported to the upper, organic layer of the bath containing the polymer solution. This involves interaction between the metal particles and the polymer macromolecules. Polymer adsorbed on the cathode surface partly shields the latter, and electrolysis occurs only at active centres free from adsorbed molecules. Two processes—passivation and metal electrodeposition—take place. Passivation of the cathode increases its polarisation, which is a measure of the energy requirement for growth of the metal crystals and the formation of new centres of crystallisation[25,26]. Low cathodic polarisations correspond mainly to the activation energy for the transfer of metal ions from solution into the crystal lattice of the metal, i.e. crystal growth of the metal. Very often this energy is insufficient for the formation of new crystal nuclei, so that at low cathodic polarisations metals separate predominantly as coarsely crystalline deposits.

Adsorption of a polymer on the original cathode surface and also on the small metal crystals that are formed, together with the associated increase in cathodic polarisation, favours the formation of highly disperse metal particles, which become lyophilic with respect to the organic dispersion medium.

Rapid transfer of the metal particles creates favourable conditions for interaction between the polymer and the active centres arising on the freshly formed metal surfaces. The nature of the macromolecules has a substantial effect on the transfer of highly disperse metal particles to the upper layer of the bath. Thus with natural rubber of polyisobutylene highly disperse metal particles do not pass into the organic layer, but are concentrated at the interface between upper and lower layers; transfer to the organic layer becomes possible only as a result of inversion of the selective wetting by the addition of small amounts of simple surface-active agents, e.g. oleic acid[19].

If polymers having polar functional groups are present in the organic layer during electrolysis, the metal particles formed pass into the organic layer even in the absence of simple surface-active agents. The polar macromolecules are adsorbed irreversibly on the surface of the metal particles with formation of the corresponding surface chemical compounds[17]. Stable concentrated sols of metallopolymers can be obtained in this way. With a small content of highly disperse metal particles in the organosol, removal of the solvent yields solid or rubber-like products; with high (above 50%†) metal concentrations powders are obtained which can easily be processed.

A series of investigations[27–30] has been made on the effect of various factors—cathodic current density, temperature, electrolyte and polymer concentrations, nature of electrolyte and of polymer, pH of medium—on the current efficiency and the degree of dispersion of the metal particles formed at the cathode. All these relations are extremal in character. Optimum conditions for obtaining metallopolymers by the electrolytic method can be found experimentally for each metal–polymer system. The nature of the polymer has a decisive effect not only on the dispersion and yield of metal but also on its particle shape. Particles formed at the cathode usually have a strongly developed surface owing to their production as dendrites and other complicated forms with strong dimensional anisotropy[29–32].

2. Electroflotation Method

During electrolysis a solution of a surface-active agent of low or high molecular weight in an organic solvent is fed continuously through the pores of a stationary cylindrical cathode in a vertical position, and is sorbed at the electrolyte surface. The metal particles deposited on the strongly passivated cathode surface adsorb the surface-active substances from the organic medium, so that their surface becomes hydrophobic. The sorption of polymer molecules on the fresh particle surfaces favours their detachment from the cathode surface and flotation into the upper layer of the bath[33,34]. Flotation is promoted by a stream of nitrogen along the walls of the cathode during electrolysis. At the same time the nitrogen protects the highly disperse metal particles from oxidation.

The electroflotation method is more suitable than the electrolytic method for industrial use. On an industrial scale the latter method of obtaining metallopolymers in a two-layer bath with a rotating cathode encounters certain difficulties, caused by the need to design electrolytic cells with a rotating shaft and cathode, as well as current leads with a special device to prevent sparking. Moreover, the continuous production of metallopolymers is impossible in this case. The electroflotation method is free from these defects, and permits easy control of the degree of dispersion and the morphology of the metal particles formed at the cathode.

†Percentages by weight are indicated here and subsequently.

3. Thermal Method

Several organic and inorganic compounds of metals, when heated in a reducing atmosphere or in a vacuum to a certain temperature, decompose with the separation of finely divided metal particles[35,36]. Decomposition of such compounds in an organic medium (oils, high-boiling solvents) may yield concentrated, highly disperse metal organosols[17,37].

Among compounds which decompose readily at comparatively low temperatures are certain salts of formic acid: when heated, they break down with the formation of disperse particles of the corresponding metal and volatile products (carbon dioxide, carbon monoxide, hydrogen)[36]. Silver, copper, nickel, cobalt, iron, and lead formates decompose in this way at temperatures not exceeding 250°C.[38,39] Differential thermal analysis has shown[40] that iron, nickel, and cobalt formates lose uncombined water at 102–103° and water of crystallisation at 115–137°C. The intense endothermic processes at 216°, 192°, and 203°C on the thermograms of these salts have been related to the corresponding decomposition points and the formation of finely divided particles of the metals. Chemical analysis of the metal powders showed them to contain on the average ~96.3% of the pure metal. Silver formate decomposes vigorously even at 64–67°C,[41] whereas copper formate begins to break down at 186°C.[42]

Freidlina and Bulanova established[36] that lead formate decomposes above 200°C with the separation of gaseous products, volatile liquids, metallic lead, and lead oxide. The thermograms show an intense double endothermic process at 240–260°C, ascribed to decomposition of the salt to metallic lead[43,44].

The conditions and the kinetics of the decomposition of metal oxalates, which also break down to yield the pure metals[45,46], have been considerably less investigated.

Among inorganic metal salts which decompose at relatively low temperatures with formation of a metal phase we mention the iron hexacyanoferrates. Mittasch[47,48] and Eisenhut[49], while examining the possibility of using decomposition products from iron ferrocyanides as catalysts for the synthesis of ammonia, showed that particles of α-iron are formed in a mixture of nitrogen and hydrogen above 300°C. Differential thermal analysis has established that all the following iron hexacyanoferrates—$Fe_2[Fe(CN)_6]$, $Fe_4[Fe(CN)_6]_3$, $Fe_3^{II}Fe_2^{III}[Fe(CN)_6]_3$, $Fe_3[Fe(CN)_6]_2$, $Fe[Fe(CN)_6]$, and $Fe_3^{II}Fe_4^{III}[Fe(CN)_6]_6$—decompose between 180° and 240°C.[50] Chemical analysis showed that the solid decomposition products of these salts contained 30–80% of highly disperse metallic iron with some iron carbide, the bulk of the metal being deposited during the first hour of reaction.

Thermoplastic polymers have been successfully used as the organic medium in the decomposition of such salts. The presence of the highly developed free surface of the metal particles at the instant of their formation in a polymer medium favours interaction of the surface metal atoms with functional groups and multiple bonds of the polymer, as well as with radicals formed by the partial thermal degradation of the macromolecules.

On this basis a thermal method was developed for obtaining metallopolymers[51,52], which consisted essentially in introducing easily decomposable metal salts into concentrated solutions of the polymers in a highly disperse state and precipitating the polymers with vigorous stirring. The washed and dried polymer containing particles of the salt was placed in a special apparatus[52], where it was kept in a vacuum at the optimum temperature for decomposition of the salt and formation of the metallopolymer. The time required for complete decomposition of metal salts in polymeric media is considerably longer than for the pure salts, owing to the poor thermal conductivity of polymers.

In contrast to ordinary mechanical mixtures of finely divided metals with polymers, metallopolymers obtained by the thermal method have a high degree of dispersion (1–5 μm) and a uniform distribution of metal particles in the bulk of the polymer, together with considerable irreversible adsorption of macromolecules on the surface of the metal particles at the instant of their formation. The quantity of irreversibly bound polymer is proportional to the metal content of the polymer and the duration of heating, and depends on the nature both of the polymer and of the metal[53]. The above differences between metallopolymers and ordinary mixtures have a favourable effect on the physicochemical, mechanical, and other properties characteristic of metal-filled polymeric systems[21,44,54–59].

The thermal method of obtaining metallopolymers is of especial interest in cases in which electrolytic methods are unsuitable owing to the sparing solubility of the polymer or the difficulty of depositing a highly disperse metal on the cathode. Another advantage of the thermal method is that solvent does not have to be removed before the metallopolymer is processed into articles.

4. Mechanochemical Method

The properties of polymers filled with coarsely divided metals are largely determined by the nature of the metal surface and the adhesive forces between the polymers and various metals[60]. The affinity of metal particles for a polymer can be increased by preliminary modification of their surface with substances of low molecular weight having a similar nature to the polymer[17,61,62], monomers capable of polymerisation on the solid surface[63–65], or directly by molecules of the polymer itself by means of mechanical, radiation, or other treatment of the coarse metal–polymer system[66]. Such treatment—in particular mechanical ones—produce cleavage of the polymer molecules with the appearance of free macroradicals, which may interact with the metal surface to form stable metal–polymer chemisorption bonds.

A mechanochemical method for obtaining metallopolymers has been based on these concepts. There are several varieties of this method—(*a*) the polymerisation of monomers on the freshly formed surface of the metal particles, initiated by active centres in this surface produced by the dispersion of metals in the monomers[65]; (*b*) the polymerisation of monomers on the surface of metal particles previously dispersed in a high vacuum (in an inert atmosphere or in the presence of substances which protect the metal surface from intense oxidation)[63,67]; (*c*) preliminary dispersion of metals in surface-active agents of low molecular weight, followed by the introduction of polymers containing active functional groups or multiple bonds, which promote chemisorption of the polymer on the surface of the metal particles[62,68]; (*d*) mechanical dispersion of metals in polymers[69,70]; and (*e*) simultaneous vaporisation of metal and monomer (polymer) in a vacuum, leading to the formation of highly disperse metal particles with macromolecules of the polymer chemisorbed on their surface[71,72].

Kargin, Plate, and their coworkers[73,74] investigated the processes of polymerisation occurring when metals, salts,

and oxides were subjected to vibrational milling in vinyl monomers. As a consequence of the exposure of energetically active faces the surface formed by grinding possesses considerable reactivity, which is apparent in a sharp increase in the adsorptive and chemisorption power. If monomers are present at the instant of formation of such a surface, the active centres in it of ionic or radical type interact with the monomer molecules to form a growing macroradical.

These workers investigated the polymerisation of styrene, methyl methacrylate, α-methylstyrene, acrylonitrile, and vinyl acetate on the surfaces of iron, nickel, chromium, and titanium during grinding, and proved by direct methods the formation of polymers grafted chemically to dispersed substances. The degree of conversion of the monomers increased with the duration of milling, the yield of polymer being small initially, after which it increased sharply. The degree of conversion at a constant time of dispersion depended on the proportions of the components: the highest yield of polymer was reached with small quantities of the monomer, this being associated with the better conditions for grinding.

The relatively coarse grinding of small quantities of iron with a phenol–formaldehyde resin [13,66,75] gave materials in which hardening of the resin was accelerated and its thermomechanical characteristics were improved. This can be explained by chemisorption interaction between active groups of the polymer [76] (phenolic hydroxyls, oxydimethylene groups) and the disperse metal particles.

With polyethylene and polystyrene [66] no appreciable change in properties was observed even on the introduction of considerable quantities of disperse iron. Only when concentrated solutions of these polymers were ground mechanically with the metal powder did interaction occur between the resulting macroradicals and active centres in the metal, as a consequence of mechanical degradation of the polymer macromolecules and "renewal" of the surfaces of the metal particles. The thermomechanical and mechanical characteristics of these systems varied not only with the conditions of mechanochemical treatment but also with the particulate form of the iron [77]: powders containing dendritic particles were more effective as fillers for polymers.

An optimum time of grinding was established [66] for the metal–polymer composition, since prolonged mechanical action on the system produces considerable degradation of the polymer.

Although the above papers give no direct proof of the occurrence of chemisorption interaction between polymers and metal particles when ground together, the effective improvement in several physicomechanical characteristics of these systems can be explained by the formation of surface compounds between polymers and metal, i.e. by the formation of metallopolymers.

Processes occurring at an interface between a metal and a polymer in dynamic contact have been surveyed [78]. The presence of the polymer was shown to promote finer subdivision of the metal (e.g. iron) in a ball mill. The explanation is that the polymeric molecules are activated chemically during loading, and interact with the exposed crystalline surfaces of the metal particles, diminishing their free energy, which leads to intense dispersion of the metal. Surface-active substances of high molecular weight, e.g. poly(methyl methacrylate), were considerably more effective than simple compounds, e.g. oleic acid.

The dispersion of metal powders in the presence of surface-active agents of amine type creates favourable conditions for the formation of chemically fixed adsorbed layers, consisting mainly of compounds of the type M–NH_2 or M–NH–M. [68] This makes interaction between metal particles and polymer macromolecules substantially easier, and promotes a uniform distribution of the particles in the polymer.

The introduction of highly disperse metal powders into polar rubbers (SKN-26, Nairit chloroprene rubber) improves their stability and also accelerates vulcanisation, as a consequence of interaction between the surface of the metal particles [79–81] and the polymer molecules at the instant of opening of the double bonds.

The above applications of the mechanochemical method of obtaining metallopolymers require only simple equipment, and will undoubtedly find wide use in industry in the very near future.

III. MECHANISM OF INTERACTION BETWEEN POLYMERS AND COLLOIDAL METAL PARTICLES DURING FORMATION

Several factors—nature of polymer and metal, chemical state of metal surface, conditions of contact between polymer and metal—govern the character of the interaction between polymer macromolecules and the surface of the metal particles. The present Section discusses various mechanisms of interaction at the interface between metal particles obtained by the above methods and the macromolecules of various polymers, leading to the formation of metallopolymers. In this connection it is necessary to consider also the changes occurring in the mechanism and the kinetics of polymerisation and polycondensation in the presence of highly disperse metals.

1. Metallopolymers based on Macromolecular Organic Compounds

Investigations of chemisorption interaction in the formation of metallopolymers have been made mainly on systems containing polymers having functional groups which are reactive towards metals and their oxides.

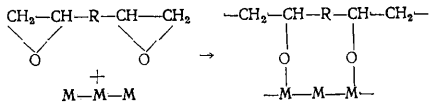
Epoxide–dian resins‡

During investigation of electrolysis in the presence of various polymers it was noted that the epoxide resin ED-5, in contrast to polymers not containing functional groups (polyisoprene, natural rubber), promotes migration of metal particles from the cathode into the organic layer with formation of a stable concentrated metal organosol [18,29,82]. In this case the metal particles are easily made lyophilic with respect to the organic dispersion medium.

Infrared-spectroscopic examination of the products of interaction of ED-5 resin with the metal (iron, lead, etc.) particles at the instant of their formation at the cathode showed a considerable diminution in intensity of the 915 cm^{-1} absorption band corresponding to bending vibrations of epoxy-groups [18], with an inverse relation between the concentration of metal in the polymer and the intensity of this band [18,27,83]. This undoubtedly proves that, at the instant of formation, the highly disperse metal particles

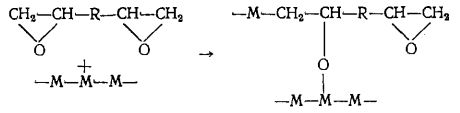
‡Dian = 1,3-diphenylpropane-*pp'*-diol (Ed. of Translation).

react chemically with macromolecules of the epoxide–dian resins. This evidently involves opening of the epoxy-rings:



Such a mechanism should yield three-dimensional structures, in which the highly disperse metal particles act as junction points. In fact ED-5 resin containing 12% of electrolytic lead but without the introduction of any hardening agent was completely hardened at 210°C in 90 min [83]; the pure resin had not hardened at this temperature after 10 h had elapsed.

Investigation of the mechanism of formation of metallopolymers from an epoxide resin and highly disperse palladium obtained by the electrolytic method yielded similar results [84,85]. Palladium metallopolymers exhibited new infrared absorption bands in the region of 440 and 420 cm^{-1}, whose intensity increased with the metal content of the polymer [86]. The appearance of these bands is obviously due to the formation of chemisorption bonds, not only of the C–O–M but also of the C–M type, during hardening [87]:



Differential thermal analysis shows that considerable thermal effects accompany the interaction of epoxide resins with highly disperse metals: they occur in the region of 190°C in the case of copper [42,88], 280–300°C with lead [89], at 293°, 322°, and 380°C with palladium [86], at 196–223°C with iron and cobalt [53], and at 186–198°C with nickel [53]. The intensity of these effects generally increases with increased metal content of the metallopolymer, while they move to lower temperatures on the differential thermal analysis curve.

The appearance of free radicals has been recorded [42,86,88] even at 200–210°C in the metallopolymers on the introduction of highly disperse copper, palladium, or lead into ED-5 epoxide resin, the majority of them being formed during the first 30–60 min of heating. The intensity of the electron spin resonance signal increased with rise in temperature, while the band width remained constant at 10.6–10.9 G. The appearance of this band can be attributed to the generation of macroradicals of the epoxide–dian resin accompanying formation of the metallopolymers. It is noteworthy that heating the pure resin to 260°C does not result in the appearance of radicals.

The radicals produced in metallopolymers based on an epoxide resin are extremely stable (their lifetime at room temperature is of the order of several months), which is obviously due to the formation of a rigid three-dimensional polymer structure. The lower temperature at which macroradicals appear in metallopolymers, in comparison with the pure resin, indicates not only polymerlike transitions in the polymer chains but also acceleration by the highly disperse metals of the thermal degradation of the polymers.

Kinetic investigation of the hardening of an epoxide resin by various highly disperse metals leads to the conclusion that the quantity of bound resin depends not only on the concentration of the metal and the time of heating at a given temperature but also on the nature of the metal (Table 1). Such substantial differences in the quantity of resin bound by different metals at a given hardening temperature and metal concentration in the resin are obviously associated with the electronic structure of the metal atoms. According to Trapnell [90] chemisorption on metals involves the formation of surface compounds with *d*-electrons of the metal atoms. Table 1 [27,29,42,82–89] shows that, during the chemisorption of the epoxide resin, the activity of the metals diminishes as the *d*-shells of the metal atoms become filled.

Table 1.

