Pre-exponential Factor in Hydrogen Abstraction Reactions

M.V.Bazilevskii and E.A.Trosman

The principal rules governing the variation in the pre-exponential factor in reactions involving the abstraction of hydrogen by atoms and radicals are examined using the activated complex theory. 205 references.

I. INTRODUCTION

The homolytic removal of a hydrogen atom is one of the reactions that have been studied most fully. The great number of quantitative kinetic measurements allow this reaction to be used for verifying theories of chemical kinetics and such attempts have been made repeatedly. Stepukhovich[1] showed that the values of the pre-exponential factor for some reactions of this type can be given with an accuracy of within an order of magnitude in the framework of the simplest version of activated complex (AC) theory. Other reviews[2-13] dealing with the reactivity of individual radicals have set out from the same position.

The present review systematises the absolute values of the pre-exponential factors for reactions in which hydrogen is abstracted by radicals or atoms, studied up to 1969. These experimental results are discussed from the position of AC theory. Unlike the reviews mentioned above we have excluded trivial geometric factors, so as to investigate the role of finer effects. In particular, the effect on the reaction rate of changes in the frequencies of the deformation vibrations of the reaction centre is examined (Johnston[14] was the first to report the significant part played by this factor). The importance of steric effects is discussed.

In investigations of this type we encounter the peculiar status of the work. On the one hand, the AC theory has recently come under criticism, justified in many respects[15-17]. On the other, at present there are no other theories for explaining such complex reactions. The situation is complicated by the absence of reliable potential surfaces (except for the $H + H_2$ reaction).

The last circumstance decides the matter. Non-empirical numerical calculations of transition probabilities are quite impossible without potential surfaces. The AC theory allows rather far-reaching conclusions to be drawn,

using only the most general ideas about the structure of the transition state. After comparison with experiment these conclusions seem quite plausible. Hence there is no choice at present. In explaining the regularities in rates of reaction AC theory is still the only working tool of the chemist, who has to use it, whilst taking note of its imperfections.

2. EVALUATION OF THE PRE-EXPONENTIAL FACTOR ACCORDING TO ACTIVATED COMPLEX THEORY

The principal equation of AC theory[18]

$$\kappa = \varkappa \frac{kT}{h} \cdot \frac{F^{\neq}}{F^{AB}} \cdot \exp(-E/kT) \qquad (1)$$

expresses the reaction rate in terms of the partition functions of the transition state $F^{\neq}$ and reagents F^{AB}. For comparison with the experimental values of the Arrhenius parameters the temperature dependence must be clearly distinguished. With an accuracy of up to an order of magnitude the temperature dependence of the pre-exponential factor in Eqn. (1) can be disregarded and the factor identified with the Arrhenius pre-exponent A:

$$A = \varkappa \frac{kT}{h} \frac{F^{\neq}_{transl}}{F^{AB}_{transl}} \cdot \frac{F^{\neq}_{rot}}{F^{AB}_{rot}} \cdot \frac{F^{\neq}_{int}}{F^{AB}_{int}} \qquad (2)$$

(here the partition functions $F^{\neq}$ and F^{AB} are expanded). It is assumed that the error involved hardly exceeds the error in AC theory itself. Furthermore, the experimental values of A are usually accurate only to an order of magnitude. Further discussion is based on Eqn. (2). In this section the relative role and methods of evaluating the individual factors in this formula are briefly examined.

a. Geometrical Factor

The contribution of the translational and rotational degrees of freedom in Eqn. (2) will be termed the geometrical factor. It is determined by the geometry of the AC and is readily calculated if the position of the saddle point on the potential surface is known. A change in the geometry within rather wide limits has little effect on the value of the geometric factor. Therefore the geometry can generally be evaluated without a knowledge of the potential surface, by assuming a reasonable distance between the reagents in the AC. The values of the other geometric parameters can be obtained without serious error by interpolation between the reagents and the products or even by putting them equal to the corresponding parameters of the reagents.

b. Internal Degrees of Freedom

To calculate the contribution of the internal degrees of freedom in Eqn. (2) the form of the potential surface close to the saddle point must be known. In this region the potential is approximatelv a quadratic function of the coordinates q_i:

$$V = \frac{1}{2} \sum U_{ij} q_i q_j . \qquad (3)$$

The force constants U_{ij} are determined from the conditions for the best agreement between (3) and the calculated potential surface. Usually calculation can only give the variation of the energy with a limited number of coordinates q. For the remaining degrees of freedom the force constants are evaluated by more or less plausible extrapolation.

After this the normal vibrations and their frequencies ω_i are determined with the aid of standard procedures well known from the theory of vibrational spectra[19].

In the system of "natural" coordinates q_i (changes in bond lengths and valence angles), unlike the cartesian system, the kinetic energy is a non-diagonal quadratic of the generalised momenta p_i:

$$K = \frac{1}{2} \sum T_{ij} p_i p_j . \qquad (4)$$

The coefficients T_{ij} in Eqn. (4) and U_{ij} in Eqn. (3) form the matrices T and U. The squares of the frequencies are given to sufficient accuracy by the eigen values of the TU matrix:

$$\omega^2 = \frac{1}{4\pi^2} Q^{-1} TUQ \qquad (5)$$

where ω^2 is the diagonal matrix of the numbers ω_i^2 and Q the unit matrix, which is directly related to the matrix which determines the form of the normal vibrations.

The frequencies found by Eqn. (5) were also used to calculate the vibrational partition functions in Eqn. (2). One of the values of ω_i^2 is always negative, corresponding to an imaginary frequency. It describes the spatially-unrestricted motion along the reaction coordinate with a maximum (not a minimum) potential at the saddle point.

This procedure has been used by Johnston[20-23].

c. Transmission Factor

Strictly speaking, the quantity κ in Eqn. (2) can be found only by completely solving the problem of the motion of a system of atomic nuclei (which are present in the reactants) in the field of a multidimensional potential with subsequent averaging over the distribution of the initial conditions. When such a solution is obtained the semi-empirical AC theory is generally not needed. Therefore the inclusion of the values of κ in Eqn. (1) is formal and is significant only when this quantity is close to unity.

In several studies[24-32] the classical equations of motion for two- and three-dimensional potential surfaces were integrated numerically. These complex calculations, which require a knowledge of all the surfaces, give a set of trajectories for the motion of representative points depending on the initial conditions. They are discussed in Nikitin's book[33]. The technique of such classical calculations has been developed sufficiently well to investigate comparatively complex systems. For example, Bunker and Pattengill[34] calculated the trajectories for the reactions H + CH_4 and its isotopic analogues (using of course, an empirical potential).

Quantum calculations for empirical potential surfaces[35-38] and also more qualitative quantum estimations[39] show that the classical approximation does not introduce serious errors in those instances where the highest vibrational levels made a negligible contribution to the rate of reaction. There is evidently only one communication about the complete quantum calculation for the reaction H + H_2.[40]

In the language of AC theory such calculations imply calculation of the interaction of the reaction coordinates with the other degrees of freedom. Eqn. (1) is based on

the hypothesis of the absence of interaction. More precisely, the Hamiltonian of the AC theory is the adiabatic Hamiltonian for the vibrational degrees of freedom. The adiabatic approximation postulates the absence of vibrational transitions in motion along the reaction coordinate: the reagents in vibrational states with definite quantum numbers are converted into products in states with the same quantum numbers.

The applicability of the adiabatic approximation is determined by two factors. The sharper the change in the parameters of the potential surface (first the vibrational frequencies and the curvature of the reaction coordinate) along the reaction coordinate and the greater the rate of diffusion along it, the higher the probability of vibrational transitions. On the other hand, this probability decreases with increase in the vibrational quanta, that is, the frequency. In this respect the hydrogen abstraction reactions considered in our review occupy a favourable position. In this case the frequencies usually change little (thus in the reactions

the frequencies of the bonds being broken and being formed are almost the same, whereas the absolute values of the frequencies for the X–H bonds are high). It can be expected that the adiabatic description is applicable here, at least while the temperature is not too high, that is, the rate of relative motion is low and the highest vibrational levels are weakly populated.

There has recently been a series of papers which specially investigated range of applicability of the AC theory[41,42] and also of the calculated reaction probabilities (in particular, for H + H_2,[43-45]) in the adiabatic approximation. Their results agree with the qualitative conclusion drawn above. It must be added that when the adiabacity breaks down and vibrational transitions are observed this effect is levelled to a considerable degree by the averaging of the reaction probabilities over the vibrational states of the products in the concluding stage of the calculation of the overall rate constants. In other words, AC theory can remain a successful semiempirical method of investigating the overall rate constants even if its approximate nature is unsatisfactory for describing the elementary transition probabilities.

If it is assumed that the reaction coordinate is an adiabatically independent degree of freedom then the chief contribution to the value of κ is from a quantum correction for tunnelling through the one-dimensional potential barrier. In essence this is a correction to the classical state sum for the reaction coordinate; it is naturally included in AC theory.

In the calculation the potential barrier (that is, the section of the potential surface along the reaction coordinate around the saddle point) is approximated by an analytical expression: by a truncated parabola[46] or an Eckart potential[20,47]. The latter expression is more admissable[20,47,48]. Le Roy and coworkers[49] calculated κ by using the quantum partition function of an inverted harmonic oscillator (with imaginary virtual frequency)—this corresponds to a non-truncated parabolic model.

In any case the correction κ is determined by the effective mass μ^* for motion along the reaction coordinate, by the curvature of the potential barrier close to the saddle point, and by the energy of the reacting molecules. The characteristic parameter is

$$\lambda = \frac{hc}{kT}(\omega^*)i,$$

where ω^* is the imaginary frequency mentioned above, in cm^{-1}:

$$\omega^* = \frac{1}{2\pi}\sqrt{\frac{U^*}{\mu^*}}$$

(U^* is the negative force constant). κ increases with λ. For a hydrogen abstraction reaction, when the reaction coordinate near the saddle point is close to an antisymmetric vibration, $\mu^* \simeq \frac{1}{2}$ a.m.u. For this reaction (and probably for it alone) the tunnelling correction is rather significant at the experimental temperatures.

Table 1. Transmission coefficients for certain reactions.

T, °K	Reaction					
	H+H_2	H+D_2	H+T_2	D+D_2	CF_3+H–CD_3	CF_3+D–CHD_3
200	44.9	12.9	7.0	10.2	—	—
250	13.1	5.3	3.5	4.5	—	—
300	6.6	3.3	2.4	2.9	18.4	6.0
350	4.2	2.4	1.9	2.2	9.3	3.9
400	3.1	2.0	1.7	1.9	6.0	2.9
450	2.5	1.8	1.5	1.7	—	—
500	2.2	1.6	1.4	1.5	3.4	2.1
1000	1.3	1.2	1.1	1.1	1.5	1.3

Table 1 gives the tunnelling corrections calculated from the Eckart potential for the reaction H + H_2 and its isotopic analogues[48], and also for the reaction CF_3 + CHD_3 [21]. In the first instance the best of the potential surfaces at present available is used. The surface for the second reaction, calculated empirically, must be regarded as a rough approximation.

The figures given in Table 1 are probably too high[20,21]. Quantum calculations on a two-dimensional potential surface give somewhat smaller values of κ [35]. Generally, according to Rankin and Light's results[36], allowance for the quantum effects in hydrogen transfer reactions below 500°K is equivalent to an effective decrease in the height of the potential barrier by 1 kcal $mole^{-1}$.

Hence the existing calculated and theoretical estimates do not give reason for assuming that the errors in determining rate constants by AC theory are too high. However, this conclusion is valid only for thermal processes with relatively low reactant energies in the "chemical" temperature interval 300–500°K. At very high temperatures the assumption that the reaction coordinate is an independent degree of freedom is ineffective. At low temperatures the quantum corrections are significant.

Allowance for tunnelling within the framework of AC theory can increase the calculated value of the constant several times.

3. THE ACTIVATED COMPLEX MODEL

Johnston and coworkers have shown[20-22] that under certain conditions a considerable simplification of the real structure of the reactants and AC by replacing atomic groups by effective point masses, facilitates the calculation and has hardly any effect on the accuracy of the predicted pre-exponential factor.

For the reaction

$$M{-}H{+}R \rightarrow M \ldots H \ldots R \rightarrow M + HR$$

we have taken the AC model shown in Fig. 1. The fragments M and R are each regarded as an entity: their

internal degrees of freedom are obviously not taken into account. With each of the fragments is associated its coordinate system, positioned at its centre of gravity; the Z axis is directed along the M–H and H–R bonds respectively. Clearly there are nine internal degrees of freedom of the reaction centre to be considered:

1. The stretching vibrations of the bonds M–H (s_M) and H–R (s_R).
2. The deformation vibrations of the angles $HMX_M(\gamma_{MX})$, $HMY_M(\gamma_{MY})$, $HRX_R(\gamma_{RX})$, and $HRY_R(\gamma_{RY})$.
3. The deformation vibrations of the angle MHR in the XZ plane (γ_{HX}) and in the YZ plane (γ_{HY}).

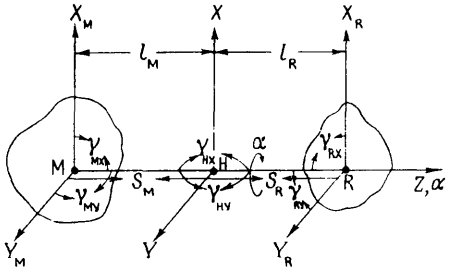

Figure 1. Model of an activated complex.

4. The internal rotation of the fragments M and R (α) relative to the axis α, coincident with the direction of the M–H and H–R bonds.

The following assumptions will be used subsequently:

I. The AC is linear—the bonds MH and HR lie in the same straight line (along axis α, common for both fragments).

II. In the calculation of the vibrational partition functions the systems of principal axes of inertia of the fragments M and R coincide with those coordinate systems introduced for these fragments in Fig. 1.

III. The above nine degrees of freedom do not interact with the internal degrees of freedom of the fragments.

IV. The stretching vibrations (s) of the reaction centre do not interact with the deformation vibrations (γ).

V. The internal rotation (α) is free and does not interact with either the stretching or the deformation vibrations.

These simplifications allow attention to be concentrated on the principal factors which determine the pre-exponential factor. Assumption (I) is almost always adopted in investigating hydrogen abstraction reactions. Assumptions (II)–(V) facilitate the assessment of the vibrational partition functions.

Refinement of the model should evidently not change the general qualitative conclusions. Quantitatively this investigation has the effect of dealing with each reaction separately only when the potential surface is known sufficiently reliably.

Since they do not depend on the form of the potential surface we tried to evaluate the rotational partition functions more accurately. Assumption (II) was not used in their calculation.

In evaluating the vibrational frequencies of the reaction centre in our model the matrix of the kinematic coefficients T_{ij} is needed (4). It has a simple form (Table 2) when assumptions (I)–(V) are used.

The following symbols are used: m_H, m_M, m_R are the masses of the hydrogen atom and the fragments M and R; I^M_X, I^M_Y, I^R_X, I^R_Y the principal moments of inertia of the fragments M or R relative to the corresponding axes; l_M and l_R the distances MH and HR;

$$\frac{1}{l_{MR}} = \frac{1}{l_M} + \frac{1}{l_R}.$$

Table 2 gives the part of the matrix to the right of the diagonal. Internal rotation is not considered, because of its separability.

4. ISOLATION OF THE GEOMETRIC FACTOR AND ITS EVALUATION

Eqn. (2) can be rewritten in the form:

$$A = A_0 A_1 \tag{6}$$

$$A_0 = \frac{kT}{h} \cdot \frac{F^{\neq}_{transl}}{F^{MH}_{transl} F^{R}_{transl}} \cdot \frac{F^{\neq}_{rot}}{F^{MH}_{rot} F^{R}_{rot}} \cdot F^{\neq}_{\alpha}, \tag{7}$$

$$A_1 = \varkappa \frac{\prod_i^7 F^{\neq}_i}{F^{M}_{\gamma MX} \cdot F^{M}_{\gamma MY} \cdot F^{M}_{sM}} \cdot \frac{F^{\neq}_{M\,int}}{F^{M}_{int}} \cdot \frac{F^{\neq}_{R\,int}}{F^{R}_{int}} \cdot \varphi_\alpha \tag{8}$$

In expression (7) $F^{\neq}_{\alpha}$ is the partition function for the free internal rotation α; the remaining symbols are obvious. In Eqn. (8), $F^{\neq}_i$ are the partition functions for the seven vibrations of the reaction centre (one stretching, six deformation); $F^{M}_{\gamma MX}$, $F^{M}_{\gamma MY}$, and F^{M}_{sM} those for the two deformation and one stretching vibrations of the C–H bond in the molecule. The remaining partition functions correspond to the internal degrees of freedom of the fragments M and R in the AC and in the reagents. The factor $\varphi_\alpha \leq 1$ is inserted into Eqn. (8) as a correction to the partition function $F^{\neq}_{\alpha}$ when the internal rotation is really restricted. When it is free, $\varphi_\alpha = 1$.

The quantity A_0 depends solely on the geometry of the AC and is independent of the form of the potential surface. It is not very sensitive to the detailed structure of the AC and therefore can be calculated reliably. The value of A_1, which is determined by the form of the potential surface, can only be estimated with a greater or lesser degree of accuracy.

Let us examine in greater detail the value of A_0 for the reaction of non-linear radicals and molecules. We obtain the first approximation by assuming that one of the reagents (the radical) is small in comparison with the other (the molecule) and the distance between the fragments M and R in the AC is not too great (<3 Å). Then

$$\frac{m_R}{m_R + m_{MH}} \ll 1; \quad \frac{I^R_X I^R_Y I^R_Z}{I^{\neq}_X I^{\neq}_Y I^{\neq}_Z} \ll 1; \quad \frac{I^R_\alpha}{I^R_\alpha + I^{MH}_\alpha} \ll 1.$$

Here m_{MH} is the mass of the molecule. The moments of inertia with subscripts X, Y, and Z are the principal moments of inertia of the radical (superscript R), molecule (superscript M), or AC (superscript ≠). The subscript α denotes calculation of the moment of inertia relative to the rotation axis α. We can assume that:

$$m^{\neq} \approx m_{MH}; \quad I^{\neq}_X I^{\neq}_Y I^{\neq}_Z \approx I^{MH}_X I^{MH}_Y I^{MH}_Z. \quad I^{\neq}_\alpha = \frac{I^R_\alpha I^{MH}_\alpha}{I^R_\alpha + I^{MH}} \approx I^R_\alpha$$

Table 2. Matrix of the kinematic coefficients for a reaction centre.

	s_M	s_R	γ_{HX}	γ_{MX}	γ_{RX}	γ_{HY}	γ_{MY}	γ_{RY}

γ_{HY}						$\frac{1}{m_H l_{MR}^2}+\frac{1}{m_M l_M^2}+\frac{1}{m_R l_R^2}$	$-\frac{1}{m_H l_{MR} l_M}-\frac{1}{m_M l_M^2}$	$\frac{1}{m_H l_{MR} l_R}-\frac{1}{m_R l_R^2}$
γ_{MY}							$\frac{1}{I_X^M}+\frac{1}{m_H l_M^2}+\frac{1}{m_M l_M^2}$	$\frac{1}{m_H l_M l_R}$
γ_{RY}								$\frac{1}{I_X^R}+\frac{1}{m_H l_R^2}+\frac{1}{m_R l_R^2}$

where $I_\alpha^{\neq}$ is the reduced moment of inertia[50]. After these simplifications we obtain an approximate value of A_0:

$$A_0' = \text{const} \cdot \left(\frac{1}{m_R}\right)^{3/2} \left(\frac{I_\alpha^R}{I_X^R I_Y^R I_Z^R}\right)^{1/2} \frac{\sigma^R}{\sigma_\alpha^R}, \quad (9)$$

where σ^R is the complete symmetry number of the radical and σ_R^α the symmetry number for internal rotation. The temperature T is included in the constant factor.

A_0' is completely independent of the nature of the molecule MH. Since A_0 Eqn. (7), is determined by the order of magnitude of the pre-exponential factor A, Eqn. (9) gives a basis for unifying reactions for molecules with a single radical into a reaction series. In such series the pre-exponential factor should be approximately constant (excluding instances where the molecules are small). The breakdown of the constancy of A in a reaction series shows a change in the structure of the reaction centre and is associated with A_1 not being constant. Table 12 gives A_0' for various radicals.

Refinement of Eqn. (9) for small molecules, which brings it back nearer to form (7), yields the expression:

$$A_0 = A_0' \cdot \left(\frac{m_R + m_{MH}}{m_{MH}}\right)^{3/2} \cdot \left(\frac{I_X^{\neq} I_Y^{\neq} I_Z^{\neq}}{I_X^{MH} I_Y^{MH} I_Z^{MH}}\right)^{1/2} \cdot \left(\frac{I_\alpha^M}{I_\alpha^M + I_\alpha^R}\right)^{1/2} \cdot \frac{\sigma^{MH}}{\sigma^{\neq}} \quad (10)$$

where σ^{MH} and $\sigma^{\neq}$ are the symmetry numbers of the molecules in the AC. It is easy to obtain formulae, analogous to Eqns. (9) and (10), for reactions of atoms and also of linear radicals and molecules.

5. CONTRIBUTION OF THE INTERNAL DEGREES OF FREEDOM TO THE VALUE OF THE PRE-EXPONENTIAL FACTOR

We will write A_1 of Eqn. (8) in the form:

$$A_1 = \varkappa \cdot A_{11} \cdot A_{12}, \quad (11)$$

$$A_{11} = \frac{\prod_{i=1}^{Z} F_i^{\neq}}{F_{\nu_{MX}}^M F_{\nu_{MY}}^M F_{s_M}^M}, \quad (12)$$

$$A_{12} = \frac{F_{M\,int}^{\neq}}{F_{int}^M} \cdot \frac{F_{R\,int}^{\neq}}{F_{int}^R} \varphi_\alpha . \quad (13)$$

The transmission factor $\varkappa$ takes into account the quantum effects of motion along the reaction coordinate and of the interaction between this coordinate and the remaining degrees of freedom. The value of A_{11} characterises the contribution to the pre-exponential factor of the vibrations of the reaction centre. The value of A_{12} is connected with changes in the internal degrees of freedom of the fragments M and R and can be regarded as a steric effect. The relative role of the factors entering into Eqn. (11) will be examined below.

a. Dependence of the Reaction Coordinate on the Symmetry of the AC

We will write the 2×2 unit of the upper left corner of the matrix of the kinematic coefficients T (Table 2).

$$T = \begin{pmatrix} \frac{1}{m_H} + \frac{1}{m_M} & -\frac{1}{m_H} \\ -\frac{1}{m_H} & \frac{1}{m_H} + \frac{1}{m_R} \end{pmatrix}$$

In the region of the saddle point it is determined by the reaction coordinate and the stretching vibration orthogonal to it. According to Eqn. (5), the form and frequency of the normal vibrations also depend on the matrix of the force constants U:

$$U = \begin{bmatrix} U_{11} & U_{12} \\ U_{21} & U_{22} \end{bmatrix}$$

For a symmetric reaction centre we can put

$$m_R = m_M = M, \quad U_{11} = U_{22} = U, \; U_{12} = u.$$

Then the frequencies of the symmetric and antisymmetric vibrations are

$$\omega_s = \frac{1}{2\pi} \sqrt{\frac{U_s}{\mu_s}},$$

$$\omega_a = \frac{1}{2\pi} \sqrt{\frac{U_a}{\mu_a}},$$

where

$$\frac{1}{\mu_s} = \frac{1}{M}; \frac{1}{\mu_a} = \frac{2}{m_H} + \frac{1}{M}; U_s = U + u; U_a = U - u .$$

At the saddle point U_a is negative and the frequency ω_a is imaginary. The reaction coordinate is an antisymmetric vibration. Since $M \gg m_H$, the effective mass μ_α is close to $\frac{1}{2} m_H$ and, as shown above, the transmission factor can acquire a rather greater value. It also increases when the barrier thickness is reduced, that is, with increase in $|U_\alpha|$.

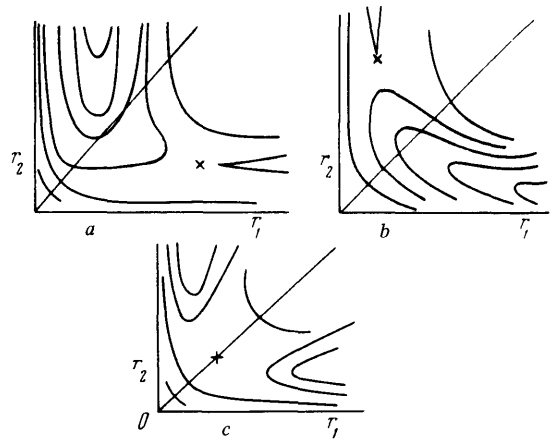

Figure 2. Types of potential surfaces for the transition states M...H...R. *a*) Attractive surface; *b*) repulsive surface; *c*) symmetric surface. $r_1 = s_{RH}$; $r_2 = s_{MH}$.

A reduction in symmetry, as is easily checked, leads to an increase in effective mass for the reaction coordinate and (at strictly the same conditions)—to a decrease in $\varkappa$ owing to the decrease in the quantum corrections. In the limiting cases the following two normal degrees of freedom are obtained:

(a) $U_{22} < 0$; $U_{11} \gg |U_{22}| \simeq |U_{12}|$: the s_{MH} vibration and the relative (counter) motion of MH and R.

(b) $U_{11} < 0$; $U_{22} \gg |U_{11}| \simeq |U_{12}|$: the s_{RH} vibration and the relative (towards opposite sides) motion of M and RH.

In considering the symmetric case in which all the force constants are essential three types of transition

states are obtained. They correspond to three types of potential surface[31,32]:
(a) "Attractive surface": the saddle point is situated on the initial linear part of the reaction coordinate; (b) "repulsive surface": the col point is situated on the final linear part of the reaction coordinate; (c) "symmetric surface": the saddle point is situated at the centre of the curvilinear part.

These surfaces are shown schematically in Fig. 2. For the first two types of AC the reaction coordinate is a relative translational motion. Only in the third "symmetric" type is it an antisymmetric vibration.

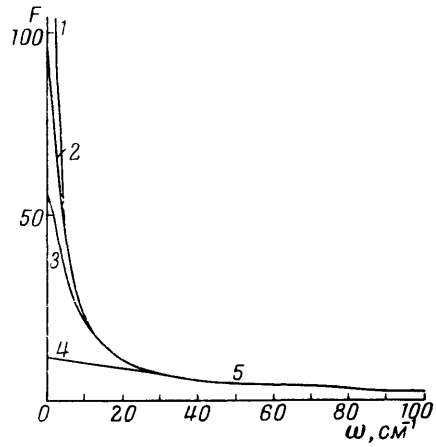

Figure 3. Variation of the vibrational partition functions with frequency (cm^{-1}). Curve *1*) calculated by Eqn. (15); curves *2*)–*4*) calculated by Eqn. (17) for specific values: *2*) for $I = 224$ (a.m.u.)Å^2 corresponds to I_X for the $(C_6H_5)_2CH$ fragment in $AK(C_6H_5)_2CH\ldots H\ldots R$; *3*) for $I = 79.4$, corresponds to the antisymmetric vibration in the XZ plane of $C_6H_5CH_2$ fragments in the activated complex $C_6H_5CH_2\ldots H\ldots CH_2C_6H_5$; *4*) for $I = 3.25$, corresponds to I_X for the CH_3 fragment in $CH_3\ldots H\ldots R$; *5*) calculated by Eqn. (14), the quantum and classical curves coincide in the range of frequencies shown.

b. Deformation Vibrations of the Reaction Centre

We have already noted that the values of the pre-exponential factor A calculated by the AC method are not very sensitive to the choice of model of the transition state. The explanation is that almost all the vibrational frequencies of the AC are high and for the corresponding degrees of freedom at the temperatures which are realised in the usual chemical experiment the higher vibrational levels are almost non-populated. Changes in these frequencies over a very wide range of values has little effect on the value of A. This very circumstance, which is quite general, means that in kinetic studies it is possible to use the AC model, which is quite unacceptable to the spectroscopist, from whose standpoint a change in any frequency by, let us say, 100 cm^{-1} already seems very great.

Fig. 3 shows the variation of the vibrational partition function with the frequency:

$$F_{vib} = \left[1 - \exp\left(-\frac{hc\omega}{kT}\right)\right]^{-1} \quad . \tag{14}$$

At frequencies of 100–300 cm^{-1} and 300–500°K this changes from the quantum kinetic inactive region to the classical:

$$F_{vib} = \frac{kT}{hc\omega} \quad . \tag{15}$$

In subsequent discussion deformation vibrations are important. For these the role of the effective mass μ is played by the effective moment of inertia I; in the one-dimension case, when U is the corresponding force constant,

$$\omega = \frac{1}{2\pi}\sqrt{\frac{U}{I}} \tag{16}$$

The classical state sum equals[51]

$$F_{vib} = \frac{kT}{hc\omega}\,\mathrm{erf}\left[\pi^2 c\omega\left(\frac{2I}{kT}\right)^{1/2}\right] \tag{17}$$

where erf is the error integral.

Eqn. (17) corresponds to a harmonic oscillator with an amplitude bounded between the limits $(-\pi, \pi)$. At very low frequencies they are converted into a one-dimensional rotational partition function $(8\pi^3 IkT)^{1/2}/h$ and at high frequencies it agrees with the classical formula (15) (Fig. 3). This model describes in the simplest manner the conversion of the vibrational degree of freedom into rotational. It was used for estimating the pre-exponential factor in recombinations, where the AC are assumed to be very loose[52].

The kinetically active frequencies are found to lie in the classical region. Frequencies in the quantum region are generally not of interest.

It is evident that the lowest values of the frequencies must be sought among the deformation vibrations. In our model (Fig. 1 and Table 2) the matrix T for six deformation vibrations is broken down into two three-dimensional blocks: vibrations in the XZ and YZ planes.

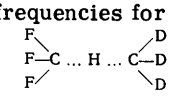
Let us consider the symmetric example (M = R) for motion in the XZ planes. We will introduce the symbols: $m_M = m_R = M$, $l_M = l_R = l$, $I_X^M = I_X^R = I_X$. The vibrations γ_{MX} and γ_{RX}, on mixing, form symmetric $\frac{1}{\sqrt{2}}(\gamma_{MX} + \gamma_{RX})$ and antisymmetric $\frac{1}{\sqrt{2}}(\gamma_{MX} - \gamma_{RX})$ vibrations with kinematic coefficients:

$$\frac{1}{I_s} = \frac{1}{I_X} + \frac{1}{l^2 M} + \frac{2}{l^2 m_H} \text{ and } \frac{1}{I_a} = \frac{1}{I_X} + \frac{1}{l^2 M} \, . \tag{18}$$

The antisymmetric vibration does not mix with the γ_{HX} vibration. It has the most effective moment of inertia, since the term which contains the small quantity m_H in the denominator is lost. According to Eqn. (16), when the force constants are approximately the same the antisymmetric frequency ω_α should be least. These qualitative discussions are still valid when the fragments M and R are different but their mass is sufficiently great and the reaction centre is symmetric or almost symmetric, that is, the M–H and H–R bonds are almost the same.

The closest vibrations of normal molecules to γ_{MX} and γ_{RX} are the in-plane deformation vibrations of the C–H bonds in aromatic molecules. Their frequencies are 400–1000 cm^{-1} [53,54]. These quantities should be reduced by approximately 50% since in comparison with the bonds in the normal molecules the CH bonds in the AC are longer, and their force constants are reduced (in some studies[20-22] it has been assumed that the force constants are reduced by 50%). The frequency ω_α of the antisymmetric vibration is further reduced as a result of

the interaction of γ_{MX} and γ_{HX}. Hence we estimate ω_α to be 100–400 cm^{-1}, lying at the boundary between the classical and quantum regions. We note that allowance for the interactions which we neglected in our model can only decrease the value of the least frequency, that is, the figure obtained can be regarded as the upper bound of the frequency ω_α. The frequencies for the AC



have been calculated[21].

An empirical potential surface was used and the estimates of the force constants were doubly approximate. Nevertheless it is helpful to compare the results of this calculation with our estimates obtained without any calculation. The values found for the vibrational frequencies of the reaction centre are 304 cm^{-1} for the symmetric stretching vibration, 1026 and 470 cm^{-1} for the two doubly degenerate, almost symmetric, deformation vibrations in the XZ and YZ planes, and $\omega_\alpha = 147$ cm^{-1} for the doubly degenerate, (almost) antisymmetric vibrations. The two antisymmetric vibrations contribute a factor of 4.3 to the vibrational partition function (the full value of this sum is ~10). In the calculation mentioned allowance was made for all interactions of the normal coordinates, including interaction with the vibrations within the fragments CF_3 and CD_3. Strictly speaking, these frequencies belong not to the above vibrations of the reaction centre but to the normal vibrations which contain these vibrations as one of their components (probably the main one). Consequently, these results confirm numerically that our model is suitable for approximate evaluations.

If the force constant U in Eqn. (16) is approximately the same for different AC then the upper bound of the deformation frequency ω_α corresponds to small values of the moment of inertia I_X in expression (18). This happens, for example, when the fragments M and R (or even one of them) are CH_3 groups, that is, only the hydrogen atoms contribute to the moment of inertia I_X. Then the effective moment of inertia I_α is also small. As an example, we give the calculated[22] least values of the frequencies for the reactions Cl + HM. For M = CH_3, CH_2Cl, $CHCl_2$, and CCl_3 they are 457, 233, 187, and 159 cm^{-1} respectively.

When the fragments M and R, or one of them, are atoms, the corresponding deformation vibrations generally disappear. Therefore the lowest frequencies for the reactions of radicals with the same molecules should be less.

Hence for a symmetric reaction complex (surface of type *c* in Fig. 2)the contribution of the deformation vibrations (mainly due to two antisymmetric vibrations) can, according to Eqn. (12), lead to values of $A_{11} \simeq 10-100$.

Considerably greater effects must be expected for potential surfaces of types *a* and *b* (Fig. 2). For these the value of one of the force constants U in formula (16) can be expected to be very small. The frequency is reduced accordingly. At the limit this corresponds to the change of the (almost) antisymmetric deformation vibrations into rotation of the fragment M or R according to Eqn. (17). Since there are thus two degrees of freedom (in the planes XZ and YZ) values of $A_{11} \simeq 10^3-10^4$ can be obtained.

We must remember that, as shown above (Section 2c), the adiabatic resolution of the variables is of little effect for low frequencies. Although the change in frequency along the reaction coordinate is also smaller in this instance, the problem of whether AC theory can describe the contribution of kinetically active low-frequency vibrations is unresolved. The conclusion about the increase in the pre-exponential factor remains in force but the estimates given of the magnitude of this effect could be greatly changed on making allowance for the exchange of energy between the reaction coordinate and the rotational degrees of freedom.

c. Internal Degrees of Freedom of the Reactants

The value of A_{12} in expression (13) is usually close to unity. This is because even if any frequencies of the fragments M and R are altered in the AC as compared with the isolated reactants, all the same these frequencies are kinetically inactive. There are exceptions when the structure of the fragments is rather complex:- there are bulky substituents. Then internal rotations which are restricted in the reactants can be freed in the formation of the AC, or on the other hand rotations which are free in the reactants can become restricted. An example of this is the restriction of the free rotation around the M...H...R bond in the AC. Such steric effects can make significant contributions to the pre-exponential factor.

6. SUMMARY OF THE EXPERIMENTAL VALUES OF THE PRE-EXPONENTIAL FACTOR

Tables 3–10 give the experimental values of the pre-exponential factors recalculated per single active (in bold type in the tables) hydrogen atom (A, litre $mole^{-1}$ s^{-1}). Reactions in the gas phase and liquid phase are considered (in the latter instance, in non-polar media). Results from existing reviews on hydrogen abstraction reactions[55-59] and from the individual papers listed in the references are used.

The absolute values of A for the reactions of a fluorine atom were obtained from results on competing fluorination and the reference value of $A = 10^{10}$ litre $mole^{-1}$ s^{-1} for the reaction F + C_2H_6. This value was calculated by assuming that the fluorine atoms react with C_2H_6 at every collision[2].

Absolute values of A in the reactions of Cl atoms were obtained from results on competitive chlorination; in the reactions of Cl with various isotopic modifications of H_2 and CH_4 the standard adopted was the value of $A = 4.1 \times 10^{10}$ litre $mole^{-1}$ s^{-1} for the reaction Cl + H_2 [2], in other instances the reference quantity was $A = 0.6 \times 10^{10}$ litre $mole^{-1}$ s^{-1} for the reaction Cl + CH_4 [2].

For the reactions of Br atoms the absolute values of the pre-exponential factor were obtained from results on competitive bromination and the absolute value of $A = 1.67 \times 10^7$ litre $mole^{-1}$ s^{-1} for the reaction Br + CH_3Br [2].

In determining the absolute values of A for the reactions of alkyl and halogenoalkyl radicals the reference quantities used were A for their recombinations. For the reaction CH_3 + CH_3 A was taken as 2.2×10^{10} litre $mole^{-1}$ s^{-1} [60], and for CF_3 + CF_3 $A = 2.3 \times 10^{10}$ litre $mole^{-1}$ s^{-1} [61]. For the recombination of other alkyl and halogenoalkyl radicals we took $A = 10^{11}$ litre $mole^{-1}$ s^{-1} [59].

The absolute values of A for the reactions of 2-cyano-2-methylethyl radical were calculated from our results[62]. $A = 2 \times 10^9$ litre $mole^{-1}$ s^{-1} was used as the reference quantity for the recombination of $C(CH_3)_2CN$ radicals[63].

7. CALCULATION OF MOMENTS OF INERTIA

The principal moments of inertia I_X, I_Y, and I_Z are determined as the eigenvalues of the I matrix of the inertia tensor. The direction cosines of the principal axes

(I_i, m_i, n_i) form a matrix of eigenvectors **I**. The matrix elements I_{ik} were calculated by the formula

$$I_{ik} = \Sigma m_n(x_n^2\delta_{ik} - x_{ni}x_{nk}) - m(a^2\delta_{ik} - a_ia_k), \qquad (19)$$

where x_n is the radius vector of the atom n, a the radius vector of the centre of inertia, m_n the mass of atom n, and $m = \Sigma m_n$ the mass of the entire system.

This standard procedure was used to calculate the moments of inertia of the molecules and radicals. Tables 11 and 12 give the results. Fig. 4 shows the geometric characteristics employed in the calculation and the choice of coordinate axes.

Since the geometry of the AC is not known precisely, it is desirable to use a simple approximate method for calculating its moments of inertia. Assuming that the radical is small in comparison with the molecule and the

distance between the fragments M and R is not too great we will model the fragment R by the point mass $m_R = \Sigma m_n$ equal to it in mass and located at its centre of inertia R with radius vector r. We choose as coordinate system the principal axes of the molecule with the direction cosines from Table 12. Then Eqn. (19) takes the form:

$$I_{ik}^{\neq} = I_i^M \delta_{ik} + m_R (r^2 \delta_{ik} - r_i r_k) - (m_{MH} + m_R) \cdot (a^2 \delta_{ik} - a_i a_k) .$$

In the system of coordinates used

$$a_i = \frac{m_R}{m_R + m_{MH}} r_i ,$$

whence

$$I_{ik}^{\neq} = I_i^M \delta_{ik} + \mu (r^2 - r_i r_k); \ \mu = \frac{m_{MH} \cdot m_R}{m_{MH} + m_R} .$$

By using perturbation theory, we obtain to the first order:

$$I_i^{\neq} = I_i^{MH} + \mu (r^2 - r_i^2) \qquad (20)$$

Formula (20) allows the moments of inertia of the AC to be found easily from the data of Tables 11 and 12. When there is a large radical and a small molecule, the moment of inertia of the molecule is replaced by the moment of inertia of the radical and the radius vector of the radical by that of the molecule.

When the moments of inertia I_i^{MH} in formula (20) are the same or very similar to one another, the error in the individual values of $I_i^{\neq}$ can be rather high (then perturbation theory with allowance for degeneracy leads to the full task of diagonalisation of the I matrix) but the product $\Pi I_i^{\neq}$ is also determined with acceptable accuracy in this instance (cf. the calculation for methane). Table 13 compares the calculations by Eqn. (20) with the full calculations.

In the complete calculation the geometry of the fragments M and R is unchanged in the AC. The distance between the carbon atoms of the reaction centre C—H—C was assumed equal to 2.4 Å. For a reaction centre X—H—Y, where although one of the atoms X and Y is not a carbon atom, the lengths of the bonds X—H and Y—H in the AC were evaluated by the Pauling formula[23,199],

8. ANALYSIS OF THE VALUES OF A_i FOUND FROM EXPERIMENT

Having determined the value of A_0 from formulae of the type of Eqn. (10) with moments of inertia calculated by the method described in the previous section, "experimental" values of A_i can be obtained. According to Eqn. (6) the experimental values of the pre-exponential factor must be separated from A_0. Table 14 gives the values of A_i thus found. The values of A_0 were calculated for 373 °K.

In discussing the values of A_1 caution is necessary because both the experimental results and the AC theory itself, which form the basis of the discussion, are imprecise. We will examine the effects which seem to be unquestioned: either they are of the order of 10^2-10^3, or (for effects of the order of 10^1) they are repeated with sufficient regularity in several reaction media.

According to Eqn. (11), A_1 is the product of three factors. The transmission factor κ can be either greater or less than unity owing to the competition of two effects: tunnelling and the interaction between the reaction coordinate and the remaining degrees of freedom (strictly,

* High value.
** Low value.

the transmission factor). The vibrational factor A_{11} is greater than or equal to unity. The steric factor A_{12} can be either greater or less than unity.

The last two factors are not present in reactions of atoms with diatomic molecules. On the basis of the data in Table 14 in this instance $A_1 \simeq \kappa \leqslant 1$. Consequently, the opposing effects which contribute to κ are either insignificant or compensated. When a factor of 2 – 5 is taken for the tunnelling, the transmission factor proper is 0.1 – 0.5. Thus or otherwise, κ is of the order of unity ($\kappa \simeq 0.3-1$), that is, the simple AC theory does not contradict experiment in any instance. Subsequently we will take $\kappa = 1$.

For the remaining reactions it is possible with sufficient confidence to distinguish those instances in which the steric effect is absent ($A_{12} \simeq 1$). These are reactions with molecules of simple structure. From Table 14 we find $A_1 \simeq A_{11} \geqslant 1$ for them. Table 15 gives values of A_1 for typical pairs of reactants.

From the results of Table 15: (1) In the reactions of one molecule with a series of radicals A_{11} is least for the radical CH_3; (2) in the reactions of one radical with a series of molecules it is least for the CH_4 molecule.

The quantity A_{11} is a minimum for the reaction CH_3 + CH_4, where it is ~1. As the hydrogen atoms in the radical and molecule are replaced it gradually increases, reaching values of 10^2-10^3 for complete replacement. This is a qualitative conclusion, following from an analysis of a large number of reactions, which we think reliable. It can be explained with the aid of the arguments given in sections 5 and 6.

Considering the reaction complex to be approximately symmetric, we assume that the value of A_{11} is determined by the contribution of two antisymmetric deformation vibrations. By using Fig. 3 we estimate their frequencies ω_α:

A_{11}	1	10	100	1000
ω_a	200	50—100	20—30	5—10 cm^{-1}

For the reaction of $CH_3 + CH_4$ calculations[20-22] give $\omega_\alpha \simeq 200$ cm^{-1}. For a tenfold decrease in ω_α the moment of inertia I_a must be increased a hundredfold. The last quantity is mainly determined by the value of I_X for the corresponding radical or molecule, Eqn. (18). According to Table 11 the values of I_X for the radicals CH_3, CF_3, CCl_3, and Ph are respectively 2, 50, 170, and 170. Hence an observable effect within the framework of our model is naturally explained by a change in the kinematic coefficients for corresponding AC.

A natural exception is the radical $C(CH_3)_2CN$ for which the value A_{11} is anomalously low. We will assume that the AC for the reaction of this radical (for example, with toluene) is more "rigid" than the typical AC for the reactions considered above, that is, one or both C–H bonds of the reaction centre are shorter for it. Most probably there is a shortening of the newly formed bond in accordance with the Hammond rule, since the $(CH_3)_2CCN$ radical is much less active than other radicals considered—for example, the activation energies for the reactions of CH_3, CF_3, and $(CH_3)_2CCN$ with toluene are 8, 6, and 11 kcal $mole^{-1}$ respectively. Then an increase in the moment of inertia I_X seems to be compensated by an increase in the force constant for the R–H bond being formed. This assumption agrees with the more detailed discussion given below.

Now let us examine the effect which is evidently due to the steric factor A_{12}. In the reaction for hydrogen abstraction from the carbonyl group of the aldehydes the value of A_1 is in many instances anomalously high (Tables 14 and 15). This can be explained as follows. During the course of the reaction the hybridisation of the carbonyl carbon atom changes from trigonal to digonal. The angle between the R–C and C=O bonds in R–C(=O)–H alters from 120° to 180°. Here the internal rotation of the substituent R or its fragments, restricted in the initial aldehyde by steric interaction with the oxygen atom, is freed. In the AC such an "aldehydic" effect should appear, even if only partly. In addition the effect of the moment of inertia, considered above, must be considered. From Table 14, clearly when the substituent R has a simple structure and a steric effect cannot be expected, the value of A_1 for RCHO and for molecules with a tertiary hydrogen atom are approximately the same. An anomalous increase in the pre-exponential factor is observed for aldehydes having a substituent of complex structure.

Table 11. Calculated values of the principal moments of inertia (a.m.u.).Å² and of $Å_0$ for radicals and molecules.

Let us discuss yet another effect. As shown above, the value of A_1 for the radical $C(CH_3)_2CN$ in reactions with small molecules is anomalously low. However, it becomes rather and possibly even too great ($\sim 10^3$) in reactions with complex molecules: diphenylmethane, dibenzyl ether, tribenzylamine (Table 14). This result can be interpreted in two ways. On the one hand, it could be supposed that in the latter instance, steric interactions in the AC make its structure looser than the structure of the AC for reactions with simple molecules, where there is no such interaction[62]. Then the pre-exponential factor is increased owing to a decrease in the force constants for the C–H bonds in the reaction complex, which involves a decrease in the antisymmetric frequencies ω_a. Hence a relative increase in the activation energy is to be expected.

Table 12. Calculated values of the coordinates of the centre of mass a_i, Å, and of the direction cosines of the principal axes for radicals and molecules.

Actually in these reactions show a clearly expressed compensation effect.

On the other hand, a change in the hybridisation of the carbon atom of the molecule from tetrahedral to trigonal can lead to the freeing of internal vibrations: similar to what is observed in aldehydes.

In the first instance A_{11} increases, in the second, A_{12}. In each specific reaction either the first or the second can predominate; they can also act simultaneously. In the next section we will investigate the reaction with diphenylmethane as an illustration.

9. STERIC EFFECTS IN THE REACTIONS OF THE 2-CYANO-2-METHYLETHYL RADICAL WITH DIPHENYLMETHANE

The model calculation given below clearly shows the complex picture of steric interactions in the reaction

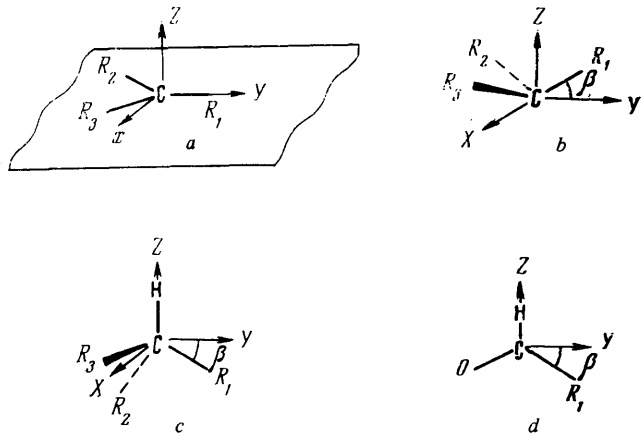

Figure 4. Configurations of molecules and radicals. The Z axis coincides with the direction of the molecule's CH bond that is being broken; one of the bonds of the central carbon atom (in the molecule or radical) lies in the YZ plane. All the angles β for the exit of C−R bonds from the XY plane for a given system are the same. *a*) $\beta = 0°$, alkyl radicals; *b*) $\beta = 15°$, CF_3 or CCl_3 radicals, *c*) $\beta = 19°\ 28'$, removal of H from a tetrahedral carbon atom; *d*) $\beta = 30°$, removal of H from a trigonal carbon atom (aldehydes). Standard values were adopted for the bond lengths and angles in the molecules and radicals.

Table 14. Experimental values of A_1, the contribution of the internal degrees of freedom to the pre-exponential factor.

Radical or atom	Molecule	A_0, litre mole^{-1} s^{-1}	A_1
1	2	3	4
H	H_2	$7.8\cdot10^{10}$	0.8

* In calculating A_1, the value $A = 3.2\times10^{10}$ litre mole^{-1} s^{-1}, obtained[200] as the mean of the available[58-60,200] values of A, was used.

** In calculating A_1, the value $A = 0.3\times10^{7}$ litre mole^{-1} s^{-1}, corresponding to the loss of H from a methyl group in the n-C_5H_{10} molecule, was used.

*** The experimental value of A for mesitylene[62] was used.

$(CH_3)_2CCN + H_2CPh_2$. The energy of the steric interactions between the reagents in the linear AC is investigated as a function of their relative orientation and the positions of the individual groups. Our results give information about the contribution of the internal rotations to the pre-exponential factor.

Table 15. Values of A_1 for some typical reactions.

Fig. 5 shows the geometry of the AC and the reactants. For the radical all the angles are assumed to be tetrahedral. The rotations of the methyl groups are characterised by the angles Ψ_1 and Ψ_2. The rotation of the phenyl rings in the molecule were described by angles ρ_1 and ρ_2 between the plane of the corresponding ring and the plane of the angle ω between the C – Ph bonds. The angles between the C – H bond being broken and the CH and C – PH σ-bonds were assumed to be the same for all three bonds (~107°). The rotation around the C... H... bond was characterised by the angle α (Fig. 5*a*). The relative position of the methyl and phenyl groups at $\alpha = 0$ for various values of the remaining angles are shown schematically in Fig. 6.

The interaction energy U was regarded as the sum of the pairwise intermolecular interactions $U_{rr'}$ between the atoms (not bound by valence) r of the radical and r' of the molecule. The interaction due to changes during the reaction with the hydrogen atom were not taken into account. The generally accepted approximation

$$U_{rr'} = A\exp(-al) - Bl^{-6},$$

where $l \equiv l_{rr'}$, the distance between the atoms, was used. The empirical coefficients A, a, and B were evaluated for various pairs of atoms from published data[201-205]. The steric interaction energy is

$$U = \Sigma U_{rr'}$$

First let us examine the effect of the angle ω in the isolated diphenylmethane molecule. Fig. 7 shows the interaction energy between the phenyl rings as a function of the angles of their rotation ρ_1 and ρ_2. Rotation of the rings is impossible, and only torsional vibrations about the equilibrium position at $\rho_1 = \rho_2 = 90°$ are admissible. As ω is varied from 109° to 120° the energy at the minimum changes from 8 to 3 kcal mole^{-1} and the potential well as a whole becomes much more shallow. The absolute value of the energy does not affect the pre-exponential factor (it makes a contribution solely to the activation energy). The decrease in the curvature of the potential surface $U(\rho_1, \rho_2)$ corresponds to a decrease in the force constants for the torsional vibrations, that is, to some freeing of the internal motions which was postulated above. For aldehydes, when the angle between the bonds is changed by 60, not 11, degrees, this effect is probably more significant.

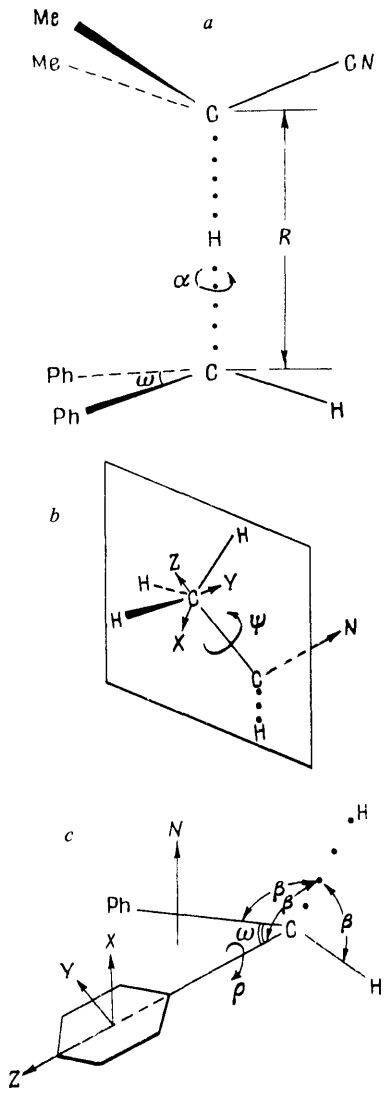

Figure 5. Geometric parameters of activated complexes for the reactions. *a*) Model of an activated complex: the C – CN bond of the radical and the C – H bond of the molecule lie in the plane of the diagram. The rotation angle α is reckoned from this plane; for the configuration shown $\alpha = 0$; *b*) rotation of methyl groups in the radical. The coordinate system is rigidly attached to the methyl group: the Z axis is directed along the C – C bond, the Y axis lies in the plane passing through one of the C – H bonds and the rotation axis; Ψ is the angle between the X axis and the normal N to the plane represented on the diagram (in the Figure, $\Psi = \pi/2$); *c*) rotation of the phenyl rings in the molecule. The coordinate system is rigidly attached to the ring, which lies in the YZ plane; the rotation angle ρ is the angle between the X axis and the normal to the plane of the PhCPh angle (in the Figure, $\rho = 0$), the angles β equal 106° 47′.

Subsequently it was assumed that in the AC a more favourable (and in energetic and in statistical respects) configuration with $\omega = 120°$ is realised. All the values of ρ_1 and ρ_2 were taken from the region situated close to the minimum.

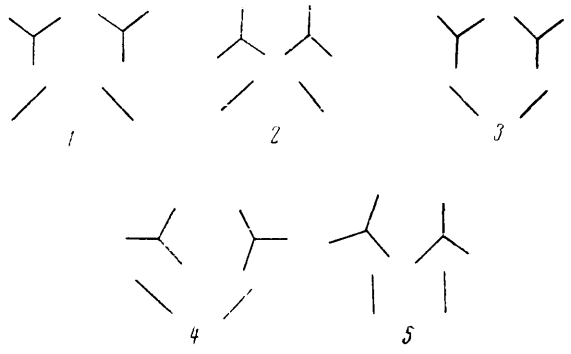

Figure 6. Schematic representation of the various configurations of the activated complex at $\alpha = 0$; ⟩⟨ denotes a methyl group, / the plane of the phenyl ring. *1*) $\Psi_1 = \Psi_2 = 0$, $\rho_1 = 120$, $\rho_2 = 60$; *2*) $\Psi_1 = 60°$, $\Psi_2 = 300°$, $\rho_1 = 120°$, $\rho_2 = 60°$; *3*) $\Psi_1 = \Psi_2 = 0°$, $\rho_1 = 60°$, $\rho_2 = 120°$; *4*) $\Psi_1 = 30°$, $\Psi_2 = 330°$, $\rho_1 = 60°$, $\rho_2 = 120°$; *5*) $\Psi_1 = 30°$, $\Psi_2 = 60°$, $\rho_1 = \rho_2 = 90°$.

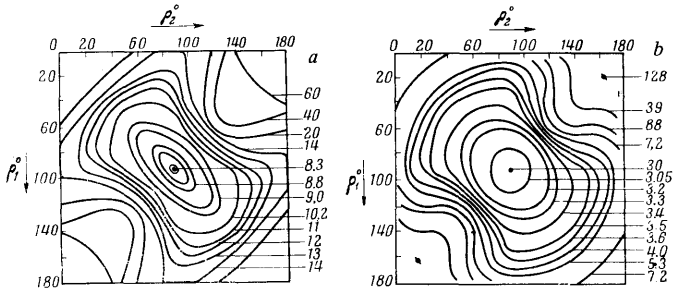

Figure 7. Potential surfaces for the interaction of the rings in diphenylmethane; energy in kcal mole^{-1}. *a*) $\omega = 109° 28'$; *b*) $\omega = 120°$.

Fig. 8 gives the relation between the intermolecular steric interaction in the AC from angle α in the fixed position of the methyl groups ($\Psi_1 = 60°$, $\Psi_2 = 300°$) and a distance of $R = 2.2$ Å between the carbon atoms of the reaction centre. Curves 1–5 correspond to different pairs $\rho_1 - \rho_2$. Of the five conformations considered rotation around the C–H–C bond seems possible for only one: $\rho_1 = 120°$, $\rho_2 = 60°$. For all the other instances steep and deep potential wells are characteristic.

The conformation with $\rho_1 = 120°$, $\rho_2 = 60°$ was investigated more thoroughly. Potential curves $U(\alpha)$ at various orientations of the methyl groups were constructed for these values of ρ. From Fig. 9, clearly for most of the conformations considered the rotation is strongly restricted or quite impossible. Hence the internal rotation α is practically free only for the conformations rigidly held about the values $\rho_1 = 120°$, $\rho_2 = 60°$, $\Psi_1 = 60°$, $\Psi_2 = 300°$. In other words, the rotation of the methyl groups is restricted, and the region of admissible values of ρ is greatly restricted. These motions might be made freer—with the same reagents at certain fixed values of angle α, that is, at the price of restricting the internal rotation around the C–H–C bond. The internal rotation as a whole in such an AC is greatly restricted.

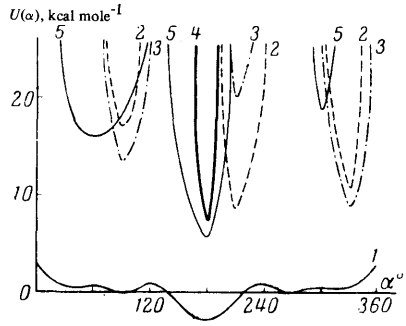

Figure 8. Variation of the energy of the intermolecular steric interaction in an activated complex with the angle α in a fixed arrangement of the methyl groups ($\Psi_1 = 60°$, $\Psi_2 = 300°$). *1*) $\rho_1 = 120°$, $\rho_2 = 60°$, *2*) $\rho_1 = \rho_2 = 40°$; *3*) $\rho_1 = 20°$, $\rho_2 = 80°$; *4*) $\rho_1 = \rho_2 = 90°$; *5*) $\rho_1 = 160°$, $\rho_2 = 100°$.

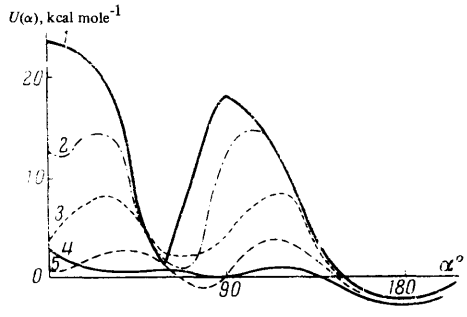

Figure 9. Variation of the potential curves $U(\alpha)$ with the orientation of the methyl groups for the conformations $\rho_1 = 120°$, $\rho_2 = 60°$. *1*) $\Psi_1 = \Psi_2 = 0$; *2*) $\Psi_1 = 15°$, $\Psi_2 = 345°$; *3*) $\Psi_1 = 30°$, $\Psi_2 = 330°$; *4*) $\Psi_1 = 60°$, $\Psi_2 = 300°$; *5*) $\Psi_1 = 45°$, $\Psi_2 = 315°$.

The calculations quoted relate to a rigid AC with the distance $R = 2.2$ Å. The variation with R of the potential curves $U(\alpha)$ is illustrated in Fig. 10. The deep minima characteristic for small R are gradually smoothed out. At $R = 2.5$ Å, the "poorest" of the curves given in Fig. 9 already permits restricted rotation; for $R = 2.7-2.8$ Å the rotation is free.

Of course, this result is obtained for optimal values of $\rho_1 = 120°$, $\rho_2 = 60°$. For other pairs ρ_1, ρ_2 free internal rotations occur at $R \geq 3$ Å. It can be considered

that in the range 2.6–3.0 Å the rotations Ψ and α are already sufficiently free, but the motion of the phenyl rings is still restricted in comparison with the isolated diphenylmethane molecule.

Now we can discuss more specifically the values of A_1 found for the $(CH_3)_2CCN$ radical. $A_1 \simeq 20$ for reactions with toluene†, for example. This is a low value: for the reaction $CF_3 + CH_3-Ph$, $A_1 \simeq 700$. In the previous section we assumed that the AC for the first reaction is more rigid, owing to the shortening of the R–H bond. Then an increase in the force constants explains the decrease in A_1. The value $R \simeq 2.6$ Å was taken[20-22] for reactions of CH_3 and CF_3 radicals. Consequently, we can take $R \simeq 2.4-2.5$ Å for the AC in the reaction $(CH_3)_2CCN + H_3C-Ph$. Calculations analogous to those given above show that in this system there is no steric interaction even at $R = 2.2-2.3$ Å.

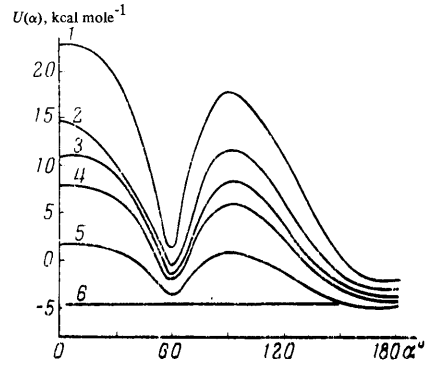

Figure 10. Variation of the potential curves $U(\alpha)$ with R at fixed positions of the methyl groups in the radical ($\Psi_1 = 0°$, $\Psi_2 = 0°$) and of the phenyl rings in the molecule ($\rho_1 = 120°$, $\rho_2 = 60°$). R, Å: *1*) 2.2; *2*) 2.25; *3*) 2.3; *4*) 2.35; *5*) 2.5; *6*) 2.8.

However, for AC of reactions with diphenylamine at $R < 2.5$ Å the steric effects are considerable. We therefore assume that in the AC represented in Fig. 5 R is increased to the value $R \leqslant 2.6$ Å, at which the change in internal motions compared with those of the reagents can be neglected. Such a system has a reaction centre close to the reaction centres of active radicals, for example, CF_3. Correspondingly (owing to the decrease in the force constants) the value of A_1 has increased to $A_1 = 2400$.

It is most probable that the increase in R takes place owing to the stretching of the C–H bond in diphenylmethane in accordance with the Hammond rule. A change to the favourable trigonal hybridisation with $\omega = 120°$ is facilitated thereby. The high values of A in the reactions of the isobutyronitrile radical with dibenzyl ether ($A_1 \simeq 3000$) and tribenzylamine ($A_1 \simeq 10\,000$) can probably be explained in approximately the same way but the details of the action of the "steric factors" should, of course, change.

It is impossible to maintain that this explanation is absolutely true, although it seems plausible. Information about the true values of R for various AC is not available and empirical calculations of the interaction energies are very approximate. The figures obtained (distances and angles) have an illustrative nature in every instance. But steric factors undoubtedly play an important part in the reactions of rather complex molecules.

Our calculations show certain specific mechanisms by means of which the internal degrees of freedom can affect the value of the pre-exponential factor.

† More precisely, the value of A_1 given in Table 14, relates to mesitylene, not toluene.

Photoemission of Electrons from Metals into Electrolyte Solutions

Yu.V.Pleskov and Z.A.Rotenberg

Photoemission of electrons from a metal into an electrolyte solution occurs when the metal is irradiated with sufficiently energetic light quanta through a layer of the solution. The emitted electrons become solvated and take part in various chemical and electrochemical reactions. Hence, photoemission studies in electrochemical systems can form the basis of a method for investigating the kinetics of various reactions, the structure of the electrical double layer at the metal-electrolyte interface, and the behaviour of electrons in liquids.
The theory of photoelectron emission, the relevant experimental techniques, and the most important results obtained in this new branch of electrochemistry are discussed. 117 references.

I. INTRODUCTION. HISTORICAL REVIEW OF THE PHOTOEFFECT IN ELECTROCHEMICAL SYSTEMS

The phenomena which have been termed photovoltaic (and photogalvanic) at the boundary between a metal and an electrolyte solution have been studied for over 130 years. In 1839 Becquerel found[1] that the potential of metal electrodes immersed in salt solutions or in solutions of acids or alkalies is affected by illumination. This effect, known as the "Becquerel effect", has been the object of detailed studies†. It is clear, from the multiplicity of systems which have been examined and of explanations which have been put forward, that the "Becquerel effect" is a complex combination of different phenomena. Only recent progress in photoelectrochemical research has made it possible to separate the effect into its "component elements".

The revival of interest in photoelectrochemistry in the early 1960's was due to the efforts of three workers, each of whom put forward his own explanation of the origin of the photocurrent (or of the photopotential)‡.

Berg studied the effect of light[11-20] on the dropping mercury electrode by the standard techniques of polarographic analysis ("photopolarography"). He ascribed the appearance of a photocurrent to the increase in the energy of an electron within a metal resulting from the absorption of light by the metal. The probability of electron transfer from the metal to ions or molecules is enhanced on such a "hot" electrode, and hence the rate of electrochemical reactions becomes greater.

According to Heyrovský[21-26], the photo-effect is associated with the decomposition (under the influence of light) of a surface charge-transfer complex formed by the metal electrode with molecules of the solvent (water, ethanol, etc.) or of the solute. The polarisation of the chemical bond in a complex of this type can be of either sign, depending on the electron donor or acceptor properties of the adsorbate. Absorption of a light quantum can break this bond: the bonding electrons are transferred either to the electrode (anodic photocurrent) or to the absorbed molecule, which then migrates away from the electrode surface (cathodic photocurrent). It should be noted that the idea of photodesorption or photodecomposition of a surface compound as the elementary act in photogalvanic processes is implicit in the earlier work of Veselovskii[27].

Lastly, Barker showed[28,29] that over some ranges of light frequency and electrode potential the primary process consists in electron transfer from the metal to the solution (the external photoeffect).

Strictly speaking, the concept of photoemission of electrons in the metal–electrolyte system is not new: it was first put forward in the 1920's to account for the photopotential of a number of metals[30] and for the effect of light on the rate of decomposition of alkali metal amalgams[31,32]. The same concept is found in the work of Berg[33,34]. However, only Barker was able to prove (albeit by indirect but reliable methods) the reality of photoemission into solutions and to delineate the actual limitations of the concept. Barker's work stimulated further experimental and theoretical developments in the study of photoemission into solutions, and in particular it led to the formulation of a quantum-mechanical theory of the effect (Brodskii, Gurevich, Levich[35-41]).

These three hypotheses have been considered to be mutually incompatible. However, we now have grounds to believe that each can be applied over a particular range of experimental conditions.

† The early work has been reviewed by Copeland and coworkers[2]. The work of Bowden[3], and of Hillson and Rideal[4], on the influence of light on the rate of cathodic hydrogen evolution deserves a special mention.

‡ We shall not be concerned with phenomena associated with the absorption of light by the solution, which give rise to homogeneous photochemical reactions. In this case the change in potential (or current) at the electrode is simply due to the photolysis products, excited molecules, etc. (see, for example, Refs. 5 and 6). The following photoelectrochemical processes are also beyond the scope of the present review: processes on semiconductor electrodes[7,8], on metals covered with semiconducting oxide films[9], and on "insulator" electrodes[10].

This review is concerned with the present state of the theory of photoemission into solutions§. A few photoelectrochemical phenomena not involving photoemission but frequently associated with it are briefly considered in Section VI.

II. THEORY OF THE EXTERNAL PHOTOEFFECT AT THE METAL–ELECTROLYTE INTERFACE

1. Photoemission of Electrons into Electrolyte Solutions

Photoemission at the metal–electrolyte interface differs in a number of important respects from the photoemission of electrons from a metal into a vacuum. Processes involving photoelectrons can be divided[29,35] into the following consecutive steps (Fig. 1): 1) intrinsic photoemission, i.e. the transfer of an electron through the interface following the absorption of a light quantum by the metal; 2) thermalisation and solvation of the electron, which lowers the energy of the emitted electron to thermal values and results in the formation (in times of the order of 10^{-11} s[44,45]) of a solvated electron¶; 3) chemical reaction between the solvated electron and species with electron-capturing properties present in solution (electron acceptors). The commonest acceptors are the ions H_3O^+ and NO_3^-, the molecules O_2 and N_2O, etc.

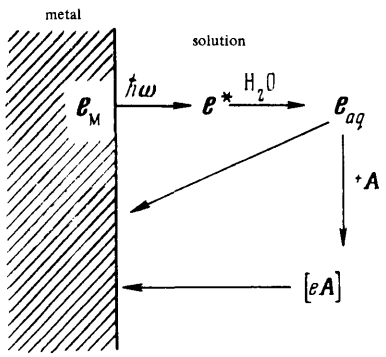

Figure 1. Processes occurring in photoemission.

In the absence of acceptors, the solvated electrons are quickly recaptured by the electrode, and the net photocurrent is approximately zero†. Thus, photocurrents in solutions (unlike photocurrents in the metal–vacuum system) can be observed experimentally only in the presence of electron acceptors.

Because there is an electrical double layer at the metal–electrolyte interface, where practically the whole of the externally applied potential difference appears, a new photoemission parameter has to be considered: the electrode potential. (This parameter is not relevant to the metal–vacuum interface.) The emission properties of the electrode can be drastically altered by varying the electrode potential‡.

Lastly, the work function of an electron is lower for the metal–electrolyte than for the metal–vacuum transition, because the electron gains interaction energy when it is emitted into a condensed medium. The motion of the electron in solution during the period preceding thermalisation and solvation is also different from the motion of an electron in a vacuum.

The photoemission of electrons from a metal into an electrolyte solution shows features similar to those of electrochemical reactions: both types of electron transfer reaction at the metal–electrolyte interface are described by essentially similar fundamental laws.

2. Quantum-mechanical Theory of Photoemission

The general theory of photoemission phenomena, including emission into electrolyte solutions, was developed by Brodskii and Gurevich[35–41]. Previous theories had a limited, phenomenological approach (Fowler's theory, for example[55,56]), and included a number of artificial assumptions or relied on models of doubtful generality[57,58]. Measurements of photoemission into a vacuum at frequencies close to the threshold value ω_0 agree very well with Fowler's parabolic law[56] $I \sim (\omega - \omega_0)^2$. However, attempts to apply Fowler's theory to photoemission into an electrolyte have been unsuccessful[29,59].

The modern quantum-mechanical theory of photoemission phenomena at the metal–electrolyte interface has been discussed in detail by Brodskii and Gurevich[41], and in this review the discussion will be confined to the underlying physical concepts.

Let a semi-infinite metal sample ($x < 0$) be irradiated with light of frequency ω (Fig. 2). Energies will be measured relative to that of an electron in solution, and the thickness of the layer affected by surface forces at the interface will be denoted by δ. In the present case, the thickness δ is that of the electrical double layer. The work function for the transfer of an electron from the metal to the solution is equal (but opposite in sign) to the energy of an electron at the Fermi level.

The current density of the emission from a microscopically uniform metal surface can be expressed in the form[41]

$$I = \int J(E, p_\parallel, A) \frac{1}{e^{\frac{E-\mu}{kT}} + 1} \rho(E, p_\parallel) dE dp_\parallel. \qquad (1)$$

§ A simplified treatment of the problem can be found in the semi-technical literature[42,43].

¶ The formation of a hydrated electron in aqueous solutions, first suggested by Platzman[46] in 1953, can now be taken as established. In particular, the hydrated electron appears as an intermediate in radiation-chemical and photolytic reactions. Many publications and monographs[45,47–51] have dealt with the methods of preparation of solvated electrons, their physicochemical properties, and their reactivity.

† The hydrated electron can undergo further reaction with a water molecule: $e^-_{aq} + H_2O \rightarrow H + OH^-$. However, the rate of this reaction is very slow, and in practice the electron can reach the electrode before interaction with H_2O can occur.

‡ At very negative potentials (for example, on mercury in alkaline solutions) thermal emission of electrons from the metal into the solution cannot be excluded[52,53]. The resulting hydrated electrons can be treated as intermediates in cathodic electrochemical reactions. However, a more recent analysis[54] has shown that the probability of thermo-electron emission into aqueous solutions is very low.

In this expression, E and $p_{\parallel} = \{p_y, p_z\}$ are the energy and the momentum (in a direction parallel to the surface) of the emitted electrons; A is an arbitrary term which allows for interactions with any external electromagnetic field; $J(E, p_{\parallel}, A)$ is the asymptotic value (i.e. at a point far removed from the metal surface) of the partial current density; $\rho(E, p_{\parallel})$ is the function which describes the distribution of the density of states for the electrons in the metal; μ is the chemical potential of the electrons.

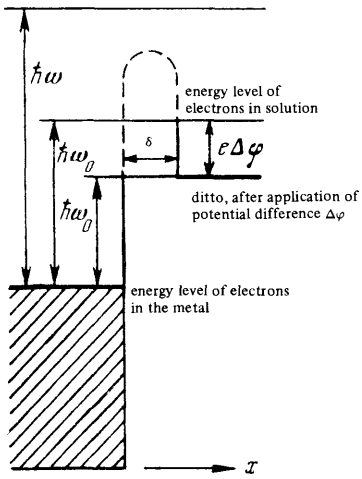

Figure 2. Electronic energy level diagram for photoemission from a metal into an electrolyte.

The limits of integration with respect to E and $p_{\parallel}^2$ are obtained from the law of conservation of energy:

$$p = \sqrt{2m(E + \hbar\omega) - p_{\parallel}^2}, \tag{2}$$

where p and m denote the x-component of the momentum and the mass, respectively, of the emitted electron. Since the partial photocurrent J differs from zero only for real values of p, the integration must extend over all values of E and $p_{\parallel}$ which satisfy the condition

$$\begin{gathered} 2m(E + \hbar\omega) \geqslant p_{\parallel}^2 \text{ or} \\ 0 \leqslant p_{\parallel}^2 \leqslant 2m(E + \hbar\omega), -\hbar\omega < E < \infty. \end{gathered} \tag{3}$$

Essentially, the quantum-mechanical problem consists in calculating the partial photocurrent $J(E, p_{\parallel})$. The motion of the electrons with an energy higher than kT can be treated as the motion of free particles with an effective mass m; in this case the wave function of the electron far from the metal surface has the form $\psi_f = A(p)\exp(ip_x/\hbar)$. It follows from the general expression for the quantum-mechanical current density operator [60] that our expression for J must be of the form

$$J = e(p/m)|\psi_f|^2. \tag{4}$$

The function $|\psi_f|^2$ can be treated as independent of the momentum of the emitted electron as long as its kinetic energy is less than $\hbar^2/2m\delta^2$. In other words, the de Broglie wavelength of the emitted electron must be greater than the thickness of the double layer,

$$\lambda > \delta. \tag{5}$$

Another condition for constant $|\psi_f|^2$ is given by the inequality

$$\hbar(\omega - \omega_0) < E_F, \tag{6}$$

where E_F is the energy of the Fermi level, measured from the bottom of the conduction band. The significance of inequality (6) is the following: the frequency of the light is so close to the threshold frequency that only those electrons within $\hbar(\omega - \omega_0)$ of the Fermi surface can take part in the photoemission process.

Eqns. (5) and (6) are the conditions for the threshold approximation, which allows the problem to be solved without reference to any specific model of the metal or of the interface. This approach has been used to discuss quantum-mechanical threshold phenomena [61].

Image forces, which operate at long range, play an important role in electron emission into a vacuum. At sufficiently low energies, $|\psi_f|^2 \sim p^{-1}$ and $J = \text{const}$ [35,37]; this justifies Fowler's approach, which involves substituting into Eqn. (1) some constant (for $p > 0$) or zero (for $p < 0$) instead of Eqn. (4).

However, when the electrons are emitted into an electrolyte, and conditions (5) and (6) apply, $J = \text{const} \cdot p/m$, and the electron density in the metal can be treated as constant to a first approximation and equal to the electron density at the Fermi surface.

Inserting the value of J into Eqn. (1), and simplifying, gives the following expression for the density of the emission current:

$$I = A_0\left(\frac{kT}{\hbar\omega}\right)^{1/2} T^2 \chi \int_0^{\infty} \frac{u^{3/2}}{e^{u-\beta} + 1} du. \tag{7}$$

where A_0 is Sommerfeld's constant, equal to 120 A cm^{-2} deg^{-1}, χ is a dimensionless function depending on the properties of the metal and the interface, and $\beta = \hbar(\omega - \omega_0)/kT$. At $T = 0$,

$$I = 0 \qquad \text{for } \omega < \omega_0, \tag{8a}$$

$$I = A_0\chi \frac{2\hbar^2}{5k^2\omega^{1/2}}(\omega - \omega_0)^{5/2} \qquad \text{for } \omega > \omega_0. \tag{8b}$$

Eqn. (8) shows that Fowler's parabolic law for the photocurrent as a function of frequency close to the threshold value is replaced by a "five-over-two" law. Formula (8b) applies also at ordinary temperatures if $\hbar(\omega - \omega_0)/kT \gg 1$.

The current–voltage characteristic for the photocurrent can be obtained by allowing for the effect of the electrode potential on the electron energy in the metal. A negative shift of the potential by φ raises the Fermi level of the metal by $e\varphi$. Thus, the electronic work function from the metal into the solution varies linearly with potential: $\hbar\omega_0(\varphi) = \hbar\omega_0(\varphi{=}0) + e\varphi$. Hence, the current–voltage characteristic takes the form

$$I \simeq A(\hbar\omega - \hbar\omega_0 - e\varphi)^{5/2}. \tag{9}$$

The work function $\hbar\omega_0$ applies for $\varphi = 0$, and is (of course) a function of the chosen reference electrode.

It follows from the inequality (5) that the "five-over-two law" should hold only in concentrated solutions of electrolytes ($\geqslant$ 0.1 M). In dilute solutions the thickness of the double layer is greater than the wavelength of the electron, and condition (5) is not satisfied. If the thickness of the diffuse part of the double layer is much greater than the de Broglie wavelength, the final state of the emitted electron in solution will be altered by an amount

$-e\psi_1$, where ψ_1 is the potential at the outer Helmholtz plane. Therefore we must re-write Eqn. (9) in the form

$$I \simeq A\,[\hbar\omega - \hbar\omega_0 - e(\varphi - \psi_1)]^{4/3} \qquad (10)$$

(which in any case is correct for $\psi_1 > 0$). In dilute solutions, therefore, we expect a linear relationship between $I^{0.4}$ and $(\varphi - \psi_1)$. Thus, the "five-over-two law" applies also to dilute solutions, but the electrode potential in this case must be "corrected" by subtracting the ψ_1 potential. An analogous correction of the ψ_1 potential appears also in the electrochemical kinetic equations[62]. In both cases (photoemission and discharge at the electrode) the rate of the electron transfer process is controlled by $\varphi - \psi_1$ rather than by φ.

A quantitative analysis of photoemission, allowing for the finite thickness of the fixed part of the double layer[63], has yielded an expression for the photocurrent which differs from the five-over-two law only in having an additional factor depending on the potential and on the energy of the light quantum. The deviation of the photocurrent from the five-over-two law at high potentials can be used to calculate the thickness of the fixed part of the double layer.

Lastly, Brodskii and Gurevich[41,64] have developed a multiphoton theory of the external photoeffect.

3. Theory of Photodiffusion Currents[29,65,66]

As stated above, the photoemission of electrons from a metal into an electrolyte is accompanied by successive steps leading to the formation of solvated electrons in solution. The products of the reaction between the electrons and acceptor species in solution can take part in electrode reactions. This process gives rise to "photodiffusion" currents in solution, resulting from discharge of the solvated electrons and their reaction products. The observed photocurrent, corrected for the backward migration (towards the electrode) of the solvated electrons and their reaction products, is described (at steady state) by the equation§

$$j = \nu \int_0^\infty f(x)\{1 - \exp[-(kc/D_e)^{1/2}x]\}dx. \qquad (11)$$

The function $f(x)$ of the electron source describes the rate of formation of solvated electrons as a function of distance from the electrode; k is the rate constant for the reaction between electrons and acceptors (present in solution at concentration c); D_e is the diffusion coefficient of the solvated electron; the stoichiometric number ν characterises the reactions, at the electrode and in solution, of the products formed by the capture of solvated electrons. For example, $\nu = 0$ corresponds to oxidation of free radicals formed by electron capture, and $\nu = 2$ corresponds to reduction of these radicals with emission of one additional electron from the electrode for each particle undergoing reduction.

At low acceptor concentrations, and noting that the source function differs from zero only in a narrow region close to the electrode, the expression for the current can be simplified by a series expansion of the exponential in Eqn. (11) to give

$$j = \nu\sqrt{kc/D_e}\,\langle x\rangle\, I, \qquad (12)$$

where $\langle x\rangle$ characterises the average distance from the electrode at which solvation occurs. It follows from formula (12) that the potential dependence of the photocurrent is the same as that of the photoemission current to the precision of the factors ν and $\langle x\rangle$. The variation of ν and $\langle x\rangle$ with potential will be discussed below by considering real examples.

If the electrode is illuminated with light of variable intensity, or polarised with a fluctuating potential, a significant difference is found experimentally between the time dependence of the photocurrent and that of the emission current. In particular, j and I show a phase shift whose magnitude and sign are determined by the diffusion rate of electrons and free radicals in solution and by the rate constants of the chemical reactions in the solution and at the electrode surface. The phase angles for some specific cases have been calculated[29,66].

Rotenberg and coworkers[67] have calculated the photoimpedance Z_φ of electrochemical systems, measured at an illuminated electrode polarised with a fluctuating potential of amplitude φ_0, and defined by the expression $\varphi_0 = Z_\varphi I_0$ (where I_0 is the amplitude of the fluctuating photocurrent). The equivalent circuits of a cell undergoing various photodiffusion processes have been discussed by Barker and coworkers[29].

III. EXPERIMENTAL TECHNIQUES USED IN PHOTOEMISSION STUDIES

Photoemission studies in metal–electrolyte systems are usually made by illuminating the electrode with light of 250–450 nm wavelength (quantum energy 2.5–5 eV). The most popular light sources are high-pressure mercury and xenon lamps, giving a continuous spectrum or line spectra. The required part of the spectrum is isolated with a high-intensity monochromator or with interference filters. The latter can produce a spectral band 5–10 nm wide. The cell and its associated optics are made of quartz.

Experimental assemblies for photoemission studies can be arbitrarily divided into three types (direct current, alternating current, and pulsed) according to the mode of illumination used and therefore also to the design of the measuring circuit. In assemblies of the first type the light intensity is kept constant and d.c. measuring circuits are used. For the light intensities most commonly used, the measured photocurrent densities are of the order of 10^{-6}–10^{-7} A cm^{-2}.

Time-modulation of the light intensity offers (in principle) a solution to two problems: the scientific problem of identifying processes in the electrochemical cell which may result in slow relaxation of the photocurrent (for example, the diffusion of reactants or of intermediates), and the experimental problem of exploiting the more convenient measuring systems based on a.c. amplifiers. In the first case, frequencies above 10 kHz are required, but in the second case it is sufficient to modulate the intensity of the light at a frequency of the order of 100 Hz, either mechanically (by inserting a rotating, perforated disk in the path of the light beam), or by modulating the power supplied to the lamp. The photocurrent (or photopotential) is measured with a selective amplifier tuned to the chosen modulation frequency. The most sophisticated

§ Eqn. (11) was obtained making the following assumptions: the emitted electron reacts with an acceptor only after being solvated; the concentration of solvated electrons is so low that interaction between these species can be ignored; no electric field exists in the solution.

apparatus of this type was described by de Levie and coworkers[68-70]. It uses a dropping mercury photocathode, with a constantly renewed surface, and the photocurrent is measured at a predetermined stage in the life of the drop. The state of the surface is monitored by measuring the components of the electrode impedance as well as the photocurrent.

The technique developed for flash photolysis[71] is used in pulsed measurements. The light source is a flash lamp, fired by discharging a condenser. The normal duration of a flash is 10^{-4}–10^{-3} s, the energy of the flash can be as high as 100 J.

We have shown, in Section II. 2, that the photoemission current density is a fundamental characteristic of the photoemission process which readily lends itself to experimental determination. For accurate measurements, the potential of the electrode must be kept constant and independent of the intensity of illumination. Under steady light, or with low-frequency modulation of the light beam, this condition is easily satisfied by practically any design of potentiostatic current source. On the other hand, a potentiostat for high-frequency or pulsed measurements is much more difficult to construct, because the low impedance of the electrode (determined by the capacity of the interfacial double layer) requires a circuit with a very low source resistance. Under these conditions, measurements are usually made in the galvanostatic rather than the potentiostatic regime (i.e. with a constant current flowing through the electrochemical cell¶), and the measured quantity is the photopotential instead of the photocurrent. Provided that the differential capacitance of the electrode is known, no difficulty arises in converting one measured quantity into the other. Delahay and coworkers[59,72] used a pulsed coulostatic apparatus to study the photoemission from stationary and dropping mercury electrodes.

Comparing the merits of the three methods, we note that steady illumination offers the simplest and most accurate measurement of photocurrent, but the method is not applicable in the presence of significant dark currents, and it cannot give any information on the relaxation processes involved. The pulse method has a low precision, and it requires correct measurements of the electrode capacity, which introduces additional uncertainty. The most universally applicable method is undoubtedly the modulated beam method.

Most of the work on photoemission published so far has been done with a dropping, or stationary, mercury electrode in aqueous solution. The most widely used electron acceptors are hydrogen ions and nitrous oxide.

IV. EXPERIMENTAL STUDIES ON THE BASIC LAWS OF PHOTOEMISSION

1. Dependence of Photocurrent on Electrode Potential and Quantum Energy of the Light

As shown in Section II. 2, existing theories of the photoeffect predict different variations of the photocurrent with electrode potential and with the energy of the light quanta. According to Fowler's modified theory, used to explain some of the early experimental measurements of photoemission in solutions[29,59,72], the photocurrent is a quadratic function of the quantity $(\hbar\omega - \hbar\omega_0 - e\varphi)$. The theory of Brodskii and Gurevich leads to the "five-over-two" law. Lastly, Heyrovský's model (photodissociation of surface charge-transfer complexes) predicts an exponential dependence of the photocurrent on potential or quantum energy.

The inadequacy of the quadratic law when applied to photoemission in solutions was demonstrated by Gurevich and coworkers[35]. The first experimental test of the "five-over-two" law was reported by Korshunov and coworkers[73], but these workers used a pulse method without allowing for the potential dependence of the electrode capacity.

In order to provide the data for a rational choice between the "five-over-two" law and Fowler's law, measurements of photocurrent have been made[74,75] as a function of potential under steady illumination, i.e. under conditions likely to yield the required precision and uncomplicated by considerations of double layer capacitance. The experimentally measured photocurrents were plotted in both $j^{0.5}$–φ and $j^{0.4}$–φ coordinates. Straight lines were drawn through the experimental points, using a computer for the least-square calculations. The intercept of the straight line on the potential axis (termed the threshold potential φ_a) was noted in each case, and used to calculate the work function of electrons in water and also the dispersion of the results (standard deviation of the experimental points from the best straight line).

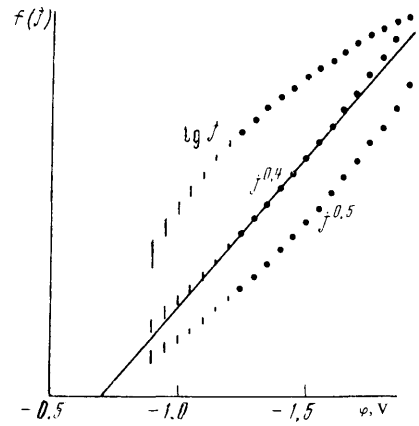

Figure 3. Graphical treatment of the experimental photocurrent–potential curve according to the theoretical formulae of Fowler ($j^{0.5}$), Heyrovský (lg$j$), and Brodskii and Gurevich ($j^{0.4}$). 0.1 N KF solution saturated with N_2O; light of 436 nm wavelength[70].

The dispersion was found to be much lower for the $j^{0.4}$–φ plot than for Fowler's $j^{0.5}$–φ plot. On this evidence, therefore, we must conclude that the "five-over-two" law is the more satisfactory.

These results were later confirmed by other workers. Fig. 3 shows the results of photocurrent measurements[70] on a dropping mercury electrode with modulated illumination, plotted as $j^{0.4}$–φ (according to Brodskii and Gurevich),

¶ The coulostatic method (zero current through the cell, constant charge on the electrode) is a special case of this regime.

$j^{0.5}-\varphi$ (according to Fowler), and $\lg j-\varphi$ (according to Heyrovský). It is evident from the Figure that a good straight line can be drawn only in the first plot†.

Although the reliability of the above results is lessened by occasional failure to comply with the condition of high acceptor concentration (see Section IV. 5), we may nevertheless conclude that photoemission in electrolyte solutions (in contrast to emission into a vacuum) is more accurately described by the "five-over-two" law than by Fowler's law.

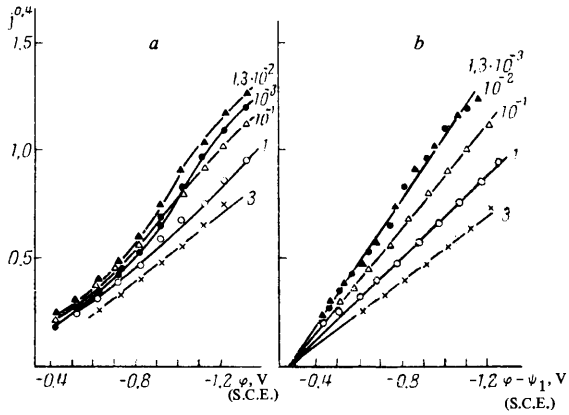

Figure 4. Plots of $j^{0.4}$ against (*a*) φ, and (*b*) $\varphi - \psi_1$ for KF solutions of different concentrations, saturated with N_2O.[76] In Figs. 4, 6, 7, 9, 10, and 13 the wavelength of light is 365 nm and the potential is referred to the saturated calomel electrode.

2. Photoemission into Dilute Electrolyte Solutions

The diffuse potential barrier found in dilute electrolyte solutions leads to a potential dependence of the photocurrent different from that observed in concentrated solutions (the "modified five-over-two law", Eqn. (10))‡.

Fig. 4 shows plots of the photoemission current in KF solutions at different concentrations, with N_2O as the electron acceptor[76]. Straight lines in $j^{0.4}-\varphi$ coordinates are obtained only in concentrated solutions (1 M and 3 M, see Fig. 4*a*).

In Fig. 4*b* the same experimental data are re-plotted as $j^{0.4}-(\varphi - \psi_1)$. The plots now show linear portions over a wide potential region for all concentrations of indifferent electrolyte. Furthermore, all the curves can be extrapolated to the same point on the potential axis, showing that the threshold potential is the same for all concentrations. The linearity of these plots, and the fact that they can be extrapolated to the same threshold potential, are convincing evidence that Eqn. (10) can be confidently applied to dilute solutions of electrolytes§.

Similar results were reported by Korshunov and coworkers[77]. However, de Levie and Kreuser[70] found that the potential dependence of the photocurrent was satisfactorily described by Eqn. (9) in dilute as well as in concentrated solutions: the reason for this discrepancy is not clear.

An attempt has been made[78] to allow quantitatively for the drift of solvated electrons in the field of the electrical double layer in dilute solutions.

3. Lack of Dependence of Photoemission Threshold on the Electrode Metal and on Adsorption

When photoemission proceeds in a vacuum the "red edge" of the photoeffect depends on the electronic work function of the metal: the standard method of measuring work functions is based on this effect. By analogy, we could expect the threshold potential at the metal–electrolyte interface to be a function of the metal: in other words, the intercept at $j = 0$ of the $j^{0.4}-\varphi$ straight lines obtained for different metals should be shifted by an amount equal to the difference in work function (or in the point of zero charge) of the metals[59].

However, there is one very important difference between the metal–electrolyte and the metal–vacuum interface: the former is the seat of an additional variable—the electrode potential. Changes in electrode potential are reflected in the work function, and therefore the latter must always be referred to some defined potential. However, if we assign a potential to the electrode we simultaneously fix the initial energy level of the electron. In practice, different metals at the same electrode potential have the same Fermi level. On the other hand, the final energy level of the electron in solution is independent of the nature of the metal. The specific properties of the metal influence only the height and the shape of the potential barrier at the interface (i.e. the region of thickness δ, as shown in Fig. 5). But under the conditions of the threshold approximation ($\lambda > \delta$) the properties of the barrier are irrelevant to the energetics of the photoemission process, which are determined only by the difference between the initial and the final state of the electron. Hence, the photoemission threshold in an electrolyte should be independent of the electrode metal.

This conclusion is fully consistent with the general laws of electrochemical kinetics. Indeed, the electronic work function of a metal in a vacuum does not appear explicitly in the kinetic equations if potentials are measured with respect to that of some arbitrary but constant reference electrode[79–81]. Photoemission, like any other type of electron transfer process at the metal–solution interface, must obey this law. Yet, photoemission offers a new insight into the role of the electronic structure of metals in electrochemical kinetics, because (unlike the majority of "classical" electrochemical reactions) it does not involve

† The deviations from linearity at voltages close to threshold are discussed more fully in Section IV. 5.

‡ If the measured photocurrent is lower than its limiting value, secondary effects of the ψ_1 potential on the photocurrent are also possible: changes in the concentration of charged acceptors near the electrode, and also drift of solvated electrons in the electric field of the diffuse part of the double layer.

§ It would be incorrect to conclude, however, that the emission of electrons proceeds only as far as the Helmholtz plane. The potential continues to vary (albeit slowly) beyond this plane. Hence, even if the point which describes the final state of the emitted electron is further from the electrode surface than the Helmholtz plane, the barrier presented by the diffuse part of the double layer remains practically impermeable to electrons, and the applicability of Eqn. (10) is unaffected.

the formation and breaking of chemical bonds, which complicate the interpretation of experimental results.

The lack of dependence of the photoemission threshold upon the nature of the metal was discovered experimentally in an investigation of mercury and of thallium and indium amalgams [74,82] (Fig. 6), and subsequently confirmed for various other metals [83]. In spite of the large difference between the points of zero charge of the metals examined (up to 0.4 V), the photoemission threshold potentials are indistinguishable within experimental error (±0.03 V).

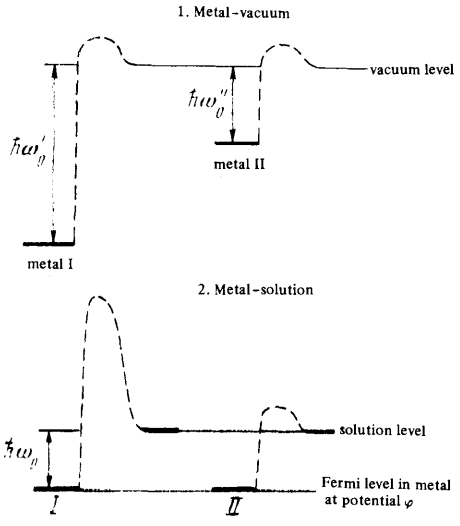

Figure 5. Energy diagram for photoemission into electrolytes from metals with different work functions.

Specific adsorption of surface-active ions or molecules is also not expected to shift the photoemission threshold provided that the condition $\lambda > \delta$ is not violated, i.e. as long as the thickness of the adsorption layer remains smaller than the wavelength λ of the emitted electron. (This wavelength is ~ 10 Å for an electron energy of ~ 1 eV.) For example, with the relatively small halide ions the conditions are satisfied and the photoemission threshold of a mercury electrode is practically unaffected by adsorption (Fig. 7) in spite of significant changes in the point of zero charge¶. Similar results were obtained for the adsorption of small organic molecules [70,84]. Adsorption of organic molecules with long carbon chains invalidates the condition $\lambda > \delta$ and (as expected) influences the potential dependence of the photocurrent. Thus, photoemission experiments can provide information on the extent of adsorption and on the characteristics of the adsorbed layer [85,86].

¶ The reported [72] shift in threshold following adsorption of halide ions on mercury is due to a misunderstanding. The shift was observed in the so-called "rational" potential scales for the adsorption of halide ions, and was effectively equal to the difference between the origins of these scales. When the results are recalculated for a common reference electrode the shift in photoemission threshold for different ions almost completely disappears.

4. Influence of Polarisation of the Light on the Photoemission Current

A characteristic feature of photoemission, which distinguishes it from other photoelectrochemical phenomena (such as photodissociation of surface charge-transfer complexes), is its sensitivity to polarisation of the light.

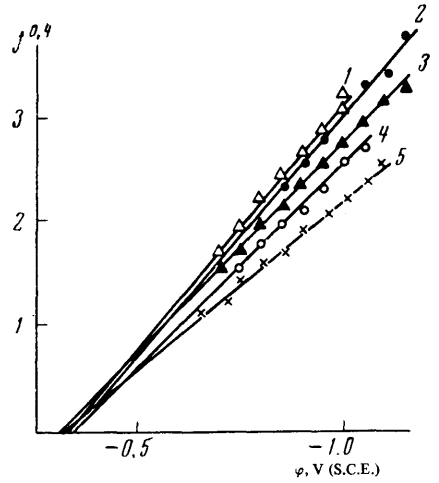

Figure 6. $j^{0.4}$–φ curves for different metals: *1*) mercury, *2*) thallium amalgam (3%), *3*) indium amalgam (18%), *4*) indium amalgam (50%), *5*) lead [74].

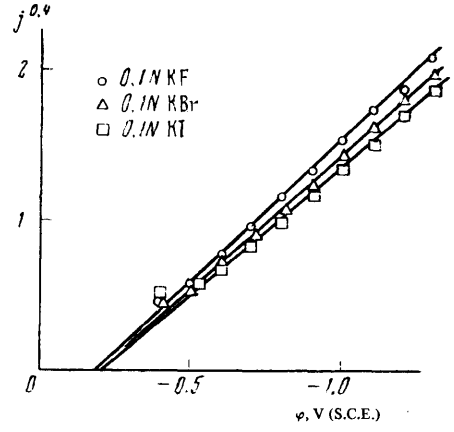

Figure 7. $j^{0.4}$–φ curves for a mercury electrode in 0.1 N solutions of KF, KBr, and KI saturated with N_2O. [84]

An electron cannot emerge from the metal after absorption of a light quantum unless its momentum in a direction perpendicular to the interface is greater than zero. It follows from the law of conservation of momentum that the transition can be induced only by the x-component of the electric vector. The absorption of a wave which is polarised in the plane of the surface cannot generate a

significant amount of photocurrent. Hence, we expect the photocurrent to increase with the projection of the electric vector on the normal to the metal surface ($j \sim \sin^2\theta \cdot \cos^2\psi$, where θ is the angle of incidence of the light and ψ is the polarisation angle in the plane of incidence, see Fig. 8).

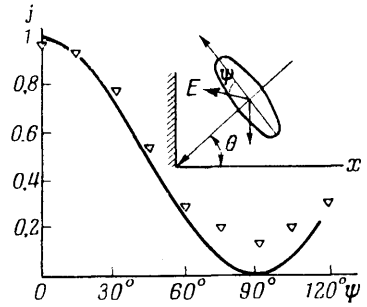

Figure 8. Effect of polarisation of the light on photoemission. Mercury electrode in 0.1 N K_2SO_4 solution (open triangles). The full curve is a plot of $\cos^2\psi$.[88]

The variation of photoemission current with polarisation of the light, which had been previously observed experimentally at the metal–vacuum interface[87], has been reported also in electrochemical systems[31,32,70,88]. Fig. 8, reproduced from the paper by Korshunov and coworkers[88], shows the photocurrent at a mercury electrode in K_2SO_4 solution saturated with N_2O (electron acceptor) as a function of the polarisation angle ψ of the light (for a fixed value of θ). The relatively small discrepancy between the experimental points (triangles) and the expected $\cos^2\psi$ law (solid line) is obviously due to incomplete polarisation of the incident light.

Experiments with polarised light allow us to separate photoemission from other concomitant photoelectrochemical processes which do not show polarisation selectivity (photoeffect in the bulk electrolyte, photodissociation of charge-transfer complexes, etc.).

5. Photoemission into Solutions with Low Concentrations of Electron Acceptors

If the concentration of acceptors is insufficient, some of the emitted electrons will be recaptured by the electrode and the measured photocurrent will be smaller than the true emission current. The expected proportionality (at low acceptor concentrations) between the photocurrent and the square root of acceptor concentration (Eqn. (12)) has been observed experimentally[29,89,78,89-91]. The proportionality coefficient can be used to assess the mean distance $\langle x \rangle$ from the electrode surface at which hydrated electrons are formed in solution. In concentrated electrolyte solutions (0.1–1 M) this distance is found[89,90] to be ~ 20 Å, but as the ionic strength of the solution decreases $\langle x \rangle$ appears to increase to ~ 100 Å.[89]

The calculated value of $\langle x \rangle$ is a mean over the whole energy spectrum of the emitted electrons for given values of φ and $\hbar\omega$. The function $f(x)$, i.e. the distribution of velocities of the solvated electrons along the coordinate x, can be evaluated in principle from the dependence of the photocurrent on the concentration of acceptors (at intermediate concentrations), or alternatively from relaxation experiments[92]. The calculation has not yet been attempted, because of the inadequate precision and reproducibility of photocurrent measurements[78], but it may already be stated that $\langle x \rangle$ increases with the electron energy E, since $\langle x \rangle$ increases when the potential is shifted towards more negative values (for $\hbar\omega$ = const.)[29,89]. It should be noted that Korshunov and coworkers[90] arrived at the opposite conclusion from their measurements of photocurrent as a function of electrode potential and acceptor concentration. But we must stress that the precision of measurements on concentration dependence is often suspect. A more reliable argument for the dependence of $\langle x \rangle$ on electron energy is the experimentally observed shift[93] of the threshold potential (found by extrapolating the $j^{0.4}$–φ straight lines) on increasing the concentration of acceptors in solution (Fig. 9).

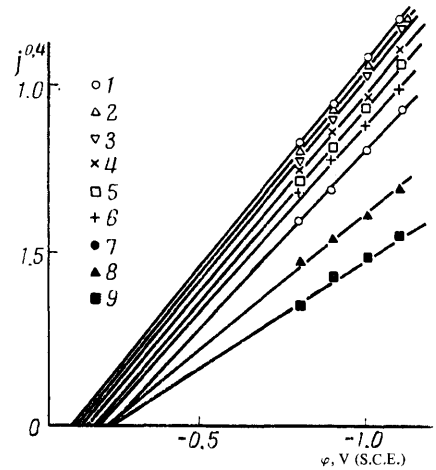

Figure 9. Effect of acceptor concentration (H_3O^+) on the apparent photoemission threshold: *1*) 0.42, *2*) 0.25, *3*) 0.11, *4*) 0.063, *5*) 0.044, *6*) 0.03, *7*) 0.018, *8*) 0, *9*) 0.0012 mole litre^{-1}.[89]

This shift does not imply a change in the "true" work function of the electrode metal with respect to the electrolyte; it is merely the result of a change in the dependence of the photocurrent on potential as the concentration of acceptors is varied but the method of graphical interpretation of the results is kept unchanged. By assuming an explicit form of the function $\langle x \rangle$ (E) we can calculate a j–φ curve which is not described by the "five-over-two" law. The positive deviations from this law (see Fig. 3) have been explained qualitatively by these arguments.

As already stated, the precision of present-day experiments is insufficient to calculate the functions $f(x)$ and $\langle x \rangle$ (E). The greatest accuracy is obtained in measurements of photoemission at high acceptor concentrations, when diffusion processes play only a minor role[78,93].

The true photoemission threshold has been determined[93] by correcting the apparent shift due to diffusion of hydrated electrons, and used to calculate the work function for electron emission from mercury into water at the zero-charge potential (3 eV). (This value is lower by 0.2–0.3 eV than the previously accepted value[73,74], which did not

include a diffusion correction.) The lower work function of mercury in water as compared with the vacuum value (4.5 eV) is due, as we have already pointed out, to the interaction of a super-thermal electron with the polar solvent medium. The lowering (1.5 eV) is less than the hydration energy of the electron (1.7 eV[45]). Hence, the final state of the photoemission process is a quasi-free electron rather than a fully thermalised and hydrated electron.

The electronic work function in other solvents, measured by the photoemission method, has also been found to be lower than the work function in a vacuum. The lowering is close to the energy of the electronic polaron in these solvents, and is evidently due to the electronic polarisation of the medium by the emitted electron[82].

6. The Multi-photon Effect

The experiments discussed above relate to the one-photon photoeffect, in which the energy of a single light quantum is sufficient to cause photoemission. Korshunov and coworkers[94] discovered two- and three-photon external photoeffects at the mercury–solution interface. A laser was used as the light source: a ruby laser in the first case (quantum energy $\hbar\omega = 1.78$ eV), and a neodymium laser in the second ($\hbar\omega = 1.18$ eV). As in the one-photon effect, the photocurrent varies with potential according to the "five-over-two" law. The relationship between the photocurrent and the light intensity is, as expected from the theory, an exponential function with an exponent approximately equal to the number of photons absorbed for every emitted electron.

V. PHOTOEMISSION AS A METHOD OF STUDYING THE KINETICS OF CHEMICAL AND ELECTROCHEMICAL REACTIONS

When electrons are emitted into a solution as a result of irradiation, many processes in which the solvated electrons are involved in further transformations can occur in the layer of solution adjacent to the electrode. The most interesting of these are homogeneous and heterogeneous reactions involving free radicals. The kinetics of these reactions are reflected in the magnitude of the experimentally measured photocurrent, and therefore we may think of photoemission as a convenient method of monitoring such processes. We shall limit the discussion to the simplest systems, for which quantitative experimental data are available.