Metal	Metal in metallopolymer, wt.%	Hardening temp., °C	Bound resin, wt.%, after 2 h	6 h	12 h
Iron[a]	10		98.27	98.84	99.40
	20	230	98.32	93.03	99.48
	30		98.30	99.08	99.49
Nickel	10		75.80	96.39	98.30
	20	230	94.00	97.40	98.60
	30		94.40	97.88	98.88
Palladium	11		8.8[b]	74[e]	
	21.9	225	27.5[c]	92.7[b]	
	26		79.3	94.0	
Lead	12	240	92.0[d]		
Cadmium	10	220	21.0		
Copper	10	240	57.0		
	10		30.5		
	20	210			
	30		60.12		

[a]Identical results obtained for cobalt.
[b–e]Heated for 1, $1\frac{1}{2}$, $2\frac{1}{2}$, and 4 h respectively.

Cadmium and palladium possess comparatively low chemisorption activity, although the latter is a metal of variable valency. The high activity of lead in comparison with the other metals cited here is obviously due to its tendency to form covalent compounds, for the surface compounds formed by an epoxide resin with metals are of this type [16].

The suggested mechanism of the formation of metallopolymers is supported by a comparative study of the conditions under which the pure epoxide–dian resin and metallopolymers formed from it are hardened when exposed to γ-rays [91,92]. Whereas in the radiation hardening of the pure resin a decrease in the concentration of epoxy-rings is accompanied by an increase in the concentration of carboxyl and hydroxyl groups, the carboxyl content remains constant during irradiation of the lead metallopolymers, while the concentration of hydroxyl and epoxide groups decreases sharply. This is obviously due to the accelerating action of γ-rays on the chemisorption of the resin on the surface of the highly disperse metal particles.

X-Ray examination of the γ-irradiated pure resin and metallopolymers based on it indicates that increase in the duration of exposure produces increased ordering of the epoxide–dian resin molecules with the appearance of a quasi-crystalline structure [93]. The introduction of highly disperse copper into the resin promotes a considerable increase in the ordering of the macromolecules after irradiation, but this is not observed in the presence of lead.

Poly(vinyl acetate)

Several studies have been made [31,94–97] of the formation of metallopolymers of poly(vinyl acetate) $[CH_2.CH(OCOCH_3)]_n$ with highly disperse lead and palladium.

Investigation of the effect of the molecular weight of this polymer in the range 117 000–4000 showed that a decrease to ~ 13 000 was accompanied by an increase in the activity of the polymer during electrolysis. A decrease in molecular weight favours a diminution in the blocks of the mosaic of metal particles and also a decrease in size of the particles themselves. These phenomena are probably associated with the adsorption activity of poly(vinyl acetate) [98].

Study of the nature of the bond formed when a polymer is adsorbed on the surface of disperse metal particles indicates ion–dipole interaction between carbonyl groups of the poly(vinyl acetate) and the metal surface. Further evidence of this is the shift in the 1734 cm^{-1} infrared band to 1711–1706 cm^{-1} in the spectrum of the metallopolymer (at a palladium content of 5–10%).

Heating poly(vinyl acetate) metallopolymers produces marked cross-linking of the system [99,100], as a consequence of the detachment of acetate groups from the polymer and interaction of the resulting radicals with the metal surface to form an M–C chemisorption bond [86].

Increase in the concentration of metal, in particular palladium, in the polymer is accompanied by a considerable increase in the concentration of free radicals and a lowering of the temperature at which they are detected. The appearance of free radicals at extremely low temperatures (Table 2) [86] is evidence of chemisorption interaction of the highly disperse palladium particles with macromolecules of poly(vinyl acetate) in the formation of metallopolymers.

Table 2.

Pd in metallopolymer, %	Free radicals in metallopolymer, spins g^{-1}	Radicals detected at, °C
22.45	$4.75 \cdot 10^{17}$	180
47.25	$2.19 \cdot 10^{18}$	100
80.0	$3.40 \cdot 10^{18}$	30

Rubbers

The early publications showed [18–20,101,102] that polyisobutylene and natural rubber, possessing neither functional nor other active groups, do not interact directly with the surface of metal particles at the instant of their deposition on the cathode. A metal organosol is formed only in an oleic-acid solution of the polymer. In neither case did infrared spectroscopy detect a metal–rubber macromolecule chemisorption bond. However, investigation of the swelling and desorption of metallopolymers obtained in this way has established that irreversible adsorption of the polymer on the metal surface nevertheless takes place. In this case interaction between rubber macromolecules and the surface of the metal particles is evidently accomplished through an adsorbed layer of oleic-acid molecules [20].

Electrolysis in the presence of a carboxylate or other polar rubber produces direct chemisorption interaction between rubber macromolecules and particles of various metals [18,28,69]. The swelling and the desorption of such rubbers show this process to be irreversible, and infrared spectroscopy has established ion–dipole interaction between the metal and functional groups of the polymer. The band at 1720 cm^{-1} in the infrared spectra of the metallopolymer, corresponding to vibrations of the C=O group, shifts and diminishes in integral intensity with increase in the concentration of metal in the rubber and rise in temperature, which confirms a chemisorption mechanism of interaction between polar rubbers and metal particles. In this case the latter act as hardener, and promote the formation of a three-dimensional structure in the metallopolymer.

The hypothesis was put forward [74,103] that, when iron is ground in the presence of polyisoprene, the rubber macromolecules initially undergo rupture at the tertiary carbon atom as the weakest point in the chain, and the resulting macroradicals then interact with the metal surface. Investigation of the semiconductor properties of mechanical mixtures of polyisoprene with iron and of compositions where chemisorption interaction between polymer and metal takes place as a consequence of mechanochemical processes, and of the polymerisation of isoprene on freshly formed faces of particles of the metal, shows that chemisorption interaction between the components determines the type of conduction of the resulting systems.

Polystyrene

Metallopolymers have been prepared from polystyrene and highly disperse lead, copper [58], and silver [41] by the thermal method; bismuth and manganese [104] have been introduced by a mechanochemical method. The accompanying chemisorption interaction at the metal–polymer interface results in the formation of a stable three-dimensional structure in the polymer. Furthermore, heat-treatment of the polystyrene–metal system produces significant rises in the glass and flow points of the polymer even in the presence of small amounts of the metal. As in the case of an epoxide resin, the nature of the metal influences the bonding of the polymer and the change in its thermomechanical properties. Metallopolymers based on polystyrene and highly disperse metals are not formed by the electrolytic method, as in the case of non-polar rubbers.

The cathodic deposition of lead [43] and cadmium [104] in the presence of polystyrene and oleic acid in the upper layer of the bath is accompanied by interaction between polymer and metal particles only at the level of van der Waals forces, as was to be expected. The equilibrium swelling for such systems is independent of the content of highly disperse metal in the polymer, but the rate of swelling of filled specimens is even higher than that of pure polystyrene. The introduction of a highly disperse metal into polystyrene, in the absence of chemisorption interaction between them, obviously causes the formation of loose layers of polymer at its interface with the metal, which facilitates penetration of the solvent into the polymer and swelling of the latter [8].

Study of the polymerisation of styrene in the presence of highly disperse metals obtained by various methods is of interest in connection both with the mechanism of the formation of metallopolymers and with the polymerisation of monomers on a solid surface. The rate of polymerisation of styrene in the presence of highly disperse iron, chromium, bismuth, and manganese [106,107] increased, especially during the early stages, if the concentration of these metals did not exceed 1.5%. The yield of polymer also increased, but the variation in the molecular weight was extremal. The increases in the rate of polymerisation and in the yield of polymer are obviously explained by the catalytic action of highly disperse metals on the decomposition of a peroxide initiator of polymerisation. At the

same time, the high rate of formation of growing macroradicals leads to a decrease in the mean molecular weight of the polymer. This process was so intense that the softening point of the metallopolymer fell with increase in the concentration of metal in it [67].

The polymerisation of styrene in the presence of chloride salts is accelerated [108] by additions of colloidal palladium and gold. It is suggested [108] that the polymerisation of styrene, on the freshly generated surface of the colloidal metal particles, is initiated by the formation of π-complexes involving *d*-orbitals of metals with variable valency and vinyl groups of the monomer. It is supposed that the metal particles are not regenerated, but are bound similarly to fragments of an ordinary initiator: i.e. chemical grafting of the polymer on to the surface of the metal particles is assumed.

A Japanese study [109] of the polymerisation of styrene on combined catalysts of the activated metal–organic halide type confirms that polymerisation is most active with metals having a freshly formed surface.

Thus the introduction of highly disperse metals having an active surface into styrene undergoing polymerisation creates favourable conditions for chemisorption interaction between metal and polymer, which should have a significant effect on the physicochemical properties of the resulting polymers, despite the small amounts of metal introduced. The addition of 1.5% of manganese or bismuth to styrene undergoing polymerisation [55] raises the temperature at the start of thermo-oxidative degradation of the polymer from 280° to 337°C.

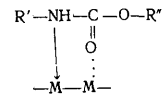
Nitrogen-containing Polymers (polyurethanes, polyamides)

The presence of tervalent nitrogen atoms of well defined π-donating character in a polymer chain should have a significant influence on the adsorption of these polymers on metal particles. In any case, hydrogen bonding may be expected between a hydrated or oxidised metal surface and amide groups in the polymer. However, Bills [110], in an investigation of the swelling of polyurethane–polyisobutylene filled with glass, salts, and also disperse aluminium and tin, did not observe any significant interaction between the polymer and the fillers. This was obviously due to the conditions of filling, which did not guarantee adequate and reliable contact between polymer macromolecules and the filler surface.

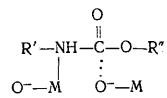
Examination of metallopolymers obtained from polyurethane rubbers and highly disperse cathodically deposited iron particles [111] support Trapnell's view [90] that coordinate interaction occurs at the interface between nitrogen-containing polymer and metal. The infrared spectra of these metallopolymers exhibit a shift to lower frequencies of the 1727 cm^{-1} band representing stretching vibrations of the C=O groups of polyurethane, the displacement being larger the higher the concentration of metal in the metallopolymer. Furthermore, the band in the region of 700 cm^{-1}, due to deformation vibrations of NH groups in the pure polymer, disappears, which may indicate that this bond is partly ionic in the metallopolymer.

Especially large differences in the spectra are observed in the range 600–400 cm^{-1}. Polyurethane exhibits several absorption bands, with maxima at 560, 518, and 495 cm^{-1}, these being due to deformation and out-of-plane vibrations of C–N bonds. The 560 cm^{-1} band is much weaker in the spectrum of the metallopolymer, and has shifted to the range 630–620 cm^{-1}. A new band appears in the region of 507 cm^{-1}, whose intensity increases with the metal content of the polymer; this band is due to stretching vibrations of the M–N bond.

Similar results have been obtained for metallopolymers based on capron [Soviet polyamide-6] and copper [112], iron, nickel, and cobalt [113,114]. These experimental results are consistent with the views of Rutzler [16] and Trapnell [90] on the nature of the adhesive bond between a nitrogen-containing polymer (nylon) and steel, according to which the interaction between metal and polymer involves the formation of surface coordination compounds—(1) with an unoxidised metal surface



or (2) with an oxidised metal surface



Chelate polymers

Chelate (coordination) polymers are similar to nitrogen-containing metallopolymers in the character of their interaction with metals.

Many chelate polymers containing conjugated bonds in their chain possess semiconductor properties [115]. The introduction of highly disperse metals, forming coordinate bonds with the polymer macromolecules, has a substantial effect on the type of conduction and the conductance parameters of these materials. Berlin et al. [115,116] worked out methods for obtaining, and investigated the electrophysical properties of, compositions consisting of disperse metals and chelate polymers. They used tetracyanoethylene as monomer [117], capable on polymerisation of interacting with metal surfaces to form polymeric chelate compounds.

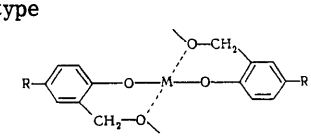
Information has been published also on the polymerisation of phthalocyanines [118], and the synthesis of polymeric Schiff bases and polyazaporphyrins [119] in the presence of powdered metals, accompanied by the formation of coordinate bonds between the surface of the metals and the polymeric molecules.

Since these polymers themselves possess several interesting semiconducting, electrical, and catalytic properties, the further addition of highly disperse metals should obviously intensify these properties in several cases or change their character.

Other organic polymers

The nature of the interaction between polyethylene glycol maleate phthalate, a polyester containing polar ester groups and unsaturated bonds, and the surface of cathodically deposited highly disperse iron has been investigated by infrared spectroscopy, which has established that double bonds are opened with the formation of a chemisorption C–Fe bond [120].

Interesting investigations have been made [121] on the mechanism of the interaction of metals with phenol–formaldehyde resins, which are able to form chelate bonds [76] of the type



with an oxide film on a metal.

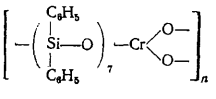
The possibility of forming chemisorption bonds with metals is not confined to polymers containing functional groups or unsaturated bonds. The thermo-oxidative degradation of polyethylene containing disperse iron is sharply accelerated at 240°C, with the formation of chemisorption compounds between macroradicals of the degraded polyethylene and iron.

2. Metallopolymers based on Organometallic Siloxane Polymers and Polyorganosiloxanes

Metallopolymers based on organoelementary siloxane polymers and polysiloxanes are of considerable interest because of the great thermal stability of the initial polymers, which can be still further improved by the introduction of highly disperse metals. Investigation of the mechanism of the formation of these metallopolymers is thus closely connected with problems of the thermal stability, thermal degradation, and stabilisation of the above polymers filled with highly disperse metals [124].

Polydiphenylsiloxanoxychromium

Polydiphenylsiloxanoxychromium has the cyclolinear structure



and possesses excellent thermal stability [125,126]. Metallopolymers have been obtained from it by a thermal method. The decomposition of lead formate in the polymer [127] at 240°C for 6 h yields a metallopolymer, whose structural forms differ considerably, according to differential thermal analysis data, from those described for the pure polymer [126].

Atkins et al. [128], who studied the thermal stabilisation of polydimethylsiloxane rubbers by metals, including lead, suggested that at high temperatures lead oxides rupture the chain of the siloxane polymer, and then react with the macroradicals thus produced, forming a new polymer containing lead in the main chain. Andrianov [129], in work on the stabilisation of cyclolinear polymethylphenylsiloxanes by metal oxides, showed that chrome yellow may cause rupture of silicon–carbon bonds and also the cleavage of rings in the polymer. Analogous changes obviously occur in the structure of polydiphenylsiloxanoxychromium on the formation of metallopolymers containing lead.

The infrared spectra of these metallopolymers reveal a direct dependence, on the concentration of lead in the polymer, of the decrease in integral intensity of absorption bands at 1050 and 1010 cm^{-1}, due to silicon–oxygen stretching vibrations in small rings, and a considerable strengthening of bands at 1090–1080 cm^{-1}, due to silicon–oxygen stretching vibrations in linear polymer chains [130]. Thus the spectroscopic results provide experimental evidence of ring-opening in polydiphenylsiloxanoxychromium under the influence of highly disperse lead. Furthermore, the infrared spectra of the metallopolymers contain a new band at 620 cm^{-1}, whose intensity increases with increased concentration of lead in the polymer. This band is obviously due to vibrations of the chemisorption SiO–Pb bond, formed by interaction between polymer radicals and the surface of the lead particles.

Both infrared spectroscopy and differential thermal analysis suggest that, when a mixture of polydiphenylsiloxanoxychromium and lead formate is heated at 240°C, polymer molecules are adsorbed on the freshly formed surface of the deposited lead particles, which catalyse ring-opening and obviously the detachment of phenyl radicals. The resulting macroradicals undergo chemisorption interaction with the surface of the lead particles, to form linear, branched, and perhaps cross-linked polymer macromolecules containing lead atoms as well as chromium.

Similar results have been obtained for metallopolymers based on polydiphenylsiloxanoxychromium and highly disperse iron formed by the thermal decomposition of iron ferrocyanide in the polymer [131].

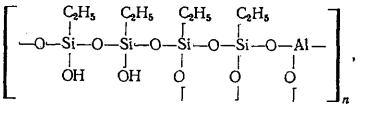
Investigations of the thermomechanical properties of these metallopolymers [132] have revealed no simple relation between softening temperature and concentration of metal in the polymer, such as occurs with linear organic polymers. At low metal concentrations (up to 4%) the softening point of the metallopolymers rises, as a consequence of the increased number of sorbed macromolecules on the solid surface. However, further increase in concentration (5–10%) is accompanied in all cases by a fall in the softening point. At higher metal concentrations the softening temperature either rises slightly or else remains unchanged.

The lowering of the softening point at metal concentrations of 4–10% is obviously due to intense decyclisation of the polymer under the catalytic influence of the highly disperse metals, with the formation of linear polymer molecules, which are more mobile than cyclolinear molecules. This process probably occurs to a considerable extent only when the metal concentration reaches 4%. It continues at concentrations above 10%, but is accompanied by intensified cross-linking of the polymer, so that only a slight rise in softening temperature of the metallopolymers is observed. This type of dependence of the softening temperature on the metal content in the polymer has been found with all metallopolymer systems based on cyclic and cyclolinear organometallic siloxane polymers [133].

Highly disperse metals are efficient catalysts of ring-opening in organometallic siloxane polymers. This is evident with polydiphenylsiloxanoxychromium in particular in the fact that the introduction of a small quantity of highly disperse metal (by the thermal decomposition of suitable salts in the polymer) makes the polymer capable of softening.

Polyethylsiloxanoxyaluminium and oligomeric αω-dihydroxypolydimethylsiloxane

Polymethylphenylsiloxane contains no active functional groups, and is therefore neutral in the electrochemical crystallisation of highly disperse iron [134]. Polyethylsiloxanoxyaluminium



which is a cyclolinear polymer, contains a sufficient number of hydroxy-groups [135] for metallopolymers to be obtained [30] by the electrolytic method. The electrochemical crystallisation of highly disperse cadmium in the presence of this polymer and the transport of metal to the

upper, organic layer of the bath are ensured by interaction between polymer hydroxyls and the surface of the cadmium particles deposited on the cathode.

Differential thermal analysis and infrared spectroscopy show that, when metallopolymers based on polyethylsiloxanoxyaluminium and cadmium are heated at 200°C, the radicals formed by the detachment of hydroxyls interact with highly disperse cadmium particles[30].

Investigation of the electrochemical crystallisation of highly disperse cadmium in the presence of $\alpha\omega$-dihydroxypolydimethylsiloxane—a reactive organosilicon oligomer—in the upper, organic layer of the bath[32] has shown that here also the metal particles interact with hydroxyls of the oligomer to form a chemisorption bond. This is accompanied by polycondensation of the oligomer under the catalytic influence of the metal particles formed at the cathode.

Polydiphenylsiloxane

Metallopolymers of the type described above have been obtained both from the ready made organometallic polymers and oligomers containing hydroxy-groups and by the polycondensation of hydroxylated organosilicon monomers (e.g. diphenylsilanediol) in the presence of highly disperse metals.

At temperatures above 200°C diphenylsilanediol undergoes condensation[136] with the liberation of water and benzene, owing to the occurrence of two reactions—(1) interaction of the monomer hydroxyls with elimination of water and formation of a siloxane bond, and (2) interaction between hydroxyls and phenyl radicals with elimination of benzene and formation of a siloxane bond.

In the polycondensation of diphenylsilanediol in the presence of highly disperse lead[137] and iron[50] obtained by thermal decomposition of lead formate and iron ferrocyanide in the monomer, reaction (1) predominates with increase in the content of these salts. This may be due to the action either of the liberated metals or of the salts themselves and their volatile decomposition products (formic acid, cyanogen), which are acidic in character.

Acids catalyse the condensation of this monomer with the formation of a cyclic trimer—hexaphenylcyclotrisiloxane—and the elimination of water.

The polycondensation of pure diphenylsilanediol at 240°C is a rapid process, complete within 15–20 min. This excludes any effect of the highly disperse metal on the process, since appreciable quantities of the metal are formed only on more prolonged heating. The kinetics of the condensation of the monomer and of the decomposition of the metal salts indicate that the salts catalyse condensation of the monomer with elimination of water and formation of the cyclic trimer. However, the infrared spectra of the final condensation products containing highly disperse lead or iron indicate the formation of linear products, the quantity of which increases with the concentration of metal in the polymer. This apparent contradiction between kinetic and spectroscopic results disappears if the cyclic trimers formed in the initial period of condensation open up under the influence of highly disperse metals in the second stage with the formation of linear macromolecules. The occurrence of two stages in the formation of metallopolymers from diphenylsilanediol is also confirmed indirectly by the dependence of the softening point of the metallopolymers on the concentration of metal, which is similar in character to that found with polydiphenylsiloxanoxychromium.

Since the salts and their volatile decomposition products affect the mechanism of the polycondensation of diphenylsilanediol, it was desirable to investigate its polycondensation in the presence of a highly disperse metal already introduced into it by the electrolytic method. The infrared spectra of diphenylsilanediol containing electrodeposited lead[139], in comparison with the spectrum of the pure monomer, show a considerable shift to higher frequencies (940–920 cm^{-1}) of the 890–845 cm^{-1} doublet, corresponding to deformation vibrations of the hydroxyl in the Si–OH bond[130]. The broad absorption band at 3200 cm^{-1}, due to hydroxy-stretching vibrations in the solid monomer[130], is also displaced to shorter wavelengths (3400 cm^{-1}). Such a considerable shift in these bands is obviously due to chemisorption of the monomer on the surface of the lead particles at the instant of their deposition on the cathode.

The energy of interaction of hydroxyls with the metal surface calculated from the shift[140] is ~7 kcal $mole^{-1}$, which corresponds in magnitude with the energy of a hydrogen bond. Chemisorption on a freshly formed lead surface diminishes the mobility of the monomer molecules and causes a redistribution of the electron density of all the bonds, which should affect the reactivity of individual groups in the molecules and the mechanism of condensation of diphenylsilanediol as a whole. The thermal condensation of diphenylsilanediol containing electrolytic lead, unlike its condensation in the presence of lead formate decomposing to the metal, takes place only by reaction (2)—with the elimination of benzene.

The above results suggest a mechanism for the polycondensation of diphenylsilanediol in the presence of highly disperse electrodeposited lead in which, at the instant of deposition of the lead particles, monomer molecules are adsorbed by one hydroxyl on the freshly formed metal surface. When the monomer is heated phenyl radicals, unhindered by adsorption, interact readily with the hydrogen atom of a hydroxy-group in an adjacent molecule, benzene being eliminated. This should yield mainly a linear polymer adsorbed by hydroxyls on to the metal. Under these conditions there is little likelihood of the formation of cyclic trimers, owing to the rigidity of the growing macromolecule adsorbed at one end. These conclusions are supported by infrared-spectroscopic examination of the metallopolymers.

Although the dependence of the softening point of the metallopolymers on the metal concentration is the same in character as that for cyclolinear and cyclic polymers, the fall in softening temperature in the concentration range 4–10% is considerably less pronounced, obviously owing to the formation of small amounts of cyclic molecules. It should also be noted that, for the same lead content, the absolute softening points of metallopolymers obtained by the electrolytic method are higher than those of specimens obtained by a thermal method. The probable reason is more effective interaction in the former case between the monomer—later also the polymer—and the highly disperse metal.

Briefly summarising the investigations on the mechanism of the formation of metallopolymers based on organo-elementary polysiloxanes and polyorganosiloxanes, we note that all cyclic and cyclolinear polymers undergo ring-opening under the influence of highly disperse metals[133]. This may be accompanied by the formation of chemisorption bonds of the type Si–O–M between the macroradicals and the metal surface. Among the metals examined, highly disperse lead was the most active[50]. Linear polyorganosiloxanes containing functional groups react with highly disperse metals under ordinary conditions;

on heating such interaction involves chain breakage and incorporation of the heteroatom into the polymer chain [128].

IV. PHYSICOCHEMICAL PROPERTIES AND APPLICATIONS OF METALLOPOLYMERS

Chemisorption interaction with a highly disperse metal affects also the boundary layers of a polymer to a certain depth, appreciably changing its properties in compositions. The physicochemical properties and the applications of metallopolymers pose vast and many-sided problems, a full consideration of which could form the subject of a separate review.

Electrical Properties

The electrical properties of metallopolymers are determined by the nature and the concentration of the metal, the method of its introduction, and also the character of the interaction [150] between metal and polymer.

With metallopolymers based on rubbers (natural rubber and polyisobutylene) and highly disperse iron [19] cobalt, and nickel [20] obtained electrolytically, the conductivity increases only slightly as long as the metal concentration does not exceed 20–40%. The explanation is that, under the influence of the metal particles, the rubbers acquire an ordered network structure.

At higher metal concentrations the particles form chain structures and are in contact with one another; the conductance shows an avalanche-like increase. As the metal concentration increases to 80%, the systems become almost as highly conducting as metals, their conductance falling with rise in temperature. A similar type of conductivity has been found for the polystyrene–silver system [41] and for those formed by an epoxide resin with copper [57] and with iron [141].

The explanation of the sudden increase in conductance at metal concentrations exceeding 40% is that, in metallopolymers having low metal contents, the metal particles are mostly separated by distances exceeding their mean diameter, and the probability that particles will be incorporated into a chain of a certain length is small. At metal concentrations above 40% the distances between the particles become comparable with their diameter, so that the further addition even of small quantities of metal will lock a series of adjacent particles, and this is responsible for the sharp increase in conductance at these concentrations.

The conductance of metallopolymers is due not only to metal chain structures but also to the tunnel effect [57]. At energies corresponding to a particular voltage the current carriers are able to overcome the potential barrier of the polymer shell, when the number of carriers in the system will increase exponentially.

Several researches have shown that the mode of preparation of the specimens has a great effect on the conductance of metal-containing polymer systems. Thus raising the temperature and the pressure at which the samples were prepared leads to a considerable increase in the conductivity [151]. This effect is especially strongly developed in the region of plastic deformations of the systems.

If a magnetic field is applied during the formation of metallopolymers, which gives a directed orientation of metal particles in the polymer, anisotropy of the conductance is observed [152].

Levina et al. discovered [74,103] that the vibrational milling of iron in isoprene, which polymerises on the fresh faces of the metal particles, yields a semiconductor material having electronic conduction; if the vibrational milling is conducted in ready made polyisoprene, material having positive-hole conduction is formed. The character of the interaction between polymer macromolecules and iron particles must obviously be taken as responsible for the type of conduction.

Dielectric Constant

Experimental values of the dielectric constant and the loss angle for the metallopolymers formed by an epoxide resin with copper [57] and with palladium [153] differ from the theoretical values, which is explained by the presence of radicals fixed on the surface of the metal particles. The dielectric constant of the metallopolymers is diminished by chemisorption interaction and cross-linking of the epoxide resin on the metal surface, which leads to bonding of the epoxy-groups.

Formation of radicals is intensified during hardening, and the dielectric constant of the system increases. When the system is completely hardened, with formation of a dense three-dimensional structure, the kinetic mobility of the remaining free radicals diminishes, as also the dielectric constant and the tangent of the loss angle.

Catalytic Properties

The use of polymers as stabilisers and carriers of the active phase in hydrogenation catalysts has for a long time attracted the attention of many investigators [154–158].

During recent years Sokol'skii and his coworkers have made extensive investigations [159–167] on the hydrogenation of organic compounds, containing double and triple bonds, over platinum-group catalysts deposited as finely divided reduced metal powders on a polymeric carrier—polyacrylonitrile, polyvinyl alcohol, anid, poly(ethylene terephthalate). The selectivity and the activity of these catalysts are determined in considerable measure by the nature of the polymer [168]. This is evidently related to the deformation of the electron shells of atoms of the disperse metal adsorbed on polar groups of the polymer, and to the orientation of molecules of the unsaturated compound as it approaches the catalyst surface along the polymer chain, with the unsaturated groups located on the active centres of the metal [168].

Metallopolymers based on polydimethylphenylsiloxane and highly disperse electrolytic iron have been studied [169–172] as catalysts for the synthesis of ammonia. Thermostable polysiloxanes proved to be resistant stabilisers of the surface of the active phase (100–120 $m^2 g^{-1}$), and provided reliable protection against sintering of the metal particles. The above metallopolymers were comparable in efficiency with an industrial iron catalyst.

The great catalytic activity of metallopolymers based on an epoxide resin, poly(vinyl acetate), and highly disperse electrolytic palladium for the hydrogenation of unsaturated organic compounds remains almost unchanged on prolonged storage of the catalyst under ordinary conditions [86].

Investigation of the catalytic properties of metallopolymers requires further development both in the search for new systems suitable for definite catalytic reactions

and in the establishment of the interrelation between the semiconductor and the catalytic properties of metallopolymers [173].

Metallopolymers are used also in the purification of petroleum products from organosulphur compounds at normal pressures and temperatures [174,175].

Antifriction Properties

Metallopolymers find application as antifriction materials [56]. The combination of polymers, which possess low coefficients of friction or abrasion, with the highly disperse metals traditionally employed in friction joints (copper, lead, etc.) yields antifriction materials having low coefficients of friction and, what is very important, high thermal conductivity and good mechanical properties [60].

Thermomechanical Properties

Chemisorption interaction between polymers and metals greatly restricts the mobility of individual macromolecules and supermolecular structures [8] in contact with the surface of the metal particles, so that the softening and glass points of metallopolymers are particularly high [21] compared with those of ordinary filled polymers. The thermomechanical properties of a polymer are affected significantly not only by the type of interaction between polymer and metal but also by the concentration, degree of dispersion [66], particle shape [77], and nature of the surface of the filler. The high degree of dispersion and uniformity of distribution of metal particles introduced into polymers by the methods described above are already sufficient to ensure considerable differences in thermomechanical properties between metallopolymers [41] and ordinary filled systems.

The effect of the character of interaction between polymer and metal on the thermomechanical properties of the compositions can be clearly traced from the variation in the softening points of metallopolymers based on polystyrene [41,58,67], where interaction between polymer and metal surface is weak, and in those based on an epoxide–dian resin [21,84,85,141], poly(vinyl acetate) [99], and capron [112–114], where chemisorption interaction between macromolecules and metal surface has been established. At the same concentrations of different metals the softening temperatures of the second group of metallopolymers are always far higher. Furthermore, whereas the first group of metallopolymers exhibit an almost linear dependence of softening point on metal concentration, metallopolymers based on the epoxide–dian resin with copper [21] and especially iron [141] already exhibit a sharp rise in softening temperature at comparatively low metal concentrations, and then loss of deformability, which is associated with complete hardening of the resin by the metal.

Raising the temperature [99] and increasing the duration [84,85] of preliminary heat-treatment with the second group of metallopolymers will raise the glass and softening points for a given concentration of metal in them.

Mechanical Properties

Study of the thermomechanical properties of filled polymers provides a clearer idea of the processes that occur when a polymer interacts with metal particles and of their effect on the mechanical properties of metallopolymers.

The introduction of lead by the thermal method into an epoxide–dian resin [89] increases the breaking strength and the elongation (up to a certain concentration of the metal), as well as the modulus of elasticity of the specimens, lead serving in this case as hardener. Raising the lead concentration above an optimum value leads to the formation of a more brittle and rigid system, which sharply lowers the strength characteristics of the metallopolymer.

The particle shape of the metal also affects the mechanical characteristics of the compositions. Powders comprising dendritic particles are most effective in improving the mechanical properties of filled polymers [77]. The introduction of highly disperse aluminium, manganese, iron, and silicon powders [67], made lyophilic towards rubber, has a vulcanising and reinforcing action on compositions of chloroprene and butadiene–nitrile rubbers. The improvement of the mechanical properties of rubber [68,90,81] in the presence of highly disperse metals is obviously due to the formation of stable rubber–metal bonds.

Swelling

The introduction of a filler into polymer systems may form additional cross-link in the three-dimensional network, but may also decrease its density. These additional cross-links are usually broken by swelling, with a considerable increase in the apparent degree of swelling of the polymer [142]. Swelling of this character is found with metallopolymers based on polystyrene and lead [43,104], where only weak van der Waals interactions link polystyrene macromolecules and metal particles.

However, in the thermal preparation of metallopolymers from polystyrene and a more active metal, silver [41], when a stable three-dimensional structure can be formed by thermal degradation of the polymer macromolecules followed by chemical interaction between the macroradicals and the surface of the silver particles, the ability of the metallopolymer to swell diminishes with increase in the metal content. Chemisorption interaction of polymers with the surface of metal particles leads to a sharp restriction of the mobility of the polymer chains, owing to the formation of additional chemical cross-links in the polymer network.

The introduction of highly disperse iron into non-polar rubbers (natural rubber, polyisobutylene) produces a considerable decrease in their swelling, and specimens containing 80% of the metal hardly swell at all [19]. A similar pattern is observed with these polymers on the electrolytic introduction of nickel and cobalt [20]. When the same quantities of these metals are added to a rubber, the decrease in the equilibrium degree of swelling depends on the nature of the metal. Furthermore, equilibrium swelling is reached more rapidly with metallopolymers than with the corresponding pure polymers, owing to the loose packing of surface layers of the polymer in the former case [8].

Metallopolymers based on an epoxide resin and copper, prepared by a thermal method, also show a decrease in swelling with increase in the copper content from 1% to 40%. [52] The character of the swelling changes sharply at copper concentrations above 40%. Samples containing 50–60% of copper hardly swell at all in 180 min. The swelling of specimens containing 60% of copper is one-tenth of that observed with 40% of copper.

Theoretical values of the degree of swelling of metallopolymers based on poly(vinyl acetate) and palladium [99], calculated by means of the Flory–Rehner equation [142], exceed the experimental values, the difference being larger the higher the palladium content.

All this indicates that bonds formed between metal surface and polymer in the preparation of metallopolymers are not broken during swelling.

Thermal and Thermo-oxidative Degradation

The influence of highly disperse metals on the thermal and thermo-oxidative degradation of metallopolymers has been by no means fully investigated, although it is of great interest. The introduction of up to 33% of highly disperse iron into an epoxide resin somewhat increases the rate of thermal degradation of the latter, but aluminium has no appreciable effect on this process [143,144]. Polyethylene also undergoes considerably more vigorous thermo-oxidative degradation when filled with disperse iron [122].

Differential thermal analysis has been used to examine the effect of the concentration of various metals on the thermo-oxidative degradation of metallopolymers, in particular those based on the epoxide–dian resin with copper [21] and on polystyrene with bismuth, manganese, and lead [54,55]. In all cases an appreciable rise in the temperature at which degradation began was observed only at low metal concentrations (up to 1.5%). The same method has shown that the optimum temperatures for the start of the thermo-oxidative degradation of metallopolymers based on an epoxide resin were reached at contents of 40–80% of copper [21] and of iron [141]. Similar results have been obtained for systems based on natural rubber and various metals [145].

However, the use of differential thermal analysis will not give a complete understanding of the role of metals in the degradation of metallopolymers. Quantitative investigations are necessary on the loss of weight of specimens and the evolution of volatile products, and their nature and the structural changes in the solid residue must be established; these may give more definite information on the mechanism of the degradation of metallopolymers. The investigation of purely thermal degradation is especially important, since the degradation of metallopolymers in air leads to oxidation of the highly disperse metals, so that degradation of the polymer is then affected actually by the metal oxide.

The introduction of certain disperse metals retards the oxidative degradation of organosilicon polymers [126,146,147]. This was explained by the orienting influence of the particles, which are able to become centres for the formation of secondary structures: i.e. physical factors are regarded as having the predominant effect on thermal degradation. Other authors [148,149] are inclined to attribute the enhanced stability of polysiloxanes when filled with metals to the formation during degradation of a new polymer with the metal heteroatom in the chain: i.e. they explain the stabilisation effect by the chemical action of the metal. The role of the physical or the chemical factor is obviously decisive in each specific case, but the influence of the other factor can be by no means excluded.

The above methods of preparation, mechanism of formation, and physicochemical properties of products obtained by the interaction of polymer macromolecules with the surface of colloidal metal particles at their instant of formation indicate that a chemisorption bond is established in these products between polymer and metal. This allows such two-phase systems of limiting homogeneity to be classed as a separate group under the name "metallopolymers". The chemisorption interaction of the macromolecules with the metal surface, the high degree of dispersion of the metal particles, and also the uniformity of their distribution in the bulk of the polymer guarantee a considerable improvement in the physicomechanical and physicochemical properties of metallopolymers in comparison with ordinary polymers filled with metals.