1. Kinetics of the Electrochemical Conversion of Atomic Hydrogen at a Mercury Electrode

Atomic hydrogen is formed in solution by the capture of a hydrated electron by a hydrogen ion:

$$e_{aq}^- + H_3O^+ = H + H_2O. \qquad (A)$$

The hydrogen atom undergoes reduction over a wide range of potentials (from −0.7 to −1.5 V against the saturated calomel electrode)

$$H + HS + e^- = H_2 + S. \qquad (B)$$

In the above equation the symbol HS denotes a source of protons, which could be H_3O^+ or H_2O. At more positive potentials the ionisation of atomic hydrogen becomes increasingly important

$$H + H_2O = H_3O^+ + e^-, \qquad (C)$$

leading to a drop in the measured cathodic photocurrent (first observed by Barker[29]).

We shall outline the results of some kinetic studies of the conversion of atomic hydrogen, obtained from photoelectrochemical measurements[95,96]. Photoemission is used as a source of atomic hydrogen in the region of the electrode surface: the procedure is more convenient than others used so far[97–99].

The photocurrent experimentally measured in the electrochemical system is defined by the expression $j = j_0 + \vec{j} - \overleftarrow{j}$, where j_0 is the emission current (not including the current of electrons recaptured by the electrode without having reacted), $\vec{j}$ is the cathodic current of reaction (B), $\overleftarrow{j}$ is the ionisation current of atomic hydrogen. The variation of j_0 with potential, as already stated, has approximately the form $j_0 \sim (\varphi - \varphi_a)^{5/2}$, where φ_a is the threshold potential for light quanta of a given energy.

A hydrogen atom can take part in reactions (B) and (C) either in an adsorbed state at the surface of the metal or in the layer of solution adjacent to the electrode.

At negative potentials, when the rate of oxidation of the H atom can be ignored, $j = 2j_0$, and the experimental dependence of the photocurrent on potential is (to a first approximation) the same as that of the emission current. In the more general case, when reaction (C) cannot be neglected, the photocurrent j is given by the expression[96]

$$\varphi = \frac{2.3RT}{(\alpha+\beta)F}\left[lg\left(\frac{2j_0}{j} - 1\right) + lg\frac{\kappa_1}{\kappa_2}\right], \qquad (13)$$

where α and β are the transfer coefficients of reactions (B) and (C) respectively, and κ_1 and κ_2 are the rate constants of these reactions at $\varphi = 0$†.

Eqn. (13) predicts a linear relationship between φ and $\lg(2j_0/j - 1)$, with a slope determined by the transfer coefficient of the appropriate reaction. The current $2j_0$ (in the absence of oxidation of the atomic hydrogen) can be found either by extrapolating the linear portion of the $j^{0.4}$–φ plot to the potentials where non-linearity sets in owing to the oxidation of hydrogen (see Fig. 10), or by measuring the photocurrent with a different acceptor, reacting with the hydrated electron to give products which are not oxidised at the electrode. One such acceptor is nitrous oxide, which forms the $OH^\cdot$ radical after capturing an electron. This radical is reduced at the electrode to the hydroxyl ion over the whole of the accessible range of potential.

Fig. 10 shows some plots of the photocurrent ($j^{0.4}$) against potential in KCl, KBr, and KI solutions containing 0.01 g-equiv. litre^{-1} of HCl. The relationship is linear at negative potentials, and the deviations from linearity (i.e. decrease in photocurrent) set in at increasingly negative potentials on going from Cl^- to I^-. It is evident from Fig. 10 that specific adsorption of the iodide ion has a strong positive effect on the anodic current $\overleftarrow{j}$ (as compared with the cathodic current $\vec{j}$). The experimental data for all solutions give linear plots in φ–$\lg(2j_0/j - 1)$ coordinates, thus confirming the correctness of Eqn. (13). The slopes of these straight lines (100–120 mV) indicate that $\alpha + \beta = 1/2$, i.e. the transfer coefficient of one of the

† The logarithmic term $2j_0/j - 1$ is identically equal to $\overleftarrow{j}/\vec{j}$.

conjugated reactions is zero and hence its rate is independent of potential. Additional information on the mechanism by which atomic hydrogen is removed from solution can be obtained from the effect of pH in decreasing of photocurrent.

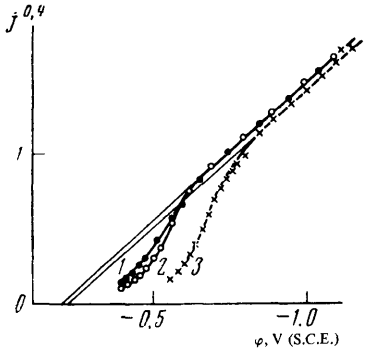

Figure 10. Effect of oxidation of H on the photocurrent. Mercury electrode in 0.1 *N* solution of: *1*) KCl, *2*) KBr, and *3*) KI containing 0.01 *N* HCl.[96]

Fig. 11 shows the variation of the potential φ^*, at which $\vec{j} = -\vec{j}$‡, with the concentration of hydrogen ions, over the $c_{H_3O^+}$ range between 10^{-3} and 1 *N* in solutions containing a total concentration of electrolyte of 1 *N*. As the Figure shows, φ^* increases monotonically with acidity, the increase being most marked in the most strongly acid solutions. At low acid concentrations (10^{-2}–10^{-3} *N*) φ^* is practically independent of pH.

From these results it was concluded[96] that two mechanisms of hydrogen removal are possible: the two conjugated reactions proceed without an adsorption step, or both reactions involve adsorbed hydrogen, in which case one of the reactions is non-activated§. Further experimental data are needed to identify the potential-independent reaction: in particular, we need information from other metals, having a hydrogen adsorption energy different from that of mercury.

The variation of the φ^* potential with pH suggests a new type of electrochemical desorption, involving hydrogen ions and water molecules simultaneously¶. The removal of adsorbed hydrogen by an electrochemical mechanism involving water molecules in acid solutions was first considered by Krishtalik[102].

Specific adsorption of anions accelerates the ionisation of hydrogen (if activated) by producing a more positive potential difference across the fixed part of the double layer. At the same time, anion adsorption should accelerate the electrochemical desorption involving hydrogen ions. As Fig. 10 shows, adsorption of iodide influences ionisation more markedly than electrochemical desorption (particularly, since water takes part in the latter)†.

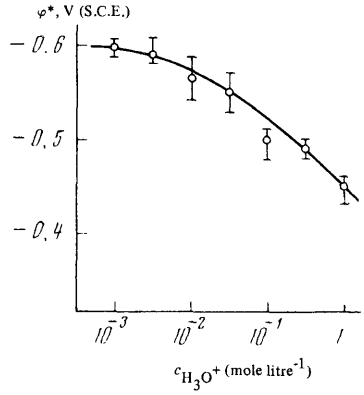

Figure 11. Variation of φ^* potential with concentration of H_3O^+.[96]

The concept of a non-activated electrochemical reaction was first put forward in 1936[103,104], but it has not been possible so far to observe limiting currents due to non-activated discharge in direct experiments. Krishtalik's barrierless processes[100] may be quoted as an indirect experimental proof of the reality of non-activated reactions.

2. Homogeneous Chemical Reactions Involving Free Radicals

The most detailed studies of homogeneous chemical reactions involving the radicals H, OH[105], and NO_3^{2-} [106-108] have been made by the photoemission method.

Barker[105] studied the reaction between methanol and ethanol, on the one hand, and H and OH radicals formed by the photoemission of electrons into acid solutions and into solutions containing N_2O, on the other hand. We know, from radiation-chemical experiments, that the H and OH radicals attack the α-hydrogen in alcohols. The resulting RĊHOH radicals are easily oxidised at the electrode to the corresponding aldehydes. For the case of the oxidation of RĊHOH radicals, the coefficient ν which appears in the kinetic equations (11) and (12) takes the form

$$\nu = \left(1 + \frac{\sqrt{k_R \cdot c_R / D_R}}{\sqrt{k \cdot c / D_e}}\right)^{-1}, \qquad (14)$$

‡ It follows from Eqn. 13 that

$$\varphi^* = \frac{2.3\,RT}{(\alpha + \beta)\,F} \lg \frac{\varkappa_1}{\varkappa_2}. \qquad (D')$$

§ The hydrogen removal mechanism through the adsorbed state seems the more probable, since both reactions (ionisation and reduction in solution) should be non-activated at these potentials[100], and hence the experimentally observed loss of photocurrent cannot be ascribed to them.

¶ The observed variation of φ^* with pH can be formally explained by assuming the formation (in acid solutions) of the H_2^+ radical, which is subsequently reduced at the electrode. However, the rate constant for the reaction between H and H_3O^+ is very small (10^4 litre mole^{-1} s^{-1})[101], and therefore the contribution of this reaction to the photocurrent cannot be substantial.

† The effect of iodide adsorption can be explained in a similar way by assuming that the ionisation of hydrogen is non-activated.

where c_R is the concentration of alcohol present in solution, k_R is the rate constant for the capture of a radical by the alcohol, and D_R is the diffusion coefficient of the H or OH radical.

Eqn. (14) predicts a decrease in photocurrent in the presence of alcohol. The decrease is observed experimentally at $\varphi > -1.4$ V. At more negative potentials the photocurrent is the same as in the absence of alcohol ($\nu \to 2$). The linear relationship predicted by Eqn. (14) between the reciprocal of the current and the square root of the alcohol concentration has been satisfactorily demonstrated (Fig. 12) for the case of OH radicals. The rate constants for the reaction of OH with methanol and ethanol, calculated from the experimental results by means of Eqn. (14), are both equal to 2×10^9 litre mole^{-1} s^{-1}. For the reaction involving H the result is $k_R = 8 \times 10^6$ litre mole^{-1} s^{-1}.

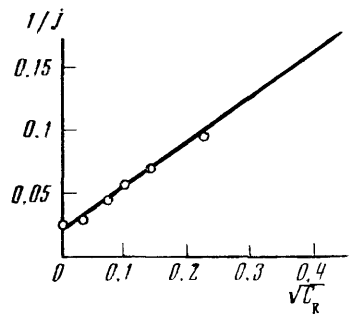

Figure 12. Reciprocal of the photocurrent in 0.2 N KCl solution containing N_2O against square root of ethanol concentration[105].

In the presence of alcohol, the variation of the photocurrent with the concentration c of electron acceptors (N_2O and H_3O^+) is also altered. When the products of the capture of H and OH by the alcohol are not oxidised at the electrode, and at low concentration of acceptors, we have $j \sim \sqrt{c}$ [Eqn. (12)]. If the RĊHOH radicals are oxidised, and the second term in Eqn. (14) is large compared with unity, we have $j \sim c$. This dependence has been observed experimentally.

Barker, using pulsed illumination, was able to monitor the kinetics of the electrochemical oxidation of RĊHOH radicals on mercury by studying the anodic photocurrent which persists after the period of illumination‡. The observed exponential decay of the anodic photocurrent was taken as evidence that the oxidation of RĊHOH radicals is preceded by an adsorption step. The rate constant of the oxidation was $\sim 10^{-3}$ cm s^{-1} at −1.4 V (S.C.E.).

The rate constants for the reaction of H and OH with alcohols found by the photoemission method are in good agreement with experimental results obtained by pulse radiolysis of the same solutions[105].

‡ Levin and Delahay[109] observed anodic currents during the pulse irradiation of acid solutions in the absence of added materials. Their results have not yet been explained satisfactorily.

The chemical reactions of the ion-radical NO_3^{2-} have been studied by two photoelectrochemical methods, using pulsed[106,108] and steady[95,107] illumination. This radical is formed when electrons are photo-emitted into solutions containing NO_3^-. The following chemical reactions take place at the electrode and in its immediate vicinity

$$\left.\begin{aligned} NO_3^- + e_{aq}^- &= NO_3^{2-} \\ NO_3^{2-} &= NO_2^- + O^- \end{aligned}\right\} \text{in solution}, \quad \begin{matrix}(D)\\(E)\end{matrix}$$

$$NO_3^{2-} = NO_3^- + e^- \quad \text{at the electrode}, \quad (F)$$

$$O^- + H_2O = OH + OH^- \text{ in solution}, \quad (G)$$

$$OH + e^- = OH^- \text{ at the electrode}. \quad (H)$$

The NO_3^{2-} ion-radical is oxidised at the electrode at potentials more positive than −1.2 V leading to a decrease in the measured photocurrent[29].

A quantitative study of this reaction by Eletskii and coworkers[107] showed that two "limiting" portions appear on the photocurrent curve (at negative and positive potentials respectively). Both portions obey the "five-over-two" law, and extrapolate to the same threshold potential. Fig. 13 shows the $j^{0.4}$–φ plot for a concentrated solution of $NaNO_3$.

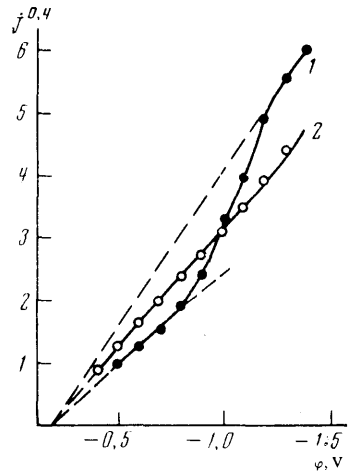

Figure 13. $j^{0.4}$–φ curves in: *1*) 1 N solution of $NaNO_3$ and *2*) the same solution containing 10^{-4} N tetrabutylammonium salt[95].

The experimental results are in good agreement with the theory. Two linear portions (for high and low potentials respectively) are separated by a curvilinear portion extending from −0.7 to −1.2 V relative to the saturated calomel electrode. Small additions of tetrabutylammonium salt (10^{-4} mole litre^{-1}) produce a marked change in the shape of the curve: all the points now lie on the same straight line at potentials more positive than −1.4 V.

The influence of tetrabutylammonium is the result of two separate effects: adsorption at the mercury surface suppresses the emission current[84], but it also inhibits the oxidation of NO_3^{2-}, thus suppressing the decrease in photocurrent at positive potentials. The rate constant k_d for the decomposition of NO_3^{2-} in solution, and the transfer coefficient β of the electrochemical oxidation of NO_3^{2-}, have

been determined from the experimental results: $\beta \simeq 0.25$, $k_d = 6 \times 10^6\ s^{-1}$. A similar value of the transfer coefficient has been obtained by other workers [106,108].

A much lower value of the rate constant ($k_d = 10^4\ s^{-1}$) has been reported [106,108] from measurements of the emitted charge under pulsed illumination of the electrode. Those workers [106,108] ascribe the increase in charge in the presence of NO_3^- to electrochemical reduction of the OH radicals formed from the decomposition of NO_2^- by reactions (E) and (G); k_d was calculated from the kinetics of this growth of charge.

It is evident, from the examples considered in this Section, that the study of photoemission phenomena in aqueous solutions offers a wealth of information on homogeneous and heterogeneous processes in the layer of solution adjacent to the electrode.

3. Competing Solvated-electron Capture Reactions

Competing reactions take place in solution when several electron acceptors are present together. The competing acceptor method is widely used in radiation chemistry to determine relative rate constants. Barker and coworkers [29] have made a quantitative study of the photocurrent in the presence of two competing electron acceptors (A and B).

Acceptors		$10^{-10} k_A$, litre mole^{-1} s^{-1}	
A	B	photo-emission	pulse radiolysis
H_3O^+	N_2O	1.5	1.4
Zn^{2+}	H_3O^+	0.046	0.06
Cd^{2+}	N_2O	3.6	2.1
Ni^{2+}	N_2O	1.5	0.9
NO_3^-	N_2O	2.0	1.76
NO_2	N_2O	0.5	0.63

In the general case, the dependence of the photocurrent on the concentration of the two acceptors (c_A and c_B) can be written in the form

$$j = j_0(\nu_A k_A c_A + \nu_B k_B c_B)/(k_A c_A + k_B c_B)^r. \qquad (15)$$

In this expression k_A and k_B are the rate constants for the reaction of electrons with the acceptors A and B respectively, ν_A and ν_B are the stoichiometries for these reactions. The exponent r depends on the concentration of acceptors. At high acceptor concentrations $r = 1$; when both c_A and c_B are low $r = 1/2$. Eqn. (15) is strictly applicable if the stoichiometries ν_A and ν_B are independent of acceptor concentration. Furthermore, the product of the reaction of an electron with one of the acceptors must not undergo further reaction with the other acceptor.

It follows from Eqn. (15) that the ratio of the rate constants (k_A/k_B) can be determined by studying the variation of the photocurrent with the concentration of both acceptors. The absolute values of the rate constants can be deduced from the relative value if the rate constant of one of the competing reactions is known. Absolute values of the rate constant for the capture of a hydrated electron by various acceptors, measured by the photoemission variant of the method of competing reactions, are listed in the Table [29]. The values obtained by the pulse radiolysis method are also given for comparison.

In the calculations the absolute rate constant k_{N_2O} was taken, on the basis of radiation-chemical measurements, as 5.6×10^9 litre mole^{-1} s^{-1}. The satisfactory agreement between the two methods is evident from the Table.

VI. SOME NON-EMISSION PHENOMENA ASSOCIATED WITH THE EXTERNAL PHOTOEFFECT

As was stated above, photoemission is only one of the many photochemical effects which make up the "Becquerel effect". A brief description of some of these phenomena is appropriate here, because, like photoemission itself, they can be used to study the structure of the interface between an electrode and an electrolyte, and the kinetics of reactions at such an interface.

1. Anodic Photocurrents

To explain the photoeffect, Heyrovský suggested the formation of a charge-transfer complex between the surface of a metal electrode and molecules of solvent or solute decomposed under the influence of light. This explanation cannot be applied to a mercury electrode at potentials more negative than its point of zero charge, i.e. in the region of cathodic photocurrents. In this case, photoemission is a more probable process. But at more positive potentials, where emission is inconceivable and the observed photocurrents are usually of the opposite sign (i.e. anodic), Heyrovský's explanation is probably correct. Anodic photocurrents are observed in solutions of oxalic, chloroacetic, tartaric, and other organic acids and their salts [26]. The molecules of all these compounds contain the $-\overset{\overset{O}{\|}}{C}-\overset{\overset{X}{|}}{C}-$ group, where X denotes an electronegative substituent. When these species are adsorbed at the mercury surface a chemical bond is formed between the metal (acceptor) and the O or X atom (electron donors). The resulting bond can absorb light of greater wavelength than the compound originally in solution. On illumination the adsorption bond is broken, the electrons are transferred to the electrode, and the organic substance (in an oxidised form) is returned to the solution.

A similar mechanism was invoked [110] to explain the photoeffect at a platinum electrode under the influence of u.v. light.

The study of anodic photocurrents can yield valuable information on the energy spectrum of the surface electronic levels of the metal corresponding to the adsorbed particles.

2. Pulse Heating of the Electrode

According to Berg, light adsorption "excites" the electrode and (in the presence of a depolariser) enhances electrochemical reactions which are hindered in the dark. The concept of a "hot" electrode has been tested by looking for evidence of light-induced changes in properties such as surface tension and differential capacitance [70,111]. No significant change in the surface properties of mercury was observed on illuminating a mercury electrode with steady light from a super-high pressure lamp. However, a change in the differential capacity (due to the heating of the electrode and the adjacent layer of solution) has been observed by using very high energy light pulses.

In dilute solutions the differential capacity of the electrode is determined mainly by the capacity of the diffuse part of the double layer, and therefore decreases with increasing temperature. In the galvanostatic and the coulostatic regime a change in capacity produces a shift in the electrode potential; in the potentiostatic regime it produces a change in the current flowing in the external circuit. In both cases the sign of the effect depends on the sign of the charge on the electrode. Korshunov and coworkers [73] have proposed a method of measuring the zero-charge potential of metals based on this effect: as the (dark) potential of the electrode is varied, the sign of the photoeffect is found to change at a value of the potential corresponding to zero charge on the electrode. Long-wave light, which does not cause photoemission, is used in this experiment§.

Other interesting photoelectrochemical phenomena, on which we shall not dwell, include electrode reactions of light-excited depolariser molecules [5,112], photoemission of electrons from the surface of electrolyte solutions into the surroundings [113], and electro-reflection at the metal–electrolyte boundary [114-116].

VII. FUTURE PROSPECTS

The special properties of the metal–electrolyte interface (in particular, the independently variable potential of the electrode) offer a number of valuable facilities in studies of photoemission. Studies of this phenomenon in electrochemical systems can provide information on the electron density in the metal and its distribution, on the properties of the Fermi surface of the metal [117], and on the mechanism of light absorption by the metal surface.

Furthermore, photoemission studies have led to the solution of a number of purely chemical problems. For example, the structure of the electrical double layer and various adsorption phenomena have been studied in detail. The potential variation within the fixed part of the double layer can be investigated by monitoring deviations from the "five-over-two" law. Also, definite conclusions regarding the structure of the fixed part of the double layer can be based on data obtained from the study of photoemission into solutions.

Lastly, it is possible to study the behaviour of electrons in liquids, and in particular to measure the rate of solvation of electrons and the rate of capture of solvated electrons by acceptors and by the electrode surface.

Thus, the photoeffect at the metal–solution interface offers not only an insight into purely photoemission phenomena but also a powerful new method of studying the structure and properties of this interfacial boundary and the physicochemical processes of which it is the seat.

Oxidation of Silicon

V.A.Arslambekov, I.D.Kazarinova, and K.M.Gorbunova

Work on the oxidation of silicon in various gaseous media has been reviewed. Particular attention has been paid to the mechanism of formation and the kinetics of the growth of oxide films on silicon during high-temperature oxidation. Published data on the composition and structure of the resulting film of reaction products, the dependence of the rate of oxidation on the pressure of the oxidising medium, and the possible participation of silicon ions in the growth of the oxide film have been discussed. The bibliography contains 120 references.

1. INTRODUCTION

The interest in oxide films on silicon is due to the development of semiconductor electronics with the use of these films to protect the surfaces of semiconductor devices and also as active and passive elements in solid silicon functional circuits.

The many methods for preparing these films have been for the most part the result of empirical research. In addition to methods involving the thermal[1-23] and anodic[24-30] oxidation of silicon, methods involving the deposition of silicon dioxide films from the gaseous phase have been developed. Methods of this kind which have found application include those involving the volatilisation of oxides of silicon in a vacuum[31-37], cathodic sputtering and sputtering in a high-frequency discharge[30,36-39], the pyrolytic decomposition of organosilicon compounds[30,41-43], and the chemical transport and hydrolysis of silicon halides[30,44-56].

When oxide layers are used as masks in processes of diffusion alloy-formation or the surface protection of a semiconducting device, the purity and continuity of the oxide are important, whereas when silicon dioxide is used as an active element, for example in MOS-structures (metal–oxide–semiconductor), the electrical properties of the film itself and more particularly of the interface between it and the semiconductor acquire considerable importance.

Such properties of the oxide film as the electrical conductivity and charge density in the bulk of the film and at the interface between it and the semiconductor, which determine the parameters of the device and their stability, depend chiefly on the conditions of formation of the oxide. It is the physicochemical conditions of the process (temperature, pressure, the oxidising medium, etc.), and hence of the formation of the oxide film, and the interface between it and the semiconductor, which determine its degree of stoichiometric and structural perfection and the related electrical properties of the MOS-structures.

Thus the detailed study of the mechanism and kinetics of the growth of oxide films, particularly in the initial stages of their formation, is of considerable importance for the production of films with required properties.

The present review deals with problems of the kinetics and mechanism of the thermal oxidation of silicon, which provides one of the basic methods for obtaining silicon dioxide films.

2. KINETICS OF THE GROWTH OF OXIDE FILMS ON SILICON

The initial stage of the reaction of silicon with oxygen when the silicon surface has been effectively cleaned should involve the adsorption of the gas on the surface. Subsequently, the oxygen may dissolve to some extent in the silicon, after which the production of oxide in the form of individual nuclei or a continuous film will take place.

In all the work dealt with in this review, the observation of the course of the high-temperature oxidation process was begun not with an atomically-clean silicon surface but with a surface carrying a thin oxide film, formed during the preliminary treatment of the specimens studied.

These films may have different thicknesses. The subsequent growth of the primary oxide film formed may obey different relationships, depending on its thickness, structure, and composition, and also on the actual conditions of oxidation.

The large number of studies of the kinetics and mechanism of the oxidation of various metals have been reviewed in a number of monographs[57-60], and they show that low-temperature oxidation in most instances is characterised by logarithmic or inverse-logarithmic relationships, whereas high-temperature oxidation most frequently shows a time dependence of parabolic type, deviations from which are observed in a number of instances in the initial stage of the oxidation. The parabolic law for high-temperature oxidation generally means that the rate of oxidation is limited by the rate of diffusion of the reacting components through the oxide film. A theoretical basis for this mechanism was proposed by Wagner[61,62]. His theory is based on the concept of conductivity in ionic crystals and semiconductors. The movement of ions through the oxide film is due to the cation concentration gradient which always exists as a consequence of the constant enrichment of the surface of the oxide layer in oxygen and of the internal interface in cations. Wagner's theory does not deal with the initial stages of the oxidation and is restricted to a consideration of the growth of oxide films after they have reached a definite thickness. The regular features of the initial stage of the oxidation have been interpreted in different ways by different authors. This problem will be discussed after an examination of published data on the kinetics of the high-temperature oxidation of silicon.

The kinetic features of the high-temperature oxidation of single crystals of silicon have been studied by various

methods by a number of authors over a wide range of temperatures and pressures.

Thus Atalla and coworkers [1] studied the stabilisation of the surface of silicon by oxide films grown at 1000° in an atmosphere of water vapour and oxygen.

McAdam and Geil [2] studied the growth of oxide films on silicon, using an optical method to measure the thickness of the oxide. They established that at temperatures in the range 500–950° the results can be described by the parabolic film-growth law:

$$\frac{dn}{dt} = \frac{k}{n} \quad (1)$$

where n is the number of molecules of oxygen reacting in time t, and k the oxidation rate constant.

Brodsky and Cubicciotti [3] studied the oxidation of silicon at p_{O_2} = 200 mmHg by recording the change in the oxygen pressure with time; they obtained at 950° and 1160° a parabolic relationship, and at 1015° and 1020° a logarithmic relationship of the form

$$W = k \lg(1 + at), \quad (2)$$

where W is the quantity of oxidant used in time t, and a and k constants.

The growth of the oxide according to a logarithmic relationship was attributed to the formation of a vitreous oxide of silicon, in which the concentration gradient of the diffusing particles changes not linearly but according to a relationship of the form $\partial c/\partial x = -c_0 \alpha e^{-\alpha x}$ (c_0 is the concentration of diffusing particles at a distance x from their starting point, and α a proportionality efficient). The estimated activation energy of oxidation is E = 26 kcal mole^{-1}.

Law [4] used a manometric method to study the kinetics of the oxidation of silicon at temperatures in the range 727–1027° at pressures of dry oxygen in the range 10^{-3}–5×10^{-2} mmHg. Under these conditions the rate of oxidation is described by a parabolic equation of the form

$$n = 2k\left(\frac{t}{n}\right) + c, \quad (3)$$

where n is the number of oxygen molecules which have reacted in time t, and c and k constants. According to Law's data, E = 36 kcal mole^{-1}.

Evans and Chatterji [5] studied the kinetics of the oxidation of silicon in dry oxygen by a gravimetric method and found that in the temperature range 1200–1400° the rate is given by a parabolic law (E = 43 kcal mole^{-1}). In their opinion, the straight lines shown in Fig. 1 do not, as might have been expected, pass through the origin of coordinates, because at all temperatures the rate of the process in the initial stage is greater than would be expected from a parabolic oxidation law.

Sah and coworkers [6] obtained a parabolic law for the oxidation of silicon in moist oxygen in the range 1200 to 1300° (E = 34 kcal mole^{-1}).

Ligenza and Spitzer [7] studied the oxidation of silicon by oxygen at p_{O_2} = 1 atm and 950°, and concluded that the kinetics of the oxidation can be described by the equation

$$x^2 = 8.4 \cdot 10^{10} \cdot p^{1/4}\left[\exp\left(-\frac{40000}{RT}\right)\right] \cdot t, \quad (4)$$

where x is the thickness of the oxide, Å; t the time, min; and p the pressure, atm.

Later, Ligenza [8] studied the oxidation of silicon in water vapour at a high pressure (25–500 atm) in the range 500–950°, and showed that the growth of the oxide film takes place linearly with time, and that its rate is directly proportional to the vapour pressure.

Yeh [9] used an optical method to determine the thickness of the growing oxide and established that the oxidation of silicon by water vapour at p_{H_2O} = 1 atm and 970° obeys a parabolic law.

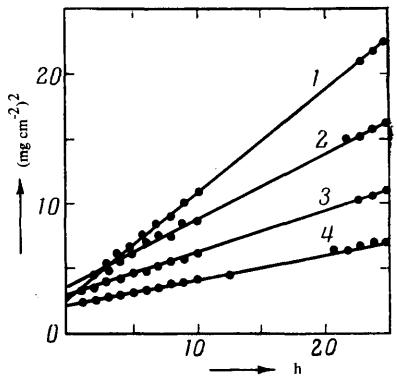

Figure 1. Oxidation of silicon [5]: *1*) 1360°; *2*) 1303°; *3*) 1255°; *4*) 1201°.

Claussen and Flower [10], using an ellipsometric method, found that the oxidation of silicon in dry moist oxygen or water vapour at 1200° also obeys a parabolic relationship.

A similar growth law for the oxide film on silicon in atmospheres of dry oxygen, moist oxygen, or water vapour in the range 1000–1200° was derived by Deal [11], who established that the rate of oxidation in water vapour is greater than that in moist or dry oxygen. The activation energy values obtained by Deal for the three oxidation conditions indicated are given in the Table.

Medium	Activation energy (kcal mole^{-1}) calculated from data	
	gravimetric	optical
Dry oxygen	28.4	30.2
Moist oxygen (95% H_2O)	21.4	20.8
Water vapour	20.0	19.9

Deal [11] noted that at ~1000° the growth of the film takes place according to the law

$$W^2 + k_1 W = k_2 t \quad (5)$$

where W is the quantity of oxide formed, t the duration of oxidation, and k_1 and k_2 constants.

The oxidation of silicon in dry oxygen and water vapour at elevated temperatures was studied by Edagawa and coworkers [12], who obtained the following experimental equations characterising the kinetics of the growth of the films: in an atmosphere of water vapour

$$x_0^2 = 3.35 \cdot 10^9 \cdot t \cdot \exp(-23000/RT) \quad (6)$$

and in an atmosphere of dry oxygen

$$x_0^2 = 4.84 \cdot 10^9 \cdot t \cdot \exp(-32200/RT) \quad (7)$$

where x_0 is the thickness of the oxide film, t the time, and R the gas constant.

Fuller and Streiter [13] studied the oxidation of silicon in an atmosphere of water vapour or dry oxygen in the range 700–1200°. To determine the thickness of the oxide layer they used an ellipsometer and a table of interference colours. In both media, for the reactions taking place below 1070°, they obtained a parabolic law of oxide growth with activation energy equal to 39 kcal mole^{-1}. The reactions taking place at higher temperatures are also characterised by a parabolic oxidation law, but with a lower activation energy.

Revesz and Zaininger [14] found that the oxidation of silicon in an atmosphere of water vapour obeys a parabolic relationship if the thickness of the film formed is greater than 3000 Å. A film of smaller thickness, in the opinion of the authors cited, grows according to a linear law.

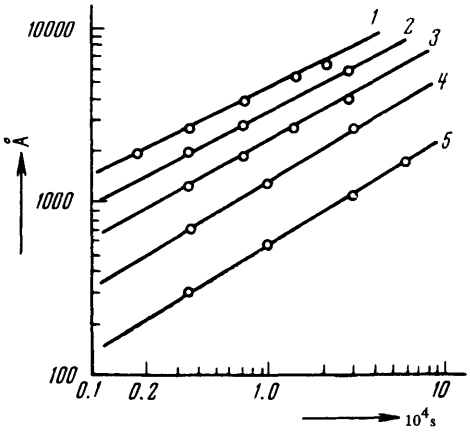

Figure 2. Oxidation of silicon [16]:
1) 1300°, *2*) 1200°, *3*) 1100°, *4*) 1000°, *5*) 900°.

Sladkova [15] used a polarimetric method to study the oxidation of silicon in air. In the range 300–560°, oxide could not be detected. In the range 560–950° the oxidation obeyed the linear law

$$d_1 = k_1\tau + d_0 \quad (8)$$

where d_1 is the thickness of the film, d_0 the initial thickness of the film, τ the time, and k_1 a constant. The value of k_1 depended on temperature: $k_1 = at^2 + b$, where t is the temperature, and a and b constants. In Sladkova's opinion, the oxidation of silicon in the range 950–1000° is described by the parabolic law

$$d_2^2 = k_2\tau + d_0^2 \quad (9)$$

where d_2 is the thickness of the film, d_0 the thickness of the original film, and k_2 a constant.

Evitts and coworkers [16], using an optical method, found the following relationships describing the rate of growth of oxides at temperatures equal to or greater than 1100° and a pressure equal to 1 atm:
for water vapour

$$x^2 = 1.21 \cdot 10^9 \cdot t \cdot \exp(-18400/RT) \quad (10)$$

and for dry oxygen

$$x^2 = 3.53 \cdot 10^9 \cdot t \cdot \exp(-30590/RT) \quad (11)$$

where x is the thickness of the oxide, Å, and t the time, s. The results [16] for the oxidation of silicon in dry oxygen are given in Fig. 2.

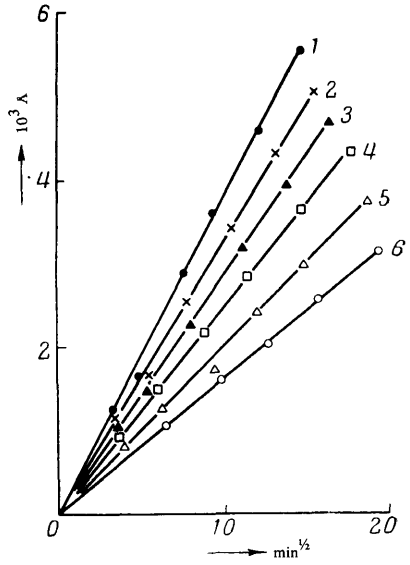

Figure 3. Oxidation of silicon [17]:
1) 1300°, *2*) 1247°, *3*) 1205°, *4*) 1150°, *5*) 1100°, *6*) 1050°.

Lukes and Schmidt [17] used an optical method to study the oxidation of single crystals of silicon in an atmosphere of dry oxygen at 1050° and 1300° and obtained a parabolic law for the oxide film growth (Fig. 3):

$$d^2 = kt, \quad (12)$$

where d is the thickness of the oxide film, t the duration of oxidation, and k a constant. They found that the temperature dependence of the parabolic rate constant k in Eqn. (12) was not exponential, but satisfied the relationship

$$k = A(T - T_0)^2 \quad (13)$$

where A is a constant, and $T_0 = 860°$ (from the experimental data).

The data of Deal and Grove [18] on the oxidation of silicon in dry oxygen, obtained by determining the thickness of the oxide by an optical method, are given on logarithmic coordinates in Fig. 4. The slope of the lines on the graph corresponds to the exponent n in the equation

$$x_0^n = kt \quad (14)$$

where x_0 is the thickness of the oxide film, t is the time, and k a constant.

It can be seen from Fig. 4 that the value of n at 1200° is close to 2, whereas at lower temperatures and smaller oxide thicknesses the value of n at first decreases to 1.5 and then increases again. Thus the data obtained by these authors cannot be described by a simple power law. The difference in the kinetics of the oxidation of silicon in dry

and moist oxygen is demonstrated in Fig. 5. The curve characterising the kinetics of the oxidation in dry oxygen intersects the axis of ordinates at $x_0 = 250$ Å. The authors conclude that this course of the curve is due either to the presence of an oxide film of definite thickness on the silicon surface before the start of the measurements or to the manifestation of a different oxidation mechanism in the first stage of the process. Since in the oxidation of silicon in moist oxygen a primary oxide film was not observed, the authors used the second alternative to explain the results obtained on oxidation in an atmosphere of dry oxygen. The rate of oxidation was higher at the start of the process in dry oxygen at 700° (Fig. 6).

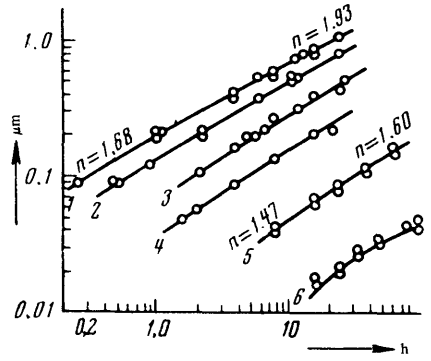

Figure 4. Oxidation of silicon in dry oxygen[18]: *1*) 1200°, *2*) 1100°, *3*) 1000°, *4*) 920°, *5*) 800°, *6*) 700°.

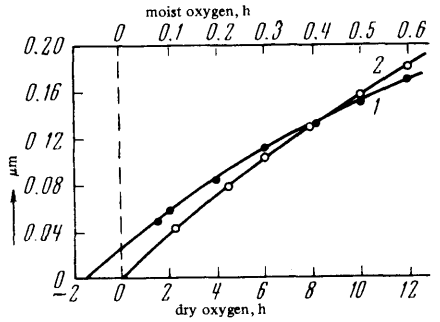

Figure 5. Oxidation of silicon in dry and moist oxygen[18]:
1) dry, *2*) moist.

Deal and Grove[18] consider that the kinetics of oxidation of silicon over a wide range of temperature and pressure by the action of oxygen or water vapour obeys a relationship of the form

$$x_0^2 + Ax_0 = B(t + \tau) \qquad (15)$$

where x_0 is the thickness of the oxide film, t the time, and A, B, and τ are constants for the oxidation.

According to Pliskin[19], the oxidation of silicon in an atmosphere of water vapour also obeys a linear–parabolic law.

Nakayama and Collins[20] studied the kinetics of the growth of films of SiO_2 on silicon in a mixture of water vapour and oxygen or argon in the range 850–1217° and partial pressures of water in the range 4.6–355 mmHg. In this temperature range the authors observed a mixed linear–parabolic oxidation law of the form

$$Ax + Bx^2 = t \qquad (16)$$

where x is the thickness of the oxide, t the time, and A and B constants. Hikaru and Dzenti[21] give data on the influence of the treatment of the surface of the specimen, the moisture content of the oxidising medium, and the crystallographic characteristics of the crystal plane studied, on the rate of oxidation of silicon. They did not observe any differences in the rates of oxidation of specimens subjected to mechanical and chemical polishing. The rate of oxidation increased with increase in the moisture content. In the range 995–1050° the rate of oxidation depended on the orientation of the crystal plane studied, as follows: $v_{[111]} = v_{[110]} > v_{[100]}$. It was found that the activation energy of oxidation changes on going to the temperature range below 1100°. The authors cited conclude that at low temperatures the mechanism of oxidation is different, and the growth of the oxide film does not follow a quadratic law.

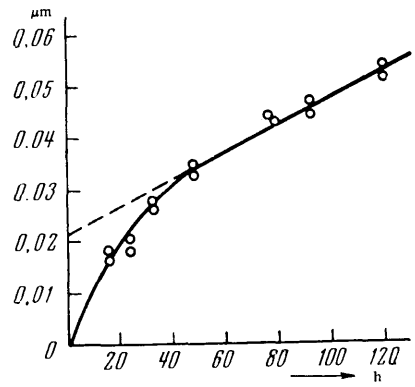

Figure 6. Oxidation of silicon in dry oxygen at 700°.[18]

According to the data of Mai[22], the growth of the oxide film in the successive oxidation of silicon in dry oxygen, moist oxygen, and water vapour at 1150° obeys a parabolic relationship, the rates of the corresponding processes decreasing in the order: $v_{\text{water vapour}} > v_{\text{m.o.}} > v_{\text{d.o.}}$

Burkhardt and Gregor[23] determined the volume of oxygen used in the oxidation from the position of a mercury seal in a measuring tube; adopting the interpretation of the oxidation put forward by Deal and Grove[18], they obtained a linear–parabolic relationship for the growth of oxide films as far as thickness of 5000–6000 Å.

3. MECHANISM OF FORMATION OF OXIDE FILMS

Analysis of published data on the thermal oxidation of silicon shows that at high temperatures the growth of the oxide film follows a parabolic time dependence, deviations from which have been observed by a number of authors[5,11,13,18,23] in the initial stages of oxidation.

Many authors try to explain the formation of the primary oxide films on silicon on the basis of the mechanism of formation of thin oxide films put forward by Cabrera and Mott[63]. This mechanism assumes that in the film of oxide formed on chemisorption, the electrons of the metal, moving independently of the ions, pass through the thin layer of oxide, either by a tunnel effect or as a result of thermionic emission, and react with oxygen on the outer surface of the film, that is at the oxide–gas interface, forming oxygen anions. Metal cations are formed correspondingly at the metal–oxide interface. As a result, in the opinion of the authors cited, a strong electric field, which facilitates the transfer of positive ions to the oxide–gas interface, is created inside the oxide film. The rate of ion transfer should show an exponential dependence on the field intensity, and the oxidation is described by a corresponding inverse logarithmic equation.

In a recent paper, Mott and Fehlner[64], taking into account the ideas of Eley and Wilkinson[65], dealt with the role of the structural factor in oxidation for the example where the growth of the oxide film involves the migration of oxygen through the oxide film.

Other authors[4,13] attribute the deviation from the parabolic law in the initial stage of the oxidation to the production of a space charge, in accordance with the ideas of Engell and Hauffe[66–68]. According to these ideas, exchange of charge carriers between the gas molecule being adsorbed and the semiconductor takes place on chemisorption, so that this stage leads to charging of the surface. As a result, a space charge is produced in the layer of the semiconductor next to the surface, leading to the manifestation of a diffusion potential, resulting from the difference in the mobilities of the electronic and ionic defects in the thickness of the oxide. In the opinion of this group of authors, a parabolic oxidation law should not be observed so long as the thickness of the growing layer is comparable with the region of the space charge influencing the ion diffusion responsible for the growth of the film.

Deal and Grove[18], using the model of oxidation proposed by Evans[57,69], suggest that for "short" times, the duration of which is determined by the specific conditions of the oxidation, a linear law of oxide growth should operate. Evans, however, in the interpretation of the equation which he derived, of the form

$$k_1 y^2 + k_2 y = k_3 t + k_4 \qquad (17)$$

where y is the thickness of the oxide film, t the time, and k_1, k_2, k_3, and k_4 constants, considered that for small values of t and y, Eqn. (17) becomes a simple parabolic equation, and at high values of t and y it may approach a linear equation.

Growth of the oxide film according to a linear law is possible if the oxide splits with the passage of time, as a consequence of a difference in the volumes of the oxide and the metal. In this instance, oxygen has free access to the metal surface, and the stage determining the rate of oxidation will be the reaction at the oxide–gas interface. It should be noted that a linear oxide growth law is also possible at very low oxygen pressures, when the oxygen being supplied is unable to compensate the loss of oxygen during its reaction with the cations passing through the oxide film, as observed, for example, by Gulbransen and coworkers[70], who made a gravimetric study of the oxidation of silicon at oxygen pressures equal to 9×10^{-3}, 4×10^{-2}, and 1×10^{-1} mmHg and temperatures of 1100, 1200, and 1300°. The authors cited put forward four equations to describe the reactions involved in the oxidation of silicon

$$Si_{(s)} + {}^1/_2 O_{2(g)} \rightleftarrows SiO_{(g)}, \qquad (18)$$

$$Si_{(s)} + O_{2(g)} \rightleftarrows SiO_{2(s)}, \qquad (19)$$

$${}^1/_2 Si_{(s)} + {}^1/_2 SiO_{2(s)} \rightleftarrows SiO_{(g)}, \qquad (20)$$

$$SiO_{2(s)} \rightleftarrows SiO_{(g)} + {}^1/_2 O_{2(g)}. \qquad (21)$$

A small increase in weight, indicating the formation of a layer of oxide on the surface according to Eqn. (19), was observed only at $p_{O_2} = 1 \times 10^{-1}$ and a temperature of 1100°. Under all other conditions, a decrease in weight as a result of the formation of the volatile monoxide according to Eqn. (18) was observed. Gulbransen and coworkers[70] established that the rate of oxidation is linearly dependent on the rate of flow and pressure of oxygen. They concluded that the rate of oxidation at low oxygen pressures is a function of chiefly the pressure and velocity of the gas stream, and is almost independent of temperature. In this case the rate of the process is determined by the transfer of gas to the surface of the specimen.

An analysis of the primary stage of the oxidation would be incomplete without consideration of the importance of the active sites on the metal surface, the role of which may be extremely significant, particularly in the examination of the influence of the pressure of the oxidising medium on the oxidation.

Arslambekov[71] has examined the kinetics of the formation and growth of the primary oxide film from the viewpoint of kinetic theory. The rate of the process in this instance can be represented by the equation

$$\frac{\partial n}{\partial t} = (N_0 + N_{\text{diff}} - n) \cdot \sigma \cdot Z \cdot e^{-E/RT} \qquad (22)$$

where N_0 is the initial number of active metal atoms on the surface, N_{diff} the number of active metal atoms coming out on the surface as a result of diffusion, n the number of metal atoms reacting, δ the effective cross-section of the metal atom–gas molecule reaction, Z the number of oxygen molecule collisions taking place on 1 cm² of the surface, and t the time.

The solution of this equation for low temperatures and low pressures, that is for the conditions under which the formation of thin oxide films can be followed, has the form

$$n = N_0(1 - e^{-kt}) \qquad (23)$$

where $k = 6 \times 10^6 \frac{p}{\sqrt{T}} \cdot e^{-E/RT}$ is the rate constant; p the pressure, mmHg; E the activation energy; and T the temperature, °K.

On the basis of the theoretical considerations developed in Refs. 71–73, Arslambekov put forward a mechanism for the formation of the oxide film, describing the interaction between oxygen and an atomically-clean metal surface, with allowance for local superheating.

In the elementary stage of the interaction of a gas molecule with a metal surface, all the heat of reaction is liberated in a negligibly small volume, and this leads to a local increase in temperature. The next gas molecule entering the local superheating zone undergoes reaction with a greater probability than that for the cold regions. This leads to additional liberation of heat and an increase in the temperature of the surface. The latter will increase until a steady state, in which the quantity of heat supplied by the reaction is equal to the quantity of heat removed by the thermal conductivity of the metal, is established.

At low oxygen pressures, the frequency of collisions against the surface is low, so that in the time interval

between two successive collisions of oxygen molecules in the same zone the heat from each elementary stage of the interaction is able to undergo complete scattering. Each new molecule of oxygen then reacts with a cold surface, so that the formation of the oxide film should take place relatively slowly, and the thickness of the layer formed may be very small (only several monolayers).

It should be noted that in all the above theories of formation of the primary oxide films, attention was not paid to the role of the crystal lattice type of the metal being oxidised and the oxide, or the crystal-chemical relationships between them. Allowance for the crystal-chemical correspondence between the structures of the metal and the oxide, however, reveals significant features of the actual mechanism of formation of oxide layers on metals.

According to Dankov's crystal-chemical theory of oxidation [74,75], the establishment of a stoichiometric relationship between the components takes place as soon as a monomolecular layer of oxide is formed. The characteristic feature of the primary stage of the oxidation is that in this stage there is direct contact between the oxygen molecules and the chemically non-combined metal atoms, whereas in the subsequent stages the O_2 molecules encounter the chemical compound M_xO_y on the surface.

A characteristic feature of the oxidation, observed when the reaction takes place at room temperature, is the attainment of a limiting oxide film thickness; this limit lies in the range of submicroscopic thicknesses. In the mechanism proposed by Dankov for the formation of oxide films of limiting thickness, it is assumed that the growth of the oxide film at moderate temperatures, in which diffusion of the components through the oxide is required, is made possible by the penetration of defect sites in the oxide lattice. The latter results from the non-coordinated growth of a large number of oxide blocks consisting of stoichiometric saturated formations.

On the basis of the theory that there is a gradual decrease in the concentration of the defects which are responsible for the diffusion and hence which determine the rate of formation of the oxide, Dankov derived an equation which characterises the change in the thickness of the oxide with time and which indicates the existence of an oxidation limit:

$$y^2 = \frac{2k''}{k}(1 - e^{-kt}), \qquad (24)$$

where y is the thickness of the oxide, k'' and k constants, and t the time.

A development of Dankov's principle of orientational and dimensional correspondence as applied to solid-phase chemical reactions was provided by the scheme proposed by Arkharov [76] for the nucleation of the primary crystal of a chemical compound. According to Arkharov, the reaction of a metal with a gas involves the formation of a supersaturated solid solution, in the volume of which the primary nucleus of the oxide phase is formed.

The reasons and conditions for the formation of nuclei of the oxide phase on a metal surface in its reaction with an oxidising medium have been examined by a number of authors [58,77,78].

The following scheme for the growth of oxide films on silicon in dry oxygen was proposed by Ono and coworkers [79]. In the initial moment of oxidation, isolated oxide units are formed around the defects in the silicon surface (impurity atoms, dislocations, lattice defects, etc.). Subsequently, each isolated unit expands, and its surface acquires a planar form. The upper layers of these regions consist of SiO_2, and the inner layers consist of a series of lower oxides of silicon. The secondary projections produced between the isolated oxide units on subsequent oxidation expand and join up with one another, and when the process lasts for a sufficiently long time they cover the Si surface completely.

Arslambekov and coworkers [80] give experimental data on the kinetics of the oxidation of silicon at temperatures in the range 700–1180° and oxygen pressures in the range 10–320 mmHg, obtained by continuous weighing on an automatic vacuum micro-balance. They also give a theoretical analysis of the kinetics of the growth of oxide films on silicon with allowance for the defects produced in the oxide film in the primary stage of the oxidation, and also with allowance for the possible counter-diffusion of oxygen and metal through the oxide. The experimental data are effectively described by the derived kinetic equation, which takes account of a number of possible stages in the high-temperature oxidation:

$$(Q + Q_0)^2 = 2kt + 2A\tau_a(1 - e^{-t/\tau_a}) + 2B\tau_b(1 - e^{-t/\tau_b}) + Q_0^2 \qquad (25)$$

where Q is the quantity of oxygen absorbed in the oxidation, Q_0 the quantity of oxygen absorbed in the primary stage of the oxidation, k the parabolic oxidation rate constant, t the time, A and B coefficients making allowance for the influence of the concentration of defects in excess on the diffusion of the components (oxygen and silicon respectively), and τ_a and τ_b the non-equilibrium defect relaxation time constants for oxygen and silicon respectively.

The accelerated growth of the oxide film at small thicknesses ($t < 3\tau$)—compared with the parabolic—which follows from the relationship derived by the authors cited, is due to the presence of an excess of structural defects produced in the primary stage of the reaction between silicon and oxygen. When the concentration of defects reaches the equilibrium value for the given temperature, when $t > 10\tau$, the exponential terms become much less than unity, and the growth of the oxide film will be described by a parabolic equation of the form

$$Q^2 + 2QQ_0 = 2kt + c \qquad (26)$$

where

$$c = 2A\tau_a + 2B\tau_b + Q_0^2 . \qquad (27)$$

4. COMPOSITION AND STRUCTURE OF OXIDE FILMS ON SILICON

The reliable determination of the mechanism of oxidation requires continuous measurement of the change in the weight of the specimen over a fairly prolonged period, and comparison with the composition and structure of the reaction products. The detailed analysis of the nature of the oxide films on silicon is made difficult by their amorphous structure, established by a number of authors [81–86] by X-ray and electron diffraction.

Pavlov and Shitova [87] made an electron diffraction study of films on silicon, produced by oxidation in water vapour under pressure (p_{H_2O} = 0.25 atm, temperature 650°) and in a high-frequency discharge plasma with tetramethoxysilane as starting material. Depending on temperature and pressure, crystalline silicon dioxide can exist in various structural modifications: quartz (α, β), tridymite (α, β, γ), and cristobalite (α, β) [88], which have been shown by X-ray diffraction [89] to be based on SiO_4 tetrahedra which are joined at their apices and are

arranged in space according to a definite law. In the cristobalite structure, closed cavities are formed, whereas in the tridymite structure, channels penetrating the entire framework are left. It has been shown[87] that irrespective of the method of production, all the films have an amorphous structure, in which the short-range order is identical to that in the structures of β-cristobalite and β-tridymite. Experiments on the diffusion of boron and phosphorus at 1200° gave very low values for the diffusion coefficients (10^{-15} cm^2 s^{-1}) for all types of film[90], and it was concluded that the cristobalite structure is the most probable from the energetic viewpoint.

Revesz[84] studied the structure of films obtained by different methods: thermal oxidation in moist or dry oxygen, anodic oxidation, and pyrolytic decomposition of tetraethoxysilane. In all instances the diffraction patterns contained only a diffuse ring or "halo" indicating that the oxide has an amorphous structure. Revesz considers that the small crystallites which may be formed in the initial stage of the growth of the oxide when the silicon surface carries projections and cracks facilitating the formation of nuclei of the crystalline phase are subsequently "displaced" to the oxide surface and no longer serve as crystallisation centres. He points out that the refractive indices and absorption of the films in the infrared range of the spectrum are very similar to those for vitreous silica, the structure of which is similar to that of cristobalite. In Revesz's opinion, the "vitreous" oxide formed is a non-crystalline chemically homogeneous material characterised by short-range order and the presence of Si–O bonds.

Thus according to modern theories[30,91], amorphous silica consists of a disordered three-dimensional network of silicon–oxygen tetrahedra, which are connected only through their apices, and not via edges or faces. The tetrahedra in quartz glass are similar to those in crystalline quartz, but in the glass they form a disordered network, and in crystalline quartz they form a regular lattice; even in quartz glass, however, many of the tetrahedra are grouped to form the hexagonal rings characteristic of crystalline quartz. According to modern theories of the vitreous state, the arrangement of the tetrahedra is not completely random[92]; the short-range order in the network of tetrahedra may be characterised by regions of crystallinity with dimensions from 10 Å to 100 Å. Thus the terms "quartz lattice", "vacancy", "interstitial atoms", etc. are used to describe the structure of the glasses.

In an examination of the problem of the phase composition of the oxide films formed on silicon, it must be borne in mind that since the free energy of the silicon–oxygen interface is different from that for the bulk of the material, there is a probability that compounds which are unstable in the volume of the material may be formed in this region. Thus the thermo-dynamic characteristics of the films formed on the surface may differ significantly from those of the same material in compact form.

The existence of the following oxides of silicon has now been established: SiO, Si_2O_3, SiO_2, and Si_3O_4[93].

Published data on the nature of solid silicon monoxide are contradictory. Most authors, on the basis of X-ray diffraction studies, regard it as an amorphous material[94-97]. Some workers consider that it is a fine mixture of silicon and silica (indistinguishable by X-ray diffraction[98-100], but direct proof for this hypothesis has not been given. Only two papers[101,102] describe SiO specimens with a cubic lattice with constant $a = 5.16$ Å.

Valuable information on the properties of silicon monoxide can be obtained by optical methods, particularly in the infrared range[103-106]. It has been noted[104-106] that the optical properties of a condensed film of silicon monoxide differ significantly from the properties of films of elementary silicon and of silicon dioxide. York[107] considers that data on the absorption spectra of silicon oxide films in the ultraviolet, visible, and infrared ranges can be used to establish quantitatively the proportions of the phases SiO, Si_2O_3, and SiO_2 in films obtained by condensation in a vacuum. According to Nishimura and coworkers[108], analysis of the infrared absorption spectrum indicates that the oxide films deposited in a high vacuum with a source at an elevated temperature contain SiO, whereas the films obtained in a low vacuum and with a source at a low temperature contain Si_2O_3. Litvinova and coworkers[93] report that it is possible that the phases Si_2O_3, Si_3O_2, and Si_3O_4 exist in the compact state in addition to the phase SiO. The materials studied were specimens of silicon oxides obtained by the condensation of SiO vapour in a vacuum. Films of oxides richer in oxygen than SiO were obtained under conditions in which small quantities of air were supplied to the vacuum chamber of the furnace. The compositions of the phases were established by high-precision chemical analysis and X-ray micro-analysis, and verified by carrying out the oxidation with continuous weighing. The authors cited concluded that the gaseous monoxide SiO, on condensation, can pass directly into the solid state, but that in order to prevent its disproportionation it is necessary to ensure a sufficiently high rate of cooling of the SiO vapour. In their opinion, the oxides SiO, Si_3O_4, and Si_2O_3 are stable only at high temperatures, have a high vapour pressure, and can exist indefinitely in solid form. albeit in a metastable state.

The explanation given by Sladkova[15] for the increase in the refractive index of oxide films on silicon from 1.48 to 1.55 is that in some instances the films formed on the silicon surface contain an SiO phase.

An attempt has been made[109,110] to establish the phase composition of the oxide films formed in the thermal oxidation of silicon in dry oxygen, by the analysis of data characterising the volatilisation of these films. Silicon itself, and some of its oxides, have an appreciable volatility. If the heats of evaporation of the individual phases differ significantly, it is sometimes possible, by carrying out studies over a wide range of temperatures, to reveal regions in which the kinetics of the overall process are determined by the volatilisation of one of these phases. In this instance, if the oxide film consists of several phases with different heats of volatilisation, inflections should be observed on the graphs giving the temperature dependence of the volatilisation rate constants on coordinates $\lg k$ against $10^4/T$. In both of the works cited, the analysis of the temperature dependence of the rate of volatilisation did in fact reveal three regions corresponding to volatilisation in the temperature ranges 810–1010, 1010–1082, and 1082–1150° (Fig. 7). The values of the heats of volatilisation calculated from the experimental data for these regions were found to be ~60, ~145, and ~117 kcal $mole^{-1}$ respectively. Microscopic analysis of the silicon surface after oxidation[110] showed that the oxide film had a marked defect structure, probably due to the change in the temperature conditions during oxidation and the long duration of the experiments. The presence of micropores and cracks in the oxide film probably also explains the fact that at about 950° the specimen showed a decrease in weight, due to the volatilisation of silicon monoxide present under a layer of silicon dioxide. This suggestion may also explain the difference in the data on the course

of the volatilisation of oxide films from a silicon surface in its initial stages [109,110].

Thus the oxide film on silicon, as on most metals, consists of several oxides: the outer layer consists of the dioxide, and the inner layer consists of silicon monoxide.

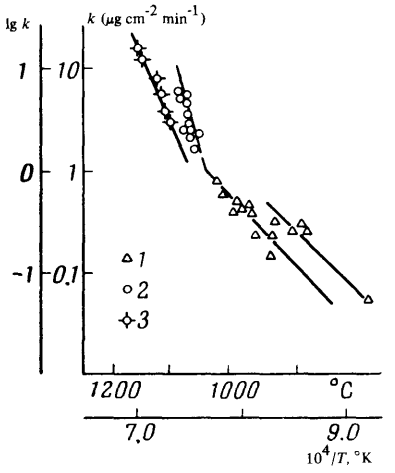

Figure 7. Volatilisation of silicon oxide films obtained by oxidation in dry oxygen at p_{O_2} = 40 mmHg in the range 816–916° for 44 h [110]:
1) volatilisation of SiO, *2*) volatilisation of SiO_2, *3*) volatilisation of Si.

5. DEPENDENCE OF THE RATE OF GROWTH OF OXIDE FILMS ON SILICON ON THE PRESSURE OF THE OXIDISING MEDIUM

A detailed understanding of the high-temperature oxidation of silicon requires a knowledge of the dependence of the reaction rate on the pressure of the oxidising medium.

If the rate of oxidation is limited by adsorption, the reaction usually depends markedly on the oxygen pressure. Under limiting conditions at very low oxygen pressures, the rate of oxidation is proportional to the rate of collision between oxygen and the surface, and hence to the oxygen pressure. At higher oxygen pressures the rate of oxidation is often proportional to $(p_{O_2})^{1/2}$. This is observed, in particular, in oxidations obeying the linear relationship, when the reaction rate is determined by processes beyond the limits of the phases.

Law [4] considers that the parabolic oxidation rate constant for thin oxide layers (100–1000 Å) is described by an equation of the form:

$$k = k_0 \ln p_{O_2} + \text{const} \qquad (28)$$

where k is the oxidation rate constant, and p_{O_2} the oxygen pressure.

A more marked dependence of the rate of oxidation of silicon on the pressure of oxygen, reflected by the empirical equation (29), was established by Arslambekov [109]:

$$x^2 = 1.1 \cdot 10^6 \cdot t \cdot p^{1/3} \cdot e^{-40000/RT} \qquad (29)$$

where x is the thickness of the oxide film, Å; p the pressure of oxygen, mmHg; and t the time, min.

6. NATURE OF THE DIFFUSING PARTICLES IN THE OXIDATION OF SILICON IN VARIOUS GASEOUS MEDIA

A number of papers [7,8,30,83,111–113] have been devoted to the investigation of the nature of the diffusing particles in the oxidation of silicon in various gaseous media.

Some authors [30] suggest that in the oxidation of silicon by water vapour, the first layers of oxide are formed by the chemisorption of water. Since these layers prevent further contact between water and silicon, the reaction takes place either between surface silicon atoms, combined in the crystal lattice, and water molecules, present in the interstices of the oxide, or between an intermediate silicon hydroxide group and silicon.

In the first instance the oxide is formed in the reaction

$$H_2O + Si{-}Si \rightarrow Si{-}O{-}Si + H_2 . \qquad (30)$$

In the second instance the following reactions take place: close to the gas–oxide interface

$$H_2O + Si{-}O{-}Si \rightarrow 2\,(Si{-}OH) , \qquad (31)$$

at the oxide–silicon interface

$$2\,(Si{-}OH) + Si{-}Si \rightarrow 2\,(Si{-}O{-}Si) + H_2 . \qquad (32)$$

In both reactions of oxide formation, described by Eqns. (30) and (32), the hydroxyl groups reacting with silicon must diffuse through the oxide layer in order to reach the oxide–silicon interface. It is assumed that the hydrogen, the rate of diffusion of which is fairly high ($D_{(H_2)_{1050°}} = 2.2 \times 10^{-6}$ cm² s⁻¹), diffuses through the oxide layer to the oxide–gas interface.

If a loose oxide layer is formed in the oxidation of silicon in an atmosphere of water vapour, the diffusion of hydroxyl groups or water molecules is facilitated. In this instance the process retarding the oxidation may be the reaction of the diffusing particles with silicon. Confirmation that the reaction rate is the factor limiting the oxidation can be provided, in the opinion of the authors cited, by the dependence of the rate of oxidation on the crystallographic characteristics of the surface being oxidised; this dependence is shown particularly clearly at high vapour pressures and low temperatures. It is found that $v_{[110]} > v_{[311]} > v_{[111]}$, where v represents the rates of oxidation of the corresponding faces.

The presence of impurities on the surface and in the volume of the semiconductor may lead to the production of pores of molecular dimensions, micro-cracks, dislocations, and other defects and inhomogeneities in the oxide. The pores and cracks make the oxide layer permeable to gases [115–118], and this must influence the regular features of the growth of the oxide.

In oxidation by water vapour, the presence of impurities in the volume of the silicon may influence both the rate of the surface oxidation and the diffusion coefficient of the reacting particles. For example, phosphorus influences chiefly the rate of the surface reaction: the surface containing a high concentration of the element is oxidised more rapidly than a surface containing a low concentration [118]. On silicon containing boron, the growing oxide "extracts" a large quantity of boron from the volume of the silicon [119]. The increasing defect nature of the oxide lattice leads to an increase in the rate of diffusion of the components of the reaction through the oxide.

Under conditions of prolonged oxidation at pressures of ~100 atm, dissolution of the oxide in water vapour is possible [8]. At even higher pressures, the silicon surface is etched as a result of the increased intensity of this process.

Study of the oxidation of silicon in a mixture of water vapour, oxygen, and argon[20] established that the concentration of water in the gas stream is the most important variable determining the rate of growth of the oxide at a given temperature. Change in the ratio of the partial pressures of water and oxygen may lead to a significant change in the kinetics of oxidation. Thus the activation energy of oxidation in moist oxygen decreases with increase in the concentration of water vapour. The process takes place much more rapidly in water vapour than in moist or dry oxygen, and the rate of oxidation in moist oxygen is greater than that in dry oxygen.

The nature of the diffusing particles in the oxide in the reaction of silicon with oxygen has been studied by various methods[83,112,113]. Thus Karube and coworkers[112] deposited the radio-active tracer ^{32}P on the oxidised surface of a specimen. The oxidation was then repeated under the same conditions (in a stream of oxygen at 1250°). The distribution of the diffusing particles was determined from the radio-activity values obtained by successively etching away layers of the oxide. The study was based on the following considerations: if silicon diffuses in the repeated oxidation, it will react at the gas interface, and the surface containing the radio-active tracer will again be covered by the growing oxide. If the process takes place as a result of the diffusion of oxygen, the chemical reaction will take place on the $Si-SiO_2$ interface, and the surface of the oxide obtained in the first oxidation will remain the gas–oxide interface. The results of the experiment confirmed the second mechanism, according to which the oxidation takes place with the transfer of oxygen through the oxide lattice.

Jorgensen[113] used a combination of methods involving the deposition of a Pt tracer on the surface and the application of an electric field. A layer of platinum with thickness 1 μm was deposited on the surface of a silicon crystal with a specific resistance of 1000 Ω.cm. A layer of silicon monoxide was deposited on the platinum and then oxidised to the dioxide. The position of the tracer was determined by measuring the resistance. If the resistance between the tracer and the silicon had remained unchanged on oxidation, this would have indicated that the platinum remains at the metal–oxide interface and that the oxidation product is formed under the platinum. The experiment showed that the resistance was equal to 4000 Ω before oxidation, and 6000 Ω after oxidation. On the basis of these results the author cited concluded that during the oxidation, the oxygen diffuses through the deposited layer of SiO, the platinum, and the layer of SiO_2 formed in the process, and then reacts at the oxide–silicon interface. To determine whether the oxygen diffuses in the oxide in the form of atoms or ions, Jorgensen carried out experiments, the results of which showed that the rate of oxidation is influenced by an electric field applied at right angles to the silicon surface. This increases the rate of oxidation when the silicon at the $Si-SiO_2$ interface is at a higher positive potential than that at the SiO_2-O_2 interface, indicating that oxygen diffuses in the form of negatively changed ions. Laverty and Ryan[120], however, carried out analogous studies at different oxygen pressures and concluded that in addition to the ionic component, neutral oxygen in molecular form takes part in the diffusion responsible for the growth of the oxide film.

Balk and coworkers[83] used electron microscopy to study the structure of a silicon surface subjected to thermal oxidation in dry oxygen and in water vapour, and established that the relief of the original silicon surface in the first stages is preserved in the outer layers of oxide, whereas the internal surface after removal of the oxide is smoothed. The explanation put forward by the authors cited for this phenomenon is that both with dry oxygen and with water vapour, the oxidation takes place at the silicon–oxide interface, so that the diffusing particles responsible for the growth of the oxide are oxygen particles.

In all the above work on the investigation of the nature of the particles diffusing through the oxide, the reaction of silicon with oxygen was carried out with gas at atmospheric pressure. While stating that the growth of the oxide films takes place under these conditions chiefly as a result of the diffusion of oxygen, the authors cited do not exclude the possibility of diffusion of silicon.

Arslambekov and coworkers[80], in an investigation of the influence of pressure on the kinetics of the oxidation of silicon, found that with decrease in pressure the activation energy of oxidation increases. The experimental results can be explained on the basis of the following considerations. At increased oxygen pressures the rate of oxidation of silicon is determined chiefly by the diffusion of oxygen through the oxide film. With change in the oxygen pressure there is a change in its concentration in the surface layer of oxide, and this leads to a change in the difference in the concentrations of oxygen at the gas–oxide and oxide–silicon interfaces. This should lead to a change in the overall diffusion stream, and hence to a change in the oxidation rate constant k. The difference in the concentrations of silicon at the interfaces, and the chemical potential gradient, are almost independent of the oxygen pressure. With marked decrease in the oxygen pressure in the system, the ratio of the diffusing atoms of silicon and oxygen taking part in the formation of the oxide film changes considerably. There are grounds for assuming that at a certain critical oxygen pressure in the system the quantity of oxygen diffusing in unit time may become commensurate with the quantity of silicon diffusing in unit time. Further decrease in the oxygen pressure may lead to a situation in which the process will be determined chiefly by the diffusion of silicon atoms. Since the activation energies for the diffusion of oxygen and silicon are different, we should also expect a change in the effective activation energy of the oxidation as a whole, as observed experimentally[80].

---o0o---

The variety of complex phenomena observed in the oxidation of silicon explains the observed differences in the properties of the oxide films obtained under different conditions, and indicates the possibility of directed control of a number of these properties. This follows primarily from the dependence of the diffusion stream of silicon and oxygen on the conditions under which the process is carried out. In accordance with this, the zone which moves should be that in which the characteristic chemical reaction corresponding to the kinetic measurements takes place with the greatest probability. The distribution of heat in the oxide layer takes place accordingly.

Displacement of the regions in which the reaction takes place and heat is liberated should naturally influence the nature of the distribution of the stresses in the oxide and also the structural defects responsible for the electrical properties of the system.

The properties of oxide layers may also be influenced significantly by the conditions of the primary reaction of oxygen and silicon, the mechanism of which is also examined in this review.

Influence of Metallic Additives on the Reduction of Solid Oxides

N.I.Il'chenko

The present review deals with one type of topochemical heterogeneous-catalytic reaction—the reduction of solid oxides by gaseous reducing agents (chiefly molecular hydrogen) in the presence of small quantities of metallic additives. Experimental data on the influence of these additives on the reduction of various oxides have been systematised, and the general regular features characteristic of these processes have been formulated. These regular features have been interpreted from the viewpoint of an electronic-chemical reduction mechanism. Methods for the practical utilisation of these reactions have been indicated. The bibliography contains 34 references.

CONTENTS

I. Introduction 47
II. Methods of preparing catalysts and their physical properties 47
III. Catalytic action of small quantities of metallic additives on the reduction of oxides by molecular hydrogen 48
IV. General regular features and mechanism of action of metallic additives on the reduction of oxides by molecular hydrogen 50

I. INTRODUCTION

Reactions involving the reduction of metal oxides by gaseous reducing agents (hydrogen, carbon monoxide, etc.) form the basis of many metallurgical processes, are widely employed in preparative inorganic chemistry, and are used for the preparation of various metallic and oxide catalysts.

Comparatively recently it was found that the rates of these processes are increased appreciably if the oxide being reduced contains a very small quantity of a foreign metal, such as platinum or palladium; in the presence of these additives, the temperature at which the reduction can be carried out is reduced considerably. Thus the addition of only 0.1 wt. % of metallic platinum to V_2O_5 lowers the temperature of the start of the reduction of V_2O_5 by molecular hydrogen by 180 deg[1].

An important characteristic feature of these systems is that the metallic additive under the conditions of the reaction does not form chemical compounds or solid solutions with the original oxide or the products of its reduction—it forms a distinct (usually highly dispersed) phase, separated by an interface from the phase of the oxide being reduced and its reduction products. The thermodynamic characteristics of the original oxide remain unchanged when the metallic additive is added. For example, the energies of the bonds formed by oxygen with pure V_2O_5 and with V_2O_5 containing 0.1 wt. % Pt are identical; this was proved experimentally by study of the adsorption-chemical equilibria, the temperature dependence of the equilibrium pressure of oxygen over V_2O_5,[2] and the rate of isotopic exchange of oxygen with V_2O_5.[3]

Thus the metallic additive, without influencing the thermodynamics of the reduction, increases its rate considerably, that is it catalyses the reduction. Since the catalyst (the metallic additive) and the reagents (the oxide being reduced, and the gaseous reducing agent) are in different phases, reactions of this type represent a unique form of heterogeneous catalysis.

These reactions are in some respects similar to gaseous heterogeneous-catalytic reduction processes; the rates of the latter are also increased by group VIII metals, which activate molecular hydrogen and other gaseous reducing agents. On the other hand, these reactions are heterogeneous topochemical reactions, in which one solid substance (the original oxide) is converted into another (lower oxide or metal); the reactions are characterised by certain specific features (nucleus formation, autocatalysis by the solid product, etc.).

The mechanism of the reduction of oxides in the presence of metallic additives is undoubtedly extremely complex. Its study is difficult, if only because the detailed mechanisms of heterogeneous catalysis and topochemical reactions are not yet clear. Nevertheless, the detailed study of the kinetics and mechanism of these reactions is opening up extremely interesting possibilities from both theoretical and practical viewpoints.

A fairly large amount of isolated experimental facts and observations providing evidence of the marked effect of metallic additives on the reduction of oxides, chiefly by molecular hydrogen, has now accumulated. The experimental data relating to different systems, however, are scattered—they have not been summarised from a single viewpoint, and indeed they have not until now been systematised.

This systematisation is undertaken in the present review, which attempts to reveal and where possible explain various common regular features characteristic of reactions of this type, and also to indicate methods for their practical utilisation.

II. METHODS OF PREPARING CATALYSTS, AND THEIR PHYSICAL PROPERTIES

Several methods for introducing a metallic additive into oxides to be reduced are known.

(1) Impregnation of the oxide with a solution containing a compound of the metal, followed by decomposition of this compound with the formation of the metal. Usually, the powdered oxide is impregnated with a solution of a compound such as H_2PtCl_6, $PdCl_2$, $AuCl_3$, etc., after which the powder is dried and heated to temperatures which ensure formation of the metal.

(2) Deposition of the oxide and metal on an inert carrier. The metal is first deposited on the carrier (Al_2O_3, SiO_2,

etc.) by the method described above, after which the specimen is impregnated with a solution of a salt which is decomposed to give the oxide to be reduced.

(3) Mechanical mixing; a) highly dispersed metal powder, for example platinum black, is mixed with the powdered oxide, and the mixture is shaped to form tablets; b) in a variation of this method, the oxide to be reduced is mixed with a powdered carrier (Al_2O_3, $BaSO_4$, etc.) on which the metal has been deposited beforehand. In addition to these basic methods, ion exchange[4] or spraying of the metal on to oxide granules[5] are also sometimes used.

Metals deposited even in small quantities on oxides or inert carriers are present chiefly in the crystalline state, in the form of fine crystals, the dimensions and distribution of which depend on the nature of the carrier, its surface area and porosity, the method of deposition and concentration of the metal, and the conditions of treatment[6]. Electron microscopy[7] has shown that in V_2O_5.0.5% Pt specimens the discrete platinum crystals do not penetrate into the V_2O_5 lattice or distort it, but are present in contact with the oxide. The direct deposition of the metal on the oxide ensures closer contact between the catalyst and the oxide being reduced than mechanical mixing.

III. CATALYTIC ACTION OF SMALL QUANTITIES OF METALLIC ADDITIVES ON THE REDUCTION OF OXIDES BY MOLECULAR HYDROGEN

1. Reduction of Vanadium Oxides

The catalytic action of very small quantities of platinum on the reduction of V_2O_5 was first established by Il'chenko and Yuza[1], who made a detailed study of the influence of various factors on the kinetics of this reaction†. The experiments were carried out by a gradient-free stationary–circulation method (the water formed was frozen out) under conditions free from the distorting influence of the macro-factors. The platinum was introduced into the specimens by method (1): its concentration was varied from 0.0005 wt. % to 0.5 wt. %, relative to the original oxide, the specific surface of which was 4.9 $m^2\ g^{-1}$.

The accelerating effect of platinum is shown even with trace quantities (0.0005%). The reduction of pure V_2O_5 begins at 420°. The addition of platinum lowers the temperature of the start of the reaction considerably (Table 1).

X-Ray diffraction and chemical analysis of specimens of pure and platinised V_2O_5, reduced to different extents, showed that in both instances the reduction takes place in three macro-stages:

$$3\,V_2O_5 + 2\,H_2 = V_6O_{13} + 2\,H_2O\,,$$
$$V_6O_{13} + H_2 = 3\,V_2O_4 + H_2O\,,$$
$$V_2O_4 + H_2 = V_2O_3 + H_2O\,.$$

The kinetic curves for the reduction have the S-shape characteristic of autocatalysis by a solid reduction product.

The addition of platinum increases the rates of all three macro-stages, but the catalytic action of platinum is greater at low degrees of reduction. In this range, which corresponds to the conversion of V_2O_5 into V_6O_{13}, the rate of reduction of platinised specimens containing up to 0.01% Pt is proportional to the concentration of the metallic catalyst and the hydrogen pressure to the first power. Increase in the platinum concentration (C_{Pt}) leads to a change in the kinetic relationships: at $C_{Pt} = 0.1\%$ the order with respect to hydrogen becomes less than unity, and at $C_{Pt} = 0.25\%$ a saturation effect is observed—further addition of platinum does not influence the temperature of the start of the reduction (Table 1).

Table 1. Dependence of the temperature of the start of the reduction of V_2O_5 by hydrogen on the concentration of platinum (hydrogen pressure 400 mmHg).

Platinum concn., wt.%	Temperature of the start of reduction, °C
0	420
0.001	360—370
0.01	300
0.1	240
0.25	220
0.5	220

The catalytic action of platinum begins to be shown at very low degrees of reduction, when the removal of oxygen from the oxide being reduced has not led to a phase transformation. Il'chenko and coworkers[2] studied the adsorption-chemical equilibrium

$$(O) + H_2 \rightleftarrows (\ ) + H_2O,$$

with the participation of V_2O_5, where (O) denotes oxygen of the oxide, and ( ) an oxygen vacancy; the quantity of oxygen removed does not exceed that corresponding to a monolayer. It was found that the addition of platinum, without altering the equilibrium constant for this process, leads to a sharp increase in the rate of attainment of equilibrium. Similar relationships were observed for V_2O_5 on which platinum had been deposited directly and for specimens prepared by mechanical mixing of V_2O_5 with $Pt/BaSO_4$.

Platinum also has a significant effect on the regular features of nucleus formation in the reduction of V_2O_5: in the reduction of the pure oxide, the nuclei of the solid product are produced according to a power law, whereas in the presence of platinum the nuclei are formed according to a more rapid exponential law[9]. An increase in the ease of nucleus formation in the presence of platinum is also revealed in the fact that the addition of platinum leads to a sharp decrease in the duration of the induction period observed in the reduction of V_2O_5.[1]

2. Reduction of Tungsten Oxides

Khoobiar[10,11] found that platinum has a marked catalytic action on the reduction of WO_3. He established that WO_3 powder, mixed with Pt/Al_2O_3 (0.5 wt. % Pt) is reduced by molecular hydrogen even at room temperature; under these conditions, pure WO_3 is not reduced and reacts with H_2 at temperatures above 400°.

A detailed study of the influence of added platinum on the reduction of WO_3 was made by Benson and coworkers[12], who used a gas-volumetric method. Most of their work was carried out with specimens obtained by grinding WO_3 powder with platinum black: metal concentration 2.5 wt. %, specific surface of metal 23 $m^2\ g^{-1}$, specific surface of WO_3 11.1 $m^2\ g^{-1}$ and 17.4 $m^2\ g^{-1}$.

† Even earlier, Yuza and Roiter[8] found that the rate of reduction of V_2O_5 by hydrogen was increased considerably after the V_2O_5 had been melted in a platinum crucible.

In the reaction of WO_3 with hydrogen, water was not liberated, and a pale-blue powder with the composition $H_{0.35}WO_3$ (the hydrogen analogue of the tungsten bronzes) was formed. Pure WO_3 begins to absorb hydrogen very slowly at 435°; in the presence of platinum the dry oxide begins to be reduced at 105°, and a specimen covered beforehand with a monolayer of water begins to be reduced at room temperature. Thus the catalytic activity of platinum is increased considerably in the presence of water adsorbed on the oxide surface.

The accelerating influence of platinum is more marked, the closer the contact between its micro-crystals and the surface of the oxide being reduced. Thus the rate of reduction is greater when the metal is deposited on WO_3 by impregnation than when the tungsten(VI) oxide is ground with platinum black, and much greater than when WO_3 powder is simply ground with platinum. An interesting feature is that the preparation of WO_3 specimens in platinum crucibles leads to an appreciable decrease in the temperature of the start of the reduction of this oxide, compared with specimens prepared in porcelain crucibles [13]. An analogous effect was observed for V_2O_5 (see p. 86).

Hegedüs and coworkers [13] made a detailed study of the influence of various metallic additives on the reduction of WO_3. The specimens were prepared by method (1) and contained 0.5 wt. % metal relative to W; the studies were made by a thermogravimetric method (the specimens were heated in a stream of gaseous reducing agent with continuous increase in temperature), with X-ray diffraction study of the solid products. Experimental data characterising the catalytic action of palladium, platinum, and osmium are given in Table 2.

Table 2. Influence of metallic additives on the reduction of WO_3 by a 30% H_2 + 70% N_2 mixture [13].

Additive	Temp. of the start of reduction, °C	Temp. at which $WO_{2.88}$ is formed, °C	Temp. corresponding to the end of the reaction, °C
Pd	284	345—529	768
Pt	290	351—527	779
Os	350	446—546	794
Pure WO_3	430	530	800

A strict quantitative comparison of the catalytic action of the different metals on the basis of Hegedüs' data [13] is difficult, since their surface concentrations might have been different, but it is clear that the order of activities of the additives is: Pd > Pt > Os. Neugebauer and coworkers [14] found that the activity of added palladium in the reduction of WO_3 is particularly high in the presence of water.

Unfortunately, the experimental data given by Hegedüs and coworkers [13] were not systematised and discussed. Analysis of these data led us to the following conclusions.

1. The accelerating action of the additives decreases with increase in the degree of reduction of WO_3 (Table 2). The temperature of the start of the reaction and the temperature of the start of the conversion of WO_3 into the blue β-oxide of tungsten ($WO_{2.88}$) is lowered appreciably in the presence of metals, whereas the temperature at which this change is complete is approximately the same as in the reduction of pure WO_3. Additives also have comparatively little influence on the temperature corresponding to the completion of the reduction.

2. Hegedüs and coworkers [13] also studied the influence of various other additives, in particular Hg, Al, Sn, Pb, Sb, and Bi, on the reduction of tungsten(VI) oxide. The additives were present in the original WO_3 specimens as the metal chlorides. The true chemical state and concentration of these additives under the conditions of the reaction were unknown; allowance must be made for the fact that the chlorides of these metals are volatile, and the metals themselves readily fusible, so that most of them (Hg, Sn, Pb, and Bi) are in the liquid state at the temperature of the start of the reduction. These additives (apart from Bi) do not accelerate the reduction of WO_3, and even retard it (Table 3).

Table 3. Influence of added readily fusible metals on the reduction of WO_3 by a 30% H_2 + 70% N_2 mixture [13].

Additive	Temp. of the start of reduction, °C	Temperatures at which $WO_{2.88}$ is formed, °C
Hg	433	521
Al	481	552
Sn	469	539
Pb	476	535
Sb	439	504
Bi	343	440—575
Pure WO_3	430	530

3. Reduction of Molybdenum Oxides

The influence of various metallic additives on the reduction of MoO_3 was studied by Hegedüs and coworkers [15], who used the same procedure as in the study of the reduction of WO_3. [13] The regular features observed in this instance were completely analogous to those found for the reduction of tungsten(VI) oxide. The addition of noble metals increases the rate of reduction of MoO_3 (Table 4), the catalytic activity decreasing in the order: Pd > Pt > Ag > Os. The addition of readily fusible metals (Hg, Al, Sn, Pb, Sb, or Bi) has little influence on the reduction of MoO_3.

4. Reduction of Nickel(II) Oxide

Verhoeven and Delmon [5] studied the reduction of NiO by hydrogen at 210–220° in the presence of added platinum, palladium, copper, gold, and silver. It was found that the first three metals increase the rate of the process considerably, and decrease sharply the duration of the induction period. The kinetic curves for the reduction are S-shaped, as in the reduction of pure NiO, that is the autocatalytic action of the solid product—metallic nickel—is also shown in the presence of the additives.

Added gold and silver have little influence on the rate of reduction of NiO, and added cadmium has a slight retarding action at 277–293°.

The accelerating action of palladium and platinum on the reduction of NiO by hydrogen was also demonstrated by Nowak and Koros [16]. In their experiments, both the metal and the oxide being reduced were deposited in small quantities on aluminium oxide. The catalytic activity of palladium was greater than that of platinum.

5. Reduction of Iron Oxides

Sancier and Inami[4] studied the influence of added palladium, platinum, copper, gold, and a palladium–gold alloy on the reduction of Fe_2O_3 (and Fe_3O_4) by hydrogen at 500°; the reaction rate was measured by the EPR method. The specimens for reduction were prepared by various methods: by depositing the metal and the oxide on Al_2O_3 or SiO_2 by impregnation; by mechanically mixing Fe_3O_4 and a carrier containing the metal additive; and by using a molecular sieve containing the metal cation and iron ions. The following order of catalytic activities was found: Pd > Pt > Cu ~ Pd–Au > Au.

Table 4. Influence of metallic additives on the reduction of MoO_3 by a 30% H_2 + 70% N_2 mixture[14].

Additive	Temp. of the start of reduction, °C	Temperatures at which MoO_2 is formed, °C
Pd	185	—
Pt	260	—
Ag	420	585—625
Os	500	625—645
Pure MoO_3	510	645

The activity of Pd–Au alloys containing 20 at. % and 60 at. % Au was found to be lower than that corresponding to the volume concentration of Pd; this was attributed to an increase in the concentration of gold on the surface compared with the volume. The rates of reduction of specimens obtained by the joint deposition of catalyst and oxide being reduced, and also by ion exchange, were greater than that for mechanical mixtures. According to Samchenko and Rusov[17], small quantities of platinum (0.01 wt. % and 0.1 wt. %) produce a marked increase in the rate of reduction of iron oxides (also containing K_2O, Al_2O_3, CaO, SiO_2, etc.) by a nitrogen–hydrogen mixture‡. At 450° and a pressure of 60 atm, the time required for a given degree of reduction to be achieved is much shorter in the presence of platinum. According to the data of Murata and Kasaoka[18], added copper increases the rate of reduction of Fe_2O_3 and Fe_3O_4 below 250°.

6. Reduction of Copper Oxides

The accelerating action of platinum on the reduction of copper oxide films was detected by Vorontsov and Koshkina[19]. In the absence of catalyst these films are reduced completely in 97 min at 200°, whereas in the presence of platinised platinum the reaction is complete in 7 s. In the presence of the catalyst the process is rapid even at 40°.

IV. GENERAL REGULAR FEATURES AND MECHANISM OF ACTION OF METALLIC ADDITIVES ON THE REDUCTION OF OXIDES BY MOLECULAR HYDROGEN

In the analysis of the above experimental facts, we observed various regular features characteristic of these processes.

1. An extremely high catalytic activity in the reduction of a given oxide is shown by palladium and platinum (usually, Pd > Pt); copper, and also osmium, are less active; silver and gold have little activity; and readily fusible metals—cadmium, mercury, lead, tin, and aluminium—are inactive.

2. The accelerating influence of metallic additives is particularly marked in the initial period of reduction, at low degrees of reduction; the active catalysts in a number of instances decrease the temperature of the start of the reaction by hundreds of degrees.

The action of the additives is also shown at high degrees of reduction, but to a smaller extent. If the reaction is carried out at a sufficiently high temperature, it is possible to achieve a greater degree of reduction in the presence of the metallic catalyst than in the absence of the additive (within the limits allowed by thermodynamics).

3. In those instances where the reduction of the pure oxide is autocatalytic, the autocatalytic action of the solid product is usually preserved in the presence of the additive.

4. Metallic additives decrease sharply the duration of the induction period and apparently alter the kinetics of nucleus formation.

5. The catalytic action of the additives (for very small quantities) is proportional to the metal concentration; at sufficiently high concentrations, a saturation effect is observed—further addition of metal has little influence on the course of the process.

6. The catalytic activity of a metal with respect to the reduction is greater, the closer its contact with the oxide being reduced and the greater the degree of dispersion. The direct deposition of a catalyst on the oxide being reduced gives better results than mechanical mixing. Nevertheless, the accelerating action of palladium and platinum is also shown in instances where the microcrystals of the oxide being reduced and the additive, deposited on an inert carrier, are separated in space.

7. The catalytic action of metallic additives is increased in the presence of water (this conclusion was reached by a number of authors[12,14]).

These regular features can be explained on the basis of the electronic-chemical theory of catalysis and reduction, proposed by Roiter[8] and developed by a number of authors[1,7,20].

According to this theory, the limiting stage of the reduction of an oxide by molecular hydrogen§ is usually the donor process of electron transfer from the adsorbed molecules of reducing agent (H_2) to the solid oxide; this process leads to a decrease in the oxidation state of the cations of the oxide and the formation of positive hydrogen ions, which subsequently react readily with negative oxygen ions with the formation of water.

If the oxide is in contact with micro-crystals of a metallic additive able to bring about the specific activation (ionisation) of hydrogen, the transfer of electrons from H_2 to the oxide is greatly facilitated, so that the rate of the overall reduction is increased.

In fact, the above order of decreasing catalytic activity of metallic additives with respect to the reduction of oxides agrees qualitatively with their ability to activate molecular hydrogen. Palladium and platinum adsorb hydrogen rapidly even at low temperatures and can dissolve hydrogen[21]; these metals are extremely active catalysts for

‡ This process gives the industrial iron catalyst for the synthesis of ammonia ("SA-1" grade contact catalyst).

§ It is assumed that the reduction is a quasi-steady-state reaction[22].

various gaseous reactions involving H_2 [23] and have the lowest overpotential for the cathodic liberation of hydrogen[24]. Copper has a lower catalytic activity with respect to gaseous reactions involving H_2, and silver and gold have little catalytic activity in these reactions[23]. Metals such as cadmium, mercury, aluminium, bismuth, lead, and tin have little activating effect on molecular hydrogen (very high overpotential for the cathodic liberation of hydrogen; low catalytic activity with respect to reactions involving H_2 [24]). It should also be borne in mind that the metals of this last group are readily fusible, and at the temperatures of the start of the reduction of oxides difficult to reduce (MoO_3, WO_3) most of them are in the liquid state. The liquid metal may flow over the surface of the oxide, blocking it and thus hindering the reaction of the oxide with the gaseous reducing agent; this explains the slight retarding action of these additives on the reduction of MoO_3 and WO_3 (pp. 48 and 49).

In the reaction of molecular hydrogen with Pd or Pt, dissociative adsorption takes place, and the adsorbed species exhibit surface mobility. Among the transition metals, the platinum metals have the lowest heats of chemisorption of hydrogen, that is the lowest metal–hydrogen bond strength[21]. According to Aston[25], hydrogen adsorbed on platinum is mobile at 7° and above; hydrogen dissolved in palladium is also mobile over a wide temperature range. It is natural to assume that hydrogen adsorbed on Pd or Pt can migrate from the palladium or platinum centres to the regions of the oxide in contact with these centres; if the micro-crystals of the metal and the oxide being reduced are deposited on the same inert carrier (for example Al_2O_3) and are at a certain (small) distance from one another, the hydrogen first migrates to regions of the carrier adjoining the metal and then to the oxide being reduced¶.

The possibility of surface diffusion in this way is proved by a number of experimental facts. It was established[26] that in the adsorption of hydrogen from solution on Pd/Al_2O_3 and Pt/Al_2O_3 specimens with a low concentration of metal (up to 1 wt. %), the number of hydrogen atoms corresponding to one metal atom at 25° is several times greater than unity. Since hydrogen is not adsorbed on the pure carrier, the only explanation for this result is that the hydrogen migrates from the palladium or platinum centres on to the carrier. An analogous interpretation of their results was put forward by Robell and coworkers[27], who showed that in the presence of small quantities of platinum (0.2% and 1%) the rate and extent of the adsorption of hydrogen and deuterium on carbon increase considerably. A similar result was previously obtained by Frumkin and Burstein[28]. The ability of hydrogen adsorbed on platinum to undergo surface diffusion is also indicated by the fact that small quantities of deposited platinum actively catalyse the exchange of deuterium and the hydrogen of the surface OH groups of aluminium oxide[29].

It is suggested that the increased rate of reduction of oxide containing adsorbed water in addition to platinum is due to an increase in the rate of diffusion of hydrogen, brought about by water, probably as a consequence of the formation of hydroxonium ions[12].

It is quite understandable that the closer the contact between the micro-crystals of the metallic additive and the granules of the oxide being reduced, the greater the ease of electron transfer from hydrogen to the oxide being reduced, through the metallic catalyst, on which hydrogen is ionised, and the greater the ease of diffusion of hydrogen from the palladium or platinum centres to the oxide surface.

In the initial period of the reduction, when the metallic catalyst is in direct contact with the oxide being reduced, the catalytic action of the metallic additive is naturally greatest and involves primarily a marked decrease in the temperature of the start of the reaction and a sharp increase in the initial rate of reduction. This effect is greater in the reduction of oxides difficult to reduce (V_2O_5, MoO_3, WO_3), for which the temperature of the start of the reaction is decreased by hundreds of degrees†.

The higher the concentration of additive, the greater the increase in the rate of activation of hydrogen and hence of the overall process. When a definite concentration of catalyst has been reached [for platinised vanadium(V) oxide this concentration is about 0.1–0.25%], the rate of the donor stage is increased to such an extent that it ceases to be the limiting stage. The slow stage of the reaction is then another process, probably diffusion in the solid phase or crystal-chemical transformations, since at increased concentrations of additive the reaction takes place at a low temperature. The presence of a metallic additive does not influence the rates of these processes, so that further increase in the concentration of catalyst does not lead to an additional increase in rate (saturation effect)[20].

Since the gaseous reducing agent is activated on the surface of the micro-crystals of the additive, the points of contact between it and the oxide being reduced become centres for the rapid production and growth of nuclei of the new phase. As a result, in the presence of active metallic catalysts there is a sharp decrease in the duration of the induction period and a change in the kinetics of nucleus formation, as observed in the reduction of V_2O_5.[9]

With increase in the degree of reduction of the oxide, the micro-crystals of the catalyst (Pd or Pt centres) are isolated to an increasing extent from the original oxide by a layer of solid reaction product—a lower oxide or metal. The catalytic action of the additive is also shown at this stage, since the transfer of electrons from the hydrogen, ionised on Pd or Pt, to the oxide being reduced cannot be prevented by a layer of semiconducting oxide or metal surrounding the palladium or platinum centres. The catalytic action of the additive becomes weaker, however, with increase in the degree of reduction. A possible reason for this is that the diffusion of hydrogen to the reaction surface, which is steadily moving further away, is hindered.

Judging from the form of the kinetic curves, the growth of the new phase takes place on a layer of solid product already present, that is the autocatalytic action of the reduction product is preserved in the presence of the metallic additive (if this product does not form a solid

¶ A heterogeneous–homogeneous reduction mechanism, in which H atoms are transferred from the platinum or palladium surface to the gaseous phase to start a chain reaction, is unlikely. Benson and coworkers[12] demonstrated this experimentally for the WO_3–H_2 system by using γ-radiation and an electric discharge to produce H atoms specially in the gaseous phase (reduction of WO_3 at 400° was not observed).

† Oxides which are readily reduced (such as Ag_2O and MnO_2) begin to be reduced at low temperatures even without a catalyst, so that in this instance the influence of metallic additives will apparently be less marked. Unfortunately, there is as yet no direct experimental evidence for this.

solution with the original oxide). Thus in this stage, two catalysts are operating—the metallic additive and the solid reduction product. The role of the first catalyst involves the activation of hydrogen, accompanied by the transfer of electrons to the oxide being reduced; the role of the solid product involves chiefly an increase in the ease of crystallisation of the new phase at the interface between it and the original oxide. In those instances where the reduction leads to the formation of metals such as Ni, Co, Fe, and Cu, which exhibit hydrogenating power, it is possible that they themselves play some part in the activation of hydrogen.

---o0o---

The study of the influence of metallic additives on the reduction of solid oxides opens up interesting possibilities for the study of the mechanisms of reactions involving solid oxides.

An example is provided by the study of the mechanism of the catalytic oxidation of hydrogen on V_2O_5 and the reduction of this oxide by hydrogen. On the basis of kinetic data it was suggested that the limiting stages of the two reactions are analogous, both involving the donor process of hydrogen ionisation with the transfer of electrons to the oxide[6]. If this suggestion is correct, we would expect that when platinum is added to V_2O_5, the rate of the limiting stage would increase, so that the rates of both the catalysis and the reduction would increase. In actual fact, in the presence of added platinum the rate of reduction of V_2O_5 increases sharply[1], and the same additive also produces a marked increase in the catalytic oxidation of hydrogen on V_2O_5.[7] It was noted above that with high concentrations of platinum (0.1–0.25%) the donor stage is no longer the slowest stage in the reduction of V_2O_5, that is, the limiting stage is replaced. Analogously, in the catalytic oxidation of hydrogen on platinised V_2O_5 at a platinum concentration of 0.1%, the rate of activation of hydrogen increases to such an extent that the slow stage of the reaction becomes the acceptor stage of activation of molecular oxygen[20]. Thus the study of the influence of metallic additives in oxides assists in the investigation of the nature of the limiting stage in heterogeneous reactions involving these oxides.

Studies of this kind are also of assistance in the investigation of the mechanism of action of bifunctional reforming catalysts of the Pt/Al_2O_3 type containing small quantities of metal. It is often suggested that a necessary stage in these processes is the surface diffusion of hydrogen, adsorbed on platinum, to the aluminium oxide regions[11]. This idea has been used to explain the increased rate of hydrogenation of ethylene on a Pt/SiO_2 catalyst mixed with Al_2O_3.[30] Experimental proof of the possibility of this migration is provided by the ease of reduction of WO_3–Pt/Al_2O_3 specimens[11].

The use of metallic additives as catalysts for the reduction of solid oxides opens up extremely important practical possibilities for increasing the activity of catalysts, as indicated in our earlier paper[1].

The reduction of oxides by gaseous reducing agents is a widely used method for preparing catalysts, including industrial catalysts. Decrease in the temperature of reduction often leads to an increase in the surface area of the catalyst as a consequence of the decrease in sintering and recrystallisation and the associated increase in the efficiency of contact. The introduction of catalytically active metal additives such as Pd or Pt into the original oxide may decrease considerably the temperature of reduction and hence lead to an increase in the total activity of the catalyst.

Small quantities of copper decrease the temperature of the reduction of Fe_2O_3 [18] and at the same time increase the activity of the reduced iron catalyst for the synthesis of hydrocarbons from CO and H_2.[31] The last effect is possibly achieved to some extent during the preparation of the catalyst.

In some instances it is extremely important that the reduction of the oxide to the metal be complete, since the presence of even small quantities of oxide in the metallic contact catalyst has an unfavourable influence on its catalytic properties. The main difficulty is that it is the last portions of oxygen which are most difficult to remove from the oxide. The introduction of catalytically active additives makes it possible to overcome this difficulty and achieve complete reduction. This technique was used by Nowak and Koros[16], who reduced NiO in the presence of small quantities of added palladium and platinum to obtain a more active and selective catalyst for the isomerisation, aromatisation, and hydrogenolysis of n-heptane.

The most successful combination is evidently that for which the additive, while increasing the rate of reduction of the original oxide, also acts as a promoter for the catalyst when it is formed. Thus Pd and Pt additives not only increase the rate of formation of the nickel catalyst mentioned above, but also apparently promote it[16]. The addition of small quantities of palladium to the zinc–chromium oxide catalyst for the preparation of alcohols from CO and H_2 leads to an increase in selectivity with respect to the formation of methanol[32].

In conclusion it may be noted that many of the regular features formulated above may be of more general significance and may also be applicable to the reduction of oxides by reducing agents other than molecular hydrogen. Thus small quantities of added palladium increase sharply the rate of the reduction of V_2O_5 by carbon monoxide: pure V_2O_5 begins to be reduced at 575°, whereas the temperature of the start of the reduction of a V_2O_5–0.1% $Pd/BaSO_4$ specimen is 25°.[33] According to the data of Blejean and coworkers[34], the addition of Pd increases the rate of the reduction of V_2O_5 by *o*-xylene and ethylene. Unfortunately, the available experimental data on the reduction of oxides by reducing agents other than H_2 in the presence of metallic additives are extremely scanty and insufficient for detailed discussion.

The systematic accumulation of new experimental data on the catalytic reduction of oxides by molecular hydrogen is also extremely desirable. Detailed kinetic studies by modern methods, combined with X-ray diffraction study and chemical analysis of the oxide being reduced, and measurement of the surface areas of the additives and the oxide, are required; in each instance it is necessary to investigate the influence of various factors (temperature, the composition of the reaction mixture, the concentration, chemical character, and physical state of the additive, the degree of reduction of the oxide, etc.) on the rate of the process. An extremely interesting unresolved problem concerns the relationship between the catalytic action of a given additive and the chemical structure of the oxide being reduced and its solid reduction products.

Reactions of Phosphoramidic Acids

N.N.Preobrazhenskaya

The mechanisms of the hydrolysis and solvolysis of phosphoramidic acids have been examined. The concepts of phosphoramidates as donors of the phosphate residue in phosphorylation reactions of acids, alcohols, and amines are discussed. The use of phosphoramidates as phosphorylating agents in synthetic chemistry and also their possible involvement in biological phosphorylation processes have been demonstrated.
The bibliography includes 142 references.

I. INTRODUCTION

During the last decades derivatives of orthophosphoric acid have been continually attracting the attention of many organic chemists and biochemists in connection with the outstanding advances in the study of nucleic acids, protein, biosynthesis and the investigation of bioenergetics, the structure of complex phospholipids, phosphoproteins, etc. Many studies have been made on phosphoric acid esters and anhydrides, in particular pyrophosphates, triphosphates, and acyl phosphates. Nowadays, yet another type of phosphoric acid derivatives—phosphoramidates—has aroused considerable interest.

Phosphoramidates include phosphonocreatine, phosphonotaurocyamine, phosphonoarginine, and other phosphonoguanidines isolated from the muscles of various animals and involved in the formation of ATP and ADP in muscular contraction, (see, for example, Straub[1]). The study of biological phosphorylation involving these compounds promoted the use of phosphoramidates as starting materials in the synthesis of pyrophosphates and triphosphates, including nucleoside derivatives (nicotinamide-adenine dinucleotide, coenzyme A, ADP, ATP, etc.). On the other hand, the study of biological phosphorylation showed that it involves labile intermediate phosphoramidates, namely enzymes phosphorylated at the imidazole ring of the histidine residue.

The determination of the role of phosphonoimidazoles in enzymatic processes is closely related to the study of the effect of organophosphorus poisons, pesticides, insecticides, etc. Thus there are data showing that di-isopropyl phosphonofluoridate—an effective inhibitor of many enzymes with a powerful toxic activity—phosphorylates the imidazole residue of the enzyme (see, for example [O'Brien][2]). Many powerful poisons, insecticides, and pesticides are phosphoramidates (Tabun, Schradan, etc). The synthesis of many phosphoramidates with carcinostatic activity has been described (see, for example, Stock[3] and Burstone[4]). (P–N)-aminoacid derivatives of nucleotides constitute an interesting variety of phosphoramidates. There are data suggesting that DNA- and RNA-peptides with a P–N bond between the nucleotide and the amino-group of the peptide are involved in the formation of the structure and in the functioning of nucleic acids (see, for example, Shabarova and Prokofiev[6]). One of the approaches employed to establish the structure and role of phosphoramidates is the study of model compounds—synthetic nucleotidoamides. Many interesting facts were observed in these studies, significantly supplementing the available knowledge of the reactivity of phosphoramidates, particularly about the intramolecular catalysis of their reactions (see the reviews of Preobrazhenskaya and Shabarova[5] and Shabarova and Prokofiev[6]).

The amides of nucleotides have found a novel application for synthetic purposes: the use of the amide derivative of the nucleotide for the blocking of the phosphate group in the synthesis of the dinucleoside phosphate has been described[7]; a method has been proposed whereby the nucleotide can be fixed on a polymeric carrier in the synthesis of oligonucleotides via the formation of a phosphoramidic bond between the phosphate residues of the nucleotides and the amino-group of the polymeric carrier[8].

Yet another cause which has stimulated interest in recent years in phosphoramidates is the discovery of enzymes cleaving these compounds—the so called phosphoamidases.

Despite the important role of phosphoramidates and the large number of studies on their chemistry and biochemistry, there are virtually no reviews of such investigations. Phosphoramidates are briefly mentioned in a discussion of phosphoesters[9–14] are dealt with only in a single review by Peacock[15] and in a chapter in the book by Bruice and Benkovic[16].

II. THE STRUCTURE OF PHOSPHORAMIDATES†

Phosphoramidates, like other derivatives of orthophosphoric acid, have a tetrahedral structure in the ground

† For a more detailed treatment see Refs. 9, 13 and 14.

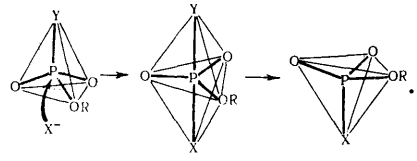
state having the phosphorus atom in the centre of the tetrahedron, and the four bonds directed to the vertides. The vacant 3*d* orbitals of the phosphorus atom may be involved in the formation of additional π bonds with the unshared electron pairs of nitrogen and oxygen (the so called $d_\pi-p_\pi$ conjugation). Thus the P–N and P–O bonds in phosphoramidates have some double-bond character[22]. This hinders attack by nucleophilic reagents and is shown particularly in a considerable resistance of phosphoramidates (in contrast to carboxylic acid amides) to the action of alkalis[17-21].

A necessary condition for nucleophilic substitution reactions at the phosphorus atom is the breakdown of $d_\pi-p_\pi$ conjugation in order to liberate the 3*d* orbitals of phosphorus and make them available for interaction with the *p* electrons of the nucleophilic reagent in the transition state.

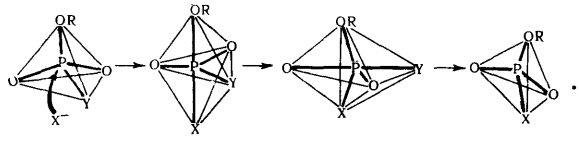
The most probable structure of the transition state in nucleophilic substitution at the phosphorus atom is a trigonal bipyramid[12-14,22]. Hence the entering and leaving groups can be located at the vertices of the bipyramid (a transition state of S_N2) type and the reaction takes place with inversion of configuration at the phosphorus atom. Such a transition state has been assumed for the majority of reactions of phosphoramidates on the basis of a study of nucleophilic substitution of optically active amido-derivatives of phosphoric acids (methyl *N*-cyclohexylphosphoramidothionate)[23] and also of intermolecular substitution reactions involving phosphoramidate derivatives with an additional amino-group[24].

However, these data do not fully exclude transition states of other types. The attack by nucleophilic reagents on the phosphorus atom can be facilitated if it is not directed along the P–N axis, since the unfavourable charge distribution then has a smaller effect[15]. This type of reaction is accompanied by so-called "pseudorotation", which is well known for phosphoesters (see, for example Refs. 25–28). As a result of pseudorotation, the nucleophilic reagent (X^-) attacking the phosphorus atom at an angle to the P–N axis passes from the plane of the base of the bipyramid to its vertex. Unfortunately, the stereochemistry of nucleophilic substitution at the phosphorus atom in phosphoramidates has been hardly investigated and therefore one can only speak of the possibility of "pseudorotation" in principle.

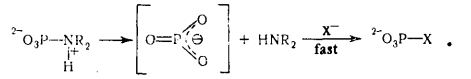
"Linear" substitution:



Substitution with "pseudorotation":



An extreme case of a trigonal bipyramid with an axial disposition of the entering and leaving groups is a transition state in which a labile intermediate metaphosphate is eliminated[24]. Its formation has been postulated for the reactions of many acyl phosphates, phosphoesters, and phosphoramidates, the common feature of which is the presence of a powerful electron-accepting substituent at the oxygen or nitrogen atom undergoing elimination and its marked dependence on the pK_a of the group eliminated[29]. Metaphosphate has a planar structure and therefore reactions involving it should take place with racemisation. However, the process has not been investigated for phosphoramidates. In reactions involving the intermediate metaphosphate, the rate-determining stage is unimolecular decomposition of the protonated phosphoramidate:



There are also many reactions in which a transition state, intermediate between the trigonal bipyramid and the planar metaphosphate[15,30-32] and characterised by a long P–N bond and a short bond between the phosphorus atom and the nucleophilic reagent being eliminated, has been postulated[30]. Such reactions exhibit the features of both bimolecular (in particular, the selectivity with respect to the nucleophilic reagent) and unimolecular reactions.

Table 1. Dissociation constants of phosphoramidic acids [and their esters]

Compound	pK_1	pK_2	References
Phosphoramidic acid	3.00	8.15	37
	4.6	7.7	17
	3.3	8.28	38
	2.83	8.03	39
	2.8	8.2	40
	2.72		15
	2.92	7.68	40
N-(*p*-Chlorophenyl)phosphoramidic acid	1.6	6.8	37

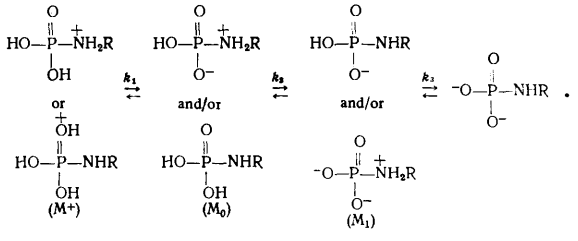
Methyl *N*-cyclohexylphosphoramidothionate	3.1		18
Ethyl *NN*-diethylphosphoramidate		7.2	42
Phenyl *N*-benzoylphosphoramidate	1.9	13.4	41
N-Phosphorourethane	2.4	6.3	44

The reactions of phosphoramidates depend significantly on their degree of ionisation. Depending on the conditions and structure, phosphoramidic acids can exist in the form of the conjugate acid species (M^+), the neutral molecular (M_0), the monoanion (M_1), and the dianion (M_2). For example



Phosphoramidic acid may be protonated both at the nitrogen and at the phosphoryl oxygen. Its conjugate acid (M^+) is probably an equilibrium mixture of two forms: protonated at the oxygen and nitrogen atoms[33,34]. The neutral species (M_0) and the monoanion (M_1) can probably

exist in a zwitterionic form[35,36], and it is most likely that the derivatives of aromatic amines (for which $pK_a < pK_2$ for orthophosphoric acid) are protonated at the oxygen atom of the phosphate residue, while those of aliphatic amines (for which $pK_a > pK_2$ for orthophosphoric acid) exist mostly in a zwitterionic form[32] (Table 1).

III. HYDROLYSIS AND SOLVOLYSIS OF PHOSPHORAMIDATES

1. Hydrolysis of Phosphoramidates

The study of the hydrolysis of unsubstituted phosphoramidic acid as a function of pH showed[37] the presence of a plateau in the pH range 3.5–6.5; at higher pH the hydrolysis is retarded and at pH ≥ 10 phosphoramidate is virtually stable; at pH < 3 the rate of hydrolysis increases. These data show that the phosphoramidate dianion (M_2, $NH_2PO_3^{2-}$) is resistant to the action of water. The pH range 4.5–6.5 corresponds to the monoionic form (M_1), at lower pH the neutral form (M_0) makes a significant contribution, and at pH < 2 the cationic form (M^+) appears and the hydrolysis is acid catalysed.

When aromatic substituents are introduced at the phosphoramidate nitrogen, the profile of the curve relating the rate of hydrolysis of the phosphoramidate to pH hardly changes[45]. Only at pH < 3 is the hydrolysis of *N*-arylphosphoramidates somewhat slower than that of unsubstituted phosphoramidate. The explanation is probably that the electrons of the nitrogen atom are involved in conjugation with the aromatic ring, as a result of which the concentration of the active protonated form of the *N*-arylphosphoramidate (M^+) diminishes.

When powerful electron-accepting substituents (benzoyl[42], diphenylphosphoryl[42], benzenesulphonyl[46], and ethoxycarbonyl[44,46]) are introduced at the phosphoramidate nitrogen, the variation of the rate of hydrolysis with pH changes very significantly: the corresponding curves have a maximum at a pH of about 4 and at higher and lower pH the rate of hydrolysis falls sharply. Acid catalysis is as a rule not observed for these compounds[46,47] (*N*-benzoylphosphoramidate occupies an intermediate position: the acid catalysis of its hydrolysis occurs only in a very acidic medium[42]).

Probably acyl substituents, which are very powerful electron acceptors, hinder the protonation of the phosphoramidate and decrease the fraction of the neutral (M_0) and cationic (M^+) forms, which determine the rates of hydrolysis of the phosphoramidate at pH < 3.

There is no unanimous view at present concerning the possible reaction mechanisms. Therefore we present in Table 2 the suggested mechanisms of the solvolysis of various ionic forms of phosphoramidates according to different investigators and shall attempt to consider the motives which led them to give preference to a particular mechanism.

Phosphoramidic acid. The reactive ionic species are M_1, M_0, and M^+. Chanley and Feageson[37] attribute the activity of M_0 and M_1 to their ability to exist in a zwitterionic form. Conclusions concerning the solvolysis mechanism have been arrived at on the basis of a study of the composition of the solvolysis products in methanol–water mixtures: since for the monoionic form (M_1) the alkyl phosphate : phosphoric acid ratio is appreciably higher than the alcohol : water ratio in the reaction mixture, a bimolecular S_N2 (P) mechanism was assumed. This is consistent also with the catalysis of the solvolysis by pyridine and nicotine but not by the sterically hindered 2-methylpyridine.

However, Oney and Caplow[49] suggest a unimolecular solvolysis of the M_1 form of phosphoramidate, since it reacts at a rate close to that of the neutral form (M_0). They believe that with a bimolecular mechanism one should expect greater differences between the rates of solvolysis of the two forms owing to the more intense electrostatic repulsion of the nucleophilic reagent by the first form compared with the second.

Table 2. Suggested mechanisms of the solvolysis of phosphoramidates.

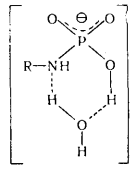
Compound	Ionic forms hydrolysed			Refs
	M^+	M_0	M_1	
Phosphoramidic acid	unimolecular bimolecular bimolecular *	unimolecular bimolecular	intermediate unimolecular bimolecular intermediate	15 48 37 11
N-Arylphosphoramidic acids	unimolecular * bimolecular	unimolecular bimolecular	unimolecular intermediate	37 11 32
N-Acylphosphoramidic acid			unimolecular * *	44 47 42

*The authors adduce data supporting both the unimolecular and bimolecular mechanisms without giving preference to either.

Cox and Ramsay[11] adduce evidence in favour of both the bimolecular and unimolecular mechanisms for the M_1 form of phosphoramidate. They suggest that, in the case of a direct attack by water on the monoanion (S_N2 mechanism), one should expect that phosphoramidate would react much more slowly than its aromatic derivatives. However, in fact phosphoramidate is hydrolysed approximately 10^3 times faster. On the other hand, if the solvolysis in aqueous alcohol proceeded via metaphosphate, the same ratio of alkyl phosphate and phosphoric acid should have been obtained as in the solvolysis of *p*-nitrophenyl phosphate under the same conditions, for which a unimolecular mechanism has been generally assumed. In fact phosphoramidate gives rise to approximately twice as much alkyl phosphate as does *p*-nitrophenyl phosphate[45]. Thus it is most likely that the solvolysis of the M_1 form proceeds via a transition state characterised by features of both the bimolecular and unimolecular mechanism. Peacock[15] arrives at this conclusion by considering the entropy of activation for the solvolysis of phosphoramidate.

A bimolecular solvolysis mechanism has been proposed[11,37,49] for the cationic form (M^+) of phosphoramidic acid in view of the lower yield of alkyl phosphate in solvolysis in aqueous alcohol compared with M_0 and M_1 (8, 44, and 72% respectively in 50% methanol[37,49]). However, the rate of hydrolysis of phosphoramidic acid is proportional to the Hammett acidity function H_0 and the corresponding plot has a slope of unity[17], which is characteristic of hydrolysis with elimination of metaphosphate[11]. Peacock is also inclined to favour the unimolecular mechanism[15].

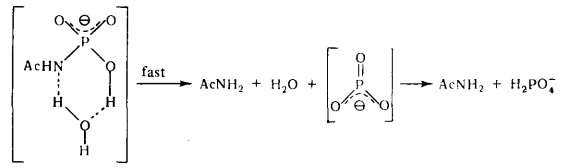
N-Arylphosphoramidates. A unimolecular solvolysis mechanism has been proposed for the monoionic (M_1) and neutral (M_0) forms of *N*-arylphosphoramidates, and it is suggested that M_0 is hydrolysed faster owing to the extremely high reactivity of its zwitter-ion[37]. However, in solvolysis in aqueous alcoholic mixtures with different alcohols different selectivities are observed compared with water[32]. This is inconsistent with the formation of free metaphosphate in the course of these reactions, since it cannot exhibit selectivity in relation to the nucleophilic reagent. On the other hand, the composition of the products in the methanol–water mixture is independent of the presence of an adjacent carboxy-group near the phosphoramidate group, which can be explained by a unimolecular mechanism[32]. In accordance with these data, it is suggested that the solvolysis of the monoanions of *N*-arylphosphoramidates includes a transition state with both unimolecular and bimolecular characteristics[32]. Possibly the hydrolysis of the monoanions involves the formation of a cyclic intermediate in which water participates[11,45], by analogy with that proposed for the hydrolysis of the monoanions of phosphate monoesters[50].



The neutral form (M_0) of *N*-arylphosphoramidic acids is selective with respect to the nycleophilic reagent in solvolysis in aqueous alcohol[32,37]. In addition, it is very sensitive to steric factors[32]. This suggests a bimolecular mechanism for the solvolysis of the M_0 form of *N*-arylphosphoramidic acids.

Examination of the solvolysis products in aqueous alcohol shows that the protonated form (M^+) is hydrolysed unimolecularly[37] (the alkyl phosphate : phosphoric acid ratio is close to the alcohol : water ratio in the solution). However, Benkovic and Benkovic[32] preferred a bimolecular pathway, including attack by the solvent on the protonated phosphoramidic acid. According to Cox and Ramsay[11], the linear relation between the rate of hydrolysis and the molarity of the acid which they observed[45] suggests that the hydrolysis of the M^+ form includes bimolecular attack by water, but the ratio of the products suggests that the reaction is unimolecular.

N-Acylphosphoramidates and *N*-phosphourethane. The reactive form of *N*-acylphosphoramidates and also of *N*-phosphourethane is the monoanion (M_1). The decrease of its proportion as both the dianion and the neutral form are formed retards the hydrolysis fairly markedly[42,44,47], which resembles somewhat the situation in the hydrolysis of monoalkyl phosphates[10]. The absence of an effect of nucleophilic (NaF, di-n-butylamine, butanethiol, aniline) and electrophilic (Ag^+, Cu^+) reagents on the hydrolysis of *N*-phosphonourethane[47] and the absence of exchange of the phosphoryl oxygen in the hydrolysis of *N*-phosphonourethane in $H_2^{18}O$ are inconsistent[47] with both unimolecular and bimolecular reactions. One of the possible mechanisms for the hydrolysis of *N*-acylphosphoramidates and *N*-phosphonourethane[41,42,47] is the cleavage of a hydrated cyclic intermediate, as in the hydrolysis of *N*-arylphosphoramidates examined above:



2. Hydrolysis of Phosphoramidate Monoesters

Phosphoramidate monoesters are cleaved at the P–N bond only in an acid medium[6,7,48,51–58]. The linear relation between the hydrolysis rate constant and the concentration of H^+ ions is evidence that the hydrolysis is acid catalysed[48].

The neutral forms of methyl phosphoramidate and unsubstituted phosphoramidic acid are both hydrolysed and solvolysed in 50% aqueous methanol at similar rates[48]. This finding indicates a bimolecular reaction mechanism for both compounds; in a unimolecular reaction involving an intermediate metaphosphate one would expect lower rates for the methyl ester because the resonance stabilisation of metaphosphate esters is more difficult than that of the metaphosphate ion. The bimolecular hydrolysis and solvolysis of phosphoramidate esters was demonstrated also for methyl *N*-cyclohexylphosphoramidate[43]: the lower yield of ethyl methyl phosphate (10%) in the solvolysis of this compound in 50% ethanol contradicts the formation of a highly reactive intermediate metaphosphate, which should not exhibit selectivity with respect to one of the nucleophilic reagents. However, in the catalysis of the solvolysis of methyl *N*-cyclohexylphosphoramidate by pyridine, for which the formation of active *O*-methylphosphonopyridinium has been suggested, the yield of ethyl methyl phosphate virtually corresponds to the content of ethanol in the reaction mixture, so that in this case one cannot rule out the possibility of the formation of an intermediate metaphosphate[43]. Thus it is extremely likely that the mechanism of the reaction of phosphoramidate monoesters depends on the type of groups eliminated, in other words on the substituents at the amide nitrogen.

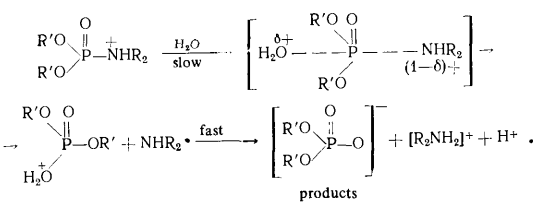
The view that the reactivity of phosphoramidates increases with the basicity of the initial amine[42,43,51], based on a study of the hydrolysis of three compounds (the piperidide, morpholide, and *p*-anisidide of adenosine 5′-monophosphoric acid)[51], has been very widely expressed in the literature. However, this conclusion contradicts the results obtained in the study of the hydrolysis of many other alkyl phosphoramidates[34,51,59,60], for which a decrease of reactivity with increasing basicity of the initial amine can be clearly traced.

In this connection a comparative study of the hydrolysis of many aliphatic and aromatic phosphoramidates derived from uridine 5′-monophosphate[61] is of interest. Comparison of the rates of hydrolysis of these compounds in 0.05 *N* HCl (37 °C) shows that the rate of hydrolysis of derivatives of weak amines (aromatic amines and 2,2,2-trifluoroethylamine, $pK_a = 1–5.7$) increases with the basicity of the initial amine, while the rates of hydrolysis of derivatives of strongly aliphatic amines ($pK_a = 9.34$ to 10.64) falls as the basicity of the initial amine rises. These results are consistent with the hypothesis of the dual effect of the substituent at the nitrogen atom on the hydrolysis of phosphoramidates[34]: on the one hand, electron-donating substituents promote the protonation of the

phosphoramidate, stabilising the positive charge generated, and, on the other hand, electron-accepting substituents facilitate the formation of the transition state, reducing the electron density at the phosphorus atom and promoting thereby nucleophilic substitution at this atom. Possibly[61] in the case of derivatives of weak amines the first effect predominates and therefore the rate of hydrolysis of the P–N bond increases as the electron-donating properties of the substituent become more pronounced. On the other hand, in the case of derivatives of strong amines the formation of the transition state is decisive and accordingly the rate of hydrolysis falls for more powerful electron-donating substituents.

3. Hydrolysis of Phosphoramidate Diesters

Phosphoramidate diesters are also hydrolysed at the P–N bond in an acid medium and are stable in an alkaline medium (see, for example, Sokolova et al.[62]). The study of the kinetics of the acid hydrolysis of phosphoramidate diesters, for 2,4-dichlorophenyl methyl *N*-alkylphosphoramidates, showed that the reaction is bimolecular and most probably involves direct attack on the phosphorus atom by the water molecule with simultaneous elimination of the amine[34]:



The results of a study of the hydrolysis of dimethyl phosphoramidate in D_2O and its solvolysis in 50% aqueous methanol[49] and also the results obtained in a study of the hydrolysis of dimethyl *NN*-dialkylphosphoramidates[60,63] are consistent with this mechanism.

Phosphoramidate diesters are much more stable in acid solutions than the corresponding phosphoramidic acids and phopshate monoesters[62,64–67]. In some cases, as a result of the stabilisation of the P–N bond in phosphoramidate diesters, the phosphate ester and not the phosphoramide bond is the first to be cleaved in an acid medium[34,64].

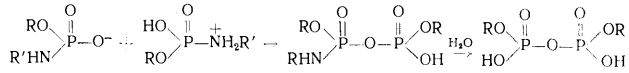
The reason for this change in the stabilities of the P–N and P–O bonds may involve[64] a change in the d_π–p_π – conjugation of the lone electron pairs of the nitrogen and oxygen atoms linked to the reaction centre and in the population of the 3*d* orbitals of the phosphorus atom in these compounds compared with phosphoramidic acids and phosphate monoesters. Conjugation of the electrons of the oxygen atom with the phosphorus atom in the P–OH and particularly the $P–O^-$ bond is known[22] to be much more pronounced than for the P–OR bond. This should have two consequences: firstly, a decrease of the stability of the P–O bond in phosphate diesters and secondly a decrease of the population of the 3*d* orbitals of the phosphorus atom in such diesters and consequently their greater accessibility to the electrons of the nitrogen atom, which should entail an increase in the stability of the P–N bond. The appreciably higher stability of diphenyl phosphoramidates compared with di-n-butyl phosphoramidates is consistent with these concepts[59]. It is also possible that the hydrolysis of phosphoramidate diesters is slower than that of the monoesters because, owing to the absence of a hydroxyl capable of dissociation in the phosphate residue of the diesters, their monomolecular hydrolysis via an intermediate metaphosphate is precluded.

IV. INTERACTION OF PHOSPHORAMIDATES WITH NUCLEOPHILIC REAGENTS

When phosphoramidates react with nucleophiles such as phosphoric acid and its esters, pyrophosphoric acid and its esters, carboxylic acids, amines, alcohols, etc., they can behave as donors of the phosphate group.

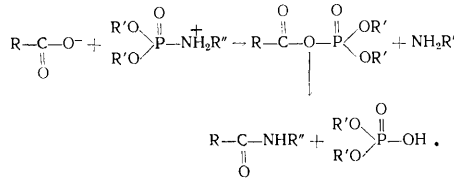
In the transfer of the phosphate residue from phosphoramidates to phosphoric acid or its esters, pyrophosphates are formed; if the nucleophilic agent is pyrophosphoric acid or its esters, triphosphates are formed. The formation of pyrophosphates from [unsubstituted] phosphoramidate was already observed in the previous century[68]. Later it was established that other phosphoramidates are readily converted into symmetrical pyrophosphates[51,67,69,70].

Kinetic studies showed that pyrophosphates are formed as a result of the attack by the phosphoramidate anion on the protonated molecule with elimination of one mole of the base[23,36,43,71]:



This reaction and also the known capacity of biological systems to employ phosphoramidates the so-called phosphagens, for example; phosphonocreatine, phosphonotaurocyamine, phosphonoglycocyamine, and phosphonolombricine (see, for example, Refs. 1, 72, and 73)—for the synthesis of pyrophosphates have served as a basis of preparative methods for the synthesis of pyrophosphates and triphosphates, including nucleotide coenzymes[69,74–77]. The most convenient amides of nucleotides for the synthesis of pyrophosphates are morpholides[51]. Many nucleoside polyphosphates have been synthesised from them. This problem has been considered in detail in monographs[78,79]. Mention should be made of those later studies[80] where the effect of reaction conditions on the yield of nucleoside diphosphate derivatives was investigated.

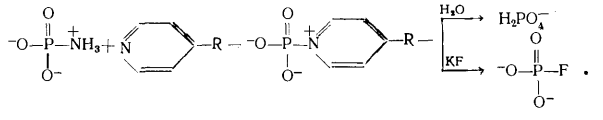
When the phosphate residue is transferred from phosphoramidate to carboxylic acids, acyl phosphates are formed[43,67,83]. Then the amine present in the reaction mixture (this may be a specially added amine[43,67,70] or the amine liberated as a result of the reaction between phosphoramidate and carboxylic acid[81]) can react with the acyl phosphate to form a carboxylic acid amide. When carboxylic acids are heated with phosphoramidate diesters and particularly with phosphoric triamide $PO(NH_2)_3$, the corresponding amides are formed in yields of 40–80%:[82]



The phosphate group in phosphoramidates can be transferred to another amine. The free phosphoramidic acids $(HO)_2PONR_2$ (R = H, Alk, or Ar) are least effective as phosphate donors in the phosphorylation of primary amines[19,39], probably because under conditions where

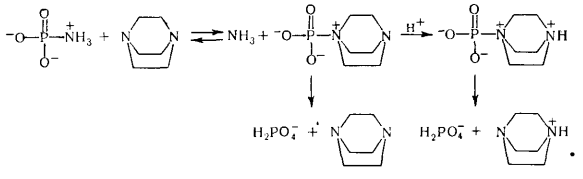
phosphoramidates are active the majority of primary amines are protonated and therefore cannot function as nucleophilic reagents. Nevertheless, the preparation of *N*-phosphonoaminoacids and *N*-phosphonopeptides using phosphoramidate as the phosphorylating agent has been described recently[84]. The phosphorylation of hydrazine in its reaction with phosphoramidate has also been described[39]

Phosphoramidate monoesters and particularly diesters are much more active as donors of the phosphate group, probably because of their higher p*K* values. However, the phosphate group is transferred only to weak amines. Thus methyl *N*-cyclohexylphosphoramidate and its thioanalogue enter into transamination reactions with 1-naphthylamine, 2,2,2-trifluoroethylamine, and *O*-methylhydroxylamine[23,43]. Among bases, the most effective acceptors of the phosphate group are tertiary bases[18], particularly pyridine and its homologues. Synthetic reactions are frequently carried out in pyridine (see the synthesis of pyrophosphates mentioned above), which is well known to catalyse the transfer of the phosphate group. The formation of an intermediate labile phosphonopyridinium ion has been frequently postulated in these reactions[18,37,85-90]. Its formation has been demonstrated in the reaction of phosphoramidic acid; in the presence of pyridine its hydrolysis is accelerated, and when fluoride ions are added, phosphorofluoridate is also formed[39]:



Pyridine derivatives catalyse also the hydrolysis of diisopropyl phosphorofluoridate and dimethyl phosphorofluoridate, 3- and 4-methylpyridines being more effective and 1-methylpyridine equally as effective as unsubstituted pyridine[85].

Other tertiary bases behave similarly, for example triethylenediamine is a still more effective catalyst (probably because of steric strain and the ready protonation of the second nitrogen atom, a more readily eliminated group is formed)[39]:



Phosphorylated tertiary amines can be useful phosphorylating agents in syntheses owing to their high reactivity and particularly because they remain reactive in an alkaline solution—under conditions where other phosphoramidates lose a proton and become inactive[39]. Examples of this kind are diphosphonoimidazole (see Section VI) and 4-methyl-*N*-phosphonopyridinium, which reacts completely with 0.5 M solution of methylamine at pH 11.7 in less than one minute[39].

An important problem in the chemistry of phosphoramidic acids is the transfer of the phosphate residue to the hydroxy-group of alcohols. The achievement of this reaction on a preparative scale would provide a method for the phosphorylation of alcohols which would be convenient for the following reasons: (a) the relative simplicity of the synthesis of the phosphorylating agent (phosphoramidate); (b) the possibility of storing it for a fairly long time; (c) the possibility of carrying out the reaction in an aqueous medium, this being particularly important in the phosphorylation of nucleosides and nucleotides, which are sparingly soluble in organic solvents. In this connection, a number of studies have been made on the solvolysis of phosphoramidates in water–alcohol mixtures. However, despite the fact that phosphoramidates effectively phosphorylate phosphates, carboxylic acids, and certain amines, in the vast majority of cases they proved to be unsuitable for the phosphorylation of alcohols[43,67]. This is because alcohols as a rule cannot compete as nucleophilic agents with water (hydrolysis) or with a second molecule of phosphoramidate (the formation of pyrophosphates). Thus, although in very dilute aqueous ethanol methyl *N*-cyclohexylphosphoramidate yields methyl phosphate (hydrolysis product) and ethyl methyl phosphate (ethanol phosphorylation product), in more concentrated aqueous ethanol considerable amounts of pyrophosphoramide are formed, the product being gradually hydrolysed, so that ultimately more than 90% of phosphorus is detected as methyl phosphate[43].

However, it is noteworthy that the ratio of the hydrolysis and phosphorolysis products depends considerably on the structure of the phosphoramidate, namely on the presence and nature of ester substituents at the phosphorus atom and of substituents at the nitrogen atom: the yield of methanolysis products depends on the introduction of a methyl group into the phosphate residue and amounts to 8, 21, and 12% for unsubstituted phosphoramidate, monomethyl phosphoramidate, and dimethyl phosphoramidate respectively[49].

The yield of phosphorylation products depends significantly on the reaction conditions, probably due to the specific mechanism of the solvolysis of phosphoramidate. But, in the solvolysis of the monoanionic form of phosphoramidate (bimolecular reaction), the ratio of the alkyl phosphate and phosphoric acid formed greatly exceeds the ratio of the alcohol to water in the reaction mixture[37]. This may be due to the greater nucleophilicity of alcohols compared with water. On passing to a unimolecular mechanism (for example acid-catalysed solvolysis), the effect of the nucleophilicity of the reactant diminishes and there is a corresponding decrease of the percentage of phosphorolysis. Until recently, the formation of alkyl phosphate and phosphoric acid in the solvolysis of phosphoramidates in water–alcohol mixtures in proportions close to those of the alcohol and water was regarded as evidence of a unimolecular mechanism involving the formation of an intermediate metaphosphate[37]. However, it was shown recently that the product ratio depends to a considerable degree on the nature of the group eliminated even when the mechanisms are known to be identical[29,91] and on the nature of the alcohol[29]. The latter finding had been explained previously by steric factors, but this explanation is invalid, since in the phosphorylation of amines significant differences as a function of the structure of the group are not observed. It has been suggested that the difference between the reactivities of alcohols can be due to a non-static distribution of solvent molecules in the solvation shell around the phosphate group[29], the degree of solvation in the transition state being apparently important[49]. This suggests that phosphoramidates are in principle unsuitable for the phosphorylation of alcohols with a bulky alkyl group.

However, the role of the alcohol alkyl group is abolished in the phosphorylation by phosphoramidates derived from tertiary amines. Above it was already mentioned that

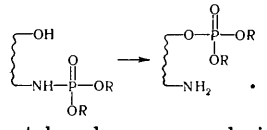
pyridine derivatives catalyse the reactions of phosphoramidates with phosphates and amines by forming active phosphorylating compounds. This is also observed in the reaction of phosphoramidates with alcohols. Thus in the solvolysis of methyl *N*-cyclohexylphosphoramidate in aqueous ethanol (50 mole %) in the presence of pyridine, the yield of ethyl methyl phosphate increases to 40% compared with 8% in the absence of pyridine[43].

N-Benzoylphosphoramidate proved to be an effective phosphorylating agent for alcohols on a preparative scale. It was used successfully in the phosphorylation of ethyl and benzyl alcohols, cyclohexanol and phenol (yield 40–80%); ethanolamine was phosphorylated to 2-aminoethylphosphoric acid. The reaction was carried out in the presence of triethylamine; the highest yields were obtained when it was used in an equimolar amount in relation to the phosphoramidate[41].

Thus apart from the phosphonoimidazoles, which will be discussed separately in Section VI, only phosphoramidates with powerful electron-accepting substituents at the nitrogen atom are of preparative value as phosphorylating agents for alcohols.

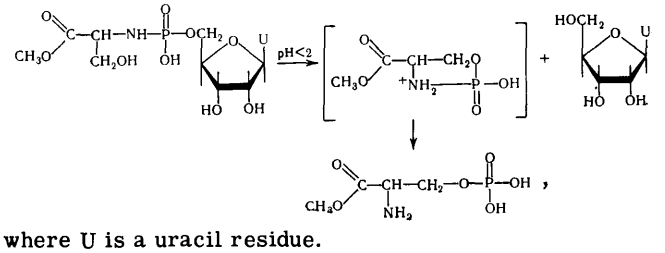
The situation is different when the phosphoramide group and the alcoholic hydroxyl are near one another in space: the intramolecular phosphorylation of hydroxy-groups is achieved under a wide variety of conditions and with high yields. It is possible to distinguish two types of reactions.

1. The amino-group of a hydroxylated compound is phorphorylated. In this case intramolecular phosphorylation results in N → O migration of the phosphate residue:



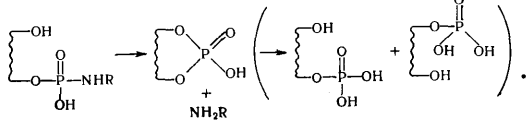
These reactions take place as a rule in an acid medium (see, for example Plapinger and Wagner-Jauregg[92]).

The finding that intramolecular phosphorylation of hydroxy-groups by phosphoramidates takes place only with esterified phosphono-derivatives is striking[18]. This phenomenon is attributed to the necessity for a cyclic intermediate, which in the case of monoesters and diesters can be formed fairly readily as a result of transesterification whereas in the case of a non-esterified phosphate group its formation is difficult[18]. N → O migration of this kind with transesterification in the acid hydrolysis of (P–N)-serine derivatives of nucleotides has been described[93]:

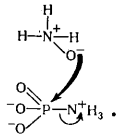


where U is a uracil residue.

2. The hydroxy-compound contains a second OH group esterified by the phosphoramidate residue. In this case intramolecular phosphorylation leads to the elimination of the amine and the formation of a cyclicphosphate, which under sufficiently severe conditions may be hydrolysed further to the monophosphate[7,94–98]:



Among other nucleophilic reagents capable of reacting with phosphoramidates, hydroxylamine should be mentioned. A study of its reaction with unsubstituted phosphoramidate at pH 7 established that it attacks the phosphorus atom via its oxygen atom rather than the nitrogen[39]:



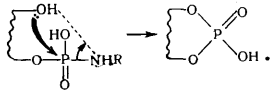
The reaction of hydroxylamine with phosphoramidates has been suggested for the specific cleavage of nucleotido-(P–N)-peptides[99,100]. When they are treated with hydroxylamine at pH 5, hydroxylamine derivatives of nucleotides are formed together with peptides, and the latter can be determined quantitatively by conversion into dinitrophenyl derivatives[99]. *N*-Methylhydroxylamine proved to be more reactive and *O*-methylhydroxylamines less reactive than unsubstituted hydroxylamine[100], in agreement with the mechanism described above.

Finally, phosphoramidates react with hydrogen halides. Hydrogen fluoride is the most reactive in this process. It reacts with any phosphoramidate, in contrast to hydrogen chloride and hydrogen bromide, which reacts only with *NN*-disubstituted phosphoramidates[101,102].

In aqueous solutions phosphoramidates react with fluoride ions to form phosphorofluoridates, rapidly in a weakly acid medium[17,103] and slowly in neutral and alkaline media[39]. Phosphorofluoridate is formed from phosphoramidate and potassium fluoride in the presence of pyridine or triethylenediamine, which are responsible for the nucleophilic catalysis of the transfer of the phosphate residue[39] (see pp. 58, 59).

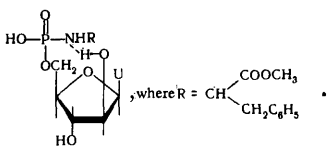
V. GENERAL INTRAMOLECULAR ACID CATALYSIS OF THE REACTIONS OF PHOSPHORAMIDATES

The transfer of the phosphate residue from the amino-group to the hydroxy-group with formation of cyclicphosphates, described in the preceding sections, probably constitutes a special case of general intramolecular acid catalysis in which the hydroxy-group behaves as a proton donor for the amide nitrogen, disrupting the $d\pi$–$p\pi$ conjugation between nitrogen and phosphorus and increasing the electrophilicity of the latter[93,98]:



In the majority of the examples quoted above, general acid catalysis involving the hydroxyl-group leads to a sharp change in the properties of the phosphoramidates: the P–N bond becomes labile not only in acid but also in neutral and alkaline media. In other cases, catalysis by the hydroxyl group can lead only to an increase of the reactivity of phosphoramidates in an acid medium. Thus the methyl ester of 1-B-D-arabofuranosyluracil 5′-phospho-(P–N)-phenylalanine is hydrolysed faster at pH 1–5 than the corresponding ribose derivative, probably

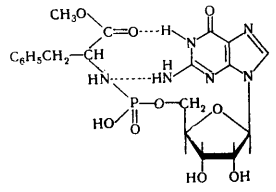
because in the former the 2'-OH group is in the *cis*-position relative to the 5'-P–N bond and may protonate its nitrogen atom[96]:



Apart from the hydroxy-group, the undissociated carboxy-group can function as a proton donor in the general intramolecular acid catalysis of reactions of phosphoramidates. Thus *o*-carboxylphenyl phosphoramidate is hydrolysed faster (in the monoanionic and neutral forms) than the corresponding *p*-carboxyl-derivative[32]. A similar effect of the carboxyl group is observed in the hydrolysis of phosphonocreatine[104].

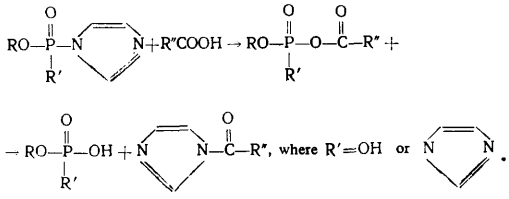
The increase of the reactivity of the P–N bond as a result of the catalytic effect of the amino-group as the proton donor is observed in the hydrolysis of phosphonohistidines. Histidine derivatives are less stable than the corresponding imidazole derivatives both in hydrolysis and in the transfer of the phosphate residue to imidazole derivatives, the P–N bond in the 1-position of the imidazole ring being the most labile. The protonated α-amino-group is responsible for the increase in the lability of phosphonohistidines[84,105].

An intramolecular acceleration of the hydrolysis of the phosphoramide bond by the amino-group has been observed also for 5'-guanylyl-(P–N)-phenylalanine[57]:



VI. IMIDAZOLE DERIVATIVES OF PHOSPHORIC ACID

Imidazolides occupy a special place among phosphoramidates. They are distinguished by high reactivity towards nucleophilic reagents of various types. Thus phosphonoimidazole monoesters and diesters give quantitative yields of pyrophosphates in reactions with phosphoric acids and its esters[108-109]. In the reaction with carboxylic acids, phosphonoimidazole monoesters and also the esters of phosphoric acid di-imidazolide yield acyl phosphates, which react further with the liberated imidazole, forming acylimidazole and a phosphate monoester[107,108]:



Among phosphoramidates, phosphonoimidazoles are the most active donors of the phosphate residue towards amines. Phosphonoimidazole and its esters phosphorylate aromatic and aliphatic amines, the latter reacting more readily[107,108,110,111]. Diphosphonoimidazole is particularly effective in the phosphorylation of amines. It phosphorylates primary aliphatic amines at alkaline pH. Diphosphonoimidazole can be used to prepare phosphoramidic acid (75%) and to phosphorylate aminoacids[40,112], ethanolamine, aromatic amines, *p*-aminobenzoic acid, and sulphanilic acid[18].

Phosphonoimidazoles are even more effective phosphorylating agents towards alcohols, phosphonoimidazole esters being the most reactive[107,108,111].

Evidently (see Sections VI and V) the intramolecular phosphorylation of an alcoholic hydroxyl by phosphonoimidazoles would be most effective. In this connection, the synthesis of dinucleoside phosphates on a polynucleotide matrix by the reaction of the nucleotide imidazolide with the nucleoside is exceptionally interesting[113-115]. The complementary interaction of polyuridylic acid with a mixture of *N*-(5'-adenylyl)-imidazole and adenosine ensures relative positions of the phosphoramide group and the alcoholic hydroxyl resembling those in the intramolecular reaction, as a result of which the phosphate residue is transferred from imidazole to the hydroxy-group of the nucleoside, i.e. a dinucleoside phosphate ApA is formed (yield 41%).

Thus phosphonoimidazoles are the most active donors of the phosphate residue in the phosphorylation of phosphates, carboxylic acids, amines, and alcohols. On the other hand, imidazole is the most effective acceptor of the phosphate group from phosphoramidates[18,39,116]. This has served as a basis for a preparative method of phosphorylating imidazole by phosphoramidic acid[84,105].

The imidazole residue can be phosphorylated not only by phosphoramidates but also by phosphonoimidazoles. Examples of this are the reaction between diphosphonoimidazole and histidine with formation of phosphonohistidine and the hydrolysis of 1-phosphonoimidazole, where one molecule probably phosphorylates another[18] and also the conversions of 1-phosphonohistidine into the corresponding 3-derivatives[84], for example: 1-phosphonohistidine + histidine → histidine + 3-phosphonohistidine; 1-phosphonohistidine + α-*N*-acetylhistidine → histidine + α-*N*-acetyl-3-phosphonohistidine.

The unique capacity of phosphonoimidazoles to function as effective donors and acceptors of the phosphate residue probably constitutes the basis of their catalytic effect in the reactions of many phosphoric acid derivatives. Thus imidazole catalyses the hydrolysis of phosphoramidate[18,39,116], *p*-nitrophenyl phosphate[31], dialkyl phosphorofluoridates[35], and ethylene methyl phosphate[117]. It has been suggested[85] that the catalytic properties of imidazole can be accounted for by the intermediate formation of phosphorylated imidazole. Indeed, the exceptional lability of di-isopropylphosphonoimidazole—the potential intermediate in the hydrolysis of di-isopropyl phosphorofluoridate—has been demonstrated. In a bicarbonate buffer at pH 7.6 at 30°C it hydrolyses to the extent of 50% in 2.7 h and 100% in 13 h.[85]

The catalytic activity of imidazole in reactions *in vitro* suggests that phosphonoimidazoles may be intermediates in the reactions of phosphorylated compounds *in vivo*. Imidazole in the form of the histidine residue enters into the active centres of transphosphorylation enzymes. Phosphonohistidine has been isolated in many cases. The involvement of histidine is particularly likely, since its *N*-1-phosphono-derivative is much more labile than *N*-1-phosphonoimidazole[84]. As stated above (see section V), this is associated with the effects of the histidine side chain, namely its protonated amino-group, which is

close to the *N*-1-position. In protein the histidine amino-group is of course most likely to be combined in a peptide chain, but the labilisation of the P–N bond of phosphono-imidazole may be induced by the amino-group of another aminoacid located in its vicinity owing to the specific conformation of the enzyme. Evidently, in principle, there is then a possibility of the activation of both phosphor-amide groups, in the 1- and 3-positions of imidazole, and the specific result will be determined by steric factors.

It is interesting to note that phosphonoimidazole itself is not more reactive than phosphoramidic acid but its esters are much more reactive towards nucleophilic attack. One may suppose therefore that phosphonohistidine partici-pates in enzymatic processes associated with the transfer of the phosphate ester residue (for further details, see Section VIII).

VII. INTERACTION OF PHOSPHORAMIDATES WITH ELECTROPHILIC REAGENTS

General and specific acid catalysis (see Sections V and III) and catalysis by metal ions are special cases of elec-trophilic catalysis. Catalysis by metal ions (Zn^{2+}, Mn^{2+}, Fe^{3+}, Co^{2+}, and Cu^{2+}) has been described for phospho-guanidines—natural phosphagens[118]. It is known that *in vitro* they are much more stable than simple phos-phoramidates. This is because of the delocalisation of the positive charge at the amide nitrogen. The catalytic effect of the metal ion consists in preventing the delocalisation by the formation of a phosphoramidate–metal cation com-plex[72,73,118].

Electrophilic catalysis has been investigated in detail in the hydrolysis of phosphoramidates in the presence of formaldehyde, pyridoxal, and hypochlorite[30], nitrous acid, and isopentyl nitrite[119]. The role of such catalysts is probably the conversion of the amino-group into a more readily eliminated group. For example, the following mechanism has been suggested[30] for the hydrolysis of phos-phoramidate in the presence of formaldehyde:

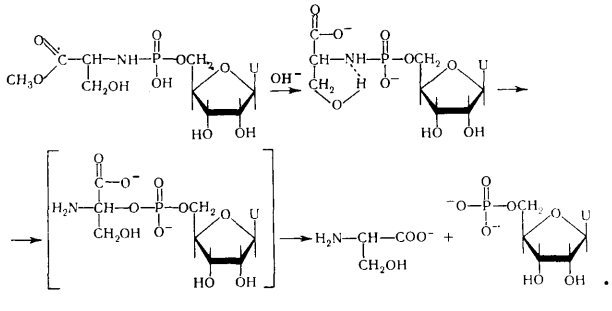
$$^{-2}O_3P\overset{+}{N}H_3 + HCHO \overset{\text{fast}}{\rightleftharpoons} {}^{-2}O_3P\overset{+}{N}H_2CH_2OH\,,$$

$$^{-2}O_3P\overset{+}{N}H_2CH_2OH + HCHO \overset{\text{fast}}{\rightleftharpoons} {}^{-2}O_3P\overset{+}{N}H(CH_2OH)_2\,,$$

$$^{-2}O_3P\overset{+}{N}H_2CH_2OH \rightarrow H_2PO_4^- + NH_2CH_2OH\,,$$

$$^{-2}O_3P\overset{+}{N}H(CH_2OH)_2 \rightarrow H_2PO_4^- + NH(CH_2OH)_2\,.$$

Electrophilic catalysis combined with nucleophilic catalysis, particularly when they take place intramole-cularly, is most effective in relation to phosphoramidates. For example, in the case of 5′-uridilyl-(P–N)-serine[93] and other nucleotidoamines containing the OH group capable of approaching the amide nitrogen[97], combined electro-philic and nucleophilic catalysis results in the lability of the P–N bond in an alkaline medium:



VIII. PHOSPHORAMIDATES AS INTERMEDIATES IN BIOLOGICAL PHOSPHORYLATION REACTIONS

The exceptional sensitivity of phosphoramidates to nucleophilic and electrophilic catalysis and in particular to combined intramolecular nucleophilic and electrophilic catalysis suggests that they can play the role of active intermediates in biological phosphorylation processes.

A number of enzymes cleaving phosphoramidates, the so called phosphoamidases (here we are not considering phosphagens), have been described. However, hitherto in all cases the phosphoamidase activity has been merely supplementary to the main activity of the enzyme—usually phosphoesterase of phosphotransferase activity[120–127]. Only ribonucleoside 5′-phosphoamidase from mammalian tissue extract has not so far shown any additional activity[128]. Phosphoamidase activity is also shown by certain proteo-lytic enzymes[127].

The phosphoesterase and phosphotransferase activity of phosphoamidases and the fact that free phosphoramidates have not been detected in biological systems, synthetic compounds being employed as substrates in enzymatic reactions, suggest that the phosphoamidase activity of the enzymatic preparations described is a kind of artefact reflecting certain details of the mechanism of enzyme action.

Possibly, in phosphoesterase and other reactions, intermediate enzyme–substrate compounds of the phos-phoramidate type are formed and this is why the enzymes are capable of cleaving phosphoramidates when these are supplied in a finished form.

The phosphorylation of the enzyme protein during the reaction has been described for a number of enzymes[129–142]. For certain enzymes involved in nucleic acid metabolism, it has been suggested[110,127,138–140] that the substrate can interact initially with the active centre of the enzyme, forming intermediate active nucleoside 5′-phospho-enzyme derivatives. In many cases it has been suggested that phosphate adds to the imidazole moiety of the histidine residue[105,129–135,142]. Phosphonohistidine was also isolated from mitochondria and from a preparation of succinate thiokinase and was identified by reference to a synthetic specimen of 3-phosphonohistidine[105]. However, subse-quently the exceptional case of the transfer of the phosphate residue from the 1-position of histidine to various acceptors, including the *N*-3-position in histidine, was demonstrated. Thus the problem of the site where histi-dine is phosphorylated in the enzyme remains open[84].

In connection with the possibility of the formation of enzyme–substrate complexes with a P–N bond between the fragments, synthetic phosphoramidates can be regarded as models of such complexes. The differences between them and natural phosphoramidates consists in the fact that the enzyme has been replaced by an amine residue as a donor of amide nitrogen. If the phosphoramidate can approach the active centre of the enzyme without affecting sifnifi-cantly its structure, there is a possibility of nucleophilic-electrophilic activation of the phosphoramidate site with participation of the functional groups of the enzyme, which under "normal" conditions acts on the enzyme's own phosphonoimidazole system. Ultimately, when a phos-phate acceptor is present, transphosphorylation takes place, while in the absence of a specific acceptor the phos-phoramidate is hydrolysed. This hypothesis has been discussed in detail for ribonucleoside 5′-phosphoamidase and it was suggested that, like other phosphoamidases, this enzyme has no independent importance and its activity is based on the formation of intermediate phosphoramidate structures in the synthesis of hydrolysis of internucleotide bonds of RNA.[61]

Polytriazines

V.A.Pankratov and S.V.Vinogradova

The review deals with studies on the synthesis and properties of polymers containing the *s*-triazine ring in the main chain (polytriazine). These polymers have found large-scale application in many branches of engineering. Attention has been concentrated on studies dealing with the preparation of thermostable and heat resistant polymers based on *s*-triazine derivatives and also new and novel methods of synthesising these polymers, particularly such as the polycyclotrimerisation and polycyclocondensation reactions.

The bibliography includes 250 references

III. Polytriazines obtained by polycyclocondensation and polycyclotrimerisation reactions 72

I. INTRODUCTION

Polymers containing the cyclic *s*-triazine group in the main chain have been attracting attention for a long time. As early as in the 1930's a melamine-formaldehyde polymer was obtained by the polycondensation of melamine with formaldehyde[1] and subsequently found large-scale industrial application.

Recently there has been a considerable increase of interest in polymers containing *s*-triazine rings because the majority of polymers of this kind exhibit high thermal stability owing to the aromaticity of the *s*-triazine ring[2-4].

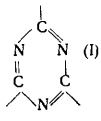
Polymers containing *s*-triazine rings may be obtained in two ways: (1) by the polycondensation or polymerisation of monomeric *s*-triazine derivatives and (2) by the polycyclotrimerisation of nitriles or by the polycyclocondensation of nitrile derivatives (iminoethers, amidines, etc.). Since the synthesis and properties of melamine-aldehyde polymers have been thoroughly reviewed[5-12], we shall not consider here (with some exceptions) studies dealing with triazine polymers of this type.

In the present review attention will be concentrated on problems of the thermal stability of polytriazines and also new, novel methods of their synthesis.

II. POLYTRIAZINES OBTAINED BY THE POLYCONDENSATION AND POLYMERISATION OF MONOMERIC *s*-TRIAZINE DERIVATIVES

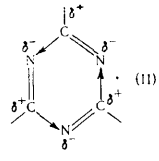
1. Polycondensation of Monomeric *s*-Triazine Derivatives

As mentioned above, *s*-triazine behaves like an aromatic compound[2-6]. It consists of a six-membered cyclic system of alternating N and C atoms:



(I)

which resembles the benzene cyclic system. The nitrogen atoms in *s*-triazine are more electronegative than the carbon atoms and the carbon–nitrogen bond tends to undergo type (II) polymerisation:



(II)

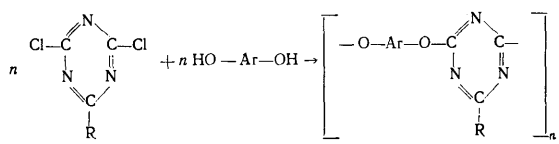
Apart from the χ-electron system, the *s*-triazine ring contains six unpaired electrons of the nitrogen atoms. Calculation of electron density in *s*-triazine[13] showed that it is 1.179 at a nitrogen atom and 0.821 at a carbon atom. This is probably the reason for the fundamental differences between the *s*-triazine and benzene systems: the *s*-triazine ring is less aromatic[14-16]. This is shown, in particular, by the lower chemical stability of the *s*-triazine system compared with the benzene ring.

Studies on *s*-triazine showed its inability to undergo electrophilic substitution reactions characteristic of benzene (nitration and sulphonation), so that it was impossible to synthesise nitro-derivatives of cyanuric chloride[2]. This can be explained only by the reduced electron density at the carbon atoms of *s*-triazine and the same explanation is also given for the greater mobility of the halogen atoms in its halogeno-derivatives, particularly of chlorine atoms in cyanuric chloride, which distinguishes the latter from benzene derivatives.

Cyanuric chloride and dichloro-*s*-triazines readily enter into substitution reactions with various compounds and therefore they constitute the main starting materials for the synthesis of polytriazines.

A number of polyesters—poly(aryl cyanurates)—with enhanced heat resistance and thermal stability have been

synthesised by the reaction of cyanuric chloride and dichloro-*s*-triazines with various bisphenols[17-35]:



Depending on the functional groups in the initial *s*-triazines, both linear soluble and cross-linked insoluble poly(aryl cyanurates) were obtained.

Thus Nakamura and coworkers[17] synthesised poly(aryl cyanurates) by the interfacial polycondensation of di-(4-hydroxyphenyl)propane with 2-R-4,6-dichloro-*s*-triazines, where R = OCH_3, $OCH_2CH{=}CH_2$, OC_6H_5, $N(C_2H_5)_2$, $N(CH_2CH{=}CH_2)_2$, $N(CH_2)_5$, $N(C_6H_5)_2$, C_6H_5, $PhNSO_2C_6H_4CH_3$, or Cl. Some of the poly(aryl cyanurates) obtained are crystalline and soluble in chloroform, *o*-dichlorobenzene, etc., films being formed from the solutions.

Cross-linked polymers[18-20], insoluble in the usual solvents but decomposing in hot alkalies and amines, have been synthesised by the interfacial polycondensation of cyanuric chloride with bisphenols [resorcinol, quinol, 4,4′-dihydroxybiphenyl, di-(4-hydroxyphenyl)methane, and di-(4-hydroxyphenyl)propane]. Vigorous thermal degradation of these polymers begins about 450°C.

Nakamura and coworkers[21,22] synthesised a number of poly(aryl cyanurates) using 2-diphenylamino-4,6-dichloro-*s*-triazine and various bisphenols and also a phenol-formaldehyde resin of the novolak type. The polymer based on di-(4-hydroxyphenyl)propane (dian) proved to have the highest molecular weight. It was found that the temperature of the onset of decomposition of the poly(aryl cyanurate) synthesised depends little on the type of the initial diol and is in the range 320–360°C (for an average molecular weight of about 5000). The majority of polymers dissolved in chloroform and nitrobenzene, but polymers based on quinol, 4,4′-dihydroxybiphenyl, di-(4-hydroxyphenyl)propane, and di-(4-hydroxyphenyl) sulphone were partly soluble only in nitrobenzene. Polymers with a fairly high molecular weight (in excess of 5000) are capable of forming colourless transparent films with high mechanical strength and a characteristic absorption in the ultraviolet.

Seta and Nakamura[23] obtained and successfully employed as dyes and stabilisers for various resins coloured poly(aryl cyanurates). Triazine dyes of this kind are synthesised by the polycondensation of diazo-derivatives of dichloro-*s*-triazine with bisphenols such as di-(4-hydroxyphenyl)propane, fluorescein, aurin, etc. The low-molecular polymers of different colours thus obtained (η_{inh} between 0.09 and 0.6 dl l^{-1}) proved to be readily soluble in chloroform, dimethylformamide (DMF), and dimethylacetamide.

In a later study Nakamura and coworkers[24] investigated the effect of the structure of poly(aryl cyanurates) on their thermal and mechanical properties. A large number of dichloro-*s*-triazines with 35 different substituents R in the ring were employed as the starting materials together with the following initial bisphenols: quinol, 4,4′-dihydroxybiphenyl, di-(4-hydroxyphenyl)methane, di-(4-hydroxyphenyl)propane, 4,4′-dihydroxybenzophenone, di-(4-hydroxyphenyl)sulphone, and phenolphthalein. The polymers obtained had high inherent viscosities (η_{inh} up to 3.52 dl g^{-1}) and their softening temperatures were in the range between 200° and more than 360°C. The authors established that the temperature of the onset of decomposition of these poly(aryl cyanurates) in air depends greatly on the structure of the substituents R in the triazine ring and is in the range 300–400°C. Poly(aryl cyanurates) with substituents such as $N(C_6H_5)_2$, $N(C_6H_5)$(β-naphthyl), C_6H_5, etc. have the highest temperatures of the onset of decomposition. Poly(aryl cyanurates) based on phenolphthalein, 4,4′-dihydroxybenzophenone, and di-(4-hydroxyphenyl) sulphone are distinguished by high thermal stability.

Poly(aryl cyanurates) based on phenolphthalein and 2-diphenylamino-4,6-dichloro-*s*-triazine were described simultaneously by Devdariani and Kutepov[25], but they had less satisfactory thermal characteristics (softening temperature 160–210°C, temperature of the onset of decomposition 250–300°C) than those synthesised by Nakamura and coworkers[24], probably due to the lower molecular weights of the polymers synthesised (η_{inh} = 0.08–0.12 dl g^{-1}).

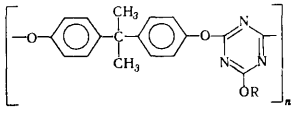
Vinogradova and Frenkel'[26] obtained poly(aryl cyanurates) by the high-temperature polycondensation in solution of 2-amino-4,6-dichloro-*s*-triazine with the anilide of phenolphthalein and 9,9-di-(4-hydroxyphenyl)fluorene in the presence of potassium or sodium carbonate. The polymer based on 9,9-di-(4-hydroxyphenyl)fluorene had η_{inh} = 0.18 dl g^{-1} in sulphuric acid and a softening temperature in excess of 320°C.

Later Anderbert and Neel[27] achieved under similar conditions the polycondensation of substituted dichloro-*s*-triazines $C_3N_3Cl_2R$ (R = NC_5H_{10}, C_6H_5, or OC_6H_5) with quinol, 4,4′-dihydroxybiphenyl, di-(4-hydroxyphenyl)sulphone, and di-(4-hydroxyphenyl)propane. The poly(aryl cyanurates) obtained had softening temperatures between 270° and 380°C and a temperature of the onset of decomposition (according to thermogravimetric data) in the range 305–415°C. These temperature characteristics of the polymers depend both on the structure of the substituent in the triazine ring and on the structure of the initial bisphenol. The poly(aryl cyanurates) based on 2,4-dichloro-6-phenoxy-*s*-triazine and quinol showed the highest thermal stability (380° and 415°C respectively)[27].

Korshak and Kutepov and coworkers carried out the high-temperature condensation of 2-anilino-4,6-dichloro-*s*-triazine with di-(4-hydroxyphenyl)propane and other bisphenols in solution[28-30] and in the melt[31], and established that, together with the main reaction, there is a homocondensation side reaction leading to the formation of three-dimensional products. When employed as hardening agents for epoxy-resins, the resulting oligomers and polymers increased the thermal stability of the resins[30,31].

Korshak, Kutepov, and coworkers[19,20,25,28-31] synthesised poly(aryl cyanurates), based on substituted dichloro-*s*-triazines [R = C_6H_5, $N(C_6H_5)_2$, $N(C_2H_5)_2$] and bisphenols such as 2,2-di-(4-hydroxyphenyl)propane, 2,2-di-(3-chloro-4-hydroxyphenyl)propane, 2,2-di-(2,5-dichloro-4-hydroxyphenyl)propane, and phenolphthalein as well as bisphenols containing various substituents at the central carbon atom, by high-temperature polycondensation in ditolylmethane in a stream of inert gas at 180–240°C. It was established that, depending on the structure of the substituents at the central carbon atom, the reactivity of bisphenols decreases in the series H, H > CH_3, C_6H_5 > H, C_6H_5 > C_6H_5, C_6H_5.

Breed and Elliott [32] synthesised two poly(aryl cyanurates) with the following structures by the polycondensation of substituted dichloro-*s*-triazines:

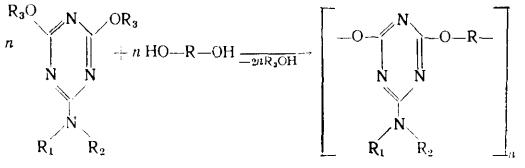


where R = $(CH_2)_4CH_3$ and $CH_2(CF_2)_4H$.

According to thermogravimetric analysis of polymers with similar inherent viscosities (0.89 and 1.24 dl g^{-1}), the polymer with the fluorinated substituent in the triazine ring has a higher thermal stability. Thus at 400°C the poly(aryl cyanurate) with R = $(CH_2)_4CH_3$ loses in air 19% of its weight (heating rate 6 deg min^{-1}) and 30% in an inert atmosphere (heating rate 3 deg min^{-1}), while the poly(aryl cyanurate) with R = $CH_2(CF_2)_4H$ loses only 3% of its weight in air and 3% in an inert atmosphere.

Anderbert and Neel [33,34] obtained linear polytriazines by the polycondensation in a high-boiling solvent at 200–240°C of substituted dichloro-*s*-triazines (R = NC_5H_{10}, C_6H_5, and OCH_3) with di-(4-hydroxyphenyl) sulphone, 2,2-di-(4-hydroxyphenyl)propane, 4,4′-dihydroxybiphenyl, and quinol. The resulting polymers were soluble in aniline, hexamethylphosphoramide, *N*-methylpyrrolidinone, etc. The polytriazines had a high softening temperature (270 and 585°C) and a temperature of the onset of decomposition in an inert atmosphere in the range 260–420°C.

Many polymers containing the *s*-triazine ring were obtained by the transesterification of dialkoxy-*s*-triazines with glycols [36]. The transesterification reactions proceed according to the mechanism



where R_1, R_2, and R_3 were varied from H to C_4H_9 and the glycols were ethylene glycol, di- and tri-ethylene glycols, hexa- and deca-methylene glycols, and also higher polyglycols with molecular weights up to 400.

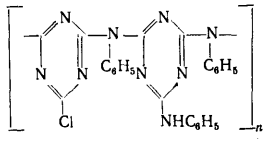
The degree of reaction was 85–90% and the polymerisation coefficient n = 4–5. The polymers were synthesised *in vacuo* at 80–160°C, the alcohol formed in the course of the reaction being distilled off. It has been noted that the transesterification reaction takes place in stages and at a high temperature infusible and insoluble polymers may be formed. Nakamura and coworkers [37–39] carried out the polycondensation of 2-R-4,6-diphenoxy-*s*-triazines, where R = OCH_3, OC_2H_5, $OCH_2CH{=}CH_2$, $N(C_2H_5)_2$, $N(CH_2CH{=}CH_2)_2$, $N(CH_2)_5$, $N(C_6H_5)_2$, *m*-$C_6H_3(CH_3)_2$, and Cl, with 2,2-di-(4-hydroxyphenyl)propane at 180–270°C in the presence of cadmium acetate. Low-molecular-weight linear polymers with a polymerisation coefficient of 3–10 were obtained. All the polymers, except that with R = Cl, were soluble in chloroform and dimethylformamide and had softening temperatures in the range 120–270°C. On further heating in the presence of dicumenyl peroxide, the polymers with R = $OCH_2CH{=}CH_2$ and $N(CH_2CH{=}CH_2)_2$ become cross-linked and insoluble.

Nakamura et al. [40] obtained linear polytriazines by heating (220–240°C) 2-amino-4-6-diphenoxy-*s*-triazine with 2,2-di-(4-hydroxyphenyl)propane *in vacuo*. It was established that in the first stage the reaction is of second order with an activation energy of 16.7–17.8 kcal $mole^{-1}$. Further heating of the polymer to 270°C without catalyst or in the presence of cadmium acetate leads to the formation of a cross-linked product, probably as a result of the elimination of phenol when phenoxy- and amino-groups interact. The authors [40] showed that the last reaction is identical with the homocondensation of 2-amino-4,6-diphenoxy-*s*-triazine on heating, since both processes are of second order and have similar activation energies (40.3–47.8 and 42.7 kcal $mole^{-1}$ respectively). The thermal stability of the cross-linked polymer thus obtained is somewhat higher than that of the product of the cross-linking of the linear polymer by paraformaldehyde, dimethyl terephthalate, tolylene di-isocyanate, etc.

Polyamides, polyimides, polyureas, and other classes of polymers obtained from triazine derivatives are distinguished by high thermal stability and heat resistance. Depending on the functional groups in these derivatives, polymers with both linear and three-dimensional structures can be obtained, as in the case of poly(aryl cyanurates).

One of the main starting materials for the synthesis of polymers of this type is cyanuric chloride and its various derivative, which Sheehan et al. [41] were the first to employ for this purpose.

Thus Ehlers and Powers [42] described the synthesis of thermostable polytriazyleneimides from cyanuric chloride and 2,4,6-triphenylamino-*s*-triazine, whose structure may be represented by the following formula:

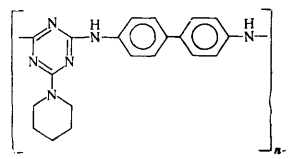


Thermostable and chemically stable polymers have been obtained by the polycondensation of cyanuric chloride or dichloro-*s*-triazines with various aromatic diamines [19,20,26,27,42–46].

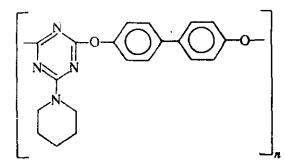
Triazine-containing polymers based on 2-amino-4,6-dichloro-*s*-triazine and hexamethylenediamine, *p*-phenylenediamine, and anilinephthalein have been described [26]. The polycondensation was carried out in a stream of nitrogen in n-butyl alcohol in the presence of triethylamine (12 h with a gradual increase of temperature from 85° to 115°C) or in decalin in the presence of sodium carbonate (at the boiling point of the solvent for 18 h). The polymers of hexamethylenediamine and *p*-phenylenediamine, synthesised in n-butyl alcohol, had inherent viscosities of 0.13 dl g^{-1} (in dimethyl sulphoxide) and 0.14 dl g^{-1} (in sulphuric acid) respectively. Their softening temperatures were 290–320°C and about 450°C respectively. The polymer based on anilinephthalein had a softening temperature of 260–270°C and was more soluble than the above polymers (it was soluble in dimethyl sulphoxide, dimethyl formamide, and dioxan). The polyamide based on hexamethylenediamine and synthesised in decalin was infusible and insoluble.

Andebert and Neel [27] carried out the high-temperature polycondensation of various dichloro-*s*-triazines with diamine derivatives or related compounds such as piperazine hydrochloride, benzidine, 2,4-diamino-6-phenyl-*s*-triazine, and hexamethylenediamine in decalin. It is noteworthy that the polyamides greatly surpass (by 100–150°C) in both heat resistance at thermal stability the poly(aryl cyanurates) with comparable structures obtained

in the same study[27]. Thus the polyamide based on benzidine,



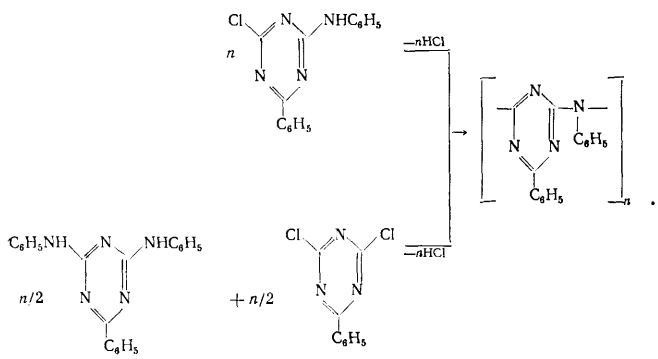
has a softening temperature at 470°C and begins to decompose *in vacuo* at 460°C (η_{inh} = 0.32 dl g^{-1}), while the corresponding temperatures for the poly(aryl cyanurate) having a similar structure and based on 4,4′-dihydroxybiphenyl,



are 315–320° and 365° respectively (η_{inh} = 0.23 dl g^{-1}).

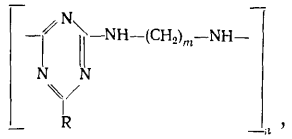
Polycondensation of 2,4-diphenoxy-6-chloro-*s*-triazine with di-(4-aminophenyl) sulphone yielded a polymer melting at 360°C and stable on heating in air to 400°C.[43] Among polymers of this type, polyperfluoro-4,4′-diphenylmelamine proved to be the most thermostable[44]. It is stable up to 500°C but at 700°C in air it loses 63% of its initial weight.

Ehlers and Ray[45] established that it is more convenient to employ chloro-derivatives of *s*-triazine rather than phenoxy-derivatives in the polycondensation with the aim of obtaining linear polytriazyleneimides:



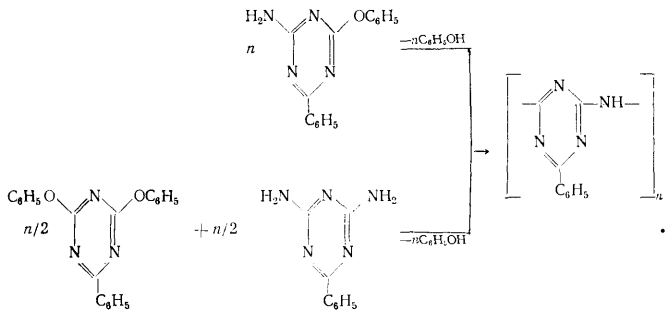
They also established that the polycondensation is best performed in an inert atmosphere at 200–250°C without reducing the pressure; the latter condition is necessary owing to the ease of sublimation of the initial monomers at a high temperature (about 200°C), while at a 150°C the reaction hardly occurs. It was shown that acids, alkalies, peroxides, and HCl acceptors do not affect the molecular weight of the polymer formed. It is noteworthy that the polymers containing terminal and side chain chlorine atoms are hydrolysed in air, becoming brittle and insoluble. Attempts have been made to replace these chlorine atoms by phenoxy-groups by treating the polymer with phenol, but the polymer decomposed under these conditions.

Infusible and insoluble polymers thermostable up to 400°C are formed in the high-temperature homocondensation of a number of amino-derivatives of *s*-triazine[45]. The most thermostable of these proved to be the polymer obtained from 6-anilino-4-chloro-2-phenyl-*s*-triazine. It loses 5% of its weight at 400°C and not more than 25% at 900°C. Polymers containing guanamine units separated by aliphatic bridges were obtained by the polycondensation of cyanuric chloride or its derivatives with aliphatic diamines:



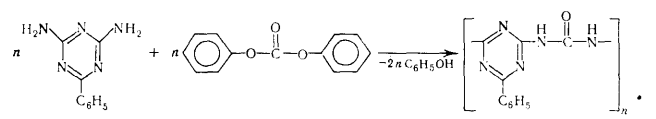
where R = Cl, C_6H_5, a monoamine residue, etc. and m = 6–12.[26,27,47]

Linear soluble polyamides containing *s*-triazine rings were obtained by the homocondensation of 4-amino-6-phenoxy-2-phenyl-*s*-triazine or by the reaction of 4,6-diphenoxy-2-phenyl-*s*-triazine with guanamines[48,49]:



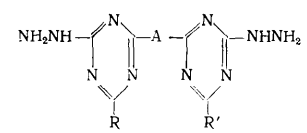
The transamination reaction was performed in an atmosphere of nitrogen above the melting point of the monomers; the optimum reaction temperature is 260–300°C. Polymers with maximum molecular weights (according to viscometric data) are obtained when the synthesis is carried out at a reduced pressure. The homopolymer of 4-amino-6-phenoxy-2-phenyl-*s*-triazine and a polymer based on 4,6-diphenoxy-2-phenyl-*s*-triazine and benzoguanamine have the same physical properties, which is evidence of the identity of their structures. This is also confirmed by infrared spectroscopic data.

The polymer obtained by the polycondensation of 2,4-diamino-6-phenyl-*s*-triazine with diphenyl carbonate exhibits a high heat resistance[48]:



It is soluble in sulphuric acid and melts at 350°C.

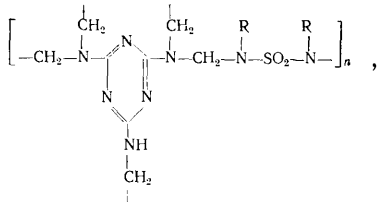
Insoluble polymers are formed in the homopolycondensation of 2,4-diamino-6-phenoxy-*s*-triazine and 2-amino-4,6-diphenoxy-*s*-triazine[50,51]. Gehm et al.[52] obtained film-forming polymers with viscoelastic properties by the interaction of linear polyhydroxy-compounds, modified using isocyanate (M = 750–6000), with compounds of the type:



where R and R′ = H, Cl, alkyl, aryl, etc. and A is a bivalent diamino-residue linked via N atoms to the *s*-triazine rings, for example a diamino-residue with 2–12 carbon atoms in the chain.

Polymers with high thermal stability and resistance to oxidation were obtained by heating a mixture of dihalogeno-derivatives of aromatic compounds (for example *p*-dichlorobenzene) and 2,4,6-tri-(*p*-chlorophenyl)-*s*-triazine with sulphur in the presence of alkali or alkaline earth metal carbonates, sulphides, and oxides[53]. The decrease of the weight of the resulting polymers was 3.3% after heating for 100 h at 300°C and 5.3% after 20 h at 400°C.

Polymers with the following structure were obtained by the polycondensation of formaldehyde with sulphamide or its mono- and di-alkyl-substituted derivatives (RNH–SO_2–NH–R) and melamine[54,55]:



where R = CH_3, t-C_4H_9, etc. These polymers lose 25% of their weight at temperatures up to 225°C; the N–H and N–SO_2 bonds in the polymers persist up to 225°C; the *s*-triazine ring does not break down up to 300°C.[54]

Kabaivanov and Alaminov achieved the synthesis of low-molecular-weight thermoplastic resins by the polycondensation of phenol, formaldehyde, and cyanuric acid in the presence of both acid[56] and alkaline[57] catalysts. They established that the reaction proceeds via the formation of hydroxymethyl derivatives of cyanuric acid. Articles made from the resulting Resol resins are distinguished by high thermal stability, water resistance, good mechanical strength, and incombustibility.

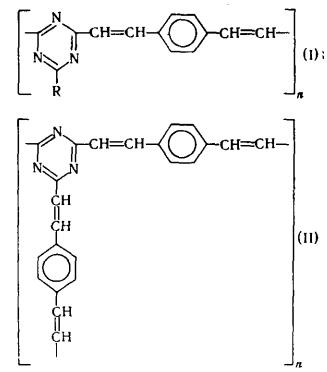
The same authors[58,59] obtained resins based on cyanuric acid, 2,2-di-(4-hydroxyphenyl)propane, and formaldehyde. The polymers were synthesised in an acid medium with different proportions of the initial components. The polycondensation reaction was investigated spectroscopically. It was shown that cyanuric acid reacts in the keto-form; at 130°C methyl ether groups are formed predominantly, rearranging at a higher temperature (170°C) to methylene bridges with liberation of formaldehyde[60].

A characteristic feature of the majority of the polytriazines discussed above is the presence in the macromolecular chain of heteroatoms (O and N) linking the *s*-triazine rings either directly with one another or via another group.

Next we shall consider studies on the synthesis and properties of polytriazines in which the *s*-triazine rings are linked via hydrocarbon groups.

Greth and coworkers[61,62] described the synthesis of polymers with a system of conjugated double bonds containing *s*-triazine rings in the chain and investigated some of their properties. The authors undertook the synthesis of these polymers on the basis of the fact that the *s*-triazine ring is an aromatic system with a high resonance energy and therefore polytriazines should have a high thermal stability.

Polycondensation of 2,4-dimethyl-6-phenyl-*s*-triazine, 2-methoxy-4,6-dimethyl-*s*-triazine, and 2,4,6-trimethyl-*s*-triazine with terephthalic dialdehyde yielded linear (I) or cross-linked (II) conjugated polytriazines[61,62]:

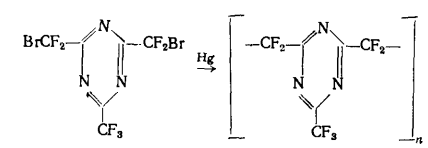


where R = C_6H_5 or OCH_3. Polymers of type (I) begin to decompose in a stream of nitrogen at 380°C (4% weight loss) and decompose vigorously at 530°C; at 730°C they lose 40% of their weight. In oxygen the polymer loses at 380°C only 4% of its weight but at 700°C its combustion is complete.

A polytriazine of type (II) loses 8% of its weight at 500°C in a stream of nitrogen, 30% at 700°C, and 40% at 875°C. The degradation of this polymer in a stream of oxygen begins, like that of polymer (I), at 380°C and at about 600°C its combustion is complete[63].

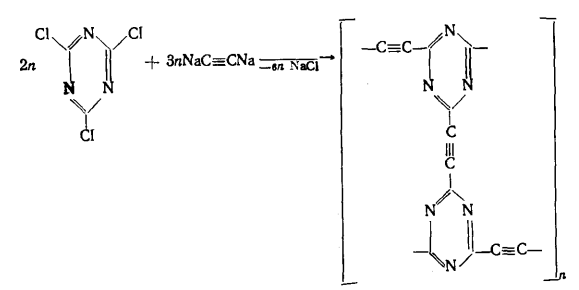
Nitriles, which are usually formed in the depolymerisation of low-molecular-weight triazines, were not detected in the degradation products of polytriazines[63].

Linear polyperfluoroalkylenetriazine polymers, which are of considerable interest as high-temperature elastomers (temperature at the onset of decomposition about 400°C, see below—pp. 72–74), were synthesised by the polycondensation of difunctional fluorinated triazine monomers containing an active halogen[64] at 250–300°C in the presence of metallic mercury. The reaction of 2,4-di(bromodifluoromethyl)-6-trifluoromethyl-*s*-triazine takes place according to the mechanism:



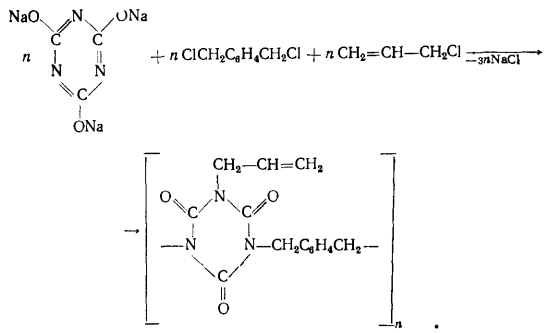
Above 40°C the resulting polymer exhibits rubber-like properties.

Paushkin et al.[65] obtained polymers by the polycondensation of cyanuric chloride with sodium carbide by the reaction



The infrared spectrum of the polymer has absorption bands in the region of 1540 and 1570 cm^{-1} which in all probability characterise the triazine rings in the polymer.

Fusible and soluble polymers with a softening temperature of about 200°C and containing isocyanurate rings in the chain were synthesised by the joint polycondensation of allyl chloride and *p*-xylylene dichloride with sodium cyanurate[66]:



2. Polymerisation of Monomers Containing the *s*-Triazine Ring

As already mentioned at the beginning of the review, one of the common methods for the introduction of the *s*-triazine ring into the polymer chain is by polymerising monomeric *s*-triazine derivatives. Depending on the functional groups in the unsaturated triazine derivatives, both linear and three-dimensional polymers may be obtained.

Data have been published both on the homopolymers of unsaturated *s*-triazine derivatives[67-76] and on their copolymers with other unsaturated compounds[68,71-73,76-90]. *s*-Triazine derivatives are as a rule introduced into copolymers to improve their thermal stability. Moreover, the presence of a large number of unsaturated functional groups in the triazine ring promotes the formation of a large number of cross-links, which also lowers the rate of thermal degradation of highly-structured polymers based on them.

One of the most widely used unsaturated monomers containing the *s*-triazine ring is triallyl cyanurate[77-88,91]. It is readily miscible with unsaturated polyesters and therefore has come to be widely used as a modifying and structure-forming agent in alkyd resins[77-85].

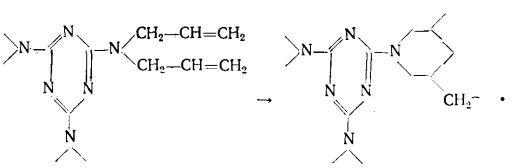
According to the data of Cohen and Cypher[86], who investigated the copolymers of poly(ethylene glycol maleate) and poly(diethylene glycol maleate) with diallyl phthalate, isophthalate, and terephthalate and with triallyl cyanurate, the thermal stability of the copolymers varies in the following sequence as a function of the monomer employed in the copolymerisation: triallyl cyanurate > diallyl terephthalate > diallyl isophthalate > diallyl phthalate. The high thermal stability of copolymers with triallyl cyanurate is due, according to the authors, to the thermal stability of the *s*-triazine ring in the initial monomer. In the same study[86] it was shown that the replacement of the allyl group in triallyl cyanurate by the ethoxy-group does not alter the thermal stability of the polymer: the methyl group decreases and the β-hydroxyethyl group sharply increases the thermal stability of the polymer. This finding was explained by the increase in the number of substituents in the monomer as a result of the side reaction involving the formation of dimeric cyanurate. Another explanation may be the involvement of the hydroxyethyl group of the monomer in the cross-linking of the polyester.

There are data on the use of triallyl cyanurate also for other purposes, for example for the preparation of transparent materials used to make lenses and other articles[87]. The products of the transesterification of triallyl cyanurate with glycols are used as plasticisers for a number of resins[87,88]. Oswald[91] stabilised halogen-containing polyolefins with cyanurates or isocyanurates. It was found that chlorinated polyethylene stabilised with 0.5–10% of triallyl cyanurate does not change over a period of 1 h at 200°C.

Linear triazine polyesters with allyl groups in the side chain were obtained by the transesterification of triallyl cyanurate with glycols in the presence of sodium methoxide as a catalyst[88]. Linear unsaturated triazine polyesters were synthesised only in the very initial stage of the reaction; when the degree of reaction is more than 0.15, polymers with three-dimensional structures are formed exclusively.

The synthesis of unsaturated polyesters by the copolymerisation of alkenyl alkyl esters of cyanuric acid with unsaturated aliphatic and alicyclic hydrocarbons in the presence of radical polymerisation initiators has been reported[79,88].

Gillham and Petropolous[67] investigated hexa-allylmelamine polymers. Piperidine rings alternating with *s*-triazine rings may be formed in the radical polymerisation of hexa-allylmelamine by the reaction



Owing to the high degree of cross-linking, these polymers have good mechanical properties and a high thermal stability. The polymers are stable up to 370°C on heating in air and up to 400°C on heating in nitrogen. Their thermal stability is higher than that of polymers based on triallyl cyanurate. Transparent plastics based on hexa-allylmelamine are stable in air up to 260°C

Oligomeric unsaturated polyesters based on hexa(hydroxymethyl)melamine, partly esterified with allyl alcohol and maleic acid, have been described[92].

There are also literature data on the modification of unsaturated polyesters by compounds based on *s*-triazine. Thus the use of cyanuric acid and its derivatives as modifying components has been described[93].

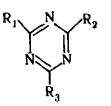
Widmer[89] described the synthesis and structure of new resins suitable for the preparation of varnishes, based on the allyl ether of hydroxymethylmelamine and its copolymers with vinyl monomers. The varnishes obtained from these resins dry rapidly and the coatings are distinguished by high hardness and resistance to solvents.

Kugel and coworkers[68] achieved the synthesis of 2,4-dimethyl-6-vinyl-*s*-triazine by the pyrolysis of the corresponding acetoxyethyldimethyl-*s*-triazine, polymerised it, and investigated the properties of the polymer. They found that the initial monomer polymerises at 20°C under the influence of free-radical initiators (benzoyl peroxide, etc.) or radiation, and readily copolymerises with styrene, methyl methacrylate, and acrylonitrile. The kinetics of its copolymerisation with styrene and methyl methacrylate have been investigated. The homopolymer softens at 105°C and readily dissolves in water and the usual organic solvents, with the exception of aliphatic hydrocarbons.

Pyrolysis of the corresponding acetoxyethyl- or acetoxyisopropyl-*s*-triazine also yielded 2,4-diethyl-6-isopropenyl-6-methyl-2,4-divinyl-, 2-butyl-4,6-divinyl-, 2,4,6-trivinyl-, 2,4-di(trichloromethyl)-6-vinyl-, 2,4-di(pentabromoethyl)-6-vinyl-, and 2,4-di(pentafluoroethyl)-6-isopropenyl-*s*-triazines[76]. They have been homopolymerised and copolymerised with alkyl acrylates, styrene, vinyltoluene, and other monomers in the presence of radical initiators. These homopolymers may be used in the manufacture of thermostable sheets and fibres.

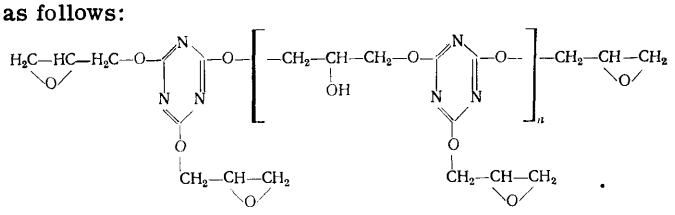
Vinyl derivatives of guanamines—2,4-diamino-6-(α-vinyloxyalkyl)-*s*-triazines[69] and acylamino-*N*-(vinyloxyalkyl)guanamines[70]—are polymerised in the presence of strong acids (H_3PO_4) or are used for polycondensation with formaldehyde. The copolymerisation of hexahydro-1,3,5-triacryloyl-*s*-triazine with styrene, vinyl acetate, methyl methacrylate, and acrylonitrile has been investigated[90]. There are various patent data on the vinyl esters, amides, and other derivatives of *s*-triazine[71-73] which form homopolymers and copolymers with vinyl monomers.

Holtschmidt[75] obtained polytriazines with a high thermal stability by radical polymerisation of compounds of the type



where R_1 =  and R_2 and R_3 = R_1, H, halogen, etc.

Poly(glycidyl cyanurates)[94-99], obtained by the reaction of cyanuric acid with epichlorohydrin or of cyanuric chloride with 2-hydroxymethyloxiran, have been described[94-99]. The initial product was triglycidyl cyanurate, which subsequently forms poly(glycidyl cyanurate) resins. The general structure of such resins can be represented as follows:



(where n = 0 - 2).

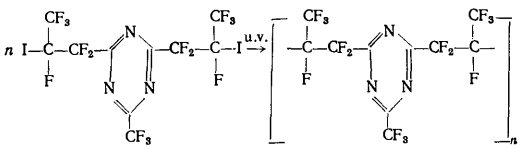
Usually poly(glycidyl cyanurate) resins contain between 0.8 and 10% of chlorine, which is evidence of an incomplete conversion of the chlorohydrin groups. In order to reduce the chlorine content, the resin is subjected to additional dehydrochlorination with a solution of alkali, which makes it possible to increase the number of epoxy-groups. Poly(glycidyl cyanurate) resins, hardened with the usual hardening agents employed for epoxy-resins, have a higher thermal stability and lower dielectric losses at high temperatures than ED-6 epoxy-resin.

Apart from the polymers of triglycidyl cyanurate, the polymers of other epoxy-derivatives of *s*-triazine have been described[100-104].

Three-dimensional polymers insoluble in organic solvents are obtained by heating a mixture of cyanuric acid with the di-isocyanate esters $R(NCO)_2$, $R-PO-(NCO)_2$, or $R-P(NCO)_2$, where R is an aliphatic or aromatic group. The reaction is carried out in the presence of an excess of cyanuric acid. The polymers are stable up to temperatures in excess of 300°C.[105]

Nakamura and coworkers[37-39] described a method for the preparation of novolaks containing *s*-triazine rings with unsaturated side groups: 2,4-diallylamino-6-chloro-*s*-triazine was allowed to react with phenol, t-butylphenol, and novolak. Polycondensation in the presence of alkali at 100–105°C yielded unsaturated products with different molecular weights and different numbers of functional groups. Such polymers may be hardened with radical-polymerisation initiators or may be structured with methyl methacrylate and styrene.

Griffin[64] investigated the possibility of using the polyrecombination reaction for the synthesis of polyfluoroalkyltriazine polymers. In particular, these polymers are formed by the following mechanism when di(iodoperfluoroalkyl)-*s*-triazines are exposed to ultraviolet light:



Thermostable elastomers were obtained in this way. However, owing to the high cost of the monomers, this method of preparing fluorinated triazine elastomers cannot as yet compete with other syntheses of these polymers (see below—pp. 72–74).

III. POLYTRIAZINES OBTAINED BY POLYCYCLOCONDENSATION AND POLYCYCLOTRIMERISATION REACTIONS

In contrast to the methods of preparation of polytriazines described above, where the *s*-triazine ring was introduced with the initial monomers, this section deals with the formation of the *s*-triazine ring in the course of the synthesis of the polymer. Since in this case polytriazines (and also other polymers) may be formed by polycondensation or polymerisation reactions in which three functional groups of the initial monomers must be involved at once, these reactions have been called, following the suggestion of V. V. Korshak, polycycloconden-sation and polycyclotrimerisation respectively.

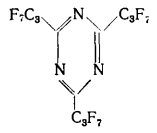
The synthesis of polytriazines (as well as other polymers) by these two methods has been widely used only in recent years. However, the high promise of these syntheses is already evident.

The advantages of the synthesis of polymers by polycondensation and particularly by polycyclotrimerisation include the possibility of the specific synthesis of both highly structured polymers, the rings of which are separated by various bridging groups, and linear polymers. The polycondensation or polymerisation may be interrupted at the oligomer stage, the oligomers being processed by the usual methods.

1. Polycyclocondensation of Nitrile Derivatives

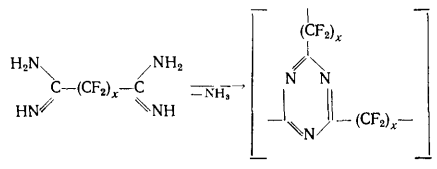
As already stated above, the polycyclocondensation reaction has only comparatively recently come to be widely employed for the synthesis of polytriazine polymers. This method of polycondensation became particularly interesting in connection with Brown's discovery of the class of polyperfluoroalkylenetriazine elastomers with high thermal stability and physicomechanical parameters[106-108].

Fluorocarbon elastomers are known to be stable for a long time at temperatures not exceeding 300°C. At the same time the exceptionally high resistance of perfluoroalkyltriazines with the structure[109]

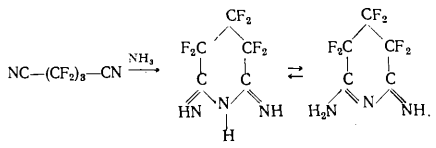


to thermal oxidation suggested that the problem of increasing the thermal stability of fluoro-polymers may be solved by introducing *s*-triazine rings into their structure. Perfluoroalkylenetriazine polymers, which combine a high thermal stability (about 400°C), exceeding the thermal stability of fluorocarbon elastomers by about 100 deg, with resistance to strong oxidising agents and radiation, constitute such a system[64,106-108,110-122].

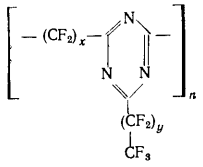
Cross-linked polymeric products containing repeating units of the above type were obtained by the thermal cyclisation of perfluoroalkylenediamidines[108]. The polycondensation of the starting materials takes place with the evolution of ammonia according to the following mechanism:



The initial diamidines were obtained by the action of ammonia on perfluoroalkyldinitriles. Perfluoroglutaronitrile yields a cyclic product—perfluoroglutaroimidine:



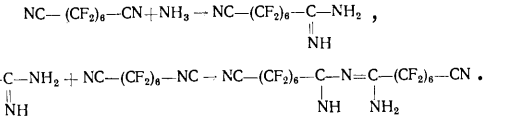
The polycondensation is usually carried out in the melt, solid infusible polymers being formed. Polymers with the following structures have been obtained from a mixture of mono- and di-functional reactants:



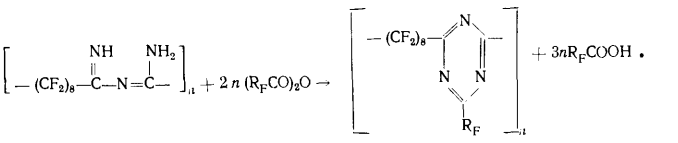
The physicomechanical properties of the cross-linked polymers of this structure depend greatly on the proportions of the initial reactants, i.e. both rubber-like materials with low strength and rigid non-elastic polymers may be obtained. The tensile strengths of these polymers vary as a rule in the range 7–35 kgf cm^{-2} with an elongation on rupture of about 100%.[108,115]

Cross-linked polyperfluoroalkylenetriazine polymers have a high thermal stability; they remain stable on heating to 420°C.[108,115] The polymers are also resistant to the action of hydrocarbon fuel and other liquid media employed in aviation up to a temperature of about 370°C; promising results have been obtained as regards their resistance to radiation[64].

It has been suggested that the development of methods for the synthesis of linear non-cross-linked triazine polymers will yield materials with improved physicomechanical properties. For this purpose, a study was made of the possible synthesis of polymers by the direct action of ammonia on the dinitrile, omitting the stages involving the synthesis and isolation of the diamidine[113]:



Together with the monocyanoamidine, a diamidine can also be formed as an intermediate. The low-molecular-weight products formed in the second stage of the reaction may be more numerous than shown in the above scheme. However, it is important that the polymerisation reaction in the presence of ammonia may be divided into two consecutive stages—the addition of ammonia to the nitrile with formation of the amidine and the addition of the latter to the nitrile in the growing chain of the imidoylamidine polymer. By adding a solution of the imidoylamidine polymer to the anhydride of a perfluoroalkanecarboxylic acid, a triazine polymer is obtained by the following mechanism:



Best results were achieved when the anhydrides of trifluoroacetic, perfluorobutyric, and perfluorocaprylic acids were employed[113]. The resulting high-molecular-weight perfluorotriazine polymers were rubber-like materials soluble in ethyl perfluorobutyrate, ethyl acetate, and di(trifluoromethyl)benzene. The glass temperatures of the polymers varied in the range between −17° and −5°C. Rapid degradation began at 420°C.

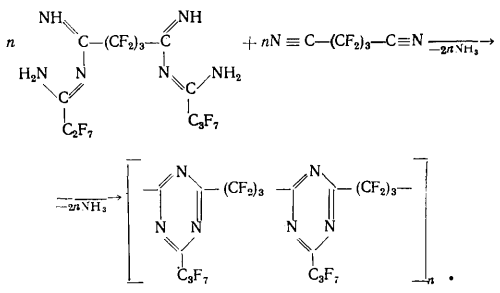
Graham[119] obtained from the triazine elastomers vulcanised materials with a high strength and thermal stability up to 315°C. The polyimidoylamidine necessary for the synthesis of the elastomers was obtained by the copolymerisation of the dinitrile and diamidine of perfluorosebacic acid.

When this polymer reacted with an excess of perfluorobutyric acid anhydride, with an excess of a mixture of perfluorobutyric acid anhydride and cyanoperfluorobutyryl chloride, or a mixture of the anhydride of perfluoroacetic acid and cyanoperfluorobutyryl chloride, triazine elastomers, containing perfluoroalkyl side groups, were synthesised. The vulcanised triazine polymers are resistant to the action of strong acids but are decomposed by strong bases. The mechanical strength of these vulcanised materials, determined at an elevated temperature or after thermal ageing, is close to that of fluorocarbon vulcanisate but, in contrast to the latter, these materials remain flexible at 300° and 370°C.

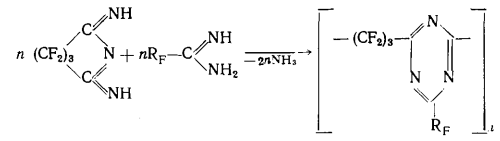
Polymers with high thermal stability and satisfactory dielectric properties were obtained by the joint polycondensation of the monomers

where $n = 2-4$ and $m = 2-3$, followed by vulcanisation with *p*-phenylenediamine, benzidine, triethylenetetramine, and other compounds[116].

In order to synthesise linear polyperfluoroalkylenetriazine polymers with a linear structure, a study was also made[64] of the reaction between di(perfluorobutylimidoyl)-perfluoroglutaroamidine and the dinitrile of glutaric acid:



Fedotova and Dolgopol'skii obtained polymers based on C_2–C_7 perfluoroalkylamidines and perfluoroglutaroimidines according to the mechanism



where R_F = CF_3, C_2F_5, C_3F_7, C_4F_9, or C_6F_{13}, in an attempt to elucidate the effect of the size of the perfluoroalkyl group of the monoamidine on the joint polycondensation and properties of the perfluoroalkylenetriazine polymers[120].

The principle of the method of synthesis of linear perfluoroalkylenetriazine polymers, proposed by Brown[107,108,121], is based on the joint polycondensation of mono- and di-functional perfluoroamidines. Monoamidines suppress to a considerable degree the structure-formation process but nevertheless they do not eliminate it owing to the considerable difference between the reactivities of mono- and di-functional monomers. Fedotova and Dolgopol'skii[120] showed that, starting with the C_4 amidine, the size of the perfluoroalkyl substituents has almost no influence on the properties of the polymers and the conditions of their synthesis. Moreover it was established that low-molecular-weight polymers with $[\eta]$ = 0.04–0.07 dl g^{-1}, obtained with the molar ratio monoamidine : diamidine = (1.6–1.8) : 1, are cross-linked by perfluoroglutaroimidine with formation of insoluble high-molecular-weight polymers thermostable up to 400–420°C.

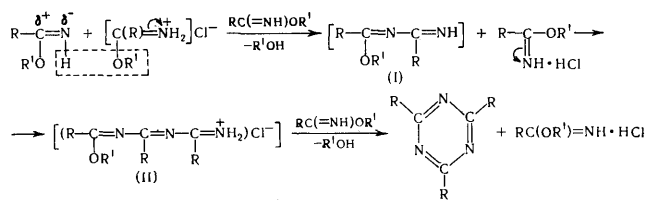
The polycondensation of pentafluorobenzamidine with perfluorophthalodiamidine has been described[114].

Kardash et al.[118] investigated the thermal degradation at 400–500°C of polyperfluorotriazine polymers, obtained by the copolycondensation of the diamidine of perfluorosebacic acid with perfluorobutyramidine and of perfluoroglutarodiamidine with perfluoroacetamidine. The thermal stabilities of these polymers were compared with that of polytetrafluoroethylene and it was shown that the introduction of *s*-triazine rings into the fluoromethylene chains enhances their thermal stability. However, this effect decreases to some extent in polyperfluorotriazines owing to the presence of amide groups, which increase the initial rate of degradation of the polymers. The formation of amide groups in such polymers is possible both in the synthesis of the polymers itself and during their storage, since perfluoroalkyl derivatives of *s*-triazine are hydrolysed on prolonged storage in air. The presence of amide groups in the polymers was confirmed by infrared spectroscopy (showing the C=O absorption band at 1735 cm^{-1} and the absorption bands at 3430, 3160, and 1680 cm^{-1}, which are characteristic of the NH_2 group in amides). The principal gaseous degradation product of polyperfluorotriazines is tetrafluoroethylene. In addition, hexafluoropropene, carbon dioxide, and silicon tetrafluoride, formed evidently when the CF_3 radicals react with the glass of the reaction vessel, have been identified. The liquid degradation products are low-molecular-weight analogues of polyperfluorotriazines. The water formed on decomposition of the amide groups hydrolyses the *s*-triazine rings and the radicals induce their polymerisation with formation of the azomethine structure $[-\underset{\displaystyle R}{\underset{|}{C}}=N-]_n$, as in the polymerisation of 2,4,6-tri(trifluoromethyl)-*s*-triazine under the influence of radicals[109]. On the other hand, in the absence of radical sources, 2,4,6-tri(trifluoromethyl)-*s*-triazine is stable up to 500°C.[109]

Polyperfluoroalkylenetriazine elastomers are regarded as promising raw materials for the preparation of fuel tanks, electrical insulation, and rubber components of hydraulic systems operating at temperatures in the range 300–400°C.[64]

The application of perfluorinated triazine rubbers in aviation and space engineering has been described[117]. It has been stated that elastomers based on *s*-triazine, with the triazine groups linked by perfluoroalkyl units, are processed by the usual methods using standard equipment[110].

Yakubovich and coworkers[123-128] obtained polytriazines with aliphatic, aromatic, and perfluorinated aliphatic bridges between the *s*-triazine rings by the polycyclotricondensation of the corresponding iminoethers. They employed the diethyl and dimethyl esters of bisiminoadipic, bisiminoterephthalic, bisiminoperfluoroglutaric, and bisiminoperfluoroadipic acids as the starting materials for the preparation of polytriazines. Non-fluorinated iminoethers are readily cyclised in the presence of catalytic amounts of their hydrochlorides, while the fluorinated analogues react also in the absence of catalysts. Yakubovich et al.[125] believe that the condensation of iminoether groups to the *s*-triazine rings proceeds via a series of consecutive stages leading to the formation of a linear "dimer" (I) and "trimer" (II). The resulting hydrochloride of the linear "trimer" (II) cyclises to the more stable *s*-triazine system according to the mechanism[129]

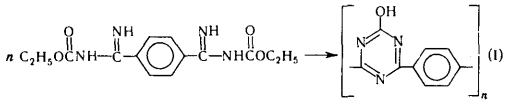


One may suppose that the electrophilicity of the carbon atom in iminoethers is insufficient to ensure the addition of a second iminoether molecule at the C=N double bond and the free bases of the iminoethers are not cyclised. When the reaction mixture contains the hydrochloride of the iminoether, in which the electrophilicity of the carbonyl carbon atom is higher than in the iminoether itself owing to the appearance of a positive charge at the nitrogen atom (the 'onium nitrogen) in $C{=}\overset{+}{N}H_2Cl$ and the associated considerable shift of the π-electron pair of the double bond, the reactivity of the system increases.

The replacement of hydrogen atoms by fluorine in the alkyl group of bisiminoethers increases the electrophilicity of the carbonyl carbon atom so much that condensation with the initial formation of the "dimer" and then of triazine derivatives occurs even in the absence of a catalyst[128].

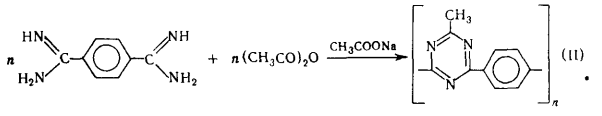
As mentioned above, for the formation of linear triazine polymers it is necessary that in the synthesis of the *s*-triazine ring one position in the latter should be occupied by a stable side group and the remaining two should participate in the formation of the polymer chain.

On this basis, Greth and Elias[61,63,130] obtained linear polytriazines by the thermal decomposition of the diethyl ester of terephthalamidine-*NN*-dicarboxylic acid:



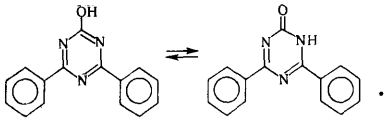
(I)

and by the interaction of terephthalamidine with acetic anhydride:



(II).

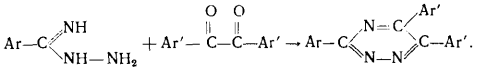
The structure of the resulting polymers was demonstrated chemically and by infrared spectroscopy (absorption bands characteristic of the *s*-triazine ring at 1540, 1450, and 1360–1390 cm^{-1}). An intense absorption band in the region of 1660 cm^{-1}, showing that these compounds may be present in the tautomeric keto-form, was observed in the spectra of poly-2-hydroxy-4,6-diphenyl-*s*-triazines:



Contrary to the authors' expectations, polytriazines obtained in this way had a much lower thermal stability than polymers synthesised by the same workers from methyltriazines and terephthalic dialdehyde[63], which were described above (see Section I, p. 70).

The temperature of the onset of decomposition in nitrogen of type (I) polymers is in the range 250–300°C. They lose 65% of their weight at 500°C and 85% at 850°C. The thermal decomposition of type (II) polymers takes place in two stages: in the first stage the decrease in weight is 12% between 200° and 325°C and in the second stage the polymer loses 50% of its weight on subsequent heating to 800°C.

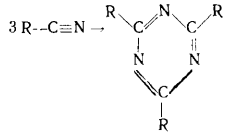
In recent years a large number of polymers with symmetrical triazine rings were synthesised and investigated; polymers containing asymmetric triazine rings were unknown until recently. A recent communication[131,132] reported the synthesis of model compounds containing asymmetric triazine rings from hydrazidines and α-diketones:



Hergenrother[133] employed this reaction to synthesise high-molecular-weight soluble poly-*as*-triazines. When 2,6-pyridinediyldihydrazidine was allowed to react with *pp'*-oxybis(phenyleneglyoxal hydrate) and *pp'*-oxydibenzil, poly[3,3'-(2'',6''-pyridinediyl)-5,5-(*pp'*-oxydiphenylene)di-(*as*-triazine)] (PT) and poly[3,3'-(2'',6''-pyridinediyl)-5,5'-(*pp'*-oxydiphenylene)di-(6-phenyl-*as*-triazine)] (PTP) were obtained. The polycondensation was carried out in *m*-cresol solution at 200°C. The resulting polymer solutions were employed without additional purification to prepare sheets, coatings, adhesives, etc. ($\eta_{log} = 0.5 = 1.25$ dl g^{-1}). The softening temperatures of the polymers were in the range 300–340°C, while according to thermogravimetric data PT and PTP exhibit the same resistance to thermal and thermo-oxidative degradation—the thermograms have a single inflection at 400°C in air and at 450°C in helium. The polymer specimens heated at 316°C for 200 h lost between 3 and 8% of their weight.

2. Polycyclotrimerisation of Monomers Containing C–N Groups

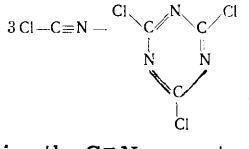
The capacity of nitriles for polymerisation with formation of triazines (the cyclotrimerisation reaction of nitriles) via the mechanism



was already known in the previous century[134,135].

Numerous subsequent studies established that the cyclotrimerisation reaction is more readily undergone by nitriles with electronegative substituents in the α-position relative to the nitrile group. Electronegative substituents in the α-position give rise to a comparatively low electron density at the carbon atom of the nitrile group and hence an enhanced electrophilic reactivity of such nitriles[136–138].

Thus chlorocyanogen is readily cyclotrimerised in the presence of various catalysts with formation of cyanuric chloride[137,139,140]:

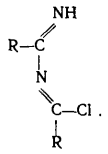


Compounds containing the C≡N group tend to form a stable cyclic trimer because trimerisation involves the loss of the enthalpy of the π bond and in addition the cyclic trimer is stabilised because of the combination of the most favourable valence angles (about 120°)[15,141] with the planar structure of the ring[15,141,142], which allows the formation of a $p\pi-p\pi$ aromatic system. The high stability of the ring in *s*-triazine is shown by the fact that many *s*-triazine derivatives do not polymerise at temperatures up to 500°C.[41]

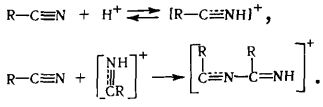
The cyclotrimerisation of nitriles may be accelerated by many catalysts. Thus the halides of coordination-unsaturated metals are active catalysts of this reaction. The presence in the C≡N: group of nitriles of a lone electron pair and also of electron-donating π bonds promotes the addition of Lewis acids to the electron pair of the nitrogen with the formation of highly electrophilic molecular compounds. Probably the addition to the nitrile of more than one equivalent of the electrophilic compound is due to the formation of the so called π-complexes[143].