The simplicity of the methods of preparation combined with the series of valuable specific properties of metallopolymers opens up wide possibilities for their application in the national economy. Metallopolymers based on film-forming and lacquer-depositing polymers may find application as corrosion-resistant and other protective coatings. The exploitation of, for instant, the magnetic, semiconducting, ferromagnetic, catalytic, and antifriction properties of metallopolymers is most promising in practical terms.

Detailed investigations are required on the mechanism of the thermal and thermo-oxidative degradation of metallopolymers obtained from a variety of metals and macromolecular compounds. Such investigations would serve as a basis for producing metallopolymers possessing high thermal stability, which would considerably expand their field of application.

Further examination of the mechanism of the formation of metallopolymers based on the most diverse classes of macromolecular compounds and various metals would make possible a general theory of the formation of metallopolymers.

Researches on the formation of metallopolymers by the polymerisation or polycondensation of monomers and oligomers on the freshly formed surface of highly disperse metals would be especially interesting for both theory and practice, involving both problems of polymerisation and structure formation on solid surfaces and those of the strengthening of filled polymers.

Structural Course of the Polymerisation of Diynes

M.G.Chauser, V.D.Ermakova, and M.I.Cherkashin

Examination of the available information shows that polymers of diverse structure—linear (with polyene and cumulene fragments), cyclolinear (including ladderlike), and three-dimensional—can be obtained by the polymerisation of diynes having conjugated and non-conjugated triple bonds. The structural course of the process is determined by the nature of monomer and catalyst and the conditions. Linear organometallic polymers, whose main chain comprises alternating double bonds and atoms of Group IV elements, can be obtained by the polyaddition of hydrides of these elements to $\alpha\omega$-diynes. A list of 58 references is included.

I. INTRODUCTION

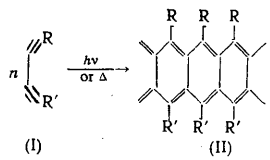
The polymerisation of acetylenic compounds, especially diynes, has been much less studied than that of alkenes and dienes. During recent years, however, polymers based on acetylenic monomers have been attracting increasing attention from research workers in connection with the intensive search for new materials possessing high thermal and thermo-oxidative stability with specific magnetic, catalytic, electrophysical, and other properties.

Whereas the polymerisation of mono- and di-substituted derivatives of acetylene usually leads to the formation of substituted polyenes (Ref.1 and Ref.2, p.378) and/or substituted cyclomers (Ref.2, p.327, and Refs.3 and 4), diynes having conjugated and non-conjugated acetylenic bonds may yield polymers in which the main chain of the macromolecule has a polyene, cumulene, or aromatic cyclic (including ladderlike) structure.

II. SYNTHESIS OF POLYMERS FROM DIYNES WITH CONJUGATED TRIPLE BONDS

It has been discovered comparatively recently[5-11] that certain crystalline monomers of the type R.[C:C]$_2$.R′ (diacetylenic dicarboxylic acids, alkadiynediols, diurethanes, anacycline), which are stable in solution or in a melt, become coloured when illuminated or when heated rapidly to a temperature below the melting point. The colour is red — violet, dark blue, or black depending on the nature of the substituents R and R′, and more or less soluble polymers are formed with degrees of polymerisation of 3 — 20.

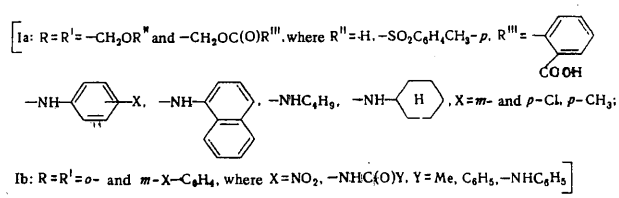
From a study of the ultraviolet spectra of the resulting polymers and the discovery of phthalic acid among their oxidative decomposition products it was suggested[5-8] that the energy communicated to the monomer in the crystalline state, i.e. with a parallel arrangement of the diyne chains, was used to serve only one pair of π-electrons in each triple bond. This destroyed the rigidity of the diyne molecule, and polymers having a substituted acene structure were formed:



(I) (II)

This interpretation, which disregarded the specific nature of the substituents R and R′, has found a place in subsequent reviews[12,13].

More detailed investigation of reactions of this type has shown[14-17] that in general such behaviour is exhibited only by those diynes which, because of the nature of their substituents



can form hydrogen bonds or develop dipole — dipole interactions.

Solid-phase polymerisation requires that the triple bonds in the monomer molecules should be arranged in such a way that the process can occur without any great change in the crystal lattice of the monomer. For this reason *ortho*-substituted compounds of type (Ib) are sometimes less reactive than the corresponding *meta*-derivatives, while *para*-isomers of (Ib) do not undergo polymerisation at all[17]. The modification of R.C:C.C:C.R (where R = CH_2.O.CO.NH.C_6H_5) free from dioxan also does not polymerise, since dioxan is responsible for the necessary packing of the monomer molecules in which the phenylurethane groups are bound by hydrogen bonds to neighbouring diyne and dioxan molecules[18].

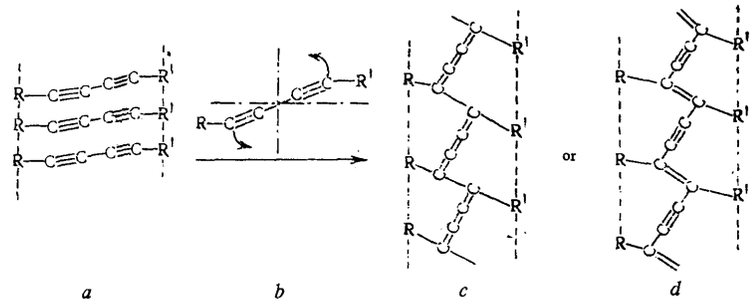


Figure 1.

Individual molecules are evidently regularly arranged in the crystal lattice of the monomers in the form of a "ladder" (Fig.1*a*), the "rungs" of which are formed by diyne fragments, and the "uprights" by hydrogen bonds or groups with strong dipole — dipole interaction (shown by the broken lines in Fig.1). Reaction occurs as a result of the rotation of each individual "rung" about its centre (Fig.1*b*) or shearing of the whole "ladder", while the separate "crossbars" are joined by 1,4-addition to form three cumulative double bonds in the unit[14-17] (Fig.1*c*) or perhaps an enyne structure[18] (Fig.1*d*).

Polymer systems obtained by the polycondensation of diynediols with di-isocyanates or dichlorides of dicarboxylic acids exhibit analogous structural changes to those observed in the polymerisation of monomeric diacetylenic derivatives in the solid state[19]:

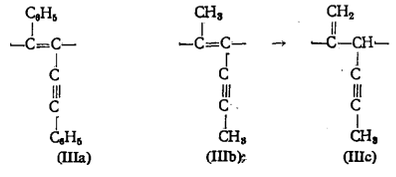
$$\mathrm{HO{-}X{-}(C{\equiv}C)_2{-}X{-}OH + OCN{-}Y{-}NCO \rightarrow}$$
$$\rightarrow \ldots{-}O{-}X{-}(C{\equiv}C)_2{-}X{-}OC(O)NH{-}Y{-}NHC(O){-}\ldots,$$

where $X = CH_2$, $CH_2(OCH_2CH_2)_2$; $Y =$ $(CH_2)_6$, $p\text{-}C_6H_4CH_2C_6H_4\text{-}p$.

$$\mathrm{HO{-}CH_2(C{\equiv}C)_2CH_2{-}OH + ClC(O)(CH_2)_4C(O)Cl \xrightarrow[-HCl]{\text{pyridine}}}$$
$$\rightarrow \ldots{-}O{-}CH_2(C{\equiv}C)_2CH_2{-}O{-}C(O)(CH_2)_4C(O){-}\ldots$$

In the case of polymers the replacement of a diyne by a cumulene or an enyne group leads to intermolecular cross-linking. Since the reaction is catalysed by radical initiators (benzoyl peroxide and azoisobutyronitrile) and is retarded by radical inhibitors (quinol), while ionic systems have no effect on the process, a radical mechanism of polymerisation is extremely probable.

The thermal and catalytic polymerisation of conjugated diynes follows a different course in solution or in a melt. The polymerisation of diphenylbutadiyne (I: R = R′ = C_6H_5) on the tri-isobutylaluminium — titanium tetrachloride catalytic system yields a linear polymer with a substituted polyene structure (IIIa), but on thermal polymerisation in the melt, i.e. above the melting point of the monomer, a block copolymer is formed consisting of substituted polyene (IIIa) and acene (II: R = R′ = C_6H_5) fragments (deduced from the results of ultraviolet, infrared, nuclear magnetic resonance, and electron spin resonance spectroscopy, luminescent, thermochemical, and X-ray examination, and also study of the chemical reactions of the products)[1,20-29].



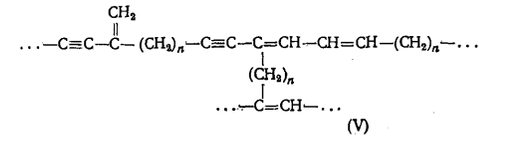
Heat-treatment and bromination, which cause intramolecular cyclisation of polydiphenylbutadiynes, increase the number of acene segments in the macromolecule[30], but in no case is a polymer obtained having a completely acene (ladderlike) structure.

The thermal polymerisation of dimethylbutadiyne (I: R = R′ = CH_3), like that of diphenylbutadiyne, involves predominantly formation of a block copolymer, consisting of (II: R = R′ = CH_3) and (IIIb) units. However, this is accompanied by the production of not more than 3% of methylene side-groups (IIIc) because of intramolecular isomerisation[31], which is responsible for the ready oxidisability and subsequent cross-linking.

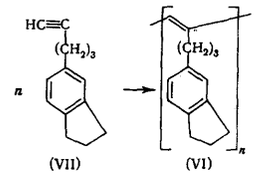
III. POLYMERISATION OF DIYNES WITH NON-CONJUGATED TRIPLE BONDS

The course of the polymerisation of diynes of the type HC:C.X.C:CH (IV) is determined by the nature of the group X separating the triple bonds and by the reaction conditions.

The polymerisation of diynes (IV) in which X = $[CH_2]_n$ (where $n = 2-5$) on the complex catalytic system $Ni(CO)_2.2(C_6H_5)_3P$ leads to the formation of compounds of high molecular weight[32]. The high-melting insoluble polymer from hexa-1,5-diyne (IV: X = $[CH_2]_2$) has the structure (V)



as a result of simultaneous linear polymerisation and dehydropolycondensation. Hepta-1,6-diyne (IV: X = $[CH_2]_3$) gives (together with the aromatic trimer 1,3-di(indan-5-yl) propane) a 75 — 80% yield of a soluble resinous product of degree of polymerisation <20, which infrared spectroscopy shows to be a substituted polyene (VI). This structure results from polymerisation at the triple bond of the dimer (VII) obtained initially[32]:



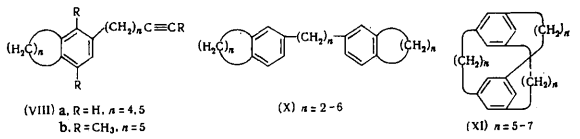
The number of 1,2,4-trisubstituted aromatic groups in polyocta-1,7-diyne is less than in polyhepta-1,6-diyne. Under these conditions nona-1,8-diyne forms only an insoluble polymer containing no aromatic groups. Copolymers of diynes with equimolecular quantities of hept-1-yne contain both aromatic groups and conjugated double bonds.

Thus the number of aromatic groups in products of the polymerisation of non-conjugated diynes of the type (IV) on the catalytic system $Ni(CO)_2.2(C_6H_5)_3P$ decreases in the sequence

hepta-1,6-diyne > octa-1,7-diyne ≫ hexa-1,5-diyne, nona-1,8-diyne

This may be determined by the conformations of the intermediate complexes of the diynes with the catalyst.

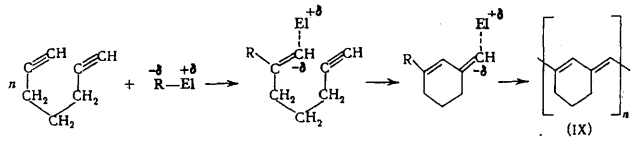
The polymerisation on the catalyst $Hg[Co(CO)_4]_2$ of diynes (IV) in which X = $[CH_2]_n$ and n = 4, 5 leads to the formation of a small quantity of dimers (VIIIa; R = H, n = 4, 5)



(VIII) a. R = H, n = 4, 5; b. R = CH_3, n = 5 (X) n = 2-6 (XI) n = 5-7

and soluble polymers, whereas undeca-2,9-diyne yields only insoluble products under the same conditions[33]. The corresponding dimer from this latter compound (VIIIb: R = CH_3, n = 5) is obtained in 44% yield under conditions of high dilution[33]. The dimer (VIII) formed initially is evidently converted by polymerisation at the triple bond into a polymer of structure analogous to that suggested in Ref.32.

According to American workers[34] hepta-1,6-diyne (IV: X = $[CH_2]_3$) is converted on Ziegler — Natta catalysts by a mechanism of intra- and inter-molecular polymerisation into a polymer whose absorption spectra and chemical reactions (dehydrogenation, halogenation, and ozonolysis) suggest a cyclic polyene structure (IX):



(IX)

Under the same conditions octa-1,7-diyne and nona-1,8-diyne (IV: X = $[CH_2]_4$ and $[CH_2]_5$) give mainly cross-linked polymers. The soluble products of the polymerisation of octa-1,7-diyne contain seven-membered rings in the main chain, formed similarly to the rings in (IX), and perhaps long side-chains as a consequence of independent linear polymerisation at triple bonds. Of the monomer units in the soluble portion of polynona-1,8-diyne 25 — 30% contain one unchanged acetylenic group[34].

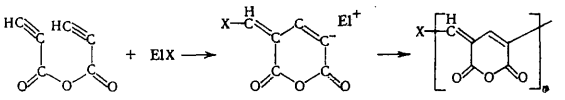
These results contradict those obtained by other investigators[33,35,36]. The polymerisation of hepta-1,6-diyne on the catalytic system $(C_2H_5)_3Al - TiCl_4$, as on the catalyst $Ni(CO)_2.2(C_6H_5)_3P$, gives a polymer having the structure (VI)[35]; but octa-1,7-diyne[33] and nona-1,8-diyne[33,36] form small amounts of cyclic trimers (X) and (XI) together with soluble and insoluble polymers. Since the infrared and nuclear magnetic resonance spectra of the trimers were identical with those of the polymers, the polymerisation of non-conjugated alkadiynes on Ziegler — Natta catalysts was supposed[33,36] to involve polycyclotrimerisation.

The copolymerisation of hepta-1,6-diyne with phenylacetylene probably yields a structure in which (VI) and $CH{:}C(C_6H_5)$ units alternate[35].

As with the polydimethylbutadiyne discussed above structure (V(should be characterised by migration of a hydrogen atom from the methylene side-group into the main-chain, which is responsible for the ready oxidisability of the resulting structure of type (IIIc). In fact, if freshly isolated polyhepta-1,6-diyne contains ~2% of oxygen, subsequent treatment and storage lead to an increase in the oxygen content to 10% and a loss of solubility by the polymer[35].

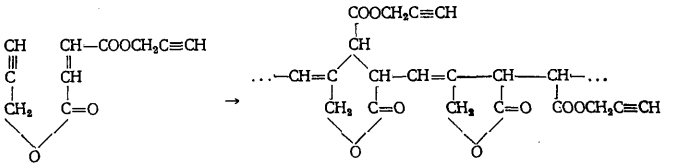
Acetylenic α-carboxylic acid anhydrides of general formula R.C:C.CO.O.CO.C:C.R (R = H, Alk, Ar) in the presence of anionic catalysts in an inert organic solvent at 50 — 100°C give black polymeric powders; these are insoluble in water and in most organic solvents but soluble in dimethylformamide[37]. The yield of polymer (3 — 92%) increases with rise in temperature and increase in duration of the process. In dimethylformamide halide ions are active catalysts — even such a weak nucleophile as the chloride ion[38].

The polymerisation of propiolic anhydride (IV: X = CO.O.CO) involves an intramolecular cyclisation step by a mechanism analogous to that discussed above for hepta-1,6-diyne:



where El = Na, K and X = CNS, CN, Hal. Contamination with propiolic acid inhibits polymerisation and depresses the molecular weight of the resulting polymers[37-39]. Acetylenic α-carboxylic acid anhydrides do not undergo polymerisation with cationic, radical, or thermal initiation (with respectively the ether complex of boron trifluoride, benzoyl peroxide, and a toluene solution at 100°C)[39].

Diprop-2-ynyl maleate (IV: X = $CH_2.O.CO.CH{:}CH.CO.O.CH_2$), in the presence of radical initiators in bulk and in solution at 70 — 130°C, is converted by inter- and intramolecular interaction between double and triple bonds into a polymer containing lactone units in the main chain[40]:



Diethynylarenes can be regarded as monomers intermediate in structure and properties between conjugated and non-conjugated diynes. A study of the crystal optics and spectra in the solid-phase polymerisation of single crystals of *p*-diethynylbenzene (IV: X = *p*-C_6H_4), initiated by ultraviolet radiation and by cobalt-60 γ-rays at ~20° and 77°K, has shown[41-43] that the polymer chains grow along a definite axis (N_p) of the refractive-index ellipsoid of the monomer crystal, which forms an angle of about 53° with the plane of the benzene rings.

Polymerisation involves predominantly one acetylenic group in each *p*-diethynylbenzene molecule (Fig.2). The chain evidently grows "head to tail", since a "head to head" construction requires that the inner carbon atoms of the triple bonds should come closer together, which is hardly possible in a crystal.

The reason why the crystal lattice of the monomer remains undisturbed is that the acetylenic groups of different molecules are close together, and the regrouping of atoms required for polymerisation is accomplished both by the formation from a triple bond of a longer double bond and also perhaps by some displacement of the molecules or deflection of acetylenic groups. These displacements accompanying polymerisation lead to the accumulation of mechanical stresses near the end of the polymer chain in the crystal, which causes the chain to terminate. The mechanical stresses produced may also be responsible for the absence of branching in the growing chain and the participation in polymerisation of only one acetylenic group from each molecule.

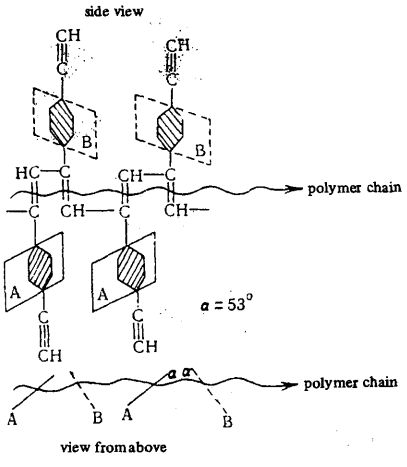


Figure 2.

Polymers of different structure are obtained when the process is conducted in solution or in a melt, as with the polymerisation of conjugated diynes.

The thermal (100 — 300°C) or catalytic polymerisation of *p*-diethynylbenzene, or its copolymerisation with phenylacetylene, diphenylacetylene, and several other acetylenic derivatives, yields insoluble and infusible polymers, probably of planar or three-dimensional structure[44-47].

In the presence of cobalt and other transition-metal complexes, diethynyl compounds (IV: X = $[p\text{-}C_6H_4]_n$, $p\text{-}C_6H_4.El.C_6H_4\text{-}p'$; n = 1 — 3, El = O, Se, etc.) in bulk or solution form by polycyclotrimerisation polymers with aromatic groups in the main chain[48-50].

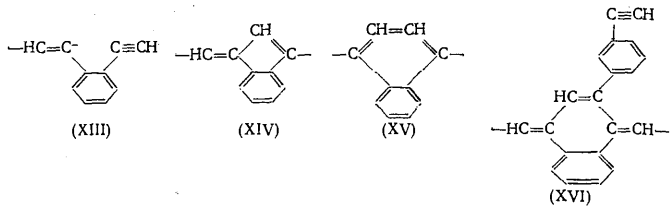
The copolymerisation of mono- and di-ethynyl derivatives enables the degree of branching in the products to be controlled. Copolycyclotrimerisation can in general be represented by the scheme

$$HC{\equiv}C{-}X{-}C{\equiv}CH + HC{\equiv}CR \rightarrow \left[\begin{array}{c} -Ar- \\ | \\ R \end{array}\!\!\begin{array}{c} \\ \\ \end{array}\!\!\begin{array}{c} -Ar- \\ \\ \end{array}\right]_n$$

(XII)

The actual structure is probably more complicated than (XII). Thus a study by infrared spectroscopy and ozonolysis of the copolymerisation of *p*-diethynylbenzene with phenylacetylene on the tri-isobutylaluminium — titanium tetrachloride catalytic system has established[51] that the soluble copolymerisation products contain polyene segments together with phenylene fragments, independently of the initial molar ratio of monomers and components of the catalytic system.

A polymer consisting of the units (XIII) — (XVI)[52]



has been obtained by coordination, radical, and cationic polymerisation of *o*-diethynylbenzene (IV: X = $o\text{-}C_6H_4$)—on the systems $R_2AlCl - TiCl_4$, $R_3Al - TiAcac$, $R_2AlCl - TiAcac$, and $RAlCl_2 - TiAcac$ (R = C_2H_5; Acac = acetylacetonate); isobutyronitrile; and titanium tetrachloride respectively. The polymer obtained in the presence of titanium tetrachloride contained no cyclic groups; with radical and coordination polymerisation the degree of cyclisation of the polymer was respectively 30% and 50 — 70%. The polymer evidently consists mainly of (XIII) and (XIV) units, and the chain grows by "head to head" addition — e.g. (XV), (XVI).

IV. SYNTHESIS OF ORGANOMETALLIC POLYMERS BY POLYADDITION

The method for obtaining linear organometallic polymers is based[53-55] on the quite easy addition to a carbon — carbon triple bond of hydrides of Group IV elements in which all but two hydrogen atoms have been substituted by organic groups. The polyaddition of the "dihydrides" RR′ ElH_2 to αω-diynes can be represented by the scheme

$$n\,RR'\,ElH_2 + n\,HC{\equiv}C{-}X{-}C{\equiv}CH \rightarrow n\left[\begin{array}{c} R \\ | \\ H\text{-}El\text{-}CH{=}CH{-}X{-}C{\equiv}CH \\ | \\ R' \end{array}\right] \rightarrow$$

(XVII)

$$\left(\begin{array}{c} R \\ | \\ -El-CH{=}CH{-}X{-}CH{=}CH- \\ | \\ R' \end{array}\right)_n$$

(XVIII)

where R, R′ = Alk, Ar; El = Si, Ge, Sn; X = $[CH_2]_n$, $p\text{-}C_6H_4$, ElRR′. Since a triple bond is considerably more reactive than a double bond under the conditions of synthesis, the intermediate compound (XVII) probably passes into the polymer (XVIII)[55]. The properties of the resulting polymers (high decomposition temperatures, their infrared spectra, electrical conductivities, and activation energies of conduction) indicate that *d*-orbitals of the elements are involved in chemical bond formation[54].

---o0o---

The information surveyed above shows that polymers varying widely in structure — linear (with polyene and cumulene units), cyclolinear, ladderlike, and three-dimensional — can be obtained from diynes depending on the nature of the monomer, the catalyst, and the conditions of polymerisation.

Since diacetylenic derivatives are able to form polymeric products not only by addition polymerisation at the carbon — carbon triple bonds but also in other ways — the most important of which are addition of unsaturated

compounds (1, 3- and 1, 4-cycloaddition[56,57]) and oxidative dehydropolycondensation[58]—further study of the reactions of diynes leading to the formation of polymers of diverse structure is desirable and promising.

Internal Reflection Spectroscopy. Applications in Chemistry and Industry

V.I.Yakutin and O.G.Strukov

Published information on the application of internal reflection spectroscopy (IRS) in chemistry and industry is systematically discussed, and the theory of IRS is briefly reviewed. The apparatus and experimental techniques are described. 297 References.

I. INTRODUCTION

Many papers dealing with the application of internal reflection spectroscopy (IRS) in chemistry and in related areas of science and industry have appeared in recent years.

The importance of IRS stems primarily from the fact that systems which are difficult or impossible to study by absorption methods can be examined by this method. In contrast to absorption methods, which rely on the transmission of light through the experimental medium, IRS is based on the phenomenon of total internal reflection.

The principle of the method is the following: during total internal reflection, a beam of light can penetrate from the optically denser into the optically less dense medium to a depth of the order of one wave length. If the less dense medium is absorbing, the beam is attenuated and reflection is not total. If the experimental medium is strongly absorbing, its attenuated total reflection (ATR) spectrum can be obtained by measuring with a suitable spectrometer its reflectivity R ($R = I/I_0$, where I_0 is the intensity of the incident light and I is the intensity of the reflected light).

Since total internal reflection does not involve any loss of radiant energy, the method known as multiple attenuated total reflection (MATR)† can be used to measure the spectra of very weakly absorbing media such as thin films and monomolecular layers.

The internal reflection (IRS) spectra of bulk materials, measured under standard conditions, are very similar to their transmission spectra, and in the case of very thin layers the two types of spectrum are practically identical. Hence, IRS spectra can be interpreted in much the same way as transmission spectra. Furthermore, IRS spectra often yield more detailed information on the structure of the sample than transmission spectra.

† OPO and MOPO are the Russian terms for the IRS methods known in English as ATR and MATR (attenuated total reflection and multiple attenuated total reflection). Non-Russian publications sometimes refer to FTR (frustrated total reflection), which is best rendered in Russian as NPVO. The term FMIR (frustrated multiple internal reflection), often encountered in the Western literature, is synonymous with MATR. The physical significance of the methods used in IRS is perhaps most clearly indicated by the terms ATR and MATR (in Russian, OPO and MOPO).

Almost the whole of the spectrum, from ultraviolet to far infrared, can now be explored by IRS.

In practice, the most important results have been obtained by i.r. IRS. The availability of commercial i.r. spectrometers with suitable attachments has greatly increased the scope of i.r. IRS: in particular, chemical, physicochemical, and biochemical processes have been investigated directly in media hitherto inaccessible by conventional methods.

Because its sensitivity and (in some cases) its precision are higher than those of i.r. transmission spectroscopy, i.r. IRS has been used to investigate surfaces, and it has also been applied in analytical procedures. It is now widely used in chemical and related industrial practice as an efficient and reliable method of process control.

The use of total internal reflection to study optical properties of materials is not an entirely new approach. As early as 1914, Mandel'shtam[1] and, somewhat later, Baryshanskaya[2] had used the phenomenon of total internal reflection to investigate fluorescence in thin layers, relying on Eikhenval'd's theoretical model[3]. A much more recent review of the possibilities offered by this method has been published by Hirschfeld[4].

Taylor and Glover[5] used total internal reflection to investigate the spectrum of an aqueous solution of potassium permanganate, and Korobko-Stefanov[6] discussed the advantages of this method in studies of strongly absorbing media.

However, the widespread penetration of IRS into research techniques began in the 1960's, when the remaining theoretical and experimental difficulties were finally overcome.

Unfortunately, existing Russian reviews of the practical application of IRS [7,8] are lacking in both breadth and depth. The only bibliography of the subject[8] dates back to 1967, and is therefore wholly inadequate.

Many review articles have been published outside the Soviet Union[9-17], but none of these consider work published since 1967. However, the number of publications has increased very rapidly in the last few years, and the scope of IRS has grown very significantly. None of this recent work is dealt with in existing reviews, whether Russian or foreign.

The aim of the present review is to discuss as fully as possible the applications of IRS in chemistry and in related areas of science and technology, and to familiarise the reader with the underlying theory, the apparatus, and the experimental methods.

II. THEORETICAL BASIS OF INTERNAL REFLECTION SPECTROSCOPY

Total internal reflection occurs when a light beam strikes the boundary between a medium of high optical density (n_1) and a medium of lower optical density ($n_2 < n_1$) at an angle greater than the critical angle of incidence (θ_c).[18] The critical angle is defined by the expression

$$\sin\theta_c = n_{21} \qquad (1)$$

where n_{21} is the relative refractive index ($n_{21} = n_2/n_1 < 1$), and n_1, n_2 are the absolute refractive indices of the two optically transparent media.

The condition for total internal reflection is written

$$\theta > \theta_c = \arcsin n_{21}. \qquad (2)$$

However, as pointed out by Newton[19], the light penetrates into the optically less dense medium during total internal reflection.

This optical penetration effect, which could not be explained by the corpuscular theory of light, is now clearly understood in terms of the electromagnetic theory.

As pointed out by Eikhenval'd[3], the electromagnetic field associated with the light wave does not suffer a discontinuity at the boundary between the two media during total internal reflection: it penetrates from the medium n_1 into the medium n_2, where it decays exponentially. The decreasing amplitude E of the electrical oscillations of the light wave in the second medium is given by the expression

$$E = E_0 e^{-\gamma z} \qquad (3)$$

where $\gamma = 2\pi(\sin^2\theta - n_{21}^2)^{1/2}/\lambda_1$, E_0 is the amplitude at the interface, z is the distance from the interface into the medium of lower refractive index, λ_1 is the wave length of the light in the denser medium.

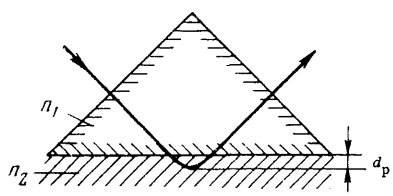

Figure 1. Penetration of light into the medium of refractive index n_2 during total internal reflection (d_p is the depth of penetration).

We must stress that in total internal reflection the intensity of the reflected light (I) is equal to the intensity (I_0) of the incident light: the penetration of the light into the second medium does not cause any loss of radiant energy. According to Eikhenval'd, the incident beam "strays into the second medium" where it follows a curvilinear path "before re-emerging, unaltered, in the first medium as the reflected beam" (see Fig. 1).

Defining d_p as the depth of penetration for which the amplitude E decreases by a factor of e, we obtain

$$d_p = \frac{\lambda_1}{2\pi(\sin^2\theta - n_{21}^2)^{\frac{1}{2}}} \qquad (4)$$

Examination of Eqn. (4) shows that: 1) for angles $\theta \gg \theta_c$ the depth of penetration is less than one wave length, 2) for $\theta = \theta_c$ the depth of penetration is very large, 3) the depth increases with critical angle, and 4) it increases with the wave length.

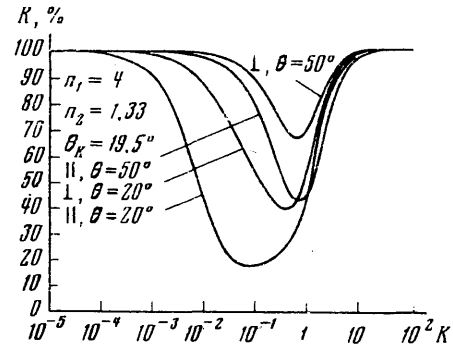

Figure 2. Plots of R against K for different values of θ and for different polarisations.

If the light penetrates into an absorbing medium, then $I \neq I_0$. In this case the reflectance R depends not only on the absorption coefficient K, but also on θ, n_{21}, and λ in Eqn. (4). The functional dependence, as shown in Fig. 2, is very complicated. The variation of R with K, θ, n_{21}, and polarisation of the light can be calculated in two ways. One method is to express the reflectivity as a function of the above variables.

The calculations are usually made by applying the Fresnel formulae, suitably modified for attenuated total reflection conditions. The modifications consist in replacing the refractive index n_2, which adequately characterises the optical properties of a transparent medium, by a complex refractive index[23] n_2^*, which characterises the optical properties of the absorbing medium:

$$n_2^* = n_2(1 - iK), \qquad (5)$$

where n_2 and K are the effective refractive index and the effective absorption coefficient.

The relationship between K and α (the absorption coefficient in the Beer — Lambert law) is given[24] by

$$\alpha = \frac{4\pi n_2 K}{\lambda_0}, \qquad (6)$$

where λ_0 is the wave length of the light in a vacuum, related to the wave length in a denser medium by the expression $\lambda_0 = \lambda_1 n_1$.

For ATR conditions, the Fresnel formulae become[25]

$$R_\perp = \left| \frac{(n_{21}^{*2} - \sin^2\theta)^{\frac{1}{2}} - \cos\theta}{(n_{21}^{*2} - \sin^2\theta)^{\frac{1}{2}} + \cos\theta} \right|^2 \qquad (7)$$

$$R_\parallel = R_\perp \left| \frac{(n_{21}^{*2} - \sin^2\theta)^{\frac{1}{2}} - \sin\theta\tan\theta}{(n_{21}^{*2} - \sin^2\theta)^{\frac{1}{2}} + \sin\theta\tan\theta} \right|^2, \qquad (8)$$

where the subscripts $\perp$ and $\parallel$ indicate that the vector of the electrical oscillations is perpendicular ($\perp$) or parallel ($\parallel$) to the plane of incidence.

Calculations of R as a function of K, θ_c, and θ, and also of polarisation, have been reported and discussed in a number of papers[9,24-29]. We shall confine ourselves to a consideration of some general rules which relate specifically to the practical exploitation of the ATR method.

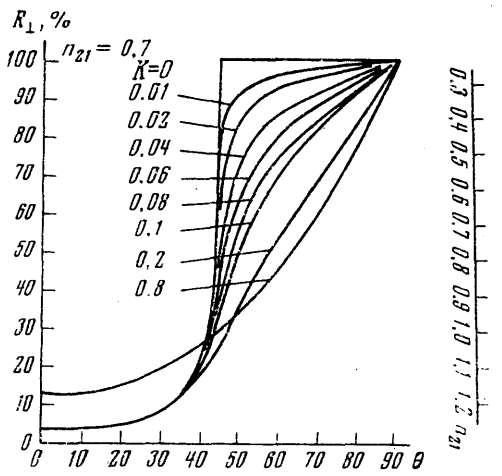

Figure 3. $R_\perp$ as a function of K and θ.

It is evident from Figs. 2, 3, and 4 that the method offers maximum sensitivity in the range $0 < K < 0.2$, which includes the i.r. absorption bands of most organic compounds.

We note also that the reflectivity depends not only on K, but also on θ, θ_c, and polarisation: R decreases as θ decreases and as θ_c increases.

Other conditions being equal, $R_\perp < R_\parallel$.

R falls off sharply as $\theta \to \theta_c$; in other words, the conditions for maximum sensitivity and therefore precision of the ATR method are found[26,28] close to the critical angle of incidence, the best choice of which depends on the value of K.[26]

However, the IRS bands observed at the optimum critical angles are distorted relative to the transmission spectra: they are broadened towards the long-wave end of the spectrum, and their peaks are shifted towards lower frequencies[7,9-11,13,29-31]. Yet, it would be desirable to obtain IRS spectra as similar as possible to the corresponding transmission spectra.

Calculations based on the Fresnel formulae have shown that undistorted IRS spectra can be obtained from very weakly absorbing samples only at angles $\theta \gg \theta_c$.[29,30,32]

The values of R for weakly absorbing samples can be calculated by means of simple expressions, derived from Eqns. (7) and (8) by expanding them into a power series and retaining terms up to K^3:[29,32]

$$R_\perp = 1 - \alpha \cdot d_{\text{eff}\perp} \quad (9)$$

$$R_\parallel = 1 - \alpha \cdot d_{\text{eff}\parallel} \quad (10)$$

where d_{eff} is an effective thickness having the same order of magnitude as the wave length.

It follows from Eqns. (9) and (10) that the role of the effective thickness is analogous to that of the optical path length in transmission spectroscopy, and that this parameter can be calculated from the expressions[9,20,29,33,34]:

$$d_{\text{eff}\perp} = \frac{n_{21}\cos\theta\lambda_1}{\pi(1-n_{21}^2)(\sin^2\theta - n_{21}^2)^{\frac{1}{2}}} \quad (11)$$

$$d_{\text{eff}\parallel} = \frac{n_{21}\cos\theta(2\sin^2\theta - n_{21}^2)\lambda_1}{\pi(1-n_{21}^2)[\sin^2\theta(1-n_{21}^2) - n_{21}^2](\sin^2\theta - n_{21}^2)^{\frac{1}{2}}} \quad (12)$$

It is not hard to show that Eqns. (9) and (10) are analogues of the Lambert – Beer equation for the case of very weak absorption[9,35], and therefore they can be re-cast in the form

$$R = e^{-\alpha d_{\text{eff}}} \quad (13)$$

Thus, the Lambert – Beer law is formally applicable to the undistorted IRS spectra[26,32], and we may use these IRS spectra for quantitative measurements in the same way as transmission spectra.