Grundman et al.,[144] who investigated the mechanism of the synthesis of *s*-triazines from nitriles in the presence of hydrogen halides, showed that a compound of the nitrile

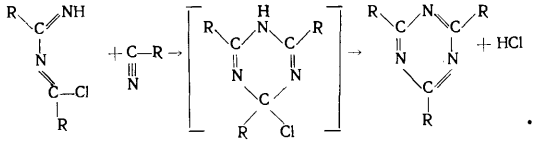
with the hydrogen halide of the type of a substituted imino-chloride,



is formed as an intermediate in this reaction. The formation of the substituted imino-chloride may be regarded as a nucleophilic reaction of the nitrile group, where the electrophilic agent is the same nitrile:

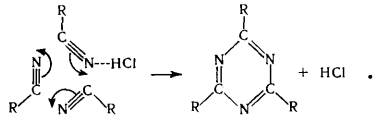


The reaction of the imino-chloride with a third nitrile molecule takes place similarly. Grundman[144] regards the interaction of imino-chlorides with nitriles as diene synthesis reactions:



However, the treatment of the adduct $2CCl_3CN.HCl$ with acetonitrile does not yield the expected *s*-triazine, although the joint cyclotrimerisation of trichloroacetonitrile with acetonitrile in the presence of hydrogen chloride leads to the formation of the corresponding di(trichloromethyl)methyl-*s*-triazine[144].

Zil'berman[138], who considered the cyclotrimerisation of nitriles, proposed a different mechanism for the formation of *s*-triazine. He believes that the reason for the comparative ease of formation of *s*-triazines may be cyclic electron transfer via the mechanism



Both the free nitrile and its complex with hydrogen halide are involved in the formation of triazines by this mechanism.

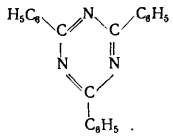
Hydrogen halides are most often employed as agents inducing the cyclotrimerisation of nitriles[136] but alkaline and acid agents, such as sulphuric and chlorosulphonic acids, Lewis acid, etc. can also serve as catalysts[136,145].

The cyclotrimerisation of benzonitrile in the presence of acid agents with formation of triphenyl-*s*-triazine (cyaphenine) has been known for a very long time[134,146-148].

Recently Kargin, Kabanov, and coworkers[149-154] carried out a number of studies on the polymerisation of nitriles via the C≡N bond in order to obtain conjugated azomethine structures. With benzonitrile as an example, they investigated the mechanism of the formation of both linear polyconjugated structures and of a cyclic trimer (triphenyltriazine).

Although the aim of these studies was not to obtain polytriazine structures, nevertheless they are of undoubted interest for the elucidation of the formation of polymers by polycyclotrimerisation and therefore some of them must be considered in this review.

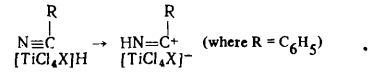
The mechanism and kinetics of the polymerisation of benzonitrile complexes in the presence of compounds such as titanium tetrachloride, zinc chloride and boron trifluoride have been investigated[150]. It has been found that, when benzonitrile complexes are heated, two types of products are formed. One of them is a polymer with an azomethine structure, $[-C(C_6H_5)=N-]_n$, and the other is a benzonitrile trimer (cyaphenine):



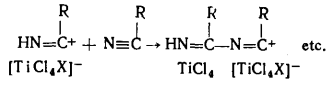
It was established that the rate of reaction and the ratio of the products formed are significantly influenced by small amounts of promoting agents such as proton-containing substances (inorganic acids, water, amides, organic acids) and organic compounds with mobile halogen atoms, for example benzoyl chloride, benzyl chloride, etc.

When the complex of benzonitrile with BF_3 is heated for 10 h at 250°, 275°, and 300°C, only the trimer with traces of a polymer is formed. The same result was obtained with the benzonitrile complex of zinc chloride. If, on the other hand, a proton initiator (HPO_3) is introduced into the reaction mixture, a polymer is formed in both cases[150].

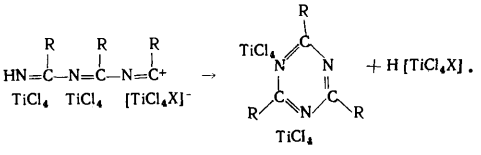
When the pure complex $(C_6H_5CN)_2.TiCl_4$ is heated in the presence of metaphosphoric acid below 300°C, the reaction proceeds at an appreciable rate, but the sole reaction product is triphenyl-*s*-triazine. At a higher temperature, a polymer is formed[153]. On the other hand, when an organic promoting agent (benzoyl chloride) is added to the system, a polymer is formed at an appreciable rate even at 270°C. The authors explain these results as follows. The centre for chain initiation is the complex $[TiCl_4X]H$ formed when the complex-forming agent reacts with the proton-containing additive:



Chain propagation takes place as follows:

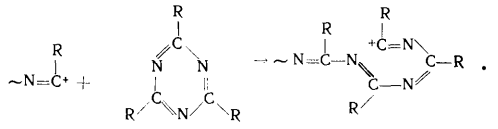


The formation and accumulation of the trimer in the initial stages of reaction can be explained by the fact that, after the addition of the third monomer molecule, there is a possibility of the formation, in addition to chain propagation, of a stable six-membered ring with regeneration of the initial initiating proton complex:



The consumption of the trimer can be accounted for by its polymerisation at an elevated temperature with the

opening of the triazine ring under the influence of the carbonium ion of the growing linear chain, which in fact leads to the formation of a polynitrile chain:

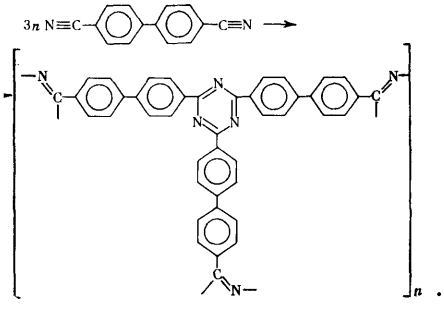


In order to test the hypothesis of the involvement of the trimer in the reaction, a study was made of the possibility of its polymerisation as a complex with $TiCl_4$, which would indeed result in a polymer with an azomethine structure.

The difference between the effects of proton-containing acids (HX) and aprotic organic acids (RX) on the linear polymerisation of benzonitrile consists in the fact that the aprotic acids are in this case more powerful promoting agents. This may be due to the higher rate of ring opening following the attack by the R^+ ion, which is a more powerful electrophilic agent than the proton[155], and to the decrease of the possibility of the cyclisation of the linear trimer when RX is employed.

Free-radical polymerisation of triazine rings is known to occur in the presence of a source of either free radicals or complex-forming agents[156]. The nature of the substituents in triazines then has a significant influence on the stability of the ring. Thus triazines with electronegative substituents (CCl_3, CF_3, and C_3F_7) form a polyene chain with conjugated double bonds $[-\underset{\displaystyle R}{\underset{|}{C}}=N-]_x$ in the presence of a source of free radicals at 250–300°C, while triazines with electropositive substituents (CH_3, C_2H_5) are polymerised only at 520°C.[156]

The cyclotrimerisation of nitriles with the aim of synthesising polytriazines was achieved for the first time by Anderson and Holovka[44], who obtained thermostable polymers with triazine rings from aromatic dinitriles under the influence of chlorosulphonic acid:

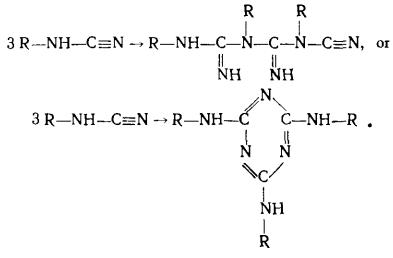


The polycyclotrimerisation of, for example, 4,4′-dicyanobiphenyl was continued until the characteristic absorption band of the C≡N bond disappeared from the infrared spectra of the polymer. In order to confirm the structure of the polymer obtained from 4,4′-dicyanobiphenyl, it was hydrolysed in the presence of concentrated hydrochloric acid and biphenyl-4,4′-dicarboxylic acid was identified. According to thermogravimetric data, the polymer synthesised exhibits a high thermal stability up to 350–400°C.

For comparison, Anderson and Holovka[44] synthesised a number of aromatic melamine polymers by the polycondensation of cyanuric chloride with aromatic diamines. All the polymers showed a high thermal stability (up to 400°C) and the polymer based on ring-fluorinated aromatic diamines was stable up to 500°C.

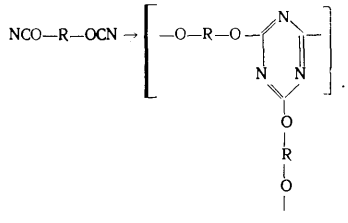
The polymerisation of 2,4,6-tricyano-*s*-triazines, which may result in the formation of both polyazomethine and polytriazine structures, has been reported[157]. These polymers, which have semiconducting properties and are used to manufacture thermistors, are obtained by heating a mixture of 2,4,6-tricyano-*s*-triazine in an excess of quinoline at the boiling point of the latter.

Sugino et al.[158–163] obtained polymers from alkylenedicyanamides with the general formula $N\equiv C-NH-(CH_2)_m-NH-C\equiv N$, where m = 4–10. Compared with nitriles having a similar structure, the C≡N groups of cyanamides are much more reactive, which may be due to the higher electrophilicity of the carbon atoms in this group. Alkylenedicyanamides are readily polymerised below 100°C and slowly at room temperature with formation of infusible and insoluble polymers. The authors believe that the polymers obtained may have the structure of polydicyanodiamides or polymelamine, which may be represented as follows for monocyanamide as an example:



Cyanamide polymers may be used to prepare ion-exchange resins, transparent plastics, coatings, and also adhesives for glass, metals, ceramics, and wood[159–163]. The strength of the joint produced by sticking together glass with these polymers is 400 kgf cm^{-2}.[162,163]

Grigat et al.[164,165] obtained cross-linked poly(aryl cyanurates) by the polycyclotrimerisation of various dicyanate esters of bisphenols via the mechanism

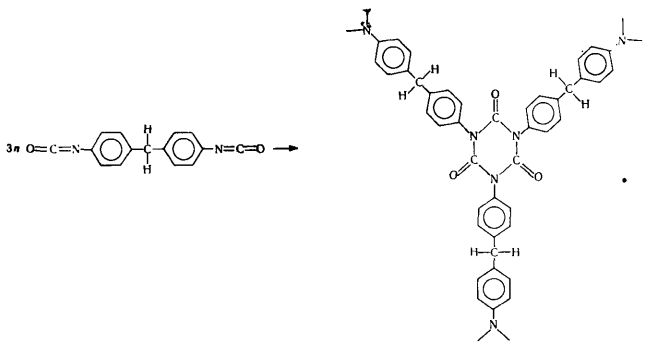


The starting materials employed were the dicyanate esters of resorcinol, quinol, 2,2-di-(4-hydroxyphenyl)propane, and 2-nitroresorcinol. The resulting cross-linked poly(aryl cyanurates) had fairly satisfactory physicomechanical properties [specific impact strength about 20 kgf m cm^{-2}, ultimate bending strength 1300–1800 kgf cm^{-2}, thermal stability (after Martens) up to 212–240°C].

The polycyclotrimerisation process was carried out in several stages. In the initial polymerisation stages fusible and soluble pre-polymers were obtained, and were converted into an infusible and insoluble state on heating to 200–250°C.

The presence of stable aromatic systems between oxygen atoms (–R–) in similar structures promotes the synthesis of polymers with even higher heat resistance and thermal stability[166].

Ball et al.[167] described the results of technical tests on a rigid isocyanurate foam plastic, which they obtained by the cyclotrimerisation of di(isocyanatophenyl)methane:



The cyclotrimerisation reaction was regulated by basic catalysts. The temperature of the onset of decomposition of the isocyanurate foam plastic is in the region of 300°C according to thermogravimetric analysis in air. The isocyanurate foam plastic exhibits a higher fire resistance than the usual urethane foam plastics, due to the formation on its surface under the influence of flames of a carbonaceous fibrillar network, reproducing the initial structure of the foam. The isocyanurate charcoal formed breaks down very slowly even at 1200°C.

The kinetics of the cyclotrimerisation of di-isocyanates were investigated by Petrov et al.[168] using infrared spectroscopy. They studied the "pre-polymer" obtained by the reaction of one mole of low-molecular-weight polybutadiene (M = 4000) containing terminal OH groups with two moles of 2,4-tolylene di-isocyanate. The catalyst components were glycidyl phenyl ether and benzyldimethylamine in different molar proportions.

The authors showed that the cyclotrimerisation of isocyanate groups is a quasi-unimolecular reaction up to a conversion of 70–90%. The rate of cyclotrimerisation is directly proportional to the product of the initial concentrations of the tertiary amine and the epoxy-derivative of the olefin.

It has been suggested that the cyclotrimerisation reaction is a special case of anionic polymerisation[168].

The results obtained were explained by Beitchman's stepwise mechanism[169], according to which the addition of the first, second, and third isocyanate molecules (M) to the catalytic complex (N) takes place in the same manner:

$$N + M \xrightarrow{k} NM,$$

$$NM + M \xrightarrow{k} NM_2,$$

$$NM_2 + M \xrightarrow{k} M_3 + N.$$

However, it was noted that, although according to Beitchman's mechanism the closure of the isocyanate rings with elimination of the catalyst is most likely in the trimer stage, other reactions are possible in principle, for example the partial formation of the dimer or of a linear polymer.

---o0o---

The s-triazine ring, which has aromatic properties, exhibits high thermal stability, approaching that of the benzene ring[41,170]. Therefore, when polytriazines contain fairly thermostable groups (phenyl groups, fluorinated aliphatic chains, etc.) binding and surrounding the s-triazine rings, the polymers show enhanced thermal stability.

The ready availability of the starting materials for the synthesis of the majority of polytriazines and also the versatility of the synthetic reactions (particularly the use of polycyclotrimerisation and polycyclocondensation reactions) have promoted a large-scale practical application of these polymers in the newest branches of engineering, where materials with enhanced thermal stability and heat resistance are required. Polytriazines are used as thermostable elastomers, as binders for reinforced plastic, adhesives, coatings resistant to ultraviolet irradiation, etc.

During the preparation of the manuscript for the press, a number of interesting studies on the synthesis and properties of polymers containing s-triazine rings were published.

Polycondensation of monomeric s-triazine derivatives yielded polyesters[171-179], polyamides[180-183], and other polymers of different classes[184-192]. The thermal degradation of certain polymers containing triazine rings in the chain was investigated[193-197].

New data were published on the synthesis and properties of triazine polymers synthesised by the polymerisation of unsaturated side groups[198-209] and polymers obtained by the migration copolymerisation[210-217] of s-triazine derivatives.

Interesting results are reported in studies published recently on the polycondensation of nitrile derivatives[218-228].

A number of studies have been made on the linear polymerisation of nitriles[229-232] and the polymerisation of s-triazine rings with formation of polymers having the azomethine structure.

New results have also been obtained in the study of the polycyclotrimerisation of nitriles of different structures[235-239], cyanate esters[240-242], and isocyanates[243-250].

Contemporary State of the Problem of the Polymerisation and Copolymerisation of Alkene Sulphides [Epithioalkanes]

L.A.Korotneva and G.P.Belonovskaya

Studies of the polymerisation and copolymerisation of alkene sulphides, including those published in 1971, are reviewed. The literature is classified according to the nature of the action of the catalytic systems—polymerisation under the influence of anionic and cationic excitants, modified organometallic compounds, and charge-transfer complexes. A separate chapter gives the results of studies on the copolymerisation of thio-oxides. 176 references.

CONTENTS

I. Introduction 83
II. Polymerisation of alkene sulphides 83
III. Copolymerisation of alkene sulphides 92

I. INTRODUCTION

The polymerisation and copolymerisation of cyclic sulphides (alkene sulphides, thio-oxides, episulphides, thiirans, thioethanes) has only recently attracted the attention of investigators, but every year the number of papers dealing with these problems increases. The problem is of interest both theoretically as regards the formation of polymers by the opening of heterocycles, and also from the standpoint of the practical use of a new class of polymers which contain monosulphide bonds in the main chain. Unlike their oxygen analogues—the cyclic oxides, the polymerisation of which has been studied in sufficient detail and many polymer compositions based on which have found wide practical application—information about the polymerisation and copolymerisation of cyclic sulphides, and also the physicochemical properties of the polymers formed has been unsystematic until recently and in several instances only qualitative.

Nevertheless, the available published information shows that the formation of a polymeric chain in opening cyclic thio-oxides is quite unique and the crystalline and rubbery polymers and copolymers which are formed exhibit a series of valuable working properties, above all increased radiation resistance, high adhesion and dielectric properties, specific in relation to various solvents, increased resistance to oxidants, etc.

A feature of the behaviour of cyclic sulphides, and in particular of thiirans, in nucleophilic and electrophilic reactions, which appears in ionic polymerisation, is connected with the specific structure of their molecules, examined in detail in several contemporary reviews[1-5]. In this connection we thought it undesirable in the present review to state the physicochemical properties of the cyclic sulphides and compare them with the properties of other small heterocyclic compounds.

II. POLYMERISATION OF ALKENE SULPHIDES

Over a long period of time the existence of thiirans was demonstrated only on a basis of a study of the structure and composition of the polymeric products formed in attempts to synthesise them by various methods[6,7]. The ease of opening of the ring of the α-thio-oxide to form polymeric compounds led Grishkevich-Trofimovskii[7] to conclude that they could not exist in the free state. Later Délépin, who was the first to succeed in synthesising and isolating the simplest α-thio-oxides in the pure state, showed their extreme ability to polymerise under the influence of various agents.

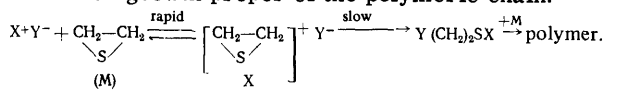
After the development of simple universal methods of synthesising the thiirans from oxides[12], and cyclic carbonates[13,14] interest in this class of compound increased greatly and in addition to the investigation of the physicochemical properties of the thio-oxides papers also appeared on the study of their polymerisation—mainly the simplest and most accessible thiirans—ethylene sulphide [thiiran or epithioethane (Ed. of Translation)] and propene-sulphide [1,2-epithiopropane (Ed. of Translation)]—which are relatively stable when pure at low temperature[4].

An attempt to polymerise thiirans under the influence of radical type initiators did not give positive results[15,16]; only for perfluorinated α-thio-oxides was the possibility of polymerisation under the influence of free radicals demonstrated, brought about by the breaking of a C–S bond[17]. The first papers dealing with the study of the ionic polymerisation of thiirans appeared in 1954, but systematic investigations in this field began to appear in the sixties. The Table gives information about the polymerisation of alkene sulphides in the presence of various catalytic systems. The most interesting investigations dealing with the polymerisation of the thio-oxides can be classified into four main groups according to the type of catalytic system used: polymerisation under the influence of anionic inducers, modified organometallic compounds, cationic inducers, and charge-transfer complexes. A separate section gives the principal results of work on the copolymerisation of alkene sulphides.

This classification is extremely provisional because in the variety of initiating systems often within the framework of qualitative observations it is difficult to draw a boundary between the individual groups of inducers according to the mechanism of their action. Thus, for the α-oxides[86] and α-thio-oxides[87-89] it is known that the $Zn(C_2H_5)_2-H_2O$ system can be cationic or coordination-anionic, depending upon the ratio of the components and in excitation polymerisation but in the induction polymerisation of propene sulphide with a charge-transfer complex the nature of the initiation and growth processes of the polymeric chain are different.

1. Polymerisation of Alkene Sulphides under the Influence of Inducers of the Anionic Type

The polymerisation of alkene sulphides in the presence of Lewis bases can be represented as a succession of reactions: (1) the addition of a molecule of the monomer to the inducer with the formation of an active centre, and (2) the successive addition of the monomer to the mercaptide formed—growth proper of the polymeric chain:

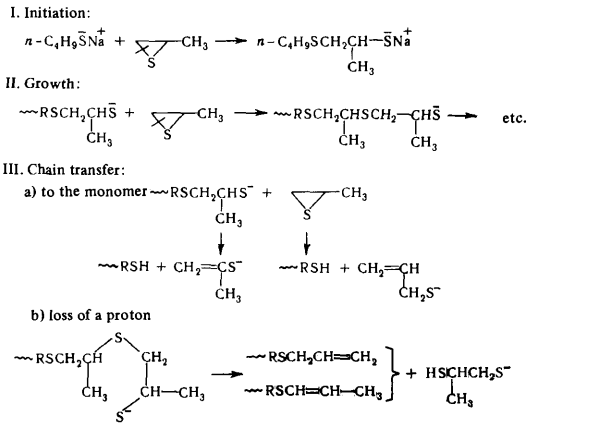


Reactions of this type are close to the break-free polymerisation of monomers of the vinyl series. The principle of the polymerisation of α-thio-oxides which corresponds to ideas about the "living" polymers, was described in a series of papers [16,22,23,38–42,57,70,74,90].

Marvell and Weil [34] obtained low-molecular-weight polypropene sulphide poly(epithiopropane) under pressure at 95–100°C in the presence of an alcoholic solution of sodium ethoxide and represented this process by the following scheme:

Culvenor and coworkers [91] also associate the polymerisation of ethylene sulphide under the action of NaOH or other alkali agents (NaX) with the formation of $NaSCH_2CH_2OH$ (X); they showed that the α-thio-oxides do not polymerise when the molecule of the attacking agent is constructed so that the product of its condensation with one molecule of the monomer is a stable cyclic compound (for example, trithiocarbonate in the reaction of ethylene sulphide with thiourea or thiocyanates).

In 1964 Ishii and coworkers [35], in studying the polymerisation of propene sulphide (PS) in the presence of various organometallic compounds showed that the alkoxides effective for the induction of the polymerisation of α-oxides (sodium, iron, and titanium ethoxides; aluminium 2-propoxide, Pr^i_2AlOH) are not effective in the polymerisation of episulphides and suggested that Marvel's results [34] are due to the presence of traces of moisture in the system and hydrolysis of the alkoxide. In the same work Ishii showed that sodium, cadmium, zinc, copper, nickel, cobalt, and iron mercaptides at 0–80°C are capable of bringing about the polymerisation of PS with the formation of viscous oils. The use of polar solvents increased the rate of the process. They used infrared spectroscopy to show the presence of C=C groups in the polymer, which allowed them to propose a scheme for the polymerisation of PS by an anionic mechanism which includes a chain transfer reaction:



The same investigators studied the polymerisation of PS under the influence of $Al(C_2H_5)_3$, $Zn(C_2H_5)_2$, and $Al(C_2H_5)Cl$ [35] at 0°C and showed that the presence of water in the system reduces the catalytic activity of the inducer.

Catalytic systems used for initiating the polymerisation of alkene sulphides.

Initiating system	Monomer	Reference
Ultraviolet, γ-radiation, peroxides diazo-compounds	CHS, perfluorinated and unsaturated episulphides	17–19
Organic and dilute mineral acids	ES, PS, BS, CHS, TE, TECH	9–11, 16, 20, 21
Lewis acids: BF_3, PF_5, SbF_5, $BF_3O(C_2H_5)_2$; $AlCl_3$; $TiCl_4$, AsF_5	PS, ES, TE, 7-TBCH, 6-TBCH, 3,3-DMTE, CHS	19–31
Onium salts: $R_3\overset{+}{O}-\bar{B}F_4$, $R_3\overset{+}{S}-\bar{B}F_4$	PS, TE, DMTE, 7-TBCH, 6-TBCH	23, 25, 26.
Metals, their oxides, and hydroxides (M = Na, K, Mg, Al, Ca, Fe, Co, Ni, Sr, Pb etc.)	ES, PS, BS	16, 22, 32, 33
Alkoxides (M = Na, K, Al, Fe, Zn)	PS, SS, ES	22, 34–37
Mercaptides (M = Na, K, Fe, Co, Cu, etc.)	ES, PS, SS	32, 35, 36, 38–48
MR, MRX	PS, ES, OS, TE, IBS	19, 22, 23, 32, 35, 36, 42, 43, 49–57
MR_2 + modifier (M = Zn, Cd, Mg)	ES, PS, BS, CHS, SS, TE	19, 42, 58–68
AlR_3 + mercaptides (Zn, Cu, Co, Ni, Fe); chelates	PS PS	35 69
Mineral salts of Cd, Zn, Mg, Hg	PS, ES, BS, SS, CHS	9–11, 70–76
Amines, polyamines, pyridine, carbazole, guanidine, hydroxylamine, *o*-aminophenol	CHS, PS, ES	77, 78
$NaNH_2$ and other amides	ES, PS	22, 79, 80
Xanthates, dithiocarbonates, thiocarboxylates of metals	ES, PS, BS	67, 81
$LiAlH_4$	1-OS	82
Charge transfer complexes	PS	83–85

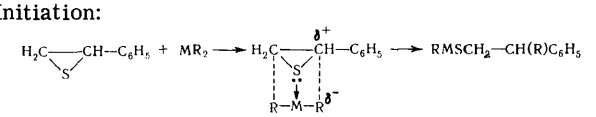
Symbols: ES ethylene sulphide [thiiran or epithioethane], PS propene sulphide [1,2-epithiopropane], BS butene sulphide [1,2-epithiobutane], CHS cyclohexene sulphide [1,2-epithiocyclohexane], SS styrene sulphide [$\alpha\beta$-epithioethylbenzene], TECH thioepichlorhydrin [3-chloro-1,2-epithiopropane], 1-OS 1-octene sulphide [1,2-epithiooctane], IBS isobutene sulphide [1,2-epithio-2-methylpropane], TE thiethane, TBCH thiobicycloheptane, DMTE dimethylthiethane.

From these results it was concluded that the hydrolysis products of organoaluminium compounds are ineffective for the induction of the polymerisation of thio-oxides. In 1968 the same investigators re-examined their previous results and published an article in which they examined in

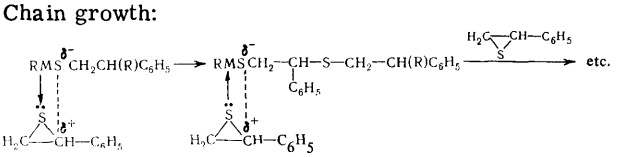
detail the $Al(C_2H_5)_3-H_2O$ system as an initiator of the polymerisation of PS. The results of this work will be considered in the appropriate section.

Nashay and Price[36] studied a large number of catalysts in the polymerisation of styrene sulphide [$\alpha\beta$-epithioethylbenzene], but only the use of triethylaluminium and chlorcadmiumbutylmercaptide at and below room temperature allowed poly(styrene sulphide) with rather high molecular weight to be obtained. It is assumed that chain initiation and growth is neither radical nor ionic in nature and a coordination mechanism is suggested:

Initiation:



Chain growth:



In considering the anionic polymerisation of the PS mention must be made of Kabayashi[70], who first observed that salts of elements of Group IIB, and especially cadmium compounds, give an excellent catalytic effect. CdS, CdO, $Cd(OH)_2$, $CdCO_3$, and $CdSiO_3$ were most active. Whereas zinc catalysts lead to the formation of amorphous, mainly atactic poly(propene sulphide), cadmium sulphides form crystalline polymers which are evidently isotactic ($T_f = 40-45°C$, $Tg = -52.5°C$) with a high value of the characteristic viscosity (up to 10). When cadmium silicates are used, addition of water is needed to increase its activity, which leads to an increase in the molecular weight of the polymer and the rate of the process. Addition of NaOH (up to pH 8) leads to a similar effect. Spectroscopic investigations confirmed the presence in the polymer of the metal used as catalyst. The investigators did not examine the mechanism of the catalytic action of water and sodium hydroxide, but suggested that the polymerisation was stepwise anionic for all types of cadmium salts.

In the presence of the $CdCl_2 + NH_4Cl + K_2S$ [71] or of cadmium or zinc carbonates[72] PS is also polymerised and copolymerised with the formation of high-molecular-weight and oligomeric polymers[73,92].

The studies of Cooper, Morgan, and Wragg[38-41,74] show the special effectiveness of cadmium compounds in the polymerisation of episulphides. The investigators studied the polymerisation of alkene sulphides in the presence of mercaptides, which model the active centres of the process, which is completely reproducible. However, the study of the mechanism and kinetics of the process is hindered by the restricted solubility of mercaptides[36] or by the presence in homogeneous systems of traces of mercaptides which are extremely active chain transfer agents[35].

Wragg and coworkers[38-40] obtained poly(propene sulphide) and poly(ethylene sulphide) of practically any molecular weight by using soluble heavy metal (Zn, Cd, Cu, Ni, Co, Pb, etc.) mercaptides as catalysts. Having studied the initiating capability, of mercaptides of various structures, they showed that the most effective inducers of polymerisation are cadmium and zinc thiolates; the mercaptides $M(SCH_2CH{=}CH_2)_2$ obtained from unsaturated thiols have good solubility, and the dialkayldiaminoalkylthiolates

$$M[SCH(CH_3)CH_2S-CHCH_2N(n\text{-}C_4H_9)_2]_2$$

dissolve almost instantaneously. They associate the increased solubility of the heavy metal mercaptides with their tetragonal structure, due to the presence in the initial thiol in the β-position of a substituent capable of coordination with a metal. All these compounds are stable in air and the presence of moisture does not affect their activity. Wragg and coworkers arranged the most active cadmium mercaptides in the following series:

$$Cd(SCH_2CH{=}CH_2)_2 \simeq Cd(SCH(CH_3)CH_2NR_2)_2 \simeq$$
$$\simeq Cd(SCH_2CH_2SBu)_2 > Cd(SCH_2CH_2OBu)_2.$$

By carrying out a detailed kinetic investigation, Wragg and coworkers[38-40] showed that polymerisation under the influence of heavy mercaptides proceeds by a "living" chain mechanism with an induction period, the length of which depends on the nature and solubility of the inducer. On the stationary part

$$v_p = k_p\,[\text{alkene sulphide}][\text{catalyst}].$$

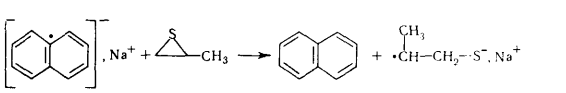
The first order of the reaction with respect to the monomer and the similarity in the growth rate constants in using cadmium mercaptides of various structures show that the coordination of the monomer with a metal does not play a decisive part. However, the latter is supported by the stereospecificity of the inducers used, leading to the formation of a crystalline poly(propene sulphide), and the suppression of polymerisation or a decrease in the rate of the process in the introduction of strong electron-donating additions (amines). As regards the use of aminothiols as polymerisation inducers they did not exclude the possibility of inter-chain interactions, leading to the cross-linking of polymers. The part played by thiols as chain carriers in the polymerisation of thio-oxides was proved convincingly in these studies.

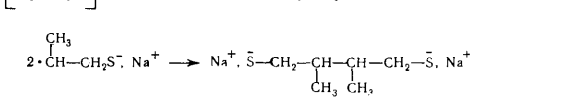
Over a long period there was systematic investigation of the anionic polymerisation of propene sulphide by French scientists led by Sigwalt[22,42,49-55,79].

In the first papers[22,79], which were qualitative, they showed that poly(propene sulphide) of high molecular weight can be obtained by using an anionic type of catalyst—sodium naphthalene in tetrahydrofuran (THF), sodium amide, sodium films. Subsequently, by studying the polymerisation of PS under the influence of the sodium–naphthalene complex in dilute THF solutions[49] they found that the process takes place by a "living" chain mechanism, not complicated by chain breaking or transfer reactions and the mean degree of polymerisation of the polymer formed at any stage of the transformation strictly calculated by the formula:

$$\overline{DP}_n = \frac{\Delta M}{{}^1/_2\,[\text{cat.}]} \quad \left(\text{in which } \frac{\bar{M}_w}{\bar{M}_n} \to 1\right)$$

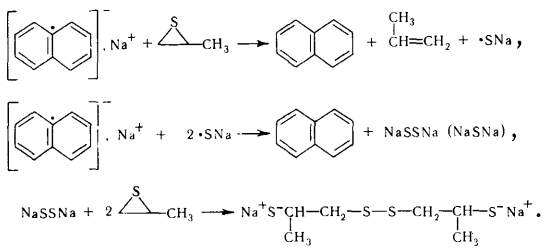
It was suggested[54,55] that the initiation of the polymerisation of PS in the presence of the sodium naphthalene complex takes place by a mechanism according to which, by analogy with vinyl compounds[93], there is transfer of an electron to the monomer with subsequent dimerisation of the anion-radical by the scheme:





Confirmation of this bifunctional mechanism was provided by the almost complete regeneration of the naphthalene (up to 98%). Although the instantaneous disappearance of the naphthalene anion-radical was observed at −78°C, chain growth was noted only above 0°C, which was attributed to the low reactivity of the primary active centre—sodium dimercaptide.

Subsequent kinetic, conductimetric, and spectrophotometric studies of the polymerisation of PS under the influence of the sodium naphthalene complex showed that the initiation is more complex and polymerisation can be effected below 0°C. In later studies[50-52,54] it was observed that the polymerisation of PS in this system is accompanied by the release of propene and the existence of an induction period which is most pronounced at low temperature (−30°C), and which can be avoided by the use of "seed" "living" polymers obtained in the presence of any anionic inducer (sodium naphthalene, sodium mercaptide, sodium carbazyl, or potassium carbazyl)[54]. The characteristic conductometric curves also confirm the slow initiation. On the basis of these results the act of primary interaction of the monomer with sodium naphthalene and the subsequent stages are formulated as follows:



The intermediate active compounds were not identified.

In the range of catalyst concentrations up to 1×10^{-3} M an expression was obtained for the overall rate of the process,

$$v_p = k_p[M][\text{cat.}]^{1/2},$$

where k_p is the overall growth rate constant, and [M] and [cat.] are the monomer and catalyst concentrations respectively. The variation of the rate of the process with the catalyst concentration is linked with the possibility of parallel growth of the polymeric chain into ion-pairs and free ions, present in equilibrium. By use of the Szwarc method[94,95] the individual rate constants of the reactions at free ions and ion-pairs with sodium counter-ions in THF and tetrahydropyran (THP) solution were calculated[54].

The change in the electrical conductivity of the system during the polymerisation of PS in THF [51] and THP [54] solution gave the dissociation constant K_d for the ion-pair S^-, M^+ with counter-ions Na^+, K^+, Li^+, and NR_4^+.[96] The sequence of activities of the counter-ions was found to be opposite to that observed for a carbanion[95], owing to the reduced contribution of the solvating effects. In studying the polymerisation of PS in THF it was found that with an initiator concentration above 1×10^{-3} M the rate of the process is not described by the above equation. This phenomenon is connected with the existence in the system of a series of equilibria involving ion-pairs and free ions:

$$(S_2Na)^- + Na^+ \overset{k_3}{\rightleftharpoons} (S,Na)_2 \overset{k_2}{\rightleftharpoons} 2\,S,Na \overset{k_1}{\rightleftharpoons} 2S^- + 2Na^+$$

where (S,Na) is a thiolate active centre in the form of an ion-pair, $(S_2Na)^-$ an associate of the ion-pair with a free ion, and $(S,Na)_2$ an associate including two ion-pairs.

The existence of associates under these conditions agrees with the departure of the electrical conductivity of the system from linearity in the same concentration region and this was proved by viscosimetric measurements by Morton's method[97] involving comparison of the time of flow of solutions of the reaction mixtures before and after disturbance of the active centres $\sim S^-, M^+$ by the terminating agent (ethyl bromide).

It has been shown[52] that in working with a monofunctional excitant (sodium triphenylmethyl) the regularity of the process is analogous to that in working with sodium naphthalene. It was assumed that bifunctional compounds of the SNa_2 or S_2Na_2 type or their mixtures are also polymer chain initiation agents. The use of sodium and potassium carbazyls as initiators of PS polymerisation[98] allowed a truly monofunctional polymer to be obtained, the formation of which obeys all the kinetic rules established for bifunctional poly(propene sulphide).

Another type of anionic inducer of polymerisation, butyllithium, has been investigated[23,32,43,99]. Under block polymerisation conditions in solution in non-polar solvents the polymerisation of PS under the influence of butyllithium proceeds at a low rate. The introduction of 10 to 70 mole % THF causes a marked increase in the rate of the process. In the temperature range from −25° to +20°C over a wide range of monomer and initiator concentrations the homogeneous process of polymerisation proceeds without an induction period up to complete disappearance of the monomer and is described as a quasi-stationary process with a constantly acting number of active centres and a total activation energy of 11.8 kcal mole^{-1}. The nature of the dependence of the molecular weight on the polymerisation conditions (temperature, concentrations of the initial reactants, degree of conversion) shows that the process takes place with participation of "live" polymeric chains with complete use of the initiator introduced and allows the formula for calculating the degree of polymerisation found for the uninterrupted processes to be used.

However, the investigation of the variation of the molecular-weight distribution (MWD) of poly(propene sulphide) with the extent of conversion and temperature of the reaction, made at various monomer and initiator concentrations and in the absence of a solvent showed the complexity of the process. In every instance the MWD curves were unimodal with an inflexion in the high molecular weight range (Fig. 1) and polydispersity coefficients of $\bar{M}_w/\bar{M}_n \to 1.5$ and $\bar{M}_z/\bar{M}_w \to 1.33$. In the absence of reaction the limit of the polymeric chain growth of the type of distribution of poly(propene sulphide) according to molecular weight was thought to be linked with the presence in the system of "pseudo-rupture" phenomena consisting of the occurrence throughout the entire process of a spontaneous deactivation of the $\sim S^-, Li^+$ active centres, due to the ability of the organolithium compounds to be associated and subsequently reactivated when they react with the monomer. Hence at every moment in the acts of polymeric chain growth only some of the active centres that are formed, and not all the initiator, participate. On the other hand, the fact that irrespective of the conditions under which the polymerisation is carried out the distribution of the macromolecules by size obeys the relation

$$q_w(M) = \frac{(\alpha M^2)e^{-\alpha M}}{\bar{M}_n},$$

where M is the molecular weight of a polymer fraction, $\bar{M}_n$ the number mean molecular weight, and α is either

proportional to M or is a constant ($2/\bar{M}_n$), and the polydispersity coefficients $\bar{M}_w/\bar{M}_n$ and $\bar{M}_z/\bar{M}_n$ are 1.5 and 1.33 respectively, is thought to show that under the chosen conditions each polymer chain is constructed from two statistically independent polymeric chains growing on a bifunctional active centre, which agrees with the observed values of the number mean molecular weights. Chromatographic analysis of the gaseous products formed showed the identity of the mechanism of interaction of butyl-lithium and sodium naphthalene with PS in THF medium and in the absence of the latter through the sulphur-elimination stage.

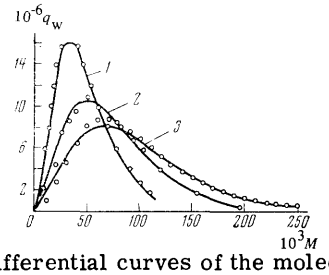


Figure 1. Differential curves of the molecular weight distribution of polypropene sulphide obtained at $[C_4H_9Li] = 4.8 \times 10^{-3}$ M; [PS] = 2.46 M, $t° = -25°C$, in a tetrahydrofuran medium. The experimental points are plotted along curves calculated by the formula

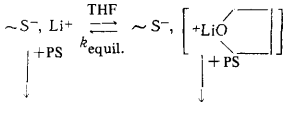
$$q_w(M) = \frac{(\alpha \cdot M)^2 \cdot e^{-\alpha M}}{\bar{M}_n}:$$

Conversion, %: *1*) 46.0; *2*) 71.5; *3*) 100.

The main kinetic parameters of the polymerisation of PS were studied at 0°C. In the range of butyl-lithium concentrations from 1×10^{-3} to 1.8×10^{-2} M the order of reaction with respect to the excitant was varied from 1 to 0. The dependence of the rate of polymerisation of PS on its concentration in THF is shown in Fig. 2. The total rate of the process is

$$v_p = k_p[M]^2[\mathrm{THF}]^2[\mathrm{cat.}].$$

It was assumed that the nature of the relation between the polymerisation rate and the concentrations of the initial reagents is determined by the fact that butyl-lithium is present in a medium of two strongly electron-donating agents, of which PS is the more polar ($\epsilon_{PS} = 10.2$, $\epsilon_{THF} = 7.6$), but THF is the stronger complexing agent[100,101], due to the presence in the polymerising system of the equilibrium:



A study of the electrical conductivity of the PS–butyl-lithium + THF system[99] enabled us to draw conclusions about the decisive part played by ion-pairs in polymer chain growth and to find that THF participates in the specific solvation of the low-reactivity contact ion-pair $\sim S^-, Li^+$, converting it into a "loose" (separated by the solvent) ion pair $\sim S^-, [Li^+, THF]$ the reactivity of which is 50–80 times greater than the reactivity of the contact pair.

A study of the copolymerisation of PS with α-, β-, and γ-thio-oxides: ethylene sulphide, thiethane, and thiophan, which are distinguished by the basicity of the heteroatom and the strain of the ring enabled us to answer the problem which is crucial in the growth stage: coordination of the sulphide with the counter-ion or the introduction of complex-bound monomer at the S–Li bond (ring opening, thermal effect). The results of infrared spectroscopy and elemental analysis show that the copolymers are enriched with the component with the more highly strained ring, which is also the determining factor in ring opening under the action of a nucleophilic reagent. However, the retardation of polymerisation on the addition of small amounts of the compounds of greater basicity (thiophan, thiethane) suggests that a significant part is also played by the coordination of sulphide with the counter-ion, which modifies the active centre and shows the kinetics of the process but does not alter the direction of the chain formation. On the basis of the results obtained a coordination-anionic mechanism of polymerisation of the PS under the influence of butyl-lithium is proposed, including stages of initiation, growth, "pseudo-breaking", reactivation, and the corresponding kinetic calculations are given[99].

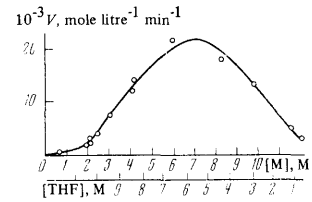


Figure 2. Variation of the rate of polymerisation of propene sulphide with the concentrations of the monomer and tetrahydrofuran at 0°C and $[C_4H_9Li]_0 = 3 \times 10^{-3}$ M.

Some regularities in the polymerisation of PS initiated by $Al(C_4H_9^i)_2Cl$ in benzene and diethyl ether solution have been studied by gas–liquid chromatography[44]. It was shown that polymerisation can be effected at temperatures from −20° to +20°C with an overall activation energy of 11.4 kcal mole^{-1}. Thermogravimetric analysis of the poly(propene sulphide) *in vacuo* and in air showed that the decomposition of the polymer takes place almost entirely in the range 225–320°C, to give propene, ethane, and isopropylthiol and is accompanied by appreciable endothermic effects. No suggestions were made as to the mechanism of the initiation, growth, or breaking of the polymeric chain.

Hence in the opinion of most authors, in the anionic polymerisation of alkene sulphides irrespective of the initial initiator the growth of the polymeric chains is effected by the thiolate anion S^-, M^+. When growth precedes the coordination of the active centre with the monomer, the polymerisation is effected by a coordination-anionic mechanism.

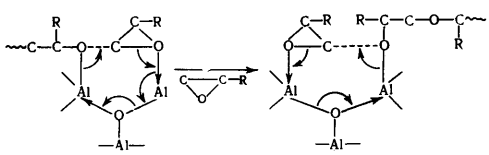
2. Polymerisation of Alkene Sulphides under the Influence of Modified Organometallic Compounds

Catalytic systems based on organozinc and organoaluminium compounds in the presence of cocatalysts are

widely used for the preparation of high-molecular-weight polyoxyethylenes with a high degree of tacticity[58-62,102-113].

Despite the prolonged and serious study of the polymerisation and copolymerisation of alkene oxides under the influence of modified organometallic compounds, the mechanism of their action is far from being explained completely. Whereas in the first studies of Furukawa and Saegusa[102] catalytic activity was attributed to the O–M–O bond, at which coordination of the monomer took place, Colclough and Wilkinson[103] and Vandenberg[104] thought that the growth of the polymeric chain takes place by a cationic mechanism with participation of stable onium ions formed during the interaction of the monomer with the hydrated form of the organoaluminium compound. Many investigators drew conclusions about the "onium" nature of the polymerisation of oxygen-containing heterocycles at AlR_3 + H_2O and $Zn(C_2H_5)_2$ + H_2O systems on the basis of a study of the constants of the copolymerisation of the various oxides and their comparison with results on copolymerisation under the influence of catalysts of typically cationic nature [$BF_3.(C_2H_5)_2O$, $SnCl_4$].[105-108]

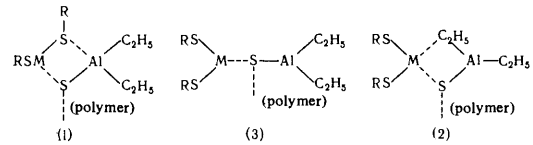
Recently a series of papers by Vandenberg[114,115] and Price[116,117] has reported that the polymerisation of oxides, which leads to the production of regularly constructed crystalline polymers, is due to the coordination of the monomer at an active centre having more than one metal atom:



This was proved convincingly by Osgan and coworkers[118,119] in investigating bimetallic μ-oxoalkoxides as catalysts of the polymerisation of epoxides by an injection mechanism. The part played by electronic and structural factors and also by other cooperative effects in the mechanism of coordinated polymerisation under the influence of the catalysts employed was examined and the possibility of bridging oxygen participating in the monomer addition stage was demonstrated. Some new aspects of the catalysis of the polymerisation of heterocycles by organometallic compounds were examined in a paper published recently by Furukawa[120].

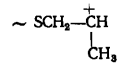
As recent studies have shown, in the presence of various modifying additions the $Al(C_2H_5)_3$ and $Zn(C_2H_5)_2$ systems are active for the induction of directed polymerisation of α-thio-oxides, but we have found only a few publications and these contain extremely limited material[35,63,67,68,70,121-125]. Nevertheless, the results of these studies allow our ideas about the nature of the active centres and the mechanism of polymerisation of the heterocyclic compounds in using organozinc and organoaluminium compounds to be extended.

Coordination leading to a regular structure of the chain and the production of a crystalline polymer were observed by Ishii and coworkers[35] in the polymerisation of PS under the influence of AlR_3, modified with water and various metal mercaptides. They showed that whereas Na, Co, Zn, Ni, and Cu mercaptides form low-molecular-weight amorphous polymers but triethylaluminium both in the absence of additions and in the presence of water is of little effect on the induction of polymerisation, a combination of trialkylaluminium with mercaptides leads to the formation of a high-molecular-weight crystalline polymer. The greatest activity is observed in using iron and cobalt mercaptides. It was found, by the example of $Al(C_2H_5)_3$ + $Co(SBu^n)_n$ and $Al(C_2H_5)_3$ + $Fe(SBu^n)_3$, that on varying the Al/M ratio from 0.5 to 2 the degree of conversion is increased, but the maximal value of the molecular weight ($[\eta] = 2.0$) is reached at the ratio Al/Co = 1.0. This was attributed to the phenomenon of chain transfer from the excess of $Al(C_2H_5)_3$ but the mechanism of this process was not examined. It was assumed that in the initial stage of the polymerisation takes place under the action of $Al(C_2H_5)_3$ but subsequently the polymeric ions coordinate with the metal mercaptide, acquiring form (1), (2), or (3), and polymerisation takes place at the $S^- - M^+$ bond, which ensures stereoregular growth of the chain. Growth of the polymeric chain at complexes of structure (1) and (2) is preferred by the investigators.



The non-stereospecificity of the $Al(C_2H_5)_3$ + $Ni(SR)_2$ system is attributed to the monomeric structure of nickel mercaptides in which the sulphur atoms are arranged non-regularly[126]. Some conclusions drawn in this study concerning the reactivity of the O–M bond were disproved by the French investigators Machon and Sigwalt[121,122] and also subsequently by Ishii[124]. In a later paper, Ishii and coworkers[124] showed that under strict control of the water content the $Al(C_2H_5)_3$ + H_2O system is active for the polymerisation and copolymerisation of alkene sulphides in toluene at 0–50°C. The influence of the ratio of the components in the initial mixture, the polarity of the medium, and the concentrations of the monomer and catalyst on the rate of the process and the molecular weight of the polymer were investigated. It was found that in comparison with pure $Al(C_2H_5)_3$ the $Al(C_2H_5)_3$ + H_2O system is more active for polymerisation over a wide range of component ratios, and maximal activity is observed at the ratio $Al/H_2O = 1$.

On the basis of various kinetic regularities the polymerisation of PS in the presence of the $Al(C_2H_5)_3$ + H_2O system and its copolymerisation with other α-thio-oxides, conclusions were drawn about the cationic nature of the polymeric chain growth at active centres of the



type and about the presence of intensively developing chain transfer reactions at the monomer or sulphur atoms of the polymeric chain but we do not think that the proposed scheme for these reactions is sufficiently clear.

From the standpoint of the stereospecificity of the catalyst used, the diethylzinc–water system proposed in 1958 by Furukawa and coworkers[111,127] for the polymerisation of cyclic oxides is interesting. This system attracted the attention of many investigators and is now being studied intensively. Many papers have been published about the use of various modifiers with the aim of increasing the effectiveness of this system[58-63,67,115,128].

It is stated in several patents[60-63,67] that $Zn(C_2H_5)_2$ and other organometallic compounds of Group II, modified with compounds which contain atoms with an unshared electron pair or proton-donating additions, are effective in the polymerisation of α-oxides and episulphides and their copolymerisation.

Recently Shozo and Teiji[86] thoroughly investigated the $Zn(C_2H_5)_2 + H_2O$ system for the polymerisation of α-oxides and found that the mechanism of its action (cationic or anionic) is connected with the change in the molar ratio of the components, which is reflected in the structure of the hydrolysis products formed, leading to polymerisation. According to recent results[110], obtained by infrared spectroscopy, gas–liquid chromatography, and X-ray diffraction, $C_2H_5(ZnO)_n.Zn(C_2H_5)$ (I), $C_2H_5(ZnO)_nH$ (II), and $HO(ZnO)_nH$ (III), which have a disordered würtzite structure containing a Zn–O–Zn bond, are excitants of the polymerisation of propene oxide, depending on the degree of hydrolysis. Their relative acidity increases in the order: (III) < $Zn(C_2H_5)_2$ < (I) < $Al(C_2H_5)_3$.

The possibility of the use of this catalytic system for the polymerisation of episulphides was first shown in 1963 by Kabayashi and Ishii[70]. The French investigators Machon and Sigwalt[121,122] made a more detailed investigation of the effect of the addition of water on the extent of the conversion and the properties of the polymer obtained in the polymerisation of PS in benzene solution—the catalytic $Zn(C_2H_5)_2/H_2O$ system. It was shown that the system is effective for the excitation of polymerisation over a wide range of ratios $\rho = H_2O/Zn(C_2H_5)_2$ but the crystallinity of poly(propene sulphide), which was estimated from the solubility of the polymer in ethyl methyl ketone, reaches a maximum at $\rho = 1$. On the basis of extremely few experimental results it is difficult to draw any conclusions about the actual mechanism of the system being studied, but a preference was expressed for the anionic nature of the initiation and growth of the polymeric chain independently of the value of ρ.

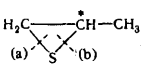
The poly(propene sulphide) obtained is an elastomer with increased rigidity and breaking resistance, its crystallinity is connected with the ratio of the components in the initiating system.

Interesting information about the nature of the active centres in the polymerisation of α-oxides and α-thio-oxides was obtained by Lal[123]. The new systems $Zn(C_2H_5)_2$ + sulphur and $Zn(C_2H_5)_2 + H_2O_2$ were investigated and their action was compared with that of the $Zn(C_2H_5)_2 + H_2O$ system. It was found that sulphur emerges as a cocatalyst and the $Zn(C_2H_5)_2$ + S system effects the heterogeneous polymerisation of α-oxides and α-thio-oxides over a wide range of ratios of the components. During the course of the investigation an effect by the polarity of the medium was not observed and it was shown that all the three systems have similar stereospecificity but the sulphides were polymerised more rapidly than the oxides and had a lower molecular weight. The results obtained led Lal to assume that the effectiveness of the $Zn(C_2H_5)_2$ + S system is associated with the presence of polysulphide bonds. This assumption was confirmed in studying the polymerisation of propene oxide in the presence of model mercaptides of the type: RSZnR, RSZnSR, RS_XZnS_YR, RS_XZnR, and RS_XZnSR (where $x + y = 2-8$). It was shown that the compounds which contain monosulphide bonds of the RSZnR type and the mercaptides obtained *in situ* in the $Zn(C_2H_5)_2$ + S system are ineffective for exciting the polymerisation of α-oxides and thio-oxides. Prolonged ageing of the catalyst $Zn(C_2H_5)_2$ + S (0.5–19 h) facilitates the formation of active polysulphide bonds RS_XZnS_YR, in which the R–S structure also plays a significant part. It is thought that polymerisation proceeds by a coordination mechanism but this problem was not discussed.

To understand and identify the mechanism of polymerisation of α-thio-oxides under the action of various excitants there was great interest in studying the synthesis of optically active polymers from monomers containing asymmetric carbon atoms. It is known that an optically active polymer can be prepared when the polymerisation of the optically active form of the monomer (enantiomer) is carried out, or by using the racemate of an optically active excitant to initiate the polymerisation. Spassky and coworkers[68,75,87,88] used both these possibilities to obtain optically active poly(propene sulphide).

As Machon and Sigwalt showed[121,122], the stereospecific polymerisation of racemic PS allows a high-molecular-weight polymer with up to 50% crystalline phase to be obtained. Spassky[88] thought that the crystallinity of this polymer could be due either to the simultaneous presence of two types of polymer, obtained on the basis of each of the enantiomers, or to the existence of a single polymeric chain consisting of successions of each enantiomer of various lengths. Therefore the preparation of polymers of each antipode should give valuable information about the mechanism of the stereospecific polymerisation of episulphides.

On the other hand, a comparison of the optical activity of the polymers obtained with various catalytic systems allows the presence of an irregularity in the macrochain, due to opening of the ring at the C–S bond at the primary or secondary carbon atom, to be observed. Actually, under the influence of various agents the ring of the optically active PS



can be opened to form a polymer of type (a) (anionic polymerisation) with retention of the configuration at C* and consequently with increase in optical activity, or of type (b) (cationic polymerisation), or of a mixture of types (a) and (b) with loss of or decrease in the optical activity of the polymer. As follows from Spassky's results[68,87], in the polymerisation of *d*- and *l*-propene sulphide under the influence of anionic excitants (sodium, KOH, cadmium tartrate) polymers with increased-optical activity are formed, but under the influence of boron trifluoride–diethyl ether, polymers with reduced optical activity are formed. In this connection there is considerable interest in studying the nature of the action of the $Zn(C_2H_5)_2 + H_2O$ system at various ratios of the initial components. For $Zn(C_2H_5)_2/H_2O = 1:1$ the optical activity is close to that obtained in an anionic system. A reduction in the proportion of water decreases the optical activity, which could be linked with the appearance of a cationic nature in the active centre formed. The system with $Zn(C_2H_5)_2/H_2O = 1:0.5$ is similar in its action to the $Al(C_2H_5)_3/H_2O = 1:0.7$ system and is a cationic excitant[105], but $Zn(C_2H_5)_2/CH_3OH = \frac{1}{2}$ and $Zn(C_2H_5)_2$ + glycol[68] is anionic, which agrees with the results of Inoue and coworkers[128]. It was noted[68,75,87-89] that in the polymerisation of episulphides there is not a complete analogy in the behaviour of the $Zn(C_2H_5)_2/MOH = \frac{1}{2}$ and $Zn(C_2H_5)_2/H_2O = \frac{1}{1}$ systems, since the latter shows a tendency to a cationic nature.

The polymerisation of the racemic *d,l*-propene sulphide in the presence of organolithium and organozinc compounds modified with optically active additions [LiC_4H_9 + LiOR*, $Zn(C_2H_5)_2$ + 2ROH*] was studied by Aliev and Krentsel'.[129,130] In an investigation of the lithium system low-molecular-weight polymers exhibiting a comparatively high optical activity (up to −63.7 deg) were obtained. The polymerisation was accompanied by the release of propene and under certain conditions there was almost complete decomposition of the poly(propene sulphide) into propene and

elemental sulphur. The process could also be directed to the production of a polymer with S–S bonds. It was suggested[129] that under the action of a strongly nucleophilic agent polymerisation takes place in three successive directions: (a) desulphidation of the PS and polymerisation, (b) decomposition of the polymer chains with release of propene and formation of oligomeric products with ~S–Li groups at both ends of the chain, (c) oxidation of the oligomers either by elemental sulphur or by lithium polysulphide with the formation of polymers with disulphide bonds.

Another probable mechanism of initiation and chain growth with formation of disulphide bonds has been suggested[130]. The formation of propene and polysulphide bonds in a macromolecule was also observed in a study[41] of the polymerisation of PS in the presence of zinc and cadmium mercaptides, which the investigators attributed to the act of elimination of sulphur in the coordination of S–Zn–S bonds of a polymeric chain with a monomer.

3. Cationic Polymerisation of Alkene Sulphides

The ability of alkene sulphides to polymerise in the presence of excitants of cationic type has been noted repeatedly[8,24,43,49,50]. In 1920 Délépin[8], who had been the first to synthesise episulphides, drew attention to the fact that they are readily polymerised under the influence of dilute mineral acids and acetic acid. In 1960 Dermer showed[24] that boron trifluoride and tetramethylammonium chloride bring about the polymerisation of episulphides in bulk with great velocity, and Boileau[49,50] polymerised PS in the presence of boron trifluoride–diethyl ether and of titanium and aluminium chlorides. However, in these studies only the fact of the formation of a low-molecular-weight polymer was noted and the mechanism of polymerisation under the influence of electrophilic agents was not taken into account.

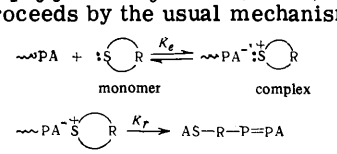
In 1951 Tarbell and Harnish[131] examined the polymerisation of episulphides in the presence of acidic agents and first suggested the formation of an intermediate sulphonium ion of the type

The "onium" mechanism lies at the basis of modern views on the mechanism of cationic polymerisation of heterocycles[132–137]. In the general instance, the initiation of polymerisation is regarded as the interaction of the electron-withdrawing part of the catalyst (Lewis acid) with the unshared electron pair of the heteroatom of the monomer with the formation of a stable onium pair, which is also an active centre of polymerisation:

The capability of the reacting substances to form onium (or sulphonium) ion is linked with the strain and basicity of the heterocycle, and also with the acidity of the catalyst, which ensures that the ionic complex is of sufficient stability.

Oddon[138] made a detailed study of the reactivity of three-membered sulphur-containing heterocycles in relation to electrophilic agents; Stille and Empen[25,26] attempted to correlate between the physicochemical parameters of various cyclic sulphides and their capability for polymerisation.

In the first publication[25] the possibility of polymerisation of alkene sulphides with rings of various sizes in the presence of $Al(C_2H_5)_3$ and PF_5 was reported; it was suggested that it proceeds by the usual mechanism:



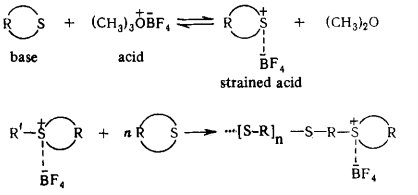
where PA is the growing polymer and A the electron acceptor.

Subsequently[26], by assuming that the polymerisation, at the start of which coordination or complex formation occurs, should be determined both by the basicity of the cyclic sulphide and by its tendency to ring opening, Stille and Empen determined the basicity of six cyclic sulphides:

and investigated their capability for polymerisation under the influence of the systems: (1) $AlR_3 + H_2O$ + epichlorhydrin, (2) PF_5, (3) $BF_3:O(C_2H_5)_2$ + epichlorhydrin, (4) $R_3O:BF_4$.

The basicity was estimated from the shift of the absorption band of the OH group in the infrared spectra of solutions of phenol and sulphides in CCl_4 and also from the heat of complex formation with iodine. The order of basicity found for alkene sulphides with various ring sizes ($5 > 6 > 4 > 3$) differs from that for oxides ($4 > 5 > 6 > 3$) and agrees with other results[100,139–143]. The basicity series for the oxides and thio-oxides are connected with the difference in size of the heteroatoms, the strain of the ring, and the polarisability of the bonds. On comparing the heats of formation of the complex and the heats of polymerisation it was concluded that the conversion of a cyclic sulphide into a polymer is determined not so much by its basicity as by the ring strain.

On considering the mechanism of polymerisation of alkene sulphides under the influence of trialkyloxonium salts we have suggested that, by analogy with the reactions studied by Meerwein[144,145], leading to the formation of trialkylsulphonium salts from trialkyloxonium salts and dialkyl sulphide—in this instance a stable trialkylsulphonium salt is formed, brought about by polymerisation:

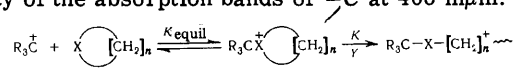


Extremely interesting results dealing with the reactivity of thio-oxides and the stability of sulphonium ions were given by Japanese scientists[146]. They measured the constants of the equilibrium

$$\text{carbonium} \underset{}{\overset{K_{equil}}{\rightleftharpoons}} \text{oxonium and}$$

$$\text{carbonium} \underset{}{\overset{K'_{equil}}{\rightleftharpoons}} \text{sulphonium}$$

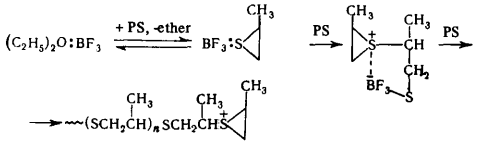
for the reactions of trityl hexachloroantimonate with various cyclic oxides and thio-oxides from the decrease in the intensity of the absorption bands of $\rangle\overset{+}{C}\langle$ at 408 mμm:



where X = S, O; Y = nucleophile.

It was shown that in every instance the equilibrium of the reaction is shifted to the right and the equilibrium constants (K_{equil}) for the thio-oxides considerably exceed those for the oxides. Sakai and coworkers associate these results with the greater stability of the sulphonium salts. They used K_{equil} and K'_{equil} to calculate the apparent rate constant for the opening of the heterocycle (k) and found that according to reactivity the sulphides can be arranged in the order 4 > 5 > 3, which agrees with the results on their basicity but not with those on their ability to polymerise (3 > 4 > 5). The stability of the sulphonium salts, which depends on their structure and the nature of the counter-ion, determines the temperature range in which they can be used for the excitation of the polymerisation of PS. It has been shown[23] that despite the similar values for the activation energy of the polymerisation of PS in the presence of boron trifluoride–diethyl ether, and of its trialkyloxonium and trialkylsulphonium salts (E_{act} = 18 ± 2, 16 ± 0.5, and 20 ± 0.5 kcal mole^{-1} respectively) in the last instance the polymerisation is effected only above 50°C whereas for the first two inducers polymerisation proceeds effectively from 0° to 20°C.

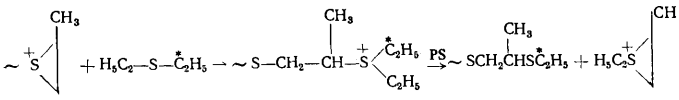
The polymerisation of PS under the influence of a typically cationic inducer, boron trifluoride–diethyl ether, has been studied repeatedly[99,147,148]. In ethyl chloride, nitroethane, or diethyl ether solution at 20°C and monomer concentrations of 3.5–6.4 M and inducer concentrations of 1.5×10^{-3}–9.0×10^{-3} M the polymerisation develops with participation of "living" polymeric chains without an induction period, irreversibly until complete depletion of the monomer, with the formation of a polymer which exhibits relatively broad MWD. The total activation energy of the process in 18 ± 1.5 kcal mole^{-1}. By initiating the polymerisation with seed "living" polymers the investigators showed that the high value of E_{act} is determined mainly by the limiting stage of the opening of the episulphide ring. The overall expression for the initial rate is $v_p = k_p[PS][cat]$, where k_p = 3.35 litre mole^{-1} min^{-1}. It is assumed that growth of the polymeric chain is effected by the stable sulphonium ion, formed according to the scheme:



It was shown[99,147,148] that the polymerisation of PS in the presence of boron trifluoride–diethyl ether is complicated by interchain exchange interaction the contribution of which increases with the degree of conversion. This is proved by the change in the nature of the MWD curves during the polymerisation and after its completion, the decrease in the molecular weight of the polymer during the polymerisation in the presence of dialkylsulphides and the possibility of the preparation of block-copolymers during the polymerisation of ethylene sulphide in a solution of "dead" poly(propene sulphide).

Enikolopyan and coworkers[149,150] developed the theory of interchain exchange interaction by the example of oxygen-containing heterocycles. A similar conversion of macromolecules is now known as a chain transfer reaction with chain breaking (CTB).

By making certain assumptions, a quantitative estimation of the contribution of the CTB in the polymerisation of PS under the influence of boron trifluoride–diethyl ether in the presence of diethyl sulphide (DES) labelled with ^{14}C was made[23,99]. The great stability of the sulphonium ions and the specific structure of the polymeric chain in which the basicity of the heteroatom is close to the interaction of the active centre not only with the monomer but also with the DES modelling the polymeric chain:



The polymerisation was studied at various stages of the conversion and characterised by the ^{14}C content in the polymeric chain. E_{act}CTB was calculated from the change in the rate of reaction of CTB in the temperature range 20–50°C and found to be 15 ± 2 kcal mole^{-1}, which corresponds to published results on the activation energy of thioether exchange[151]. By considering the polymerisation of PS under the action of boron trifluoride–diethyl ether as a "pseudocopolymerisation", in which $k_{DES-DES} = 0$, the relative value of the constant of the CTB reaction as

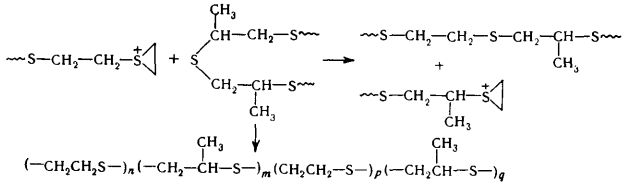
$$\frac{k_{CTB}}{k_{growth}} = [M]/[DES]\frac{\Delta DES}{\Delta M},$$

where [M] and [DES] are the concentrations of the monomer and DES in the initial mixture, and ΔM and ΔDES are the mole fractions of PS and DES in the polymer respectively.

By calculations from the radioactivity of the polymer, obtained at various compositions of the initial mixture,

$$k'_{CTB} = \frac{k_{CTB}}{k_{growth}} = 2 \cdot 10^{-3},$$

which shows the insignificant contribution to the CTB reaction at the stages which do not exceed 10% conversion. The CTB reaction develops more intensively on replacing DES by the already polymerised chain, that is, when there is a considerable increase in the concentration of thioacetal groups[99,147,148,152]. The polymerisation of ES under the influence of a cationic-type inducer in a solution of "dead" poly(propene sulphide) leads to the formation of statistical block-copolymers and was used for the direct proof of the existence of CTB reactions.



The phase composition of the fractions isolated by the method of fractional precipitation and selective extraction was controlled by elemental analysis and calorimetrically. The individual fractions of block-copolymers were investigated by physicochemical methods. The different proportions of crystalline poly(ethylene sulphide) links in the chain of the amorphous poly(propene sulphide) are readily

fixed by X-ray diffraction and are shown by the melting point of the fraction, determined from the thermomechanical curve.

4. Polymerisation of Propene Sulphide under the Influence of Complexes with Charge Transfer Complexes (CTC)

The presence of a lone pair of electrons localised at the sulphur atom in the thiirans suggested that compounds of this class can act as electron-donating partner in interaction with various electron-acceptors, by forming donor–acceptor CTC with development of polymerisation [83-85].

Stotskaya and coworkers showed, by the example of PS, that when it reacts with organic acceptors coloured CTC of the p–π type are formed with a specific absorption band maximum in the ultraviolet range which brings about the polymerisation of PS without the introduction of additional initiating agents. The principal kinetic parameters of the polymerisation of PS in the presence of a weak acceptor of electrons—maleic anhydride (MA) (E_a = 0.5 eV)—and of a strong acceptor—tetranitromethane (TNM) (E_a = 1.2 eV) in polar and non-polar solvents were studied. The polymerisation of PS had specific features which distinguish it from the polymerisation of the thiirans so far studied in the presence of cationic and anionic excitants. Independently of the nature of the acceptor and the polarity of the solvent, the kinetic curves were S-shaped, which the investigators associated with retardation of the initiation. The polymerisation was accompanied by intensively developing chain transfer and breaking reactions. The consumption of the acceptor not only in the formation of CTC but also in other side-processes was also found to be specific. The nature of the acceptor and the polarity of the medium determined the composition of the CTC which appear in the orders of the reaction with respect to the monomer and to the acceptor. Thus in the PS–MA system in a non-polar solvent and in the bulk

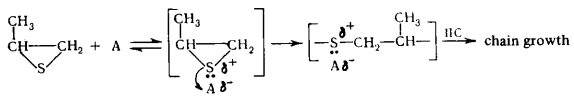
$$v_p = k_1 [PS]^2[MA];$$

in a polar solvent

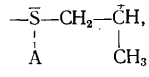
$$v_p = k_p [PS]^2[MA]^2,$$

and when the strong acceptor TNM was used the reaction was of variable order with respect to the acceptor (from 0.5 to 0) and of first order in relation to the monomer. The composition of the donor–acceptor complexes of PS with MA and THM was studied spectrophotometrically and the equilibrium constants for their formation in polar and non-polar media were calculated.

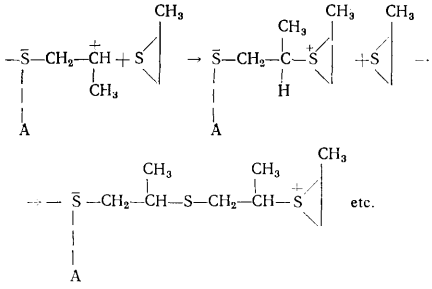
Sitnikova and coworkers [83] first supported a purely coordination mechanism for polymeric chain growth at an active centre formed during the opening of the thiiran ring in the CTC:



Subsequently [85] they concluded that the initiation of polymerisation is effected through a CTC stage, ring opening, and formation of an active centre:



and subsequently the chain growth proceeds by a cationic mechanism with participation of stable sulphonium ions which include the stages of chain transfer and breaking:



Sitnikova and coworkers did not give any experimental facts which confirm the correctness of the proposed mechanism of polymer chain growth.

III. COPOLYMERISATION OF ALKENE SULPHIDES

There is considerable theoretical and practical interest in the rules of copolymerisation of α-thio-oxides with derivatives of the same homological series and with other compounds, and in the properties of the copolymers obtained. The very few papers and patents have shown that the introduction of monosulphide bonds into the main chain of a polymer of another type gives a series of specific valuable properties [153-157]. Two- and three-component copolymers of α-thio-oxides in which one of the monomers has a C=C bond to ensure the possibility of their vulcanisation are of definite practical interest.

Kabayashi and Morivaki [76] obtained such a rubber on the basis of PS and allyloxypropene sulphide in the presence of various cadmium compounds. Thanks to the presence of thioether groups the rubber had good acid resistance and antioxidants were not needed in the vulcanisation usual for rubber.

Adamek and coworkers [72] used a three-component system of ethylene sulphide, PS, and allyloxymethylthiiran, and by employing zinc and cadmium carbonates as catalysts also obtained a vulcanising rubber. In comparison with the rubbers obtained by Kabayashi, the three-component copolymer had increased mechanical strength associated with the presence of a crystalline phase due to the ethylene sulphide links. The copolymer is stable to ozonation, certain chemical reagents, and over a wide range of temperatures it exhibits physicomechanical properties close to standard butadiene–styrene rubber. One of the features of the ternary copolymer is the rapidity of the vulcanisation (thrice as rapid as for the copolymer based on propene oxide). The capability of thiirans to give "living" polymeric chains has been used by many investigators for the production of block-copolymers. Thus Pstrosky [158] obtained block copolymers of ethylene sulphide with styrene and 4-vinylpyridine but Robert and Pearce [159] prepared block-copolymers of ethylene and propene sulphides with methyl methacrylate, styrene, and α-methylstyrene. French scientists obtained block copolymers of dienes with episulphides [153,154].

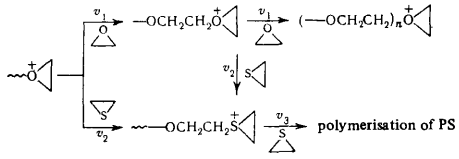
In every instance for the preparation of block copolymers in the initiation of polymerisation of episulphides by "living" polymers obtained in the anionic polymerisation of vinyl monomers or of dienes the quantitative conversion of the $-C^-$ active centre into $-S^-$ was used.

The relative reactivity of thiirans in anionic and cationic copolymerisation was studied by Bualo [190] and

Spassky[27]. It was found that the basicity of thiiran does not affect its activity during anionic copolymerisation[160]. On the basis of a comparison of the constants for the copolymerisation of PS and cyclohexene sulphide—initiating systems of boron trifluoride–diethyl ether and of $Zn(C_2H_5)_2 + H_2O$ at a component ratio of 1 : 1—Spassky drew conclusions about the common mechanism of action of these catalytic systems and the basicity of the monomers determined their relative reactivity[27].

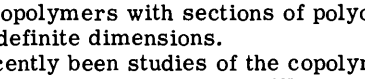
Copolymers of α-oxides with α-thio-oxides have been described in the patent literature[61,62,155-157,161]. Copolymerisation is effected under the influence of alkali metal hydroxides or of modified organometallic compounds at 25–175°C. The polymers formed exhibit high resistance to oxidation and are recommended for practical use as dielectrics and additions to lubricating oils and consistent lubricants. Copolymers of trioxan with a small quantity of thiiran obtained from boron trifluoride–diethyl ether[56,162] exhibit a thermal stability greater than that of homopolymers or other copolymers of trioxan.

The possibility of the copolymerisation of thiirans with their oxygen analogues under the influence of inducers of the cationic type has been studied[163,164]. It was shown that in the presence of boron trifluoride–diethyl ether and trialkyloxonium salts over a wide range of PS and propene oxide, or epichlorhydrin concentrations polymers enriched in thiiran are formed. Having studied certain kinetic regularities of the process and the composition of the polymers formed, the investigators showed that the irreversible and quantitative conversion of the oxonium ion into the stable sulphonium ion rules out the possibility of the formation of a statistical copolymer of thiiran with oxiran, and in this instance only block copolymers or their mixtures with a homopolymer of thio-oxide could be obtained. The composition and structure of the polymer are determined by the ratio of the rates v_1, v_2, and v_3 of the processes which occur:



The irreversible change oxonium → sulphonium was used to prepare block-copolymers in the initiation of the polymerisation of thio-oxides by "living" polymers of polyoxides. On taking into account the intensely developing interchain exchange reactions which are characteristic of cationic polymerisation of heterocyclic compounds, we thought it possible to obtain[163] block-copolymers of a specified composition, but it was difficult to calculate for the formation of copolymers with sections of polyoxide and polythio-oxide of definite dimensions.

There have recently been studies of the copolymerisation of thio-oxides with carbon disulphide[165] and isothiocyanates[166]. Under the action of tertiary amines first an oligomeric ethylene trithiocarbonate is obtained, then low-molecular-weight crystalline copolymers with the structure:

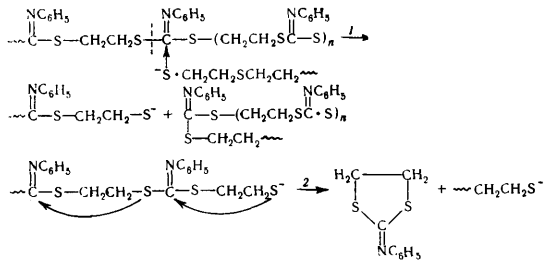


These investigations have progressed considerably[23,167-172]. In studying the copolymerisation of thio-oxides with isothiocyanates under the influence of butyllithium or the sodium–naphthalene complex in THF solution it was found that the process proceeds by a "living" chain mechanism with the formation of high-molecular-weight products exhibiting increased resistance to radiation. Some of the rules for the process were investigated by the example of the copolymerisation of ethylene sulphide with phenyl isothiocyanate. The isothiocyanate, which is active in relation to the inducer and to the $-CH_2CH_2S^-$ anion, reacts at a high rate with butyllithium, forming the anion of low activity $-C(=NR)S^-$, which is incapable of breaking the C=S bond of the isothiocyanate, but breaks the α-thio-oxide ring. Such selective interaction of the monomer with anions of different activity leads to the preparation of a copolymer of strictly alternating structure. In this process the relative reactivity of the phenyl isothiocyanate is considerably greater than that for alkyl isothiocyanates[170].

At equimolecular ratios of the reactants or with an excess of isothiocyanate a copolymer is formed in quantitative yield. An excess of ethylene sulphide (which is capable of homopolymerisation) does not lead to the production of the block-copolymer

$$[-SCH_2CH_2SC(=NR)S-]_n \cdot [-SCH_2CH_2]_m,$$

of calculated composition; the process is complicated by secondary phenomena arising after the disappearance of isothiocyanate from the system. The active polymeric anion $\sim CH_2CH_2SCH_2CH_2S^-$, by acting on the chain of the copolymer, brings about its breakdown to cyclic 2-phenylimino-1,3-dithiolane:



Finally, in the excess of ethylene sulphide there is complete breakdown of the copolymer that has been formed into cyclic dithiolane and the quantitative formation of the homopolymer of ES. In the copolymerisation of equimolecular quantities of phenyl isothiocyanate and PS it was shown that at 20°C even at different stages of the conversion the growth of the chain of the copolymer is accompanied by the formation of 2-phenylimino-4-methyl-1,3-dithiolan and above 65°C the process is shifted completely to the side of formation of the less strained cyclic dimer. Carrying out the copolymerisation under milder conditions in the presence of hexamethylphosphortriamide leads to a minimum in the decomposition of the copolymer[171].

From the published results discussed above the polymerisation and copolymerisation of thio-oxides under the influence of various catalytic systems has attracted great attention. In the most recent publications special sections are devoted to these problems[57,90]. There have been communications dealing with the possibility of the practical application of polymeric materials based on poly(alkene sulphides).[174-176] This all provides a basis for suggesting the wide use of polymers based on alkene sulphides in the not too distant future.

Tautomerism of Aromatic Azo-compounds

I.Ya.Bershtein and O.F.Ginzburg

Recent results on the tautomeric properties of aromatic azo-compounds in neutral and acid solutions are reviewed. The tautomerism of the conjugate acids of azo-compounds (the *trans*-azonium cations) is discussed, and also the tautomeric equilibria between azo-forms and quinone hydrazones in acid solutions of *p*-aminoazo-compounds and in neutral solutions of hydroxyazo- and aminoazo-compounds. Available qualitative and quantitative results on the effects of substituents and of the properties of the medium on the position of tautomeric equilibrium are compared. The problem of applying correlation analysis to tautomeric systems is analysed. A list of 179 references is included.

CONTENTS

I. Introduction	97
II. Tautomerism of hydroxyazo-compounds	98
III. Tautomerism of aminoazo-compounds	101
IV. Tautomerism of conjugate acids of azo-compounds	101
V. Tautomerism of conjugate acids of *p*-aminoazo-compounds	103

I. INTRODUCTION

Azo-compounds constitute an extraordinarily interesting and important class of compounds from both practical and theoretical points of view. The ready availability, cheapness, and versatility of properties have guaranteed to azo-compounds a high proportion of the range of organic dyes manufactured by industry[1]. Azo-compounds have found wide application in the laboratory as acid–base, redox, metallochrome, and other indicators, stains for bacteriological and histological investigations, standard materials in adsorption chromatography, etc.

The study of azo-compounds has been of great value for the development of theoretical organic chemistry. Together with triphenylmethane, keto–enolic, and certain other classes of compounds, azo-compounds have been widely used in developing and testing theories of colour and constitution, indicator action, and acid–base and tautomeric transformations.

The tautomeric properties of certain aromatic azo-compounds were detected as early as the beginning of the twentieth century. Hantzsch and several other investigators (see list of references[2]) studied the tautomerism of the conjugate acids of *p*-aminoazo-compounds. Somewhat later[3] tautomerism was confirmed between azoid and quinone hydrazone forms in neutral solutions of hydroxyazo-derivatives of naphthalene. Finally, the tautomerism of the conjugate acids of *trans*-azo-compounds was studied as early as the 1960s.[4]

It can be stated without exaggeration that almost all known methods of investigating tautomeric equilibrium have been used for the quantitative and qualitative study of tautomeric relations in various classes of azo-compounds. Many of these methods were in fact first developed in connection with azo-compounds.

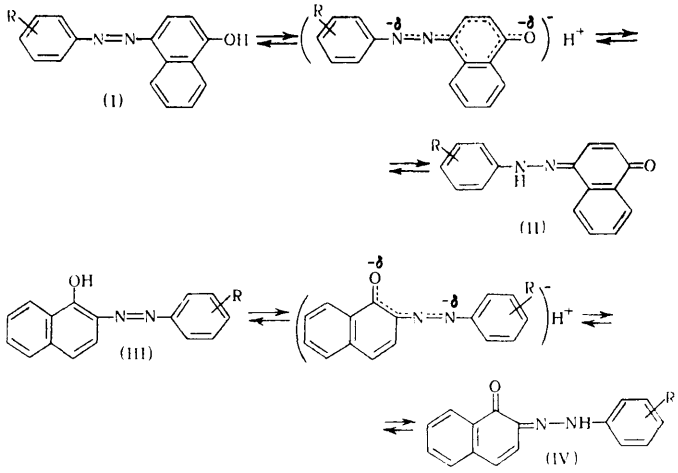
The total number of papers on the tautomerism of aromatic azo-compounds can hardly be fewer than those on classical keto–enol tautomerism. However, no

reviews are available on the present state of this problem. The present survey deals mainly with papers dating from 1955 (up to the beginning of 1970 inclusive). Bibliographies of earlier investigations will be found in the monographs by Venkataraman[1] and by Zollinger[5] and also in reviews[2,6].

II. TAUTOMERISM OF HYDROXYAZO-COMPOUNDS

1. Hydroxyazo-compounds of the Naphthalene Series

A wide circle of investigators became interested in the tautomerism of hydroxyazo-compounds after Zincke and Bindewald[7] had shown that the same product is obtained by coupling the benzenediazonium ion with 1-naphthol and by condensing phenylhydrazine with naphtha-1,4-quinone. The structure of this product, which could be represented by either formula (I) or (II) (both with R = H) became a matter of controversy (lists of references will be found in papers[8,9] and in monographs[1,5]).



Zincke had already suggested[7] that a mobile equilibrium between the two forms might be established in solution. A similar suggestion was made for the product of the condensation of phenylhydrazine with naphtha-1,2-quinone, which proved to be identical with 2-phenylazo-1-naphthol (III: R = H). The concept of tautomerism between azo-forms (I and III) and quinone hydrazone forms (II and IV) in solutions of *p*- and *o*-hydroxyazo-compounds of the naphthalene series has since been put forward several times, but it became generally accepted after the classic work of Kuhn and Bär[3].

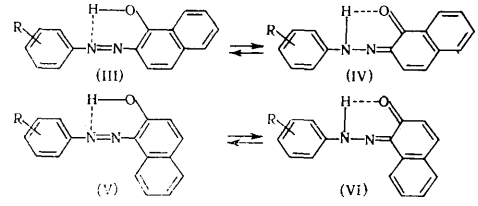
These workers suggested that the absorption spectrum of (I) should be analogous to that of its *O*-methyl ether, and the spectrum of (II) to that of its *N*-methyl derivative. On comparing the spectra of 4-phenylazo-1-naphthol in various solvents with the spectra of its *O*- and *N*-methyl derivatives, they concluded that the tautomeric equilibrium (I) $\rightleftharpoons$ (II) was established in all the solutions studied. The position of this equilibrium (according to modern views it should involve a common ion) depends in considerable measure on the nature of the solvent: e.g. it is displaced towards (I) in pyridine, but towards (II) in glacial acetic acid. In the case of *o*-hydroxyazo-compounds of the naphthalene series, according to these workers[3], the tautomeric equilibrium (III) $\rightleftharpoons$ (IV) is displaced in favour of the quinone hydrazone form (IV) in the majority of solvents.

The concept of tautomerism was developed in a large number of studies on the absorption spectra of *o*- and *p*-hydroxyazo-compounds of the naphthalene series[10-22]. The spectra of derivatives of 4-phenylazo-1-naphthol exhibit two maxima at 390–420 and 470–510 nm, due to the presence respectively of azoid and quinone hydrazone forms in solution. Variation in the polarity and also the solvating power of the solvent leads to a shift in the tautomeric equilibrium: the optical density at the absorption maximum of one form increases, while that at the maximum of the other form decreases. In some cases an isosbestic point is observed in the spectra with variation in the solvents (mixtures of alcohols with water[15,19]). Frequently, however, such a point cannot be distinguished, owing to the effect of the solvent on the spectra of the tautomers[3,14].

Increase in the polarity of the solvent displaces the equilibrium (I) $\rightleftharpoons$ (II) towards the more polar quinone hydrazone form. At the same time, the formation of hydrogen bonds with the solvent stabilises the azo-form. The overall sequence of solvents, producing an increasing proportion of the quinone hydrazone form according to Burawoy and Thompson[14], is—hexane < alcohol < benzene < chloroform < 50% aqueous alcohol < acetic acid. Increase in the alkalinity of the medium leads to a shift in the equilibrium towards the azo-form[21].

Solvation stabilisation of the quinone hydrazone form is prevented by substituents *ortho* to the azo-bond. Hence solvents have opposite effects on *o*- and *p*-hydroxyazo-compounds: in aprotic solvents the quinone hydrazone is preferred, but in alcohols the azo-form[14].

The influence of substituents on the equilibrium (I) $\rightleftharpoons$ (II) has been assessed from the relative intensities of the absorption maxima due to the two tautomeric forms[10,13,14,17,23]. Electron-donating *meta*- and *para*-substituents in the benzene ring of (I) increase the proportion of the azo-form; but electron-accepting substituents shift the equilibrium towards the quinone hydrazone form (II)

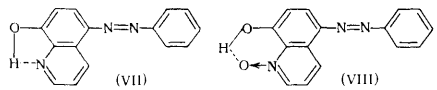


With *o*-hydroxyazo-compounds of the naphthalene series—notably with derivatives of 2-phenylazo-1-naphthol (III) and 1-phenylazo-2-naphthol (V)—the influence of solvents on the equilibria (III) $\rightleftharpoons$ (IV) and (V) $\rightleftharpoons$ (VI), and hence on the spectra of solutions of these compounds, is considerably smaller than in the case of *p*-hydroxyazo-compounds[3,13]. The explanation is that the tautomeric equilibrium of *o*-hydroxyazo-compounds is displaced to a considerable extent towards the quinone hydrazone forms[3,10,13,20].

The shift in equilibrium towards forms (IV) and (VI) of *o*-hydroxyazo-compounds is explained by the presence of a strong intramolecular hydrogen bond, first suggested by Oddo and Puxeddu[24]. This hypothesis has since been confirmed by a study of the infrared spectra[20,25-28]. An intramolecular hydrogen bond stabilises the quinone

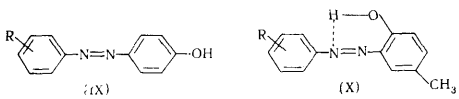
hydrazone form† and leads to a sharp decrease in the overall basic strength of the *o*-hydroxyazo-compound [30,31], together with the appearance of chelating properties. These are particularly strongly developed in *oo'*-dihydroxyazo-compounds, which are often used as analytical reagents for metals.

The intramolecular hydrogen bond in compounds of the type (III) and (V) forms part of a quasi-aromatic six-membered ring [32,33], the energy of formation of which may reach 16 kcal mole^{-1}. [33] This explains the absence of frequencies due to the hydroxy-group from the infrared spectra of *o*-hydroxyazo-compounds of the naphthalene series [27,34], the bathochromic shift in the ultraviolet spectra of *o*-hydroxyazo-compounds compared with the *para*-isomers [35], and also the difficulty of exchanging the hydroxyl hydrogen for deuterium by boiling in heavy water [36].



(VII) (VIII)

8-Hydroxy-5-phenylazoquinoline (VII) and especially its *N*-oxide (VIII) provide examples of intramolecular hydrogen bonds which stabilise azo-forms [16].



(IX) (X)

The influence of substituents on the strength of the hydrogen bond, and also the effect of the bond on the basic strength, have been assessed from the difference in basicity between the substituted *p*- and *o*-hydroxyazobenzenes (IX) and (X). [31,37] If the hydroxy-group has the same electronic effect in *para*- and *ortho*-positions, and the presence of an unchanged substituent—the 5-methyl group in (X)—can be neglected, the hydrogen bond in (X) can be characterised by the difference $pK_{(X)} - pK_{(IX)} = pK_H$.

Electron-acceptor substituents R produce a decrease in pK_H by diminishing the electron density on the nitrogen atom [31,37]. The correlation of pK_H with the σ-constants of the substituents is characterised by the parameter $\rho = -0.531$ [37] or -0.489 [31], while the relation $pK_{(X)} = f(\sigma)$ has $\rho = -1.21$ [37]. Comparison of these values confirms that the influence of substituents on the basicity of *o*-hydroxyazo-compounds is largely transmitted through the nitrogen atom and the hydrogen bond.

A similar conclusion was reached by Korolev and Stepanov [38], who used a two-parameter correlation of the pK_a of derivatives (X) with the σ^-- and σ-constants of the substituents. Here the σ^--constants represented the effects of substituents transmitted through the azo-group and the oxygen atom; while the σ-constants represented effects transmitted through one of the nitrogen atoms and the hydrogen bond. The values obtained for ρ_1 and ρ_2 were respectively -0.396 ± 0.108 and -0.757 ± 0.180.

Spectrophotometric data indicate [13] that the influence of the nature of substituents on the position of the (III) ⇌ (IV) equilibrium is similar to that found for the (I) ⇌ (II) equilibrium. Quantitative results have been obtained by means of ^{14}N-nuclear magnetic resonance spectroscopy (Table 1). Azobenzene and 10-*p*-methoxyphenylazo-9-phenanthrol were used as model compounds having an azoid and a quinone hydrazone structure. The presence of a mobile proton in the latter form impedes accurate determination of the signal to a greater extent the higher the concentration of this form. Therefore the values in Table 1 are insufficiently accurate for the application of correlation analysis to investigate the relation between the position of tautomeric equilibrium and the nature of the substituent.

Table 1. Content of quinone hydrazone form in solutions of 1-phenylazo-2-naphthol derivatives in deuterochloroform [39].

Substituent	Quinone hydrazone, %	Substituent	Quinone hydrazone, %
4'-CN	97	H	79
3'-CN	91	4'-Cl	78
3'-Cl	81	4'-Me	69
3'-Me	80	4'-OMe	52
3'-OMe	81	H (in hexane)	38

The proton magnetic resonance spectra could not be used for accurate determination of the position of tautomeric equilibrium [40,41], owing to rapid proton exchange between the two forms (lifetime of each form ~ 0.2 ms [39]).

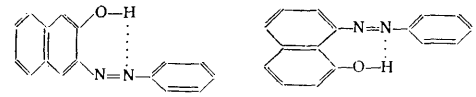
Studies have been made also of the polarographic behaviour [42,43], the surface tension of solutions [44], and the semiconductor characteristics of solid hydroxyazo-compounds [45,46]. These properties show little correlation with the tautomeric equilibrium position.

The ^{15}N-nuclear magnetic resonance spectra have been used to investigate the temperature dependence of the tautomeric equilibrium of 1-phenylazo-2-naphthol [47,48]. In dichloromethane the equilibrium shifts towards the quinone hydrazone form as the temperature falls ($\Delta H = 1.38$ kcal mole^{-1}). A similar conclusion was reached from a study of the absorption spectra at low temperatures [18,49]. With 4-phenylazo-1-naphthol cooling displaces the equilibrium towards the azo-form in ethanol, but towards the quinone hydrazone in methylcyclohexane ($\Delta H = 2 \pm 0.2$ kcal mole^{-1}) [18,50].

The basicity of derivatives of (V) has been studied in 50% aqueous ethanol [51], when the correlation

$$pK_a = 12.53 - 1.44\sigma^0 \quad (r = 0.99) \qquad (1)$$

was obtained. The dependence of the exponents of the effective basicity constants of a tautomeric mixture on the σ-constants of the substituents will be discussed in Section IV. Here we note merely that the linear relation (1) is due to a considerable shift in the equilibrium towards one of the tautomeric forms (cf. Table 1).



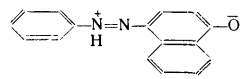
(XI) (XII)

3-Phenylazo-2-naphthol (XI) constitutes a special case among *o*-hydroxyazo-compounds of the naphthalene series.

† Quantum-chemical calculations by the Hückel molecular-orbital method, disregarding the effect of the hydrogen bond, predict for (III) that energy considerations will greatly favour the azo-form. With 4-phenylazo-1-naphthol the conjugation energy is similar for the two forms [29].

The diminished order of the 2–3 bond in naphthalene is responsible for the existence of (XI) only in the azo-form[52,53]. The presence of a hydrogen bond in (XI) has been proved by means of the infrared spectra[53] and is apparent in the lower activation energy of *cis–trans* isomerisation of (XI) in comparison with its *O*-methyl ether[54]. A similar phenomenon—the presence of a hydrogen bond in the absence of azo-quinone hydrazone tautomerism—has been shown also with *peri*-hydroxyazo-compounds of the naphthalene series (XII).[55]

Formulae (II), (IV), and (VI) probably do not represent accurately the structure of the quinone hydrazone forms of hydroxyazo-compounds. The lower frequency and intensity of vibrations of the CO group in the infrared spectra of (I) and (V)[26,53] indicate that zwitterionic structures of the type



(XIII)

which diminish considerably the order of the C=O bond, make a large contribution, a conclusion supported by measurements of the dipole moments of (I).[56] Since the hydroxy-group is a strong electron-donor substituent, there is no need to take into account the possible appearance of hydrazone tautomers with the proton on the α-nitrogen atom (Section IV).

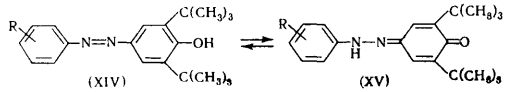
Infrared spectra indicate that hydroxyazo-compounds which are capable of tautomerism are present in the solid state as quinone hydrazones or as tautomeric mixtures[15].

2. Hydroxyazo-compounds of the Benzene and Anthracene Series

It has been concluded, from a comparative study of the ultraviolet spectra of hydroxyazobenzene, its derivatives, and their *O*-methyl ethers[10,11,22,57–59], proton magnetic resonance[40] and infrared[60] spectra, and polarographic investigation[42,43], together with a study of *cis–trans* isomerisation[61,62], that both *ortho*- and *para*-hydroxy-derivatives of azobenzene exist in the azo-form. The weak fluorescence observed with *o*- and *p*-hydroxyazobenzene[49] suggests that their solutions may contain very small quantities of the quinone hydrazone forms. True azo-compounds are incapable of fluorescence, which, on the other hand, is characteristic of all compounds having a hydrazone structure.

Dual reactivity is probably the explanation of published information on the reaction of 4-hydroxy-2′(or 4′)-nitroazobenzene derivatives with 2,4-dinitrophenylhydrazine[63] and also on their Diels–Alder reaction with cyclopentadiene[64].

The only known exception among hydroxyazo-compounds of the benzene series is provided by derivatives of 2,6-di-t-butyl-4-hydroxyazobenzene (XIV), for which the equilibrium

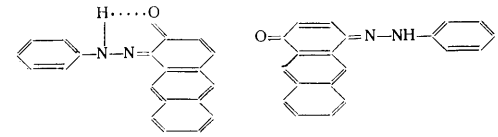


(XIV) (XV)

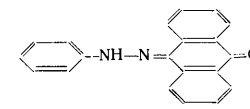
has been demonstrated (for all R other than $N(CH_3)_2$ and OCH_3)[65]. This exception is explained by the greater tendency of sterically hindered phenols to pass into quinoid forms[66]. The corresponding equilibrium constants, determined spectrophotometrically[67], show that the introduction of electron-acceptor substituents R increases the proportion of (XV), as with hydroxyazo-compounds of the naphthalene series.

Investigation of the basicity of *o*- and *p*-hydroxyazobenzene derivatives revealed in all cases a linear dependence of pK_a on the σ-constants of the substituents[31,37,68,69]. In 96–100% sulphuric acid doubly charged cations may be formed, probably by protonation not only of the azo-group but also of the hydroxyl[70].

When the absorption spectra of the products obtained by coupling 1-, 2-, and 9-anthrols with the benzenediazonium ion are compared with those of their *O*-acetyl derivatives, it is evident that *p*-hydroxyazo-compounds of the anthracene series exist predominantly in the quinone hydrazone form[11,71,72]. The tautomeric properties of (XVI) are confirmed by the strong fluorescence of its solutions, and also by the fact that the product (XVI) obtained by condensing phenylhydrazine with anthraquinone is identical with 10-phenylazo-9-anthrol prepared by azo-coupling[73].

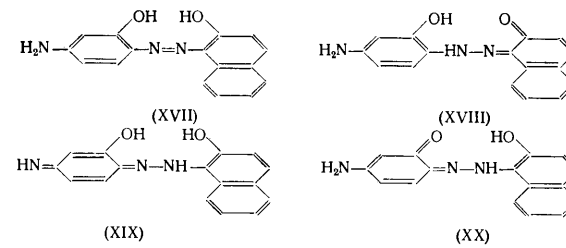


$\lambda_{max} = 511$ nm[11] $\lambda_{max} = 506$ nm[11]



(XVI)

The displacement of the tautomeric equilibrium towards the quinone hydrazone form on passing from hydroxyazo-derivatives of benzene to those of polyacenes was attributed by Ospensen[11] to a fall in the redox potential of the corresponding quinones on passing from *p*-benzoquinone (E_0 = 0.715 V, alcohol) to naphtha-1,4-quinone and anthra-1,4-quinone (0.484 and 0.401 V). This rule breaks down when we compare *p*- and *o*-hydroxyazo-derivatives of naphthalene with the redox potentials of the *o*-naphthaquinone (0.555 V, water) and *p*-naphthaquinone, which is explained by the presence of an intramolecular hydrogen bond in the *o*-hydroxyazo-compound. Similar results on a shift in the tautomeric equilibrium on passing from hydroxyazo-derivatives of benzene to those of naphthalene and anthracene were obtained[74] in a study of monolayers of azo-compounds having long alkyl groups.



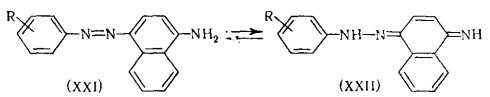
(XVII) (XVIII)

(XIX) (XX)

An interesting case of tautomerism has been described recently by Dedkov and Kotov[75] with 1-*p*-amino-*o*-hydroxyphenylazo-2-naphthol, for which the four tautomeric forms (XVII)–(XX) are possible. The ultraviolet spectra, supported by Hückel molecular-orbital calculations, indicate that three forms (XVII)–(XIX) are in equilibrium in the proportions 1 : 1.2 : 1.25.

III. TAUTOMERISM OF AMINOAZO-COMPOUNDS

The possibility of tautomerism between the azo-form (XXI) and the quinone hydrazone (XXII) in neutral solutions of *o*- and *p*-aminoazo-compounds of the naphthalene series has been investigated by many workers, mainly by comparing the absorption spectra of the compounds, their *N*-acetyl derivatives [35,71,76,77], and their *NN*-dimethyl derivatives [35] with those of the corresponding azo-compounds containing no auxochromic group [78,79]. Most authors have concluded that the quinone hydrazone form (XXII) is absent from solutions of *p*-aminoazo-derivatives of naphthalene.

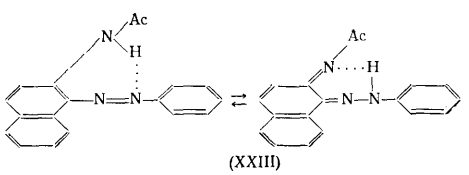


(XXI) (XXII)

No definite conclusion can yet be reached concerning *o*-aminoazo-compounds. There are results indicating that they exist in the quinone hydrazone form containing an intramolecular hydrogen bond [35], and also that tautomerism is absent in this case [78,80]. The presence of a strong intramolecular hydrogen bond in the naphthalene derivatives is confirmed by infrared spectroscopy [81,82].

The existence of aminoazo-compounds in the azo-form is confirmed by comparing their dipole moments with those of the corresponding aniline derivatives [83] and also by polarographic investigations [84]. Filippychev [85] reported that the solid hydrazone forms (XXII) could be obtained by heating the compounds in concentrated hydrochloric acid. The products could not be diazotised. However, no elementary analysis or other evidence of structure was given [85].

The *N*-acyl derivatives cannot be regarded as model compounds having an undoubted azo-structure. By diminishing the basic strength of the amino-group and thereby levelling out those of the two reaction centres [86] the acyl group makes azo–quinone hydrazone tautomerism more probable. Skulski and Urbanski [77] have mentioned the possibility of such tautomerism with 2-acetamido-1-phenylazonaphthalene

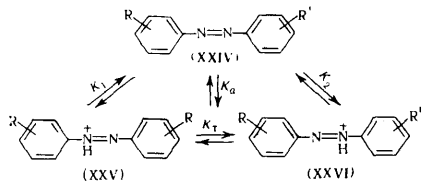


(XXIII)

Spectroscopic results indicate that aminoazo-derivatives of anthracene are probably capable of tautomerism with quinone hydrazone forms [71,72], but this equilibrium has not been examined in detail.

IV. TAUTOMERISM OF CONJUGATE ACIDS OF AZO-COMPOUNDS

Salt formation by azo-compounds in concentrated mineral acids has been known for a long time [87–89], but the structure of the products has only recently become a matter of controversy. If it is postulated that an azo-group contains two potentially basic centres, monosubstituted and unsymmetrically disubstituted azobenzenes (XXIV) may be expected to form two tautomeric conjugate acids (XXV) and (XXVI):



(XXIV) (XXV) (XXVI)

The effective basicity constant K_a and the tautomeric equilibrium constant K_T will then be related to K_1 and K_2 by the formulae [90]

$$K_a = \frac{K_1 \cdot K_2}{K_1 + K_2} \tag{2}$$

$$K_T = \frac{[XXV]}{[XXVI]} = \frac{K_2}{K_1} \tag{3}$$

Jaffé and his coworkers used correlation analysis to examine the possibility of the tautomerism (XXV) ⇌ (XXVI) in the cases of monosubstituted [91] and disubstituted [68] azobenzenes. If the influence of the substituents on the acid–base properties of these tautomers is described by Hammett's equation

$$pK_1 = (pK_1)_0 - \rho_1\sigma \tag{4}$$

$$pK_2 = (pK_2)_0 - \rho_2\sigma \tag{5}$$

and (4) and (5) are expressed as powers of 10, on substituting for K_1 and K_2 in Eqn. (2), we obtain

$$K_a = \frac{(K_1)_0 (K_2)_0 \cdot 10^{(\rho_1+\rho_2)\sigma}}{(K_1)_0 10^{\rho_1\sigma} + (K_2)_0 10^{\rho_2\sigma}} \tag{6}$$

or, taking logarithms,

$$pK_a = (pK_1)_0 + (pK_2)_0 - (\rho_1 + \rho_2)\sigma + \lg[(K_1)_0 10^{\rho_1\sigma} + (K_2)_0 10^{\rho_2\sigma}] \tag{7}$$

Equation (7) shows that the dependence of the exponents of the effective basicity constants of the tautomeric system on the σ-constants of the substituents is represented by a curve having the straight lines (4) and (5) as asymptotes. Analysis of Eqn. (7) by Kabachnik [92,93] and by Jaffé [91,94] indicates that this generally non-linear relation becomes linear when

$$\rho_1 = \rho_2 \tag{8}$$

i.e. when the substituents do not affect the position of the tautomeric equilibrium. Furthermore, the curvature of the pK_a–σ relation becomes slight with closely similar values of ρ_1 and ρ_2, with a considerable shift in the equilibrium towards one of the tautomers

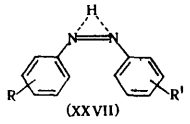
$$K_1 \gg K_2 \quad \text{or} \quad K_1 \ll K_2 \tag{9}$$

and finally with large absolute values of ρ_1 and ρ_2. [95] In all these cases the dependence of pK_a on σ for the tautomeric systems can be represented approximately by a straight line with a high correlation coefficient‡.

Jaffé and his coworkers [68,91] showed that values of pK_a for salt formation by a large number of azobenzene derivatives vary linearly with the σ^+-constants of the substituents (in the case of disubstituted derivatives the sum of

‡ By plotting model curves of Eqn. (7) we have shown that, if the experimental error is taken into account, the curvature becomes significant when very narrow boundary conditions, $|\rho_1 - \rho_2| \geq 2$ and ρ_1 or $\rho_2 < 3$, are satisfied simultaneously. For the compounds studied K_T varies between 0.3 and 3.

the σ^+-constants was taken) (Fig. 1). Since in this case it could not be predicted *a priori* that condition (8) or (9) would be satisfied, these workers concluded that the azo-group acts as a single reactive centre in salt formation. The structure of the conjugate acids of azobenzene and its derivatives would then be represented by the formula



(XXVII)

in which the proton is attached to both nitrogen atoms.

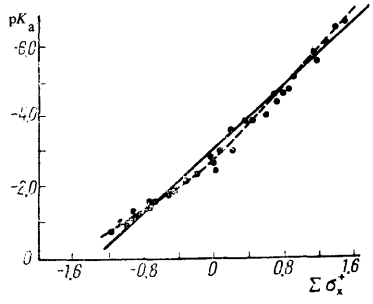


Figure 1. Dependence of pK_a for substituted azobenzenes on the σ^+-constants of the substituents[68] (sulphuric acid containing 20 vol.% of alcohol). The broken curve has been plotted from Eqn. (7) with $\rho_1 = 1.7$ and $\rho_2 = 3.0$ (see Section IV).