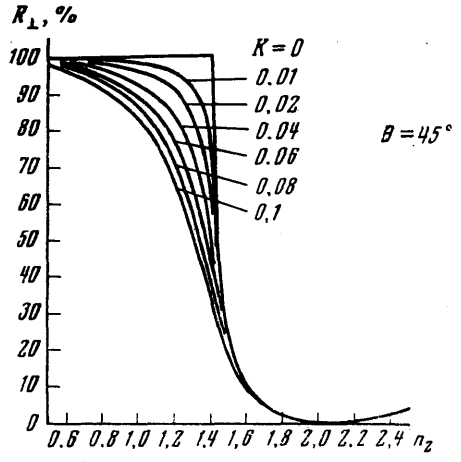

Figure 4. $R_\perp$ as a function of K and n_2.

Although these generalisations of the Fresnel equations provide a theoretical foundation for the practical application of the ATR method, they do not give a physical picture of the interaction of light with the absorbing medium. It should also be noted that the use of Eqns. (7) and (8) in daily laboratory work is complicated by the need for electronic computation[20].

Hence, an alternative solution of the problem could be attractive if it relied on simple mathematical expressions describing the mechanism of light absorption and the main features of IRS spectra in cases of practical interest ($0 < K < 0.2$) without resorting to the use of computers.

Let us consider the case of weak absorption. As stated above, in this case R can be found from Eqns. (9) – (12), whence it follows that d_{eff}, and therefore also n_{21} and θ, are independent of α. From the same equations we can show that the product $\alpha . d_{\text{eff}}$ is simply the fraction of radiant energy absorbed by the medium of lower refractive index. Thus, the behaviour of the electric field in a weakly absorbing medium can be discussed independently of α.[9,20,29,32-34]

According to Harrick[20], the absorption a, i.e. the interaction between the light beam and the weakly absorbing medium over the whole of the penetration path, can be described by the equation

$$a = \alpha \frac{n_{21}}{\cos\theta} \int_0^\infty E^2 dz \qquad (14)$$

where $E = E_0 \cdot e^{-\gamma z}$ is the amplitude of the electric field in the less dense medium relative to the amplitude of the incident light.

From Eqn. (14) we find

$$\frac{n_{21}}{\cos\theta} \int_0^\infty E^2 dz = \frac{a}{\alpha} \qquad (15)$$

where the expression on the left-hand side denotes the effective thickness[9,20,33,34]

$$d_{\text{eff}} = \frac{n_{21}}{\cos\theta} \int_0^\infty E^2 dz \qquad (16)$$

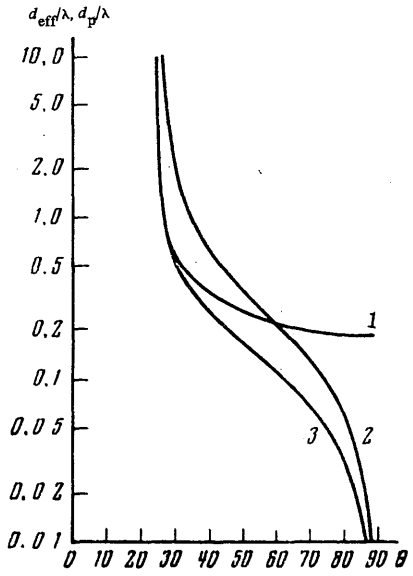

Figure 5. Relative depth of penetration and relative effective thickness as a function of θ (n_{21} = 0.423): *1)* d_p/λ, *2)* $d_{\text{eff}_\parallel}/\lambda$, *3)* $d_{\text{eff}_\perp}/\lambda$.

It follows from Eqn. (14) that the absorption depends not only on the value of α, but also on the value of the integral, which defines the total intensity of the light over the whole of the penetration path. Evidently, this intensity is a function of the amplitude E_0 at the phase boundary on the side of the less dense medium. The value of E_0 as a function of the angle of incidence and of the polarisation of the light can be calculated from the equation for the standing electromagnetic wave produced at the phase boundary on the side of the denser medium by the superposition of the incident and the reflected light. These calculations, carried out by Harrick[20,33,34], have shown that: 1) E_0 is a maximum for $\theta = \theta_c$; 2) E_0 decreases as θ increases; 3) E_0 vanishes for $\theta = \pi/2$; 4) E_0 vanishes for $E_{0\perp} < E_{0\parallel}$.

We shall now discuss the dependence of d_{eff}, and therefore also of the absorption, on the factors which enter into Eqn. (16).

We have two cases, depending on whether the thickness d of the absorbing layer is greater or smaller than the depth of penetration. For "thick" layers ($d > d_p$) we obtain the following formula [from Eqn. (16)] for the effective thickness:

$$d_{\text{eff}} = \frac{n_{21} E_0^2 d_p}{2\cos\theta} \qquad (17)$$

It follows from Eqn. (17) that the effective thickness of "thick" layers depends on four factors. The physical significance of the first three (n_{21}, E_0, and d_p) has already been discussed; the fourth ($1/\cos\theta$) determines the area over which light interacts with the sample.

Fig. 5 shows the variation of d_{eff} (which determines the interaction between the tailing electric field and the weakly absorbing medium) with angle of incidence and with polarisation. It is evident that d_{eff} is greatest near the critical angle, and reaches a maximum [see Eqn. (17)] when the refractive index n_1 of the internal reflection element (IRE)‡ is very close to the true refractive index n_2, i.e. when $n_{21} \to 1$. Hence, to obtain the strongest possible bands in IRS spectra we must choose an IRE with a refractive index close to that of the experimental medium (n_2) at the maximum of the dispersion curve (Fig. 6), and use near-critical angles of incidence[26]. Under these conditions the quantities n_{21}, E_0, and d_p, which determine d_{eff}, have their maximum values.

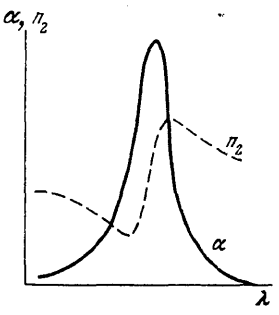

Figure 6. Absorption coefficient α (full line) and refractive index n_2 (broken line) as a function of wave length in the region of the absorption band.

As θ increases, E_0 and d_p fall off, causing a decrease in d_{eff} and hence in absorption[36]. When $\theta = \pi/2$, $E_0 = 0$, and therefore $d_{\text{eff}} = 0$ (i.e. there is no absorption). We note that when $\theta = 45°$, $d_p = (d_{\text{eff}_\perp} + d_{\text{eff}_\parallel})/2$.

It has been shown[20,33-35] that formulae (9) — (13), which are strictly applicable only to weak absorption (they can be obtained from (14) and (17) [20]), can in fact be used over a fairly wide range of K values ($0 < K < 0.2$), since they differ by only 10% from the exact Fresnel formulae when R falls to 10% (see Fig. 2).

‡ In IRS the optically transparent, denser medium is sometimes called the IRE.

Eqn. (17) can be used to explain the difference between the IRS spectra obtained with "thick" layers and the transmission spectra of the same materials. Since d_p increases with λ, the absorption also increases with λ. Hence, the intensity of the bands in the IRS spectra increases with wavelength[10,11,20,29,33,34].

As stated above, IRS spectra obtained with θ close to θ_c appear distorted. To identify the cause of the distortion we turn to Fig. 6, whence it is evident that n_2 (as well as α) varies with wave length. The largest value of n_2 is found on the long-wave side of the absorption band. Since the critical angle reaches a maximum and the difference $\theta - \theta_c$ (for a given θ) reaches a minimum on the long-wave side of the absorption peak, it is not surprising to find an increase in n_{21}, E_0, and d_p (and therefore an increase in absorption) on the long-wave side of the peak. As a result, the absorption maximum is shifted towards lower frequencies, and the band shows some broadening in the same direction[7,9-13,29-31].

Obviously, the distortion of the IRS spectra arises from the fact that the ATR method is sensitive to changes in both the optical constants K and n_2. This suggest that IRS can be used to evaluate these constants[24,25,28,37-49].

In order to obtain an IRS spectrum free from the distortion associated with anomalous dispersion we must choose conditions such that d_{eff} is not sensitive to changes in the coefficient n_2. It can be seen from Fig. 5 that when the angle θ is much greater than θ_c, i.e. when the difference $\vartheta - \theta_c$ is large, the fluctuations in this difference due to changes in the critical angle have very little influence on the depth of penetration. The same can be said of E_0, which is insensitive to changes in θ_c if $\theta \gg \theta_c$, as demonstrated by Harrick[9]. Therefore, it is essential to work with an angle of incidence much greater than the critical angle if the aim is to obtain an IRS spectrum almost identical to the transmission spectrum. However, small differences in frequency (of the order of a few cm^{-1}) are nevertheless to be expected[50].

Starting from the refractive index n_2 of the experimental medium, measured by normal refractometric methods, the expected absorption coefficient K, and the condition[29] $K/(\sin^2\theta - n_{21}^2) \ll 1$, it is possible to choose an angle of incidence and an IRE refractive index such that the IRS spectrum is free from the distortion associated with anomalous dispersion. We can readily show that this condition is satisfied for small K values, and as K increases for $\theta \gg \vartheta_c$.

However, the IRS spectrum plotted at large angles of incidence has a low intensity[7,9-11,30,35,51]. Stronger bands can be obtained by the MATR method, which produces spectra both undistorted and intense[7,9-11,30,35,52-56].

In this method, d_{eff} is increased in proportion to the number of reflections (N), and therefore the absorption is increased by a factor of N. Evidently, Eqn. (13) for the MATR method must be re-written[20,35]

$$R^N = e^{-\alpha \cdot d_{eff} N} \qquad (18)$$

Clearly, by adopting the MATR method we can not only increase the intensity of the IRS method but also use it at higher sensitivity.

We shall now turn to the case of "thin" layers ($d < d_p$). In this case the electric field penetrates beyond the thin absorbing layer into the underlying optically transparent medium§. Since the layer is very thin, the electric field may be assumed to be constant within the film[20]. Then, using Eqn. (16), we obtain

$$d_{eff} = \frac{n_{21} E_0^2 d}{\cos\theta} \qquad (19)$$

Thus, with "thin" layers as with "thick" layers the parameter d_{eff} depends on four factors. We can evaluate d_{eff} for a "thin" layer using the formulae proposed by Harrick[9,20,33,34]¶:

$$d_{eff\perp} = \frac{4n_{21} \cdot \cos\theta \cdot d}{1 - n_{31}^2} \qquad (20)$$

$$d_{eff\parallel} = \frac{4n_{21}\cos\theta\,[(1 + n_{32}^4)\sin^2\theta - n_{31}^2]\,d}{(1 - n_{31}^2)[(1 + n_{31}^2)\sin^2\theta - n_{31}^2]} \qquad (21)$$

where $n_{21} = n_2/n_1$; $n_{32} = n_3/n_2$; $n_{31} = n_3/n_1 < 1$ are the relative refractive indices. Formulae (20) and (21) are accurate when

$$\frac{2\pi d}{\lambda_1} < 0{,}1 \text{ and } K_2 < 0{,}1$$

Eqns. (19) – (21) lead to a number of generalisations applicable to IRS spectra obtained with "thin" layers.

It follows from Eqn. (19) that d_{eff} is independent of the depth of penetration. Hence, the intensity of the bands in the IRS spectra of "thin" layers does not increase with wave length. Furthermore, we can see from Eqns. (20) and (21) that d_{eff} is limited for $\theta = \theta_c$, where θ_c = arc sin n_3/n_1. Clearly, the IRS spectrum of a "thin" layer—unlike the spectra of "thick" layers—is free from anomalous dispersion distortions and is practically identical to the transmission spectrum.

It is important to note that the IRS spectrum of "thin" layers can be obtained even when the true refractive index of the thin layer is greater than the refractive index of the IRE. Furthermore, and in contrast to "thick" layers for which $d_{eff\parallel} > d_{eff\perp}$, the parameter $d_{eff\parallel}$ can be greater or smaller than $d_{eff\perp}$ in "thin" layers, depending on whether the ratio n_{32}^4/n_{31}^2 in Eqn. (21) is greater or smaller than unity.

It follows from (20) and (21) that d_{eff} for "thin" layers can be much greater than the physical thickness of the layer if $n_3/n_1 \to 1$. By using MATR, the sensitivity of the method can be dramatically increased[58] to $\sim 10^{-14}$ mole.

We had previously stated that light polarised in a parallel direction interacts more strongly with the absorbing medium than light polarised at right angles[59], which is true only for isotropic media. In anisotropic media the interaction will depend on the orientation of the dipoles. Hence, ATR and MATR methods can be used to study anisotropic media[20,25,27,60-62].

III. APPARATUS AND EXPERIMENTAL TECHNIQUES

The apparatus used to record IRS spectra consists of a standard spectrophotometer with a special attachment in the cell compartment. The optical system of the attachment is designed according to the optical and geometrical features of the IRE and of the spectrometer. Depending on the IRE, the attachment can provide single or multiple reflections. In single-reflection attachments the IRE may

§ The theory of multilayer systems, with reference to the ATR method, has been discussed by Hansen[57].

¶ Formulae (20) and (21) are given[20] without proof, but a derivation of these formulae was published later[25]. However, formula (21) is somewhat different from the corresponding formula obtained in Ref. 25.

be in the form of a prism[15,54,63-65] (mainly for work in the u.v. and visible regions), a hemisphere, or a hemicylinder[24,35,37,66-71] (for i.r. measurements).

The use of a hemicylinder is convenient because it allows an arbitrary choice of angle of incidence and hence it can replace several prisms with different angles of incidence. Furthermore, it is easy to obtain a parallel beam within the hemicylinder[9,24,25,35,68,70] over a wide range of angles of incidence, and therefore the angle of incidence can be calculated unambiguously and with great precision (~0.5′)[66]. This level of precision is essential, for example, in determinations of optical constants by the two-angle method[25,46].

Attachments using a hemicylindrical IRE have been designed for the IKS-14,[67] Hilger H-800,[68] and UR-20 [70] spectrophotometers. The operation of these attachments is easily understood from Fig. 7.

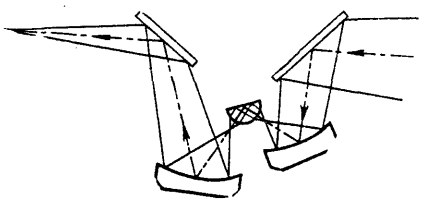

Figure 7. Single reflection attachment.

Single-reflection attachments have one serious drawback: they cannot produce intense, undistorted spectra. This drawback is overcome in multiple-reflection attachments, which can accept IRE's of different geometrical configurations such as plates with fixed or variable angles of incidence, and with single[10,11,15,72-77] or double[9,15,20,78] light transmission. IRE's can be trapezoidal[79] or rosette-shaped[80], with multiple light transmission, or in the form of a light-guide[15,81]. An IRE with a curved surface has been described[82,83]. The most commonly used of these elements is the multiple internal reflection (MIR) plate with fixed angle of incidence and single light transmission. This is because both the construction and the calculations are simpler with these plates. In the simple geometry of the plate, the number of reflections is easily calculated:

$$N = \frac{L}{t}\cot\theta \qquad (22)$$

where L is the length and t is the thickness of the plate.

It follows from Eqn. (22) that the number of reflections increases as the angle of incidence decreases. The number of reflections increases in proportion to the length, and in inverse proportion to the thickness of the plate. However, it should be remembered that the length of the plate cannot be increased indefinitely without total extinction of the light beam as a result of optical imperfections in the polished surfaces. The scattering by these imperfections is a function of wave length, and is most pronounced in the u.v. region[58]. Hence, the reflectivity of the plate depends on the quality of its optical finish[35,54]. The thickness of the plate, also, is limited, and cannot be decreased below the width of the spectrometer slit[10,11,35].

It should be noted that any divergence of the light beam within the plate causes ambiguity in the angle of incidence[9,35] even though it may be beneficial in ensuring total illumination of the surface of the plate[10,11].

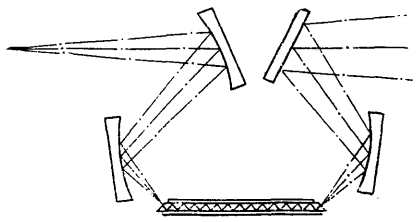

Figure 8. Multiple reflection attachment.

MIR plates are now commonly used in commercial attachments (see Fig. 8), made both in the Soviet Union and abroad. Attachments for the IKT-14,[71] UR-20 [84,85], and various Perkin — Elmer spectrometers[54-56] have been described in detail.

Attachments using an MIR plate as the IRE are used in the u.v. and the visible region[54], and also in the i.r. region[76] and in the far infra-red[86]. MIR plates giving up to 50 — 300 reflections have been constructed[87-89].

Cells for special investigations have been developed using MIR plates. Some of these, produced[54,55] by the firm of Wilks Scientific Corporation (USA), are particularly interesting because they are equally suitable for analytical work and for physicochemical research.

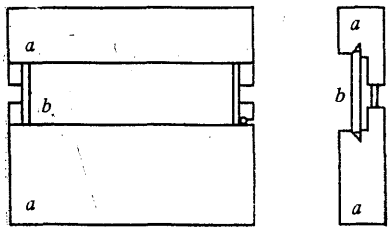

Figure 9. Cell for viscous liquids: (*a*) Teflon holder, (*b*) IRE plate.

Fig. 9 shows a cell for the analysis of high-boiling compounds (lubricants, oils, adhesives, and other viscous materials). The cell consists of a Teflon holder and an IRE in the form of a plate. The IRS spectrum is obtained by spreading the material on the surface of the plate. 25 reflections are possible.

The microcapillary cell (Fig. 10) is used to examine fractions isolated by gas — liquid chromatography. It consists of a Teflon holder and two thin MIR plates, between which the substance to be analysed is placed. Because of the large number of reflections (~50), the sample size can be very small (~10^{-4} g).