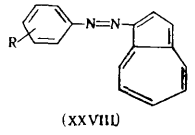
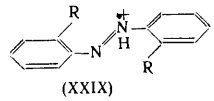
A linear dependence of pK_a on σ was found also by Gerson and Heilbronner[96] when studying the basicity of substituted phenylazoazulenes



(XXVIII)

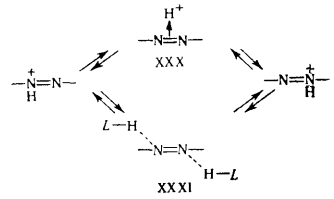
The azobenzene cation has subsequently been assumed to have a symmetrical structure in order to explain differences in the spectra of the conjugate acids of azobenzene and benzylideneaniline[97], and also in quantum-mechanical calculations of the spectra of azobenzene in concentrated sulphuric acid[98]. Simultaneous attachment of the proton to the lone pairs of both nitrogen atoms requires that the conjugate acid of azobenzene should have the *cis*-configuration, independently of the configuration of the original base. In 1960, however, Lewis[99] and Gerson et al.[100] showed simultaneously that *trans*- and *cis*-azobenzene form two conjugate acids differing in absorption spectra and in basic strength. Thus formula (XXVII) was proved to be incorrect, at least for conjugate acids of *trans*-azo-compounds.

A detailed investigation of the structure of *trans*-azonium cations has been made by Haselbach and Heilbronner[4,101], several aspects of the problem being examined. With unsymmetrical *N*-protonation the equivalence of the two identical substituents in the *ortho*- and *ortho'*-positions with respect to the azo-group in the compound



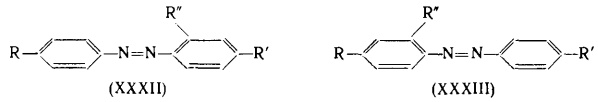
(XXIX)

should break down. Splitting of the signals due to protons in R should then be observed in the proton magnetic resonance spectra of (XXIX). Such splitting has been found with 2,2'-di- and 2,2',4,4'-tetra-methoxyazobenzenes in a mixture of trifluoroacetic and perchloric acids[4] and also with 2,2'-azoisobutane in 95% sulphuric and dideutero-sulphuric acids[101]. The absence of splitting with a large number of other methylated azobenzenes was explained[4] by rapid proton exchange between the tautomeric forms. The intermediate state is the π-complex (XXX) (intramolecular rearrangement) or a complex with two solvated protons of the solvent (XXXI) (intermolecular rearrangement)[101]:



XXX XXXI

As other evidence of unsymmetrical protonation of the azo-group Haselbach[4] examines the change in basicity on the introduction of substituents at position 2 or 2' in an unsymmetrically substituted azobenzene. If protonation of the azo-group is symmetrical, the compounds



(XXXII) (XXXIII)

should be similar in basicity. In fact (XXXII) and (XXXIII) differ in basic strength, to a greater extent the greater the difference between the properties of the substituents R and R'. With $\sigma_R - \sigma_{R'} = 1.56$, for example, the difference $pK_{(XXXII)} - pK_{(XXXIII)} = 1.90$.[4]

Finally, accepting the hypothetical unsymmetrical protonation of the azo-group, Haselbach attempted to estimate separately the effects of substituents on the nearer and on the more remote nitrogen atom by means of the arbitrary parameters R_α and R_β. He treated basicity data on 57 azobenzene derivatives by the method of least squares, and after several successive approximations he obtained values of R_α and R_β for the 4-substituents—methyl (−0.21 and −0.75), methoxyl (−0.31 and −1.85), and nitro (1.37 and 2.76).[4] This worker regards the statistically significant difference in the quantities R_α and R_β as confirmation of the starting hypothesis of unsymmetrical *N*-protonation.

On the assumption of a parallelism between the effects of substituents in the benzylideneaniline and azobenzene series Haselbach used data on the basic strengths of the former derivatives[101-103] to obtain the Hammett parameters $\rho_\alpha = 1.74$ and $\rho_\beta = 2.99$ for the effects of substituents on the basicities of the nearer and more remote nitrogen atom of the azo-group[4].

Since benzylideneaniline derivatives have a non-planar structure, in contrast to azo-compounds, the values obtained by Haselbach are extremely rough approximations. However, the following important conclusions can be reached on their basis. Thus if Eqn. (7) is plotted with $\rho_1 = 1.7$ and $\rho_2 = 3.0$ (broken curve in Fig. 1), it can be

concluded that Jaffé's results can be represented by this equation, and hence are consistent with the tautomerism (XXV) ⇌ (XXVI).

Since azobenzene itself is symmetrical, $(K_1)_0 = (K_2)_0$ in Eqns. (4) and (5). Substituting the values of ρ_α and ρ_β in these equations, we find that, when a substituent having $|\sigma| = 0.5$ is present in the azobenzene molecule, the content of one of the tautomeric forms is less than 20% ($K_T > 4.4$ or < 0.2). When the σ-constant of the substituent (or the difference between those of two substituents in different benzene rings) is unity, the position of tautomeric equilibrium will shift to 95% or more of one of the tautomers.

Unsymmetrical protonation of the azo-group is consistent with the proton magnetic resonance spectra of *p*-hydroxyazobenzene derivatives[104], the basic strengths and rates of oxidation of a series of azobenzene derivatives[105], and also the infrared spectra and the structure of complexes of azo-compounds with metal halides[106].

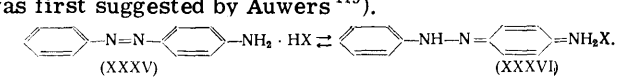
Thus it can be accepted as established that the protonation of *trans*-azo-compounds in concentrated acids is accompanied by the formation of a tautomeric mixture of the two cations (XXV) and (XXVI). This conclusion cannot be extended to the conjugate acids of *cis*-azo-compounds. Collins and Jaffé[107] showed that the basic strengths of *trans*-azo-compounds are correlated by the σ^+-constants, and those of the *cis*-isomers by the σ^--constants. The explanation of this difference is that the azo-group is an electron-acceptor reactive centre in *trans*-azo-compounds, but in *cis*-azo-compounds with their non-planar structure[108] the possibility of competing n,π-conjugation of the lone electron pairs of the nitrogen with the benzene rings confers an electron-donor character on the azo-group.

The extraordinarily deep colour of *pp'*-bisdimethylaminoazobenzene (XXXIV) in acid solution ($\lambda_{max} = 670$ nm) led Cilento[109] to attribute a π-complex structure to the conjugate acid of this aminoazo-compound. However, other results[110,111] indicate that the properties of (XXXIV) are entirely consistent with those of other azo-compounds. Thus there is no need to assume a special structure for the conjugate acid in the case of (XXXIV).

An interesting but hitherto uninvestigated fact is the change in the spectra of azobenzene (and its derivatives) in oleum[89], which is attributed to the formation of a doubly charged salt.

V. TAUTOMERISM OF CONJUGATE ACIDS OF *p*-AMINOAZO-COMPOUNDS

Derivatives of *p*-aminoazobenzene have been widely used as indicators for almost a century[112]. After Thiele[113] had shown, and Hantzsch and Hilscher[87] had confirmed, that two series of isomeric salts§—yellow and reddish violet—can be isolated in the solid form from acid solutions of *p*-aminoazo-compounds, the hypothesis was put forward that the acid solutions contain two tautomeric forms, in which the proton is attached to the amino-group (XXXV) or to the azo-group (XXXVI) (the latter formula was first suggested by Auwers[115]).



(XXXV) (XXXVI)

§ However, there is as yet no evidence that these salts differ in chemical structure. Their infrared spectra[114] suggest rather that the two series of salts of *p*-aminoazo-compounds are merely crystalline modifications.

This hypothesis is supported by spectroscopic investigations. The spectra of *p*-aminoazo-compounds in dilute acids exhibit two absorption maxima—in the region of 320 and 520 nm—in the range 300–600 nm[2] (Table 2). By analogy with azobenzene and its *p*-trimethylammonium derivative, whose spectra in neutral and weakly acid solutions have a maximum at 320 nm, the corresponding maximum in the spectra of *p*-aminoazo-compounds was assigned to the ammonium tautomer (XXXV). On the basis of a comparison with the spectra of azoanisole ($\lambda_{max} = 500$ nm[116]) and *p*-methylthioazobenzene (532 nm[117]) in concentrated acids, the maximum in the region of 520 nm was ascribed to the quinone hydrazone tautomer.

Table 2. Absorption spectra of some *p*-aminoazo-compounds in 50% alcoholic hydrochloric acid.

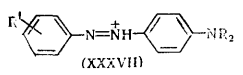
[a] Values not given in Ref. 148.

The absorption spectra of acid solutions of *p*-aminoazo-compounds were analysed in papers by Hantzsch (bibliography in Ref. 2), and the results have since been confirmed by many workers on a large number of compounds (see review[6]). This work demonstrated that the two maxima relate to different compounds. Thus Hantzsch noted long ago that increase in the acid concentration was accompanied by an increase in optical density at the 520-nm maximum but a decrease at the 320-nm maximum[2]. He interpreted this as due to a shift in the equilibrium in favour of the tautomer (XXXVI). A study of a series of methylated[118] and sulphonated[119] derivatives of *p*-dimethylaminoazobenzene showed that, if the introduction of a substituent into the molecule increases the molar extinction coefficient at 520 nm, the coefficient at 320 nm decreases. Conversely, if substitution produces a decrease in the coefficient at 520 nm, the extinction coefficient at 320 nm increases. This agrees well with the view that the solution contains two compounds, whose concentrations are interrelated.

It is now generally accepted that tautomerism occurs in acid solutions of *p*-aminoazo-compounds. Isolated papers in which salt formation by these compounds was regarded as involving addition of a proton solely to the amino-group[120–123] or solely to the azo-group[89,124,125] were

based on incomplete data or erroneous concepts. They have all been subjected to soundly based criticism[6,117,126,127].

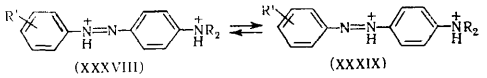
The possibility that the equilibrium may involve a tautomer with a proton attached to the α-nitrogen of the azo-group



(XXXVII)

can be assessed on the basis of the above analysis of the tautomerism of azonium cations (Section IV). Since the amino-group is a strongly electron-donating substituent (values of σ^+ for NH_2, $N(CH_3)_2$, and $N(C_2H_5)_2$ are respectively −1.3, −1.7, and −1.42[128]), it may be supposed that the proportion of the cation (XXXVII) in the tautomeric equilibrium of the conjugate acids of *p*-aminoazo-compounds should in most cases be insignificant. This conclusion is confirmed by quantum-mechanical calculations by the Hückel molecular-orbital method, which have shown that cation (XXXVII) is considerably less favoured energetically than are cations of the types (XXXV) and (XXXVI)[129].

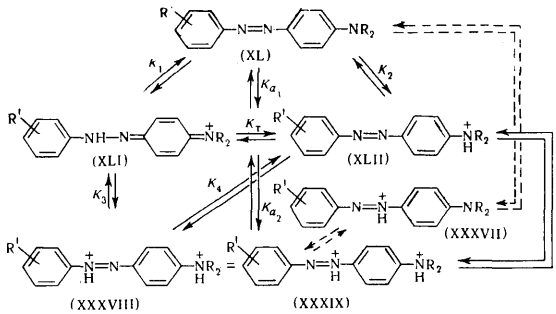
In concentrated mineral acids *p*-aminoazo-compounds add a second proton to form a doubly charged cation, whose structure is usually represented by the formula (XXXVIII). In view of the above discussion on the tautomerism of azonium cations, however, it must be assumed that a tautomeric equilibrium between the doubly charged cations (XXXVIII) and (XXXIX) is established in concentrated acids:



(XXXVIII) (XXXIX)

Whereas conversion of a *p*-aminoazo-compound into a monocationic salt will lead to a deepening of the colour of the solution from yellow to red-violet, addition of a second proton will [also] heighten its colour. The absorption maximum of the doubly charged cation usually lies in the range 410–440 nm,[130] which is approximately where the conjugate acid of azobenzene absorbs (435 nm).

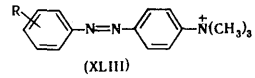
Thus the acid–base and tautomeric transformations of *p*-aminoazo-compounds (XL) can be represented over a wide range of acidities by the scheme



(XXXVIII) (XXXIX)

Values of pK_{a_1} for *p*-aminoazo-compounds vary in the range 1.8–2.5 (in 50% alcohol)[116,120,125,126,131,132]; those of pK_{a_2} lie either between −2.1 and −6.7 (aqueous sulphuric acid)[116,120,125] or between −2.3 and −8.5 (sulphuric acid containing 20 vol.% of alcohol)[95,133]. The acid–base properties of derivatives of *p*-aminoazobenzene have also been studied in aprotic solvents[134,135].

After completion of the first salt formation, changes occur in the solvation sheath of molecules of *p*-aminoazo-compounds in the acidity range $0 \geqslant H_0 \geqslant -1$. These changes are evident in the intensities of the absorption bands in the spectra of these compounds and also of *p*-phenylazophenyltrimethylammonium derivatives



(XLIII)

which are analogues of the ammonium tautomers (XLII)[130,133].

Pal'm and Khaldna[136,137] have studied similar changes with many organic bases in the same acidity range. The processes consist essentially in hydrogen bonding between the *p*-aminoazo-molecules and hydrated protons of the medium, which may be regarded as the initial stage of the second protonation.

Further increase in the acid concentration of the solution is accompanied by a shift in the equilibrium in favour of the tautomer (XLI)[68,126,131,138,139], which continues as far as the second salt formation (Fig. 2).

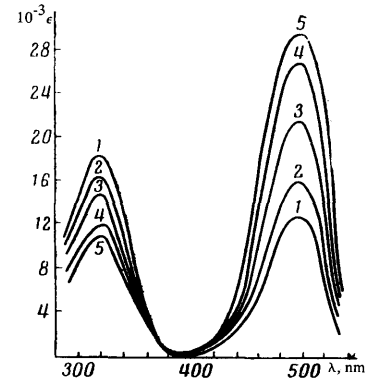


Figure 2. Absorption spectra of *p*-aminoazobenzene in different concentrations (N) of sulphuric acid: *1*) 3.2; *2*) 4.9; *3*) 6.5; *4*) 9.8; *5*) 10.7[160].

Most papers on tautomerism in acid solutions of *p*-aminoazo-compounds published during the past fifteen years had the aim of assessing quantitatively the position of the (XLI) ⇌ (XLII) equilibrium and the influence of substituents on this equilibrium. Since salt formation by *p*-aminoazo-compounds takes place almost instantaneously even at low temperatures[140], attention has been concentrated on physicochemical methods, mainly spectrophotometry. A substantial obstacle was the impossibility of obtaining a solution containing only one of the tautomers¶. It was therefore impossible to determine the molar extinction coefficients of the tautomers and to apply the usual methods of quantitative spectrophotometric analysis to the equilibrium.

¶ As Milliaresi and Izmail'skii assume[141], only the cation (XLI) is present in dichloromethane to which trifluoroacetic acid has been added, but its spectrum undoubtedly differs from the spectrum in aqueous solutions.

One attempt to avoid this difficulty was the method, used by several authors [142-146] and most consistently by Sawicki [117,127,131,147], of characterising the position of the tautomeric equilibrium by the intensity ratio of the absorption maxima corresponding to the two tautomers. The ratio ϵ_C/ϵ_A was employed, where ϵ_C and ϵ_A are the molar extinction coefficients of the solution at the absorption maxima of the quinone hydrazone and the ammonium tautomers respectively. It is easy to show that, if neither tautomer absorbs at the wavelength of maximum absorption by the other,

$$\frac{\varepsilon_C}{\varepsilon_A} = \frac{[XLI]}{[XLII]} \cdot \frac{\varepsilon_{XLI}}{\varepsilon_{XLII}} = K_T \frac{\varepsilon_{XLI}}{\varepsilon_{XLII}} \qquad (10)$$

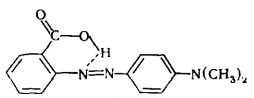
where $\epsilon_{(XLI)}$ and $\epsilon_{(XLII)}$ are the molar extinction coefficients of the tautomers at their maxima. The use of ϵ_C/ϵ_A instead of K_T is based on the postulate that the ratio $\epsilon_{(XLI)}/\epsilon_{(XLII)}$ is either constant or almost constant for all the compounds investigated.

Although such a postulate is admittedly inaccurate, it has helped to reveal several qualitative features of the effect of substituents in different positions in the molecule on the (XLI) ⇌ (XLII) equilibrium. Table 2 shows that replacing the hydrogen atoms of the amino-group by methyl groups creates a decrease in the proportion of the ammonium tautomer, probably owing to a diminution in its stabilisation by solvation energy [118]. Substitution of ethyl for methyl groups lowers ϵ_C/ϵ_A as a consequence of the larger positive inductive effect of ethyl groups, and perhaps partial emergence of the diethylamino-group from the plane of the molecule.

Substituents at position 3 or 5 in dimethylaminoazobenzene deflect the dimethylamino-group out of the plane of the benzene ring, thereby destroying its conjugation with the general π-system. Therefore the proportion of the quinone hydrazone tautomer falls with increase in the bulk of the substituent (compounds 5–7 in Table 2). This effect is present, although somewhat weaker, in aminoazobenzene derivatives [145]†.

Methyl groups at positions 2 and 6 greatly increase azo-protonation, which is explained by an increase in electron density on the β-nitrogen atom of the azo-group due to the $+I$-effect and hyperconjugation of the methyl groups [131]. In contrast, 2′-substitution sharply diminishes the proportion of the quinone hydrazone tautomer (compounds 10 and 11 in Table 2), which is interpreted by all authors as due to steric hindrance to attack by protons on the β-nitrogen atom, and also as indirect evidence of addition of the proton to the β- and not to the α-nitrogen atom. Furthermore, 2′-methyl groups somewhat disrupt the coplanarity of the molecule [104].

An exception among 2′-substituted derivatives is Methyl Red (No. 12 in Table 2). The sharp increase in ϵ_C/ϵ_A in this case is explained by the presence of an intramolecular hydrogen bond [142]



(XLIV)

Kipriyanov and Zhmurova [148] noted that even the 3-alkylation of (XLIV) does not appreciably diminish the proportion of the quinone hydrazone tautomer.

† It is interesting that 4-dimethylamino-3,5-dimethylazobenzene, which adds a proton only at the amino-group, does not possess the carcinogenic properties characteristic of most *p*-aminoazo-compounds [145].

The variation in ϵ_C/ϵ_A could not be used to indicate the effect of 3′-substituents, since the range of observable changes was narrow (compounds 13 and 14 in Table 2). Although this range is quite wide with 4′-substituted compounds, the conclusions reached by different workers [118,119,131,143] on the nature of the effect of 4′-substituents are often contradictory. The probable reason is that the constancy of the ratio $\epsilon_{(XLI)}/\epsilon_{(XLII)}$ originally postulated does not hold for these compounds. The most reliable conclusion is that the equilibrium (XLI) ⇌ (XLII) is displaced by electron-donor substituents in favour of the ammonium tautomer, and by electron-acceptor substituents towards the quinone hydrazone tautomer (compounds 15 and 16 in Table 2).

In a series of papers Jaffé and his coworkers [126,133,149-152] suggested two methods of using model compounds to determine K_T for the equilibrium (XLI) ⇌ (XLII). The compounds chosen as models were *p*-trimethylammonioazobenzene derivatives (XLIII), which are closely analogous to the ammonium tautomers (XLII). In the first of these methods, since used by Reeves [153], the molar extinction coefficients of the cations (XLII) and (XLIII) were equated:

$$\varepsilon_{(XLII)} = \varepsilon_{(XLIII)} \qquad (11)$$

The concentration of the ammonium tautomer was then calculated from the optical density of the solution of the *p*-aminoazo-compound at the wavelength of maximum absorption by the cation (XLII) (the total concentration of the tautomers was taken to be equal to the initial concentration of the base). This involved the assumption that the tautomer (XLI) did not absorb at this wavelength. Results [133] obtained by this method for a series of derivatives of dimethylaminoazobenzene in aqueous sulphuric acid containing 20 vol.% of alcohol are listed in column A of Table 3. An attempt was also made to allow for possible absorption by the tautomer (XLI) at the wavelength of maximum absorption by the tautomer (XLII). This absorption was assumed to be 2000 $mole^{-1}$ cm^{-1} (from data for 4-amino-3,5-di-t-butylazobenzene, which was considered [126] to add a proton only at the azo-group). These results are listed in column B.

Table 3. Values of K_T for dimethylaminoazobenzene derivatives (aqueous sulphuric acid containing 20 vol.% of alcohol) [133].

NO_2	4.36	7.00	57.9

The second method proposed by Jaffé et al. utilised the pK_{a_2} values. Examining the formation of a dicationic salt of the *p*-aminoazo-compound (disregarding the presence of the tautomer XXXIX), Jaffé showed that

$$K_T = \frac{K_{a_2}}{K_4} - 1 \qquad (12)$$

(for notation see above scheme). Since K_4 was unknown, he assumed that

$$K_4 = K_5 \qquad (13)$$

where K_5 is the experimental equilibrium constant for

Values obtained for K_T by this method are given in column C of Table 3. They exceeded the spectrophotometric values by factors of 3–4. On comparing the results obtained, these workers were inclined to prefer the constants in column C.

A further defect of this work, in addition to the admitted inaccuracy of Jaffé's assumptions (Eqns. 11 and 13), is his neglect of the dependence of the position of tautomeric equilibrium on the concentration of acid in the solution. Nevertheless, the actual fact that the tautomeric equilibrium shifts with change in the acid concentration has enabled a method to be developed for determining K_T without the use of model compounds[154–156]. If the total concentration of tautomers in the solutions whose absorption spectra are illustrated in Fig. 2 is constant,

$$C_{XLI} + C_{XLII} = C_0 \qquad (14)$$

where C_0 is the initial concentration of the base, and Beer's law holds for both tautomers, the optical densities of these solutions are connected by a linear relation[67]. With the absorption maxima of the tautomers as analytical wavelengths (λ_{XLI} and λ_{XLII}), and provided that neither tautomer absorbs at the wavelength of maximum absorption by the other, the equation expressing this relation will be

$$\frac{D^{\lambda_{XLI}}}{\varepsilon^{\lambda_{XLI}}_{XLI}} + \frac{D^{\lambda_{XLII}}}{\varepsilon^{\lambda_{XLII}}_{XLII}} = C_0 d \qquad (15)$$

where the D are the optical densities of these solutions at λ_{XLI} and λ_{XLII}, the ϵ are the molar extinction coefficients of the tautomers (XLI) and (XLII) at these wavelengths, and d is the thickness of the cuvette. The validity of the assumption that one tautomer does not absorb at the wavelength of maximum absorption by the other can be checked by the method suggested in Ref. 67. Equation (15) enables us to find (either analytically or graphically) the quantities

$$D^{\lambda_{XLI}}_{max} = \varepsilon^{\lambda_{XLII}}_{XLI} C_0 d \qquad (16)$$

$$D^{\lambda_{XLII}}_{max} = \varepsilon^{\lambda_{XLII}}_{XLII} C_0 d \qquad (17)$$

which give the optical density of the solution at ϵ_{XLI} and ϵ_{XLII} if the equilibrium is completely displaced towards tautomer (XLI) (i.e. when $C_{XLI} = C_0$) or tautomer (XLII) (when $C_{XLII} = C_0$). After (16) and (17) have been evaluated, determining the molar extinction coefficients of the tautomers and calculating K_T in all the solutions investigated present no difficulty.

This method has been used to study the tautomeric equilibrium of several 3′- and 4′-substituted derivatives of aminoazobenzene, dimethylaminoazobenzene, and diethylaminoazobenzene[95,156,157]. Table 4 shows that 3′-substituents have little effect on the position of tautomeric equilibrium. In conformity with the discussion in Section IV, therefore, the dependence of pK_{a_1} on σ is linear for 3′-substituted dimethylaminoazobenzene[156]. The small changes in K_T with variation in the 3′-substitution from the nitro- to the methoxy-group suggests that the equilibrium (XLI) ⇌ (XLII) is insensitive to the inductive effect of the substituent.

This conclusion is supported by the correlations of $\lg K_T$ with the difference $\sigma^+ - \sigma_I$ or $\sigma^- - \sigma_I$ for +C and –C substituents respectively, which are found with 4′-substituted derivatives of dimethylaminoazobenzene and diethylaminoazobenzene[95,156] (Fig. 3). The dominant role of conjugation in the effect of substituents on the position of the tautomeric equilibrium of conjugate acids of *p*-aminoazo-compounds is consistent with the correlation found by Isaacs and Jaffé[133] between $\lg K_T$ and the σ^+- or σ^--constants ($r = 0.968$) for the approximate values of K_T determined by them for 4′-substituted dimethylaminoazobenzenes (Table 3, column C).

Table 4. Values of K_T with $H_0 = -1.20$ and parameters of Eqn. (18) for certain *p*-aminoazo-compounds[95] (values of H_0 from Ref. 159).

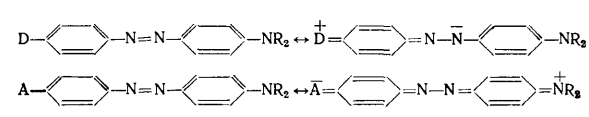
The simultaneous use in the correlation of values of σ^+ for electron-donor substituents and of σ^- for electron-acceptor substituents is explained by the presence of two reactive centres of opposite character—+C (amino-group) and –C (azo-group)—in the molecules of *p*-aminoazo-compounds. Electron-donor substituents (D) may undergo conjugation with the azo-group, and electron-acceptor substituents (A) with the amino-group:



This hypothesis explains several peculiarities of the behaviour of *p*-aminoazo-compounds containing strong –C substituents at position 4′[125,133,146]. Such compounds also exhibit an enhanced tendency to association both in solution[132,146] and in the gas phase[158].

The above effects of substituents on the (XLI) ⇌ (XLII) tautomeric equilibrium are consistent with calculations by the Hückel molecular-orbital method. Pullman and Baudel[161,162] showed that the proportion of a tautomer in the mixture varies directly with the electron density on the corresponding reactive centre. An attempt to assess separately conjugation and inductive effects on the tautomeric equilibrium has shown[129] that the π-electron densities on the reactive centres, and also the differences in delocalisation energies of the tautomers, are relatively insensitive to the inductive effect of the substituents, and also to the presence of substituents in the 3′ position.

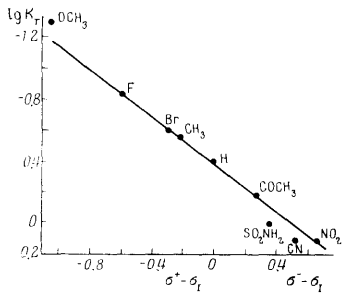


Figure 3. Dependence of $\lg K_T$ of 4′-substituted diethylaminoazobenzenes on $\sigma^+ - \sigma_I$ for electron-donor substituents and $\sigma^- - \sigma_I$ for electron-acceptor substituents[160].

The tautomeric equilibrium in acid solutions of *p*-aminoazo-compounds has been investigated quantitatively also by means of the proton magnetic resonance spectra[163]. The model compound used was 4-dimethylamino-3-methyl-3′-nitroazobenzene, which was assumed to add a proton solely at the amino-group. The calculation was based on the chemical shifts of the 2,6- and 3,5-protons and also on the position of the signal due to the *N*-methyl group. The results agree qualitatively with the above spectrophotometric data. This method could not be extended to a wide range of compounds owing to the relative inaccuracy (10–20%) of the constants obtained from the proton magnetic resonance spectra and to the inadequate solubility of the compounds.

Determination of the tautomeric equilibrium constants from the absorption spectra of solutions of *p*-aminoazo-compounds in different acid concentrations[154-156] has shown that $\lg K_T$ for the (XLI) ⇌ (XLII) equilibrium varies linearly[95,156,157] with the acidity function of the solution:

$$\lg K_T = a + b \cdot H_0 \qquad (18)$$

Parameters in Eqn. (18) are given in Table 4 for several *p*-aminoazo-compounds.

The dependence of the position of tautomeric equilibrium on the acid concentration of the solution is explained by the fact that the tautomers (XLI) and (XLII) belong to different chemical classes. Therefore their activity coefficients $f_{(XLI)}$ and $f_{(XLII)}$ vary differently with change in the properties of the medium, which in turn leads to a change in the concentration constant found for the tautomeric equilibrium:

$$K_T = K_T^* \frac{f_{XLII}}{f_{XLI}} = \frac{K_2^*}{K_1^*} \frac{f_{XLII}}{f_{XLI}} \qquad (19)$$

in which K_T* is the thermodynamic tautomeric equilibrium constant. Since K_T* is related to the thermodynamic constants K_1* and K_2* of the equilibria (XL) + H^+ ⇌ (XLI) and (XL) + H^+ ⇌ (XLII), we can express K_1* and K_2* in terms of the concentrations and the activity coefficients of the species involved in the equilibrium, substitute in Eqn. (19), take logarithms, and rearrange to obtain

$$\lg K_T^* = \lg \frac{[XLI]}{[XLII]} + \lg \frac{[H^+] \cdot f_{H^+} \cdot f_{(XL)}}{f_{XLII}} - \lg \frac{[H^+] \cdot f_{H^+} \cdot f_{XL}}{f_{XLI}} \qquad (20)$$

As

$$f_{H^+} \cdot [H^+] = a_{H^+} \qquad (21)$$

we can write from the definition of acidity function[164]

$$-\lg \left(a_{H^+} \cdot \frac{f_{XL}}{f_{XLII}} \right) = H_0' \qquad (22)$$

$$-\lg \left(a_{H^+} \cdot \frac{f_{XL}}{f_{XLI}} \right) = H_0 \qquad (23)$$

where H_0 and H_0' are acidity functions based on indicators which are respectively azo-compounds and aniline derivatives. Substituting (22) and (23) in (20) and rearranging, we obtain

$$\lg K_T = \lg K_T^* + (H_0 - H_0') \qquad (24)$$

Most acidity functions vary linearly with the normality of the acid in the range employed (3–20 *N*). Therefore Eqn. (18) follows directly from (24). Furthermore, $\lg K_T$ is a linear function of the acid normality[165].

The dependence of the position of tautomeric equilibrium on the acid concentration of the solution established for *p*-aminoazo-compounds, and also the linear relation between $\lg K_T$ and the normality and acidity function of the solution, should apply generally to any prototropic (or other) equilibria involving reactive centres of different chemical types. The slope of the relation (18) will then depend on the difference $H_0 - H_0'$ in Eqn. (24). This conclusion is not, of course, valid for the equilibrium (XXV) ⇌ (XXVI), for the reactive centres in these species are of different types.

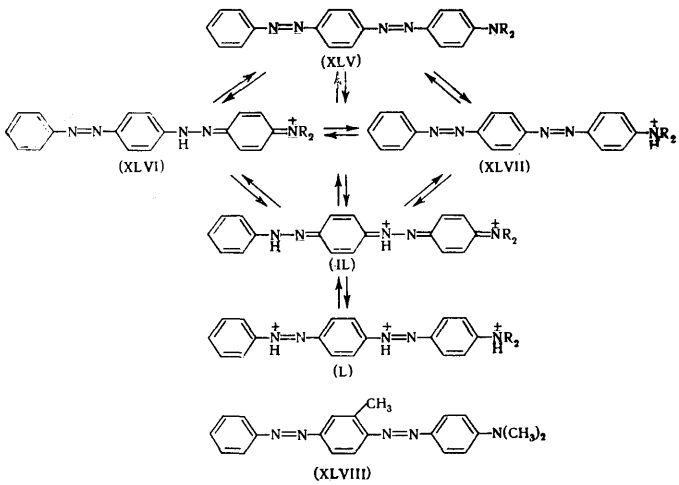
Since the basic strengths of primary and tertiary aromatic amines are described by different acidity functions[166], different values of the coefficient *b* in Eqn. (18) apply to aminoazobenzene and its derivatives and to derivatives of dimethyl- and diethyl-aminoazobenzenes (Table 4). The mean value for the latter is[95] $b = 0.103$: i.e. increase in the acidity function of the solution by unity on the H_0 scale is accompanied by an average increase of about 30% in the value of K_T for dimethyl- and diethyl-aminoazobenzene derivatives. This is probably the reason for the difference in the values obtained for K_T (Table 3) spectrophotometrically by Jaffé and from pK_{a_2} values determined at higher acid concentrations. The close similarity in the coefficients *b* in Eqn. (18) for derivatives of dimethyl- and diethyl-aminoazobenzene is apparent also in their conforming to Kabachnik's formula[167]

$$pK_{T_1} = pK_{T_2} + \text{const} \qquad (25)$$

relating the positions of tautomeric equilibrium in different solvents[156,157]. In this case K_{T_1} and K_{T_2} pertain to solutions of different acid concentrations.

The position of tautomeric equilibrium in the conjugate acids of *p*-aminoazo-compounds is influenced by additions of various salts and also by the ionic strength of the solution[146,168]. This effect has been explained by variation in the strength of hydrogen bonds between the azo-compounds and water molecules[168], and also by association phenomena[146]. However, a more probable reason is variation in the acidity of the medium on addition of the salts[169].

The electron density of the azo-group in *p*-aminoazo-compounds is increased in an excited state[170], so that the tautomeric equilibrium should be completely displaced to the quinone hydrazone tautomer ($K_T \simeq 10^{26}$).[171]



Amino-derivatives of bisphenylazobenzene (XLV), which contain five potential centres of basicity, form a special class of *p*-aminoazo-compounds. Spectrophotometric investigations[172,173] show that addition of the first proton to (XLV) yields a mixture of tautomeric cations (XLVI) and (XLVII) (λ_{max} = 540 and 355 nm). Addition of the proton to the β-nitrogen of the azo-group is proved by the marked displacement of the tautomeric equilibrium towards the ammonium tautomer on passing to 2′-methyl-4′-phenylazo-4-dimethylaminoazobenzene (XLVIII), in which the β-nitrogen atom is shielded by the methyl group.

Addition of a second proton (in 11–22 *N* sulphuric acid) is accompanied by a considerable deepening of the colour of the solution (λ_{max} = 630 nm), owing to formation of a doubly charged cation (XLIX). No other tautomeric forms are detected in these solutions. Finally, a triply charged cation (L) (λ_{max} = 500 nm) is formed in concentrated sulphuric acid. All the above characteristics of *p*-aminoazobenzene derivatives apply to the equilibrium (XLVI) ⇌ (XLVII)[173].

Aminoazo-compounds form complexes with Lewis acids[106,174-177], whose absorption spectra are completely analogous to those of acid solutions of *p*-aminoazo-compounds. From this Gutmann and Steininger concluded[106] that a mixture of two tautomeric forms is also formed on interaction with Lewis acids.

Prototropic tautomeric transitions involving the azo-group have been reported for *p*-aminoazo-compounds of the naphthalene series[131], various *N*-substituted aminoazobenzenes[111,142,178], and also amino-derivatives of phenylazoazulene[179].

Cyclocarbosiloxanes

N.S.Nametkin, T.Kh.Islamov, L.E.Gusel'nikov, and V.M.Vdovin

Cyclocarbosiloxanes are a comparatively new class of heterocyclic silicon compounds[1,2] the cyclic skeleton of which consists of alternating siloxane and carbon groups. During the last decade, considerable advances have been made in the chemistry of cyclocarbosiloxanes.
The present review considers the methods of preparative synthesis of cyclocarbosiloxanes and certain reactions leading to the formation of carbosiloxane rings (including reactions in complex polycondensation and polymerisation systems), their physical properties and structure, and also chemical properties. The latter have been divided into reactions involving the cleavage of the heterocyclic skeleton and the reactions of groups and atoms functioning as substituents in the carbosiloxane ring. The polymerisation of cyclocarbosiloxanes, thermal reactions in the gas phase, and dissociations on electron impact have been considered separately.
The bibliography includes 135 references.

I. INTRODUCTION

Cyclocarbosiloxanes (CCS) are compounds whose cyclic skeleton consists of Si–O, Si–C, and sometimes C–C bonds, i.e. the main structural elements of these compounds are siloxane and carbosilane groups.

Owing to the presence of the cyclic siloxane groups, cyclocarbosiloxanes are capable of polymerisation with ring opening, forming polymers, the main chains of which are made up of siloxane and carbosilane units. According to the data of a number of patents and publications, the characteristic features of these polymers are high thermal[3-11] and chemical[3] stabilities, resistance to a thermal oxidation[9,10,12], resistance to radiation[6], and also improved physicomechanical properties[6,10] compared with polysiloxanes. Carbosiloxane polymers can be used as brake fluids[5,13], moulding materials[13,14], rubbers[13,14], films[8,13,14], oriented fibres[14], and binding resins in the manufacture of fibreglass[15].

In addition, the study of the structure, the nature of the bonds, and the properties of this new class of heterocyclic silicon compounds with a mixed organic–inorganic skeleton is of considerable interest.

The study of the processes involving the formation of cyclocarbosiloxanes makes it possible to estimate in turn the effect of factors such as the number of carbon atoms and silicon functional groups in the initial molecule, their distribution, the inductive and steric effects of the substituents, etc. on the capacity of the molecule for cyclisation. The knowledge of these factors is extremely important in the choice of the optimal monomers for the preparation of polycondensation polymeric materials based on polyfunctional bridge-type silanes, which are of practical value, and makes it possible to assess the structure of the products formed.

The first mention of the synthesis of cyclocarbosiloxanes was made in 1947,[16] but neither the constants of the compounds obtained nor the reaction conditions were quoted. Soon after this an eight-membered heterocycle, 1,1,3,3,5,5,7,7-octamethyl-2,6-dioxa-1,3,5,7-tetrasilacyclo-octane, was obtained; this was the first characterised representative of the class of cyclocarbosiloxanes[3,17].

Among the cyclocarbosiloxanes known at the present time, compounds containing five and more atoms in the heterocycle have been described. The simplest representatives of cyclocarbosiloxanes with the four-membered 2-oxa-1,3-disilacyclobutane ring are probably chemically and thermally unstable, as a result of which all attempts at their synthesis have so far resulted in the formation of cyclic dimers or more rarely polymeric products.

This paper is a first attempt at an exhaustive review and a systematic account of data concerning compounds of the above type published in journal articles or patents.

II. METHODS OF SYNTHESIS

The most common methods for the formation of carbosiloxane rings are based on the hydrolytic and joint hydrolytic condensation of bridge compounds containing hydrolysable silicon functional groups Si–X (X = Cl, F, H, OH, OCH_3, or OC_2H_5), heterofunctional condensation of bridge-type silanes with other silanes or siloxanes, organometallic synthesis based on siloxanes containing halogen–carbon and halogen–silicon bonds, reaction of acetylenic compounds with dihydrodisiloxanes (cycloaddition), synthesis via malonic ester derivatives, and thermal and thermocatalytic rearrangement of linear carbosiloxanes. In addition, a number of reactions of cyclocarbosiloxanes are known, which, although resulting in the formation of new compounds of this class, do not involve the formation or rearrangement of the cyclic skeleton of the molecule. These reactions are considered in Section IV dealing with the chemical properties of cyclocarbosiloxanes.

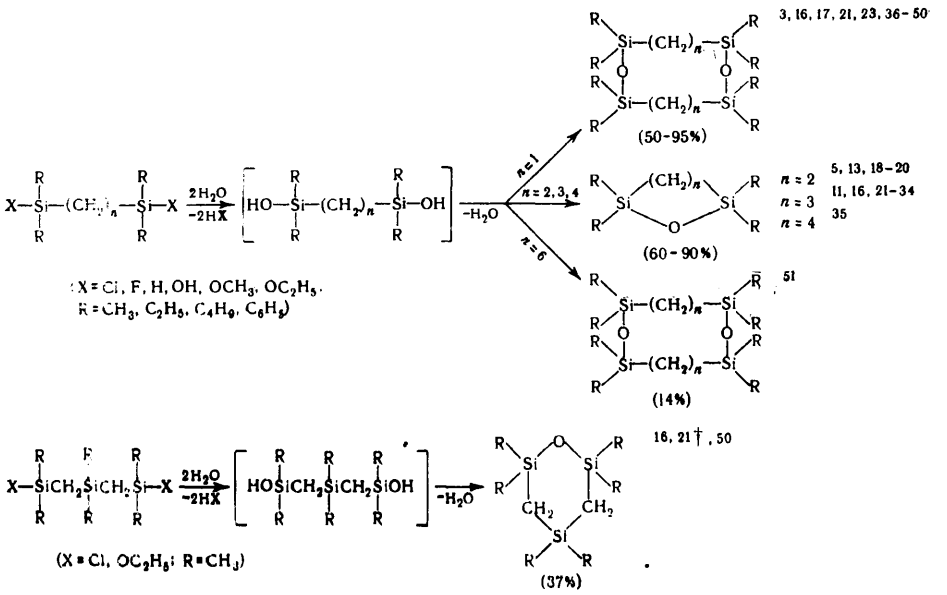
1. HYDROLYTIC CONDENSATION OF POLYFUNCTIONAL ORGANOSILICON COMPOUNDS WITH A CARBON BRIDGE BETWEEN SILICON ATOMS°

The hydrolytic condensation of polyfunctional organosilicon compounds $X_nR_{3-n}Si-A-SiR_{3-n}X_n$ [where A is a

carbon bridge of the type $(CH_2)_n$, $-(\langle\rangle)$, etc.] has been used to synthesise a large number of five-,[5,13,18-20] six-,[11,16,21-34] seven-,[35] and eight-membered[3,16,17,21,23,36-50] cyclocarbosiloxanes, cyclocarbosiloxanes with a large number of units[51], and polycyclic cyclocarbosiloxanes[11,30-32,45,46,52-55].

a. Difunctional Compounds

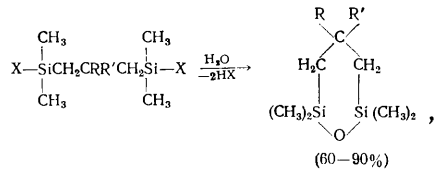
The hydrolysis of difunctional bridge-type di- or trisilanes leads to the formation of cyclocarbosiloxanes according to the following mechanism:



The condensation reaction is carried out at moderate temperatures in the bulk phase of the reactant or in solvents, frequently in the presence of an acceptor of the hydrogen halide evolved; intermolecular condensation of the $\alpha\omega$-silanediol, leading to the formation of linear carbosiloxane oligomers, is a competing reaction.

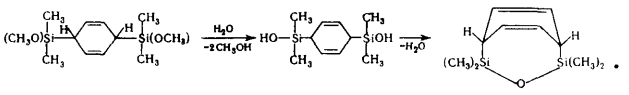
The yield of cyclocarbosiloxane depends on the concentration of the difunctional compound in the reaction mixture: on dilution, intermolecular condensation of the intermediate silanediols is facilitated. For example, the yield of 1,1,3,3-tetramethyl-2-oxa-1,3-disilacycloheptane[35] increases by a factor of two, from 43 to 85%, on dilution of the reaction mixture. In the hydrolysis of 1,3-bis-(chlorodimethylsilyl)propane in ether, the yield of the cyclic product is 60–70%;[11] in similar reactions of 1,2-bis(chlorodimethylsilyl)ethane[18], but in the absence of solvent, the oligomer is mainly formed. The latter may be converted into a cyclocarbosiloxane by thermal catalytic rearrangement (see p. 116).

The hydrolysis of bridge-type compounds with a substituted carbon atom results in the formation of the corresponding C-substituted cyclocarbosiloxanes[24-27]:

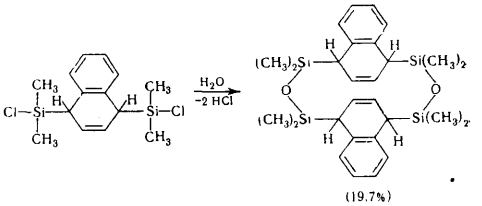


where X = Cl or OC_2H_5, R = CN or H, and R′ = COOH, COOK, $COOCH_3$, or $COOC_2H_5$.

If there is a cyclic group between the silicon atoms, the cyclisation process takes place with greater difficulty—the yield of the products of the intramolecular cyclisation of silanediols diminishes. Thus in the hydrolysis and condensation of 3,6-bis(methoxydimethylsilyl)-hexa-1,4-diene the yield of 2,2,4,4-tetramethyl-3-oxa-2,4-bicyclo-[3,2,2]nona-6,8-diene is only 20%:[56]



When the cyclohexene ring is condensed with an aromatic ring [for example, when the starting material is 1,4-bis(chlorodimethylsilyl)-1,4-dihydronaphthalene], bimolecular condensation products are formed[57]:

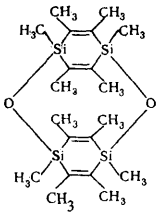


In this case the intramolecular condensation product was not detected.

If the silicon atoms in the difunctional compound are part of a cyclohexadiene ring, cyclocarbosiloxanes with a single siloxane group are not detected even when the reaction is carried out in a highly dilute solution and the corresponding cyclic dimer is formed in a yield of 1–5%.

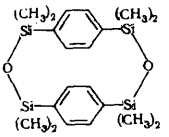
† The formula of a twelve-membered cyclocarbosiloxane $\{[Si(CH_3)_2CH_2]_2Si(CH_3)_2O\}_2$ is attributed to the product, but is probably erroneous since the physical constants of this compound are identical with those of the six-membered heterocycle[50].

Thus, when 1,4-dichlorohexamethyl-1,4-disilacyclohexa-2,5-diene is treated with anhydrous hydrazine, a certain amount of a [1,1]paracyclophane analogue is formed together with the polymer[58]:



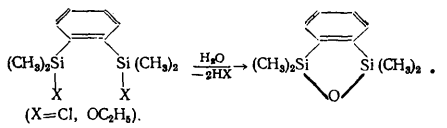
The same compound was synthesised by the reaction of equimolar amounts of 1,4-dichlorohexamethyl-1,4-disilacyclohexa-2,5-diene and 1,4-dihydroxyhexamethyl-1,4-disilacyclohexa-2,5-diene.

It has been shown[14,59] that in the hydrolysis of difunctional compounds with a *para*-substituted aromatic bridge, for example 1,4-bis(chlorodimethylsilyl)benzene, cyclic compounds are not formed at all; the main reaction product is the corresponding silanediol which forms a polymer on dehydration. However, McKay[60], who carried out this reaction in the presence of trifluoroacetic acid and in dilute benzene solution, succeeded in isolating a cyclic product of the intermolecular condensation of *p*-phenylenebis(dimethylsilanol):



It is noteworthy that later attempts to obtain this compound[61] by hydrolysing *p*-phenylenebis(dimethylsilane) or by the condensation of *p*-phenylenebis(dimethylsilanol) were unsuccessful even in dilute solution; the main reaction products were linear polymers with a molecular weight of $(2-7)\times 10^3$, the thermal-catalytic rearrangement of which results in the formation of the cyclic dimer mentioned above (see p. 116).

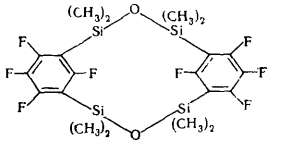
In contrast to *p*-disilyl-substituted benzene, in the hydrolysis of *o*-substituted compounds, for example *o*-bis(chloroethoxydimethylsilyl)benzene[62,63], a certain amount of an intramolecular cyclisation product is formed:



(X=Cl, OC_2H_5).

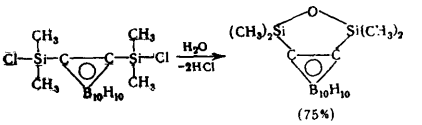
A similar compound with a perfluorophenylene ring was obtained by the hydrolysis of *o*-tetrafluorophenylenebis-(dimethylsilane).[64]

When hydrochloric acid is allowed to react with *m*-tetrafluorophenylenebis(dimethylsilanol), or on hydrolytic condensation of *m*-chlorotetrafluorophenylenedimethylsilane, or on intramolecular condensation of 1,1,3,3-tetramethyl-1,3-bis(tetrafluorophenylenedimethylsilane)disiloxane, a dimeric cyclocarbosiloxane is formed[64,65]:



(1-10%)

A cyclic oxadisilacarborane was also obtained by hydrolytic condensation[66]:

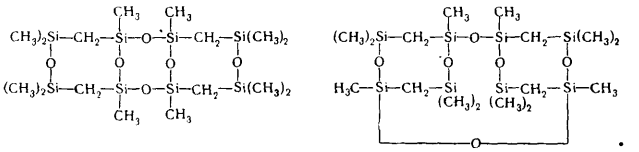


(75%)

When a benzene solution of 1-[*m*-(ethoxydimethylsilyl)-phenyl]-3-[*p*-(ethoxydimethylsilyl)phenyl]hexafluoropropane is refluxed[67,68] in 50% of sulphuric acid, a polymer is formed, which can be converted into the corresponding cyclocarbosiloxane (see p. 116).

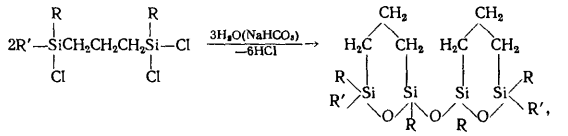
b. Trifunctional Compounds

Hydrolytic condensation of compounds with carbon bridges between silicon atoms and with more than two hydrolysable groups leads as a rule to the formation of polycyclic cyclocarbosiloxanes[11,30-32,45,46,52-55]. Thus hydrolysis of (ethoxydimethylsilyl)(diethoxymethylsilyl)-methane in ethereal solution leads to the formation of a compound in 20% yield, to which the following possible formulae have been ascribed:



According to the authors[45,46], the first structure is more likely.

Hydrolysis of trichlorodisilanes with a trimethylene bridge in ethereal solution results in the formation of bicyclic carbosiloxanes[11,30-32]:

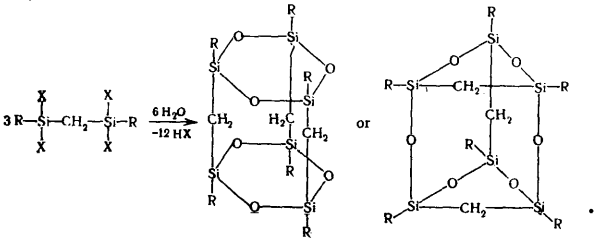


where R = R′ = CH_3 (62.5%) or R = CH_3 and R′ = C_6H_5.

Hydrolysis of an analogous compound with a phenylene bridge—1-chloromethylphenylsilyl-4-dichlorophenylsilylbenzene—in an acid medium does not result in the formation of a bicyclic compound of the above type, an oligomer being formed instead[55].

c. Tetrafunctional Compounds

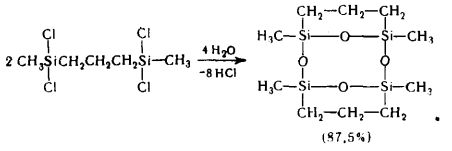
Hydrolytic condensation of symmetrical tetrafunctional disilylmethanes[45,46,52,53,69] yields cyclocarbosiloxanes with a "cage" structure:



Although the authors[45,46,52] give preference to the first structure, the second formula is probably more likely,

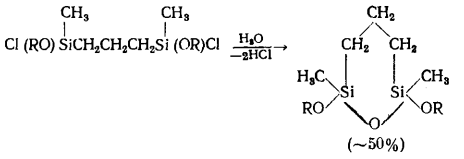
since the ^1H NMR spectra of this compound show two signals due to nonequivalent methylene protons[53,69]: in the first structure all the methylene protons should be equivalent.

A tricyclic cyclocarbosiloxane has been obtained in a high yield by the hydrolytic condensation in a neutral medium of a tetrafunctional disilane with a trimethylene bridge:



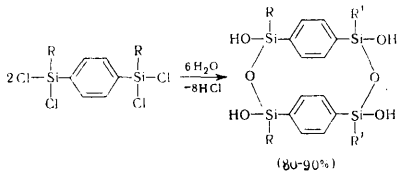
In alkaline and acid media, the yields of this compound were reduced to 60.5 and 45% respectively[11,31,32].

Hydrolysis of 1,3-bis(alkoxychloromethylsilyl)propanes in the presence of a hydrogen chloride acceptor (triethylamine or its mixture with urea) yields 2,6-dialkoxy-2,6-dimethyl-1-oxa-2,6-disilacyclohexanes[11,31,32], i.e. in this case the compound behaves like difunctional disilanes:



In the presence of sodium bicarbonate, the above tricyclic compound is mainly formed.

Hydrolytic condensation of silicon compounds with *p*-phenylene bridges [for example 1,4-bis(dichloromethylsilyl)benzene] leads to an insoluble polymer; individual cyclocarbosiloxanes were not isolated[10]. However, a more detailed study of this process[54,55] showed that the intermediates in the reaction are cyclocarbosiloxanes containing hydroxy-groups:



(R = R′ = CH_3 or C_6H_5; R = CH_3, R′ = C_6H_5), which give rise to di- and poly-cyclic compounds on prolonged standing in solution.

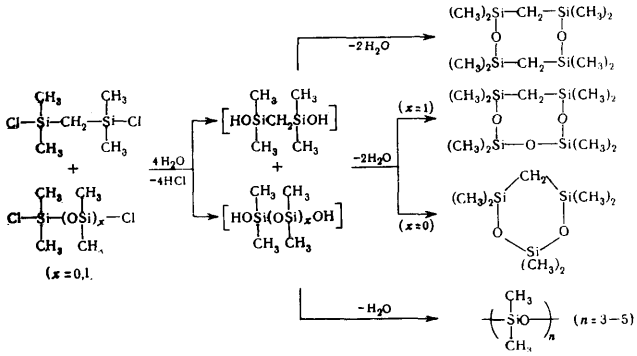
If the hydrolysis of 1,4-bis(dichloromethylsilyl)benzene is carried out in the presence of chlorotrimethylsilane, the halogen is partly replaced by the trimethylsiloxy-group; complete substitution of the chlorine can be achieved by treatment with an excess of hydroxytrimethylsilane in the presence of ammonia[70].

d. Pentafunctional Compounds

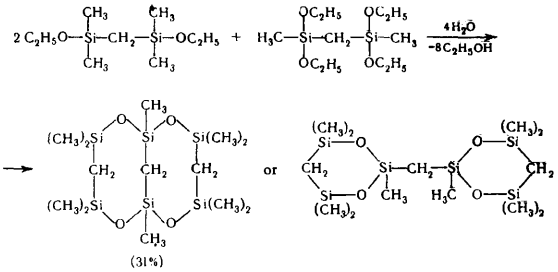
Hydrolysis of (diethoxymethylsilyl)(triethoxysilyl)-methane yielded an infusible and insoluble polymers in a yield of 96%, the structure of which could not be established[45,46]. It has been suggested that it contains cyclocarbosiloxane units of the "cage" type built into a three-dimensional network.

2. JOINT HYDROLYTIC AND HETEROFUNCTIONAL CONDENSATION

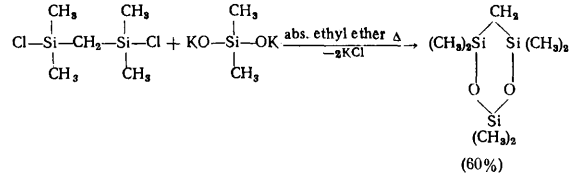
The possibility of obtaining cyclocarbosiloxanes by the joint hydrolytic condensation of bis(chlorodimethylsilyl)-methane with dichlorodimethylsilane or 1,3-dichloro-1,1,3,3-tetramethyldisiloxane had been investigated[50,71]. The composition of the joint hydrolysis product depends on the component ratio and the amount of hydrolysing agent. The optimal conditions for the preparation of 1,1,3,3,5,5-hexamethyl-2,4-dioxa-1,3,5-trisilacyclohexane (yield 64.5%) are equimolar proportions of the dichlorides and an excess of water; the maximum yield of 1,1,3,3,5,5,7,7-oxamethyl-2,4,6-trioxa-1,3,5,7-tetrasilacyclo-octane (about 40%) is also attained for equimolar proportions of the initial compounds and a stoichiometric amount of the hydrolysing agent. The principal reactions occurring on joint hydrolysis are shown below:



The joint hydrolysis of tetrafunctional compounds with di- and tri-functional silicon derivatives has been described. For example, the following possible structures have been attributed to the crystalline products obtained by the joint hydrolytic condensation of bis(ethoxydimethylsilyl)methane with bis(diethoxymethylsilyl)-methane[45,46]:

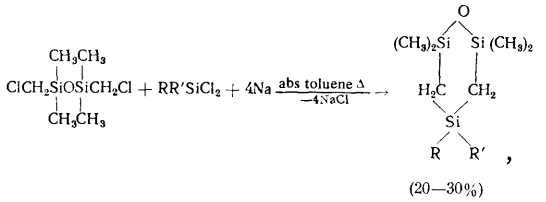


According to the authors[45,46], the first formula is more likely. Heterofunctional condensation has been hardly used for the synthesis of cyclocarbosiloxanes. Only one example of this type of synthesis is known. When bis-(chlorodimethylsilyl)methane was allowed to react with potassium dimethylsilanediolate, the main product was 1,1,3,3,5,5-hexamethyl-2,4-dioxa-1,3,5-trisilacyclo-hexane[50,71]:



3. ORGANOMETALLIC SYNTHESIS

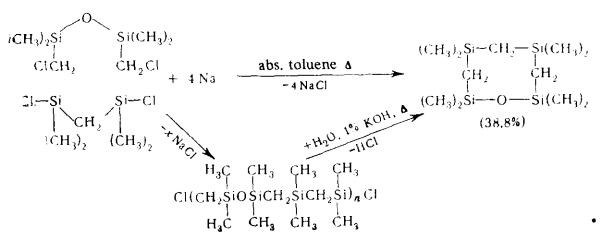
When symmetrical bis(chloromethyl)tetramethyldisiloxane and aryl(alkyl)dichlorosilanes reacted with metallic sodium, a number of six-membered cyclocarbosiloxanes were obtained[72]:



where R = R′ = CH_3 or C_2H_5 and R = CH_3 and R′ = C_6H_5. In addition, considerable amounts of oligomers are formed, which can be converted into six-membered cyclocarbosiloxane by hydrolysis and subsequent thermal catalytic rearrangement of the hydrolysate; in this case the overall yield of cyclocarbosiloxanes may be increased approximately to 70%.[50,73]

A condensation reaction with magnesium similar to that described above yielded a cyclocarbosiloxane (R = R′ = CH_3) in a yield of about 45%.[50]

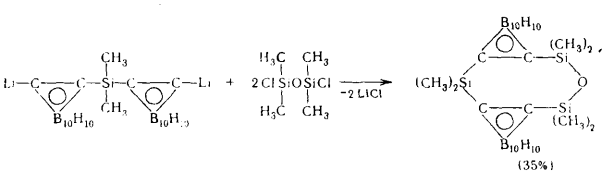
If instead of dichlorodimethylsilane one employs bis(chlorodimethylsilyl)methane, the main reaction product is 1,1,3,5,5,7,7-octamethyl-4-oxa-1,3,5,7-tetrasilacyclooctane[49,50,73]:



On condensation of 1,5-bis(chloromethyl)-1,1,3,3,5,5-hexamethyltrisiloxane and dichlorodimethylsilane in the presence of metallic sodium or magnesium, 1,1,3,3,5,5,7,7-octamethyl-2,4-dioxa-1,3,5,7-tetrasilacyclo-octane is hardly formed[50]. It was found that in both cases the main reaction products are six-membered cyclocarbosiloxanes. Their formation can probably be accounted for by rearrangements of the siloxane bonds under the reaction conditions.

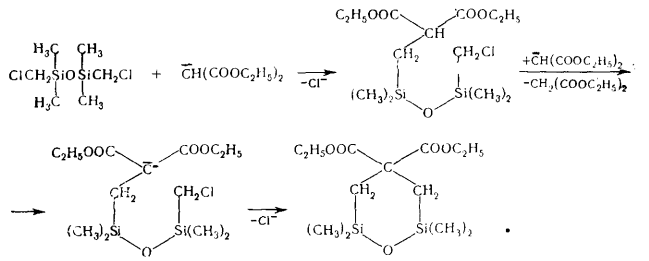
The possibility of the cyclisation of chloromethyldisiloxanes containing a halogen or an alkoxy-group at the silicon atom [$ClCH_2Si(CH_3)_2OSi(CH_3)_2X$; X = Cl or OC_2H_5] with metallic magnesium has been investigated[50]. The formation of an intramolecular cyclisation product of the initial compound—1,1,3,3-tetramethyl-2-oxa-1,3-disilacyclobutane—was not observed. The main reaction products were 6- and 8-membered methylenesiloxane cyclocarbosiloxanes.

A cyclocarbosiloxane with two carborane rings[74] was obtained via a dilithium derivative by the following reaction:

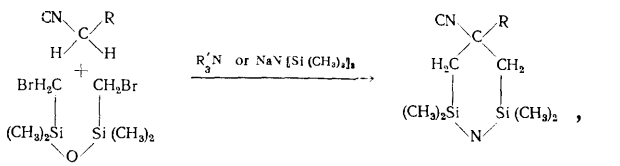


4. SYNTHESIS OF CYCLOCARBOSILOXANES BY THE CONDENSATION OF BIS(HALOGENOMETHYL)DISILOXANES WITH COMPOUNDS CONTAINING ACTIVE HYDROGEN ATOMS

The reaction of *sym*-bis(iodomethyl)tetramethyldisiloxane with sodiomalonic ester yielded a cyclic diester—1,1-diethoxycarbonyl-3,3,5,5-tetramethyl-4-oxa-3,5-disilacyclohexane[75] (yield 61%). The use of the less reactive *sym*-bis(chloromethyl)tetramethyldisiloxane reduced the yield of this heterocycle to 28%. The following reaction mechanism has been proposed:



C-substituted six-membered cyclocarbosiloxanes are formed also on condensation of *sym*-bis(bromomethyl)-tetramethyldisiloxane with cyanoacetic esters[26] (in the presence of tertiary amines) or with nitriles[27] [in the presence of sodium bis(trimethylsilyl)amide]:



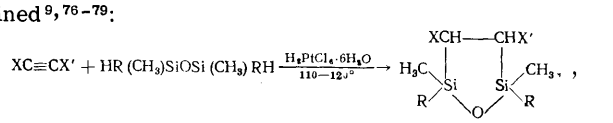
where R = H, CH_3, CN, $COOCH_3$, or $COOC_2H_5$.

In the presence of triethylamine, the condensation with cyanoacetic ester taking place with a yield of about 60%, monoalkylated products being virtually absent from the reaction mixture.

When acetonitrile and sodium bis(trimethylsilyl)amide are employed, the yield of 4-cyano-2,2,6,6-tetramethyl-1-oxa-2,6-disilacyclohexane is 60—70%. It is interesting that a reagent such as sodium bis(trimethylsilyl)amide gives rise to hardly any side reactions (cleavage of the Si—C bond in $Si-CH_2Br$, cleavage of the Si—O bond, substitution of the bromomethyl group with formation of $Si-CH_2-N$, etc.). The acetonitrile monoalkylation product is detected only in a small amount. If other compounds with active C—H bonds are introduced into this reaction, the yield of cyclocarbosiloxane diminishes[27]. For example, in the presence of diethyl malonate and ethyl cyanoacetate, the yield is about 20%. When an acetate ester is employed, only traces of cyclocarbosiloxanes are formed.

5. INTERACTION OF SUBSTITUTED ACETYLENES WITH DIHYDROSILOXANES (CYCLOADDITION)

When substituted acetylenes reacted with dihydrodisiloxanes in the presence of chloroplatinic acid as a catalyst, a number of five-membered cyclocarbosiloxanes with different substituents at the carbon atom were obtained[9,76-79]:

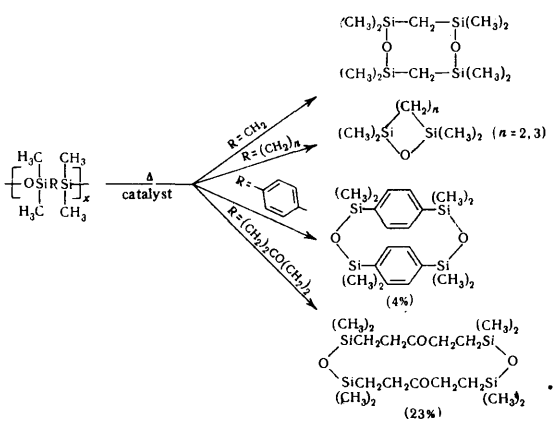


where X = H, C_6H_5, C_4H_9, or α-$C_{10}H_7$, X' = H, CH_3, or C_6H_5, and R = CH_3, C_2H_5, or C_6H_5.

The yield of cyclocarbosiloxanes varies between 5 and 75% depending on the structure of the initial reagents and the reaction conditions. It was established that the tendency towards the formation of a cyclic compound is greatly influenced by the nature of the substituents at the carbon atoms in acetylene and at the silicon atoms in dihydrodisiloxane. The substituents at the carbon atoms in acetylene can be arranged in the following sequence in terms of their effect on the formation of cyclic compounds: aryl > alkyl > hydrogen; the corresponding sequence of substituents at the silicon atoms is ethyl > phenyl > methyl.

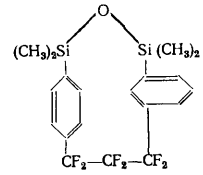
6. THERMAL CATALYTIC AND THERMAL REARRANGEMENT OF LINEAR CARBOXILOXANES

The thermal catalytic rearrangement of oligomeric products containing siloxane and silicon–carbon residues can be employed as a preparative method for the synthesis of many cyclocarbosiloxanes. Such oligomers are usually formed as side products in the synthesis of cyclocarbosiloxanes. They are obtained as the main products, for example, in the reaction involving the polyaddition of $\alpha\omega$-dihydrodisiloxanes to dienes and acetylene[9,76–85], in the copolymerisation of cyclosiloxanes with 1,3-disilacyclobutanes[50], and of course in the polymerisation of cyclocarbosiloxanes. At fairly high temperatures (up to 300°C) in the presence of catalytic amounts of alkalis or acids, the siloxane bond dissociates in linear carbosiloxane oligomers with formation of cyclocarbosiloxanes ("siloxy–siloxy" rearrangement). In particular, this method has proved convenient for the preparation of five-membered[5,13,18–20], six-membered[28,29,50,71,73], eight-membered[48,50,71,73], and sixteen-membered[86] compounds and also cyclocarbosiloxanes with *p*-phenylene bridges[61]:



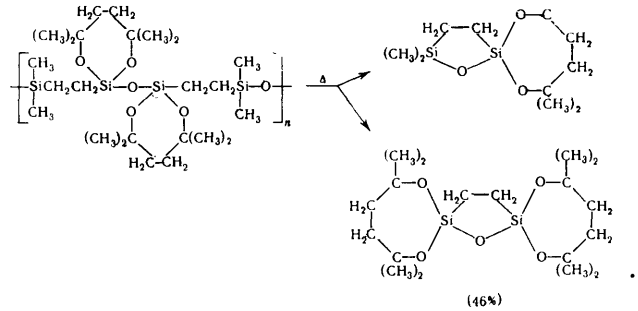
In the thermal decomposition of a polymer with the composition $[-SiCH_2CH_2CH_2SiO-]_n$, the main product was a six-membered heterocycle—1-oxa-2,6-disilacyclohexane[11].

Oxadisila-[3,3]-metaparacyclophane

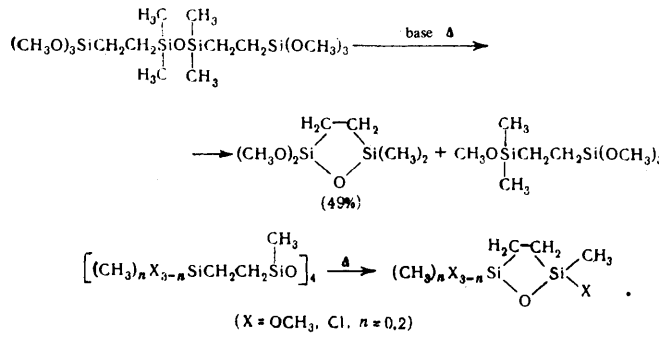


was obtained by heating *in vacuo* a linear polymer with the corresponding structure[67,68].

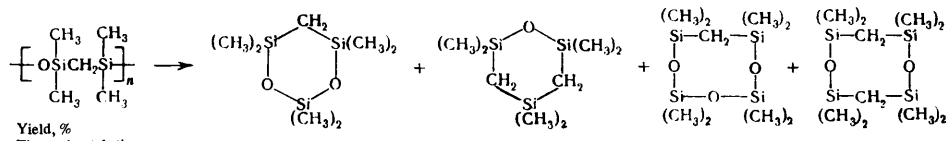
Thermal rearrangement of organosilicon oligomers also yielded oxadisilacyclopentane heterocycles[87]:



Thermal and thermalcatalytic "alkoxy–siloxy" and "chloro–siloxy" rearrangements of the corresponding compounds are varieties of the above method for the preparation of cyclocarbosiloxanes[87]:



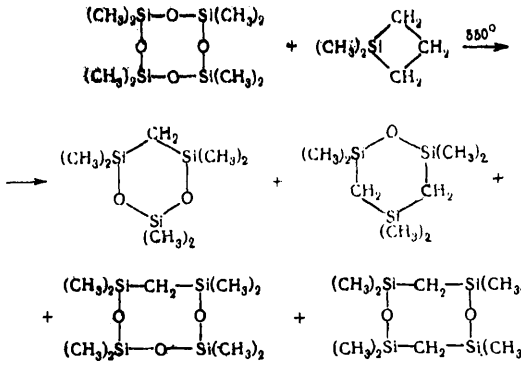
Examples of thermal and thermalcatalytic rearrangements of oligomeric carbosiloxanes involving the dissociation not only of Si–O but also of Si–C bonds in the chain are given below[50]:



Yield, %				
Thermal catalytic rearrangement (1% KOH; <300°)	43.1	32.2	10.6	7.5
Thermal rearrangement (>500°)	48.	24.8	9.6	3.1

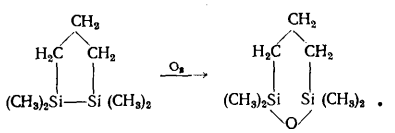
7. OTHER METHODS

Apart from the reactions discussed above, there are others leading to the formation of carbosiloxane rings, but these are without preparative value. Thus it has been shown that cyclocarbosiloxanes can be formed, in principle, on joint pyrolysis of cyclosiloxanes and cyclocarbosilanes[50,88]:

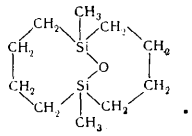


The formation of the same cyclocarbosiloxanes was observed on thermolysis of 1,1,3,3-tetramethyl-1,3-disilacyclobutane in the presence of water vapour at 550°C.[50,88] However, in both cases the yield of cyclocarbosiloxanes does not exceed several per cent.

Like 1,2-digermacyclopentanes[89], 1,2-disilacyclopentane can be oxidised with formation of the corresponding oxadisilacyclohexanes[135]. Thus 1,1,2,2-tetramethyl-1,2-disilacyclopentane is converted on prolonged standing into 2,2,6,6-tetramethyl-1-oxa-2,6-disilacyclohexane:

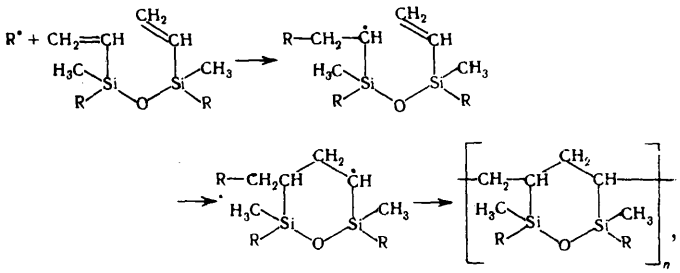


1,2-Disilacyclohexanes (*cis*- and *trans*-) are converted into the corresponding seven-membered *cis*- and *trans*-cyclocarbosiloxanes on interaction with perbenzoic acid. The reaction is distinguished by high stereospecificity[90]. A bicyclic compound with a similar structure is also readily oxidised by perbenzoic acid, yielding 1,6-dimethyl-11-oxa-1,6-disilabicyclo[4,4,1]undecane[91]:



It is interesting to note that, regardless of which (*cis*- or *trans*-) initial isomeric compound was oxidised, the reaction products always had the *cis*-configuration. Construction of molecular models for *cis*- and *trans*-isomers shows that, in contrast to the *cis*-isomer, the *trans*-siloxane isomer has a strained structure giving rise to steric hindrance. Oxidation with trimethylsilyl peroxide proceeds similarly, but the yield of the oxidation product is only 22% in the case of the *trans*-isomer.

The formation of cyclocarbosiloxane structures in the polymer chain has been noted in the free-radical and radiation-induced polymerisation of certain polyfunctional vinylsiloxanes[28,29,92]:



where R = CH_3 or C_6H_5.

Thermal rearrangements of cyclocarbosiloxanes with a change in the skeleton may be of definite interest for the synthesis of other cyclocarbosiloxanes (see p. 125).

III. PHYSICAL PROPERTIES

Cyclocarbosiloxanes are liquid or crystalline substances (Tables 1–2). The boiling points, refractive indices, and specific gravities of cyclocarbosiloxanes vary steadily as siloxane oxygen is replaced by methylene groups. Thus in the series of six- and eight-membered heterocycles the boiling points and refractive indices increase linearly and the specific gravity decreases with increase in the number of methylene groups[49,50,73].

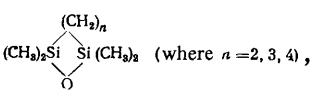
The thermal conductivities of the compounds in the gaseous state also decrease linearly with the number of methylene groups[50], except for cyclosiloxanes, the thermal conductivities of which are lower than those of the corresponding cyclocarbosiloxanes with a single methylene group.

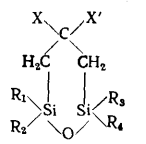
The infrared spectra have been widely employed by many investigators[9,11,18,24,35,48-58,60,62-69,71,79,87,92-99] to study the structures of various cyclocarbosiloxanes. In the spectra of compounds of this class the bands due to the stretching vibrations of the siloxane bonds are the most characteristic; in many cases useful information about the structure of cyclocarbosiloxanes may be obtained by analysing bands due to the carbon bridge. Comparison of the position of the band associated with the Si—O—Si bond in the compounds



showed that, with decrease of ring size, the band is displaced from 1018 cm^{-1} in the seven-membered ring[35] to 990 and 930 cm^{-1} in the six-membered[2,25-33] and five-membered[18,76-79,97,98] rings respectively. In the spectra of acyclic compounds the band due to the Si—O—Si group is observed in the region 1050—1100 cm^{-1}.[9,48,89,96,103-105] This shift is due to the fact that, with decrease of n, the Si—O—Si angle diminishes; it has been estimated[98,99] as 125° (for n = 4), 120° (n = 3), and 105° (n = 2). As a result, the strain in the above cyclocarbosiloxanes increases as n diminishes. For example the strain energy in five-membered cyclocarbosiloxanes is 8—12 kcal $mole^{-1}$.[18]

The Si—O—Si band in the spectrum of 1,1,3,3-tetramethyl-2-oxa-1,3-disilaindane has also been observed[63,97-99] in the region of 930 cm^{-1}.

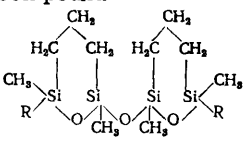
In six-membered cyclocarbosiloxanes of the type



X=H, CN;
X′=H, $COOCH_3$, $COOC_2H_5$, COOH, COOK,
$CONH_2$, CH_2NH_2
R_1, R_2, R_3, R_4 = alkyl, aryl, alkoxy-group.

the position of the maximum of the Si—O—Si band is almost independent of the nature of the substituents at the carbon or silicon atom[11,26-33,102] and is in the region 990 to 1000 cm^{-1}, which corresponds to an SiOSi angle of about 110—120°.[25,26,95] The 992 cm^{-1} absorption by the Si—O—Si group has also been observed in the infrared spectrum of the bicyclic compound *cis*-1,6-dimethyl-11-oxa-1,6-disilabicyclo[4,4,1]undecane[91].

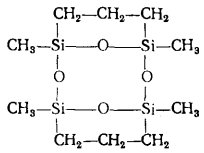
If the cyclocarbosiloxane molecule contains cyclic and acyclic siloxane bonds, the two corresponding bands are observed in the infrared spectrum as expected, the first being at a longer wavelength. Thus in the infrared spectrum of the compound



(R=CH_3, C_6H_5)

there are Si–O–Si absorption bands at 990 and 1080 cm^{-1} characterising the linear and cyclic structures respectively[2,11,30].

In the infrared spectrum of the compound



two Si–O–Si bands are also observed—at 1006 cm^{-1} (for the six-membered carbosiloxane ring) and at 1067 cm^{-1} (for the eight-membered siloxane ring).[11,32,97-99]

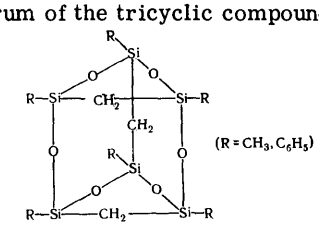
In the spectra of many six-membered compounds (I–IV) the band due to the asymmetric vibration of the Si–O bond[48-50,103-105] is in the region 1020–1030 cm^{-1}, while the CH_2 deformation vibration band is displaced from 980 to 1050 cm^{-1} [in the infrared spectra of compounds (II) to (IV)]. Thus the band due to the deformation vibrations of the ring CH_2 groups in the infrared spectra of compounds (II)–(IV) is more sensitive to changes in the skeleton of the cyclic structure than the siloxane band.

Calculation of the integral intensities of the bands associated with the asymmetric stretching vibrations of the Si–O bonds and the deformation vibrations of the endocyclic CH_2 groups in the infrared spectra of compounds (I), (II), and (IV) [for the spectrum of compound (III), such calculation is difficult owing to the impossibility of resolving the bands] shows that the integral intensity of the Si–O band remains constant, but the intensity of the CH_2 deformation vibration band is variable. The latter finding may be due to the effect of the conformational isomers on these vibrations.

Proton Magnetic Resonance Spectra

The ^1H NMR spectra of six- and eight-membered siloxanylmethylenecyclocarbosiloxanes (II), (III), and (VI)–(VIII) have two or more signals due to the non-equivalent methyl and methylene protons, the latter occurring in stronger fields[50,73]. With increase of ring size, the spin–spin coupling constant $J(^{13}CH_2)$ decreases, probably owing to an increase of the *p*-character of the carbon in the C–H bonds; there is a corresponding increase of $J(^{29}SiCH_2)$, which may be due to an increase of the *s*-character of the Si–C bond. On the basis of these results, it has been concluded that in the cyclocarbosiloxanes investigated the silicon atoms in the Si–C bonds in the ring have less *s*-character than in the Si–C bond directed to the methyl groups.

In the spectrum of the tricyclic compound

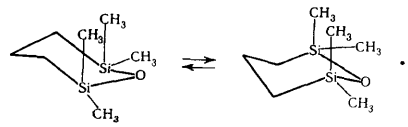


(R = CH_3, C_6H_5)

there are two signals of methylene protons, occurring at higher field (τ = 9.90 and 9.93 p.p.m.) than the signals of the methyl group protons (τ = 9.61 and 9.67 p.p.m.).[53,69]

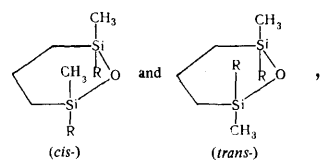
Analysis of the ^1H NMR spectra of a number of derivatives of oxadisilacyclohexane (see p. 121) led to the conclusion that such heterocycles have the "chair" conformation[26,106].

The ^1H NMR spectrum of 2,2,6,6-tetramethyl-1-oxa-2,6-disilacyclohexane[106] consists of a singlet due to methyl protons (δ = 0.07 p.p.m.), a multiplet due to α-methylene protons (δ = 0.45–0.72 p.p.m.), and a multiplet due to β-methylene protons (δ = 1.65–2.1 p.p.m.). Owing to the rapid "chair–chair" inversion, the axial and equitorial methyl groups are equivalent:



The activation energy for the conformational transitions of this compound has been estimated as about 3.5 kcal $mole^{-1}$, which is much lower than the corresponding value for 1,1,4,4-tetramethylcyclohexane (11 kcal $mole^{-1}$)[107,108] and approaches the activation energies for the "chair–chair" inversion in 1,1-dimethyl-1-silacyclohexane (5.5 kcal $mole^{-1}$)[109] and 1,1,4,4-tetramethyl-1,4-disilacyclohexane (6 kcal $mole^{-1}$).[110]

The *cis*- and *trans*-isomers of oxadisilacyclohexane,



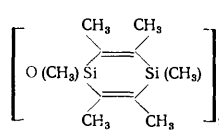
(*cis*-) (*trans*-)

where R = OAlk or C_6H_5, have characteristic ^1H NMR spectra[106]. The signal due to the protons of the methyl group located on the same side of the ring as the alkoxy-substituents is displaced towards lower field compared with the signal of a similar methyl group located in the *cis*-position with respect to a methyl or another alkyl group. In the spectra of methylphenyloxadisilacyclohexanes[106], the signal due to the methyl group in the *cis*-position is displaced towards higher field, while the signal of the *trans*-methyl group is displaced towards lower field.

The ^1H NMR method has also been used to analyse five-membered[9,18,78,79] and other cyclocarbosiloxanes[27,58,64,68,69].

Electron Spin Resonance

The application of the ESR method in studies of the radical-anions obtained from



by reduction with potassium in 1,2-dimethoxyethane solutions at –80°C, has been described[58]. The resulting radical-anion was stable for several hours at –80°C, disappearing rapidly on heating to room temperature. Analysis of the spectrum showed that the unpaired electron is fully delocalised owing to a transannular interaction, the delocalisation over the Si–O–Si bond being insignificant.

Mass Spectra

The application of mass spectroscopy to determine the molecular weight[11,58,97,111] and the mode of dissociation of

cyclocarbosiloxanes on electron impact[11,58,111] has been described. The latter is discussed in greater detail in Section IV.

IV. CHEMICAL PROPERTIES

The characteristic chemical properties of cyclocarbosiloxanes are determined primarily by the reactivity of the bonds forming the heterocycle. In the reactions investigated the Si–O bonds show the highest activity and the Si–C the lowest; the C–C bonds of the carbon bridge are as a rule stable in chemical reactions of cyclocarbosiloxanes. On the other hand, the reactions of cyclocarbosiloxanes can also involve functional groups linked to silicon and carbon atoms.

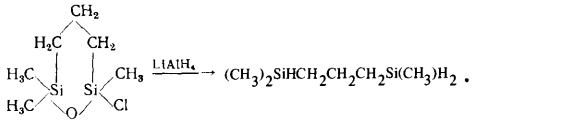
1. REACTIONS WITH CLEAVAGE OF THE HETEROCYCLE SKELETON

a. Heterolytic Cleavage of Si–C Bonds

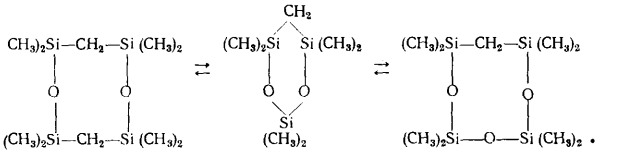
The opening of the carbosiloxane rings in the presence of electrophilic or nucleophilic agents takes place as a rule with cleavage of the siloxane bond. Like cyclosiloxanes, five-membered cyclocarbosiloxanes can be titrated with tetra-n-butylammonium hydroxide in pyridine[112]:

where R = CH_3 or C_6H_5.

When 6-chloro-2,2,6-trimethyl-1-oxa-2,6-disilacyclohexane is hydrogenated with lithium aluminium hydride in ether, not only the chlorine at the silicon atom is reduced but also the Si–O–Si bond, which results in the formation of a compound with a linear structure[11,33]:



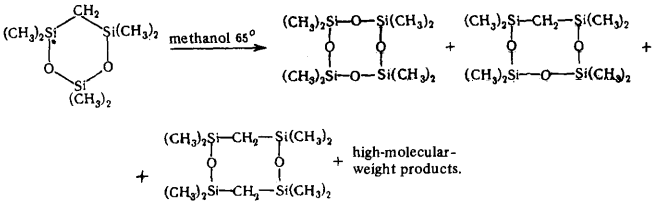
In pyridine solutions containing catalytic amounts of tetramethylammonium hydroxide, six- and eight-membered cyclocarbosiloxanes undergo a rearrangement with ring expansion or contraction even at 60°C:[50,113,114]



The rate of cleavage of heterocycles of the above type decreases with increase in the number of methylene groups in the molecule. Together with cyclic products, the rearrangement here gives rise also to high-boiling oligomers. It has been established that reactions of this kind are also accompanied by dissociation of the ring Si–C bond, as shown by the formation of six-membered heterocycles from eight-membered heterocycles (the cleavage of the Si–C bond of these cyclocarbosiloxanes by nucleophilic agents is described on p. 125).

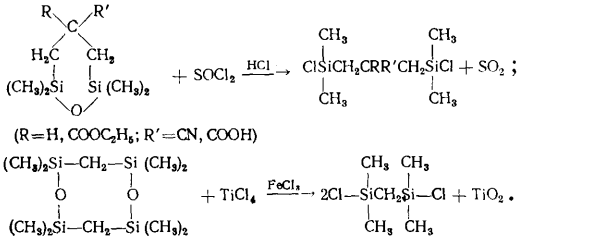
At the same time it is interesting to note that in the presence of an alcoholic solution of NaOH, KOH, and also H_2SO_4 (70%) and $H_2SO_4.SO_3$, 1,1,3,3,5,5,7,7-octamethyl-2,6-dioxa-1,3,5,7-tetrasilacyclo-octane is not cleaved[45,46,115].

In methanol solution, 1,1,3,3,5,5-hexamethyl-2,4-dioxa-1,3,5-trisilacyclohexane gives rise to rearrangement products[50,114]:



A compound having a similar structure and two methyl groups—1,1,3,3,5,5-hexamethyl-2-oxa-1,3,5-trisilacyclohexane—does not undergo any change under identical conditions. Probably the mechanism of this reaction is similar to that of the rearrangements of six-membered cyclosiloxanes in methanol[106,116-118].

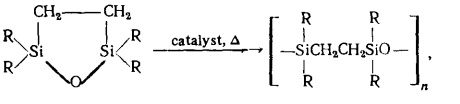
On treatment with chlorinating agents ($TiCl_4$, $SOCl_2$) in the presence of catalysts (HCl,[27] $FeCl_3$,[47] etc.) the siloxane bond of cyclocarbosiloxanes is cleaved and the corresponding linear dichlorides are formed in high yields (80–95%):



b. Polymerisation of Cyclocarbosiloxanes

This section deals with reactions involving the cleavage of the Si–O bond and leading to the formation of linear carbosiloxane polymers. Owing to the presence of the siloxane bond in the ring, cyclocarbosiloxanes can polymerise with ring opening in the presence of the usual catalysts for the polymerisation of cyclosiloxanes. Polymers whose main chain consists of alternating siloxane and carbosilane units have been obtained in this way. However, the polymerisation activity of cyclocarbosiloxane is as a rule lower than that of cyclosiloxanes with similar structures.

As already mentioned, five-membered cyclocarbosiloxanes are the most strained compounds of this class[18], as a result of which they readily polymerise in the presence of anionic [NaOH, KOH, LiOH, $(CH_3)_4NOH$, $(CH_3)_3SiONa$, $(CH_3)_3SiOK$] and cationic (H_2SO_4, CF_3COOH) catalysts[13,18]:



where R = CH_3 or C_6H_5.

The polymers obtained in the presence of anionic catalysts have a high molecular weight (up to about 10^6).

The ease of cleavage of the siloxane bond in these heterocycles depends on the nature of the substituents at the silicon and carbon atoms. Phenyl substituents at the silicon atoms increase the activity of five-membered

cyclocarbosiloxanes in anionic polymerisation[119]. Thus, 2,2,5,5-tetraphenyl-1-oxa-2,5-disilacyclopentane polymerises approximately 18 times faster than the corresponding tetramethyl-substituted cyclocarbosiloxane (Table 3).

Table 3. Relative reactivities of five-membered cyclocarbosiloxanes and six-membered cyclocarbosiloxanes in base-catalysed polymerisation at 25°C.[119]

No. of cpd.	Monomer	Relative reactivity

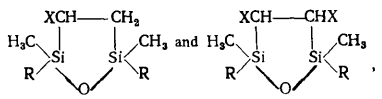
*Data obtained at 40°C in copolymerisation with compound (II).

On the other hand, the reactivity of five-membered cyclocarbosiloxanes under the conditions of cationic polymerisation increases when methyl substituents at the silicon atom are replaced by ethyl or phenyl groups.

In the series of C-substituted five-membered cyclocarbosiloxanes[9,76-79]

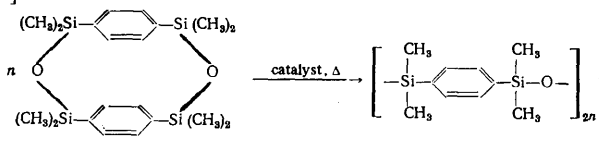


where R = CH_3, C_2H_5, C_6H_5, and X = C_4H_9, α-$C_{10}H_7$, or C_6H_5, the monosubstituted compounds show a greater tendency towards polymerisation. When they are polymerised in the presence of H_2SO_4, KOH, NaOH, and alkali metal silanolates, oily products with molecular weights in the range $(1.5-18)\times10^3$ are formed. Thermal polymerisation of the C-phenyl-substituted compound with R = CH_3 (molecular weight of the polymer up to 2×10^4) and its catalytic polymerisation in the presence of $AlCl_3$, BF_3, and $ZnCl_2$ + chloromethyl ether have been noted. In contrast to the monosubstituted derivatives, cyclocarbosiloxanes disubstituted at carbon atoms are not converted into polymers under the action of acids or bases.

In the copolymerisation of the cyclocarbosiloxanes $R_2SiCH_2CH_2SiR_2$ (R = CH_3 or C_6H_5) with six-membered cyclosiloxanes [hexamethyl(phenyl)cyclotrisiloxane] in the presence of basic catalysts, copolymers of different structures and molecular weights were obtained. The copolymerisation constants found were used to calculate the relative reactivities of the cyclocarbosiloxanes (Table 3).[119] Copolymers of the above type are suitable for conversion into rubbers and can also be used as moulding and casting resins, filling oils, and protective coatings[119,120].

Cyclocarbosiloxanes containing phenylene groups in the ring can also be polymerised in the presence of bases. Thus five-membered heterocycles with an *ortho*-phenylene bridge form at 100–140°C in the presence of 1% KOH low-molecular-weight polymers[11,62,63], while in the presence of H_2SO_4 the Si–C bonds in the ring are cleaved (see p. 125).

Cyclic carbosiloxane dimers and trimers with a *para*-phenylene bridge are converted in the presence of 0.01% potassium dimethylsilanolate at 180°C into high-molecular-weight soluble polymers [molecular weight $(0.7-4)\times10^5$]:[61]



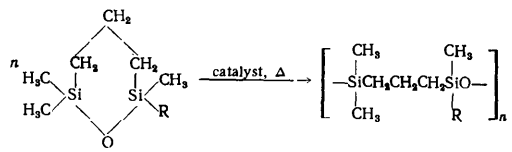
These polymers are thermally stable up to 350°C and are resistant to oxidation.

When 1,2-(1′,1′,3′,3′)-tetramethyldisiloxanyl-(1′,3′)-carborane is treated with bases, the Si–C bonds are dissociated and a siloxane polymer is formed[74] (see p. 125).

In the series of six-membered cyclocarbosiloxanes containing alternating siloxane and silmethylene groups, the polymerisation activity falls as oxygen atoms are replaced by methylene groups[50,113,114]. While the cyclocarbosiloxanes formed by replacing one oxygen atom in hexamethylcyclotrisiloxane by a methylene group polymerise more slowly in the presence of an anionic catalyst than their cyclosiloxane analogue and form a polymer with a molecular weight of 2×10^5, under analogous condition the corresponding compound in which two oxygen atoms have been replaced by methylene groups does not polymerise at all. It can be polymerised under more severe conditions (1.4% KOH, 120°C, 33 h) with formation of a low-molecular-weight oily product in a yield of 19%.[72] The formation of a condensation product of this compound has also been observed in the presence of 6 wt. % $AlCl_3$.

As in the case of five-membered cyclocarbosiloxanes[119], the replacement of a methyl group at a silicon atom by a phenyl group increases the reactivity of six-membered heterocycles in anionic polymerisation[72]. Six-membered heterocycles (oxadisilacyclohexanes) are also polymerised with greater difficulty[11,27,75,101] than hexamethylcyclotrisiloxane; they are less reactive than five-membered cyclocarbosiloxanes.

The anionic and cationic polymerisation of 2,2,6,6-tetramethyl-1-oxa-2,6-disilacyclohexane and certain other derivatives of this heterocycle has been investigated[11,102,109,121,122]:



where R = CH_3, C_2H_5, C_3H_7, C_4H_9, C_5H_{11}, C_6H_5, or C_6H_4Cl.

Under optimal polymerisation conditions (0.6% KOH, 110°C, 640 min), the yield of the polymer (with R = CH_3) was 93% and the molecular weight was 3×10^3. In the presence of sulphuric acid or polydimethylsiloxysulphonic acid, a polymer with a molecular weight of about 10^4 was formed.

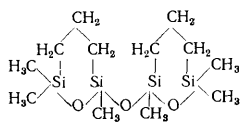
The rate of polymerisation of 2,2,6,6-tetramethyl-1-oxa-2,6-disilacyclohexane in the presence of KOH and H_2SO_4 is lower by two powers of 10 than the rate of polymerisation of hexamethylcyclotrisiloxane and the activation energies are respectively 21 kcal mole^{-1} for anionic

polymerisation and 7 kcal mole^{-1} for cationic polymerisation[11,101,121,122]. The intrinsic viscosity (molecular weight) of the polymers increases linearly with the degree of conversion. On this basis, the authors conclude that the polymerisation has a stepwise mechanism. In the initial stages the reaction is of first order with respect to the monomer; at higher conversions, the reaction order becomes fractional.

The effect of the substituent at the silicon atom on the rate of polymerisation of oxadisilacyclohexanes in the presence of cationic and anionic catalysts has been investigated[11,102]. Replacement of the methyl group by ethyl and higher alkyl groups lowers the rate of polymerisation in the presence of KOH approximately by a factor of 10. The introduction of electron-accepting substituents (phenyl, chlorophenyl) increases somewhat the rate of reaction. As was to be expected, in the case of cationic polymerisation aryl substituents lower the rate. It is interesting to note that electron-donating substituents also lower the rate of cationic polymerisation of oxadisilacyclohexanes, which has been explained by the swamping of the inductive effect by the steric effect.

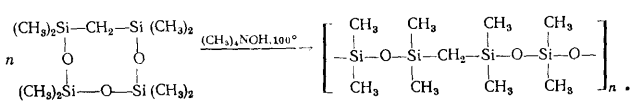
The linear relation between the logarithm of the relative rate of polymerisation of oxadisilacyclohexanes with phenyl substituents and the σ^* constant in the Hammett–Taft equation is evidence of a correlation between the rate of polymerisation and the inductive effect of substituents.

The polymerisation of the bicyclic compound



in the presence of KOH and polydimethylsiloxysulphonic acid takes place with formation of insoluble polymers[11,102].

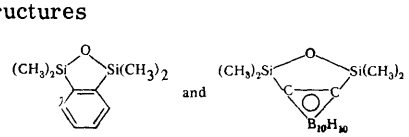
In the series of eight-membered methylenesiloxane heterocycles, only 1,1,3,3,5,5,7,7-octamethyl-2,4,6-trioxa-1,3,5,7-tetrasilacyclo-octane could be polymerised in the presence of anionic catalysts[50,113,114]:



A polymer with a molecular weight of 7.5×10^4 was obtained. The corresponding cyclocarbosiloxanes with two and three methylene groups are not polymerised under these conditions, i.e. in this case the polymerisation activity decreases with the number of methylene groups, probably owing to their positive inductive effect (relative to oxygen), which leads to an increase of electron density at the silicon atoms as a result, nucleophilic attack on the latter is hindered.

c. Heterocyclic Cleavage of Si–C Bonds

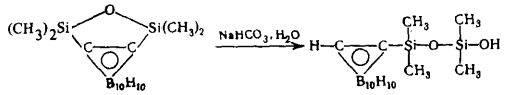
When cyclocarbosiloxanes with a carbon bridge having marked electron-accepting properties are treated with alkalis or acids, the ring Si–C bonds are cleaved. For example, in an attempt to polymerise compounds with the strained structures



(X) (XI)

in the presence of acids [compound (X)] or bases [compound (XI)], the formation of a polydimethylsiloxane and the removal of a phenyl or a carborane group respectively was observed[11,62,63,74].

At room temperature an aqueous solution of sodium bicarbonate also causes the dissociation of the Si–C bond[74]:

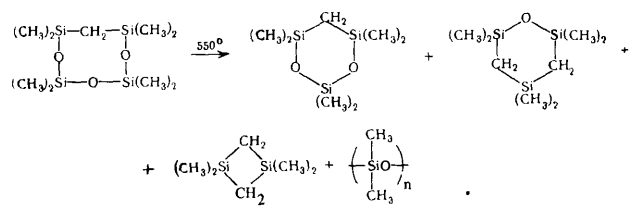


The cleavage of endocyclic Si–C bonds has likewise been observed when certain eight-membered cyclocarbosiloxanes were treated with nucleophilic agents[50,113,114]. In pyridine solutions containing catalytic amounts of $(CH_3)_4NOH$, 1,1,3,3,5,5,7,7-octamethyl-2,6-dioxa-1,3,5,7-tetrasilacyclo-octane gave rise to 1,1,3,3,5,5,7,7-octamethyl-2,4,6-trioxa-1,3,5,7-tetrasilacyclo-octane and 1,1,3,3,5,5,-hexamethyl-2,4-dioxa-1,3,5-trisilacyclohexane together with other products at a temperature as low as 60°C (see the scheme on p. 123). The formation of these heterocycles indicates the dissociation of Si–C bonds in the carbosiloxane ring. The weakening of endocyclic Si–C bonds in cyclocarbosiloxanes is probably due to the effect of the adjacent oxygen atom of the siloxane bond.

d. Thermal Reactions of Cyclocarbosiloxanes in the Gas Phase

At 500–600°C in the gas phase cyclocarbosiloxanes undergo rearrangements accompanied by the dissociation of endocyclic Si–O and Si–C bonds. In the first place this applies to cyclocarbosiloxanes consisting of alternating siloxane and silmethylene groups (p. 117).[48,50,88].

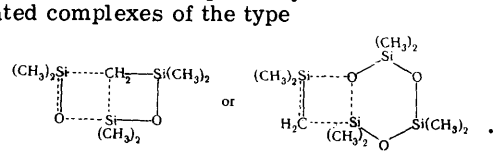
The principal effect of the rearrangements is ring contraction. Thus eight-membered cyclocarbosiloxanes form mainly six-membered compounds; in addition 1,3-disilacyclobutane and cyclosiloxanes are formed, for example:



$(n = 3,4)$

The characteristics of the thermal decomposition of cyclocarbosiloxanes are very similar to those of the thermal decomposition of cyclosiloxanes: the latter is a monomolecular process involving a four-centre mechanism[50,123,124].

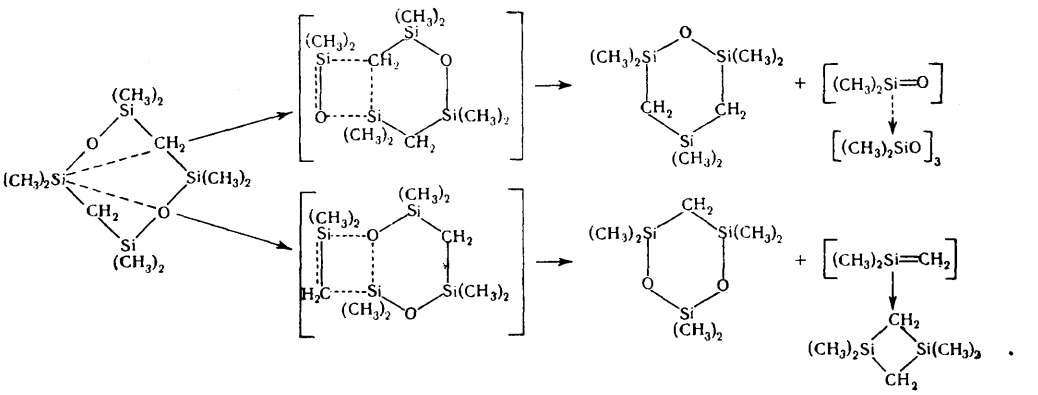
It has been suggested that the thermal rearrangement of cyclocarbosiloxanes has a similar molecular mechanism involving transannular interactions between the oxygen or carbon atoms on the one hand and silicon atoms on the other[50,88,124]. The latter probably lead to the formation of activated complexes of the type



A qualitative assessment of these activated complexes shows[125–127] that the activation energy for the dissociation

of the first is higher than for the second which is consistent with the higher thermal stability of six-membered cyclocarbosiloxanes noted in some investigations[50,88] compared with the eight-membered compounds. The proposed activation mechanism also accounts for the preferential dissociation of endocyclic bonds.

The structures of activated cyclocarbosiloxane complexes presented below show that their dissociation should lead to the formation of unstable intermediates: methylenedimethylsilane or dimethylsilanone, which are probably in fact responsible for the formation of 1,3-disilacyclobutane and cyclosiloxanes:



Oxadisilacyclohexanes behave differently in gas-phase thermolysis. Thus it has been noted[11,128] that the decomposition of 2,2,6,6-tetramethyl-1-oxa-2,6-disilacyclohexane begins with the removal of methylene groups, after which the siloxane bond is cleaved.

e. Dissociation of Cyclocarbosiloxanes on Electron Impact

The primary process occurring in the dissociative ionisation of cyclocarbosiloxanes (as for many other acyclic and heterocyclic organosilicon compounds) is the removal of a methyl group from the molecular ion (M^+):[11,58,67,111]

$$M^+ \xrightarrow{-CH_3} [M-15]^+.$$

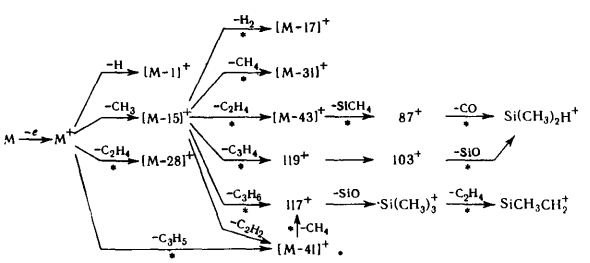
The resulting ion $[M-15]^+$ is more stable than the molecular ion; the formation of all other fragment ions can be as a rule explained by its decomposition and rearrangement. As in the case of cyclosiloxanes[129], the heaviest of the cyclocarbosiloxane fragment ions (II), (III), (VI)–(VIII) (see p. 117) are formed as a result of the loss of neutral fragments originating from the surrounding methyl group, but the cyclic skeleton of the molecule persists. With increase of the number of methylene groups in the ring, the intensity of the fragmentation of compounds (I)–(IV), due to the decomposition or rearrangement of the cyclic skeleton of the molecule, increases.

An interesting feature of the dissociative ionisation of these cyclocarbosiloxanes is the formation of metastable ions due to the loss of the neutral fragments $(CH_3)_2SiO$ and $(CH_3)_2SiCH_2$, which are structural elements of cyclocarbosiloxanes.

The mass spectra of the above six- and eight-membered cyclocarbosiloxanes contain a group of ions with the general formula $(CH_3)_3Si_2O_2{-}_n(CH_2)_n$ (n = 0, 1, or 2): the cyclosiloxane ion with m/e = 133, the cyclocarbosiloxane ion with m/e = 131, and the cyclocarbosilane ion with m/e = 129. The liberation of a considerable amount of kinetic energy on formation of the first ion[129] and the detection of an ion with a high intensity (m/e = 129) in the mass spectrum of 1,1,3,3-tetramethyl-1,3-disilacyclobutane[130] suggest that ions of this group have a cyclic structure.

Together with the above ions, doubly charged fragment ions formed by the successive removal of hydrocarbon groups from the $[M-2CH_3]^{2+}$ ions were observed in the mass spectrum. However, on passing from cyclosiloxanes to cyclocarbosilanes, the intensity of the doubly charged $[M-2CH_3]^{2+}$ ions falls. In addition, $[M-CH_3]^{2+}$ doubly charged ions were found in the mass spectra of six-membered cyclocarbosiloxanes [compounds (II) and (III)].[111] This is evidence of a particularly high resistance of the six-membered ring to dissociation on electron impact.

In the case of 2,2,6,6-tetramethyl-1-oxa-2,6-disilacyclohexane[11,128], the formation of the principal fragment ions is due to the decomposition of the $[M-15]^+$ ion and is associated with the removal from it of propene, ethylene, acetylene, and other fragments:

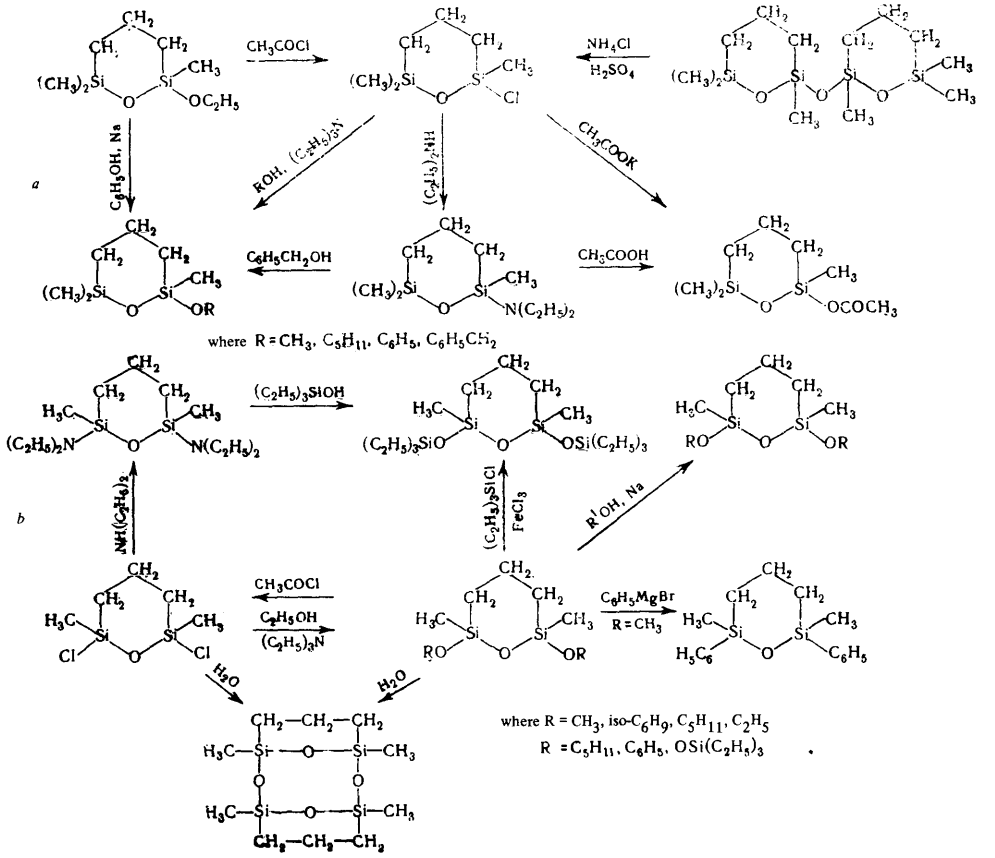


The stability of the siloxane skeleton in this compound has been noted. The number of ions containing the SiOSi group reached up to 85% of all the ions in the spectrum. An interesting feature of the mass spectrum of $[O(CH_3)Si\langle\equiv\rangle Si(CH_3)]_2$ is the presence of a fragment ion with m/e = 97 (an intensity of 14) to which the authors attributed the structure of silirene[58]:

2. REACTIONS INVOLVING THE RETENTION OF THE HETEROCYCLIC SKELETON

a. Reactions Involving Exocyclic Bonds at the Silicon Atom

As for acyclic compounds with functional groups at Si, a number of reactions of cyclocarbosiloxanes involving substitution at the silicon atom have been described; the majority of them can occur without the cleavage of the ring Si–O bonds. Thus reactions involving the substitution of halogen, alkoxy-, and amino-groups in six-membered oxadisilacyclohexanes have been described[11,31–33,54,55,70]: hydrolysis, alcoholysis, transesterification, amination, acetoxylation, alkylation with a Grignard reagent, heterofunctional condensation, and others, for example:

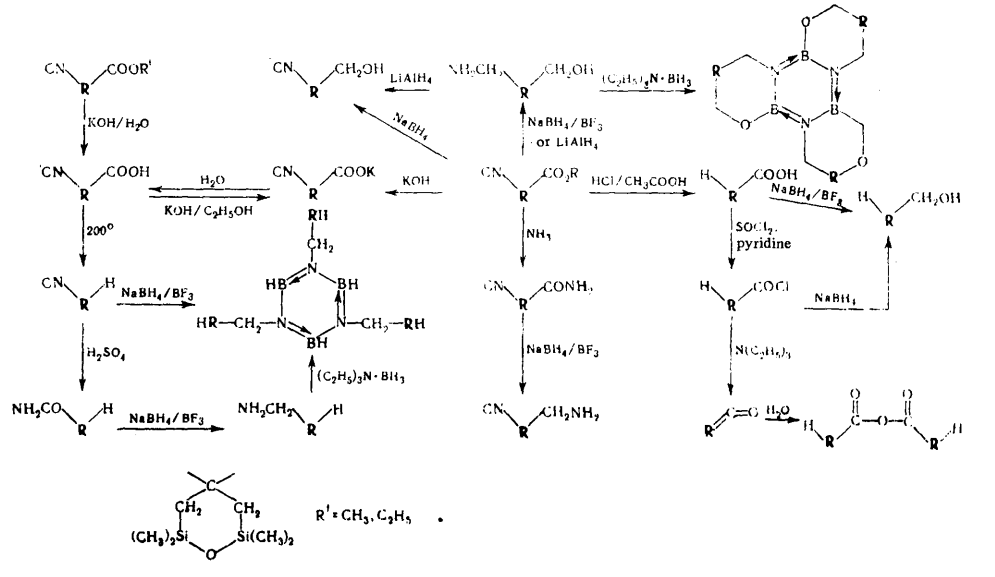


where R = CH_3, C_5H_{11}, C_6H_5, $C_6H_5CH_2$

where R = CH_3, iso-C_6H_9, C_5H_{11}, C_2H_5
R = C_5H_{11}, C_6H_5, $OSi(C_2H_5)_3$

b. Reactions of Groups and Atoms Linked to Carbon

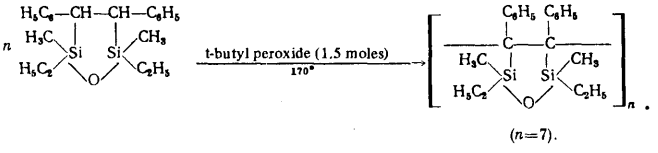
Numerous reactions of oxadisilacyclohexanes containing functional groups at the β-carbon atom of the ring have been investigated[24–27,75,131]:



$R' = CH_3, C_2H_5$

Despite the fact that many of these reactions take place under comparatively severe conditions, the carbosiloxane ring is not cleaved. In particular, it is interesting to note that, in contrast to cyclocarbosiloxanes with functional groups linked to silicon atoms[11,33], compounds with functional groups linked to carbon atoms can be reduced by $LiAlH_4$ without the cleavage of the ring siloxane bond.

When the hydrogen atoms of the methine groups of five-membered C-phenyl-substituted cyclocarbosiloxanes are attacked by free radicals, relatively unreactive cyclocarbosiloxane radicals of the benzyl type are formed and recombine, giving rise to condensation products[9,79]:



(n=7).

---o0o---

During the preparation of the manuscript for the press, new studies on the synthesis and properties of cyclocarbosiloxanes were published[132-135].

N-Nitrenes

B.V.Ioffe and M.A.Kuznetsov

This review gives an exhaustive summary of data on unstable intermediate species RR'N-N:, containing a nitrogen atom with an incomplete electron shell, bonded to another nitrogen atom. These species are analogous to aminocarbenes, and play an important role in the chemistry of organic derivatives of hydrazine. Reactions in which the formation of N-nitrenes has been postulated have been systematised, and reactions involving their subsequent transformation with the separation of nitrogen, isomerisation, or addition to other reagents have been examined. The review covers papers dealing with the chemistry of N-nitrenes, published before mid-1971. The bibliography contains 145 references.

CONTENTS

I. Introduction 131
II. Preparation of N-nitrenes 132
III. Reactions of N-nitrenes 136

I. INTRODUCTION

Progress in the chemistry of the carbenes in recent decades has led to an increase in interest in their analogues containing atoms with incomplete sextet electron shells, including the reactive intermediate compounds of formally univalent nitrogen R-N:, the so-called nitrenes (the subject of several reviews[1-5] and a recent monograph[6]).

Among the nitrenes, a unique position is occupied by the labile compounds in which the "sextet" nitrogen atom is bonded to another nitrogen atom:

(I)

Compounds of type (I) are called N-nitrenes or aminonitrenes, to distinguish them from C-nitrenes or O-nitrenes, containing C-N: and O-N: bonds respectively. The terms diazene, azene, azalene, and azamine have also been used in the literature for structures of type (I).[1] The term "diazene" is now applied to monosubstituted derivatives of di-imide R-N=NH, and this can lead to confusion. The other names have not been widely used.

We shall use the terms "N-nitrene" and "aminonitrene" as equivalent names, the nature of the radicals R and R' (I) being indicated in the name:

H_2N-N	aminonitrene
$(CH_3)_2N-N$	dimethylaminonitrene
C_6H_5NH-N	phenylaminonitrene etc.

In more complex compounds, in which the central nitrogen atom of the aminonitrene is present in a ring, it is convenient to use the names of the corresponding heterocyclic radicals, for example

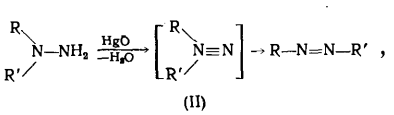
N-pyrrylnitrene .

An increasing number of facts indicate that N-nitrenes play a prominent role in the chemistry of the organic derivatives of hydrazine. Although the existence of these very unstable intermediate compounds in many instances has been only tentatively assumed, the ideas regarding aminonitrenes make it possible to understand a large number of the reactions of hydrazines, used in the production of synthetic materials and medicinal products, and in agriculture. The assumption that N-nitrenes are formed as intermediate products reveals common features in apparently completely different reactions and provides possibilities for predictions, useful analogies, and generalisations. Without a systematisation of ideas regarding N-nitrenes, the study and further development of the organic chemistry of hydrazine would be impossible.

The brief data on N-nitrenes in reviews of nitrenes[1-5], and the sections devoted to these compounds in the monograph cited[7] are inadequate and incomplete. The detailed article by Lemal in Lwowsky's book[6], published before this review was complete, covers the literature only as far as early 1969.

---o0o---

The first suggestion regarding the existence of unstable intermediate compounds with a nitrogen atom bound only to another nitrogen atom appeared as early as the end of the nineteenth century, with the need to explain the anomalous course of the oxidation of various hydrazines. In the oxidation of 1-allyl-1-phenylhydrazine and 1-allyl-1-*p*-tolylhydrazine with mercuric oxide, Michaelis and Luxemburg[8] obtained azo-compounds instead of the tetrazenes usually formed under these conditions, and they attributed this result to the rearrangement of a primary product with the unusual structure (II):



(II)

where $R = CH_2=CH-CH_2-$ and $R' = C_6H_5$ or p-$C_6H_4CH_3$. Formula (II) is not possible from the viewpoint of modern electronic theory, and it represents essentially the N-nitrene (I).

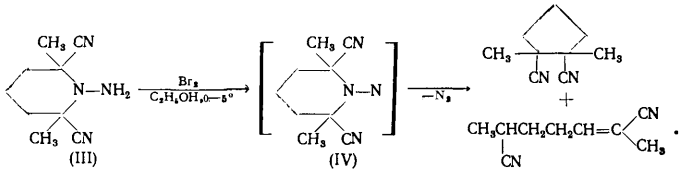
In the oxidation of dibenzylhydrazines with mercuric oxide, completely different anomalous products were obtained; nitrogen was liberated, and hydrocarbons were formed:

This reaction proceeds so smoothly that it was subsequently used for the preparation of derivatives of dibenzyl (the Busch-Weiss reaction)[10-12]. The replacement of one of the benzyl radicals by an aryl radical, however, leads

to the formation of arylhydrazones (or mixtures of arylhydrazones and tetrazenes)[13]:

$$\begin{matrix} Ar \\ Ar'CH_2 \end{matrix}\!\!>\!N\!-\!NH_2 \xrightarrow[0°,CHCl_3]{HgO} ArNHN{=}CHAr'\,.$$

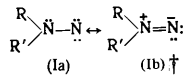
Later, it was established that the Busch–Weiss reaction is not restricted to benzylhydrazines; the oxidation of the cyclic hydrazine (III) with bromine leads to the liberation of nitrogen and the production of a mixture of dinitriles, which, in the opinion of the authors cited[14-17], are products of the decomposition of the N-nitrene (IV) formed as an intermediate product:



The hypothetical compound with a "sextet" nitrogen atom (V) was also regarded as an intermediate product in the thermal decomposition of a mixture of phenylhydrazine and its hydrochloride[18]:

$$[C_6H_5NH_2NH_2]^+ + C_6H_5NHNH_2 \rightarrow \underset{(V)}{[C_6H_5NH{-}N]} \rightarrow C_6H_5NH_2 + C_6H_6 + NH_3 + N_2 + H^+.$$

Since the nineteen-fifties, suggestions regarding the existence of intermediate species of this kind have begun to appear more frequently in papers on the chemistry of hydrazines. It has been considered that as a consequence of the presence of an unshared pair of electrons on the central nitrogen atom in these compounds, mesomerism is possible (Ia–Ib)



It has been suggested that mesomerism may lead to stabilisation and an increase in the lifetime of N-nitrenes compared with C-nitrenes or carbenes (see p. 106 of Ref. 7). Until recently, however, there was no information on the electronic structure of N-nitrenes or the relative roles of structures (Ia) and (Ib). In 1970, the structures of a number of the simplest N-nitrenes and their analogues were calculated[19] by the MO LCAO method with complete neglect of differential overlap and with allowance for all the valency electrons (the CNDO/2 method[20-22]). These calculations showed that aminonitrene itself $H_2N{-}N$ should have a planar configuration with N–N bond length 1.25 Å, which is smaller than the length of the N–N bond in hydrazine (1.46 Å) but longer than the length of the N=N bond in di-imide (1.2 Å)‡. The "sextet" nitrogen atom of the aminonitrene carries a fairly high negative charge (−0.217). For the nearest homologues of aminonitrene the negative charge on the terminal nitrogen atom is increased slightly as a consequence of the positive inductive effect of the alkyl substituents.

N-Nitrenes in which the unshared electron pair of the central nitrogen atom is involved in conjugation with substituents show the opposite effect—a definite, though small, decrease in the negative charge on the terminal nitrogen atom: −0.216 for N-pyrrylnitrene and −0.204 for phenylaminonitrene.

The populations of the π-AO of the terminal nitrogen atom in aminonitrene and its nearest homologues lie in the range 0.47–0.49, and the orders of the π-bonds between the nitrogen atoms in the range 0.81–0.84.

These results were obtained with the assumption that the ground state of the aminonitrenes is a singlet state. This assumption agrees with data on the stereochemistry of the addition reactions of various aminonitrenes at the double bond.

The comparatively large contributions of the polar structure (Ib), which reaches several percent, is an important characteristic feature of N-nitrenes, distinguishing them from C-nitrenes and from typical carbenes. The electrophilic properties characteristic of carbenes and associated with the presence of an incomplete electron shell can in the N-nitrenes be poorly defined and even masked by the distinct manifestation of the nucleophilic properties of the negatively charged terminal nitrogen atom with its high π-AO population. In this respect we must consider the nearest analogues of the N-nitrenes to be not the C-nitrenes but the so-called "nucleophilic carbenes", in particular the little-studied aminocarbenes.

Another characteristic structural feature of the N-nitrenes, which leaves a specific imprint on their reactions, is the presence of the nitrogen–nitrogen bond. As a consequence of the low energy of this bond, combined with the tendency, typical of many hydrazine derivatives, to decompose with the formation of the exceptionally stable nitrogen molecule, an extremely important role in the chemistry of the N-nitrenes is played by decomposition reactions, which are not characteristic of carbenes.

II. PREPARATION OF N-NITRENES

The fairly large number of reactions for which the formation of N-nitrenes in the intermediate stages has been postulated can be divided into two groups. One of these consists of reactions involving the formation and decomposition of unsymmetrically substituted hydrazine derivatives, including (formally at least) α-elimination according to the scheme

$$>\!N{-}N\!<^{X}_{Y} \rightarrow >\!N{-}N + XY\,.$$

These reactions invlude the oxidation of 1,1-disubstituted hydrazines by bromine in acid medium (XY = HBr), the alkaline cleavage of the hydrazides of sulphonic acids, the thermal decomposition of their N-sodium derivatives (XY = $NaSO_2P$), and also the incomplete reduction of N-nitrosamines in alkaline medium (X = OH, Y = H), the ozonolysis of hydrazones, and the reaction of secondary amines with difluoroamine HNF_2, in which the sources of the nitrenes—unstable hydrazine derivatives—are formed in the first stages of the processes.

† This mesomeric form can be regarded as a modern representation of the structure (II) proposed at an early date by Michaelis[8], whereas structure (Ia) is a more accurate general representation of structures of type (V).

‡ An interesting feature is that in an electron diffraction study of the compound N_2F_2, obtained by decomposing FN_3, it was found[23] that the intensity curves can correspond to a planar molecule of the form $\begin{matrix} F \\ F \end{matrix}\!\!>\!N{-}N$ with N–N bond length 1.16 Å.

Another less extensive group of methods for obtaining N-nitrenes consists of reactions involving the decomposition of various derivatives of hydrazine containing the fragment $\rangle N-N^{-}-Z^{+}$:

$$\rangle N-N^{-}-Z^{+}:$$

$$\rangle N-\bar{N}-\overset{+}{Z} \rightarrow \rangle N-N + Z \ .$$

The decomposition of N-azido-compounds (Z = N_2) and sulphoximines (Z = R_2SO) takes place according to this scheme.

1. Formation of N-Nitrenes in Oxidation Reactions

The first proof of the formation of N-nitrenes in oxidation reactions was obtained by McBride and Kruse[24]. In the oxidation of the simplest 1,1-dialkylhydrazines by halogens or alkali metal halates in strongly acidic medium (pH 0), the solutions showed characteristic absorption in the near ultraviolet, which could be interpreted as a consequence of the formation of the acid (VI) conjugate with (I):

$$\underset{R}{\overset{R}{\rangle}}N-NH_2 \xrightarrow[-2HBr]{H^+,Br_2} \underset{R}{\overset{R}{\rangle}}\overset{+}{N}=NH \rightleftarrows \left[\underset{R}{\overset{R}{\rangle}}N-\ddot{N} \leftrightarrow \underset{R}{\overset{R}{\rangle}}\overset{+}{N}=\bar{N}\right] + H^+ \ .$$

(VI) (I)

This acid, which was called the diazenium cation, is fairly stable in strongly acidic solutions. Neutralisation of the solutions gave the corresponding tetrazene $R_2N-N=N-NR_2$.

The existence of species of type (VI) was also proved as follows. Acid solutions of Me_2NNH_2 and Et_2NNH_2 were oxidised separately, then mixed and neutralised. The mixtures formed contained all three possible tetrazenes—the two symmetrical and the unsymmetrical.

Dimethyldiazenium perchlorate (VII) was isolated by the reaction of dimethylhydrazine with iodine and silver perchlorate:

$$Me_2NNH_2 + I_2 + 2AgClO_4 \rightarrow \underset{(VII)}{[Me_2\overset{+}{N}=NH]\,ClO_4^-} + 2AgI + HClO_4 \ .$$

Work on the electrochemical oxidation of 1,1-dimethylhydrazine[25] and 1,1-diphenylhydrazine[26,27] in acid solutions also established the formation of relatively stable products of the two-electron oxidation; the presence of these products was confirmed by coulometry and chronopotentiometry[25] and by ultraviolet spectroscopy. It was noted that these substances can be reduced to the original hydrazines in yields of up to 95%, but when the solutions are left to stand they slowly decompose.

Further proof of the formation of N-nitrenes in oxidation reactions is provided by the fact that they can be trapped in the form of stable products of addition to the multiple bonds[28-34] and the products of the cyclo-addition of diazenium salts at multiple bonds[27,35-39], and also by the reactions of N-nitrenes with dimethyl sulphoxide[28,31].

The oxidation of 1,1-disubstituted hydrazines by bromine in strongly acidic aqueous solutions has been dealt with in a number of papers[14,15,17,24,35,36,40-43]. Potassium iodate[44] and bromate[24,43,45] are sometimes used as oxidant, but yellow mercuric oxide is used most frequently[8-13,44,46-61]. The reaction with mercuric oxide is usually carried out in aqueous or absolute alcohol, and less frequently in CH_2Cl_2,[50,53,55,59] $CHCl_3$,[10,11] CCl_4,[12,56] ether[61], butanol, and dimethyl sulphoxide[57]. Activated manganese dioxide[32,53,56,59,60,62,63] and nickel dioxide[60,64] in CH_2Cl_2, potassium permanganate in acetone[16,55], N-bromosuccinimide[55,60], selenium dioxide and iodobenzene diacetate[60], *t*-butyl hypochlorite[17,65], chlorine[65], and per-acids[66] have also been used.

Lead tetra-acetate has recently been used for the oxidation of 1,1-disubstituted hydrazines[28-33,36,51,60,67-81]. The reaction is usually carried out in benzene or CH_2Cl_2.

1-Chlorobenzotriazole[82] and the diethyl ester and phenylimide of azodicarboxylic acid[83] have been used as oxidants.

In all instances it is assumed that intermediate formation of the N-nitrene takes place according to the general scheme

$$\underset{R'}{\overset{R}{\rangle}}N-NH_2 \xrightarrow[-2H]{-2e^-} \left[\underset{R'}{\overset{R}{\rangle}}N-\ddot{N} \leftrightarrow \underset{R'}{\overset{R}{\rangle}}\overset{+}{N}=\bar{N}\right] \ . \qquad (1)$$

The directions of the reactions of the N-nitrenes formed in the first stage of the reaction, and the structures of the final products, are determined by the conditions of the oxidation and also by the nature of the radicals R and R′ in the original hydrazine. If R and R′ are aliphatic or aromatic radicals, oxidation under mild conditions usually gives the tetrazenes, which are regarded as the "normal" products of the oxidation of unsymmetrical secondary hydrazines. N-Nitrenes with heterocyclic, benzyl, and certain other radicals, however, have a greater tendency to undergo other reactions, so that the oxidation of these hydrazines may take place "anomalously", with the formation of not tetrazenes but other nitrogen compounds or hydrocarbons.

The oxidation has been carried out with 1,1-dibenzylhydrazine and its derivatives[9-13,17,47-49,63,79], including optically active compounds[47,48], and also with heterocyclic compounds which can be regarded as analogues of 1,1-dibenzylhydrazine: 1-amino-2,6-diphenylpiperidine[44,46,54], 1-amino-2,5-diphenylpyrrolidine[58], and other compounds containing condensed aromatic rings[53,55,56,64,84]. The oxidation of 1-amino-2,5-diphenylpyrrole and 1-amino-2,3,4,5-tetraphenylpyrrole[56], 1-amino-1,3,4-triazole, and its 2,5-dimethyl- and 2,5-diphenyl-derivatives[78] has been studied. Studies have been reported of the oxidation of 1,1-dialkylhydrazine[24,25,34,35,40,41,45,61,83,85], 1-alkyl-1-benzylhydrazine[21,32], and also of 1,1-diarylhydrazine[26,27,63,86], and 1-aryl-1-benzylhydrazine[13]. The oxidation of 1,1-disbustituted hydrazines with allyl and aryl radicals was studied earlier[8,86].

Overberger and coworkers oxidised 1-amino-2,6-dicyano-2,6-dimethylpiperidine[14-17,42], 1-amino-2,6-dicyanopiperidine, and 1-amino-2,6-dicarbamidopiperidine[57]. The oxidation of N-aminopiperidine, N-aminomorpholine[63], and N-aminophthalimide[80] has been studied.

Considerable attention has been paid to the oxidation of compounds of the 1- and 2-aminobenzotriazole[60,68-72,77,82], 1-aminonaphtho[1,8,-*d*,*e*]triazine[73-75], and 1-amino-4,5-diphenyltriazole[82] series, in connection with the intermediate formation of dehydroaromatic systems—dehydrobenzene and 1,8-dehydronaphthalene.

1-Amino-oxindole and its derivatives[51,65] have been oxidised, and various 3-cinnolinols were obtained as final products.

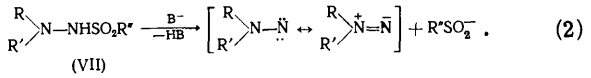
3-Aminobenzoxazoline-2-one[28,29,36], the N-aminoimides of various dibasic acids[29-32], and various other N-aminoheterocyclic compounds[29,32,33,67] were oxidised with the aim of carrying out addition reactions of the intermediate N-nitrene at the multiple bond.

3-Amino-benzo-1,2,3-triazine-4-one and its derivatives[76] were oxidised in an attempt to obtain benzocyclopropenone. The reaction of semicarbazide with per-acids has been carried out[66].

It should be emphasised that in early work on the oxidation of 1,1-disubstituted hydrazines the suggestion that N-nitrenes are formed in intermediate stages was used only to explain anomalous reactions, whereas it is now assumed that they are also formed in "normal" oxidation.

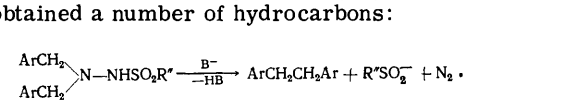
2. Decomposition of the Hydrazides of Sulphonic Acids and Their N-Sodium Derivatives

The action of alkalis on 1,1-disubstituted hydrazides of sulphonic acids (VII) leads not to their saponification but to their decomposition to the salts of the sulphinic acids and N-nitrenes, which undergo further reactions:

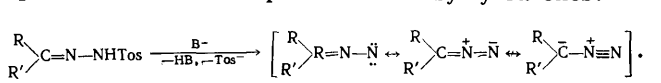


(VII) (2)

This reaction is named after its discoverer Carpino[87,88]. In the decomposition of dibenzylsulphonylhydrazines, Carpino obtained a number of hydrocarbons:



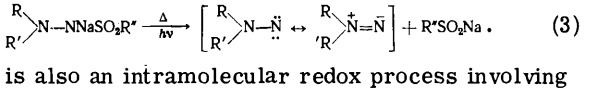
The formation of N-nitrenes from the hydrazides of sulphonic acids can be regarded as analogous to the preparation of diazo-compounds from tosylhydrazones:



In both instances an intramolecular redox process takes place, in which the hydrazine residue undergoes two-electron oxidation and the sulphonic acid residue is reduced to the sulphinate ion. In this sense the Carpino reaction is similar to the Busch–Weiss intermolecular oxidation of 1,1-disubstituted hydrazines; the final products of these reactions are also similar.

Lemal[89,90] observed a decrease in the rate of hydrolysis of 1,1-disubstituted hydrazides of sulphonic acids in strongly alkaline solutions. It was suggested that a condition for the reaction is the presence of alkali and free sulphonyl hydrazide.

The alkaline decomposition of 1,1-disubstituted sulphonyl hydrazides is closely related to the thermal decomposition[75,90–93] or photolysis[75] of their N-sodium derivatives:



(3)

This is also an intramolecular redox process involving the oxidation of the hydrazine residue to the aminonitrene and the reduction of the sulphonic acid residue to the sodium salt of the sulphinic acid. The final products of this reaction are analogous to the products of the action of alkalis on the corresponding hydrazides.

In acid medium, redox reactions involving the conversion of the sulphonyl hydrazides into diazenium salts and salts of sulphinic acids, which dissociate to give diazenium cations and sulphinate ions[94], also take place

(4)

Reaction (4) takes place in the first stage of the acid hydrolysis of 1-alkyl- and 1,1-dialkyl-2-tosylhydrazines, and the diazenium ion formed undergoes a number of further reactions.

Dissociation according to scheme (4) is also apparently the first stage of the ready exchange of sulphonic acid residues between sulphonyl hydrazides and salts of sulphinic acids[89,94]:

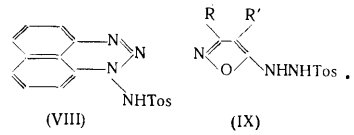
The exchange has been studied in alkaline and neutral media. The establishment of equilibrium in this exchange has been demonstrated by the NMR method, and the kinetics of exchange have been studied. It has been established that the reaction is of first order with respect to the original hydrazide and of zero order with respect to the salt (at a salt concentration greater than the equivalent concentration).

The action of alkali on 1,1-disubstituted sulphonyl hydrazides and the decomposition of their N-sodium derivatives have been most frequently studied with the readily available and easily purified tosyl hydrazides[55,56,59,62,75,87,88,91–93,95–101] and benzenesulphonyl hydrazides[87,88,91,96,101,102]. The hydrazides of alkylsulphonic acids have been less extensively studied[87,88,101].

The substituents on the tertiary nitrogen atom have been varied widely. Dibenzylhydrazides[87,88,95,96] and their derivatives[87,88] and analogues[55,62,92,97,98] have been studied. The alkaline cleavage of the 1-aryl-1-benzylhydrazides of sulphonic acids has been carried out[101,102]. The reactions of hydrazides with alkyl[90,91,96,102] and allyl[93] substituents have also been studied.

The Carpino reaction has been carried out with the tosylates of 1-aminopyrrole[91], 1-amino-2,5-diphenylpyrrole, and 1-amino-2,3,4,5-tetraphenylpyrrole[56], and also with 9-benzenesulphonimidocarbazole[91].

Hoffmann and coworkers[75] obtained 1,8-dehydronaphthalene by the alkaline hydrolysis of compound (VIII):



(VIII) (IX)

The alkaline cleavage of monosubstituted hydrazides was used in synthesis for the elimination of the hydrazine group in compound (IX)[99,100].

Most studies of the alkaline decomposotion of sulphonyl hydrazines have been carried out in aqueous or aqueous-alcoholic solutions of NaOH or KOH[55,56,59,62,87,88,91,92,97,98,101,102]. Other solvents used include ethylene glycol[56] and diethylene glycol[88], and, less frequently, aqueous K_2CO_3 solution[99,100], triethylamine in dimethylformamide[87], and pyridine[92].

3. Formation of N-Nitrenes in the Reduction of N-Nitrosamines

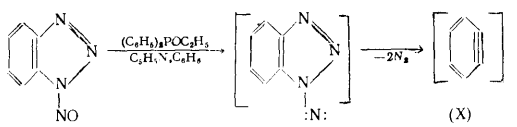
In 1957 it was discovered[103] that the reduction of dibenzylnitrosamine and its derivatives and analogues with sodium dithionite in alkaline medium gave not the usual reduction products—unsymmetrical secondary hydrazines R_2NNH_2—but hydrocarbons of the dibenzyl series:

The anomalous reduction of nitrosamines to hydrocarbons has been called the Overberger–Lombardino reaction. Since the products were found to be the same as the products of the oxidation of the corresponding

hydrazines, it was suggested that the same intermediate compounds—N-nitrenes—are formed in the two instances:

(5)

Reactions involving the anomalous reduction of nitrosamines were observed with dithionite in alcoholic alkali[47,48,58,84,103,104], lithium in liquid ammonia[104], and a benzene solution of ethyl diphenylphosphinite $[(C_6H_5)_2POC_2H_5]$.[105] Anomalous reduction is undergone not only by dibenzylnitrosamine itself[103,104] but also by N-nitroso-derivatives of benzylphenylamine, diphenylamine, and 2,6-dimethylpiperidine[103], 2,6-diphenylpiperidine[103,104], 2,5-diphenylpyrrolidine[58], and the optically active α,α'-dimethyldibenzylamine[47,48]. The formation of dehydrobenzene (X) was observed in the reduction of 1-nitrosobenzotriazole[105]:

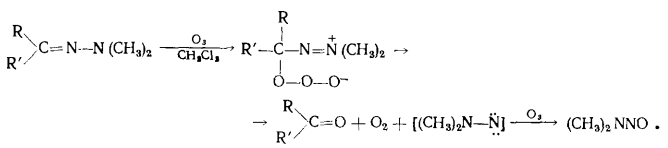


It is at present difficult to assess the possibility of formation of N-nitrenes in the reduction of N-nitrosamines taking place "normally", since the necessary experimental data are not available.

4. Ozonisation of Compounds Containing the $>C=N-N<$ Group

It has been known for a long time that in the ozonisation of compounds containing the $>C=N-N<$ group, aldehydes or ketones are formed[106,108]; the compositions of the other products of the reaction, and its mechanism, were not studied until recently. In 1961, papers were published on the ozonisation of the double bond in azines[109] and on the action of ozone on pyrazole and some of its homologues[110]; the authors of these papers assume that N-nitrenes are formed as intermediate products.

On the basis of kinetic data[111], the following mechanism for the ozonisation of the C=N bond in dimethylhydrazones was suggested:

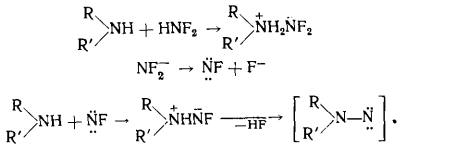


The N-nitrene formed may react with the solvent or be oxidised to the N-nitroso-compound[111].

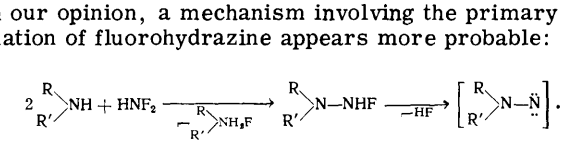
5. Reaction of Difluoroamine with Amines and Phenylhydrazones

Bumgardner and coworkers[95] studied the reaction of primary and secondary amines with difluoroamine in an excess of the amine:

The deamination of dibenzylamine with difluoroamine, the reduction of N-nitrosodibenzylamine with sodium dithionite, and the alkaline cleavage of 1,1-dibenzylhydrazine tosylate give dibenzyl in similar yields. On this basis it was concluded that N-nitrenes are formed in an intermediate stage of the deamination. The authors cited[95,112] put forward the following mechanism:

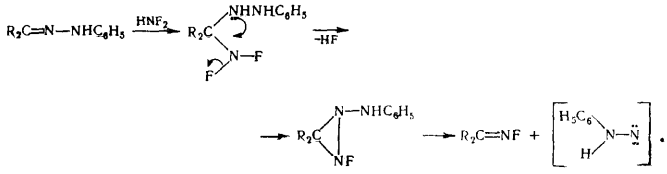


In our opinion, a mechanism involving the primary formation of fluorohydrazine appears more probable:



The reaction with difluoroamine has usually been carried out at room temperature. A variety of primary amines have been taken for the reaction—saturated[95] and unsaturated[37] amines, 3,5,5-trimethylpyrazoline[95], N-methylaniline[113], and the small-ring compounds azetidine[95] and aziridines[95,114].

It has also been assumed that N-nitrenes are formed in the reaction of difluoroamine with the phenylhydrazones of acetone and formaldehyde[113]:



Stronger evidence in support of all the above reaction mechanisms is required.

6. Formation of N-Nitrenes in the Reaction of Angeli's Salt with Secondary Amines

Lemal[96,115] described the reactions of a number of secondary amines with Angeli's salt $Na_2N_2O_3$§. Dibenzylamine, pyrrolidine, piperidine, morpholine[96], pyrroline, and its *cis*- and *trans*-2,5-dimethyl-derivatives[115] were studied.

Dibenzyl was obtained from dibenzylamine:

Other amino-compounds also gave products identical to the products of the reactions of the corresponding N-nitrenes, so that Lemal, without putting forward a reaction mechanism, concluded that the formation of N-nitrenes as an intermediate stage of the reaction of amines with Angeli's salt is possible.

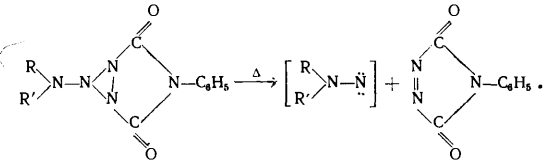
---

§ Angeli's salt has the sodium α-oxyhyponitrite structure[116]:

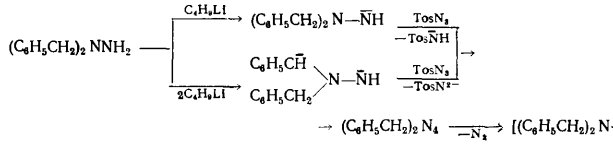
7. Formation of N-Nitrenes in the Decomposition of Their Adducts and N-Azides

Sulphoximines (XI), obtained by the addition of N-nitrenes to dimethyl sulphoxide, give N-nitrenes again as a result of photolysis[29] or thermal decomposition[31,67]:

The formation of N-nitrenes in the decomposition of N-aminotriaziridines, obtained by the addition of N-nitrenes across an N=N bond, has been assumed[83]:



A recent paper[117] dealt with the decomposition of N-azides, giving N-nitrenes and their decomposition products. The N-azides were obtained by the exchange of hydrazide anions and $TosN_3$; the intermediate N-azide was not isolated. Dibenzylamino-N-azide and the corresponding N-nitrene were obtained in this way:



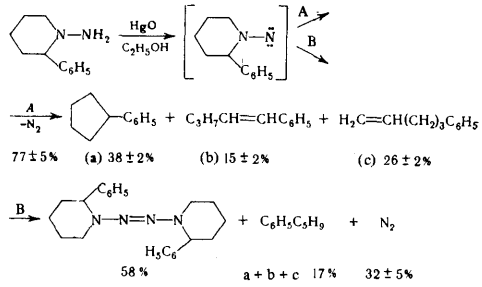
III. REACTIONS OF N-NITRENES

The previous section examined briefly reactions in which the intermediate formation of N-nitrenes has been assumed. The products of these reactions result from the subsequent transformation of the N-nitrenes. If we follow the traditional classification of chemical reactions according to the number of reactants and products, we can divide all known reactions of N-nitrenes into three types: 1) decomposition; 2) isomerisation; and 3) addition.

Examples of reactions of the first type are provided by the Busch–Weiss, Carpino, and Overberger–Lombardino reactions, in which the N-nitrenes decompose to hydrocarbons and nitrogen. The rearrangement of N-nitrenes to the isomeric hydrazones belongs to the second of the reaction types listed above, and examples of the third type are fairly widely encountered: they include the formation of tetrazenes, characteristic of N-nitrenes, and also the addition of various aminonitrenes across double bonds.

The direction of the reaction depends on many factors, which can be classified as internal factors, determined by the nature of the N-nitrene (its structure), and external factors determined by the conditions under which the reaction is carried out. The role of the medium has been little studied and is difficult to take into account. The same N-nitrenes react in different ways under different conditions, and even such an unstable species as dibenzylaminonitrene can be reduced to 1,1-dibenzylhydrazine without decomposition, whereas the comparatively stable aromatic imidonitrenes, under the conditions of the thermal decomposition of sulphoximines at 400–450°,[118] decompose with the liberation of nitrogen.

The lifetime of a given N-nitrene, and hence the reactions which it can undergo, can vary over a wide range, particularly under the conditions of heterogeneous reactions. If the probability that the N-nitrene meets and reacts with another molecule is appreciable, intermolecular reactions are observed, whereas if this probability is low, the N-nitrene decomposes before it is able to react with another molecule. This obvious situation is effectively illustrated by data on the oxidation of 1-amino-2-phenylpiperidine (XII) by yellow mercuric oxide[52].



When compound (XII) is added rapidly to a suspension of mercuric oxide in alcohol, the N-nitrene formed is able, before decomposition, to meet a molecule of the original hydrazine and react with it, giving chiefly the product of the bimolecular reaction—the tetrazene—and the decomposition products (hydrocarbons) are obtained in only 17% yield (path B). When the reagent is added slowly, the probability of the above encounter is low, and the decomposition of the N-nitrene is almost complete (path A).

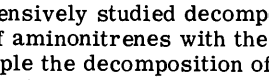
Thus in order to predict the direction of a reaction it is necessary to take into account many factors; these often have opposite effects which cannot yet be estimated quantitatively. Moreover, the picture is usually complicated by various secondary processes.

With all this in mind, we shall consider below the chief reactions of N-nitrenes and the small amount of information which has accumulated on the reaction mechanisms.

1. Decomposition of N-Nitrenes

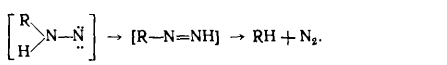
One of the most interesting and general features of N-nitrenes is their ability to decompose with the liberation of nitrogen and the formation of hydrocarbons. This reaction has been observed for N-nitrenes obtained in the most varied ways. In summarising the available data, it may be noted that the mechanism of the decomposition of N-nitrenes depends on the nature of the substituents and may vary from a completely concerted mechanism to a biradical mechanism.

The most extensively studied decomposition is the decomposition of aminonitrenes with the rupture of two bonds, for example the decomposition of dibenzylaminonitrene and its derivatives into dibenzyl and nitrogen:



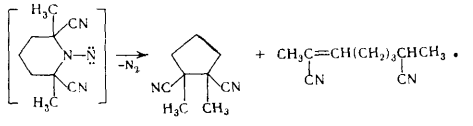
This reaction, discovered by Busch and Weiss in 1900, has attracted the attention of many research workers in subsequent decades. Dibenzyls have been obtained in the oxidation of 1,1-disubstituted hydrazines[9–12,47–49,88,104], in the anomalous reduction of nitrosamines[47,48,84,104], in the Carpino reaction[55,62,87,88,97,101], in the deamination of dibenzylamine by difluoroamine[95] or $Na_2N_2O_3$,[96] and in the decomposition of dibenzylamino-N-azide[117].

Decomposition to the corresponding hydrocarbons is also undergone by monosubstituted N-nitrenes, possibly after their rearrangement into the azo-compound[18,37,95,99,100,113,114]:



Problems related to the existence and stability of compounds of the type R–N=NH have been examined[119].

In the decomposition of N-nitrenes, in addition to combination of the residues R and R′, disproportionation with the formation of unsaturated compounds may also take place. Reactions of this kind were first observed in the oxidation of 1-amino-2,6-dicyano-2,6-dimethylpiperidine by bromine[14–17], when 2,6-dicyanoheptene-2 was obtained in addition to *cis*- and *trans*-1,2-dicyano-1,2-dimethylcyclopentanes:

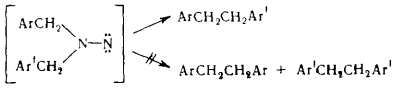


A large number of examples of reactions of this kind were subsequently studied[42,44,46–48,52,54,57,58].

The question of the mechanism of the decomposition of N-nitrenes was first raised in 1955, when a radical mechanism was proposed for the decomposition of 2,6-dicyano-2,6-dimethylpiperidyl-N-nitrene[17]. Later[44], however, it was suggested that the decomposition of aminonitrenes of this kind, and also of aminonitrenes with substituents of the benzyl type is a three-centre concerted decomposition. The data at this stage of the studies were summarised by Overberger[120]. Later, an E_2-mechanism was proposed[42], but this was later rejected when it could not explain new experimental facts[52,54,57].

A criterion for the correctness of a mechanism for the decomposition of aminonitrenes with radicals of the benzyl type must be consistent with the following experimental facts.

1. In the decomposition of aminonitrenes with different radicals, it has not been possible to isolate mixed cross-products of the combination[49,84,93,104]:



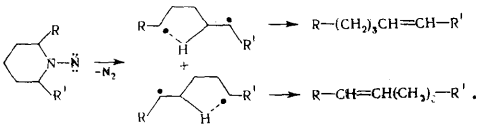
2. Decomposition with combination of the radicals takes place only if both[49,50,52,93] or at least one[52] of the substituents in the N-nitrene is capable of stabilising the intermediate state. These substituents are the benzyl, allyl, and nitrile radicals, and the carbamide and furfuryl groups. It is also known that in order to obtain a high yield of the products of the combination, the substituents should have a small volume, otherwise alkenes are formed preferentially[57].

3. For N-nitrenes with R and R′ radicals of the benzyl type, no definite conclusion can be reached regarding the influence of the inductive or mesomeric effect of a substituent in the ring on the rate of decomposition or the yield of hydrocarbons[87,88,101]. The absence of a relationship of this type is characteristic of radical reactions.

4. The stereospecificity of the decomposition of aminonitrenes in which the substituents form a cyclic system is extremely high[44,46,57,58,103,104]. For the optically active α,α'-dimethyldibenzylaminonitrene, the stereospecificity of the decomposition decreases sharply[47,48,84].

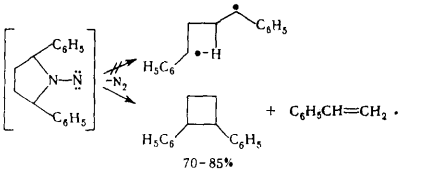
Almost all these results are consistent with the radical mechanism of decomposition, proposed by Overberger, with a strong cage effect, which prevents the formation of cross-products and increases the stereospecificity of the reaction[58]:

The formation of alkenes in the decomposition of six-membered rings, in Overberger's opinion, involves a five-membered intermediate state:



The relative amounts of combination products and alkenes will in this instance depend on steric factors.

In the decomposition of N-(2,5-diphenylpyrrolidino)nitrene, 1,4-diphenylbutenes are not formed[58], apparently due to the highly strained nature of the corresponding intermediate state (which must be four-membered):

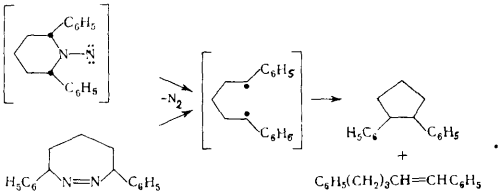


The process proceeds further with the partial formation of styrene.

The decomposition of N-nitrenes can be compared with the decomposition of the corresponding azo-compounds, the radical mechanism of which was established by the EPR method[121].

At first, the non-stereospecific nature of the thermal decomposition of the azo-compounds was noted[122,123]. Later, however, a number of authors[121,124–129] showed that under conditions favouring a marked cage effect, the decomposition of azo-compounds is extremely stereospecific. The model compounds in this work were *cis*- and *trans*-2,5-disubstituted Δ^1-pyrazolines[121,124–128] and 3,6-dicyano-3,6-dimethyl-3,4,5,6-tetrahydropyridazine[129].

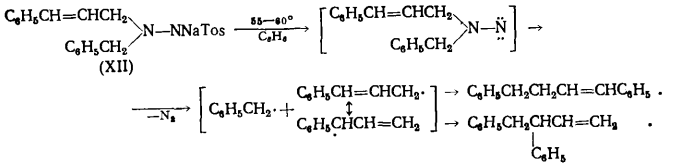
Evidence that the mechanisms of these reactions are the same is provided by the similarity in the isomeric composition of the products obtained in the decomposition of N-(*cis*-2,6-diphenylpiperidyl)nitrene[44,46,103,104] and in the decomposition of *cis*-3,7-diphenyl-1,2-diazacyclohept-1-ene[124]:



The products of the decomposition of N-(*cis*-2,5-diphenylpyrrolidino)nitrene[58] and the thermal decomposition of *cis*-3,6-diphenyl-3,4,5,6-tetrahydropyridazine[130] are also similar.

The proposed radical mechanism is effectively confirmed by the results of the decomposition of the sodium derivatives of tosylhydrazines with different allyl and benzyl radicals[93]. Thus the decomposition of compound

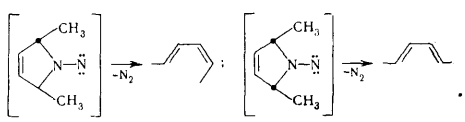
(XII) gave not only 1,4-diphenylbut-1-ene but also 3,4-diphenylbut-1-ene, in the ratio 3 : 1, with a total yield of ~ 100%:



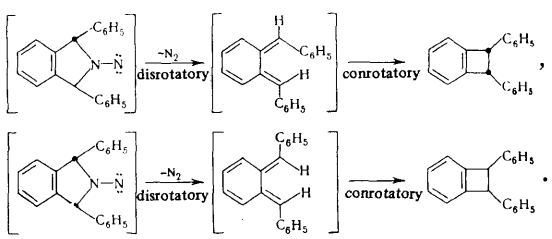
This result indicates the intermediate formation of free allyl and benzyl radicals. The absence of the cross-products—dibenzyl and diphenylhexadienes—indicates a strong cage effect.

The biradical decomposition of the aminonitrenes should however be regarded only as one possible extreme. The other extreme possibility is the concerted mechanism of decomposition.

The decomposition of a number of aminonitrenes obeys the Woodward–Hoffmann rules for concerted processes. These rules define the stereochemistry of the decomposition and are observed in those instances where these processes for the aminonitrene are allowed and are energetically more favourable than the radical processes. A common feature of the concerted processes of the decomposition of aminonitrenes is the formation of a system with a greater unsaturation than the original system. The polyene obtained may react further, and its subsequent reactions are also determined by the Woodward–Hoffmann rules. Examples of such processes are the decomposition of various N-(3-pyrrolino)nitrenes[115,132] and N-(1,3-dihydroisoindolino)nitrenes[53,55,59,64,92,98]. Lemal[115] established by means of correlation diagrams that the decomposition of N-(3-pyrrolino)nitrene should be disrotatory, and he confirmed this experimentally. The model compounds were N-(*cis*- and *trans*-2,5-dimethylpyrrolino)nitrenes:

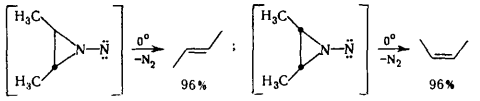


The decomposition of N-(1,3-dihydroisoindolino)nitrenes has attracted considerable attention, since it was expected to give various benzocyclobutenes. This process takes place in two stages, and for the example of N-(*cis*- and *trans*-1,3-dihydro-1,3-diphenylindolino)nitrenes it was shown[53,59,92,98] that the stereochemistry of both stages obeys the Woodward–Hoffmann rules. The yields and compositions of the products depend markedly on the conditions of the reaction[59]:

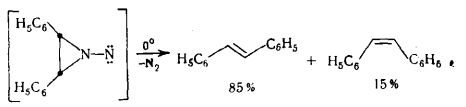


The decomposition of unsubstituted N-(1,3-dihydroisoindolino)nitrene[53,55,92,98] and the tri- and tetraphenyl-derivatives with substituents in the 1,3-positions[64] has also been studied. The intermediate products showed a tendency to undergo other concerted reactions, also possible in these systems, with the formation of various polycyclic compounds.

The decomposition of N-aziridinonitrenes gives alkenes. Data on the stereochemistry of the decomposition of three-membered rings with the formation of alkenes are contradictory, and there is still lack of agreement regarding its mechanism. Until recently it was considered that the decomposition of N-aziridinonitrenes was completely stereospecific, and this was demonstrated by the deamination of *cis*- and *trans*-2,3-dimethylaziridines by difluoroamine[114] (see also Ref. 133):

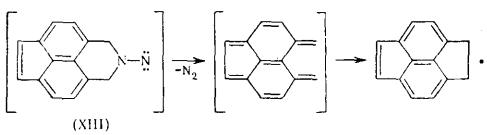


The decomposition of N-(*cis*-2,3-diphenylaziridino)nitrene is non-stereospecific, however[32]:



It was shown that under the conditions of the reaction, the isomerisation of *cis*-stilbene into the *trans*-isomer does not take place. Here, it is true, it may be assumed that the mechanism of the decomposition is intermediate between the biradical and the purely concerted mechanisms, but even this does not explain all the results obtained.

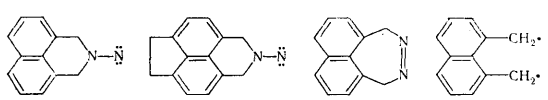
The decomposition of aminonitrenes with large rings has been little studied up to the present and has not been examined from the viewpoint of the preservation of orbital symmetry. The only example as yet is the decomposition of the aminonitrene (XIII), which gives dihydropyracylene in 8–15% yield[62]:



(XIII)

It may be assumed that this reaction takes place in two stages: linear cheletropic[131] decomposition of the aminonitrene takes place first, followed by electrocyclic closure of the ring with 12 π-electrons.

It should be noted that the aminonitrenes (XIV) and (XV) with similar structures do not decompose to nitrogen and hydrocarbons[55,62,97].

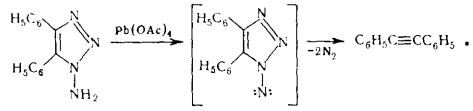


(XIV) (XV) (XVI) (XVII)

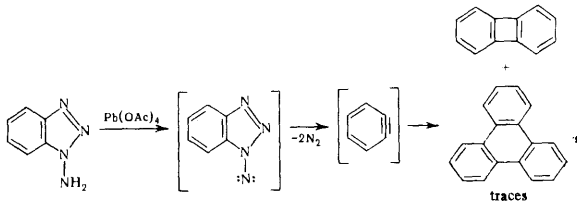
Concerted decomposition in these systems is impossible, but it is not clear why biradical decomposition does not take place. The decomposition of the aminonitrene (XIV) and the corresponding azo-compound (XVI) should take place by the same mechanism with the formation, in the first stage, of the biradical (XVII) and a molecule of nitrogen. The thermal decomposition of compound (XVI), however, as expected, gives the acenaphthene in 59% yield[55], and the aminonitrene (XIV) does not decompose to give nitrogen and hydrocarbons. No explanation for this has yet been put forward.

Let us now consider processes, involving the decomposition of aminonitrenes, in which more than two bonds in the original molecule are broken. This group includes the cleavage of 1- and 2-(1,2,3-triazolyl)nitrenes, and various other reactions.

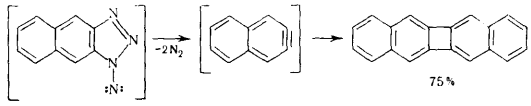
1-(1,2,3-Triazolyl)nitrene decomposes with the liberation of two molecules of nitrogen and the formation of hydrocarbons. In this way, 1-amino-4,5-diphenyl-(1H)-triazole gave tolane[82]:



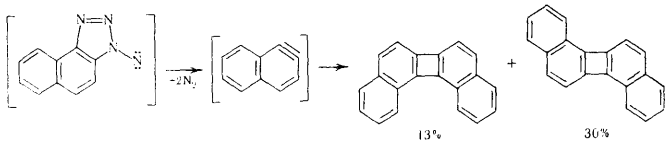
Hydrocarbons were obtained by the following reactions: from 1-aminobenzotriazole[60,69-71,82,105]:



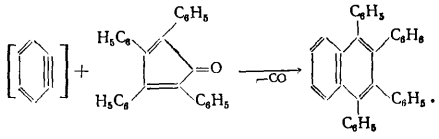
from 1-amino-[1H]-naphtho[2,3-*d*]triazole[72]:



from 1-amino[1H]-naphtho[1,2-*d*]triazole[72]:

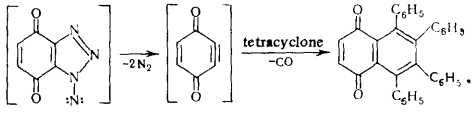


All these products are dimers of the corresponding dehydro-derivatives. The "arenes" obtained can also be trapped by "tetracyclone" (2,3,4,5-tetraphenylcyclopentadienone)[69,82,105]:

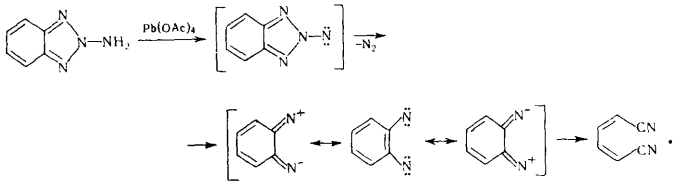


The yield of tetraphenylnaphthalene is almost quantitative, indicating the quantitative formation of dehydrobenzene in this reaction.

1-Aminobenzotriazoles with different substituents in the benzene ring also undergo splitting[69,71,77]. A similar method gave "benzynequinone" (dehydroquinone)[68,77], which with tetracyclone gave tetraphenylnaphthaquinone in 40–60% yield:

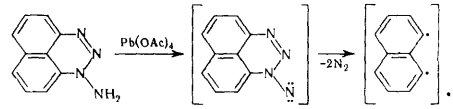


The oxidation of 2-aminobenzotriazole gives the dinitrile of *cis-cis*-mucic acid[70,71,82]:



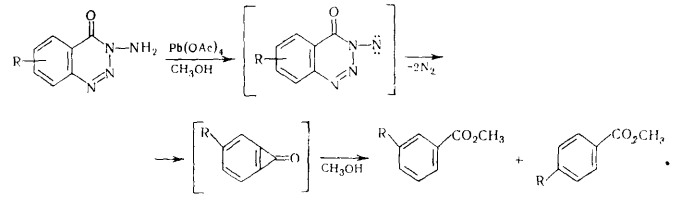
Oxidation by lead tetra-acetate leads to the partial formation of the *cis-trans*-dinitrile, apparently as a consequence of isomerisation under the conditions of the reaction. The milder conditions of oxidation by iodobenzene diacetate give only the *cis-cis*-isomer[71]. The formation of the dinitrene in an intermediate stage of the reaction is confirmed by the fact that the dinitrile of mucic acid was also obtained by the oxidation of *o*-phenylenediamine[71] by lead tetra-acetate and by the thermal decomposition of *o*-phenylenediazide[134]. Both of these reactions involve the intermediate formation of the dinitrene. *cis-cis*-2,5-Dimethoxymuconitrile was obtained by oxidising 1,4-dimethoxy-2,3-phenylenediamine[77].

The oxidation of 1-aminonaphtho[1,8-*d*,*e*]triazine gives 1,8-dehydronaphthalene[73-75]:

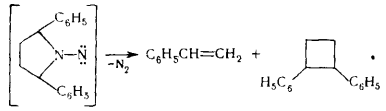


1,8-Dehydronaphthalene could not be obtained either by the thermal decomposition or by the photolysis of the sodium derivative of the tosylate of this compound. 1,8-Dehydronaphthalene is an exceptionally reactive compound. It reacts with solvents[73,74] and also adds on to C=C[73-75] and N=N[74] bonds.

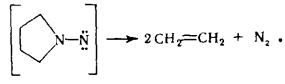
In 1969, an attempt was made to prepare benzocyclopropenone by the oxidation of 5- or 6-substituted 1-aminobenzotriazolin-8-ones, but the reaction in methanol gave only the methyl esters of the corresponding benzoic acids[76]:



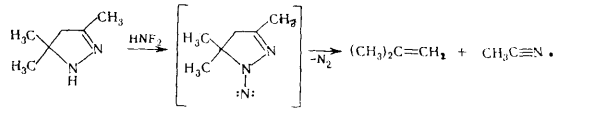
The decomposition of aminonitrenes containing a five-membered ring with different degrees of unsaturation is of considerable interest. This is important for the study of systems in which concerted decomposition is impossible. It was noted above that one of the products of the decomposition of N-(2,5-diphenylpyrrolidino)nitrene is styrene[58]:



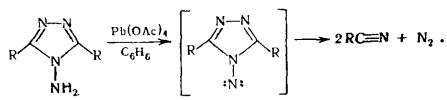
With unsubstituted N-(pyrrolidino)nitrene, dissociation into three components is the only route taken in the splitting:



This splitting with rupture of the 1–2, 1–5, and 3–4 bonds is fairly typical of nitrenes with a five-membered ring. It has been established[95] that when 3,5,5-trimethyl-Δ^2-pyrazoline is treated with difluoroamine, the N-nitrene formed decomposes to nitrogen, acetonitrile, and isobutene:



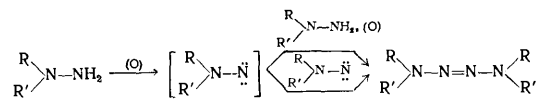
In the oxidation of 1-amino-1,3,4-triazoles with different substituents in positions 2 and 5, the liberation of 55–90% of the nitrogen and the formation of the corresponding nitriles was observed[78]:



1-Aminopyrrole derivatives, however, do not decompose in this way, but form tetrazenes and subsequently pyrrole derivatives[56,78,91]. It was therefore suggested that, other conditions being equal, the direction of the reaction is determined by the ease of rupture of the bond 3–4.[78] The explanation for the decomposition of the triazole derivatives is that the energy of the N–N bond here is smaller by 40 kcal mole^{-1} than the energy of the C–C bond 3–4 in pyrrole. This hypothesis, however, cannot explain the decomposition of aminonitrenes in the two previous instances, where the energy of the bond 3–4 is fairly high.

2. Formation of Tetrazenes

Since the time of Fischer[135] it has been known that Δ^2-tetrazenes are the chief products of the oxidation of 1,1-disubstituted hydrazines by a wide variety of oxidising agents. This "normal" oxidation is now also regarded as involving the interaction of the initially formed N-nitrenes with the original hydrazine or (which is less likely) their dimerisation[7,52]:

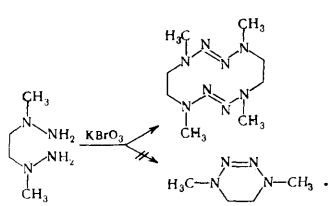


Tetrazenes are also formed in other instances on dimerisation of intermediate N-nitrenes, if the latter are sufficiently stable under the conditions of the reaction[24,55,56,66,91].

Fairly frequently, the tetrazenes formed are unstable under the conditions of the reaction and decompose with the separation of a molecule of nitrogen and the formation of secondary amines[56,78,90,91].

The possible stereoisomerism of Δ^2-tetrazenes has not been studied until recently, but recent papers deal with the isolation of *cis*- and *trans*-3,3-azobis-(2-oxazolidinone)[136] and the *cis*- and *trans*-isomers of the tetrazene obtained by oxidising N-aminophthalimide[80]. The oxidation usually gives the thermodynamically more stable *trans*-structure, but the *cis*-form can also be obtained on heterogeneous oxidation[80,136].

An attempt to prepare the *cis*-tetrazene by the oxidation of 2,5-diamino-2,5-diazahexane (this would be 1,4-dimethyl-1,4,5,6-tetrahydro-1,2,3,4-tetrazine) gave the twelve-membered cyclic bis-tetrazene[45]:



McBride developed a method for preparing tetra-alkyltetrazenes by oxidising 1,1-dialkylhydrazines with bromine in acidic aqueous solution followed by neutralisation[24,34,40,44]. The diazenium ion formed in the first stage, on neutralisation, gives the N-nitrene, which then dimerises to give the tetrazene:

3. Oxidation and Reduction of N-Nitrenes

These reactions have been insufficiently studied. The oxidation of N-nitrenes to the corresponding nitrosamines was observed under ozonisation conditions[110,111]:

It was suggested that in the electrochemical oxidation of 1,1-dimethylhydrazine in acid medium, one possible reaction of the diazenium ion is its oxidation to the nitrosamine[25].

Reduction of N-nitrenes apparently takes place in the reduction of N-nitrosamines to hydrazines. It is known that diazenium ions in acid medium can be reduced by chemical (by $SnCl_2$ or Zn in H_2SO_4) or electrochemical methods[25,26]. The corresponding 1,1-disubstituted hydrazines are obtained in yields close to 100%:

4. Rearrangements of N-Nitrenes

The rearrangements of N-nitrenes have been studied in considerable detail, but a satisfactory mechanism has not yet been proposed for any of these reactions.

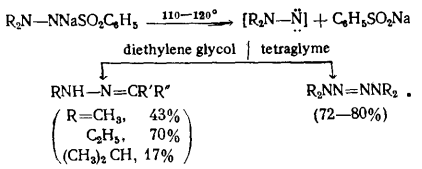
The most widely encountered and relatively fully studied reaction is the isomeric conversion of N-nitrenes into monosubstituted hydrazones, for which the name "diazene–hydrazone rearrangement" has been proposed[90]:

The formation of hydrazones in the oxidation of 1-aryl-1-benzylhydrazines by mercuric oxide was detected at an early date[13]. Later, examples of this rearrangement were studied for arylbenzylaminonitrenes[101,102], arylalkylaminonitrenes[101,113], and dialkylaminonitrenes[25,85,89,90,102]. The rearrangement has usually been carried out in alkaline medium, and only one example in acid medium is known[25].

That the rearrangement is intramolecular is indicated by the absence of the products of the cross-reaction in the alkaline cleavage of a mixture of the tosylates of 1-benzyl-1-*p*-chlorophenylhydrazine and 1-*p*-chlorobenzyl-1-phenylhydrazine (only benzaldehyde *p*-chlorophenylhydrazone and *p*-chlorobenzaldehyde phenylhydrazone were isolated)[101]. The reaction is of first order with respect to the hydrazide anion, and the rate-determining step is the separation of the sulphinate ion.

The mechanism of the diazene–hydrazone rearrangement was the subject of a special study[90] in which the N-sodium derivatives of the 1,1-dialkylhydrazides of benzenesulphonic acids were heated to 110–120° in the organic solvents tetraglyme and diethylene glycol. It was found that the composition of the decomposition products depends markedly on the nature of the solvent: in the aprotic tetraglyme, tetrazenes were obtained in good

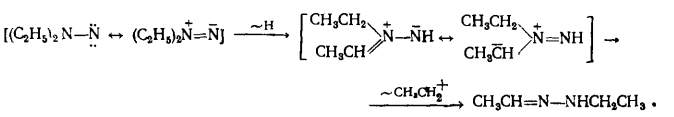
yields, whereas in diethylene glycol, only the hydrazones or a mixture of the hydrazone and the tetrazene were obtained:



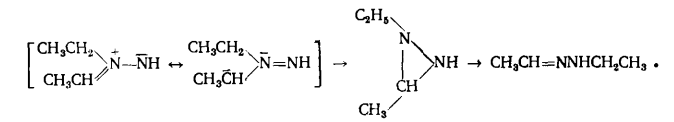
Three possible mechanisms for the rearrangement of the aminonitrenes to hydrazones were examined[90].

1. Migration of one of the substituents on the central nitrogen atom to a neighbouring atom carrying a negative charge, in the form of the carbo-cation; the azo-compound formed then undergoes isomerisation to the hydrazone:

2. A mechanism which differs from the preceding mechanism in the order of migration of the proton and the carbo-cation and which assumes the intermediate formation of not the azo-compound but an unstable ylide:

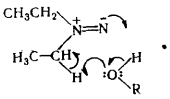


3. A mechanism involving a valency rearrangement of the initially formed ylide into the diaziridine, which then undergoes isomerisation to the hydrazone:



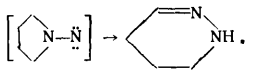
Neither azo-compounds nor diaziridines were detected among the products of the rearrangement. Since special experiments showed that under the conditions of the rearrangement[90] azoethane undergoes only partial isomerisation, and the corresponding diaziridine does not undergo isomerisation at all, mechanisms 1 and 3 were rejected.

The role of the hydroxyl-containing solvent is regarded as being to facilitate the migration of the proton by the formation of a six-membered cyclic intermediate complex with the participation of the aminonitrene:



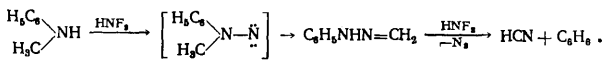
Experiments with compounds labelled with ^{15}N,[102] however, did not confirm the second proposed mechanism either. From the mechanism with the primary formation of an ylide, it follows that for a nitrene with a labelled terminal nitrogen atom the hydrazone formed should contain the tracer atom in the amino-group RCH=N–N*HCH$_2$R, but the labelled atom was found to be the imide nitrogen atom of the hydrazone RCH=N*–NHCH$_2$R, that is the rearrangement as it were involved not the carbo-cation RCH_2^+ but the alkylidene residue RCH$\langle$. Further study of the mechanism of the rearrangement of aminonitrenes to hydrazones is thus required.

Some heterocyclic aminonitrenes can undergo diazene–hydrazone rearrangement with expansion of the ring as a result of the inclusion of a second nitrogen atom in it. Thus Δ^2-tetrahydropyridazine was obtained from derivatives of N-aminopyrrolidine[96]:



The yield was 55–70%, depending on the method used to generate the nitrene. This reaction indicates new methods for the preparation of heterocyclic nitrogen compounds which are difficult to obtain.

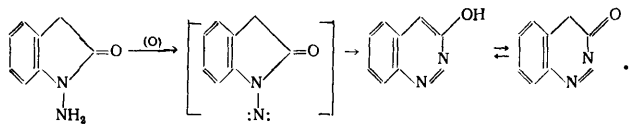
The diazene–hydrazone rearrangement has been postulated in the reaction of difluoroamine with N-methylaniline[113]:



It should however be noted that formaldehyde phenylhydrazone was not obtained in the alkaline cleavage of 1-phenyl-1-methylhydrazine tosylate[101].

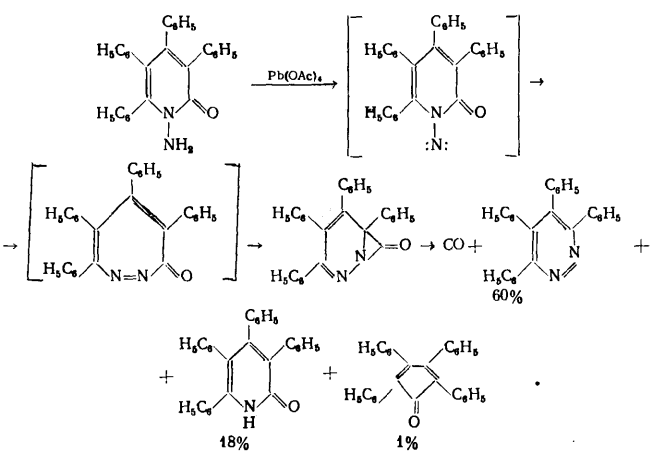
Another form of rearrangement of N-nitrenes involves their conversion into azo-compounds:

Historically, the first example of this reaction can be taken to be the formation of azo-compounds from 1-allyl-1-arylhydrazines on oxidation with mercuric oxide[8,86]. After this, no new example of the preparation of azo-compounds from 1,1-disubstituted hydrazines was described, although the analogous reactions of heterocyclic compounds were discovered by Baumgarten[51,65] and Rees[67]. In the oxidation of 1-amino-oxindole and its derivatives by lead tetra-acetate[51], *t*-butyl hypochlorite, and chlorine[65], Baumgarten observed rearrangement to 3-cinnolinol:



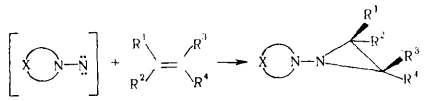
An interesting feature is that oxidation by chlorine gave the highest yield (up to 93%).

Rees and Yelland[67] discovered a similar rearrangement in the oxidation of N-amino-2,3,4,5-tetraphenylpyridone:



5. Addition of N-Nitrenes Across Multiple Bonds

The first report of the addition of N-nitrenes across the C=C bond of alkenes and conjugated dienes appeared only in 1967[28], but a fairly large amount of data has now accumulated[28,29,31-34,137], indicating the important synthetic and theoretical aspects of these reactions.



Preliminary reports of the addition of aminonitrenes to N=N[83] and C≡C[30] bonds have also appeared. All these reactions are (1+2)-cyclo-addition reactions.

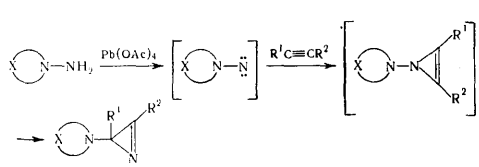
The specific features of the addition of N-nitrenes to multiple bonds are determined to a considerable extent by the negative charge on the sextet nitrogen atom and the high population of its π-orbital[19], as a consequence of which the simplest aminonitrenes exhibit nucleophilic, and not electrophilic properties, like the carbenes. In addition reactions, aminonitrenes with electron-accepting substituents which increase the electrophilic nature are used—most frequently N-amido- and N-imidonitrenes and similar compounds[28-34,137]. The addition of other types of aminonitrene to multiple bonds has not yet been observed. Aminonitrenes with very similar structures often show quite different behaviour, however, and it is difficult to predict the direction of a reaction.

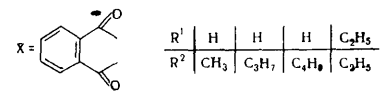
Both nucleophilic[28,29,32-34,97] and electrophilic[23,31,33,34,137] alkenes and dienes[28,29,34] have been taken for the addition reactions. Recently, to increase the yield of products, attempts have been made to use alkenes with electron-accepting substituents, but an unambiguous relationship between the yield of products and the electrophilic nature of the alkene has not yet been established[34]. An interesting feature is that *trans*-1,2-dichloroethylene and trichloroethylene give aziridines in 60–90% yield, whereas 1,1-dichloroethylene and *cis*-1,2-dichloroethylene do not form adducts at all[34]. It must be assumed that the yield of aziridines apparently characterises not so much their formation directly in the addition reaction as the stability of the resulting extremely unstable[33,34,137] aziridines under the conditions of the reaction, on isolation and purification.

The reaction of aminonitrenes and dienes gave the corresponding vinylaziridines in 35–71% yields. Adducts across both double bonds, or products of 1,4-addition, are not formed[28,29,34].

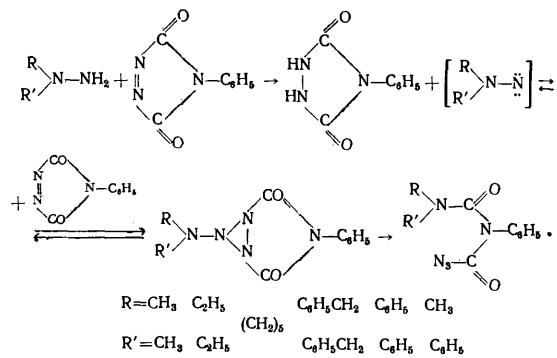
A remarkable feature is the complete stereospecificity of the addition of aminonitrenes to the C=C bond[28,29,31-34,137]. If Skell's postulates[138,139] regarding the stereochemistry of the addition of carbenes across multiple bonds are extended to aminonitrenes, it may be assumed that aminonitrenes react with a double bond exclusively in the singlet state[29,34].

In the addition of aminonitrenes across the C≡C bond, 2H-azirines are obtained in relatively low yields (5–15%)[30]. These reactions are of interest in that the 1H-azirine formed in the first stage is antiaromatic, so that it immediately undergoes rearrangement into the 2H-azirine, which is the final reaction product:



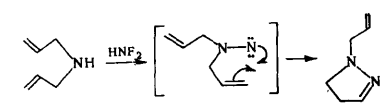


It is stated[83] that the products of the addition of aminonitrenes to the N=N bond are triaziridines. The diethyl ester and phenylimide of azodicarboxylic acid have been used as aminonitrene acceptors. In the last instance the reaction is represented:



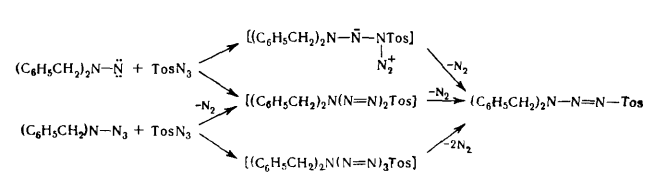
The triaziridines were isolated and characterised by their ultraviolet spectra and melting points.

With dialkylaminonitrenes, intramolecular reaction of the N-nitrene with the multiple bond was observed; the reaction mechanism was not discussed[37]:



6. Reactions of N-Nitrenes with Tosyl Azide and Dimethyl Sulphoxide

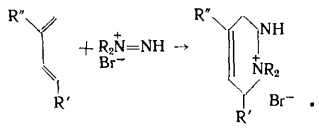
In the reaction of dibenzylaminonitrene, formed from dibenzylamino-N-azide, or possibly, of the azide itself with tosyl azide at 0°, one of the products is 3,3-dibenzyl-1-tosyltriazene (yield 13–28%)[117]:



The aminonitrenes which can add to double bonds were taken for the reaction with dimethyl sulphoxide[29,31,67]. The products obtained were called sulphoximines[29,67] or iminoxysulphuranes[31]:

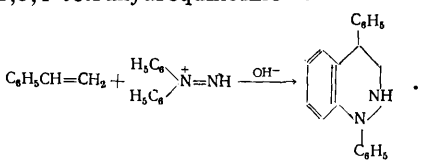
7. Reactions of Diazenium Salts

The diazenium cations formed on protonation of N-nitrenes have proved to be very active dienophiles, and this has been used for the preparation of quaternary Δ^4-tetrahydropyridazinium salts [35,36,38,39]:



The ability of 1,1-dimethyldiazenium bromide to undergo the Diels–Alder reaction with isoprene or divinyl under mild conditions was discovered by McBride and Urry [35] and later studied in detail by Zelenin and Bezhan [38,39,140] with many 1,1-dialkyldiazenium bromides, isoprene, chloroprene, and piperylene. Even cyclohexa-1,3-diene, which reacts only with very active azo-compounds, gives an adduct with 1,1-dimethyldiazenium bromide in 80% yield. The structural direction of these reactions is the usual direction for diene synthesis: 1-substituted dienes (piperylene) give the ortho-isomers, and 2-substituted dienes (isoprene and chloroprene) the para-isomers. The product of the oxidation of 1,1-di-isopropylhydrazine in acid medium, however, did not undergo the diene synthesis. The branched structure of the framework of the diazenium cations is apparently of considerable importance [39,140]. In the reaction of dimethyldiazenium bromide with isoprene, the formation of small quantities (12%) of tiglic aldehyde dimethylhydrazone was observed [35]. The reaction of the 1,1-dimethyldiazenium cation with styrene and indene leads to the formation of hydrazinium salts [36]:

When the solution is neutralised, these salts may be converted into diazetidinium salts, and also undergo more extensive decomposition. The reaction of styrene with 1,1-diphenyldiazenium perchlorate in acetonitrile, however, leads after neutralisation to the formation of 1,4-diphenyl-1,2,3,4-tetrahydroquinoline [27]:



---o0o---

A number of papers published in 1971 supplement and extend our knowledge of aminonitrenes.

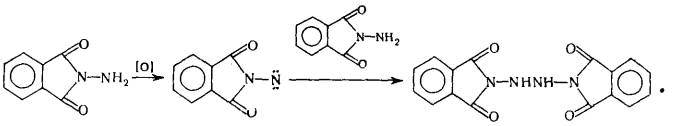
New data on the conversion of dialkylaminonitrenes into dialkylhydrazones [141] indicate that this reaction is a general reaction for aminonitrenes generated under different conditions, and can be regarded as indicating the important role of tautomeric equilibria

in the subsequent reactions of the aminonitrenes.

The analogous tautomerism of the protonated forms of aminonitrenes—the diazenium cations:

is apparently the first stage of the splitting of diazenium cations at the C=N$^+$ bond with the formation of carbonyl compounds when solutions of diazenium salts and the corresponding 2,4-dinitrophenylhydrazones are boiled—in the reaction with 2,4-dinitrophenylhydrazine [142].

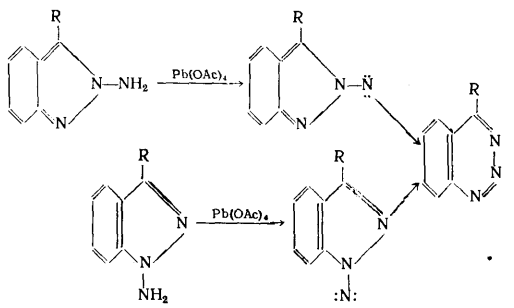
In the oxidation of various N-aminolactams with lead tetra-acetate and iodobenzene diacetate, the corresponding tetrazanes were isolated [143]:



These are capable of undergoing further oxidation to Δ^2-tetrazenes, providing evidence in support of the previously proposed mechanism of oxidation of 1,1-disubstituted hydrazines to Δ^2-tetrazenes via the tetrazanes, obtained in the reaction of intermediate N-nitrenes with the original hydrazines [7,52] (see also section III, 2 of this review).

The formation of esters of benzoic acid in the oxidation of 5- and 6-substituted 1-aminobenzotriazolin-8-ones with lead tetra-acetate in CH_2Cl_2 [144] may take place not only via the decomposition of intermediate aminonitrenes to cyclopropenones and two molecules of nitrogen [76] but also via the formation of indazolones, which have been isolated as the adducts with tetracyclone.

In the oxidation of 3-substituted 1- and 2-aminoindazoles, instead of the liberation of nitrogen, expected by analogy with the behaviour of the corresponding aminobenzotriazoles [69–72], the reaction gave 1,2,3-benzotriazines [145] in almost quantitative yields



This rearrangement of the intermediate aminonitrenes is extremely similar to other examples of ring expansion in aminonitrenes [51,65,67].

Mass-spectrometric Determination of the Configuration of Steroid Alcohols

N.S.Vul'fson, V.I.Zaretskii, and V.G.Zaikin

A large number of epimeric secondary alcohols of the 3-, 11-, 12-, 14-, 15-, 16-, 17-, 20-, and 24-hydroxy-steroid series, derivatives of androstane, pregnane, or cholestane, and also tertiary alcohols of the oestrane series which are epimeric at $C_{(17)}$ show that, in all cases in which the hydroxyl is situated in a conformationally sufficiently rigid part of the steroid skeleton, mass spectrometry can be used to establish the configuration of the steroid alcohols. The main conclusions can be drawn on the basis that, in most cases of electron impact an axial hydroxyl is split off more readily than is an equatorial hydroxyl, as a consequence of the possibility of a mechanism of 1,3- or 1,4-*cis*-diaxial elimination of the elements of water. A list of 31 references is included.

1. INTRODUCTION

Mass spectrometry, which is widely employed in solving structural problems of organic chemistry and especially the chemistry of naturally occurring compounds, has hitherto found only limited application to the solution of stereochemical problems. The primary reason is that aliphatic stereoisomers differ little if at all in internal energy. As a consequence the mass spectra of optical enantiomers are usually identical not only to each other, but also to the spectrum of their racemic mixture[1]. The presence of two or more asymmetric carbon atoms is sometimes sufficient to produce differences, though slight, in the mass spectra of the diastereomers. Thus Ryhage and Stenhagen[2] observed slight differences in the mass spectra of dimethyl *meso*- and (−)-3,4-dimethyladipates (I) and methyl 2L, 9L- and 2L, 9D-dimethyltetracosates (Ia)

$$MeOCOCH_2CHMeCHMeCH_2COOMe \quad (I);$$

$$Me[CH_2]_{14}CHMe[CH_2]_6CHMeCOOMe \quad (Ia).$$

As could be expected, alicyclic compounds exhibit sharper differences in the mass spectra of stereoisomers, which are larger the greater the conformational stability of the cyclic system. The difference in internal energy between epimeric molecules may depend significantly on the nature of the substituent, its spatial arrangement, and the character of non-bonded interactions, and this in turn leads to variation in the intensities of the characteristic peaks in the mass spectrum.

Differences in the mass spectra of cyclic epimers are due primarily to variation in the ease of elimination of substituents at the asymmetric atom, a process often accompanied by ejection of a hydrogen atom (detachment of water, hydrogen sulphide, and acetic acid from alcohols, thiols, and acetates respectively). Therefore, although all modes of fragmentation of one epimer on electron impact are usually characteristic also of the other epimer, the intensities of the corresponding peaks ($M - CH_3$, $M - H_2O$, $M - H_2S$, $M - CH_3COOH$, etc.) are different. The extent to which the migrating hydrogen atom or group of atoms is involved in specific rearrangement of the given compound may be as important as the purely energetic factor. In this case the peak intensity of the corresponding rearranged ion usually depends on the distance between the hydrogen-donating and the hydrogen-accepting atoms.

The above discussion can be summarised in the conclusion that the differences in the way in which molecular ions of epimers break down on electron impact are governed ultimately by two factors—an energy factor and a so called "distance factor"[3,4].

In one of the earliest mass-spectrometric investigations of epimeric cyclic alcohols Biemann and Seibl[5] showed, with epimeric secondary alcohols of bicyclo[3,3,0]octan-2-ol, bicyclic terpenes, and steroids as examples, that the peak due to the molecular ion is less intense in the mass spectrum of the epimer having the more "compact" configuration than in the spectrum of the less "compact" epimer.

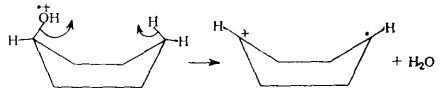
Before passing to a detailed examination of work on the mass spectrometry of steroid alcohols, we must first consider the mechanism of the dehydration of alcohols under conditions of mass spectrometry.

2. MECHANISM OF THE DEHYDRATION OF ALCOHOLS ON ELECTRON IMPACT

Momigny[6], McFadden et al.[7,8], Meyerson and Leitch[9], and also Benz and Biemann[10] showed, by means of deuterated analogues of straight-chain aliphatic alcohols, that in dehydration under the influence of electron impact ~ 90% of hydrogen atoms are lost from position 4: i.e. a mechanism of dehydration involving a six-membered transition state is preferred.

Natalis[11,12] was early able to show that all the deuterium atoms are retained when 2,2,5,5-tetradeuterocyclopentanol undergoes dehydration. It was suggested that 1,3-*cis*-diaxial elimination of water is the most probable process in the case of cycloalkanols. This question has been studied in greater detail by Shannon et al.[13] and by Djerassi et al.[14].

Investigation of 2,2,6,6-tetra- and 1,4,4-tri-deuterocyclohexanols showed[13] that the dehydration of the molecular ion of cyclohexanol (under conditions excluding random migration of hydrogen atoms) is effected by 1,3- and 1,4-elimination in the proportions 0.7 : 1. If the latter process does not involve preliminary opening of the ring, it must be assumed that the molecular ion of cyclohexanol has the boat conformation (we are concerned, of course, with the reactive conformation):

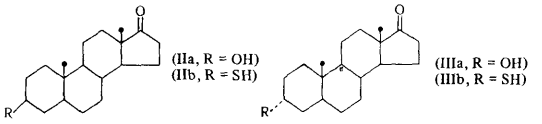


In this case *trans*-cyclohexane-1,4-diol should be more easily dehydrated than its *cis*-isomer on electron impact. In fact, the peak due to the $[M - DOH]^{+}$ ion in the spectrum of *trans*-1,4-dideuterocyclohexane-1,4-diol exceeds the corresponding peak in the spectrum of the *cis*-diol by a factor of 8.

By means of the mass spectra of deuterated cyclohexanols containing deuterium in various positions Djerassi[14] confirmed the suggested 1,3- and 1,4-mechanism for the elimination of water. However, his results indicated that the relative probabilities of the ejection of a hydrogen atom from positions 3 and 4 were 0.5 : 1.

3. 3-HYDROXY-STEROIDS

As remarked above, Biemann and Seibl[5] observed significant differences in the mass spectra of epimeric steroid alcohols. Thus the intensity ratio of the peaks $I_{M-H_2O}/I_{M^+} = 0.11$ for epiandrosterone (IIa) with an equatorial 3β-hydroxy-group, but the ratio is 0.19 for androsterone (IIIa) with a 3α-hydroxyl.

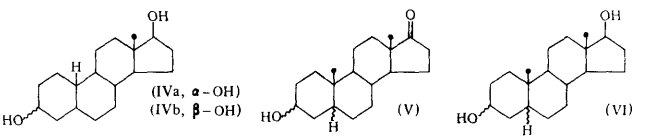


These workers found a similar but still more clearly defined difference in the mass spectra of the acetates of (IIa) and (IIIa), where elimination of a molecule of acetic acid occurs far more readily from the epimer having an axial acetoxy-group.

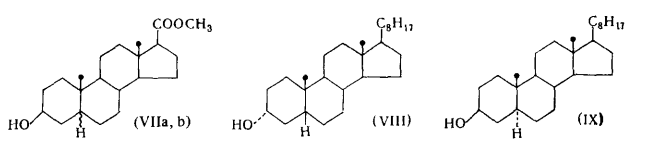
However, the work of Egger and Spiteller[15] casts about on the reliability of Biemann and Seibl's results. The mass spectra of epiandrosterone (IIa) and androsterone (IIIa), obtained by the later workers by direct introduction of the specimen into the ion source at 70°C, were completely identical, showing no difference in the intensity ratio of the peaks due to M^+ and $[M - H_2O]^{+}$ ions. Thermal effects obviously played a quite important part in Biemann and Seibl's experiment, since they used an instrument with a heated metallic admission system. Therefore their mass spectra represented a difference in thermal dehydration rather than in the degree of dehydration on electron impact.

An independent study of the mass spectra of the epimeric androsterones (IIa) and (IIIa) was made by Zaretskii and Zaikin[16]. They also detected no difference between the mass spectra of the epimers while using a system of direct introduction of the test material into the ion source† (at a temperature 20–30 deg below the melting point). Nor were differences evident in the mass spectra of their thio-analogues (IIb) and (IIIb). Thus the mechanism of the elimination of hydrogen sulphide from thiols on electron impact is evidently similar to the mechanism of the elimination of water.

In view of the results obtained by Shannon[13] and by Djerassi[14] we may suppose that the dehydration of androsterone (IIIa)[15,16], containing an axial hydroxyl, takes place mainly by the 1,3-type of elimination. On the other hand, the dehydration of epiandrosterone (IIa) may be accompanied by transition of ring A into the boat form, which evidently increases the probability of elimination of the 3β-hydroxyl, since hydrogen atoms from other rings, situated closest to the hydroxyl-group, may also be involved in the dehydration. The ultimate result is that the ratio I_{M-H_2O}/I_{M^+} is almost the same in the spectra of the 3α- and 3β-epimers. The spectra of 19-norandrostane-3α,17β- and -3β,17β-diols (IVa) and (IVb) provide some support for this view.



The peak due to the $[M - H_2O]^{+}$ ion is considerably larger in the spectrum of the 3α-hydroxy-epimer (IVa) than in that of the 3β-hydroxy-epimer (IVb)[15]. If it is assumed that on electron impact the ring A is in the boat form, conditions are favourable in the β-epimer for 1,4-elimination of water involving the 10β-hydrogen atom (which, incidentally, is absent from androstanes containing a 19-methyl group). In steroids having *cis*-fusion of rings A and B a hydrogen atom may be removed from $C_{(9)}$ (if ring A is also in the boat form). Such a possibility is not available to alcohols having *trans*-fusion of these rings, so that the 5β-alcohols undergo dehydration more easily than do their 5α-epimers. Nor are differences observed in the spectra of 3-hydroxyandrostan-17-ones (V) and of androstane-3,17β-diols (VI), whether of the 5β- or of the 5α-series, these compounds being epimeric at $C_{(3)}$.



However, compounds having the same configuration of the 3-hydroxyl but isomeric with respect to the fusion of rings A and B have significantly different spectra: dehydration under the influence of electron impact takes place more readily in the 5β-series. A more intense $M - H_2O$

† In all the work discussed below the mass spectra were obtained with direct entry of the specimen into the ion source.

peak and a less intense M^+ peak are observed also in the mass spectra of methyl 3β-hydroxy-5β-etianate (VIIa) and coprostan-3α-ol (VIII) in comparison with those of the stereoisomeric methyl 3β-hydroxy-5α-etianate (VIIb) and cholestan-3β-ol (IX) respectively[15].

The problem of elucidating the mechanism of the elimination of water on electron impact with epimeric cholestan-3-ols have been examined by Djerassi et al.[17] In order to exclude the effect of thermal dehydration preceding electron impact, these workers consider the dehydration of the $[M - CH_3]^+$ ion, not that of the molecular ion as is usually done. The mass spectra of the deutero-derivatives of cholestan-3α-ol showed (Table 1) that 73% of hydrogen atoms involved in formation of the ion $[M - CH_3 - H_2O]^+$ came from the 5α-position (ion a) and 7% from $C_{(1)}$ (ion a'). In the case of cholestan-3β-ol formation of the $[M - CH_3 - H_2O]^+$ ion involves the loss of 28% of hydrogen atoms from position 1 and 11% of 5α-hydrogen atoms (Table 2). The remaining hydrogen atoms involved in dehydration of the ion $[M - CH_3]^+$ are eliminated from other rings. If ring A is in the chair form, 1,3-diaxial detachment of hydrogen involving the 5α-hydrogen atom is possible with cholestan-3α-ol. This possibility is clearly absent from the cholestan-3β-ol molecule, where the opening of ring A and random ejection of hydrogen atoms from the other rings constitute the more probable mechanism[17].

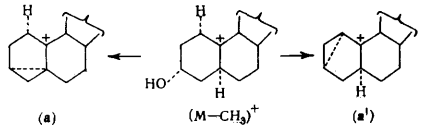


Table 1. Intensity of $[M - CH_3 - HDO]^+$ peak as percentage of $[M - CH_3 - H_2O]^+$ peak in the spectra of labelled cholestan-3β-ols.

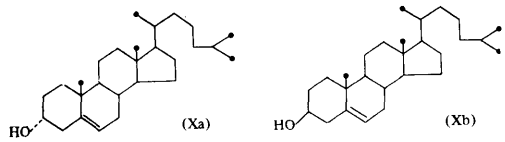
2,2,4,4-Tetradeuterated	0
1,1,3β-Trideuterated	7 ± 2
1α-Monodeuterated	4.5 ± 2
5α-Monodeuterated	73 ± 2

It follows from the above discussion that the configuration at $C_{(3)}$ has little effect on the ease of elimination of water on electron impact with epimeric saturated 3-hydroxy-steroids.



The introduction of a double bond at the 5–6 position of a steroid molecule fixes the conformation of ring A, which changes the situation significantly. In fact the mass spectra of epicholesterol (Xa) and cholesterol (Xb)[16] differ in the relative intensities of the peaks due to $[M - H_2O]^{+\cdot}$ and $M^{+\cdot}$ ions. In the case of (Xa) (axial hydroxyl) the intensity of the peak due to the former ion is 90% of that due to M^+, whereas in the spectrum of (Xb) (equatorial hydroxyl) the corresponding ratio is 50%. Thus, on the assumption that water is removed in this case by a process of 1,3-elimination (involving hydrogen from $C_{(1)}$), the axial 3α-hydroxy-group is more easily removed, owing to the 1,3-*cis*-diaxial arrangement of the groups undergoing elimination.

Table 2. Intensity of $[M - CH_3 - HDO]^+$ peak as percentage of $[M - CH_3 - H_2O]^+$ peak in the spectra of labelled cholestan-3β-ols.

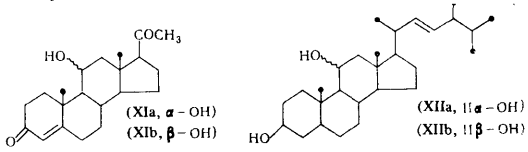
3α-Monodeuterated	0
5α-Monodeuterated	11
1,1-Dideuterated	28

4. 11-HYDROXY-STEROIDS

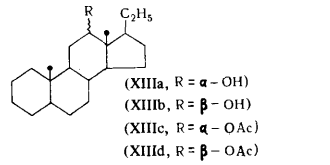
The mass spectra of steroid alcohols containing the hydroxyl in conformationally fixed rings, unlike those of 3-hydroxy-steroids, differ markedly among themselves, primarily in the peak intensity ratio $I_{M - H_2O}/I_{M^+}$. Comparison of the mass spectra of 11α- and 11β-hydroxy-progesterone (XIa) and (XIb) shows[18-20] that the alcohol (XIb), whose molecule contains an axial hydroxyl, readily eliminates a molecule of water on electron impact, whereas the molecular ion of its epimer (XIa), containing an equatorial hydroxyl, is more stable, and is dehydrated to a less extent (the intensity ratios for (XIa) and (XIb) are respectively 0.7 and 5.7).

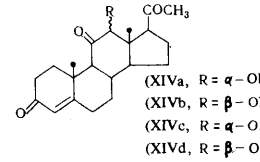


The mass spectra of ergost-22-ene-3β,11α-diol (XIIa) and of the corresponding 3β,11β-diol (XIIb), which were studied by Fitches[21], also differ in the ratio of the $M - H_2O$ and M^+ peaks: the intensity ratio is considerably smaller in the spectrum of the 11α-epimer (XIIa) (equatorial hydroxy-group) than in that of the 11β-epimer (XIIb) (axial hydroxyl).

5. 12-HYDROXY-STEROIDS

Studies have been made of the mass spectra of pregnan-12α- and 12β-ols (XIIIa and XIIIb), their acetates (XIIIc and XIIId), 12α- and 12β-hydroxypregn-4-ene-3,11,20-triones (XIVa and XIVb), and also the acetates of the latter compounds (XIVc and XIVd)[16]. The pregnan-12-ols (XIIIa) and (XIIIb) are easily dehydrated on electron impact (in both cases the peak due to the $[M - H_2O]^{+\cdot}$ ion considerably exceeds the M^+ peak). However, the $I_{M - H_2O}/I_{M^+}$ ratios in the spectra of the epimers differ markedly. As has been noted with 11-hydroxyprogesterones, an axial hydroxy-group is also eliminated more easily in the series of pregnan-12-ols.





A curious feature of the mass spectra of (XIIIa) and (XIIIb) is the difference in intensity of the peak having $m/e = 257$, corresponding to ejection of an ethyl radical from the $[M - H_2O]^{\cdot+}$ ion: this peak is considerably more intense in the spectrum of (XIIIa). It may be expected that, as a consequence of the *cis*-arrangement of the 12β-hydroxyl and the 17β-ethyl group, the elimination of water from the molecular ion of pregnan-12β-ol will be accompanied, at least partly, by loss of a hydrogen atom from the side-chain; whereas the 17β-ethyl group located *trans* to a 12α-hydroxyl is not involved in dehydration of the molecular ion of pregnan-12α-ol. This situation is probably responsible also for the diminution in the intensity of the elimination of the ethyl group from the $[M - H_2O]^{\cdot+}$ ion in the case of (XIIIb).

The mass spectra of the acetates (XIIIc) and (XIIId) differ little between themselves. Both epimers eliminate a molecule of acetic acid so easily on electron impact that the peak of the molecular ion cannot be recorded. However, breakdown of the $[M - CH_3COOH]^{\cdot+}$ ion, accompanied by ejection of an ethyl radical, occurs rather more readily with the 12α-hydroxy-epimer, as for the free alcohols.

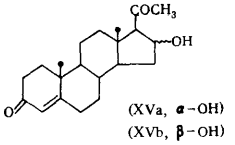
Table 3. Intensity ratios $I_{M - H_2O(CH_3COOH)}/I_{M^+}$ in the mass spectra of (XIIIa)–(XIVd).

Compound	$I_{M - H_2O(AcOH)}/I_{M^+}$	Compound	$I_{M - H_2O(AcOH)}/I_{M^+}$
(XIIIa)	57	(XIVb)	0.6
(XIIIb)	14	(XIVc)	7.3
(XIVa)	0.3	(XIVd)	4.3

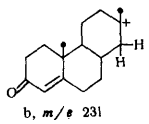
The dependence on configuration of the ease of dehydration on electron impact, which has been reported for pregnan-12-ols, is not maintained in the 12-hydroxypregn-4-ene-3,11,20-triones (XIVa and XIVb)[16]. In this case the mass spectrum of (XIVb) (equatorial hydroxyl) exhibits double the $I_{M - H_2O}/I_{M^+}$ ratio shown by (XIVa) (Table 3). This phenomenon is obviously explained by the ease of tautomerisation of α-hydroxy-ketones, on electron impact, to the corresponding 11-hydroxy-12-keto-isomers. This hypothesis is supported indirectly by the mass spectra of the acetates (XIVc) and (XIVd) of (XIVa) and (XIVb), in which high intensity of the peak due to the $[M - CH_3COOH]^{\cdot+}$ ion is characteristic of the 12α-acetoxy-epimer (XIVc) (axial acetoxy-group) (Table 3).

6. 16-HYDROXY-STEROIDS

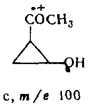
The mass spectra of 16α- and 16β-hydroxyprogesterones (XVa) and (XVb)[18,19], while indicating that both epimers are easily dehydrated on electron impact, exhibit significant differences. Firstly, the ease of dehydration of the molecular ion of (XVa) (16α-hydroxyl) exceeds that of its β-epimer (XVb) by a factor of 3 (Table 4). This indicates that an α-bond at $C_{(16)}$ is almost axial in character, and a β-bond almost equatorial.



(XVa, α-OH)
(XVb, β-OH)



b, *m/e* 231



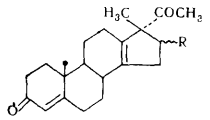
c, *m/e* 100

Secondly, the mass spectrum of (XVa) contains an intense peak due to the ion (b) having $m/e = 231$, which is almost completely absent from the spectrum of (XVb). The fragment (b) contains the rings A–C and is formed by rupture of the 13–17 and 14–15 bonds with migration of a hydrogen atom from position 16 to the charged fragment. However, rupture of the same bonds but with the charge localised on the fragment containing the atoms $C_{(15)}$–$C_{(17)}$, $C_{(20)}$, and $C_{(21)}$ yields the ion (c) having $m/e = 100$, whose peak is quite intense in the spectrum of 16α-hydroxyprogesterone (XVa) and is almost completely absent from the spectrum of its 16β-epimer (XVb).

Table 4. Intensity ratio $I_{M - H_2O}/I_{M^+}$ and intensities of peaks due to characteristic ions (% of Σ) in mass spectra of (XVa) and (XVb).

Cpd	I_{M-H_2O}/I_{M^+}	Ion (b) (*m/e* 231)	Ion (c) (*m/e* 100)
XVa	13	4.6	3.2
XVb	4.3	0.65	0.6

The above results were used to determine the configuration at position 16 in the pregnen-16-ol derivatives (XVIa) and (XVIb)[16]. In the mass spectrum of (XVIa) the ratio $I_{M - H_2O}/I_{M^+} = 20$, whereas in the spectrum of (XVIb) this ratio is only 8.7. By analogy with the 16-hydroxyprogesterones (XVa and XVb), therefore, the alcohol (XVIa) should have the α-configuration of the hydroxy-group, and the alcohol (XVIb) the β-configuration.



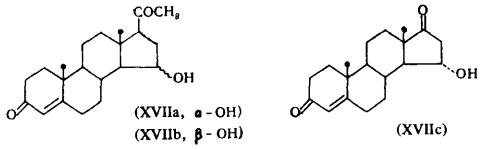
(XVIa, R = α-OH)
(XVIb, R = β-OH)
(XVIc, R = α-OAc)
(XVId, R = β-OAc)

Further confirmation of the configuration at position 16 was obtained by comparing the mass spectra of the corresponding acetates (XVIc) and (XVId). Primarily, the ratio of the peaks due to the ions $[M - CH_3COOH]^{\cdot+}$ and M^+ is different in the spectra of the epimers (120 and 36 respectively). Therefore the acetate (XVIc) must be assigned to the 16α-series, and its epimer (XVId) to the 16β-series. Another striking feature of the spectra of the four compounds (XVI) is the difference in intensity of the peak due to the ion $[M - COCH_3]^+$. The great intensity of this peak in the spectra of the 16α-OR′ epimers (XVIa and XVIc) is evidently due to the *cis*-arrangement of the 17α-acetyl and the 16α-OR′ groups, which facilitates elimination of the 17-acetyl group.

7. 15-HYDROXY-STEROIDS

Studies have been made of the mass spectra of 15α- and 15β-hydroxyprogesterones (XVIIa) and (XVIIb), and also of 15α-hydroxyandrost-4-ene-3,17-dione (XVIIc)[18,19]. The 15β-hydroxy-epimer (XVIIb) had a high $I_{M - H_2O}/I_{M^+}$ ratio (Table 5). The explanation is that the hydroxy-group

is equatorial in character in the (XVIIa) molecule, but axial in (XVIIb).



(XVIIa, α-OH)
(XVIIb, β-OH)

(XVIIc)

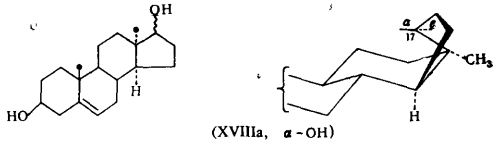
Table 5. Intensity ratio I_{M-H_2O}/I_{M^+} and intensities of peaks due to characteristic ions (% of Σ) in mass spectra of (XVIIa–(XVIIc).

Cpd.	I_{M-H_2O}/I_{M^+}	Ion (b) (*m/e* 231)	Ion (c) (*m/e* 100)
XVIIa	0.21	0.7	0.3
XVIIb	4.9	3.0	1.3
XVIIc	0.07	0.2	—

A similar situation is found in the mass spectrum of (XVIIc), in which the intensity of the peak due to the $[M - H_2O]^{+\cdot}$ ion is only 7% of the intensity of the M^+ peak, which dominates the spectrum. The characteristic difference in the mass spectrum of (XVIIb), as in the case of its 16α-hydroxyl analogue (XVa), is the considerable intensity of the peaks due to the ions (b) and (c), the mechanism of whose formation is similar to that described for (XVa) and (XVb) (Table 5).

8. 17-HYDROXY-STEROIDS

The behaviour of epimeric 17-hydroxy-steroids of the normal series on electron impact has not been studied. However, it is noteworthy that steroids of the 17β-hydroxy-series (oestradiol, 19-nortestosterone)[22], in which the hydroxyl is equatorial in character, eliminate water with difficulty under these conditions.



(XVIIIa, α-OH)
(XVIIIb, β-OH)

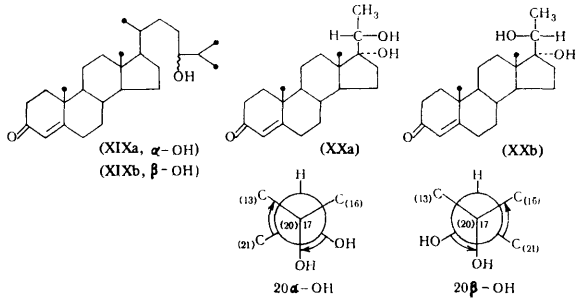
Comparison of the mass spectra of epimeric alcohols of the 13-iso-series—13-isoandrost-5-ene-3β,17α- and -3β,17β-diols (XVIIIa and XVIIIb)[16]—shows that electron impact has different dehydrating effects: the M^+ peak is more intense than the peak due to the $[M - H_2O]^{+\cdot}$ ion in the mass spectrum of (XVIIIa), but the opposite situation is observed in the spectrum of (XVIIIb). This observation is fully consistent with the equatorial character of an α-bond at $C_{(17)}$ in steroids of the 13-iso-series, and the axial character of a β-bond (in relation to ring C—see above scheme). Thus in this case also an axial hydroxyl is more easily eliminated as water than is an equatorial hydroxyl. A similar relation is found in several other fragments formed when molecular ions of compounds (XVIIIa) and (XVIIIb) break down. Thus the ratios

$$I_{M-2H_2O}/I_{M-H_2O} \text{ and } I_{M-H_2O-CH_2-H_2O}/I_{M-H_2O-CH_3}$$
$$I_{m/e\,197}/I_{m/e\,205} \text{ and } I_{m/e\,161}/I_{m/e\,179},$$

change similarly to I_{M-H_2O}/I_{M^+} on passing from (XVIIIa) to (XVIIIb). In these two cases ions having m/e = 205 and 179 are characteristic of steroids having a 5–6 double bond and contain the ring C together with parts of rings A and B[23–25].