The cell shown in Fig. 11 is used for liquid samples. The gap between the MIR plate and the metal holder is not critical, because the absorption does not depend on the thickness of the layer of sample.

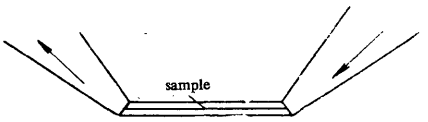

Figure 10. Micro-capillary cell.

The combined cell and reaction vessel (Fig. 12) and the flow-through cell (Fig. 13) have been designed for studies of the kinetics and mechanisms of chemical reactions[88].

In spectrophotometric studies of powders, paper, tissues, rubber, polymers, films, and various coatings, the solid-sample cell shown in Fig. 14 is used. Mechanical pressure is applied to increase the area of contact between the plate and the experimental material.

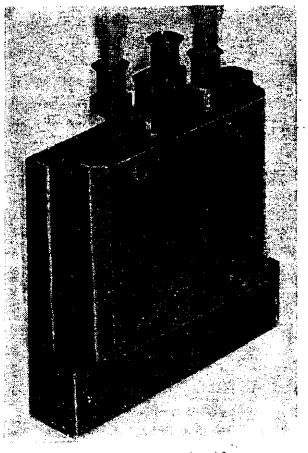

Figure 11. Liquid sample cell.

Cells for direct spectroscopic studies of aerosol particles[90], and for measurements in high vacuum[9] and at high temperatures[54,55], have also been described. Special attachments in which the IRE extends beyond the cell compartment of the apparatus have been developed for studies on large samples[10,11].

Differential spectra can be obtained, if necessary, by using single and multiple reflection cells. However, it is not always possible to compensate exactly for the differences between two IRE's. With isotropic media, the residual background absorption can be compensated with polarisers[91] or variable-area cells[54]. In addition to the various attachments, special spectrometers for IRS spectroscopy have been described[10,11,54,55,92], but in every case the essential component, which determines the quality of the spectra, is the IRE. Obviously, the material used to fabricate the IRE must have some special optical, physical, and chemical properties.

The material must have: 1) a high refractive index, so as to give undistorted spectra with samples of widely different refractive indices; 2) high purity and optical transmission, since the length of the optical path in the MIR

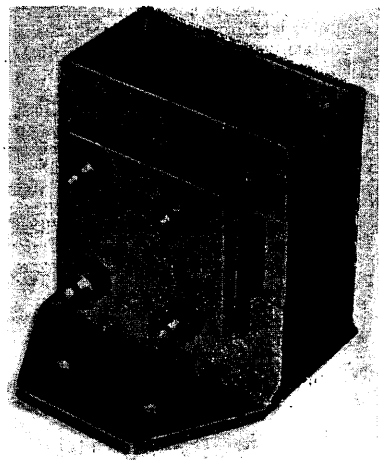

Figure 12. Reaction cell.

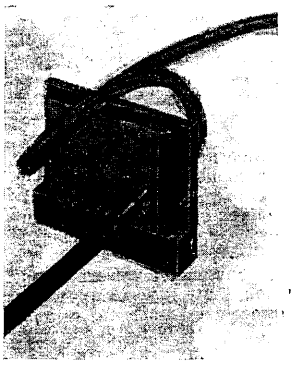

Figure 13. Flow-through cell.

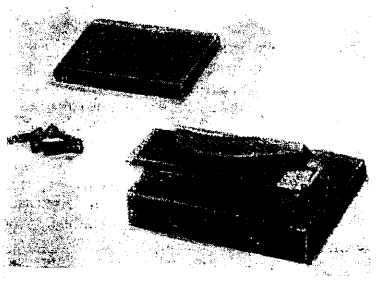

Figure 14. Solid-sample cell.

plate can be 100 mm or more; 3) high elasticity, hardness, and mechanical strength, since the IRE must not be easily deformed, scratched, or bent; 4) chemical stability, since the IRE material must not dissolve in or react with the material being analysed.

Characteristics of materials.

No.	Material	Chemical composition	n_D	θ^*_K	Spectral region, μm	Max. temp., °C	Remarks
1	Germanium		4.0	14.5	2—11.5	125	Hard, brittle, chemically stable. Used in the i.r. region.
2	Silicon		3.5	16.6	2—6.5 40—300	300	Hard, brittle, chemically stable. Used in the i.r. and far i.r. region.
3	KRS-5	42%—TlBr 58%—TlI	2.5	23.6	1—40	125	Elastic, soft, insoluble in many solvents. Sparingly soluble in water. Used in the i.r. region.
4	Irtran-4	ZnSe	2.4	24.6	2—16	300	Hard, stable, insoluble in water. Used in the i.r. region.
5	KRS-6	40% TlBr 60% TlCl	2.2	27.0	0.4—25	100	Softer,than KRS-5. Used in the i.r. region. Can be used in the visible.
6	Silver chloride	AgCl	2.0	30.0	1—20	200	Very soft, insoluble in water. Used in the i.r. region.
7	Sapphire	Al_2O_3	1.7 (above 2 at $\lambda < 0.2$ μm)	36.0	0.18—6		Very hard. Used in the u.v. and visible region.
8	Quartz (fused)	SiO_2	1.43 (1.65 at $\lambda < 0.2$ μm)	44.4	0.18—0.75		Used in the u.v. and visible region

*θ_K values calculated relative to air.

In addition, the IRE material must: 5) be easy to grind and polish, and 6) retain its transparency at high temperatures.

Because of these stringent requirements, the materials used to obtain transmission spectra are not always suitable for IRS. The literature dealing with materials for internal reflection spectroscopy is extensive[9-17,34,54-56,72,85,93]. Some properties of materials commonly used in IRS are listed in the Table.

IV. APPLICATIONS OF INTERNAL REFLECTION SPECTROSCOPY

As stated above, internal reflection spectra are qualitatively similar to transmission spectra if the distortion resulting from anomalous dispersion can be overcome. (Suitable conditions are discussed in Section II). Hence, existing data on the transmission spectra of related compounds can often be used to interpret IRS spectra. This allows IRS methods to be applied to a wide variety of problems, including the identification of various compounds, studies of their structure and reactivity, and a wide range of associated problems.

However, IRS has a number of advantages over transmission spectroscopy: it is unique in its ability to examine materials in any state of aggregation, of any consistency, and of practically any size or thickness.

1. Types of Material

The IRS method has no special advantage over transmission spectroscopy in work with liquids and some solutions, but in practically every other case it is greatly superior, and in some cases it is the only possible method.

Powders. The study of powders by i.r. spectroscopy is a very common problem. Conventional techniques (pressing into tablets with alkali halides, preparation of mulls, etc.)[94] are laborious and often unsatisfactory: they tend to contaminate the sample and to disturb its crystal structure, and chemical interaction between the sample and the matrix cannot always be avoided. Furthermore, the spectra are sometimes incomplete or otherwise unsatisfactory, due to scattering or masking by the bands of the diluent.

IRS methods are free from all these drawbacks. The only pre-treatment needed is to spread the sample on an adhesive tape[54], which is then pressed against the IRE. With amorphous powders the procedure is even simpler: the sample is deposited directly on the internal reflection plate[54]. Sands, various precipitates[95], and other fairly coarse (up to 300 μm particle size) powders have been analysed in this way, and have always yielded high-quality spectra (Fig. 15).

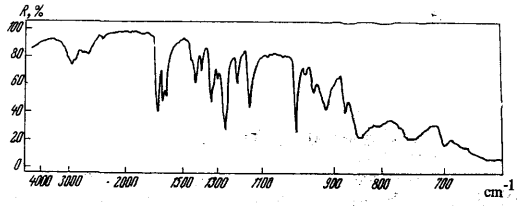

Figure 15. Internal reflection spectrum of sorbic acid powder. IRE—Ge plate (25 reflections).

Solid bodies. Solid bodies cannot be examined directly by transmission spectroscopy. A sample must first be removed, finely powdered, and examined by a standard method. In some cases (e.g. coal analysis[96]) the preparation of the sample may take up to 8 hours.

On the other hand, the study of solid bodies (including coals[97]) by IRS methods is quite straightforward: special attachments have been developed[10,11,54] for recording spectra from samples of any size.

The difficulties encountered in studying single crystals by transmission spectroscopy[98] are well known: again, this type of sample can yield IRS spectra without difficulty[60,99-103]. The IRS method is particularly effective in studies of anisotropic media: in particular, it is greatly superior to transmission spectroscopy for studying dichroism[60-62,99].

Films. The examination of fairly thick films by the classical spectroscopic methods presents a number of difficulties. Even at thicknesses of a few tens of microns[98] analysis of the film by classical methods may become impossible. In direct contrast, films are perhaps the best type of sample for IRS studies (Fig. 16). In addition to solving various problems in the physics of films[104], these methods have been used successfully for film identification[54] (including films of metal hydroxides[7,105]). Coatings on films[7] are easily analysed, including measurements of thickness[107] and composition[106,107]. IRS methods are seen at their best in the analysis of multilayer films[7,108,109], since they can yield identifiable spectra for the individual layers.

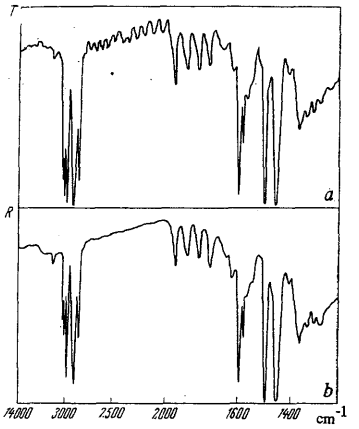

Figure 16. Transmission (*a*) and IRS (*b*) spectra of a polystyrene film. IRE—KRS-5 plate (25 reflections).

Viscous materials. Viscous materials are not easily studied by transmission spectroscopy in their natural form, yet they are almost the ideal type of sample for IRS[54]. For example, IRS spectra for a large number of adhesives have been obtained very easily[79], including industrial adhesives[110,111] and adhesive coatings[112].

Melts. Fairly complicated techniques are available for measuring the i.r. spectra of melts. They become very much simpler when IRS methods are used[113,114].

Liquids and solutions. In studies of the i.r. spectra of liquids, and some solutions, the use of IRS methods is hardly justifiable. However, the u.v. transmission spectra of liquids and concentrated solutions are almost impossible to measure. Furthermore, the scope of i.r. spectroscopy of solutions is often limited by the difficulty of finding a suitable solvent, since most solvents have strong absorption bands and therefore they can only be used over a limited region of the spectrum. Water is one of these solvents, and in many cases aqueous solutions are the only form in which the material of interest can be investigated. With biologically active substances and their model compounds aqueous solutions are vitally important because they most closely resemble natural (*in vivo*) conditions. However, the study of aqueous solutions still presents considerable difficulties[115], and several important regions of the spectrum remain inaccessible even with the thinnest available cells.

With the introduction of IRS methods the scope of aqueous i.r. spectroscopy has become much wider, and at the same time the experimental procedures have been simplified. The i.r. spectra of aqueous solutions can now be measured over practically the whole of the spectral region by using the available range of crystals (KRS-5,[115] AgCl,[116,117] Irtran-2,[118] Ge [95])†, by choosing the ATR[116-122] or the MATR[115,123,124] method as required by the problem, and by taking advantage of the most up-to-date equipment[117,119].

The possibilities and the advantages of the IRS method in comparison with the transmission method have been demonstrated by measurements on aqueous solutions of acetylcholine[125], various aminoacids[115,116,118-120], and carbohydrates[115,120,126]. IRS methods are widely used to study aqueous solutions of inorganic and organic acids and their salts[16,115,117,118,120-122,127-132], and other compounds[115,120], and also the structure of water itself[121,129,133]. IRS methods are particularly effective in studies of multiphased systems, e.g. aqueous emulsions of disperse and turbid media, etc.[95,118,120], which cannot as a rule be examined by conventional transmission methods. The IRS spectra of concentrated aqueous solutions have also been examined in the u.v. region[72,81].

The IRS technique has greatly extended the range of solvents which can be used in i.r. spectroscopy. Thus, universally acceptable solvents such as alcohols, dimethylformamide, dimethylsulphoxide, etc. can now be exploited by the i.r. spectroscopist. A comparative study[134] of the solvents most commonly used in chemistry has shown that their transmission bands are much broader in i.r. IRS spectra than in conventional i.r. absorption spectra.

2. Applications

Because of the unique features of the IRS method, its potential applications in chemistry and in related areas of science and technology are many. Some examples of the application of IRS in areas where the method appears particularly promising are discussed below.

a) Study of chemical reactions

Molecular spectroscopy is undoubtedly one of the most powerful methods of studying various types of chemical change, and important problems in chemical kinetics and reaction mechanisms. However, the scope of transmission spectroscopy in this particular area is severely limited. Thus, it is seldom possible to study a reaction without a solvent, or in concentrated solutions; unfortunately the commonest solvents are strongly absorbing, and therefore the reaction systems cannot be studied by transmission methods even in dilute solutions.

All these difficulties can be fully or partially overcome by resorting to IRS methods, whose extensive technical arsenal (various crystals with different angles of incidence and number of reflections, special reaction vessels[54,55]) allows almost any reaction to be investigated either in solution (in one of the increasing number of usable solvents[134]) or without a solvent.

A good example of the advantages of IRS over ordinary transmission methods is provided by Roberts' work[135] on

† It must be noted that KRS-5 is sparingly soluble in water, particularly in hot water[95], and that AgCl can react with aqueous solutions giving rise to corrosion of the steel parts of the cell[16,95].

reactions involving carbonium ions, based on measurements of u.v. IRS spectra. Carbonium ions absorb very strongly in the u.v., and they can be studied only at high dilution. On the other hand, they are so highly reactive that unwanted side-reactions with the solvent are almost unavoidable. For these reasons, the study of carbonium ion reactions by normal u.v. spectroscopy is not a practical proposition.

On the other hand, IRS methods have been found very effective in this case, and studies of carbonium ion reactions (including intermediates) have been successfully carried out by these methods over a range of concentration, temperature, and pressure.

Infrared IRS is widely used to study polymerisation reactions[76,136-138], including high-temperature polymerisation[138], which do not lend themselves to conventional transmission spectroscopic investigation (Fig. 17).

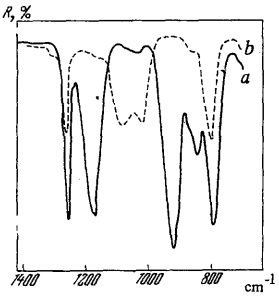

Figure 17. IRS spectra of hexamethylcyclotrisilazane during hydrolysis: (*a*) initial compound, (*b*) hydrolysis product. IRE—KRS-5 plate (25 reflections).

IRS is one of the most effective methods of monitoring surface reactions on opaque materials. For example, the effect of u.v. radiation on the stability of polymers and the effect of inhibitors on the course and the rate of reactions on polymer surfaces have been studied[139] by IRS spectroscopy. The behaviour of modifiers and other polymer additives under the influence of light has also been examined[140]. IRS has been used to study surface oxidation[141], the oxidative polymerisation reactions involved in the drying of certain oils[142], and various other processes on polymer surfaces[143].

b) Surface phenomena and adsorption

The future of IRS in the study of these important chemical problems is assured[144,145]. In particular, IRS methods are among the few which can give information on surface states in semiconductors and on their influence on the electrical properties of the surface[144]. In this case the application of the method stems from the fact that the reflectivity is a function of the electric charge at the surface, which is itself influenced by external electric fields or by adsorption. Harrick[27,53,82,146] was the first to use IRS in the study of surface states, but the method was soon adopted by other workers[147-149]. More recently, IRS has been used to study a wide range of problems in semiconductor surface chemistry, including the chemical nature and the behaviour of solid and liquid surface films formed by the action of electrolytes, during etching, etc.[73,150-157], and also adsorption processes on semiconductors[27,158].

Adsorption is the branch of chemistry where the advantages of IRS are most clearly evident, as shown by the large number of papers published on this subject. Among the most interesting are studies of the adsorption of hydrocarbons[82], fatty acid derivatives[154-159], and other organic and inorganic substances[159-161] including gases[27,158].

The various modifications of carbon are technically important as adsorbents, but the study of these materials by the traditional methods of transmission and reflection spectroscopy (particularly in the i.r. region) often presents insuperable practical difficulties arising from their very strong absorption[162] (which can exceed the absorption of organic compounds by 10^2-10^3). However, by using multiple reflection techniques in very sensitive spectrometers we can identify the functional surface groups which determine the adsorption properties of the different carbons, measure their concentration, and examine various problems bearing on the nature of the adsorption process. In particular, we can answer questions such as: how do adsorbates affect the structure of the surface, which functional groups are involved in sorption processes, what is the nature of the sorption bond, etc.[96,141,162-164].

c) Electrochemistry

The most important problems in electrochemical research are to establish the mechanism of the electrode reactions, to identify the intermediate activated states of the products formed by electron transfer, etc. Information of this type cannot be obtained directly from electrochemical measurements. Other methods, including transmission spectroscopy, are also unsuitable.

IRS, on the other hand, is ideally suited to the study of electrochemical processes *in situ*.

The theory of IRS developed by Hansen[165] for multilayer systems has been widely applied in studies of electrochemical reactions by u.v. and i.r. internal reflection spectroscopy.

The electrode for studies in the u.v. region usually consists of a glass prism or plate coated with a thin conducting layer of tin oxide[166-169], gold[149,170-172], platinum and palladium[173], or antimony[171]. For work in the i.r. region the electrode is either pure germanium[174] or germanium coated with a metallic film (e.g. gallium)[88,175].

A good example of the successful application of u.v. IRS in electrochemistry is a series of studies[166-168,173] of the electrochemical oxidation of *o*-toluidine, in which the kinetics and the mechanism of the reaction were examined under different conditions, the electrolysis products were identified on the electrode surface, and their concentration was measured. A similar study of eosin-Y has also been published[165,170,171].