9. 20- AND 24-HYDROXY-STEROIDS

Epimeric aliphatic alcohols containing a single asymmetric centre usually have completely identical mass spectra. This held for 24α- and 24β-hydroxycholest-4-en-3-one (XIXa and XIXb), which contain a hydroxy-group in the aliphatic side-chain. Nevertheless, 17α,20α-dihydroxypregn-4-en-3-ones show significantly higher I_{M-H_2O}/I_{M^+}, I_{M-2H_2O}/I_{M-H_2O}, and also I_{M-CH_3CHOH}/I_{M^+} ratios in the mass spectrum of the 20α-hydroxy-epimer (XXa) than in that of the 20β-epimer (XXb).



(XIXa, α-OH)
(XIXb, β-OH)

(XXa)

(XXb)

20α-OH

20β-OH

Inspection of Dreiding models shows that an intramolecular hydrogen bond is possible between the 20β- and 17α-hydroxyls in (XXb), whereas this possibility is difficult to realise in the case of the 20α-epimer (XXa), owing to steric hindrance caused by the close mutual approach of the 20-methyl and angular 13-methyl groups (see above scheme). Formation of a hydrogen bond is probably the reason why a water molecule and a CH_3CHOH radical are not ejected from the molecular ion of the 20β-hydroxy-epimer (XXb).

10. TERTIARY ALCOHOLS OF THE D-HOMO-SERIES

Study of epimeric tertiary alcohols derived from (±)-17a-alkyl-3-methoxy-D-homo-oestra-1,3,5(10),8-tetraen-17a-ols—(XXIa), (XXIb), (XXIIa), and (XXIIb)—revealed exceptionally large differences between the mass spectra of epimers[26–28]. First of all, the intensity of the peak due to the $[M - H_2O]^+$ ion in the spectra of alcohols having an axial hydroxyl (XXIa and XXIb) far exceeds that of the M^+ peak, whereas the opposite situation is found with

epimers having an equatorial hydroxyl (XXIIa and XXIIb) (Table 6).

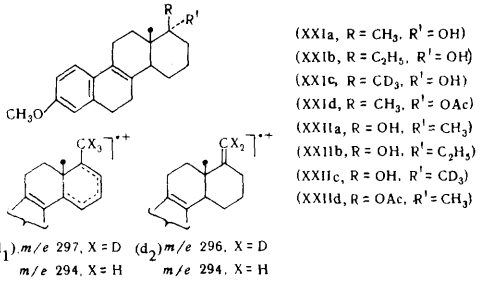


Table 6. Intensity ratios I_{M-H_2O}/I_{M^+} and $I_{M-H_2O-(17a\text{-Alk})}/I_{M-H_2O}$ in mass spectra of (XXIa)–(XXIIb).

Cpd	I_{M-H_2O}/I_{M^+}	$I_{M-H_2O-(17a\text{-Alk})}/I_{M-H_2O}$
(XXIa)	3.2	2.3
(XXIIa)	0.4	0.6
(XXIb)	2.3	3.5
(XXIIb)	0.2	0.6

The mass spectra of the 17a-trideuteromethyl analogues (XXIc and XXIIc) of (XXIa) and (XXIIa) were studied in order to elucidate the mechanism of dehydration on electron impact. Comparison of the mass spectra of (XXIc) and (XXIIc) (Figs. 1 and 2) shows that the readily dehydrated epimer (XXIIc)—and hence also (XXIa) and (XXIb)—form almost exclusively the $[M-H_2O]^{\cdot+}$ ion having m/e = 297 (ion d_1) on dehydration of the molecular ion.

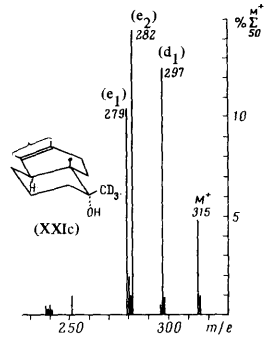

Figure 1.

Since dehydration takes place mainly by a mechanism of 1,3-elimination, the loss of hydrogen in this case takes place most probably from the atom $C_{(16)}$ or $C_{(14)}$. The epimer (XXIIc)—and hence also (XXIIa) and (XXIIb)—which eliminates water with far greater difficulty on electron impact, forms not only the ion d_1 but also the $[M-DOH]^{\cdot+}$ ion having m/e = 296 (ion D_2) with an exocyclic double bond. The formation of the fragment d_1 (not d_2) from the molecular ion of (XXIc) suggests an axial arrangement of the 17a-hydroxyl (since only then can one of the axial hydrogen atoms of the D ring be removed together with the hydroxy-group), and thus provides fresh evidence of the configuration at position 17a in the molecule of this compound. The appearance of twin $M-H_2O$ and $M-DOH$ peaks in the mass spectrum of (XXIIc) indicates an *ax*-alkyl-*eq*-hydroxyl configuration at position 17a.

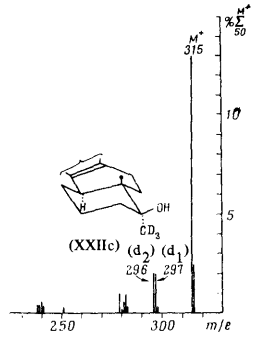

Figure 2.

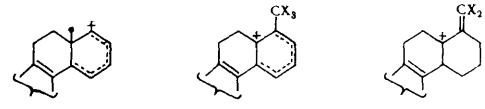
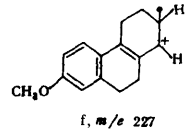
The mass spectra of these compounds differ also in the relative intensities of the ions $[M-H_2O-17a\text{-Alk}]^+$ (e) and $[M-H_2O]^{\cdot+}$. In the case of epimers having an axial hydroxyl (XXIa and XXIb) the intensity of the former peak far exceeds that of the latter, but the opposite relation is found in epimers having an equatorial hydroxyl (XXIIa and XXIb) (Table 6). Comparison of the mass spectra of the deuterated analogues (XXIc and XXIIc) with those of the unlabelled compounds (XXIa and XXIIa) shows that the peak due to the ion (e) is composite, representing the formation of ions of the types (e_1), (e_2), and (e_3). In the spectra of epimers having an axial hydroxyl this peak represents the ions (e_1) and (e_2). In alcohols having an equatorial hydroxyl, however, removal only of the angular methyl group (ion e_3) is possible after the elimination of water, since the presence of an exocyclic double bond in the ion (d_2) makes loss of the 17a-alkyl group impossible.



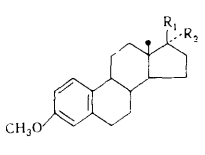
Another characteristic peak in the mass spectra of (XXIa), (XXIb), (XXIIa), and (XXIIb), whose intensity depends on the configuration of the epimer, is that due to the ion (f) having m/e = 227. Its intensity in the spectrum of the epimer with an equatorial hydroxyl is 16% (of $\Sigma_{50}^{M^+}$), whereas in the spectrum of the epimer having an axial hydroxyl it is only 1.2%. The ion (f) is formed directly from the molecular ion by detachment of ring D and migration of the hydrogen atom from the 17a-hydroxyl.



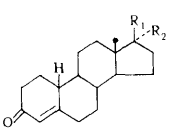
Comparison of the mass spectra of the acetates (XXId) and (XXIId)[30] reveals easier elimination of an axial than of an equatorial acetoxy-group as acetic acid on electron impact, similarly to the behaviour of the free alcohols. The mass spectra of (XXId) and (XXIId) differ also in the intensity of peaks due to ions of type (e), formed by ejection of a methyl group from ions of type (c) $[M - CH_3COOH]^{\cdot+}$. As with the free tertiary alcohols, the peak (e) is composite, the difference in its intensity being due to a difference in the mechanism of the elimination of acetic acid from the molecular ions of the epimers.

11. TERTIARY ALCOHOLS OF THE NORMAL SERIES

In contrast to alcohols of the D-homo-series, tertiary alcohols which are epimeric at $C_{(17)}$—(±)-17-alkyl-3-methoxyoestra-1,3,5(10)-trien-17-ol (XXIIIa,b–XXXVa,b) and (±)-17-alkyl-19-nortestosterone (XXXVIa,b–XXVIIa,b)[29] derivatives—have essentially similar mass spectra[29], differing only in the intensity ratio of the peaks due to $[M - H_2O]^{\cdot+}$ and M^+ ions. The ratio is higher in alcohols having an α-hydroxyl (XXIIIa–XXVa) than in their β-hydroxy-epimers (XXIIIb–XXVb) (Table 7). This result is consistent with general views on the conformation of bonds at the $C_{(17)}$ atom (an α-bond is axial in character, and a β-bond equatorial).



(XXIIIa, $R_1 = CH_3$, $R_2 = OH$)
(XXIIIb, $R_1 = OH$, $R_2 = CH_3$)
(XXIVa, $R_1 = C_2H_5$, $R_2 = OH$)
(XXIVb, $R_1 = OH$, $R_2 = C_2H_5$)
(XXVa, $R_1 = CH_2C(=CH_2)CH_3$, $R_2 = OH$)
(XXVb, $R_1 = OH$, $R_2 = CH_2(=CH_2)CH_3$)



(XXVIa, $R_1 = CH_3$, $R_2 = OH$)
(XXVIb, $R_1 = OH$, $R_2 = CH_3$)
(XXVIIa, $R_1 = C_2H_5$, $R_2 = OH$)
(XXVIIb, $R_1 = OH$, $R_2 = C_2H_5$)

Table 7. Intensity ratio I_{M-H_2O}/I_{M^+} in mass spectra of (XXIIIa)–(XXVb).

Compound	I_{M-H_2O}/I_{M^+}	Compound	I_{M-H_2O}/I_{M^+}
(XXIIIa)	45	(XXIVb)	21
(XXIIIb)	14	(XXVa)	62
(XXIVa)	41	(XXVb)	21

In the 19-nortestosterones (XXVIa,b–XXVIIa,b) the I_{M-H_2O}/I_{M^+} ratios show smaller differences in the spectra of epimers. In this case, however, the 17α-hydroxy-epimer undergoes dehydration more readily on electron impact.

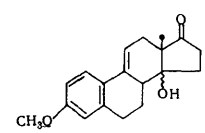
The spectra of epimers of this group differ more markedly in the ratio of the peaks due to the ions $[M - H_2O - 17\text{-Alk}]^+$ ($m/e = 255$) and $[M - H_2O]^{\cdot+}$ (Table 8). The considerable decrease in this ratio in the spectra of the 17β-hydroxy-epimers (XXVIb and XXVIIb) in comparison with the 17α-epimers (XXVIa and XXVIIa) is obviously due to a difference in the mechanism of the dehydration of their molecular ions. The process probably resembles that described for the D-homo-alcohols: removal of an α-hydroxyl from a molecular ion is accompanied by that of a hydrogen atom from the ring D, with formation of an ion of type (d_1); whereas in the case of the β-hydroxy-epimers an ion of type (d_2) having an exocyclic double bond is also formed. Ejection of the 17-alkyl is impossible in the latter case, and therefore the peak at $m/e = 255$ becomes less intense.

Table 8. Intensity ratios I_{M-H_2O}/I_{M^+} and $I_{M-H_2O-17\text{-Alk}}/I_{M-H_2O}$ in mass spectra of (XXVIa)–(XXVIIb).

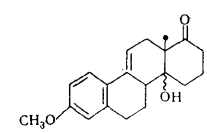
Compound	$\frac{I_{M-H_2O}}{I_{M^+}}$	$\frac{I_{M-H_2O-17\text{-Alk}}}{I_{M-H_2O}}$
(XXVIa)	36	1.8
(XXVIb)	17.4	0.3
(XXVIIa)	21	1.8
(XXVIIb)	15	0.9

12. 14-HYDROXY-STEROIDS

Mass spectrometry has been used also to determine the configuration at positions 8 and 14 in 14-hydroxy-derivatives of 3-methoxyoestra-1,3,5(10),9(11)-tetraen-17-one (XXVIII) and 3-methoxy-D-homo-oestra-1,3,5(10),9-(11)-tetraen-17-one (XXIXa and XXIXb)[31].

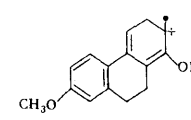


(XXVIII)



(XXIX, a α-OH; b β-OH)

The mass spectra of the hydroxy-ketones (XXIXa) and (XXIXb) differ substantially in the intensity of the peak due to the ion (g) having $m/e = 241$

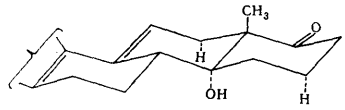


g, m/e 241

formed by cleavage of the bonds 13–17a and 14–15 in the molecular ion. The fivefold increase in this ion on passing from (XXIXa) to (XXIXb) enables us to assign the former to the *trans*-C–D series (14α-hydroxyl), and the latter to the *cis*-C–D series (14β-hydroxyl), by analogy with *cis*- and *trans*-α-decalins, 14α- and 14β-equilenins, 8α- and 8β-oestrones, etc.

Furthermore, the spectra of (XXIXa) and (XXIXb) differ in the intensity ratio of the $[M - H_2O]^+$ and M^+ peaks (1.2 and 0.3 respectively). The 8-deuterated analogues have been used to establish that the 8-hydrogen atom is not involved in dehydration. The other possible 1,2-elimination, involving the 15-hydrogen atom, is obviously also improbable. Ejection of DOH is not observed from the 17,17-dideutero-analogues, which refutes the possibility of 1,4-elimination. The most probable process is therefore the 1,3-elimination of water involving a 12- or 16-hydrogen

atom. This supports the conclusion that the ease of dehydration of the hydroxy-ketone (XXIXa) is associated with the α-configuration of the 14-hydroxyl (*trans*-C–D fusion), when the hydroxyl is located axially with respect to both rings C and D, with the preferred 1,3-*cis*-diaxial orientation of the groups undergoing elimination.



The insignificant dehydration of the molecular ion of the hydroxy-ketone (XXIXb) is evidently due to the equatorial orientation of the 14-hydroxy-group with respect to the ring which donates the hydrogen atom in the elimination of water on electron impact. This condition is feasible only with *cis*-C–D ring fusion (14β-hydroxy-configuration), since in any of the theoretically possible conformations of (XXIXb) the 14-hydroxyl is located equatorially with respect to one of the rings (C or D).

The mass spectrum of the hydroxy-ketone (XXVIII) is very similar to that of (XXIXb), so that *cis*-C–D fusion of the rings and equatorial orientation of the hydroxy-group can be attributed to the former.

---oo0oo---

Although sufficient experimental results are not yet available, it can be concluded from the above survey that mass spectrometry can be used to establish configuration in all cases in which the steroid alcohol molecule contains a sufficiently rigid cyclic system, since in most cases electron impact eliminates an axial more readily than an equatorial hydroxyl.

Electron Spin Resonance of the Excited Triplet State of Biologically Important Molecules

Z.P.Gribova and L.P.Kayushin

The excited triplet states of molecules play an important role in the mechanisms of any photochemical reaction. These states are responsible for the occurrence of two-quantum photsensitisation, photoionisation, and photoreduction reactions. The present review compiles and gives a systematic account of the principal results obtained in the application of ESR to the study of the excited triplet state of biologically important molecules.
The bibliography includes 91 references.

I. INTRODUCTION

The application of the method of electron spin resonance (ESR) in the study of the excited triplet state of molecules began with the pioneer work of Hutchison and Mangum[1,2] more than ten years ago and has yielded much information about its properties and role in the photochemistry of organic molecules. The ESR method revealed the splitting of the lowest triplet level in the absence of an external magnetic field and the effect of the size of the conjugated system, the substituents in the molecule, and the properties of the solvents on the zero-field splitting energy. Data were obtained on the direction of the transition moment, molecular symmetry, and the distribution of spin density in the lowest excited triplet state. The ESR method provided valuable information about the lifetimes, probabilities of transition to the triplet state, and quenching and energy transfer processes.

The successful application of the ESR method in the study of the mechanism of the photochemical reactions in solid solutions several years later led to the discovery of two-quantum photosensitisation, photoionisation, and photoreduction reactions[2-8] proceeding via the triplet state of aromatic compounds, including biologically important substances, such as porphyrins, chlorophyll[8-11], aromatic aminoacids[9,11-14], nucleic acid bases[15], phenoxazine, phenothiazine, and flavins[16]. The phenomenon of triplet–triplet annihilation, leading to the formation of one molecule in a highly excited singlet, triplet, or quintet state from two molecules in a phosphorescent triplet state was first observed at approximately the same time. It attracted the attention of investigators as a possible method of using low-energy quanta to achieve reactions requiring a considerable energy expenditure[17]. It was suggested that this phenomenon may play a role in photobiological reactions.

There are many biological processes where the first stage involves the transition of specific molecules to an excited electronic state. This is the photodynamic effect—inactivation of proteins by radiation, photodimerisation of nucleic acid bases, vision, and bioluminescence. Photosynthesis, which provides energy to virtually all living things on earth, takes place owing to the absorption, transfer, and storage of the energy of sunlight by the photosynthetic apparatus of plant and bacterial cells. At the molecular level this involves tetrapyrrole pigments—chlorophyll and bacteriochlorophyll in an excited state.

All these findings—the vast scope of the new research technique, the discovery reactions proceeding via the triplet state, and finally the suggested role of the triplet state in biological processes—stimulated in recent years a profound interest by photobiologists in the study of biologically important substances in an excited triplet state. Owing to the extreme complexity involved in the observation of the phenomenon at an electronic level in real biological structures, it still remains unknown whether primary photochemical reactions *in vivo* take place at a singlet or triplet electronic level. However, such information is undoubtedly important for the understanding of the mechanism of the phenomena.

To date, more than 100 publications have appeared on ESR studies of molecules in an excited triplet state, both experimental and theoretical. A systematic and critical review of these investigations is necessary for future work. This review cannot give a complete analysis of all the studies and therefore we shall consider only briefly the advances in this field of research and shall deal in greater detail with data concerning biologically important substances.

The properties of molecules in singlet and triplet excited states are significantly different. These differences concern primarily their electronic structure: the charge distribution, spin density, and the symmetry of the π-electron cloud, and hence the donor–acceptor properties of the molecules, their reactivity, lifetime, and other characteristics determining the rate of the photochemical process. The great importance of the excited triplet state in the initial stage of the photochemical process is due to the fact that it is long-lived compared with the excited singlet state.

Fig. 1*A* presents a typical scheme of the molecular energy levels originally proposed in a simplified form by Jablonski[18] to explain the prolonged afterglow of organic molecules in rigid matrices. The radiative $T_1 \rightarrow S_0$ transition is of an intercombination type and is forbidden by the spin selection rules. The lifetime of the molecule in the lowest triplet state is therefore longer than that of the excited singlet state (about 10^{-9} s), increasing to between 10^{-4} s and several seconds, particularly at low temperatures where the probability of the non-radiative $T_1 \rightarrow S_0$ transition, the $T_1 \rightarrow S_1$ thermal transition, and quenching processes of different kinds diminishes. Since the transition to the T_1 triplet state involves the inversion

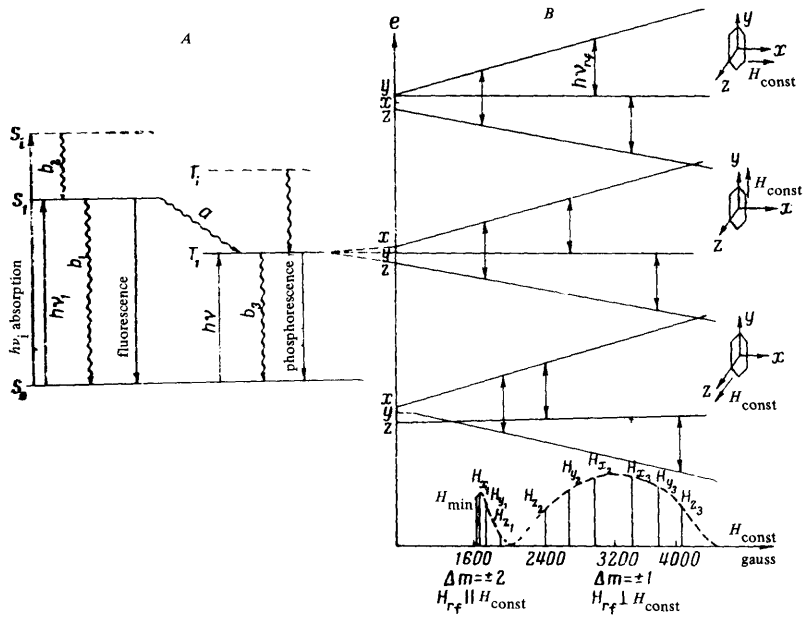

Figure 1. Schematic representation of the energy levels and transitions in an aromatic molecule. *A*—optical transitions; *B*—radio frequency ($h\nu_{rf}$) transitions in the presence of a constant magnetic field (H_{const}) and a radio frequency field (H_{rf}); S_0, S_1, S_i—the singlet energy levels; T_1, T_i—the triplet levels; *a*—intercombination non-radiative transition to a triplet state; b_1, b_2, b_3—non-radiative transitions to the corresponding lower state.

of the spin of the excited electron the overall spin of the system is unity and the multiplicity of the level is 3. Hence the term triplet is applied to this system of energy levels.

The mechanism of the transition to the phosphorescent state has been considered [19-21]. Terenin suggested that the metastable T_1 level be identified as a triplet level and put forward the hypothesis that the triplet state, characterised by unpaired spins, should play a significant role in photochemical reactions [22,23]. Lewis et al. [24] demonstrated for the first time by a static magnetic method the occurrence of light-induced paramagnetism.

We may note here also other characteristics of the excited triplet state. Firstly, as a result of the Coulombic repulsion of the unpaired electrons occupying the same orbital level, the T_1 level always has a lower energy than the first excited singlet level and therefore requires a lower activation energy. Secondly, since the lifetime in the triplet state is longer by a factor of 10^6–10^9 than the lifetime in the singlet state, favourable conditions are created for the involvement of the molecule in photochemical reactions, the rates of which are limited by diffusion processes at a low concentration of the reactants. Moreover, the energy of the triplet excitation may be readily transferred to another, unexcited molecule. Although the cross-section of the triplet–triplet transfer is lower than that of the singlet–singlet transfer, there is sufficient time for the energy of the long-lived triplet state to migrate over a long distance and therefore there is a high probability of its reaching the reaction centre.

We have already noted that the overall spin of the molecule in the triplet state S is unity and in a constant magnetic field the levels are split into three sublevels with $\Delta m = \pm 1.0$ projections of the spin on to the direction of the constant magnetic field. For molecules with a symmetry lower than spherical, the degeneracy is removed even in the absence of an external field. The zero-field splitting is due to dipole spin–spin interaction between the electrons in the triplet state, which is fairly well described by the two-electron spin Hamiltonian [1,2]

$$\hat{\mathcal{H}} = g\beta \mathbf{H}\hat{S} + DS_z^2 + E(S_x^2 - S_y^2). \qquad (1)$$

The first term defines the Zeeman energy of the interaction of the total spin S with the constant magnetic field **H** and the second, the dipole spin–spin interaction. S_X, S_Y, and S_Z are components of the overall spin S in the molecular system of coordinates, g is the spectroscopic splitting factor, and β the Bohr magneton. The zero-field splitting constant D defines the average dipole interaction between the spins along the molecular axis z and E takes into account the deviation of the spin–spin interaction tensor from axial symmetry [25,26]. The constants D and E can be readily determined from ESR spectra (the relevant equations are quoted below).

The Hamiltonian (1) transformed relative to the principal molecular axes is [26]

$$\hat{\mathcal{H}} = \mathbf{g}\beta \mathbf{HS} - (XS_x^2 + YS_y^2 + ZS_z^2), \qquad (2)$$

where X, Y, and Z are the principal values of the spin–spin interaction tensor diagonalised in the molecular

system of coordinates. They are related to the constants D and E in the following way:

$$X = {}^1/_3D + E,\ Y = {}^1/_3D - E,\ Z = -{}^2/_3D\ . \qquad (3)$$

If the constant magnetic field is directed along one of the molecular axes, for example x, eigenvalues for the triplet levels become [28]

$$e_1 = X,\ e_2 = e_3 = \frac{Y+Z}{2} \pm \sqrt{\frac{(Y-Z)^2}{4} - (g\beta H)^2}\ . \qquad (4)$$

Similar expressions can be found for the case where the field is directed along the y and z axes. Magnetic dipole transitions are allowed between two adjacent sublevels of the triplet level and involve a change in the magnetic quantum number: $\Delta m = \pm 1$. The transition moment, for example $x \rightarrow y$, is perpendicular to the xy plane (see Fig. 1*B*). When a variable magnetic field at a frequency ν such that

$$h\nu = g\beta H\,\Delta m \qquad (5)$$

is applied at right angles to the constant magnetic field, resonance absorption of electromagnetic energy takes place and is recorded by the ESR method. As a result of the occurrence of the zero-field splitting, the resonance absorption for different orientations of the constant magnetic field H_{const} relative to the three molecular axes will be observed for different values of H_{const} (Fig. 1*B*). If a single crystal is placed in the cavity and excited, being successively oriented so that the x, y, and z axes are parallel to H_{const}, three pairs of lines may be observed in the ESR spectrum—H_{x_2}, $H_{x_3}(H_{\text{const}} \parallel x)$, H_{y_2}, $H_{y_3}(H_{\text{const}} \parallel y)$, H_{z_2}, $H_{z_3}(H_{\text{const}} \parallel z)$ respectively (Fig. 1*B* below). However, the $\Delta m = \pm 1$ selection rules hold rigorously when the interaction between the spins and the external magnetic field is much greater than the intrinsic interaction between the spins, and the component of the spin angular momentum of the electrons $m(h/2\pi)$ in the direction of the field remains constant. Such transitions in a single crystal of a dilute solid solution of naphthalene in durene were observed by Hutchinson and Mangum [1,2]. However, the possibilities of growing diluted single crystals are limited. Van der Waals and de Groot [27,28] deduced theoretically and observed experimentally for the first time the forbidden transitions between the lowest and highest sublevels of the triplet level corresponding to a change in the magnetic quantum number $\Delta m = \pm 2$. The transition is observed at much weaker fields when the intrinsic interaction of the electrons is comparable to their interaction with the external magnetic field. The component of the spin angular momentum $m(h/2\pi)$ is not a constant of motion and the selection rules break down. The $\Delta m = \pm 2$ transitions are polarised parallel to the constant magnetic field and are observed in parallel fields (Fig. 1*B*). In particular, it follows from Eqn. (4) that the transitions between the sublevels take place for values of H_{const} defined by the equation

$$(e_2 - e_3)^2 = (h\nu)^2 = \frac{1}{4}(Y-Z)^2 + (g\beta H)^2\ . \qquad (6)$$

We shall employ as an example the data of Hutchison and Mangum [2] for naphthalene:

$$\frac{X-Z}{hc} = 0.0863\ см^{-1},\ \frac{Y-Z}{hc} = 0.1143\ см^{-1},\ \frac{h\nu}{hc} = 0.3221\ см^{-1} = 2.0033.$$

On substituting the numerical values in Eqn. (6), we find that the resonance absorption for naphthalene with $\Delta m = \pm 2$ will be observed for $H_{x_1} = 1602$ G, $H_{y_1} = 1650$ G, and $H_{z_1} = 1707$ G. Thus, whereas the $\Delta m = \pm 1$ transitions are recorded in the range of H_{const} from 2354 to 4490 G and the overall line width is 2196 G, for $\Delta m = \pm 2$ transitions the latter value is 105 G, i.e. the anisotropy of the transitions is smaller by a factor of 20. [27,28] Therefore,

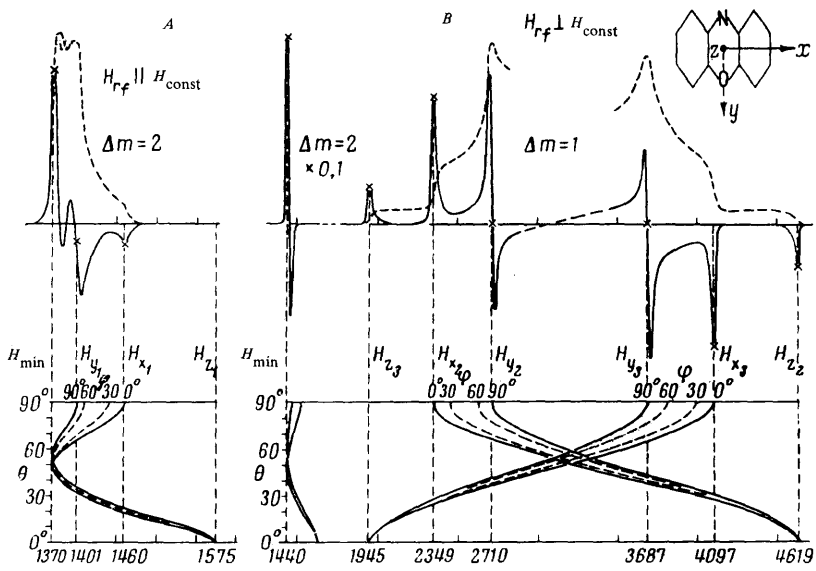

Figure 2. ESR spectrum of phenoxazine in the triplet state (molecular symmetry less than that for three axes: $x \neq y \neq z$). Below: distribution of resonance fields $F(\delta, H)$ as a function of $f(\theta, \varphi)$ for the specified ν = const.

despite the fact that the intensity of these transitions is lower by two powers of ten than that of the $\Delta m = \pm 1$ transitions, the ESR signal may be observed in specimens with a random orientation—solid solutions[28].

For an arbitrary orientation of H_{const} relative to the molecular axes, Kottis and Lefevre[29,30] used the operator (2) to find the distribution function of the resonance fields in terms of the spatial orientation of the x, y, and z axes relative to the constant magnetic field (the angles φ and θ, Fig. 2*B*). For a fixed value of the microwave quantum ($h\nu$), such a function makes it possible to determine the resonance fields for specified X, Y, and Z parameters. Figs. 1 and 2B show that, for $h\nu > D$, three resonance values of the field correspond to each molecular orientation. Two of these correspond to the $\Delta m = \pm 1$ transitions ($H_{const} \perp H_{rf}$) and the third to $\Delta m = \pm 2$ ($H_{const} \parallel H_{rf}$). Finally, there is resonance absorption for a minimal value of H_{const} (H_{min}) at the specified frequency (Fig. 2*B*). In this case the intensity of ESR absorption is independent of the relative orientations of H_{const} and H_{rf}:

$$H_{min} = (2g\beta)^{-1}[(h\nu)^2 + 4(XY + XZ + YZ)]^{1/2} = (2g\beta)^{-1}\left\{(h\nu)^2 - 4\left[\frac{D^2}{3} + E^2\right]\right\}^{1/2}. \quad (7)$$

Expressions for the calculation of the resonance fields or, if their values are known from ESR spectra, of the zero field splitting constants and energies are:

$$H_{x_1} = (2g\beta)^{-1}[(h\nu)^2 - (D-E)^2] = (2g\beta)^{-1}[(h\nu)^2 - (Y-Z)^2]^{1/2},$$
$$H_{x_2} = (2g\beta)^{-1}[(2h\nu - D - 3E)^2 - (D-E)]^{1/2} = (2g\beta)^{-1}[(2h\nu - 3|X|)^2 - (Y-Z)^2]^{1/2},$$
$$H_{x_3} = (2g\beta)^{-1}[(2h\nu + D + 3E)^2 - (D-E)^2]^{1/2} = (2g\beta)^{-1}[(2h\nu + 3|X|)^2 - (Y-Z)^2]^{1/2}. \quad (8)$$

H_{X_1} corresponds to the $\Delta m = \pm 2$ transition and H_{X_2} and H_{X_3} to the $\Delta m = \pm 1$ transition. The expressions for the H_{Y_1}, H_{Y_2}, H_{Y_3}, H_{Z_1}, H_{Z_2}, and H_{Z_3} resonance fields are similar to Eqn. (8) and can be obtained by a cyclic interchange of X, Y, and Z.

Subsequently it was found that the $\Delta m = \pm 1$ transitions can be observed not only for single crystals but also specimens with a random orientation. In a solid solution the molecules are fixed relative to one another and magneto-selection takes place. Molecules whose corresponding axes lie within 5° of the constant magnetic field contribute to the intensity of the canonical peak[27]. This was observed experimentally for the first time by Yager et al.[31] for naphthalene, coronene, and triphenylene. Similar spectra were recorded for biologically important compounds: magnesium-aetioporphyrin[32] and later for other porphyrins[33,34], chlorophyll[34], orotic and polyadenylic acids, adenosine and guanosine monophosphates[35-37], aromatic aminoacids, and certain proteins[38].

ESR absorption in a field corresponding to a g-factor of 2.0023 has been observed for certain aromatic substances[33,34,39]. This is the so called two-quantum transition ($H_{t.q.}$) caused by the simultaneous absorption of two radiofrequency quanta. The following relation must hold for a two-quantum transition to be observed:

$$(g\beta H_{t.q.})^2 = (h\nu)^2 - \frac{1}{3}D^{*2} \quad (D^* = \sqrt{D^2 + 3E^2}). \quad (9)$$

The molecular orientations for which the energy differences between two pairs of adjacent sublevels are similar or identical make a dominant contribution to the $H_{t.q.}$ absorption line.

Thus for molecules with a lower than third-order symmetry, the ESR spectrum in perpendicular fields consists of eight peaks. Such line shape corresponds to the static case where during the radiofrequency transition the nuclei of the atoms in the molecule do not undergo significant conformational, rotational, or other displacements. However, de Groot and van der Waals[40] showed that the line shape of the ESR spectra of the triplet state of certain aromatic compounds, for example benzene, triptycene, and aromatic ions, can vary significantly with temperature owing to different dynamic effects. The line shape of the ESR spectra of substances whose triplet state is orbitally degenerate varies in the same way[40]. In this case the Jahn–Teller effect leads to the instability of the fully symmetrical non-linear molecule and to the removal of the orbital degeneracy due to nuclear displacements. The high molecular symmetry breaks down, which leads to a change in the line shape of the ESR spectrum and in the zero-field splitting constants. The dynamic effect has been treated theoretically by Kottis and Lefevre[30].

Having examined the principal characteristics of the line shape of the ESR spectra common to all aromatic substances, we shall proceed to consider the characteristics of the ESR and the properties of the excited triplet state of biologically important compounds.

II. ELECTRON SPIN RESONANCE OF THE TRIPLET STATE OF BIOLOGICALLY IMPORTANT MOLECULES

1. Porphyrins

The first data on the excited triplet state of porphyrins observed by the ESR method were published in 1963.[32] Evacuated solutions of aetioporphyrin, mesoporphyrin, and protoporphyrin and their magnesium complexes, zinc-aetioporphyrin, haematoporphyrin and its mercury complex, and tetraphenylporphyrin(TPP) and its zinc complex, frozen at 77°K, were investigated[42-46]. In fields of about 1600 G (klystron frequency ν = 9260 MHz), ESR absorption corresponding to the $\Delta m = \pm 2$ transition was observed. The ESR signal consisted of a single slightly asymmetric line with a half-width ΔH = 10–12 G between the points of maximum slope. The intensity of the ESR signal did not vary with time on illumination with visible light ($\lambda \geq 400$ nm).

Among the porphyrins investigated Mg-aetioporphyrin proved to have the highest concentration of paramagnetic centres (about 10^{16} spins in a 0.03 cm^3 specimen at a porphyrin concentration of 2×10^{-3} M). For other porphyrins, the number of paramagnetic centres in the specimen at a concentration of 10^{-3} M was 5×10^{14}–7×10^{15} spins, in agreement with the shorter lifetime $\tau_{phosph} = 5 \times 10^{-2}$–$10^{-2}$ s compared with τ_{phosph} of Mg-aetioporphyrin (2×10^{-1} s).[41] The ESR absorption of the triplet states of the copper complexes of aetioporphyrin and haematoporphyrin could not be observed although it is known that the intensity of the phosphorescence of such copper complexes greatly exceeds that of the magnesium complexes and the bases. Since τ_{phosph} for the copper complexes is 10^{-4}–5×10^{-5} s, the steady-state concentration of the excited triplet molecules is lower by 2–3 powers of ten than that of the bases and magnesium complexes. Within the limits of the concentration range investigated (5×10^{-5}–10^{-3} M), the amplitude of the ESR signal is directly proportional to the concentration of the pigment[42]. The concentration-induced quenching for various porphyrins begins when a concentration of 10^{-3} M is reached. The ESR signal amplitude then falls[42,46].

For reactions proceeding via an excited triplet state, it is important to know the characteristics of molecules in the triplet state such as τ and the steady-state concentration n_{st}. Indeed, in the porphyrin series magnesium complexes are the most active, compared with the bases and zinc complexes, while the copper complexes are the least active[32,42]. This applies in particular to two-quantum reactions, since in the case of high values of τ there is a considerable population of the triplet level and hence a high probability that a second energy quantum will be absorbed.

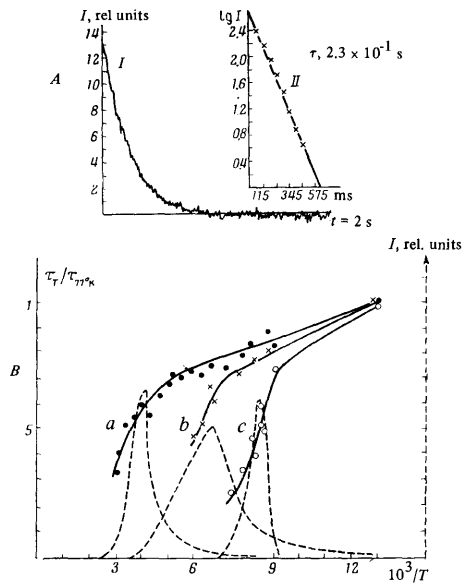

Figure 3. *A*) Kinetics of the decay of the ESR signal of the triplet state ($\Delta m = \pm 2$) of Mg-aetioporphyrin in ethanol at 77°K (I) and the same plot on a logarithmic scale (II); *B*) variation of $\tau_T/\tau_{77°K}$ with $1/T$ for Mg-aetioporphyrin in poly(methyl methacrylate) (a), in highly viscous methyl methacrylate (the initial stage of polymerisation) (*b*), and in ethanol (*c*). Lower curves —variation of the yield of radicals with temperature.

The authors of the review developed a method for the measurement of τ by ESR using a spectrum accumulator and a mechanical shutter[47]. The variation of τ and n_{st} with the concentration of the pigment and oxygen, the properties of the matrix, and temperature was investigated[47-49]. τ was determined from the time required for the amplitude of the $\Delta m = \pm 2$ ESR signal to diminish by a factor e after switching off the illumination. Fig. 3*A* presents a typical decay curve for the ESR signal of Mg-aetioporphyrin at 77°K. For all the porphyrins investigated, the decay curves are exponential. The values for τ for the triplet state are listed in Table 1. We may note that the variation of the pigment concentration in the range 5×10^{-5}–10^{-3} M, the nature of the solvent [ethanol, cyclohexanol, and poly(methyl methacrylate) (PMT)], and the presence of oxygen in the specimen at 77°K do not affect the value of τ for the triplet state.

With increase of temperature the lifetime diminishes. Table 2 presents the values of τ for Mg-aetioporphyrin dissolved in ethanol and PMT at different temperatures.

The steady-state concentration of the triplet molecules varies with τ. The parallel variation of these quantities with temperature is evidence that the factors responsible for the temperature-induced quenching are the same. A deviation from the parallel variation is observed in ethanol solutions. In all cases the $\tau_T°K/\tau_{77°K} = f(1/T)$ curves are complex and have two sections. The variation along the slow section is close to exponential[47,48], which corresponds to purely temperature-induced quenching[51] (Fig. 3B). In addition, the effectiveness of the quenching depends on the viscosity of the medium and proves to be highest in ethanol and lowest in PMT. The presence of oxygen also sharply increases the effectiveness of the quenching in ethanol and cyclohexanol, but does not affect the quenching in a polymeric matrix when there is no diffusion of oxygen. The sharp inflection in curves describing the variation of τ (and also n_{st}) (Fig. 3B) is noteworthy. The temperature at which the inflection occurs is associated with the onset of formation of free porphyrin radicals. It has been

shown[48-50] that the formation of free radicals has a two-quantum mechanism. Together with pigment radicals, the polymeric matrix stabilises the radicals of methyl methacrylate. It is noteworthy that temperature-induced quenching of the triplet molecules of the photochemically less active Zn-tetraphenylphorphin is less effective, owing to the formation of free radicals, than for Mg-aetioporphyrin. Thus the temperature-induced quenching of τ and n_{st} is analogous to the temperature-induced quenching of the phosphorescence of aromatic compounds[51] and is determined, apart from the effect purely due to temperature and associated with the redistribution of the vibrational energy of the molecule, by the structural properties of the medium, the oxygen effect, and quenching due to photochemical reactions.

The ESR spectra of $\Delta m = \pm 1$ transitions. The ESR spectra in high magnetic fields (2900–3800 G) due to $\Delta m = \pm 1$ transitions were first observed for Mg-aetioporphyrin[8,43] (as already mentioned, this substance gives rise to the highest ESR signal in low fields). Later the same investigators[33] and also Lhoste et al.[52] (for haematoporphyrin) recorded $\Delta m = \pm 1$ transitions for bases, dications, and other metal complexes of porphyrins dissolved in ethanol, pyridine, cyclohexanol, and their mixtures and also in PMT. The ESR spectra at room temperature have been recorded exclusively in PMT. The cationic forms of porphyrins have been investigated in acid ethanol solutions. The method of signal accumulation has been used to record the spectra of molecules with low values of n_{st}, particularly at room temperature[47,48].

Fig. 4 presents high-field ESR spectra of porphyrins in an excited triplet state. For the metal complexes of porphyrins with D_{4h} symmetry (Mg-aetioporphyrin, Zn-aetioporphyrin, and Zn-tetraphenylporphin), the ESR spectrum has the expected line form, i.e. four canonical peaks: H_{X, y_2} and H_{X, y_3} for the x and y molecular axes directed along the constant magnetic field and H_{Z_2} and H_{Z_3} for $z \parallel H_{const}$. The intensity ratio corresponds to the expected inequality $I_{H_{X,y}} > I_{H_Z}$. Indeed, in the absence of an external magnetic field the triplet level splits into two sublevels separated by a distance D. Since the molecular symmetry is D_{4h}, one of the sublevels remains doubly degenerate (the molecular x and y axes in the plane of the molecule are physically equivalent. We may note that, at room temperature in PMT, the $H_{X, y}$ lines are considerably narrowed (Fig. 4*b*, curve *2*). Two tetrapyrrole pigments—Zn-aetioporphyrin and chlorophyll (discussed in greater detail below)—exhibit two-quantum transitions in the region of $\Delta m = \pm 1$ (Fig. 4*c*).

For porphyrin bases with D_{2h} symmetry (according to spectroscopic data[53]), one should expect the appearance of a six-line spectrum with H_X, H_Y, and H_Z canonical peaks. However, the experimental ESR spectrum consists of four lines, which corresponds to cylindrical symmetry of the molecule in the triplet state. In the light of the latest theoretical concepts and X-ray diffraction data[54], the porphyrin bases may be represented by a superposition of structures *A*, *B*, and *C* (Fig. 4*f*) with statistical weights of 19, 32, and 49% respectively. Structures *B* and *C* with D_{4h} symmetry then represent the porphyrin bases to the extent of 80%. This finding is satisfactorily consistent with ESR data.

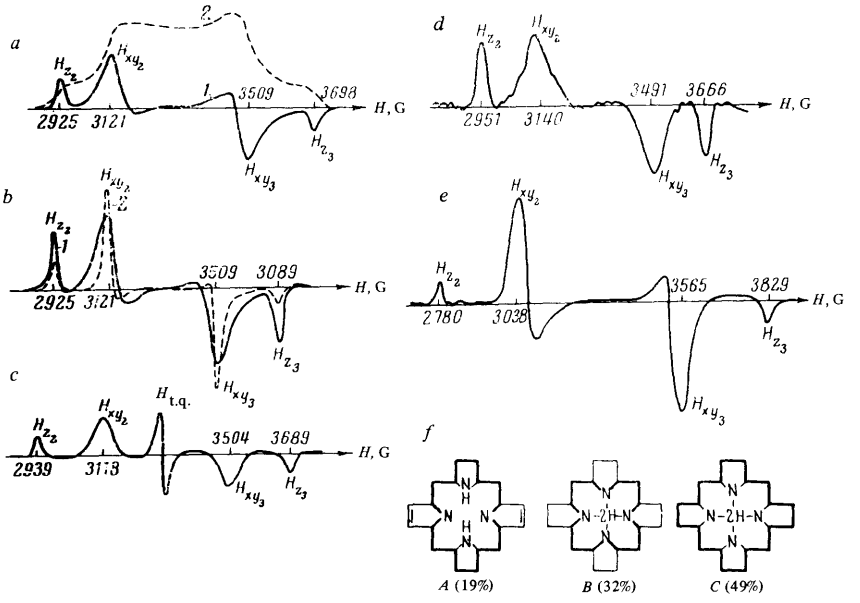

Figure 4. ESR spectra ($\Delta m = \pm 1$) of aetioporphyrins in an excited triplet state: *a*) Mg-aetioporphyrin in ethanol at 77°K [1) first derivative of the ESR spectrum; 2) the spectrum in the integral form]; *b*) Mg-aetioporphyrin in poly(methyl methacrylate) [1) at 77°K; 2) at 330°K]; *c*) Zn-aetioporphyrin in ethanol at 77°K; *d*) $2H^+$-aetioporphyrin in ethanol solution of hydrochloric acid at 77°K; *e*) aetioporphyrin in a pyridine—ethanol mixture at 77°K; *f*) π-electron structure of porphyrins.

The ESR spectra of the $\Delta m = \pm 1$ and $\Delta m = \pm 2$ transitions were also recorded at higher temperatures (up to 350°K)[33, 45, 55]. It must be emphasised that, with increase of temperature, the spectrum as a whole is displaced towards higher fields (the constant D^*/hc diminishes), the number of peaks does not change, but the lines themselves become markedly narrower and their intensity ratios change (Fig. 4*b*, curve *2*).

The zero-field splitting constants calculated from the ESR spectra are summarised in Table 1. The average values of D^*/hc calculated from the $\Delta m = \pm 1$ spectrum agree satisfactorily with the D^*/hc values calculated from the $\Delta m = \pm 2$ spectra. Analysis of the data in Table 1 leads to the following findings: (1) lateral substituents of the porphyrin ring such as CH_3, CHO, C_2H_5, and CH_2COOH do not affect the constant within the limits of experimental error, i.e. they do not affect significantly the dimensions and symmetry of the π-electron cloud of the molecule; (2) all metal complexes with aliphatic substituents also have the same zero-field splitting constants. On the other hand, phenyl substituents in Zn-tetraphenylporphin and Mg-phthalocyanine increase the size of the π-electron system and diminish the D/hc constant; (3) the values of D/hc for the metal complexes are somewhat higher than those for the dications; this finding is probably associated with some contraction of the π-electron cloud by the metal atom towards the centre of the molecule; (4) on passing to porphyrin bases, the constants increase significantly. This anomalous effect may be attributed either to the orbital splitting of the lowest triplet level or to the fact that in the porphyrin molecule in an excited triplet state the electrons spend most time in the 18-membered small ring of the molecule (Fig. 4*f*). This leads to a marked decrease of D/hc, since this structure predominates over all others under conditions of dynamic equilibrium.

Table 3. Characteristics of the ESR spectra of the triplet state of porphyrins at 77° and 320°K (ν = 9260 MHz).

Porphyrin	H_{min}, G 77°K	H_{min}, G 320°K	ΔH 77° K	ΔH 320° K	D/hc, cm^{-1} 77°K	D/hc, cm^{-1} 320°K	Symmetry
Aetio-	1626	1631	11.5	11.0	0.047	0.042	D_{2h}
Mg-aetio-	1637	1639	9.5	10.5	0.036	0.033	D_{4h}
Meso-	1627	1632	11.5	10.0	0.046	0.041	D_{2h}
Proto-	1626	1629	11.0	11.0	0.047	0.044	D_{2h}
Zn-TPP	1640	1644	11.0	12.5	0.031	0.025	D_{2h}

The values of D^*/hc are almost insensitive to the solvent (ethanol, cyclohexanol, PMT, isopentane, and pyridine). However, pyridine, which is known to exhibit complex-forming properties, causes an appreciable broadening of the ESR line. The introduction of magnesium into the centre of the porphyrin molecule narrows the ESR line compared with the spectra of the bases and dications. When the temperature is raised from 77° to 320°K, the values of D^*/hc decrease by 7–19% for various porphyrins (Table 3), which is probably associated with an increase of the size of π-electron cloud owing to the population of high vibrational sublevels of the triplet state or to dynamic effects leading to the predominance of more symmetrical porphyrin structures [40].

As already mentioned in the introduction to the review, the main contribution to the canonical peaks of the ESR spectra of the $\Delta m = \pm 1$ transitions in a system of molecules oriented at random comes from molecules for which the principal axes of the spin–spin interaction tensor are oriented in the direction of the external magnetic field H_{const} or nearly so (±5°);[27, 28] other orientations give rise to an almost constant absorption background. Thus there is a selection of molecules with respect to canonical orientation—magnetoselection. When such a system is excited by polarised light (magnetophotoselection), only the canonical peaks for which the direction of the $S_0 \rightarrow S_1$ transition moment and the electric vector of the incident light waves (E and H_{const}) coincide appear in the spectrum [56, 57]. The authors of the review [58] investigated the variation of the line form of the ESR spectra ($\Delta m = \pm 1$ transitions) as a function of the polarisation of the exciting light relative to the direction of the external magnetic field. Fig. 5A presents the ESR spectra of Mg-aetioporphyrin and Zn-aetioporphyrin in the triplet state excited

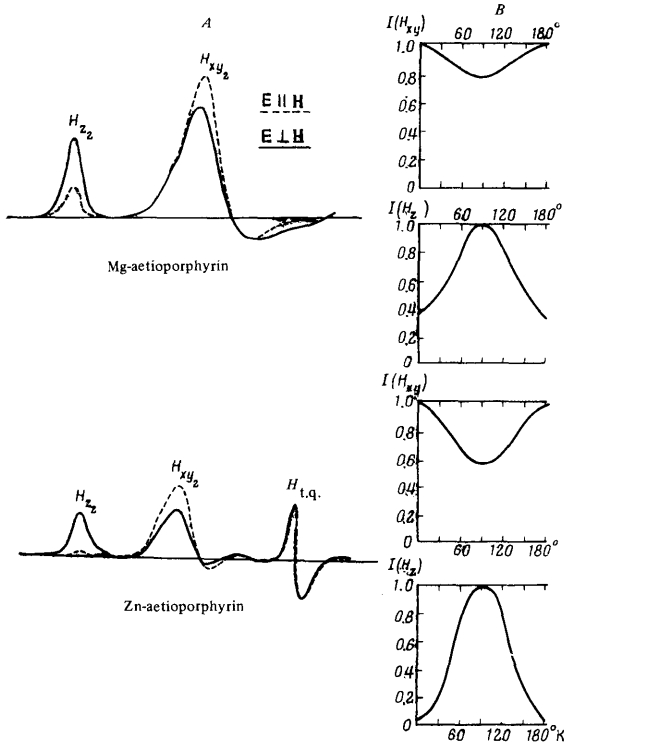

Figure 5. *A*) ESR spectra of Mg- and Zn-aetioporphyrins for different polarisations of the exciting light; *B*) variation of the height of the canonical peaks as a function of the angle between H_{const} and E.

by polarised light. On the right-hand side of the same figure, the amplitudes of the canonical peaks H_Z and H_{XY} are plotted against the angle between the directions of the polarised light vector E and of H_{const}. Evidently the limiting heights of different canonical peaks occur for parallel and perpendicular orientations. For the parallel orientation ($E \parallel H_{const.}$), the H_{XY} peak is a maximum and

the H_Z peak a minimum; for the perpendicular orientation, the situation is reversed. For intermediate orientations of E and H_{const}, the amplitude of the H_Z peak varies as $\sin^2 \alpha$ and that of the H_{xy} peak, as $1 + \cos^2 \alpha$. The amplitude of the $H_{t.q.}$ peak is independent of polarisation.

This behaviour of the canonical peaks can be readily explained if it is assumed that an oscillator oriented in the plane of the molecule is responsible for the triplet excited state. This conclusion is also consistent with optical data[53,59]. The line shape for porphyrin dications varies similarly on excitation with polarised light (Table 4).

Table 4. Effect of polarised light on the intensity of the canonical peaks in $\Delta m = \pm 1$ transitions.

Porphyrin	$\frac{I(H_z)_\parallel}{I(H_z)_\perp}$	$\frac{I(H_{xy})_\parallel}{I(H_{xy})_\perp}$
Mg-aetio-	0.23±0.05	1.44±0.1
Zn-aetio-	0.15±0.05	1.7±0.1
$2H^+$-aetio-	0.42±0.05	1.2±0.1
$2H^+$-meso-	0.7±0.1	1.5±0.2

Table 4 lists the ratios of the amplitudes of peaks 1 (H_1), for the parallel orientation of E and H_{const}, to the amplitude corresponding to the perpendicular orientation. Theoretically these ratios are given by the following formulae:

$$\frac{I(H_z)_\parallel}{I(H_z)_\perp} = 0; \quad \frac{I(H_{xy})_\parallel}{I(H_{xy})_\perp} = 2^{57}.$$

However, Table 4 shows that they do not hold exactly for porphyrins, or incidentally, for the other compounds investigated[56]. This deviation from theoretical values is associated with depolarisation effects of different types, which have been discussed in detail by Kottis and Lefevre[57].

2. Photosynthesising Pigments

The ESR signal of the triplet state of chlorophyll b was observed for the first time in a frozen ethanol solution[60]. The same investigators[61] succeeded in observing the ESR absorption of the excited triplet state using a spectrum accumulator with alcoholic and pyridine chlorophyll a, chlorophyll a + b, and phaeophytin a + b solutions at pigment concentrations of about 10^{-3} M. Transitions were observed in the range 1636–1640 G (ν = 9260 MHz) between the lowest and highest triplet sublevels ($\Delta m = \pm 2$). The amplitude of the ESR signal of the chlorophyll b triplet state is proportional to its concentration, but, starting with a 10^{-3} M pigment concentration, the amplitude falls owing to concentration-induced quenching[46,60]. When films of chlorophyll a + b, in which the pigment is in a highly aggregated state, were investigated, no ESR absorption was observed, which is also due to concentration-induced quenching[61]. The intensity of the ESR signal of the triplet state of chlorophyll *b* is two and a half times greater than that of the signal of chlorophyll **a**. This might have been expected, since τ_{phosph} for chlorophyll b is almost three times higher than for chlorophyll a.[59]

The ESR spectra of $\Delta m = \pm 2$ transitions consist of singlet slightly asymmetrical lines (Fig. 6*A*). At the temperature of liquid nitrogen, oxygen does not influence the signal intensity. Table 5 lists the ESR parameters of the triplet state of the pigments investigated.

Using a spectrum accumulator, Lhoste[34] observed the ESR signal of the triplet state of chlorophyll b in high fields ($\Delta m = \pm 1$ transitions). The ESR signal consists of seven peaks (Fig. 6*D*): H_{x_2}, H_{x_3}, H_{y_2}, H_{y_3}, H_{z_2}, H_{z_3}, and the $H_{t.q.}$ peak corresponding to the two-quantum transition. This spectrum corresponds to C_{2v} molecular symmetry. The zero-field splitting constants were estimated from the spectra: $D/hc = 0.0306 \pm 0.0010$ cm^{-1} and $E/hc = 0.0034 \pm 0.0006$ cm^{-1}. The additional peaks (IV and V) were not assigned by the authors (Fig. 6*D*), but they may be due to the presence of an admixture of chlorophyll a or phaeophytin.

Table 5. Characteristics of the ESR spectra of chlorophyll a and b in the triplet state (ν = 9260 MHz).

Pigment	H_{min}, G	ΔH, G	D^*/hc, cm^{-1}	Solvent
Chlorophyll a	1640	13	0.032	Ethanol
Chlorophyll b	1636	13	0.037	Ethanol
	1638	13	0.035	Pyridine

From the standpoint of the understanding of the role of the excited triplet state of chlorophyll in photosynthesis *in vivo*, its direct investigation in photosynthesising systems (chloroplasts, chromatophores, and leaves turning green) is of greatest interest. An attempt has been made[61] to observe the ESR signal due to photosynthesising pigments in chloroplast and "greening" leaf preparations. A study was made of pea chloroplasts. In native preparations, ESR absorption due to the triplet state was not observed. The light-induced ESR signals due to the triplet state of chlorophyll were observed in chloroplast preparations containing between 10 and 50 vol.% of pyridine (Fig. 6*C*). Pyridine is known to have a deaggregating effect on the pigment system of chloroplasts and in the given case there was a possibility of the extraction of chlorophyll into pyridine. As pointed out earlier, in studies on pigment films ESR signals of the triplet state were not observed either. Therefore one may suppose that at high pigment concentrations there is an effective transfer of excitation energy via triplet levels resulting in a sharp decrease of τ and hence also n_{st} for chlorophyll. In this connection one might have expected the appearance of an ESR signal in leaves during the process of acquisition of the green colour, which involves the formation of the monomeric components of the pigment system. A study has been made[61] of the ESR absorption of etiolated corn leaves subjected to illumination for different periods (between 1 and 30 h). However, the ESR signals due to the triplet state were not observed in these systems either. The extraction of the pigments from the leaves to a pyridine solution makes it possible to record the ESR absorption. Probably, during the first stages of the generation of the green colour in the leaves, the deactivation processes of the triplet molecules are already fairly effective. Such deactivation may be a consequence of an effective transfer and employment of the energy of the triplet excitation in the reaction centre, so that in native chloroplasts measurable steady-state concentrations of chlorophyll molecules in an excited triplet state are not observed.

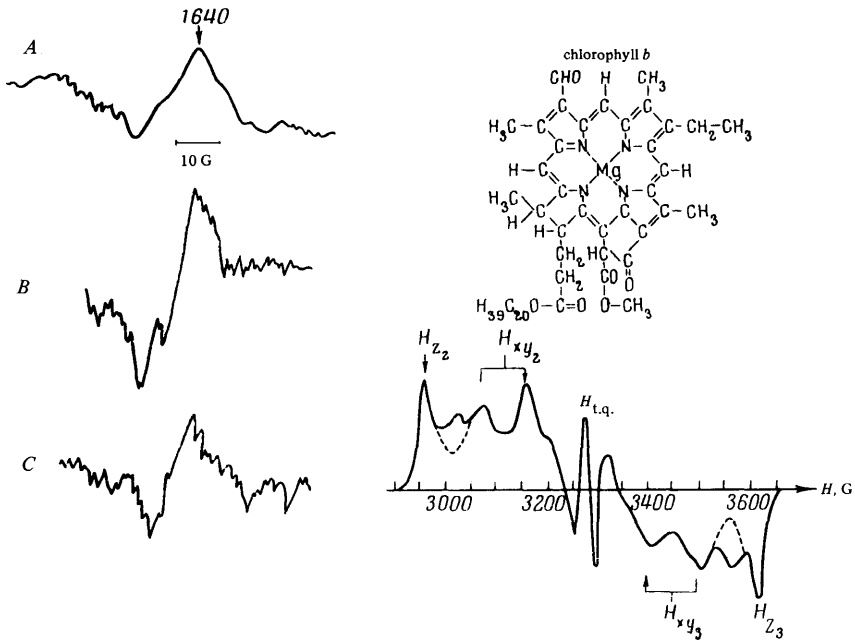

Figure 6. The structure and ESR signal of the excited triplet state of chlorophyll a (*A*), phaeophytin a + b (*B*) in ethanol and in chloroplasts treated with pyridine (*C*) ($\Delta m = \pm 2$ transitions, $\nu = 9260$ MHz), and of chlorophyll b (*D*) in ethanol ($\Delta m = \pm 1$ transition, $\nu =$ 9210 MHz). The spectrum *B* is probably the sum of two signals, due to phaeophytin a and phaeophytin b, as shown by the reproducible splitting of the line.

3. Aromatic Aminoacids, Di- and Poly-peptides, and Proteins

The observation of the excited triplet state of aromatic aminoacids by the ESR method has been reported by a number of workers, starting in 1963.[9,11,13,32,38,62-68] Ethanol and aqueous ethanol solutions of aromatic aminoacids (tyrosine, tryptophan, and phenylalanine) were excited by ultraviolet light at 77°K. $\Delta m = \pm 2$ transitions were recorded. The ESR signals consist of single asymmetric ESR lines (Fig. 7*A* and 7*B*) with the parameters listed in Table 6. After the illumination has been switched off, the ESR signal of tryptophan in ethanol decayed with the period $\tau = 2.4$ s (decrease of the initial ESR signal amplitude by a factor e), which is consistent with optical data[69]. When acetic acid was added to an ethanol solution of tryptophan, the signal intensity fell approximately by a factor of ten[32,42]. Ptak and Douzou[65] observed the ESR signals of the excited triplet state of aromatic aminoacids in methanol solutions and obtained results analogous to those of Gribova and coworkers[32,42], in particular they showed that the decay of the ESR signal is strictly parallel to the decay of phosphorescence (Fig. 7*B*). The times required for the decrease of the ESR signal by a factor of 2 ($\tau_{1/2}$) in a phosphate buffer are respectively 6.7 s for tryptophan, 6 s for phenylalanine, and 3 s for tyrosine. It is noteworthy that the ESR and luminescence characteristics of the triplet state of aromatic aminoacids depend on the nature of the matrix, the temperature, and the pH of the solution. In particular Shiga and Piette[66] noted that the nature of the solvent (water–methanol, phosphate buffer) does not influence the ESR signal line form, but significantly alters the signal decay time.

Among the three aromatic aminoacids, the highest ESR signal ($\Delta m = \pm 2$) was recorded for tryptophan and the lowest for phenylalanine in solutions at the same concentration. Shiga and Piette[66] noted that the yield of tyrosine molecules in an excited triplet state is one third of that for tryptophan. Zuclich[38] found that the intensity ratios of the ESR signals ($\Delta m = \pm 2$) for tryptophan, the tyrosinate ion, tyrosine, and phenylalanine are respectively 8 : 2 : 1 : 1. The characteristics of the ESR spectra determined from the $\Delta m = \pm 2$ transitions are listed in Table 6.

Hélène et al.[70] investigated the dependence of the parameters of the ESR spectra on the aggregation of aminoacids in solution. As for the variation of phosphorescence intensity, the authors observed an increase in the ESR signal on deaggregation when deaggregating additives (ethanol and sodium chloride) were added to the aqueous solutions of the aminoacids before freezing. They explained this effect by a change in the probability of an intersystem crossing and in the probability of energy transfer in the microcrystals.

Malig et al.[67] made a detailed study of the effect of the pH of the medium on the properties of the ESR signal of L-tyrosine in the crystalline state. They observed two ESR signals and the corresponding absorption bands of the

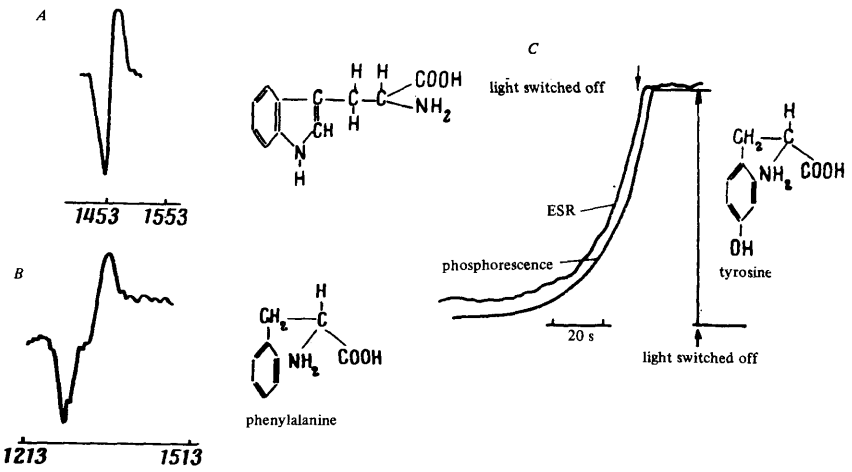

Figure 7. ESR spectrum of the triplet state of tryptophan (*A*) and phenylalanine (*B*) at 77°K in ethanol solutions ($\Delta m = \pm 2$ transitions). Curves *C* represented the decay of the ESR signal and phosphorescence of L-tyrosine under the same conditions.

two forms of tyrosine: unionised and ionised. The parameters of the spectra are presented in Table 6. The signal intensity depends on the pH of the medium. At pH 6.9 the ionic form is absent and a peak at 280 nm, due to the non-ionic form, is observed in the absorption spectrum together with the corresponding ESR signal at 1287 G ($\nu = 9138$ MHz). At pH 10 only the ESR signal at 1390 G and the corresponding absorption maximum of the ionic form at 295 nm (Fig. 8) persist. On raising the temperature from 77° to 295°K, the equilibrium is displaced towards the formation of the unionised form; $\tau_{1/2}$ for the decay of the ESR signal is about 2 s for the ionic form and about 3 s for the non-ionic form.

Table 6. Parameters of the ESR spectra of aromatic aminoacids in the triplet state ($\Delta m = \pm 2$ transitions; 77°K).

Compound	D^*/hc, cm^{-1}	ΔH, G	$\tau_{1/2}$, s	Solvent
Tryptophan	0.126	15	2.4	Ethanol (Ref.32)
	0.119	22	4.1	Methanol + 6 *N* HCl phosphate buffer (Ref.66)
Tyrosine	0.112	32	1.9	Ditto
Non-ionised L-tyrosine	0.161	32	3	H_2O + propylene glycol
Ionised L-tyrosine	0.141	47	2	H_2O + propylene glycol + HCl
Phenylalanine	0.161	63	6.4	Methanol + HCl phosphate buffer

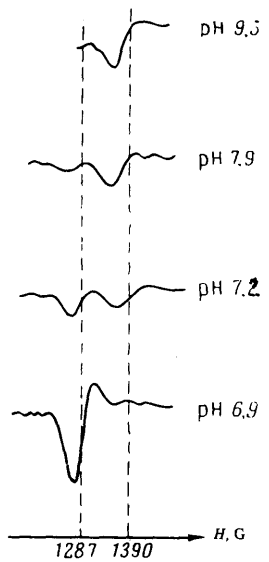

Figure 8. ESR spectrum of L-tyrosine in the triplet state as a function of pH (pH established with a tris buffer and HCl at 295°K).

Similar studies were made by Shiga et al.[68] for L-tryptophan, glycyl-L-tryptophan, and poly-L-tryptophan. The decay curves for the ESR signal and phosphorescence are identical. At an L-tryptophan concentration in excess of 2×10^{-4} M, concentration-dependent quenching is observed; we then have $\tau = 4.4$ s regardless of concentration. The intensity of the ESR signal depends non-linearly on the light intensity and saturation is attained at a fairly high intensity.

The ESR signal of the triplet state of poly-L-tryptophan is the same as that of L-tryptophan with $\tau_{1/2} = 4.2$ s, but the number of paramagnetic centres per unit optical density is smaller by a factor of 2. The authors explained the decrease of the yield by concentration-induced quenching.

$\Delta m = \pm 1$ transitions. $\Delta m = \pm 1$ transitions in tyrosine were observed for the first time by Bosch et al.[35] Recently Zuclich[38] reported the observation of the $\Delta m = \pm 1$ ESR spectra for three aminoacids. Tryptophan was

excited in pure ethanol, tyrosine in 0.1 M HCl solution in ethanol, and phenylalanine and tyrosinate in 0.25 M NaOH solution in ethanol. The zero-field splitting energies X_1, X_2, X_3 and the zero-field splitting constants ($D = -3/2$ and $Z = -\frac{3}{2}X_\perp$) are listed in Table 7. Zuclich[38] adopted X_1, X_2, and X_3 (instead of X, Y, and Z) as the symbols for the zero-field splitting energies because in a specimen with a random orientation they cannot be assigned to specific molecular axes. $X_\perp$ is the zero-field splitting energy associated with the direction perpendicular to the plane of the molecule. $X_\perp$ values were determined by studying the line form of the ESR spectrum in polarised light.

Table 7. Parameters of the zero-field splitting of aromatic acids (cm^{-1}).

Compound	$\Delta m=\pm1$						$\Delta m=\pm2$
	X_1/hc	X_2/hc	X_3/hc	D/hc	E/hc	D^*/hc	D^*/hc

The transfer of triplet excitation energy in mixtures of aminoacids. This made it possible to identify the ESR signal of the triplet state in proteins and to understand the mechanism of the interaction of photoexcited molecules *in vivo*. The transfer of triplet excitation energy in a mixture of tyrosine and tryptophan in 6 M HCl has been investigated[68,96]. During the first seconds of illumination, two ESR signals of tyrosine and tryptophan were recorded ($\Delta m = \pm2$ transitions). The intensity of the signal due to tryptophan increased with time and that due to tyrosine fell compared with the one-component system under continuous illumination. The behaviour of aromatic dipeptides in the presence of tryptophan is similar[68]. According to Tables 6 and 7, the zero-field splitting constants for various aromatic acids differ markedly and therefore the ESR signals can be identified readily and unambiguously. The ESR data for the triplet state of individual aromatic aminoacids and particularly di- and poly-peptides made it possible to identify the triplet state of proteins.

Shiga et al.[66,68] were the first to investigate the excited triplet state of proteins by the ESR method and the energy transfer in proteins was discussed by Lhoste[52] and Zuclich[38]. Bovine serum albumin, egg albumin, β-lactoglobulin, D-aminoacid oxidase (the apo- and holo-enzymes), and native oxy- and deoxy-haemocyanines were investigated. In order to record ESR signals of low intensity, a spectrum accumulator was employed. In all cases[66,68] $\Delta m = \pm2$ transitions were observed. For all the above proteins, ESR absorption gave rise to the same H_{min} and line form as for the ESR signal of L-tryptophan. Thus the triplet signal originates from the tryptophan residues. The behaviour of D-aminoacid oxidase proved to be somewhat different. It is suggested[68] that in this protein, containing flavin-adenine dinucleotide (FAD), the ESR signal is caused not only by the triplet excitation of the aromatic aminoacid but also by a considerable interaction between the aromatic aminoacid in the excited triplet state and FAD. The holoenzyme gives rise to two different signals with $H_{min} = 1450$ and 1560 G, which are respectively due to tryptophan and FAD. Proteins have a significant influence on the triplet state of FAD, but the converse effect is not shown. While the characteristics of the ESR spectra of proteins are similar, the decay time $\tau_{1/2}$ depends on the nature of the protein and on the composition of the solvent. The values of $\tau_{1/2}$ are compiled in Table 8 on the basis of the data of Shiga et al.[68]

Table 8. The $\tau_{1/2}$ values for the triplet state of proteins at 77°K.

Protein	$\tau_{1/2}, s^{-1}$					
	I	II	III	IV	V	VI
Egg albumin	3.3	4.1	4.3	4.4	—	—
Bovine serum albumin	3.7	4.6	4.0	4.7	—	—
β-Lactoglobulin	3.9	4.0	4.7	4.8	—	—
D-aminoacid oxidase						
apoenzyme	2.4	—	—	—	—	—
holoenzyme	2.8	—	—	—	—	—
Native haemocyanin						
oxy-	—	—	—	—	1.7	3.4
deoxy-	—	—	—	—	4.8	4.4
Apohaemocyanin						
deoxy-	—	—	—	—	4.8	3.8

The following notation is employed in the Table: solvent I—buffer (pH 7; 0.1 M); solvent II—1 : 1 glycerol–buffer; solvent III—buffer + 8 M urea; solvent IV—1 : 1 glycerol–buffer + 8 M urea; solvent V—tris buffer (pH 6.8; 0.05 M; containing 0.01 M Ca^{2+}); solvent VI—1 : 1 glycerol–tris buffer.

Table 8 shows that $\tau_{1/2}$ increases in the presence of urea and when glycerol is added. The authors suggest that the nature of the environment of the tryptophan residues in the protein has a significant influence on $\tau_{1/2}$. On denaturation the environment changes and some of the tryptophan residues may pass to the solution. The activity spectra and the intensities of the ESR signals of various proteins are also different. It is believed[68] that these differences are due to the following causes:
(a) different distances between the tryptophan residues and their different orientations in different proteins;
(b) different distribution of tyrosine and phenylalanine residues between the tryptophan residues; (c) different degrees of dissociation of the protons in the peptide chain relative to the tryptophan residues; (d) different environments of the tryptophan residues.

However, Zuclich's latest measurements[38] showed that in human and bovine serum albumin (in an ethylene glycol–phosphate buffer at pH 7) two ESR signals of the triplet state ($\Delta m = \pm2$ transitions) are observed. The signals undergo neither broadening, nor displacement, nor a change in the zero-field splitting constant. The relative intensities of the tryptophan signals in the three proteins investigated (human and bovine serum albumin and ovalbumin) were respectively 1 : 1 : 2. The tyrosine signal was four times more intense in human serum albumin than in bovine albumin and was completely absent from ovalbumin. This is consistent with the finding that the degree of tyrosine → tryptophan energy migration increases with the relative concentration of tryptophan. Since the tyrosine content in the albumins is the same, the author attributes the differences between the intensities to the differences between the contents of tryptophan residues

(one and two tryptophan molecules per molecule of human and bovine serum albumin respectively). In this case at least 75% of the tyrosine molecules in bovine albumin are quenched by the two tryptophan residues. The author [38] calculated the minimum radius R_0 of the region of energy transfer from tyrosine to tryptophan in bovine serum albumin and obtained $R_0 = 20$ Å. The $\Delta m = \pm 1$ ESR spectrum was observed only for ovalbumin [38] and proved to be wholly due to tryptophan residues.

4. Flavins and Their Derivatives

Flavosemiquinones are known as intermediate electron-transfer agents in the respiratory chain of mitochondria and chloroplasts. The study of the triplet state by the ESR method in solid solutions and the determination of the zero-field splitting constants made it possible to describe qualitatively the properties and distribution of electron density in the triplet state of these complex molecules [16,52,71].

The ESR spectra of the excited triplet state associated with the $\Delta m = \pm 1$ and $\Delta m = \pm 2$ transitions were recorded for substituted, tautomeric, and reduced forms of flavins and pteridines, including flavin mononucleotide (FMN), FAD, and riboflavin. The most complete data about the properties of the ESR spectra of the triplet states of flavins and peridines were obtained by Lhoste et al. [52] Table 9 gives the characteristics of the ESR spectra associated with the $\Delta m = \pm 2$ transitions. A typical ESR spectrum of the triplet state ($\Delta m = \pm 2$) for $H_{const} \perp H_{rj}$ is presented in Fig. 9*A*. The distribution of resonance fields in the region 1500–1700 G ($\nu = 9210$ MHz) is shown below (Fig. 9*B*).

At 77°K, $\Delta m = \pm 1$ transitions were observed in a concentrated ethanol solution or a propylene glycol—water-hydrochloric acid mixture. The spectrum of the FMN cations is presented in Fig. 9*A*. The parameters of the ESR spectra are listed in Table 10. The line shape of the triplet absorption in the region of $\Delta m = \pm 1$ is unusual and corresponds to equal energies of the two sublevels of the triplet level, which are comparable in absolute magnitude but have different signs. For this reason the corresponding ESR lines merge. The narrow $H_{t.q.}$ line in the spectrum corresponds to a two-quantum transition. The $\Delta m = \pm 1$ spectrum of the cation exhibits a low symmetry of the triplet state owing to the effect of the charge.

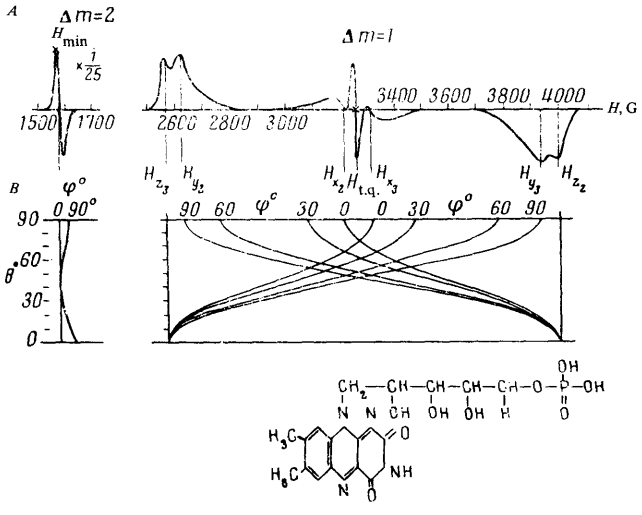

Figure 9. *A*) ESR spectrum of the triplet state ($\Delta m = \pm 2$, ± 1 transitions; $\nu = 9210$ MHz) of the cationic form of flavin mononucleotide in water–propylene glycol–6 *N* HCl solution at 77°K; *B*) distribution of resonance fields.

It is significant that the triplet state of the FMN anions does not differ from that of the neutral form either in the properties of its phosphorescence or in the parameters of its ESR spectrum. The triplet state of the cationic form is significantly different from the two preceding ones. In particular H_{min} is displaced by 20 G towards higher fields and the spin–spin interaction energy is higher (Tables 9 and 10).

Compared with other bicyclic (naphthalene, $D^* = 1.0030$ cm^{-1}) and polycyclic aromatic compounds [28], the zero-field splitting constants of pteridines and flavins are lower, which indicates a greater delocalisation of the excited-triplet electrons in the molecule. Another consequence of the lower values of the constants is that the triplet state is due to a $\pi-\pi^*$ transition and not $n-\pi^*$. For the $\pi-\pi^*$ triplet state, the energy of the molecule associated with the axis perpendicular to the molecular plane is negative. This highest value of the energy determines D/hc (Table 10). Two other values of the energy of the splitting of the triplet level in the absence of a field, associated with the axes in the molecular plane, determine E/hc. E/hc is small for pteridines and flavins.

Analysis of the data in Tables 9 and 10 leads to the following findings: (a) the nature of the substituent in the 10-position of flavins does not influence the zero-field

splitting constants, with the sole exception of tetraacetylriboflavin; (b) alkylation (3-benzyl-lumiflavin) or ionisation in the N_3 position (anionic form of FMN) do not alter the constants but alkylation in the 2-position, corresponding to the flavoquinone form, increases D^*/hc. The introduction of sulphur in the 2-position (2-thiolumiflavin) does not affect D^*/hc, but decreases the lifetime of the triplet state; (c) the alloxazine–isoalloxazine tautomerism decreases D^*/hc. A similar effect obtains with pteridine derivatives, compared with, for example, 1,3-dimethyllumazine and 8-methyl-lumazine; (d) the benzenoid ring plays a definite role in the delocalisation of electrons. D^*/hc for flavins is smaller by approximately 0.2 cm^{-1} than for pteridines. This shows that electrons in the triplet state are delocalised over the benzenoid ring.

Table 10. Characteristics of the ESR spectra of the triplet state of flavins and alloxazine compounds in concentrated solutions at 77°K ($\Delta m = \pm 1$ transitions; $\nu = 9210$ MHz).

Compound	X/hc	Y/hc	Z/hc	D/hc	E/hc	D^*/hc
	cm^{-1}					
3-Benzyl-lumiflavin	±0.0034	±0.0336	±0.0369	±0.0553	∓0.0150	0.0611
Cationic FMN	±0.0034	±0.0404	±0.0440	±0.0660	∓0.0185	0.0733
Tetra-acetylriboflavin	±0.067	±0.0309	±0.0376	±0.0564	∓0.0121	0.0602
Lumichrome	±0.0035	±0.0424	±0.0460	±0.0690	∓0.0194	0.0768
1,3-Dimethyl-lumichrome	±0.0026	±0.0415	±0.0440	±0.0660	∓0.0194	0.0741
1,3-Dimethylalloxazine	±0.075	±0.0406	±0.0481	±0.0721	∓0.0165	0.0776

Substituents in the 6- and 7-positions of the pteridine rings do not influence D^*/hc. The marked effect of various substituents in the 7- and 8-positions of the flavin ring (1,3-dimethyl-lumichrome has a smaller D^*/hc than 1,3-dimethylalloxazine) is evidence of an appreciable spin density in these positions. The introduction of CH_3 or Cl substituents in the 7- and 8-positions affects significantly the photochemical behaviour of flavins. Different substituents in the N_5 position quench the triplet state (5-acetyl-leucoflavin and 5-isopropyl-leucoflavin). A similar effect is observed for the 10-substituted derivatives Leucoflavins phosphoresce but do not give rise to ESR absorption. Reduced FMN does not show an ESR absorption either. According to Lhoste[52], the molecular skeleton of these species is non-planar in the lowest triplet state. This leads to a change in hybridisation of the N_5 orbitals. The triplet state can have a lower symmetry, which increases the spin–orbital coupling, reduces τ, and at the same time increases D^*/hc, making it impossible to observe the triplet absorption in the 3-cm range.

Thus the spin density of the triplet state of flavins is mainly localised in the quinoxaline part of the molecule. Characteristic features of these substances are a low spin density at the N_3 atom, a high density at N_5, N_1, and N_{10}, and the non-equivalence of the methyl groups in the 7- and 8-positions. These data are important in a consideration of the photochemical properties and biological functions of flavins.

5. Nucleic Acids, Purine and Pyrimidine Bases, and Nucleotides

Nucleic acids are high-molecular-weight compounds consisting of purine and pyrimidine bases, carbohydrate residues, and phosphate groups. Purine and pyrimidine bases enter into the composition of not only nucleic acids but also of a number of low-molecular-weight compounds which play an important role in vital processes, ranging from respiration to muscular contraction. Adenine play a special role in biology. In particular, adenine is a component of adenosine triphosphate (ATP), a kind of energy accumulator in a living system.

The ESR of the triplet state of nucleic acids and their constituent purine and pyrimidine bases, nucleotides, and nucleosides was investigated by Rahn, Shulman, Eisinger, and coworkers [35,36,72–77] and also by Hélène and coworkers [15; 78,79]. At a neutral pH in an ethylene glycol–water solution, adenine, adenosine, guanine, guanosine, and their monophosphates give rise to powerful ESR signals ($\Delta m = \pm 2$ transitions)[72]. Under these conditions, cytosine monophosphate gives rise to only a weak phosphorescence, while thymine monophosphate does not yield either phosphorescence or an ESR signal. The zero-field splitting constants and the values of τ are listed in Table 11.

Table 11. ESR characteristics of the triplet state of certain nucleic acid derivatives.

Compound	D/hc, cm^{-1} $\Delta m=\pm 1$	E/hc, cm^{-1} $\Delta m=\pm 1$	D^*/hc, cm^{-1} $\Delta m=\pm 2$	$\tau_{1/2}$, s

Guanine monophosphate	0.141	0.0127	0.145	1.25
pH 7				
pH 1			0.126	0.37
Thyminate ion, pH 12			0.198	0.50
Thymine monophosphate			0.198	0.45
Uridinate ion, pH 11			0.163	0.40
Orotic acid				
pH 7	0.176	0.016	0.184	0.30
pH 12			0.175	
Poly-dAT, pH 7			0.201	0.032
DNA			0.200	0.29

The triplet state ESR signal was not observed for native DNA at pH 7, although small signals due to the triplet state of guanine and adenine were recorded for denatured and degraded DNA [37,76]. At pH 12 (under these conditions thymine monophosphate ionises with a loss of a proton from the N_3 atom) the ESR signal of ionised thymine monophosphate (T^-) was observed at $H_{min} = 1067$ G for a decay time of 0.45 s, which is close to τ_{phosph} for DNA (0.3 s). The T^- signal is separated from the adenine signal by approximately 300 G and can be readily identified. A signal, analogous to that of thymine, was observed in poly-dAT at $H_{min} = 1046$ G ($\nu = 9104$ MHz) and with $\tau = 0.32$ s (see Table 11).[73]

A dilute mixture of guanine and cytosine monophosphate gives rise to an ESR signal of the triplet state of guanine monophosphate and a mixture of adenine and thymine monophosphates gives a triplet signal due to adenine monophosphate only. However in DNA there are no signals of the triplet state of the purine bases. Their triplet state is either not populated or it is populated and quenched. It is also possible that the energy of the triplet state is effectively transferred to thymine. An ESR signal was observed for native DNA from bovine thymus on ultraviolet irradiation in the same fields ($H_{min} = 1054$ G, $\Delta H = 50$ G, and $\tau = 0.29$ s) [37,72,73] as for the ionised form of thymine and poly-dAT.

$\Delta m = \pm 1$ transitions were observed together with $\Delta m = \pm 2$ transitions in frozen solutions of orotic acid and guanosine and adenosine monophosphates. The calculated constants are listed in Table 11, the analysis of the data of which shows that the zero-field splitting constants for purine and pyrimidine derivatives are significantly different. On the other hand, the constants also differ for the ionic and non-ionic forms of the bases. Rahn and coworkers [75,76] suggested that the DNA triplet is localised at a thymine residue, which is ionised when its labile proton is transferred via the hydrogen bond to adenine. The equality of the ESR absorption fields serves as an argument in favour of this hypothesis. The small difference between the values of τ is more likely to be due to a slight difference in the environment. That the DNA triplet originates from thymine was also confirmed by a detailed study of various synthetic nucleic acids and model polymers [72,73]—in all cases triplet absorption was shown by polymers containing thymine. Such unambiguous identification could not be made on the basis of spectroscopic data, since the phosphorescence of DNA is different from the phosphorescence of both individual nucleotides and their sum in solution.

6. Phenoxazine and Phenothiazine

Phenoxazine and phenothiazine belong to the class of photosynthesising dyes and also find wide application in pharmacology. They are tricyclic aromatic compounds with C_{2v} symmetry. Phenoxazine and phenothiazine readily form mixed single crystals with biphenyl; they have been investigated not only in solutions but also in single crystals.

Table 12. Parameters of the ESR spectra of the triplet state of phenoxazine and phenothiazine.

ESR constants	Phenoxazine		Phenothiazine	
	biphenyl crystal	ethanol glass	biphenyl crystal	ethanol glass
D/hc	± 0.0990	0.1249	± 0.1230	0.1237
E/hc	± 0.0154	0.0119	± 0.0142	0.0135
X/hc	± 0.0482	0.0535	± 0.0270	0.0278
I/hc	± 0.0175	0.0297	± 0.0553	0.0547

g_{xx}	2.0037	—	2.0042	—
g_{yy}	2.0037	—	2.0045	—
g_{zz}	2.0020	—	2.0014	—

A study of the triplet state of phenoxazine and phenothiazine by the ESR method was made comparatively recently by Lhoste and coworkers [52,80]. The ESR spectra associated with the $\Delta m = \pm 1$ and $\Delta m = \pm 2$ transitions are presented in Fig. 2. As expected, the spectrum for a molecule with C_{2v} symmetry has six canonical peaks and an $H_{t.q.}$ line in the region of $\Delta m = \pm 1$. The line width of the H_X and H_Y canonical peaks is about 25–30 G, while that of the H_Y peak is about 15 G (measured between the points of maximum slope). They study of a single crystal of phenoxazine in biphenyl made it possible to assign the peaks unambiguously to the molecular system of axes, as shown in Fig. 2. In parallel fields, the canonical H_{X_1} and H_{Y_1} peaks observed were displaced from H_{min} (Fig. 2A). Owing to its low intensity, the H_{Z_1} peak was not recorded. The parameters of the ESR spectra are listed in Table 12. The signs of the constants given are arbitrary, but according to McLachlan [81], D/hc for the triplet $\pi-\pi^*$ state is positive.

The surprising difference between the zero-field splitting energies of phenoxazine in the biphenyl and ethanol matrices is noteworthy. It may be due to different polarities of the solvents, their capacity to form hydrogen bonds, and finally to small differences in their geometry in solid solutions. In particular, in a biphenyl crystal these molecules can remain planar, while in ethanol they may become slightly bent. The latter leads to a change in the geometry of the π-electron cloud and the corresponding values of the D^*/hc constants. Phenothiazine has a high tendency towards bending and therefore its zero-field splitting energy changes little on passing from one matrix to another (in a single crystal it is also bent) [52]. The bending of the benzene rings of the molecule is deduced in particular from calculations of the dipole moment and the electronic structure of phenothiazine free radicals [80].

The study of the hyperfine structure of the ESR spectrum of the triplet state of phenoxazine and phenothiazine single crystals made it possible to assign the H_X peak to the long molecular axis. Of the other two peaks, the peak with a lower energy (H_Y in Fig. 2) was assigned to the short molecular axis (y) passing through the O–N atoms and the peak with the highest energy (H_Z) was assigned to the z axis perpendicular to the molecular plane. Additional studies in polarised light showed [80] that in a concentrated solution the lowest triplet state of phenoxazine is populated via S_0-S_1 excitation, the transition moment of which is parallel to the y axis. However, since in solution the molecule can be bent, the magnetic y axis cannot coincide exactly with the direction of the N–O bond. This is also confirmed by studies of the hyperfine structure of the spectra of phenoxazine free radicals [52], since the hypothesis of the sp^3 hybridisation of the nitrogen atom gives a better explanation of the experimental results than the hypothesis of sp^2 hybridisation corresponding to a planar molecule.

7. Coumarin and its Derivatives

Coumarin and related compounds are known in biology as uncoupling agents for mitochondrial oxidative phosphorylation and as anticoagulants (dicoumarol). The triplet state of coumarin and its derivatives was observed for the first time by Graber et al. [82] The spectrum of coumarin in ethanol at 77°K is presented in Fig. 10 ($\Delta m = \pm 1$ transitions). The position of the H_{X_3} peak was calculated since its measurement is hindered by the superposition of the spectrum due to the ethanol radical. The narrow line at 3201 G corresponds to $H_{t.q.}$ The zero-field splitting energies and constants and the values of τ are listed in Table 13. Except for 6-substituted coumarins, the zero-field splitting energies are intermediate between the values for benzene and naphthalene [2]. This and also the high value of τ show that the triplet state of coumarin and its derivatives is of a $\pi-\pi^*$ type. Graber et al. [82] chose for coumarin the same designation of the axes (Fig. 10) as for naphthalene [1,2]. Qualitatively this is justified by the fact that the energy of the zero-field splitting of the triplet level for planar $\pi-\pi^*$ molecules, associated with the z axis, is negative [81]. Two other energies characterise the distribution of spin density in the molecular plane. Table 13 shows that the values of D^*/hc for coumarin and

its monosubstituted derivatives are higher than for polysubstituted derivatives. This is evidence of a greater delocalisation of spin density in the latter. On the other hand, chromanone and chromanol, which contain one unsaturated ring, have still higher values of D^*/hc, which are comparable with that of benzene (0.193 cm^{-1}).

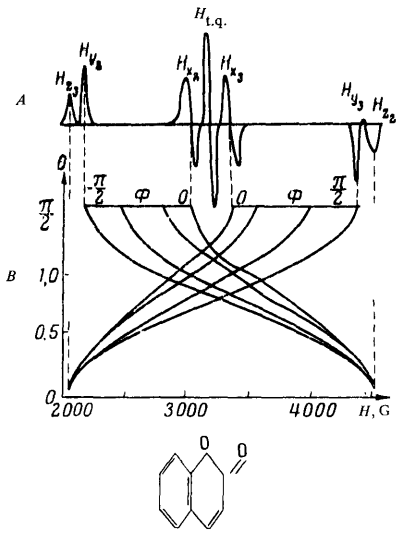

Figure 10. *A*) ESR spectrum of coumarin in the triplet state ($\Delta m = \pm 1$ transition) in ethanol at 77°K (ν = 9239 MHz); *B*) distribution of resonance fields.

Table 13. Parameters of the ESR spectra of the triplet state of coumarin and its derivatives.

Compound	X/hc	Y/hc	Z/hc	D^*/hc	τ, сек.
Coumarin	0.0094	0.0680	−0.0774	0.1244	0.54
4-Hydroxycoumarin	0.0137	0.0680	−0.0817	0.1301	1.5
7-Hydroxycoumarin	0.0147	0.0642	−0.0788	0.1177	1.1
6-Methylcoumarin	0.0026	0.0661	−0.0636	0.1124	0.6
Aesculine (6β-glucosido-7-hydroxycoumarin)	0.076	0.0600	−0.0524	0.0980	1.5
7-Nitro-3,4-benzocoumarin	—	—	—	0.0870	2.3
4-Chromanone	—	—	—	0.1584	1.8
4-Chromanol	—	—	—	0.1354	0.9
Dicoumarol	0.0172	0.0680	−0.0807	—	1.3

The excited triplet state of dicoumarol in low and high fields was observed by Gull et al.[83] in an ethanol–dimethylformamide mixture at 77°K. The $\Delta m = \pm 1$ ESR spectrum consists of six canonical peaks (molecular axes $x \neq y \neq z$). In the $\Delta m = \pm 2$ region a more intense peak with H_{min} = 1468 G (ν = 9239 MHz) was observed. The decay time τ of the ESR signal at H_{min} was 1.3 s after switching off the light (Table 10), which agrees with the phosphorescence decay time. The zero-field splitting energies calculated from the spectra are listed in Table 13.

Thus we have attempted to give as far as possible complete information about the characteristics of various classes of biologically active compounds in a triplet excited state. Summarising, we emphasise yet again that the ESR method yields the greatest amount of information, particularly in studies on large biological molecules, such as those of DNA and proteins, where the triplet states have been identified, and also for compounds which show weak phosphorescence. Next we shall discuss the role of the excited triplet state in the photochemistry of these molecules.

III. THE TRIPLET STATE IN THE PHOTOCHEMISTRY OF BIOLOGICALLY IMPORTANT MOLECULES. TWO-QUANTUM REACTIONS

1. Photochemistry of Porphyrins in Solid Solutions

When ethanol solutions of porphyrins are illuminated at 77°K with light corresponding to the long-wavelength absorption maxima of the pigments, a triplet state ESR signal arises, whose intensity persists during the period of irradiation. The formation of free-radical products is not observed. However, when solutions of porphyrins are irradiated with the unfiltered light of a mercury lamp, the intensity of the ESR signal of the triplet state falls and at the same time free-radical products accumulate[8,9,32]; they have been identified[11] as the radical products of the decomposition of ethanol ($CH_3\dot{C}HOH$, $\dot{C}H_3$, and $\dot{C}HO$) and the porphyrin radical. With increased concentration of the pigment, the yield of radicals rises. The use of calibrated photometric grids showed that the concentration of ethyl[8,32,42] and pigment[48,50] radicals varies with the square of the intensity of the incident light. Therefore it was suggested[32] that the process has a two-quantum mechanism and that free radicals are formed via a triplet state, the second quantum for porphyrins being greater than the exciting quantum.

Simultaneously with the accumulation of free radicals, the absorption spectrum of the pigment undergoes significant changes. In particular, in the spectrum of Mg-aetioporphyrin[8,42,84,85] the intensities of the initial absorption band at 542 and 578 nm and of the Soret band fall (virtually to zero in a dilute solution after prolonged illumination) and a new absorption arises at 450, 605, and 686 nm. When the temperature of an irradiated specimen is gradually raised, the 686 nm absorption vanishes, the 450 nm peak diminishes, and new bands arise between −150° and −125°C with maxima at 660 and 750 nm, the intensity of which also falls to zero on further heating and the spectrum is regenerated. In order to demonstrate that the photochemical reaction proceeds via a triplet state, the authors of the review investigated the effect of intermittent illumination (with light pulses of a duration shorter than that required for the establishment of phosphorescence) on the yield of free radicals in an ethanol solution of Mg-aetioporphyrin, Mg-mesoporphyrin, and Zn-tetraphenylporphyrin[19]. The dark intervals lasted 1–2 s, which, for an exponential phosphorescence decay law, corresponds to virtually complete decay of the glow. It was shown that, under interrupted illumination, the yield of radicals (the areas under the integral curves were compared) is lower by a factor of 15–25 (depending on the duration of the light pulse) then under continuous illumination of the same integral intensity (Fig. 11). This finding is satisfactorily consistent with calculated values[19].

In order to demonstrate directly that the process has a two-quantum mechanism, a method involving the illumination of the solution by two independent light sources was employed[7]. As already stated, the illumination of the solutions with yellow light did not result in the accumulation

of radical products at 77°K. Irradiation of the specimens with ultraviolet light (between 365 and 248 nm) also does not lead to the formation of free radicals in appreciable concentrations[16]. Under simultaneous illuminations by two independent sources, one of which excites the molecules to the triplet state and the light of the other ($\lambda \leq 320$ nm) is absorbed by the pigment molecule in the excited triplet state, free radicals of the porphyrins and the matrix accumulate (Fig. 12A). The yield of radicals increases with the energy of the second quantum. It was also shown that in this case the yield of radicals increases in direct proportion to the intensities of both the exciting (578 nm and the additional) light (302 and 248 nm). Analogous evidence for the two-quantum process mechanism was obtained in a study of the variation of the absorption spectrum of Mg-aetioporphyrin[86]. Initially the authors showed that, when an ethanol solution of Mg-aetioporphyrin is illuminated at 77°K with light having a wavelength of 578 nm, its absorption spectrum does not change. Also the authors did not observe measurable changes in the absorption spectrum of Mg-aetioporphyrin on illumination with ultraviolet light alone (λ_2 = 365, 320, and 313 nm).

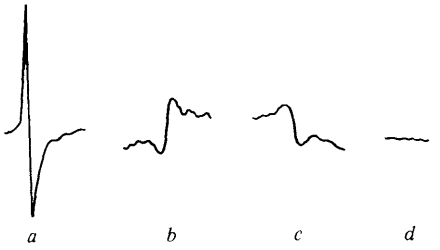

Figure 11. Yield of free radicals in alcoholic solution of Mg-aetioporphyrin as a function of illumination: *a*) with continuous light under steady-state excitation conditions for 30 s; *b*)–*d*) with intermittent illumination for 55 min with periods of exposure to light of 1.8×10^{-2} s, 9×10^{-3} s, and 6×10^{-3} s respectively.

Under simultaneous illumination by the total quanta ($h\nu_1 + h\nu_2$), the initial absorption bands of Mg-aetioporphyrins at 542 and 578 nm become less intense and a new absorption arises at 686 nm (Fig. 12*B*). The latter confirms that both radical products and the new 686 nm absorption arise by a two-quantum mechanism via the triplet state and that the product absorbing at 686 nm is a radical. Similar results were obtained for the dications of haematoporphyrin and protoporphyrin. When the temperature is raised to −165°C and above, yellow light is sufficient for the formation of Mg-aetioporphyrin radicals. The free radicals recorded give rise to only one chromophore line[11,42], the yield of radicals being again proportional to the square of the incident light intensity.

The kinetics of the formation of ethyl and pigment radicals have been investigated[48–50,93]. The logarithmic form of the kinetic curves for the destruction of triplet molecules and the accumulation of ethyl and porphyrin radicals can be fitted fairly satisfactorily by two intersecting lines. The observed photochemical process can be treated kinetically as the sum of two first-order reactions having rate constants k_1 and k_2 respectively, with $k_1 = 10k_2$. It was shown that the formation of one ethoxy-radical corresponds to one porphyrin radical[49,50] at a low light intensity. In order to demonstrate the reductive nature of the reaction, a study was made of the effect of electron-accepting additives (O_2, riboflavin) on the kinetics. It was found that electron-accepting impurities diminish the rate of destruction of molecules in the excited triplet state and the formation of radical products, the constant k_1 showing a much stronger dependence on O_2 and riboflavin than k_2.

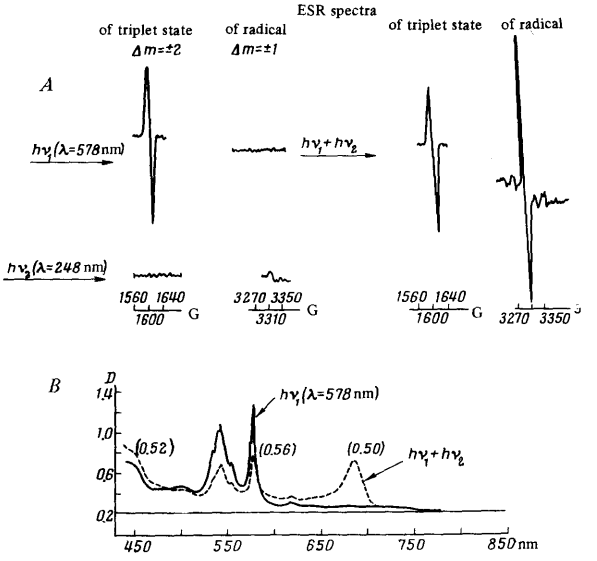

Figure 12. Effect of the two-quantum mechanism. Formation of free radicals in ethanol solution of Mg-aetioporphyrin on illumination by one ($h\nu_1$) and two ($h\nu_1 + h\nu_2$) light sources. *B*) formation of the 686 nm product under the same conditions.

It is noteworthy that, on illumination with visible light at 77°K, an appreciable change in the yield n_{st} of triplet molecules as a function of the oxygen content of the specimen was not observed. However, τ is also independent of the oxygen content of the specimen at 77°K[47]. Consequently the mechanism of the action of oxygen does not include direct quenching of the triplet state of porphyrins at 77°K. The observed inhibition of the formation of ethanol and porphyrin radicals in the presence of oxygen is consistent with the available data concerning the inhibition by oxygen of the photochemical reduction of tetrapyrrole pigments[59]. On the whole, the data permit the conclusion that the mechanism of the photochemical reaction of porphyrins in solid solutions at 77°K involves electron transfer from the alcohol to the porphyrin molecule in the excited triplet state. This results in the formation of a porphyrin radical-anion, which can then combine with a proton, forming a porphyrin radical—the semireduced form. The "686 nm" form of Mg-aetioporphyrin is a porphyrin radical-ion.

Thus the photochemical reduction reactions of porphyrins at 77°K in solid solutions proceed via the triplet state and involve a two-quantum mechanism. Although

the results have been obtained for model systems and low temperatures (the two-quantum reaction in PMT takes place at room temperature[48,49]), processes of this kind must be taken into account in a consideration of the mechanism of real photobiological processes, in particular photosynthesis.

2. Photochemical Properties of the Triplet State of Flavins

When ethanol solutions of flavins (riboflavin, lumichrome, lumazine) and pteridines are irradiated with ultraviolet light ($\lambda > 310$ nm) at 77°K, a complex ESR signal due to free radicals is observed, increasing with the duration of illumination[16]. Analysis of the contour of the signal formed in the ethanol flavin solution showed that it is due to ethyl radicals, $CH_3\dot{C}HOH$, and a species giving rise to a single line with a mixed g-factor. The shape of the single line and its g-factor resemble those of the ESR spectrum of the radical formed in aqueous solution of flavin mononucleotide. The relative intensities of the ESR lines of the ethyl and flavin radicals remain constant regardless of the duration of irradiation and light intensity. The rates of formation of the radicals are the same.

In order to elucidate the reaction mechanism, a study was made of the effect of light intensity on the kinetics of the accumulation of free radicals and the destruction of flavin molecules in an excited triplet state. It was found that the concentration of free radicals at any instant is proportional to the concentration of molecules in the excited triplet state for various light intensities and it was shown that the reaction has a two-quantum mechanism and proceeds via the higher triplet state of flavins and pteridines.

Similar behaviour of riboflavin was investigated by Azizova et al.[87] in the sensitised photochemical decomposition of ethanol and aliphatic aminoacids at 77°K. On illumination with visible light exciting riboflavin to a triplet state, sensitised deamination of aliphatic aminoacids, the spectra of which lie in the range 180–220 nm, was observed. It was demonstrated by the method of intermittent illumination that the reaction proceeds via the triplet state of riboflavin.

3. The Excited Triplet State in the Photochemistry of Nucleic Acids and Their Bases

In 1964 Pershan et al.[88] investigated the mechanism of the formation of thymine free radicals under the influence of ultraviolet light. In particular, it was shown that the concentration of free radicals formed in DNA on ultraviolet irradiation falls when cobalt(II) ions are added. On the other hand, Bersohn and Esenberg[89] showed that the ions of bivalent paramagnetic metals cause marked quenching of the phosphorescence of nucleotides and nucleosides. Later Rahn et al.[75] showed that bivalent metals quench vigorously the triplet state of DNA. In particular, at a fairly high concentration of manganese ions, the ESR signal of the triplet state falls almost to zero. Under these conditions, the DNA fluorescence is not quenched. It was also shown that the number of DNA free radicals formed is comparable to the concentration of the molecules in the excited triplet state. Since the quenching of the DNA triplet state entails a decrease of the yield of thymine radicals in the same proportion, one may assume that the thymine triplet state precedes the formation of free radicals. Thus the formation of thymine free-radical products in DNA proceeds via the excited triplet state.

In a study of quenching of the triplet state of thymine and of uracil in acetonitrile solution, Lamola and Mittel[90] showed that the photodimerisation of thymine takes place wholely via its triplet state. The photodimerisation of uracil proceeds via two mechanisms, one of which also involves the triplet state.

Finally, we shall consider in somewhat greater detail the two-photon reactions of nucleic acid derivatives: purine, adenosine, and guanosine in alkaline aqueous and ethanol solutions at 77°K. These reactions were investigated for the first time by Hélène and coworkers[15,79], who showed that, when the compounds are irradiated with ultraviolet light ($\lambda > 250$ nm) in alcoholic and aqueous solutions, the intensity of the phosphorescence and the ESR signal of the triplet state falls, but the fluorescence intensity remains unchanged. The rate of quenching of phosphorescence is proportional to the square of the incident light intensity. This relation remains unchanged within the concentration range 10^{-4}–10^{-3} M. After unfreezing and subsequently refreezing the specimen, the intensity of its phosphorescence is restored to the extent of 90%. When the phosphorescence is almost completely quenched, the optical absorption spectra remain unchanged. Very large irradiation doses result in the appearance of a new absorption in the range 300–350 nm, which is particularly distinct for purine.