Other examples of the use of IRS in the u.v. region for electrochemical studies include an investigation of discrete states at the electrode — solution interface[147,176,177] and studies of the reduction of 8-quinolinol, tetramethylbenzidine, and various carbonyl compounds[88,175]. Electrolysis mechanisms were investigated, the reduction products were identified, and their concentration was determined. The effect of electrode potential on the intensity of the spectral bands due to intermediate products was also found (Fig. 18).

d) Biochemistry, clinical chemistry, and pharmacology

Molecular spectra (and, in particular, vibrational spectra) are widely used in biochemical research. Significant advances have been made in recent years[178-180],

but the preparation of samples for spectroscopic measurements remains a complicated and laborious procedure[180], involving many preliminary operations such as homogenisation, dehydration, and pressing into alkali halide disks, which can lead to losses and contamination of the sample. However, the most serious shortcoming of these techniques is the danger of altering the properties of delicate biological samples.

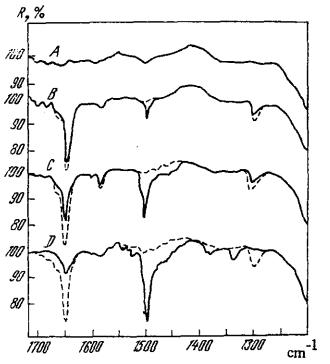

Figure 18. IRS spectra of *p*-benzoquinone (broken line) and its electrolysis products (full line): *B* at 0.7 V, *C* at 1.1 V, *D* at 2.0 V. *A* is the spectrum of the solvent. IRE—germanium plate (25 reflections) coated with a layer of gallium.

IRS methods have opened an entirely new chapter in biochemistry and clinical chemistry, because they enable biological tissues to be examined without pre-processing. Thus, spectra have been obtained from whole blood[126], bone tissues and collagens[181], tendons[181,182], etc.

One of the main advantages of the IRS methods is their unique ability to examine not only the tissues themselves but also numerous processes occurring within the tissues as a result of various influences. For example, spectra have been obtained from the upper integument of the brain cortex of the white rat, undergoing narcosis[76]. IRS methods have been used also to study stimulated chemical changes in animal tissues under the influence of biologically active preparations[183]. One of the most important discoveries has been the selectivity of these preparations towards different organs: for example, spectral changes were detected in kidney and liver tissues after the injection, but not in other tissues. Thus, IRS methods can, in principle, monitor the distribution of biologically active substances within the organism, and therefore they can be used to study the mechanism of biological interactions[183].

The use of IRS in biochemical studies of normal and pathogenic animal and human tissues may lead to significant advances in the diagnosis and study of various diseases. Results so far obtained are extremely promising. Thus, spectra have been obtained from normal and from pathological erythrocytes in human blood[76]. Infrared IRS spectra have been recorded, and studied, from the tissues of various human organs[184]: spleen, liver, blood vessels, etc. Significant differences have been found between the spectra of the aorta of a new-born infant and that of an adult suffering from arteriosclerosis. We may therefore classify IRS among the methods available for comparative studies of the chemical composition and properties of healthy and of pathological tissues. The use of IRS to study healthy and diseased tissues in the human eye (cornea, and crystalline lens) has also been proposed[184].

New prospects in biochemical and clinical research (e.g., in the diagnosis of skin diseases) may be expected from the latest refinements in the design of IRS apparatus. Thus, special attachments have been developed[185] to take IRS spectra from the surface of practically any part of the human body. These provide detailed information on the skin retention of ointments, creams, and other preparations, and on the nature of their interaction with the skin (Fig. 19).

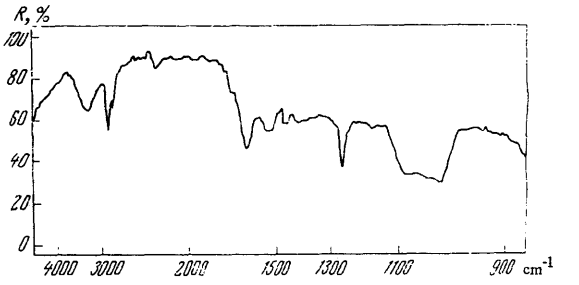

Figure 19. IRS spectrum of human skin treated with an ointment. IRE—AgBr plate.

One of the most interesting biochemical applications of IRS is the study (and, in some cases, the identification) of micro-organisms such as bacteria and algae. By using special membrane filters to "accumulate" the micro-organisms, their spectra can be recorded[95,186,187], and furthermore the organisms can be identified, since the spectra of, say, two varieties of algae show some distinct differences[95]. In principle, mixed cultures can be analysed from their IRS spectra with the help of a computer.

Among the many other biological applications of IRS, the following are particularly interesting: a study of the structure of liquid water in crystalline animal haemoglobin[76], a study of the surface reactions of bio-polymers[188,189], and also measurements of the u.v. spectra of chlorophyll[79] and of the i.r. spectra of carbohydrates[120,126,190], aminoacids[118-120], steroid hormones[191], and various biologically active substances and preparations[160,192,193].

IRS methods are very attractive in pharmacology[194], since they can be used in the structural analysis and quality control of medicinal preparations[195].

e) Chromatography

Infrared spectroscopy is one of the most effective methods of analysis and identification of chromatographic fractions. However, this method cannot always be applied: in order to achieve the optimum separation conditions, it is often necessary to work with very small samples, which may lie below the limits of sensitivity of standard methods of analysis.

In gas chromatography, the problem can be overcome by using the capillary multiple reflection cell described in the previous Section[54,185,196], which may be connected

directly to the chromatographic fraction collector. This method overcomes the loss of sample which is unavoidable in normal methods, and it offers very high sensitivity (down to 0.01 μl) by virtue of the large number of reflections possible (up to 50)[196]. The apparatus can be used with substances covering a wide range of boiling point (60 — 200°)[185, 196].

Typical examples of the use of IRS in chromatography include the analysis of fractions of steroids[191], pesticides[192], adhesives[110], and other substances[112], with samples weighing only a few microgrammes[192] (see Fig. 20).

Thin-layer chromatography and paper chromatography also involve very small samples, which cannot be analysed by normal i.r. spectroscopy after being fractionated and extracted from the substrate. Larger samples are sometimes collected by combining several peaks[192], but the procedure is time-consuming.

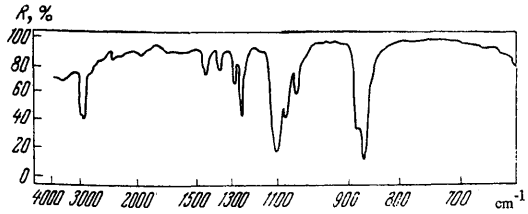

Figure 20. IRS spectrum of a chromatographic dioxan fraction isolated from a 0.7 μl sample of dioxan — acetone mixture. IRE—KRS-5 (50 reflections).

Considerable time saving, and simpler experimental procedures, can be achieved by resorting to IRS methods. Thus, it is sometimes possible to record spectra and to identify the fractions directly from the surface of the chromatogram, and even to analyse a mixture quantitatively[197]. In other cases[191,192] the chromatographic spot is extracted with a suitable solvent and the solution is applied to the IR plate. With this technique, a few microgrammes of sample are sufficient to give a strong spectrum, particularly if a plate capable of 50 or more reflections is used[54].

f) Industry

The important new features of IRS (as compared with transmission spectroscopy) offer great scope not only in scientific and research work but also in industrial laboratories responsible for the analysis of production runs. Molecular spectroscopy may now find general application as a method of process control and quality assurance in industry, whereas until relatively recently the method had been applied only in a few specialised areas.

The outlook can be illustrated by some examples.

1. Paper. IRS methods are already widely applied in the analysis of various types of paper, cardboard, etc. They are used also in the analysis of pulp and unbleached paper[198,199], and to identify and to determine the composition of paper coatings[200,201] including bonding[7,202-204] and colouring agents[16,106]. Different types of article have been analysed: paper-coated aluminium foil[205], cardboard boxes and labels[199], stamps[206]. IRS methods have been applied to specific problems such as identifying the contaminants of the matting in paper-making machinery[199], and also in determining the stability of paper coatings under the influence of temperature, light, etc.[54,204].

2. Wood. IRS methods have been used to solve problems related to the composition of wood, and to analyse various wood coatings[126].

The chemical composition of its surface determines many important properties of wood, such as its ability to bond to other surfaces. IRS spectral studies of different types of wood[207] have shown that the chemical composition of wood near a cut surface is very dependent on the angle of the cut. In particular, the xylene content of the surface region can vary by a large factor, depending on the angle of the cut.

3. Textiles. The development of IRS methods has led to the solution of a number of problems in the textile industry. Thus, both natural[54,105,208-210] and synthetic[54,99,126,210,211] fibres and fabrics have been successfully identified, glass fibres have been studied[105], and the composition of their surface coatings has been determined[105,111,208]. Because of the high sensitivity of the IRS methods, minor components of surface coatings can be detected[111] at concentrations below 1%. Other successful applications of IRS include the quantitative analysis of fibre compositions (for example, the ratio of cotton to nylon in semi-synthetic fabrics[31]), and the analysis of residues of finishing materials[208], which may include impurities harmful to the fabric[111].

4. Leather. The different types of natural[212] and synthetic[7,111] leather can easily be identified by IRS methods; it is possible also to analyse coatings and residues of finishes on the leather surface.

5. Polymers. Articles made from polymers are extensively used in industry and in everyday life. They can all be identified and analysed by IRS methods. These methods can also be applied for process control in the production of polymers[76,136,213], and for the analysis of finished articles[7,24,69]. In conjunction with special pyrolysis attachments, IRS methods can give useful information on polymer additives and fillers[185,211,214,215].

The use of IRS methods to analyse and identify polymers in the footwear industry[110], and also in the packaging and other industries[108], has also been reported.

6. Foodstuffs. I.r. IRS spectra have been measured on many food products, including margarine, gelatin[70,126], and milk powder[182]. By using membrane filters[187], components present in suspension in liquid foodstuffs can be analysed (for examples, yeasts in different types of beer[186]). In principle, IRS enables the quality of any foodstuff to be assessed and the presence of adulterants to be detected.

7. Cosmetics. The analysis of cosmetic articles by IRS methods is much more effective than analysis by the classical transmission spectroscopy methods, used until recently[216]. The most varied types of cream can be analysed[189,217] (including cream present on the skin[185]), and also toothpaste[182,217], liquid soap[218], foam[54], shampoo[218], domestic liquid detergents[218], and others[219].

The importance of i.r. spectroscopy as an operational method of quality assurance and process control in industry is well known[220]. The development of IRS has

greatly extended the scope and the range of the industrial applications of i.r. spectroscopy: as stated above, i.r. spectroscopy can now be applied in the paper, textile, food, and other industries as an analytical method. IRS may have an important part to play in the solution of some urgent industrial problems (e.g. effluent analysis[95,115]).

In the chemical industry, IRS offers exciting new prospects in the area of direct process control (e.g., on-line product analysis[24,221,222]).

Problems of these types can seldom be solved by the classical methods of spectroscopic analysis, which are severely limited by the need to use extremely thin optical cells. On the other hand, analysers based on the IRS principle can be used in a wide variety of automatic process control loops handling any type of liquid system, including very viscous liquids.

Industrial i.r. IRS analysers have been developed[223,224], and have been used successfully under factory conditions[224].

g) Trace analysis

One of the main attractions of the IRS method is its very high sensitivity, which enables quantities of the order of $10^{-6}-10^{-7}$ [54,87,95,191,193] or even 10^{-9} [35] g of sample to be detected and identified. It is thought[58] that even lower limits of detection may be practical. Hence, the IRS method is very attractive for the detection of very small concentrations of harmful and dangerous substances (a very important problem in chemical plant, storage areas, etc.).

An IRS trace analyser[139] has been developed for the detection of toxic vapours from rocket fuels, which may build up to dangerous concentrations in rocket storage sheds. A more recent modification of this equipment is used[160] to detect traces of organo-phosphorus compounds in air. The key component of the apparatus is a germanium multiple reflection plate coated on both sides with a thin platinum film which acts as the adsorption surface. Under the best conditions (film thickness 500 — 800 Å, surface temperature 15 — 20°) the apparatus can detect the presence of 10^{-7} g litre^{-1} of dimethylmethylphosphonate in air in 30 s.

The function of the platinum coating is to ensure that the adsorption is reversible: the adsorbate can be removed from the surface in a few seconds, simply by flushing the apparatus with air, and the sensitivity of the surface remains constant over long periods.

Similar devices can be used[90] to detect solid particles.

3. Quantitative Measurements

It was pointed out in Section II that the reflectivity of the surface can be approximately described by an equation analogous to the Lambert — Beer law if the refractive index and the angle of incidence of the IRE are correctly chosen. The formal optical density $\ln(R_0/R)$ then becomes a linear function of the concentration c.

From Eqn. (13) we have

$$\ln\left(\frac{R_0}{R}\right)_\nu = \alpha_\nu \cdot c \cdot d_{\text{eff}} \qquad (23)$$

Eqn. (23) can be used to calculate the concentration of the material of interest by the procedures and methods of quantitative transmission spectroscopy.

The practical aspects of quantitative analysis by IR spectroscopy were discussed by Wilks[31], who examined the dependence of the precision, reproducibility, and sensitivity of the method on factors such as the material of the plate, the number of reflections, the angle of incidence, the area of the plate covered by the sample, the position and uniformity of the sample, and the effectiveness of the contact.

It should be noted that, because of the linear dependence of the effective thickness upon wave length, the IRS band intensities are not directly comparable with those of transmission spectra. It can be shown, however, that the integral intensity of a band in the IRS spectrum is equal to the G integral in the transmission spectrum, obtained by integrating over the logarithm of the frequency[46,76]. Thus, the IRS method offers a simple way of determining the integral band intensities in the spectra of pure liquids and solutions[32].

The ATR and, particularly, the MATR method show great promise in routine analysis, when absolute methods are very seldom necessary and the main objective is to establish the effect of varying many factors. Relative methods are fully adequate in these circumstances. Typical applications of IRS methods in routine analysis include the quantitative analysis of aqueous and alcoholic solutions[72,95,112,117,118,124,127], and of coatings on paper[201,203], fabrics[203], and films[107,219]. Other reported applications of quantitative IRS methods include the compositional analysis of alkyd resins[215] and adhesives[112], semi-synthetic fabrics[31], and paper pulp[198]. Quantitative analyses of medicinal products[195], cosmetics[218,219], chromatographic fractions[197], and mixtures of powders[31] have also been mentioned. It has been shown that the method can measure the concentration of electrochemical reaction products on electrode surfaces[197], and the concentration of functional groups on adsorbent surfaces[164], and that it can be used to monitor polymerisation processes quantitatively[138]. Lastly, analysers for the quantitative control of continuous industrial processes have been developed[223,224].

The precision of quantitative IRS methods is always of the order of a few per cent[117,124,198,215,218], which is as good as in ordinary transmission spectroscopy. However, the former technique has a number of advantages over the latter, such as freedom from interference errors (Fig. 16). IRS methods also have some operational advantages by being less time consuming than transmission methods (mainly because of the simpler sample preparation procedures).

Many examples of the successful application of IRS in important areas of science and technology have been listed in this review. However, the list is by no means exclusive. It may be said, without exaggeration, that the scope of IRS, and therefore the area of application of ATR and MATR methods, is almost limitless. It would be difficult to enumerate all the areas of science and technology in which IRS methods have been successfully applied.

IRS has been used to study the liquid-crystal state[225], electrophoresis[54] and diffusion[9], and in mineralogy[103]; it has also been used to analyse asphalt[226] and tiles[156]. ATR and MATR methods are used to analyse pollutants in air[227], to determine the composition of cigarette smoke[95] and exhaust gases[186], and to identify inks[186] and wire coverings[54]. IRS methods have been proposed for the analysis of sludge deposits[95] and lunar dust[87]. There are reports of the successful use of IRS in philately[75,206] and in forensic science[10]. IRS methods may be useful in establishing the authenticity of paintings from the composition of the paints[185], which may be determined by direct IRS measurements on the painting itself. Wilks, one of the

founders of practical IR spectroscopy, rightly points out that the limitations of the IRS methods, and the specific areas of science and technology where these methods can be applied, are mainly determined by the ingenuity of the investigator.

In conclusion, we note that IRS methods can be generally recommended, in all cases where the conventional methods of transmission spectroscopy are difficult or impossible to apply. The number of such cases is ever-increasing: many new problems in science and technology are soluble in principle, but they present insuperable difficulties arising from the limitations of transmission spectroscopy methods. Therefore, a more extensive penetration of molecular spectroscopy into chemistry and industry is almost unthinkable unless accompanied by a wider application of IRS methods in research and industrial laboratories.

Many new publications have appeared while the present review was being prepared. The most important is undoubtedly Harrick's monograph[228], translated into Russian with an appendix by V. M. Zolotarev in which IRS equipment commercially available in the Soviet Union is described.

Two reviews[229,230] deal with general problems, and discuss some practical aspects of the application of IRS methods. In the latter, formulae for calculating effective thickness are obtained from a new mathematical treatment[231] of the problem.

Many interesting review papers can be found in the proceedings of a conference on applied spectroscopy held in 1970 in the USA.[232]

Section III of the present review, dealing with apparatus and techniques, would be incomplete without mention of some multi-purpose attachments for plotting u.v. and i.r. spectra[233], for adsorption studies[234], for low-temperature work[235,236], for studies of solids undergoing pyrolysis[237], and also of an attachment in which the light passes twice through the IRE.[238]

Mention must be made also of a number of interesting papers dealing with experimental methods, including the possibility of applying compensation measurements in IRS,[239] the optimum conditions for recording the spectra[240], and still further examples of the use of internal reflection spectroscopy with widely different types of sample including disperse media[241], suspensions[242], single crystals[243,244] and powders[245,246], and in particular metal oxides[247].

The practical applications of IRS methods continue to grow, as shown by the large number of papers published in the recent past. Among the most noteworthy we include IRS studies of paints[248] and textiles[249], of cellulose[250], of various foodstuffs[251], and of organic impurities in water[252].

IRS methods are being used on an increasing scale to study chemical reactions. Some of the more recent examples include studies of the interaction of proteins with polysaccharides[253], or resorcin with formaldehyde[254], and studies of the formation of elastomers in the solid phase[255] and studies of electrochemical reaction mechanisms[256-260].

In biochemistry the MATR method has recently been used in process control (separation of steroids by thin-layer chromatography[261]); in pharmacology it has been used to identify medicinal compounds and preparations[262-264].