At the same time, when aqueous solutions of purine bases are irradiated with ultraviolet light, a single ESR signal is observed with a g-factor close to 2. On subsequent irradiation with visible light, the signal amplitude falls by 15–20%. In 2% ethanol solution, the ESR spectrum of ethyl radicals is observed together with the singlet spectrum. The rate of formation of the radicals is higher by a factor of 30 than in pure ethanol. Subsequent illumination with visible light leads to a decrease of the singlet ESR signal. The authors showed that the rate of formation of ethyl radicals at any time after the start of illumination is proportional to the instantaneous concentration of the excited triplet molecules and to the square of the incident light intensity.

Thus in aqueous solutions purine bases are ionised with formation of a purine cation and an electron. Under the influence of visible light, the solvated electrons are bleached, liberated from traps, and undergo secondary interactions with cations and neutral purine and solvent molecules. In ethanol solutions two competing reactions develop—photosensitation and light-induced removal of an electron, the first predominating. According to the authors, photosensitation takes place at a high excited triplet level and does not involve the decomposition of the purine, since the absorption and fluorescence spectra remain unchanged. The base is ionised by a two-quantum mechanism. Since the sum of the energies of the triplet level (3.4 eV) (purine, adenosine, guanosine) and of the second quantum ($\lambda = 250$ nm; 5 eV) corresponds to an energy of 8.4 eV, it is sufficient to ionise the molecule in the solid phase (the ionisation potential in the gas phase is known to be about 9 eV).[79] The behaviour of pyrimidine bases and their nucleosides (cytosine, cytidine, thymine) is analogous, but the rate of accumulation of radicals is lower by a factor of 5–6 than for purine bases. Visible light does not affect the ESR signal. In the presence of ethanol, only the radicals of pyrimidine bases are formed and even after prolonged illumination ethyl radicals are

absent. Evidently pyrimidine bases are less sensitive to short-wave radiation and, when account is taken of energy transfer from purine to pyrimidine bases, this fact may help our understanding of the characteristics of the photochemistry of nucleic acids and their metabolism.

4. Two-Quantum Reactions of Aromatic Aminoacids

The first communication about the decomposition of aliphatic compounds photosensitised by aromatic aminoacids appeared in 1963.[32] The mechanism of the photochemical reaction was then investigated in detail by the same workers[11,42,85]. When ethanol solutions of aromatic aminoacids were illuminated at 77°K with the unfiltered light from a mercury lamp, the ESR signal of the excited triplet state fell and rapid accumulation of free-radical products was observed. The rate of accumulation was proportional to the concentration of aminoacids in solution, the square of the incident light intensity, and the intensity of the ESR triplet absorption. Ptak, Douzou, and coworkers[14,15] recorded the formation of free-radical products under analogous conditions.

Analysis of the ESR spectra showed[11,42] that the radicals formed are decomposition products of ethanol (ĊHO, $\dot{C}H_3$, $CH_3\dot{C}HOH$) and an aromatic aminoacid (a single line with a g-factor close to that of the free electron). The characteristics of the latter product (the radical is stable up to −143°C) are analogous to those of the radicals formed on irradiation of aqueous solutions of aromatic acids with ultraviolet light[91]. Since a correlation was observed between the kinetic curves for the destruction of the aminoacid molecules in an excited triplet state and the formation of $CH_3\dot{C}HOH$ and the aminoacid radicals (the slopes of the curves on a logarithmic scale are the same, but after prolonged irradiation the concentration of ethyl radicals increases faster owing to secondary processes), Gribova[32] suggested that the triplet state of the aminoacid is involved in the photochemical reaction (a similar process occurs in methanol and in EPA). This was demonstrated unambiguously by the method of interrupted illumination[8,9]. Santus and coworkers[15,79] observed two-quantum ionisation of aromatic aminoacids in boric acid. The two-quantum ionisation and two-quantum photosensitised decomposition of aliphatic aminoacids in the presence of aromatic aminoacids was demonstrated in a number of studies by Fesenko using the method of flash photolysis[12]. Here it is important to emphasise that, in the presence of aromatic aminoacids or dyes, which are excited by an energy much lower than the ionisation energy of aliphatic aminoacids, the latter are decomposed when the quanta are added together at the triplet level of the sensitiser.

Thus it is evident from the foregoing that the ESR method has been successfully employed in the study of complex biologically important molecules in an excited triplet state. It is also clear that the triplet state is important in chemical reactions and in the accumulation and transfer of energy in model systems *in vitro*. It is difficult to arrive at a direct conclusion concerning the involvement of the excited triplet state in photochemical processes *in vivo* on the basis of data obtained for model systems, owing to the extreme complexity of real biological structures and processes. However, the structural organisation of molecules, resembling the DNA double spiral, the close packing of protein molecules, or the structure of chloroplasts, is similar to the molecular arrangement in solid solutions. Therefore we believe that the study of the mechanism of reactions at a molecular level in simplified model systems (solutions of biologically important compounds) will permit a deeper understanding of the physical and chemical processes occurring in real biological systems.

Determination of the Thermodynamic Functions of Solutions by Gas-liquid Chromatography

A.N.Korol'

This review of the latest progress in gas-liquid chromatography is devoted to a description of the methodologi experimental technique for the gas-chromatographic determination of the thermodynamic properties of soluti are given for the calculation of the chief thermodynamic functions—the distribution constant, activity coeffi entropy, and free energy of the solution. The bibliography contains 152 references.

I. INTRODUCTION

The method of gas-liquid chromatography (GLC), discovered in 1952 by Martin and Synge, has been widely accepted as a means of analysing complex mixtures of substances[1-3]. Although in their first paper the discoverers of the method pointed out not only its possible analytical applications but also methods for studying the physicochemical properties of substances, the application of GLC in physical chemistry has been extremely limited. Since 1955, papers on the study of the properties of solutions using gas-chromatographic methods have been published[4], but up to the present the number of such papers has been measured in tens (the number of papers on the analytical applications of gas chromatography is more than 14 000), although the potential promise of the GLC method for making physicochemical measurements have been pointed out in a number of reviews[5,6].

In GLC, the components of a mixture are separated as a consequence of their different solubilities in the stationary liquid phase, so that it is quite natural to use this method primarily for the study of the resulting dilute solutions of a volatile solute in a non-volatile solvent (coefficients of mass transfer and diffusion, the thermodynamic functions of the solutions, etc.). GLC provides a unique method for the experimental study of the properties of infinitely dilute solutions of volatile substances in non-volatile solvents; a convenient and rapid method for determining the equilibrium composition of solutions is obtained if the components are analysed by gas chromatography. The measurement of solubility by a static method requires several days if the results are to be obtained over a given temperature range, whereas when GLC is used, these measurements can be made in 40–60 min. Before the development of the GLC method, there were only about ten pieces of data characterising quantitatively the solubility of volatile substances in non-volatile solvents at infinitely low concentrations of the solution; now, by means of GLC, such data are numbered in thousands.

II. CLASSIFICATION OF CHROMATOGRAPHIC METHODS FOR DETERMINING THE THERMODYNAMIC PROPERTIES OF SOLUTIONS

All chromatographic methods for determining the thermodynamic functions of solutions can be divided into three groups.

1. Determination of Solubility in a Chromatographic Column by the Development Method

In this instance a study is made of the properties of the solution formed when the solute is passed through a chromatographic column filled with a solid carrier on which is deposited the stationary liquid phase (solvent). The solute is introduced at the start of the chromatographic column in the form of vapour or liquid, and is moved along the column by a stream of carrier gas. Along the column, equilibrium is established between the concentrations of solute in the gaseous and liquid phases. The method of development gas chromatography is suitable for the study of the solubility of volatile substances in non-volatile solvents at low concentrations of the solutions (not greater than 1%) and is technically simple; however careful account must be taken of the experimental conditions. The Henry coefficient should not change with change in the concentration of the solution. The time required for the measurements and their subsequent analysis is not great.

2. Methods Using Frontal Chromatography

These methods are applicable in the study of the thermodynamic properties of solutions at any concentration. They include vacancy chromatographic methods for studying the thermodynamics of solutions. The values of the solubility at different solute concentrations are determined from the parameters of the sorption or desorption wave in the frontal method. In one experiment it is possible to obtain data on the solubility of one component at any concentration of the solution, but the calculation of the thermodynamic quantities from the parameters of the experiment requires some time and skill.

3. Methods in which the Chromatograph is Used as an Instrument for the Quantitative Analysis of the Composition of an Equilibrium Mixture

An advantage of these methods over classical static methods is the small volume of the equilibrium systems studied, since a specimen weighing less than 0.01 mg is sufficient for analysis by gas chromatography. The removal of such a small specimen produces almost no displacement of equilibrium in the system, and the decreased volume of the saturator in which the system being studied is placed facilitates the attainment of equilibrium between the phases in a shorter time. The time required to obtain the experimental data by these methods is greater than the time required for determination by the methods of the first group, but here there are no restrictions on the concentration of the solution and the volatility of the components of the mixture.

A necessary condition for carrying out an experiment by the third group of methods is that it be possible to analyse one or more of the components of the given mixture by gas chromatography. In principle, gas chromatography can be used to analyse any system, the components of which boil without decomposition at any temperature at a pressure of not less than 0.1 torr. Pyrolytic gas chromatography also makes it possible to analyse solid compounds which decompose when distillation is attempted. The apparatus required for methods of the third group is extremely simple for pressures equal to atmospheric pressures; higher or lower pressures require special attachments for the removal of the specimen.

The methods of the second group are used chiefly for the study of two-component systems, whereas this restriction does not apply to the methods in the other groups. An important advantage of chromatographic methods for studying equilibrium is the decreased requirements as to purity of the components of the solution. In the study of equilibrium by the static method from the vapour pressure, any impurities distort the experimental results, whereas gas chromatography makes it possible to determine each component of the solution with a high degree of selectivity. Moreover, if the solution contains several components, their simultaneous determination is always possible in principle, and this increases considerably the efficiency of chromatographic methods of studying solutions. For example, the chromatographic method makes it possible to study equilibria in systems containing up to 20–30 components.

The high sensitivity of gas-chromatographic instruments makes it possible to analyse extremely dilute solutions down to concentrations of $10^{-3}-10^{-4}\%$, and hence to obtain valuable experimental data for the development of the theory of infinitely dilute solutions, where it is possible to neglect concentration effects in solubility.

Thus gas chromatography not only makes it possible to obtain thermodynamic data on the properties of solutions with minimal effort but also in a number of instances provides a unique method for determining solubility in infinitely dilute solutions.

III. CALCULATION OF DISTRIBUTION CONSTANTS FROM RETENTION VOLUMES

We can consider the determination of this thermodynamic quantity using the first group of methods, that is in a chromatographic column. When the component being separated moves along a layer of sorbent, thermodynamic equilibrium is effectively established between the liquid and gaseous phases, since as a consequence of the extensively developed surface of the solid carrier the thickness of the film of stationary phase is negligibly small.

The ratio of the quantities of solute in unit volume of the liquid and gaseous phases is defined as the chromatographic distribution constant K: [6]

$$K = \frac{n_l/v_l}{n_g/v_g}, \tag{1}$$

where n_l, n_g, v_l, and v_g represent respectively the number of moles of solute in the liquid and gaseous phases and the volumes of liquid and gas in the chromatographic column.

Subsequently, for the sake of brevity, the chromatographic distribution constant will be referred to as the distribution constant. We can examine how this quantity is related to the characteristics of a sufficiently small section of the chromatographic column, in which the pressure drop of the carrier-gas approaches zero, and the average pressure is 1 atm. The rate of travel of the solute along a given section of the column (u_1) is given by Eqn. (2), [1] since only that fraction of the substance which is in the gaseous phase can be transported by the carrier gas

$$u_1 = \bar{u}f, \tag{2}$$

where f is the fraction of time for which the substance is in the gaseous phase, and $\bar{u}$ the linear velocity of the carrier gas.

We then have

$$f = \frac{n_g}{n_1}. \tag{3}$$

Combination of Eqns. (1) and (3) gives

$$\frac{n_g}{n_1} = \frac{n_g}{n_g + n_l} = \frac{n_g}{n_g + n_g \cdot Kv_l/v_g} = \frac{v_g}{v_g + Kv_l}. \tag{4}$$

If the linear velocity of the carrier gas is defined as

$$\bar{u} = \frac{u}{v_g/\Delta L},$$

where u is the volume rate of flow of gas and ΔL the length of the section of the column, we have

$$u_1 = \frac{u}{v_g/\Delta L}\frac{v_g}{v_g + Kv_l} = \frac{u\,\Delta L}{v_g + Kv_l}. \tag{5}$$

The retention volume of the solute is defined [1-3] as

$$V_R = \tau_R u, \tag{6}$$

where τ_R is the time for which the component is in the column.

Since

$$\tau_R = \frac{\Delta L}{u_1},$$

we have

$$V_R = \frac{\Delta L}{u_1} u.$$

We thus obtain the fundamental static equation in GLC:

$$V_R = v_g + K v_l. \quad (7)$$

Eqn. (7) can be used only for those systems where the pressure drop of the carrier gas in the chromatographic column can be neglected, and the total pressure in the column is equal to 760 torr. Under real conditions of chromatographic column operation, this is not attained, so that it is necessary to consider the corrections made to the retention volume to take account of the change in the pressure of the carrier gas along the column. We can consider the elution of a component from a column of finite length, divided into equal sections ΔL.[7] For a non-compressible gas we obtain

$$V_r = K \cdot v_l \cdot \Delta L,$$

where $V_r = V_R - v_0$.

If N is the number of parts into which the column is divided, we have

$$\tau_r = \frac{V_l}{N} \sum_{i=0}^{i=N} \frac{K_i}{u_i}, \quad (8)$$

where $V_l = Lv_l$.

From the equation of state for an almost perfect gas

$$p = \frac{n_g \cdot RT}{V} + \frac{RT}{V^2} \sum_{ij} B_{ij} x_i x_j,$$

where x_i and x_j are the mole fractions of the components in the gas, and B_{ij} the second virial coefficients for the components of the system, Everett[8] found that at infinite dilution of the solute in the gaseous phase

$$\tilde{v}_g = \frac{RT}{p} + B_{33}, \quad (9)$$

where $\tilde{v}_g$ is the molar volume of the gaseous phase, and B_{33} the second virial coefficient of the pure gas.

We can thus write the following expression for the distribution constant

$$K = \lim_{x_l \to 0} \left\{ \frac{x_l n_l}{x_g V_l} \left[\frac{RT}{p} + B_{33} \right] \right\}. \quad (10)$$

Everett also showed that at a pressure at the inlet to the chromatographic column $p_i < 20$ atm and a ratio $p_i/p_0 < 5$ (p_0 is the pressure at the outlet from the chromatographic column) it is possible, with sufficient accuracy, to write

$$V_R = KV_l [1 + \beta p_0 J_3^4], \quad (11)$$

where

$$J_3^4 = \frac{3}{4} \frac{(p_i/p_0)^4 - 1}{(p_i/p_0)^3 - 1},$$

$$\beta = \frac{2B_{13} - \tilde{v}_1^{\infty}}{RT},$$

B_{13} is the second virial coefficient taking account of the interaction between the solute and the carrier gas, and $\tilde{v}_1^{\infty}$ the partial molar volume of the solute at infinite dilution.

For an ideal gas, the pressure at each point of the column (p) is given by the equation

$$p = \sqrt{p_i^2 - \frac{l}{L}(p_i^2 - p_0^2)}, \quad (12)$$

where l is the distance from the column inlet to the given point.

If however the gas does not obey the laws for ideal systems, it is necessary to take account of the corrections involving the virial coefficient B_{33}:[8]

$$p = \left[p_i^2 - \frac{l}{L}(p_i^4 - p_0^2) - \frac{2B_{33}}{3RT} \left\{ \frac{p_i^3 - p^3}{p_i^2 - p_0^2} + \frac{p_i^3 - p_0^3}{p_i^2 - p_0^2}(p_i^2 - p^2) \right\} \right]^{1/2}$$

$$u = \frac{p_0 u_0}{p} \left[1 - \frac{B_{33}(p_0 - p)}{RT} \right].$$

Overall allowance for the change in the distribution constant with the carrier gas pressure, the effect of the viscosity of the gas, and its effective pressure, makes it possible to write the following equation[7]:

$$V_r = \frac{\frac{KV_l J_3^4}{p_0} \left[\frac{e^{i\beta p}}{\beta^2} \left(\beta^2 p^2 - 2\beta p + 2 \right) \right]_{p_l}^{p_0}}{0.5\,[p^2]_{p_l}^{p}}. \quad (13)$$

From this equation, using the experimentally determined values of the retention volumes of the solutes studied, it is possible to determine the chromatographic distribution constant under standard conditions and the magnitude of the second virial coefficient B_{13}. Eqn. (13) is usually solved graphically, but for analytical calculations an approximate version of this equation is usually employed[9]:

$$\ln V_R = \ln KV_l + \beta p_0 J_3^4. \quad (14)$$

For systems where the carrier gas dissolves in the stationary phase, this effect was taken into account[10] using the derived overall equation

$$\ln V_r = \ln KV_l + \beta' p_0 J_3^4 + \zeta (p_0 J_3^4)^2, \quad (15)$$

where

$$\beta' = \beta + \lambda \left[1 - \frac{\partial \ln \gamma_1^{\infty}}{\partial x_3} \right],$$

$$\zeta = \frac{3C_{133} - 4B_{13}B_{33}}{2RT} + \varphi \left[1 - \frac{\partial \ln \gamma_1^{\infty}}{\partial x_3} \right] + \frac{\lambda^2}{2} \left[1 - \frac{\partial^2 \ln \gamma_1^{\infty}}{\partial x_3^2} \right] + \frac{KV_l}{RT}.$$

The quantities λ and φ characterise the solubility of the gas in the stationary phase. In the expression for ζ the penultimate term characterises the compressibility of the stationary phase. For most systems, however, particularly if the work is carried out at temperatures up to 100°C with common carrier gases, the influence of the solubility of the carrier gas in the stationary phase on the retention volume can be neglected. A number of experiments specially carried out to study the influence of the nature of the carrier gas on the distribution constant[11-15] showed that the solubility of the carrier gas in the liquid need be taken into account only for gases such as carbon dioxide, ethane, and the heavier hydrocarbons.

Thus theoretical allowance for the various possible effects of the experimental conditions on the magnitude of the distribution constant being calculated shows that for its sufficiently accurate determination from a chromatographic experiment, the following data are required: the retention volume V_r, the volume of the stationary phase in the column, and the pressure at the inlet and outlet of the column; to introduce corrections for the non-ideal nature of the gaseous phase in the column it is necessary to take account of the molar volume of the solute at infinite dilution and the second virial coefficient. The last two corrections are rarely used, chiefly to obtain results with an extremely high accuracy, of about 0.5%. In order to introduce the minimal number of corrections in the calculation of the distribution constant from chromatographic data, it is recommended that the studies be carried out with very short columns and a solid carrier with large particle size, to ensure the minimum pressure drop along the column.

IV. EXPERIMENTAL DETERMINATION OF RETENTION DATA FOR THE CALCULATION OF THE THERMODYNAMIC PROPERTIES OF SOLUTIONS

To obtain the true values of the distribution constant, characterising the gas–liquid equilibrium, it is necessary to observe certain precautions, dictated by the nature of the processes occurring in the chromatographic column during the movement of the zone of solute.

For solutions with low concentrations the retention data of a component are independent of the presence of other compounds in the mixture, with the condition that the components of the mixture do not react with one another. Thus it has been shown[16] that in a mixture of benzene, cyclohexane, and methylcyclohexane, no mutual influence of the components of the solution on their retention volumes is observed. The interaction of solutes is observed experimentally only at solute concentrations which are so high that the solution must be regarded as a mixture of components in approximately equal concentrations. When a mixture of substances is introduced into the inlet section of a chromatographic column, all the components of the mixture move in a single zone only in the first sections of the column, after which they separate into zones containing only binary solutions. Thus the mutual influence of the components in a mixture on their retention times is shown most strongly for those substances for which the rates of movement of the zones along the column are similar. In general it is better to carry out the solubility determination with specimens of individual substances or substances with markedly different solubilities.

The stationary phase is applied to the surface of the solid carrier in a very thin film. There naturally arises doubt as to whether the nature of the dissolution is the same in these thin layers in the chromatographic column and in static experiments. The vapour pressure above a pure liquid and a layer of liquid deposited on a chromatographic carrier of the celite type has been measured[17–19] and it has been shown that the results of the static and chromatographic experiments are identical. These conclusions are applicable for fairly large quantities of stationary phase on the carrier—more than 0.03 volumes of liquid per volume of solid carrier.

The stationary phase is present on the surface of the solid carrier in two energetically different states—as an absorption layer and as capillary liquid[20]. The adsorption layer of liquid has a low entropy of solution compared with the pure liquid, whereas the properties of the capillary liquid and the pure liquid are identical. With small quantities of stationary phase on the carrier, due to the effect of the adsorption layer of liquid, the solvent power of the stationary phase is lower than that of the pure liquid[21]. With increase in the quantity of stationary phase on the carrier, the solubility increases exponentially, since the relative quantity of capillary liquid in the stationary phase increases.

When a solute passes through a chromatographic column, the maximum concentration in the solution in the zone decreases, as a consequence of spreading by diffusion[1]. If the experiment is carried out under conditions where the concentration in solution in the first sections of the column is extremely high, concentration distortion of the value of the distribution constant is observed. To decrease the influence of concentration effects it is desirable to use columns with a large quantity of stationary phase on the carrier.

The size of the specimen placed on the chromatographic column also influences the concentration of the gas-chromatographic solution. It is desirable to have a specimen which is sufficiently small, at the concentrations of the solutions formed in the stationary phase, for the values of the distribution constant to remain constant, that is for Henry's law to apply. At a ratio of the quantities of stationary phase and carrier greater than 0.01 : 1, an activity coefficient in the range 0.5–1.5, and size of specimen up to 2 μmole (column with internal diameter 4 mm), distortions of the experimentally observed values of the distribution constants were not observed for non-polar systems[17].

As the chromatographic zone moves along a column, processes of condensation and volatilisation lead to a change in the temperature of the solution. It was calculated[17] that these micro-changes in temperature under the real conditions indicated above do not exceed 0.1 deg, and this has almost no influence on the experimentally determined retention data.

When a solute passes through a chromatographic column the viscosity of the carrier gas changes as a consequence of the formation of a gaseous zone of mixed solute and carrier gas, and this produces pressure surges along the column. According to published data[5], these surges are negligibly small if the specimen size is less than 1 μmole, the activity coefficients between 0.2 and 5, and the retention volume of the solute, corrected for the dead volume, not less than 500 ml. It has been shown[17,22] that the nature of the carrier gas has no influence on the magnitude of the distribution constant (the following gases were studied: helium, hydrogen, nitrogen, oxygen, argon, carbon dioxide, and methane). On the other hand, results obtained by capillary chromatography show that the retention data depend on the nature of the carrier gas[23], although it is possible that with the large pressure drops encountered in capillary columns, the authors cited were unable to calculate the distribution constant with sufficient accuracy.

As the chromatographic zone passes through the column, its rate of movement depends on three factors: the solubility in the stationary phase (K), the adsorption at the gas–liquid interface, and the adsorption at the solid–liquid interface[24–27]:

$$V_r = Kv_l + K_{gl}s_l + K_{ls}s_s, \qquad (16)$$

where s_l and s_s represent respectively the surface areas of the liquid and solid in the chromatographic column, and K_{gl} and K_{ls} the adsorption coefficients at the gas–liquid and solid–liquid interfaces respectively. These phenomena were first observed for systems formed by a non-polar solute and a polar solvent[25,28].

To calculate the constant of this equation it is necessary to determine experimentally the dependence of the retention volume on the quantity of stationary phase in the column and the surface area of the stationary phase. The calculations are then carried out by means of the equations[27,29]:

$$\frac{V_r - \bar{V}_r}{v_l - \bar{v}_l} = K + \frac{s_l - \bar{s}_s}{v_l - \bar{v}_l}, \qquad (17)$$

$$\frac{V_r - \bar{V}_r}{m - \bar{m}} = V_g + K_{gl}\frac{s_l - \bar{s}_l}{m - \bar{m}}, \qquad (18)$$

where $\bar{V}_r$ is a selected value of the retention volume for the sorbent, characterised by the quantities $\bar{m}$ and $\bar{s}$, and V_g the specific retention volume.

Eqns. (16)–(18) are applicable for sufficiently large quantities of stationary phase on the carrier—greater than 1% of the weight of sorbent. The characteristics of adsorption at the boundaries between the phases in GLC have been calculated by a number of authors[24–30].

The adsorption of solutes on the surface of the stationary phase is most marked in the chromatography of non-polar substances on a polar stationary phase, but even when a non-polar stationary phase is used, allowance must be made for this effect[30].

A number of authors[29,31-36] have made detailed studies of the effects associated with the adsorption of a solute at the interface between the solid and the stationary liquid phase. These effects are least marked when the gas-chromatographic method is used to study non-polar systems. Polar solutes are usually readily sorbed by the surface of the diatomites used as carrier in GLC. This leads to a change in the retention time with the size of the specimen, and the effect is greatest with small quantities of stationary phase on the carrier[37,38]. Particular care in the thermodynamic treatment of chromatographic data is required for solutions of polar substances in non-polar solvents, where various concentration distortions can affect the determination of retention volumes[39]. Polar stationary phases to some extent modify the carrier surface, decreasing its adsorption activity with respect to polar compounds. The best results in decreasing the adsorption power of the carrier surface are achieved by treating the diatomites with silane; it is always best to do this when non-polar stationary phases are used. In some instances, satisfactory results have been obtained on solid carriers with a non-polar surface—Teflon[30] or polyethylene[40]. Interfacial adsorption produces particularly marked distortion of retention volume values in those instances where the substances being separated have small distribution constants. For $K > 100$ and correctly chosen experimental conditions, the fraction of interphase adsorption does not exceed 2–3% of the total retention volume[26,28].

When the first portions of stationary phase are deposited on a solid carrier, an adsorption layer of liquid is formed; the total surface area of the liquid increases until the solid carrier is completely covered. With further addition of liquid, the pores of the carrier are filled, so that the total surface area of liquid decreases exponentially towards a limiting value. The addition of liquid also increases the concentration of capillary liquid in the stationary phase, so that the total solvent power of the stationary phase increases. As a result, the curve giving the dependence of the distribution constant, calculated with allowance for adsorption at the solid–liquid interface, on the quantity of stationary phase on the carrier shows a maximum for very small quantities of stationary phase, and a minimum when the volume of staionary phase is about 2% of that of the diatomite carrier[21]. At ratios of stationary phase to solid carrier greater than 0.03 : 1, the values of the distribution constant are stabilised. The heats of dissolution remain constant for proportions of stationary phase greater than 0.01 : 1.

In general, it is best to use capillary columns to obtain information on the thermodynamics of solutions. Thus in the determination of retention data for polar compounds in non-polar stationary phases[41], marked discrepancies were observed between the results obtained on packed and capillary columns. For polar stationary phases, the retention characteristics are similar for the two types of column. The calculation of the specific retention volume of *n*-heptane in squalane on a capillary column[27] gave the values 1550 ml g^{-1} without allowance for interphase adsorption, and 416 ml g^{-1} after the necessary corrections. Littlewood[42] used packed micro-columns with a small quantity of stationary phase on a solid carrier, and this was the main reason for the difference between the experimental results and static data. Martire and Pollara[43] calculated the retention volume not from the apex of the peak, as is usually done in GLC, but from the start of the emergence of the peak, which explains the distortion of the results.

A correctly chosen procedure for the determination of the thermodynamic functions of solutions from gas-chromatographic data makes it possible to obtain reliable values for the distribution constants, agreeing with the results of static experiments[17,44-48]. According to these results, the discrepancy between the results obtained by gas-chromatographic and static methods did not exceed 1%.

To obtain precise experimental data on the thermodynamics of solutions it is necessary to take account of all the parameters of the gas-chromatographic process appearing in Eqn. (14). The procedure has been described in sufficient detail by a number of authors[16,49,50]. For the experiment, the substance being studied is introduced into the chromatographic column in the form of liquid or vapour, and the time taken for the apex of the peak for the component to emerge is measured with a stopwatch. The time correspond to the emergence of the peak for air or methane (τ_0) is then subtracted from the measured time, the carrier gas flow rate is measured with a bubble flowmeter, and all the other necessary parameters of the process are noted. The total time taken for the experiment is usually not more than half an hour per component. Use of the correct experimental procedure in the gas-chromatographic method makes it possible to obtain thermodynamic values of the distribution constant with a small error of the order of 1%.[22] In some instances this error has been halved[17,51]. A number of structural changes in chromatographic instruments, particularly improved methods for controlling the carrier gas flow, made it possible to achieve an accuracy of the order of 0.2% in the determination of the specific retention volume[52,53] or 0.02% in the calculation of the relative retention volume[54]. In the work cited[54], a chromatograph with automatically controlled carrier gas flow rate was used. When it is remembered that the results refer to solutions at limiting dilution, it is clear that such high experimental accuracy cannot be achieved by any other method.

High accuracy in the determination of solubility characteristics by GLC is realised only for components present in the mixture in medium concentrations. In the study of retention data for substances with a high concentration in the mixture it is necessary to introduce a number of corrections[55]. It has been found[56] that with change in the concentration of a trace component from 0.03% to 2% the value of the retention volume of this component changes by 2–3%.

V. CALCULATION OF ACTIVITY COEFFICIENTS

Thus experimental retention data obtained by development GLC can be used to calculate the chromatographic distribution constant K. For more universal application of this parameter it is necessary to relate it to the thermodynamic distribution constant $\bar{K}$, given by the equation

$$\bar{K} = a_l/a_g, \qquad (19)$$

where a is the activity, equal to γc (γ is the activity coefficient†, and c the concentration).

† In GLC, the standard state of the solute in the calculation of the activity coefficient is usually taken as the pure solute under normal conditions, so that for infinitely dilute solutions $\gamma \neq 1$. The quantity γ shows the departure of the solute vapour pressure from the value which would be observed for an ideal solution.

Warnings against confusion of the thermodynamic and chromatographic distribution constants have been published[57,58]. In the latter work the following relationship was derived for converting the chromatographic distribution constant into the thermodynamic constant:

$$\overline{K} = \frac{c_l/n_l}{pc_g/n_g} = \frac{K}{N_l RT} \qquad (20)$$

N_l is the number of moles per unit volume of the stationary phase. From this we can readily calculate the molar free energy of dissolution

$$\Delta G_s = -RT \ln \overline{K}. \qquad (21)$$

We can establish the relationship between the distribution constant and the activity coefficient for dilute solutions[6,59,60]. For non-ideal solutions, Raoult's law is written as

$$yp = \gamma_p^{\infty} x p^0,$$

where x and y represent respectively the mole fractions of the solute in the liquid and solid phases.

Since

$$K = \frac{xN_l}{yN_g} = \frac{xpN_l}{\gamma_p^{\infty} x p^0 N_g}$$

and

$$p/N_g = RT,$$

we obtain

$$\gamma_p^{\infty} = \frac{N_l RT}{Kp^0}. \qquad (22)$$

To take account of the non-ideal nature of the gaseous phase, we can use the equation derived by Everett[8] making the same assumptions as when correcting the distribution constant

$$\ln \gamma^{\infty} = \ln \frac{N_l RT}{Kp^0} - \frac{(B_{11} - \tilde{v}_1^0)p^0}{RT} + \frac{(2B_{12} - \tilde{v}_1^{\infty})p}{RT}, \qquad (23)$$

where $\tilde{v}_1^0$ is the partial molar volume of the solute, and p^0 the vapour pressure of the solute at the temperature of the experiment.

A similar type of equation was derived by Cruickshank and coworkers[9]. The chief difference between Eqns. (22) and (23) is that in the former, the activity coefficient is calculated with the assumption that the gaseous phase is non-ideal, and the vapour pressure of the pure solvent obeys the laws for ideal gases; the second equation takes account of all the deviations from ideal behaviour which can arise in a chromatographic experiment. Thus Eqn. (23) gives a more accurate value for the activity coefficient.

If data on the fugacity of the substance being studied are available, the activity coefficient is calculated from the equation

$$\gamma^{\infty} = \frac{N_l RT}{Kf^0}, \qquad (24)$$

where f^0 is the fugacity of the vapour of the pure solute at the temperature of the experiment.

A somewhat inconvenient feature of the above equations is the need to determine the density of the stationary phase (solvent) at all temperatures of the experiment, since the volume of the stationary phase appears in the equation for the calculation of the chromatographic distribution constant. It is therefore preferable to use the specific retention volume (V_g), where the retention volume of the component is related to unit mass of the stationary phase in the column. The last quantity is independent of temperature:

$$V_g = \frac{273.2 \cdot V_r}{m \cdot T}, \qquad (25)$$

where m is the quantity of stationary phase in the column, g. The retention volume in Eqn. (25) is also corrected for the non-ideal nature of the gaseous phase, as with the distribution constant. The activity coefficient is calculated with allowance for the specific retention volume by means of the equation

$$\gamma^{\infty} = \frac{273.2R}{MV_g f^0}. \qquad (26)$$

In estimating the selectivity of the stationary phase in gas-liquid chromatography, considerable use has been made of relative values of the activity coefficients, for which some readily available compound is taken as standard (for example benzene, carbon tetrachloride, n-alkanes). The relative activity coefficient is calculated from the minimum in the experimental data

$$\gamma_{xr}^0 = \gamma_x/\gamma_r = \frac{f_r^2}{f_x^0 V_r^0} = 1/f_{xr}^{00} V_r^0, \qquad (27)$$

where v_r^0 is the relative retention volume, and f_{xr}^{00} the relative volatility of the substances being compared.

If the activity coefficients of a large number of compounds are being determined, it is usual, for convenience, to choose one of them as standard and to calculate relative values of the activity coefficients for the others. The absolute value of the activity coefficient is measured for the standard component. The accuracy of the determination of the relative activity is then greatest, and reaches 0.05%, indicating that the extensive use of the relative values is appropriate.

GLC provides the experimentalist with extensive possibilities for studying systems with multicomponent solvents[61]. The composition of the stationary phase in the chromatographic column may be altered arbitrarily. In such instances it is necessary to make allowance for purely gas-chromatographic effects associated with the use of small quantities of added polar substances, which may be sorbed by the surface of the solid carrier and hence influence not so much the solubility of the substances in the mixed stationary phase as the degree of chemical modification of the surface of the solid carrier[49].

If the stationary phase volatilises from the column under the conditions of the experiment, it is possible in the measurements to weigh the column before and after the experiment in order to make allowance for the loss of liquid and to make a corresponding correction to the retention data[62,63]. In a number of experiments[6,48,64] with volatile stationary phases, use has been made of saturators placed in front of the chromatographic column. The saturator contains solid carrier, impregnated with a large quantity of the stationary phase. Carrier gas at the temperature of the column passes through the saturator and is saturated by the vapour of the stationary phase. The loss of stationary phase from the column is compensated by the introduction of fresh portions of material from the saturator. This method has two important advantages over weighing the column before and after the experiment; firstly, the quantity of stationary phase remains unchanged during the experiment, and secondly, the stationary phase is distributed uniformly along the entire length of the column, whereas when the method of weighing is used, the liquid volatilises primarily from the start of the column. This last feature may lead to marked distortion of the results, due to the marked concentration dependence at

the low concentration of stationary phase in the first sections of the column.

The activity coefficients in systems containing benzene, toluene, *n*-propanol, dichloroethane, and carbon tetrachloride have been determined[50]. Allowance was made for the non-ideal nature of the gaseous phase, resulting from the presence of the vapour of the volatile solvent.

The use of circulation arrangements also makes it possible to carry out the determinations in systems with a volatile stationary phase. For example, the activity coefficients of methanol and ethanol (solvent benzene) were determined at 25° on a circulation apparatus[65].

Methods for the determination of activity coefficients by GLC have been reviewed[66], and the influence of departure of the behaviour of the gaseous phase from ideal behaviour on the values of the thermodynamic quantities has been discussed[67].

VI. DETERMINATION OF THE THERMODYNAMIC PROPERTIES OF SOLUTIONS WITH MEDIUM AND HIGH CONCENTRATIONS

The above material relates to the determination of thermodynamic data at infinite dilution, that is in the very dilute solutions existing in the chromatographic column. For the theory and practical utilisation of solutions it is of interest to study solutions of substances at finite concentrations. Static methods for obtaining these results require considerable expenditure of effort and complicated experimental technique[68,69]; the chromatographic method is free from these disadvantages.

A method for determining solubility over a wide range of solution concentrations by frontal gas chromatography has been described[70]. A stream of carrier gas passes through an ordinary gas-chromatographic assembly, the column of which contains a measured quantity of stationary phase on a solid carrier. At a selected moment, the stream of carrier gas is passed through a saturator containing the solute. The temperature of the saturator is chosen to create the required vapour pressure of solute in the carrier gas. The chromatograph records the appearance of a concentration wave at the outlet from the column. When the concentrations of the substance added to the carrier gas have become the same at the inlet and outlet, pure carrier gas is passed through the column, and the chromatograph records the desorption concentration wave. The assembly is calibrated with respect to the concentration of the saturated vapour of the substance being studied in the carrier gas. The solubility is calculated from an arbitrarily selected number of points on the sorption or desorption curve. The quantity of substance sorbed is calculated from the equation

$$q = \frac{cV - q_1}{m}, \qquad (28)$$

where q_1 is the quantity of substance eluted from the column at the moment of emergence of the point of the curve corresponding to the concentration c, and v the volume of carrier gas which has left the column up to the moment when the concentration c of solute appears at its outlet.

The quantity of substance which has left the column (q_1) is determined directly from the chromatogram by planimetry. This method makes it possible to determine the distribution constants over a wide range of concentrations in one experiment.

A similar method for determining solubility by frontal chromatography was described by Condér and Purnell[71], but in this instance allowance was made for the non-ideal nature of the gaseous phase. An equation was derived[71-73] for determining the activity coefficient at finite concentrations of the solution

$$\ln\gamma = \ln\frac{RT(c_l v_l + n_l)}{p^0 K v_1} + \frac{p_0 J_3^4}{RT}[2xB_{11}J_3^4 + 2(1 - xJ_3^4)B_{13} - \tilde{v}_1^0] - p^0/RT\,[B_{33} - \tilde{v}_1], \qquad (29)$$

where n_1 is the total number of molecules of solvent in the column, and $\tilde{v}_1^0$ the partial molar volume of the solute.

The determination of the distribution constants at finite concentrations of the solutions from chromatographic data is based on the equation[71]

$$V_R = V_0 + m(1 - J_3^4 x)\partial q/\partial c. \qquad (30)$$

In practical measurements, the stream of carrier gas, saturated with the vapour of the component being studied at a definite concentration, is passed through a short column with a small pressure drop. Thus an equilibrium mixture of carrier gas and solute is passed constantly through the column, and the concentration of the solution in the column is known and constant along the entire length of the column. A small specimen of the substance being studied is introduced into the column; this gives a positive peak on the chromatogram. The retention time of this peak is used to calculate the quantity $\partial q/\partial c$ from Eqn. (30). The work cited gives equations which make it possible to make corrections for the non-ideal nature of the gaseous phase when the frontal method is used.

The methods for determining the thermodynamics of concentrated solutions, described in the works cited[70,71], differ in the time taken for the experiment. In the first, the experiment takes a comparatively short time compared with the time required for the calculation of the distribution constants. In the second method, the experiment takes more time than the calculations. The time required for the determination of the solubility isotherm by means of a McBain balance is approximately the same as that for the chromatographic method, if the solvent in the static method is deposited on a solid carrier of the diatomic type. If however the static experiment is carried out with pure liquid, the time taken for the determination of the dissolution isotherm is not less than 3 d. The chromatographic determination and calculations take 3–6 h.

The accuracies of the chromatographic and static methods for determining the solubility in concentrated solutions have been compared[17,71,74]. It has been shown that when a McBain balance is used in a purely static experiment the error in the determination of the activity coefficient is 0.1% at a mole fraction of the solute $x = 0.4$, and 0.4% at $x = 0.2$. If in the static determinations the solvent is deposited on a solid carrier[18], however, the error is 1.5% at $x = 0.4$, and 4% at $x = 0.2$. The error obtained when chromatographic methods are used to determine the distribution constants in these systems is not greater than 0.2%.[71] Thus for the same expenditure of time on the experiments and the treatment of the results, the accuracy of the static method is much less than that of the chromatographic method; for equal accuracies in the determination, the measurement of solubility by the static method requires much more time.

Some authors[75-78] have proposed a method for determining sorption isotherms from the trailing edge of the chromatographic zone (peak) leaving the column in development chromatography. In actual fact, the form of the peak depends on the sorption isotherm, but this is by no means the only factor influencing the form of the peak.

Various diffusion processes also distort the form of the peak, so that it is extremely difficult to separate the contribution of the sorption isotherm in the formation of the trailing edge of the zone in a real chromatographic experiment. Thus these methods for determining the sorption isotherms are extremely approximate, so that they can be used only in gas-adsorption chromatography for substances with a high adsorption capacity. It is more rational to determine the dependence of the time of emergence of the apex of the chromatographic peak on the height of this peak, that is on the maximal concentration of the component in the chromatographic zone. For these determinations, short columns with a small pressure drop are used, but in these instances account must be taken of the fact that the concentration of the solution changes along the length of the chromatographic column.

An original method for determining solubility (V_g) was proposed by Zhukhovitskii and coworkers [79-83]. These methods are suitable for determining the solubility of substances in solutions at concentrations as high as required. A version of chromatography without carrier gas is used for the determinations; the mixture being studied, with or without an inert gas, is passed through the chromatographic column until equilibrium is established along the entire column. Some perturbation to the flow is then created, or a small specimen of air or any substance being studied is introduced, after which the time of emergence of the peaks, the number of which is smaller by one than the number of components in the gaseous phase, is determined. The retention volume of the component, obtained in this way, is related to the distribution constant by the equation

$$V_g = n_g(\partial q_3/\partial n_3 - \partial q_3/\partial n_g) + n_3(\partial q_1/\partial n_g - \partial q_1/\partial n_3), \qquad (31)$$

where the subscripts 1 and 3 refer respectively to the solute and the diluent gas or second component of the mixture. For multi-component systems, similar equations are compiled and solved on electronic computers.

An experimental assembly for the determination of solubility for solutions with concentrations up to 12% has been described [83]. The required concentration is established by adding a sufficiently large specimen of the substance being studied to a column, and the solubility is determined by vacancy chromatography. The distribution constants and activity coefficients for non-polar systems in the concentration range 0–10% have been determined by vacancy chromatography [84]. Comparison of data obtained by the static and vacancy-chromatographic methods for the *n*-hexane–1,2,4-trichlorobenzene system [83] shows that for solution concentrations $x \leq 0.2$ the results agree satisfactorily, but differences are observed at higher concentrations. An important advantage of vacancy-chromatographic methods over frontal methods is that it is possible to study multi-component systems.

The accurate establishment of the quantity of stationary phase in a chromatographic column presents a difficult experimental problem. The accuracy of the results obtained in a gas-chromatographic experiment depends to a large extent on the solution of this problem. Thus a number of authors have tried to combine the advantages of the static method, where an accurately measured quantity of pure stationary phase (solvent) is used, with the chromatographic determination of the equilibrium composition of the gaseous or liquid phase of the system. The design of an apparatus in which the gaseous phase from the static system passes through heated connections into the inlet compartment of a gas chromatograph has been described [85]. The chromatograph is used to determine quantitatively the concentration of the component being studied in the gaseous phase. This method can be used to study multi-component systems, and the calculation requires little time [85,86]. A slightly different modification of the flow system, in which the carrier gas was saturated with vapour from a solution and passed to the inlet chamber of the chromatograph, has been described [87], but in this instance the calculation of the results is extremely complicated.

For the periodic gas-chromatographic analysis of the phase composition of equilibrium systems it is possible to use saturators of small volume with a thin layer of solvent; this makes it possible to establish thermodynamic equilibrium fairly rapidly in the system [49]. A specimen of the gaseous phase from the saturator at constant temperature is removed with a gas syringe with piston stop or with a special micro-column, and introduced into the inlet chamber of a chromatograph with a flame-ionisation detector. The design of these systems is very simple only when the total pressure in the system is equal to atmospheric; otherwise, special attachments are required for the removal of the specimen. A disadvantage of this method is the appeciable time—about 0.5 h—taken for equilibrium to be established in the system, but the calculation of the results is extremely simple.

An important advantage of combined static–chromatographic methods is that it is possible to study systems in which all the components are volatile at the temperature of the experiment. Thus this method has been used to measure the solubility of inorganic gases in electrolytes [88] and the solubility of organic gases in various solvents [89-92]. In these last experiments, the solvent was added to a vessel containing the gas being studied, after which the gas was blown from the vessel to the inlet chamber of the chromatograph and its concentration was measured.

Comparison of different methods for the chromatographic determination of the thermodynamic functions of solutions shows that at low concentrations it is best to use the purely chromatographic method of determining the distribution constants. When it is necessary to measure the solubility at finite fixed concentrations of the solutions, it is rational to use special frontal development methods and chromatography without carrier gas, and also to combine static and gas-chromatographic methods. The use of gas chromatography makes it possible to study the properties of infinitely dilute solutions, to increase the accuracy of experimental thermodynamic data for dilute solutions, and to save time in experiments in the study of concentrated solutions.

VII. CALCULATION OF THE MOLAR HEAT OF DISSOLUTION

Eqn. (22) can be written in the logarithmic form [59]:

$$\ln K = \ln N_1 RT - \ln \gamma - \ln p^0 \quad .$$

According to the basic principles of thermodynamics

$$RT \ln \gamma = \Delta\bar{H}_s - T\Delta\bar{S}_s$$

(the bar above the symbol for a function denotes that the function is an excess function, i.e. it expresses the difference between a property of the pure substance being studied and the same property of the solution), so that we can write

$$\ln K = \ln N_1 R - \Delta H_s/RT - \Delta\bar{S}_s/R + \Delta H_v/RT - \ln(1/T) \qquad (32)$$

where N_1 is the number of moles in unit volume of the stationary phase, and ΔH_V the molar heat of volatilisation. Differentiating this equation with respect to $1/T$ and multiplying by R, we obtain

$$\Delta H_s = R\partial \ln K/\partial (1/T) - RT + R \ln R\partial \ln N_l/\partial (1/T) . \quad (33)$$

This equation makes it possible to calculate the molar heat of dissolution from the experimentally determined chromatographic distribution constants[4,59]. The need to determine the specific gravity of the solvent at different temperatures of the experiment introduces some inconvenience. This can be avoided by using the specific retention volumes for the calculation of the molar heats of dissolution[93]. According to the definition of the specific retention volume,

$$K = \frac{V_g mT}{273.2 v_l} .$$

Substituting this expression in Eqn. (33) and differentiating with respect to $1/T$, we obtain

$$\Delta H_s = R\partial \ln V_g/\partial (1/T) . \quad (34)$$

This equation shows that there is no need to determine the specific gravity of the stationary phase.

The heats of dissolution can be determined experimentally using activity coefficients. The equation relating the activity coefficient and the excess enthalpy of dissolution can be written

$$\Delta \overline{H}_s/T = -\Delta \overline{S}_s - R \ln \gamma .$$

Differentiation with respect to $1/T$ gives

$$\Delta H_s = R\partial \ln \gamma/\partial (1/T) . \quad (35)$$

Since this last equation contains the activity coefficient, the calculation of which requires data on the volatility of the substances being studied, the use of these equations in physicochemical determinations is limited.

The chromatographic determination of the heat of dissolution can be simplified further by eliminating from the necessary experimental data the mass of liquid in the column. The specific retention volume can be written as

$$V_g = \frac{273.2 u \tau_r}{mT} = k' \frac{\tau_r}{\tau_0 T} .$$

Since $u = k''/\tau_0$,

$$\ln V_g = \ln V_{g1} - \ln V_{g2} = \ln \frac{\tau_{r1}\tau_{02}}{\tau_{r2}\tau_{01}} + \ln \frac{T_1}{T_2}$$

so that

$$\Delta H_s = 4.58 \frac{\lg \frac{\tau_{r1}\tau_{02}}{\tau_{r2}\tau_{01}}}{1/T_1 - 1/T_2} + 4.58 \frac{\lg T_2/T_1}{1/T_1 - 1/T_2} , \quad (36)$$

where τ_0 is the time of emergence of the non-sorbed gas (dead volume of the system) and τ_r the actual time of emergence of the solute.

By selecting from the plot of $\lg \tau_r/\tau_0$ against $1/T$ the temperature range in which $1/T_1 - 1/T_2 = 4.58 \times 10^{-4}$, we obtain the final equation for these conditions:

$$\Delta H_s \cdot 10^4 = \lg \tau_{r1}/\tau_{01} - \lg \tau_{r2}/\tau_{02} + \lg (1 + 4.58 \cdot 10^{-4} T_2) \quad (37)$$

where the heat of dissolution is expressed in calories.

Thus the use of the last equation makes it unnecessary to determine the quantity of stationary phase in the column.

In the calculation of the heat of dissolution, allowance must be made for the difference between the enthalpy and heat of dissolution. The enthalpy of dissolution in most instances is negative, whereas the heat of dissolution has the opposite sign. The heat and enthalpy of dissolution are calculated by means of the same equations, and the quantities differ only in their signs. In most papers on gas chromatography, the heat of dissolution is denoted by H, and this may sometimes lead to confusion between thermodynamic and chromatographic data, since in chemical thermodynamics, heat is denoted by Q, and enthalpy by H.

A quantity used extensively in GLC is the relative heat of dissolution $\Delta H^0_{sx} = \Delta H_{sx} - \Delta H_{st}$, where ΔH_{sx} and ΔH_{st} are respectively the molar heats of dissolution of the substance being studied and a standard substance.

By carrying out the same steps used to derive Eqn. (37), we obtain a working equation for calculating the relative heat of dissolution from the difference in the logarithms of the retention volumes for $\Delta(1/T) = 4.58 \times 10^{-4}$:

$$\Delta H^0_s \cdot 10^4 = \lg V^0_{r1} - \lg V^0_{r2} . \quad (38)$$

It can be seen from Eqn. (38) that the calculation of the relative heat of dissolution from the relative retention volumes requires a minimum of experimental data.

Heats of dissolution can also be determined from data obtained for solutions with different concentrations by frontal, development, vacancy-chromatographic, and static-chromatographic methods. In these instances the isosteric heat of dissolution is usually calculated.

Many workers have determined heats of dissolution experimentally from retention data, and the experimental procedure has been described in detail[49,59,93-97].

Since in GLC practice extensive use is made of the so-called retention index, an attempt was made[98] to calculate the enthalpy of dissolution from the temperature dependence of the retention index

$$\Delta H_s = \frac{\delta I_n}{100} (\Delta H_{sr+1} - \Delta H_{sr}) + \Delta H_{sr} \quad (39)$$

where $\delta I_n = I_1 - IT_1/\Delta T$; $\Delta I = I_1 - I_2$; $\Delta T = T_2 - T_1$; I is the retention index of the substance being studied, and ΔH_{sr} the molar heat of dissolution of the n-alkane with the same number of carbon atoms in the molecule as the substance being studied, and ΔH_{sr+1} the molar heat of dissolution of the n-alkane with one carbon atom more in the molecule than the molecule of the substance being studied. The standard deviation which can be allowed when Eqn. (39) is used to calculate heats of dissolution is about 0.1 kcal mole^{-1}; in some instances, however, the discrepancy between the values of the heats calculated from the retention indices and from the retention volumes can reach 0.4 kcal mole^{-1}.

With precision measurement of the retention volumes, the reproducibility of the experimentally determined relative heats of dissolution is 0.02 kcal mole^{-1}, and that for the absolute heats 0.05 kcal mole^{-1}. Although the values of the heats of dissolution determined chromatographically agree to within an order of magnitude with the calorimetric values, there are as yet no sufficiently accurate calorimetric data on heats of dissolution for infinitely dilute solutions, so that a quantitative comparison of the chromatographic and calorimetric values cannot be made. Thus GLC makes it possible to determine heats of dissolution for solutions with any concentration, including infinitely dilute solutions; this last feature is particularly important.

VIII. CALCULATION OF THE MOLAR ENTROPY OF DISSOLUTION

The excess molar entropy of dissolution is calculated from the equation

$$RT\ln\gamma = \Delta\bar{H}_s - T\Delta\bar{S}_s \ . \qquad (40)$$

On the other hand, we can write the following equation containing the thermodynamic distribution constant:

$$-RT\ln\bar{K} = \Delta H_s - T\Delta S_s \ . \qquad (41)$$

In the last equation, in place of the thermodynamic distribution constant, it is possible to substitute the chromatographic distribution constant or specific retention volume

$$-RT\ln\frac{K}{RTN_1} = \Delta H_s - T\Delta S_s \ . \qquad (42)$$

To calculate the relative molar entropies of dissolution it is necessary to substitute in Eqn. (40) the value of the relative activity coefficient. By expressing the last quantity in terms of the relative retention volume and relative vapour pressure of the pure substances being compared at the temperature of the experiment (p^{00}) we obtain the relationships:

$$-RT\ln p^{00}V_r^0 = \Delta H_s^0 - T\Delta S_s^0 \ ,$$

$$-RT\ln V_r^0 = \Delta H_s^0 - T\Delta S_s^0 \ .$$

The error in the determination of the entropy of dissolution by gas-chromatographic methods is made up of the errors of the determination of the activity coefficient and the heats of dissolution. For relative molar entropies of dissolution the mean error is 0.4 e.u. Examples of the calculation of molar entropies of dissolution can be found in many papers [49,99,100].

IX. CALCULATION OF THE MOLAR FREE ENERGY OF A SOLUTION

This quantity is calculated from classical thermodynamic relationships using the distribution constant or activity coefficient

$$\Delta G = -RT\ln\bar{K} \ , \qquad (44)$$

$$\Delta\bar{G} = -RT\ln\gamma \ . \qquad (45)$$

Finally, a number of points may be made regarding the interpretation of the thermodynamic quantities obtained by gas-chromatographic measurements [57]. In the treatment of data on the thermodynamics of solutions of non-electrolytes, two standard states can be used: the pure solute (the distribution constant in this instance is denoted K_3, and an infinitely dilute solution of the same substance (for this standard state the corresponding symbol is K_2). For the gaseous phase, the standard state is usually taken as the ideal gas at a pressure of 1 atm. In the first instance the activity coefficient shows the departure of the properties of the solution from the ideal: the extent to which the vapour pressure of the solute in the solution is less than or greater than the value which would be observed for an ideal system. In GLC it is this standard state which is used in the calculation of the activity coefficient. The activity coefficient for the second standard state characterises the departure of the properties of the solution from Henry's law. These two standard states lead to different quantitative expressions for the thermodynamic functions of the solutions. Thus if the subscripts 2 and 3 are used to denote the heats and entropies of dissolution obtained from K_2 and K_3, we obtain the relationships:

$$\Delta H_{s3} - \Delta H_{s2} = -RT(Td\ln\rho/dT + 1) \ , \qquad (46)$$

$$\Delta S_{s3} - \Delta S_{s2} = R\ln\frac{M}{\rho TR} - R(Td\ln\rho/dT + 1) \ , \qquad (47)$$

where ρ is the density of the stationary phase. For example, when silicone 702 with M = 530 is used as stationary phase, the difference in the heats of dissolution according to Eqn. (46) is 0.5 kcal mole^{-1}, and the difference in the entropies of dissolution 10 e.u.

C_{5-12} alkanes	C_{18-36} alkanes	101
C_{5-8} alkanes	Alkanes	102
n-Alkanes	Apiezon	99
Alkanes	Solar oil	103
C_5 alkanes	Amides	104
C_5 alkenes	Nitrobenzene, dodecane	105
Aliphatic hydrocarbons	Various	93
Alkenes	Polar liquids	106
C_{2-6} alkenes	Various	107-110
Alkenes	Silver nitrate solutions	111
Methylcyclohexanes	Various	112
Benzene	Polyethylene glycol cresyl ether	96
Benzene	C_{16-28} alkanes	113
Benzene	Polyphenyls	114
Aromatic hydrocarbons	Various	100
Aromatic hydrocarbons	Various	115-120
C_{6-10} aromatic hydrocarbons	Various	121
Aromatic hydrocarbons	*n*-Decanol	122
Aromatic hydrocarbons	Various	123
Hydrocarbons	Dinonyl phthalate	51
Hydrocarbons	*n*-Heptadecane	124
Hydrocarbons: butane, butenes	Furfural, *n*-dodecane	125
Hydrocarbons	Various	94
n-Hexane, cyclohexane, benzene	Various	126
Benzene, cyclohexane, methylcyclohexane	PEG ethers	16
Hydrocarbons	Various	23
Aliphatic hydrocarbons	Aromatic hydrocarbons	127
Hydrocarbons	Various	128
Hydrocarbons	Squalane	129
Hydrocarbons	Phthalates	130
Aromatic amines	2,4,7-Trinitrofluorenone	131
Alcohols	Squalane	132
Furan and its derivatives	Various	133
Halogenated hydrocarbons	Various	134
Halogenated hydrocarbons	Alkanes	135
Nitrogen-containing compounds	Aromatic hydrocarbons	136
Diphenyl methyl phosphates	Various	137
Chloroacetones	Various	138
Organic peroxides	Various	139
Oxygen-containing substances	Alkanes	140
Oxygen, hydrogen	Electrolytes	88
Hydrocarbons, nitrogen-containing substances	Squalane, octadecane, dinonyl phthalate	23
Alkanes, acetone, alcohols	Squalane, polyethylene glycol, water	87
Aromatic hydrocarbons, heterocyclic compounds	2,4,7-Trinitrofluorenone	141
Ditto	Various	142,143
Hydrocarbons, alcohols, ketones	Squalane, didecyl phthalate, triol	144
Benzene, cyclohexane, alcohol	Various	145
Hydrocarbons and other classes of compound	Water	146
Hydrocarbons	Water	147
Dichloroethane, propanol	Benzene, toluene	148
Glycols, aminoethanols	Polyethylene glycol, Apiezon	95
Ethanol, carbon tetrachloride	Dinonyl phthalate	149
Hydrocarbons, oxygen-containing compounds	Hydrocarbons	48
Hydrocarbons, halogenated hydrocarbons	Squalane, polyglycols	150
Review	Various	49,151 152

In a number of instances in gas chromatography, however, two different standard states are used in the same equation. For example, the departure of the properties of the solution from Raoult's law is taken into account by the expression $p_1 = \gamma p^0 x_1$, where p^0 is the vapour pressure of the pure solute. Since $K_2 = x/p$, we have

$$\Delta G_2 = -RT \ln \gamma p^0 .$$

In this equation the activity coefficient has the standard state corresponding to K_3, and the free energy that corresponding to K_2. Allowance must be made for the fact that in the determination of the chromatographic values of the distribution constants and specific retention volumes, an infinitely dilute solution is taken as standard state. From this it is clear that, for example, the values of the heats of dissolution obtained from the temperature dependence of the specific retention volumes and activity coefficients may differ. In the calculation of the entropy of solutions it is preferable to use an equation containing the distribution constant or the specific retention volume, if the heat of dissolution is calculated from these quantities. In a number of instances, change in the standard state has little influence on the numerical values of the quantities obtained, but in the treatment of thermodynamic quantities for the study of intermolecular interaction the choice of standard state is extremely important.

Thus examination of gas-chromatographic methods for determining the thermodynamics of solutions shows that these methods can give unique data for infinitely dilute solutions, and for solutions with finite concentrations the experimental data obtained by gas chromatography are distinguished by their high accuracy and by the low expenditure of time in the experiment. In the near future the use of gas-chromatographic methods in the study of solutions will apparently give results as fruitful as those obtained in analytical chemistry.

To conclude we are listing examples of work in which GLC has been used for the determination of the thermodynamic properties of solutions (see Table on p. 183).

Biological Activity of Quinolinium Salts

B.M.Gutsulyak

The review deals with problems in the study and applications of quinolinium salts as biologically active preparations; the relation between the structure of quinolinium salts and their activity is discussed.
The bibliography includes 393 references.

I. INTRODUCTION

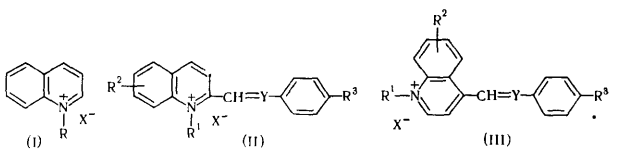
Quinolinium salts (I) have a number of very valuable physiological properties, among which the antimicrobial and antihelminthic properties have been investigated comparatively most thoroughly (although by no means completely). In the middle 1940's the antitumour properties of certain quinolinium compounds were discovered. There are data concerning the hypotensive, ganglion-blocking, carcinogenic, and mutagenic activity of various quinolinium salts. Certain quinolinium derivatives function as plant growth regulators.

During recent years, considerable advances have been achieved in the study of the physiological activity of quinolinium salts; at the present times, many such compounds have found practical application.

The methods of synthesis and chemical properties of quinolinium salts have already been reviewed [1].

II. ANTIMICROBIAL ACTIVITY OF QUINOLINIUM SALTS

In the 1920's Browning and coworkers [2] discovered the antimicrobial properties of certain quinolinium salts. The antiseptic and trypanocidal properties of styryl derivatives [(II), Y = CH] and anils [(II), Y = N], of quinaldinium were investigated in comparative detail [3-8]:



(I) (II) (III)

The analogous lepidinium (III) derivatives exhibited a very low antimicrobial activity at the beginning of the investigations, as a result of which they were not subsequently studied by this particular group of workers.

Examination of the relation between the structure and antiseptic activity revealed that even the simplest styrylquinolinium compounds [for example, II, Y = CH, R^1 = CH_3, R^2 = 6-CH_3, and R^3 = H] are active against *Staphylococcus aureus*. The presence of an amino- and particularly of a dimethylamino-group in the *para*-position of the benzene ring of the styryl substituent in compounds (IV) [II, Y = CH and R^3 = NH_2 or $N(CH_3)_2$] enhances the antiseptic activity. The displacement of these groups to the *meta*- or *ortho*-position is accompanied by a shortening of the conjugation chain involving the amino-group with a positively charged nitrogen atom and leads to a weakening of the antiseptic properties. Acylation of the aminogroup has a similar effect. When the aminogroup is shifted from the 6-position to the 4-position of the quinolinium ring, the activity against *E. coli* diminishes. However, the 4-dimethyl- or 4-diethyl-aminostyrylquinolinium salts have a very marked antiseptic activity in relation to staphylococci [9]. It is interesting that the pyridinium analogue has a lower antiseptic activity while benzoquinolinium derivatives are somewhat more active than the quinolinium salts [10].

Styrylquinolinium salts and anil derivatives of quinolinium salts are in most cases comparatively weak trypanocidal agents (against *T. brucei*) [11-14]. However, 1-methyl-2-(*p*-acetamidostyryl)-6-(aminobenzamido)-quinolinium acetate ("styryl 245") exhibits both therapeutic [15,16] and prophylactic [17] activity in relation to *T. brucei* (in mice). In addition, this compound has a synergistic effect when employed together with tryparsamide [15]. The activity of 2-(*p*-acetamidostyryl)-1-methyl-6-dimethylaminoquinolinium sulphate ("styryl 314") [18] against *T. brucei* was also investigated experimentally in mice.

It is noteworthy that the investigators were unable to discover a direct relation between the antiseptic and trypanocidal activities of the styryl and anil derivatives of the quinolinium salts investigated.

It was also established that certain styryl and anil derivatives of quinolinium salts are active against *Spirillum minus* which causes ratbite fever. 1-Methyl-2-(*p*-dimethylaminophenyliminomethyl)-6-acetamidoquinolinium chloride and sulphate show the most pronounced activity [19]. The corresponding 2-styrylquinolinium salts proved to be inactive in this respect. "Styryl 314" chloride has a very weak activity in relation to spirilla.

The work of Browning and coworkers on the above antimicrobial properties of the styryl and anil derivatives of quinolinium salts attracted the attention of scientists from many countries to these compounds. Österlin [20], who studied the relation between the trypanocidal activity of styrylquinolinium salts and their fluorescence in concentrated sulphuric acid, found that all active preparations exhibit green fluorescence. The absorption and fluorescence spectra were described in detail by Bandow [21]. Curd

and Ellingworth[22] suggested 2-styrylquinolinium compounds with amino-groups in the quinoline ring and in the styryl substituent are trypanocidal agents. Indian workers[23] investigated the effects of certain styryl and anil derivatives of quinolinium salts on paramecia. Petroff and Gump[24] studied the bacteriostatic activity of these compounds on gram-positive and gram-negative bacteria. The anils of 5,6-benzoquinolinium showed a more pronounced bacteriostatic activity: they are more active in relation to cocci but have no effect whatever on *E. coli*.

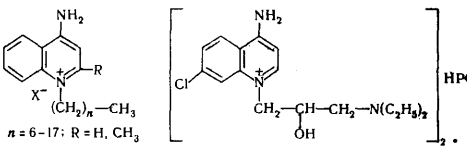
In 1941–1945 extensive studies were carried out in the U. S. A. on the antimalarial properties of many inorganic and organic substances. Various quaternary quinolinium salts were investigated among other organic compounds[25]. The activity of the compounds investigated was compared to that of quinine.

Among styrylquinolinium salts, the most active (when introduced intra-abdominally) proved to be compounds (IV) [II, $R^1 = CH_3$, $R^2 = 6\text{-}CH_3$, $R^3 = N(C_3H_7)_2$] (6 times more active than quinine), (V) [II, $R^1 = CH_3$, $R^2 = 6\text{-}CH_3$, $R^3 = N(\text{iso-}C_3H_7)_2$], and (VI) [II, $R^1 = CH_3$, $R^2 = 7\text{-}CH_3$, $R^3 = N(C_2H_5)_2$] (3 times more active than quinine). The antimalarial activity of the remaining styryl and anil derivatives of quinolinium salts did not exceed 30% of the activity of quinine. Some of them were quite inactive. It is interesting that the quinolinium salt with a phenyl group at the nitrogen atom of the quinolinium ring—compound (VII) [II, $R^1 = C_6H_5$, $R^2 = H$, $R^3 = N(CH_3)_2$, X = Cl] were described for the first time in connection with these studies. It proved to be twice as active as its *N*-methyl analogue.

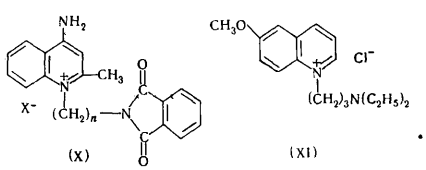
In connection with the study of chemotherapeutic properties, Rubtsov and Bunina synthesised[26] in 1943 quinolinium salts with sulphonamido-groups. The antitubercular activity of some of its compounds was tested[27].

In 1957 Japanese investigators[28] described the antibiotic activity of the "NK-458" preparation [II, $R^1 = C_2H_5$, $R^2 = 6\text{-}N(CH_3)_2$, $R^3 = N(CH_3)_2$, X = I] against trichomonads and pathogenic fungi. Taylor and coworkers[29] showed that 2-(*p*-acetamidostyryl)-1-methyl-6-methylaminoquinolinium methosulphate, an analogue of the preceding preparation, suppressed the development of pyroplasmosis in experiments on white mice. Berg[30] published a study on the synthesis and the trypanocidal properties of styrylquinolinium salts with a *m*-amidinophenyldiazoamino-group in the *para*-position of the styryl substituent. The above compounds proved to be active against *Trypanosoma rhodesiense*, *Trypanosoma congolense*, and also *Babesia rodhaini*. It was also found[31] that 1-ethyl-2-(*p*-dimethylaminostyryl)quinolinium sulphate has some fungistatic activity in relation to *Trychophyton gypseum*, *Trychothecium roseum*, *Achorion quinqueanum*, and *Epidermophyton* Kaufmann-Wolf, but is inactive against *Penicillium simplicissimum*, *Aspergillus niger*, and *Candida albicans*.

Among quaternary quinolinium salts without styryl groups in the 2- and 4-positions of the quinolinium ring, compounds containing amido- and sulphonamido-groups in the 6-position exhibit antimicrobial properties. These salts are recommended as preparations against blood parasites[32]. At the beginning of the 1930's Domagk[33] found that quaternary ammonium salts, including quinolinium salts with long-chain aliphatic substituents, have a high germicidal activity. This discovery promoted a successful search for a new antibacterial preparations. Similar compounds were suggested as disinfectants for surgical instruments, since their high antimicrobial activity is combined with a low toxicity. Shelton and coworkers[34,35] investigated the relation between the structure and germicidal activity of these salts. Some of them are produced commercially. For example, 1-laurylquinolinium bromide is used in practice as a disinfectant[36] under the name "Isotan Q-14". Tetrahydroquinolinium salts containing a long-chain hydrocarbon substituent at the nitrogen atom have antiseptic properties and their toxicity is low[37]. The fungistatic properties of certain quinolinium salts with a long chain hydrocarbon substituent at the nitrogen atom (n-hexyl, n-octyl, n-decyl, and n-dodecyl) were investigated by Zsolnai[31]. All the compounds studied proved to be inactive against *Aspergillus niger*. The last two compounds proved to be active against *Penicillium simplicissimum* and *Candida albicans*. 4-Aminoquinolinium and quinaldinium (VIII) salts with long-chain aliphatic substituents containing between 7 and 18 carbon atoms at the nitrogen heteroatom[38–41] have marked bacteriostatic and bactericidal activity:



The most effective compound in this series is 4-amino-1-dodecylquinaldinium acetate (laurolinium acetate)[42,43], which exhibits antibiotic activity *in vitro* against 32 species of gram-positive and gram-negative bacteria, pathogenic fungi, and certain protozoa. In relation to plasmodia, such salts are apparently relatively ineffective. Thus the activity of preparation (IX) amounts to 40% of that of quinine[25]:



Taylor and Austin[44] developed a method of synthesis of 4-aminoquinaldinium salts of type (X), which are intermediates in the synthesis of medicinal preparations. When the amino- or alkylamino-group is in the 2- rather than the 4-position of the quinolinium ring, the preparation loses its activity. Thus 2-alkylaminoquinolinium and 2-arylaminoquinolinium salts do not exhibit appreciable antiseptic, trypanocidal, and antimalarial activities[45].

Since 8-hydroxyquinoline has a fairly pronounced bactericidal and bacteriostatic activity, numerous quaternary derivatives of hydroxyquinolines were investigated. Müller[46] studied the toxicity and bacteriostatic activity of 8-hydroxy-1-methylquinolinium salts against cocci, *E. coli*, and brucellae. The salts containing high-molecular-weight anions (benzoates and stearates) showed a more pronounced specific bacteriostatic activity, while the corresponding sulphate does not exhibit an appreciable antibacterial activity[47]. However, it was found that salts of 1-alkyl- and 1-arylalkyl-8-hydroxyquinolinium, containing an acyl or nitro-group in the 5-position and an alkyl group in the 7-position, show an appreciable antifungal and bactericidal activity[48]. Various hydroxyquinolinium esters have been suggested as disinfectants[49–51]. Vogt[52] made a detailed study of esters of 8-hydroxyquinolinium and showed that, with increase of the chain in the aliphatic acid group (forming part of the ester group) up to 16 carbon atoms, the activity of the compound rises. The introduction of a thiocyanato-group into the quinoline ring of these compounds leads to a considerable enhancement

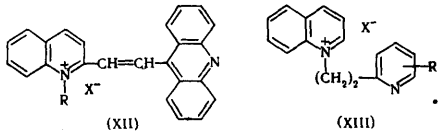
of their bactericidal activity [53,54]. One of the most active compounds of this group is 8-n-butoxy-1-methyl-5-thiocyanatoquinolinium sulphate. Its bactericidal activity against *E. coli* is still apparent at a dilution of 1 : 100 000. Buchmann [55,56] studied the activity of the methyl and ethyl ethers of 4-hydroxy-1,6-dimethyl quinolinium iodide against *Aspergillus niger*, *E. coli*, and *Staphyllococcus aureus*. Although the activity of the preparations was low, it is interesting to note that the ethyl ether proved to be 20 times more active than the methyl ether in relation to *E. coli* and almost twice as active against *Staphyllococcus aureus*. In a study of the antimalarial activity of hydroxyquinolinium derivatives, it was established[25] that, whereas 6-methoxy-1-methylquinolinium iodide exhibits 15% of the activity of quinine, its 1-benzyl analogue is twice as active and preparation (XI) is 10 times as active as quinine. It is also interesting to note that the betaine of 2-hydroxy-1-methylquinolinium has a considerable prophylactic activity against *P. gallinaceum* in chicks (it is almost 8 times as active as sulphadiazine). The antibacterial properties of certain 8-alkoxyquinolinium salts, among which the most active proved to be the 1-methyl-8-octyloxyquinolinium salt, were investigated recently [57].

Among other quinolinium salts with antimicrobial activity, mention should be made of the 1-aryloxymethyl [58], 1-alkylnaphthyl [59], and 1-β-halogenophenoxymethyl derivatives [60]. The latter also exhibit antifungal activity and are more active than the analogous pyridinium salts.

Quinolinium salts containing as the anion a sulphonic acid residue with a long aliphatic chain were also synthesised. They proved to be highly effective bactericidal and fungicidal agents [61]. Sparingly soluble quinolinium salts containing anions of heavy-metal complex acids have been recommended as antifungal and antibacterial preparations (including preparations effective against plant pests) [62].

As a rule quaternary quinolinium salts are more active than the tertiary quinoline bases. However, 4-(2′-nitrovinyl)quinolinium salts proved to be inactive against *Trichomonas vaginalis* and *Candida albicans*, while the corresponding tertiary bases are very effective in this respect [63].

The antimicrobial properties of quinolinium salts with a further heterocyclic ring have also been investigated:

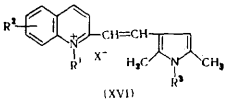


(XII)

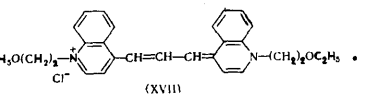
(XIII)

Compounds of type (XII) appreciably suppress the growth of staphylococci at a dilution of 1 : 40 000 in water, but are inactive against trypanosomas [64,65]. 7-Chloro-4-[1′-methyl-4′-1(1″-pyrrolidinyl)butylamino]quinolinium salts have been recommended as antimalarial preparations [66]. However, it is interesting to note that quinine ethiodide shows only 8% of the activity of the tertiary base [25]. 1-[2′-(2″-Pyridyl)ethyl]quinolinium salts (XIII) show fungicidal activity [67].

Quinocyanine dyes, the molecules of which consist of two and more heterocyclic rings (not less than one of which is a quinoline ring) joined by a polymethine chain, are interesting derivatives of quinolinium salts. The first studies on the antimicrobial activity of cyanine dyes with quinolinium rings were carried out by Browning et al. [68] Sensitol red (Pinacyanol), violet, and green were tested against *E. coli* and *Staphylococcus aureus*. Among these sensitol green [Ethyl Red, (XIV)] proved to be the most effective suppressing the growth of *Staphylococcus aureus* at a dilution of 1 : 100 000 in serum and of *E. coli* at a dilution of 1 : 10 000.



(XVI)



(XVII)

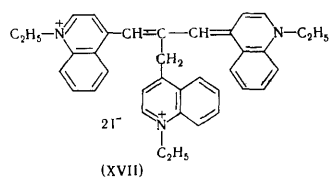
Somewhat later the same investigators[69] published the results of studies on the antiseptic properties of apocyanines, isocyanines, and carbocyanines of the quinolinium series. They did not find among these cyanine dyes compounds meriting attention. At almost the same time Karwacki and Biernacki [70] discovered that a cyanine dye has a slight effect on the micro-organisms responsible for tuberculosis. Petroff and Gump [24] studied the effect of quinolinium dyes (XIV), ethylcyanine T, orthochrome T, and Pinacyanol on gram-positive and gram-negative micro-organisms. The study of the antimalarial activity of cyanine dyes during the second World War [25] showed that the simplest cyanine dyes with two quinoline rings in the molecule exhibit as a rule a low antimalarial activity (15–30% of that of quinine). Carbocyanine (XV) proved to be more active, showing 80% of the activity of quinine. It is interesting that its isomer, 2,2′-trimethinecyanine, is almost 3 times less active (30% of the activity of quinine). Certain quinocyanine dyes—pseudocyanine, isocyanine, and dicyanine in the form of methochlorides—exhibited less than 20% of the activity of quinine in the treatment of chicks infected with *P. gallinaceum*; the activity of Pinacyanol and cryptocyanine was less than 15% than that of quinine. The data from the Rockefeller Institute of Medical Research [25] also indicate that the methochlorides of cyanine, isocyanine, Pinacyanol, dicyanine, 6,6′-dimethylcyanine, and carbocyanine are inactive in relation to these parasites. The activity of Quinolinium Blue is less than 3% of that of quinine against *P. lophurae* in ducks. Among asymmetric quinocyanine dyes, the dimethines with the general formula (XVI) were investigated in greater details. The effect of the substituents R^1, R^2, and R^3 on the antimalarial activity of the compounds was studied.

In 1947 Brooker and Sweet [71] published a short report on the results of chemotherapeutic studies on cyanine dyes. They note that preparation (XVI) ($R^1 = CH_3$, $R^2 =$ 6-CH_2, and $R^3 =$ n-C_5H_{11}) completely suppresses the growth of *L. casei*, *L. arabinosus*, *Streptococcus faecalis*, and *E. coli* at concentrations of the order of $(2–4) \times 10^{-6}$ M. Individual representatives of various classes of cyanine dyes were tested *in vivo* against *Streptococcus haemolyticus*, *Streptococcus viridans*, *Staphylococcus aureus*, *Diplococcus pneumoniae*, *Trypanosoma equiperdum*, and *Treponema pallidum*, which are responsible for encephalitis, influenza, typhus, and a group of interstinal parasites, and also *in vitro* against *Entamoeba histolytica*. Although individual compounds showed a distinct activity against the above micro-organisms, the authors believe that the activity is not high enough to be of therapeutic value. However, Silverman [72,73] reported that 1,1′-dimethyl-2,2′-cyanine iodide suppresses the growth of *E. coli*, although the Ca^{2+} cation behaves as an antagonist. It was also found [74,75] that Quinolinium Blue (1,1′-dipentyl-4,4′-cyanine iodide) is extremely active *in vitro* against the organism responsible for diphtheria and against gram-positive cocci, including *Staphylococcus aureus*. In view of its low toxicity, the preparation was recommended as a therapeutic agent. However, the compound is inactive in relation to pathogenic fungi [31]. Ryzhikov et al. [76] reported that Quinolinium Blue is a moderately strong inactivator of the

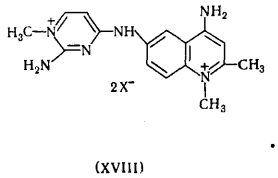
tobacco mosaic virus, suppressing its activity to the extent of 63%. However, later studies by Bobir [77] showed that the preparation is completely indifferent in relation to the above virus.

In 1951, almost 30 years after the studies of Browning [68], it was found that Pinacyanol shows a high bactericidal and bacteriostatic activity against cocci and the organism responsible for diphtheria, whilst its toxicity is very low [78].

A study was also made of the physiological properties of quinocyanine dyes with 3 ring systems. The interaction of 1-ethyl-lepidinium iodide with triethyl orthoformate in acetic anhydride or in dry pyridine are known to give a mixture of polymethine dye, called Lumin (or the Cryptocyanine OA complex). Somewhat later this mixture was separated into components, which were called cryptocyanines 1, 2, 3, 4, and 5 respectively. Cryptocyanine 1 proved to be identical with the so called neocyanine or Koha No. 1 (XVII):



(XVII)



(XVIII)

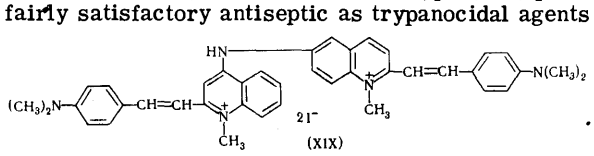
The physiological activity of both the non-purified dye (Lumin), with about 92% of Koha No. 1, as well as that of the individual components, mainly pure Koha No. 1, were investigated by Japanese workers. A detailed study was made of the optimum conditions for the formation of compound (XVII). [79] Hatano [80] found that compound (XVII) exhibits antitubercular activity. Miyazaki [81] reported that Lumin has an appreciable effect in the treatment of human leprosy, 81.9% of 371 patients showing some improvement and only 1.6% deteriorating after a 10 month course of treatment by this preparation. At the same time pure Koha No. 1 has undesirable side effects. However, investigations by other workers showed that this preparation is not quite so effective in the treatment of both experimental and human leprosy [83,84]. Sato and Chida [85] made a more detailed study of the effect of the non-purified product and pure Koha No. 1 on organisms responsible for tuberculosis and for human and experimental rat leprosy. The preparations showed tuberculostatic activity against the Aoyama strain in a dilution of 1 : 100 000–1 : 50 000. However, in relation to the natural organism responsible for tuberculosis, the activity of these compounds was shown only at a dilution of 1 : 10 000. The preparations had no effect on experimental leprosy and did not exhibit a promising therapeutic activity on human leprosy. A study was also made of the antiviral activity of Koha No. 1 in relation to coliphage [86] and of its bactericidal activity against certain pathogenic bacteria [87]. The compound has an appreciable bactericidal activity against *Staphylococcus albus*. Partial suppression is also observed in the case of *E. coli*, *Salmonella typhosa*, and *Shigella dysenteriae*. In all cases the activity increases with the alkalinity of the medium (up to pH 10).

The effect of cyanine dyes on the respiration of *Staphylococcus aureus* and *S. typhi* was investigated [88].

Diquaternary salts with one or two quinolinium rings have very interesting antibiotic properties.

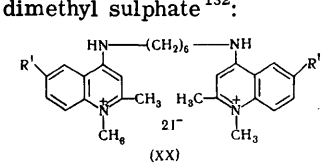
In 1949 a new very effective trypanocidal agent was described [89]; it is a diquaternary quinolinium salt called antrycide (XVIII) (synonyms: quinapyramine, pyraldine). It is active against various trypanosoma species [*T. congolense*, *T. brucei*, *T. evansi* (India and the Sudan), *T. equiperdum*, *T. equinum*, and *T. vivax*]. Veterinary field tests in Africa showed that antrycide salts are effective in both prophylactic and therapeutic treatment [90–93]. Antrycide has been used as the dichloride, the dimethosulphate, or in the form of a mixture of these two salts, the so called "pro-salt". This discovery stimulated the study of similar compounds and in recent years a number of publications dealing with the methods of synthesis of the isomers and analogues of antrycide have appeared [94–107]. New methods have also been developed for the determination of antrycide [108] in biological objects. The chemotherapeutic properties of antrycide were investigated in greater detail by workers in various countries [109–116]. Moreover, studies were performed both with a view to finding more effective therapeutic forms of antrycide in the treatment of trypanosomiases and in order to investigate the effects of antrycide on micro-organisms responsible for other diseases. Tests on mixtures of antrycide with other trypanocidal preparations led to the discovery that a complex of antrycide with suramin is less toxic than antrycide itself [117,118]. The complex also exhibits prophylactic and therapeutic effects in diseases of swine caused by *T. simiae* [119–121]. In tests of antrycide against other pathogenic agents, it was found that the preparation is active against the European trypanosomiasis of horses [122–124], su-auru [125], and the trichomoniasis of cattle [126]. The compound also effects a complete cure in mice infected with *Babesia rodhaini* [29]. Among the reviews in which antrycide is discussed, mention should be made of Williamson's review [127] dealing with the chemotherapy and chemoprophylaxis of African trypanosomiasis and also the review on the mechanism of the action of trypanocidal agents [128]. Babesicidal properties of an analogue of antrycide with a phenyl group in the 2-position of the quinoline ring have also been described [129].

Bisquinolinium salts are effective antimicrobial preparations. Jensch [130] suggested that azo-compounds in which the azo-group is joined to two quinolinium rings be employed as therapeutic preparations against blood parasites. Bis-styrylquinolinium salts of type (XIX) proved to be fairly satisfactory antiseptic as trypanocidal agents [13]:

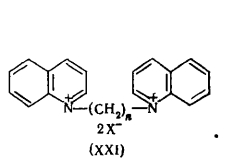


(XIX)

When two moles of 4-methoxy-1-methyl- or 6-amino-(dimethylamino- or methoxy)-4-chloro-quinaldinium iodide react with one mole of hexamethylenediamine, bisquinaldinium salts (XX), which exhibits trypanocidal properties, particularly against *T. rhodesiense*, are formed [132]. These preparations can also be obtained by the methylation of the corresponding tertiary base at the nitrogen heteroatom with dimethyl sulphate [132]:



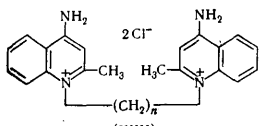
(XX)



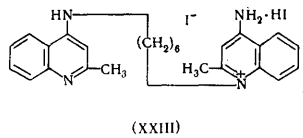
(XXI)

Collier et al. [133] tested the antifungal activity of bisquinolinium salts (XXI) in which both nitrogen atoms are joined by a polymethylene chain. The activity of these compounds, containing between 10 and 20 CH_2 groups, increases with increase of the number of methylene groups to 14–16, after which it falls again. The most active of these (XXI, $n = 14$, 16) inhibits the growth of many pathogenic fungi at a concentration of 0.3–10 μ g ml^{-1}. At the same time the preparations are relatively non-toxic for

warm-blooded animals. Subsequently, in a study of analogues of these compounds, Babs, Collier, and coworkers[134] described in 1956 a new highly effective antibacterial and antifungal agent, which they called Dequadin-1,1′-decamethylenebis-(4-aminoquinaldinium chloride) (XXII, $n = 10$). The preparation is also known as Dequalinium, Decatylene, and Decamine.



(XXII)



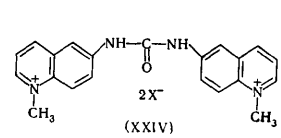
(XXIII)

The preparation is very effective *in vitro* against various gram-positive (cocci, corynebacteria) and gram-negative (intestinal bacteria, salmonellae, proteus, and cholera vibrio) micro-organisms and also against pathogenic fungi[134-136]. In addition Dequadin exhibits a synergistic activity when employed together with antibiotics. However, cases are known of an allergic response in Dequadin therapy after prolonged administration of antibiotics[137]. It is also active against certain pathogenic protozoa, in particular *Trypanosoma congolense*[138], but it is only slightly effective *iv vivo* against *Entamoeba histolytica*[139]. It is noteworthy that the isoquinolinium analogue of Dequadin showed a low trypanocidal activity. Dequadin has also been used as a disinfectant in dental practice[140] and in the surgery of the oral cavity[141], for the local treatment of wounds in humans and animals[142], for the treatment of vaginites caused by *Trychomonas* and *Candida*[143-146], trichophytosis of cattle[147], fungal affections of the skin[148-150], diseases of the throat and respiratory organs[151-153], including those of young children[154,155], and also other diseases[156-158]. Under the name Decamine, this preparation was adopted by the Soviet Pharmacopoeia as a therapeutic agent; various therapeutic forms of the substance have been developed[159-161].

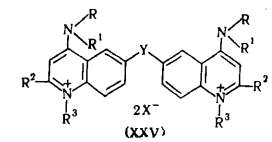
In connection with the very high antibiotic activity of Dequadin, a detailed study was made of its homologues, isomers, and analogues[134,162,163]. A number of patents have been taken out, both for the methods of preparation of Dequadin and analogues and also for its various therapeutic forms[164-170]. In many reviews dealing with new chemical preparations, a fair amount of attention has been devoted to this compound[139,148,171-173].

Homologues of Dequadin containing a smaller number of methylene groups ($n = 6$ and 8) show a considerable activity against *Trypanosoma rhodesiense*[162,174]. Buchmann[56] found that 1,1′-hexamethylenebis(7-methylquinolinium iodide), a Dequadin analogue, is active against *Staphylococcus aureus* and *E. coli*. A report was published in 1967 that certain analogues of Dequadin in the form of acetates with a secondary amino-group in the 4-position of the quinaldinium ring exhibit a higher antimicrobial activity than the unsubstituted preparation. The maximum activity is shown by substances with C_3–C_6 alkyl substituents. However, the toxicity of the preparations is also enhanced. When 4-aminoquinaldine reacts with 1,6-di-iodohexane, 6-(4-quinaldinyl)aminohexyl-4-aminoquinaldinium hydriodide iodide, called tozocide (XXIII), is formed together with the symmetrical compound (XXII, $n = 6$). The preparation is highly active against *Trypanosoma congolense* and *Trypanosoma vivax*, and is more active than both symmetrical isomers[174,176].

Among other bisquinolinium salts with antibacterial properties, mention should be made of bis-1-(6-methylquinolinium)urea salts [Babesan, Pyroplasmin, Acaprin (XXIV)][177,178] which have been recommended for the treatment of pyroplasmosis and taylorosis of domestic animals[179-182]. In addition, Babesan also exhibits an antimalarial activity[25]. The disadvantages of Babesan include the short duration of its action[181] and toxicity[183,184].



(XXIV)



(XXV)

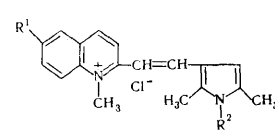
where Y = NH, O, S, or CH_2, R, R^1 = H or alkyl, and R^2, R^3 = alkyl.

Babesan analogues of type (XXV) have also been recommended as preparations for the treatment of piroplasmosis and taylorosis of animals[129,185].

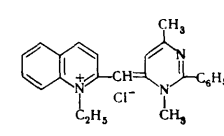
III. ANTIHELMINTHIC ACTIVITY OF QUINOLINIUM COMPOUNDS

Helminthic diseases in man, animals, and birds are very common. About 40% of the earth's population and a large number of animals are infected by pathogenic worms[186]. According to Stoll's data[187], more than 800 million people are affected by helminthiases. The losses in animal husbandry in the USSR due to helminthiases in 1960 amounted to approximately 58 million roubles per annum[188]. Therefore much attention has been devoted to the development of means of combating helminthic infestations. Thus at an SEV [significance of Russian abbreviations obscure (Ed. of Translation)] session in May, 1963 it was resolved that particular attention should be paid to the manufacture of antihelminthic preparations[188].

Among antihelminthic agents, quinolinium derivatives occupy a major place. The study of quinoline derivatives as antihelminthic agents was begun by the work of Brooker and Sweet[71], who synthesised in 1947 a number of quinocyanine dyes with pronounced antihelminthic properties[189]. Studies on a large number of similar compounds showed that two nitrogen atoms separated by an even number of conjugated bonds constitute an essential group for antihelminthic activity. Among all the compounds investigated, compounds (XXV), (XXVII), and (XXVIII) proved to be the most effective.



(XXVI, $R^1 = CH_3$; $R^2 = C_6H_{11}$)
(XXVII, $R^1 = N(CH_3)_2$; $R^2 = C_6H_5$)



(XXVIII)

The first of these, compound (XXVI), has been recommended as a therapeutic agent against *Litomosoides carinii*. Clinical tests on compound (XVIII) against *Wuchereria bancrofti* showed that the preparation is effective against microfilaria but not against the adult parasites[190]. However, when organisms responsible for onchocerciasis are acted upon, the compound kills adult filaria but does not affect the microfilaria[191]. The investigators note an undesirable[191] albeit non-systematic[189] side effect of this preparation. The mechanism of the action of compound (XXVII) on helminthes[192] and on the development of the embryos of *Litomosoides carinii* has been investigated[193]. Pyrimidoquinocyanine dyes of

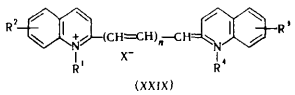
type (XXVIII) have been patented as antihelmintic preparations [194].

Compound (XVIII) has a very satisfactory therapeutic activity. It has been patented under the names Poquil, Vanquin, Povan, Moleac, Pyrvinium, and Pyrroviniquinium [195,196]. Poquil chloride has a high antihelminthic activity in the chemotherapy of enterobiasis and strongylidosis [197-203]. Apart from the chloride, the products of the interaction of phenolphthalein with Poquil is also recommended [204]. Recently reports have been published about the successful application of Poquil pamoate. This preparation is less toxic, since it is sparingly soluble in water and is not absorbed from the gastrointestinal tract in appreciable amounts [205,206] and it does not have a bitter taste [207].

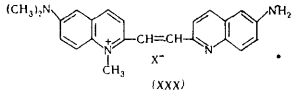
Poquil pamoate has been successfully employed in the treatment of animals and children both as an individual preparation [208-223] and in combination with piperazine [224,225] (preparation Cl-578). The antihelminthic activity of Poquil embonate in enterobiasis has also been investigated [226-228]. However, this preparation is less effective than the pamoate [sic!, embonate and pamoate are trivial names of the same anion (Ed. of Translation)].

The effect of pyrimido- and pyrrolo-quinocyanines of type (XXVI)-(XXVIII) on the metabolic processes in parasites [229-232] and also their side effects and toxicity [189-191,198,205,208,209,233-236] have been investigated.

At the beginning of the 1960's a number of patents for the application of trimethine (XXIX, $n = 1$) and pentamethine (XXIX, $n = 2$) quinocyanine dyes with symmetrical and asymmetric structures, dyes of type (XVII) with three ring systems [237], and also 2-styrylquinolinium salts (II) [238,239] were published.



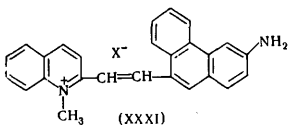
(XXIX)



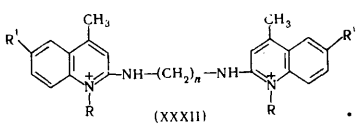
(XXX)

Pentamethine quinocyanines (XXIX, $n = 2$) are very effective antihelminthic agents with a wide spectrum of activity and are recommended for the treatment of helminthiases in man, animals, and birds. Together with a high therapeutic index, they are characterised by a low toxicity, which distinguishes them favourably from their extremely toxic benzothiazole analogue (Dithiazanine). *p*-Dimethylaminostyrylquinolinium salts show a high activity against the larvae of *Ascaris suum*, the larvae and adult forms of tapeworms and also in certain sheep helminthiases caused by *Trichostrongylus colubriformis* [238,239].

In addition the antihelminthic properties of compounds of type (XXX) and (XXXI) [240] and also of bisquinolinium, bis-4-aminoquinaldinium [241], and bis-2-aminolepidinium salts (XXXII) [242] have been investigated.



(XXXI)



(XXXII)

The latter are recommended for the treatment of animals infected with *Syphacia obvelata*, *Hymenolepis nana*, *Dypilidium caninum* and *Taenia pisiformis*.

In conclusion it should be noted that in many reviews dealing with antihelminthic agents considerable attention has been recently devoted to quinolinium derivatives [139,187,188,243-250].

IV. RADIOMIMETIC ACTIVITY OF QUINOLINIUM SALTS

The action of chemical agents on living organisms resembling the effect of radioactive ionising radiation is called radiomimetic [251]. For example, it is known that small doses of radioactive emission have an antiblastic activity, which is used in the treatment of malignant tumours. However, more prolonged action of such radiation causes the appearance of malignant neoplasms (oncogenic activity). In addition, they all have a mutagenic activity.

Certain quinolinium salts have a complete set of the above properties, but some of these have been investigated quite inadequately.

a. Oncogenic Activity of Quinolinium Salts

The oncogenic properties of certain styrylquinolinium salts were first reported by Browning [252,253], who observed that a single subcutaneous administration of 6-acetamido-2-(*p*-aminostyryl)-1-methylquinolinium acetate [Styryl 430, (XXXIII)] results in the appearance of a sarcoma at the site of administration after a certain period. This property has been used for the induction in white mice of an experimental sarcoma [254], the cell chromosomes of which were investigated by Arroyo and Murcia [255]. Another dye [(II, $R^1 = CH_3$, $R^2 = H$, $R^3 = N(CH_3)_2$, Y = CH, and X = SO_4CH_3)] causes malignant affections of the intestinal tract after systematic administration to rats in food over a period of one year (at a dose of 800 mg kg^{-1}) [256]. In connection with the oncogenic activity of compound (XXIII), its effects on the respiration of live cells [257] and on the ability of rats to swim [258] were investigated. Like other carcinogenic agents, the preparation suppresses cell respiration and reduces the capacity of rats for work.

b. The Antitumour Activity of Quinolinium Salts

In recent years the search for effective antitumour agents has been considerably intensified. Among other compounds, numerous quinolinium derivatives were investigated. Shear et al. [259] noted that certain quaternary pyridinium and quinolinium salts decompose sarcoma cells, which attracted much attention to them. However, in a more systematic study it was found that *N*-alkylquinolinium salts unsubstituted in the 2- and 4-positions do not show any activity against sarcoma 180, adenocarcinoma 755, and leukaemia L1210 [260-266] (see Table).

Compounds (XXXIV) and (XXXV) (see Table) are an exception, showing a weak activity against carcinoma and the latter also against sarcoma. At the same time many quinolinium salts containing phenylethyl [(XXXVI) and (XXXVII)], phenylacyl [(XXXVIII)-(XLVI)], and β-naphthoylmethyl [(XLVII) and (XLVIII)] groups at the nitrogen heteroatom are active against sarcoma and some also against adenocarcinoma.

It is interesting to note that, while the simplest quinolinium salts are inactive against sarcoma and carcinoma, the analogous quinaldinium salts containing a methyl group in the 2-position of the quinoline ring exhibit a distinct albeit slight activity in relation to sarcoma [(XLIX)-(LI)]. A similar activity is shown by 2-phenyl-substituted [(LIV)-(LVI)] and 2-styryl-substituted [(LVII)-(LXVI)] quinolinium salts. Some of these are active also in relation to adenocarcinoma (see Table). Quinolinium salts (LVII) with an azomethine group in the 3-position also show

Quinolinium salts active against sarcoma 180 (Sa) and adenocarsinoma 755 (Ca).

a slight activity. However, it is noteworthy that many styryl-substituted quinolinium salts proved to be virtually inactive against these types of tumours [260,263,271,274-276]. Certain 2- and 4-*p*-dimethyl(diethyl)aminostyrylquinolinium salts also proved to be inactive against leukaemia and Ehrlich ascites carcinoma when administered in combination with irradiation by X-rays [277].

In a study of the activity of styrylquinolinium salts against other malignant tumours, it was found that 1-methyl-4-(*p*-dimethylaminostyryl)quinolinium iodide (LXIX) and chloride (LXX) are exceptionally active against lymphoma 8, [278,279] suppressing completely the tumours in rats. It is interesting to note that, whereas compound (LXX) is active only when administered orally, compound (LXIX) is also active when injected subcutaneously. Slight changes in the structure of styrylquinolinium have a very marked influence on its antitumour activity. The replacement of the *p*-dimethylamino-group by the *p*-diethylamino group greatly reduces the activity of the preparation [280].

The migration of the *p*-dimethylaminostyryl group from the 4-position in the quinoline ring to the 2-position involves a complete loss of antilymphoma activity. In a study of the effect of preparations of type (LXIX) and (LXX) on other types of tumours, it was found that adenocarcinoma 11 also regressed in the majority of animals, but the effect of the preparations on this tumour is somewhat weaker. However, in experiments on mice, both in the case of spontaneously generated carcinoma of mammary glands and the transplanted carcinoma, preparation (LXIX) proved to be inactive.

In a study of the activity of this preparation and 4-styrylquinolinium against the Walker tumour [250], the tertiary base proved to be more active [281-283]. Preparation (LXIX) was found to be inactive against Nelson mouse ascites tumour [284] and against leukaemia L1210. [285,286] Compounds (LXIX) and (LXX) and also an isomer of the former, containing the *p*-dimethylaminostyryl group in the 2-position of the quinoline ring (LXXI), exhibited a cytotoxic activity to an extent proportional to their antitumour activity [287-289].

Compound (LXXI) and its 1-ethyl homologue are inactive against lymphoma 8 [280] and leukaemia [285,286,290], but they do suppress the growth of Walker carcinoma 256. [291] In addition, the activity of (LXXI) was investigated *in vitro* on cells of sarcoma 180 of mice and on four human tissue cultures [292]. A study was also made of the suppression of glycolysis by these preparations [293].

Various derivatives and analogues of compounds (LXIX)–(LXXI) were also investigated in order to elucidate the relation between structure and antitumour activity [294,295]. It was found that the vinylogue of compound (LXIX) is completely inactive against lymphoma 8. [296] The replacement of the quinoline ring by the isoquinoline ring reduces the antilymphoma activity [297] and the replacement of the *p*-$N(CH_3)$ group by F causes a complete loss of activity [298].

In an examination of the mechanism of the action of styrylquinolinium salts on normal and neoplastic cells, it was suggested that the antitumour activity of these compounds is determined by the quinoline part of the molecule, while the aminostyryl group is involved in the attachment

of the molecule to important sections of the tumour cell[295]. According to Bahner et al.[299], the above salts interact with sulphydryl groups in cysteine. The fate of styrylquinolinium compounds in the animal organism was investigated[300] and a highly sensitive method for the detection of these compounds was developed. Certain of the styrylquinolinium salts and anil derivatives of quinolinium salts containing the mustard gas group in the benzene ring of the styryl substituent have been patented as effective anticancer preparations[301].

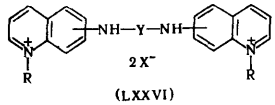
In 1963 Hirschberg[302] published a very brief compilation of the literature on the antitumour properties of certain styrylquinolinium salts.

Cyanine dyes with quinoline rings have also been tested for anticancer activity. It was found that compounds of type (XVI) are very weak carcinostatic agents or inactive. Thus compound (LXXIII) [XVI, $R^1 = CH_3$, $R^2 = 6\text{-}N(CH_3)_2$, $R^3 = C_6H_5$, and X = Cl] does not suppress sarcoma 180,[275] while its analogue with $R^1 = CH_2CH_2OH$ and $R^2 = 6\text{-}CH_3$ is inactive against carcinoma and leukaemia L1210, suppressing sarcoma very slightly (to the extent of 27%)[303]; compound (LXXI) [XVI, $R^1 = CH_3$, $R^2 = 6\text{-}CH_3$, $R^3 = C_5H_{11}$, and X = Cl] prolongs the life of animals suffering from leukaemia almost by a factor of 2.[304] 1-Methyl-4-[2′(4″-pyridyl)vinyl] quinolinium iodide is inactive against all three tumours[305]. Among symmetric quinocyanine dyes, cryptocyanine was tested for its activity against leukaemia. It proved to be inactive[306], although it suppresses the growth of a KB tissue culture to the extent of 50% at a concentration of 1.4×10^{-1} μg ml^{-1}.[268] Orthochrome T [bis-(1-ethyl-6-methylquinoline-2-yl)trimethinecyanine iodide] is also inactive against sarcoma 180, carcinoma, and leukaemia L2110.[265]

At the same time Quinolinium Blue at a dilution of 1 : 2000 proved to be very active against Ehrlich carcinoma[75,307]. The action of quinocyanine dyes with three rings against malignant tumours was also studied. Neocyanine (LXXV) suppresses sarcoma 180 to the extent of 21–51%.[265] Japanese investigators reported that it is also active against cancer tumours and its effectiveness is higher when administered orally than in local administration[308]. The use of compound (LXXV) in the treatment of Hodgkin's disease has been reported[309]. Mizuno[310] notes that cyanine dyes (the formulae and names are not quoted) suppress *in vitro* the growth of a tissue culture of Erlich carcinoma, sarcoma 180, and Yoshida sarcoma.

In a study of bisquinolinium salts of type (XXI) (X = Br), it was found that, when $n = 2$, the compound suppresses carcinoma to the extent of 45%, but the degree of suppression is only 24% when $n = 3$,[263] and when $n = 4$ the compound is inactive. The decamethylene derivative ($n = 10$) is also inactive against carcinoma but suppresses to the extent of 30% Erlich ascitices tumours[263]. A study was also made of the activity of compounds (XX) against sarcoma and carcinoma[267].

Bisquinolinium salts with a general formula (LXXVI) have recently attracted attention owing to their activity against leukaemia:



(LXXVI)

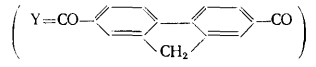
(LXXVII, Y = OC–C_6H_4–CO).

The activity of 6-substituted derivatives of quinoline is more pronounced with R = C_3H_7 and C_4H_9, falling rapidly in the case of higher homologues.

It has been found[311] that the physiological activity of compounds (LXXVI) is directly related to their lypophilic and hydrophilic properties. The replacement of the terephthaloyl residue by that of pyridine-2,5-dicarboxylic acid leads to some decrease of activity and its replacement by the isophthaloyl residue or the residue of an aliphatic dicarboxylic acid causes a loss of activity. A similar result is obtained when the –NHCOC_6H_4CONH– group joins the quinoline rings in the 5- and 7-position. A slight activity is also shown by derivatives of *p*-carboxyphenoxyacetic acid (LXXVI, Y = CO–C_6H_4–OCH_2CO).[311]

When the Y = COC_6H_4NHCONHC_6H_4CO group is introduced into (LXXVII), its antileukaemic activity is enhanced; the replacement of one of the quinoline rings by a pyridine ring has a similar effect[312].

When the phenyl group is Y = COC_6H_4CO is replaced by the biphenylyl group (Y = CO$C_6H_4C_6H_4$CO), the activity is retained; it is also retained when the Y group is in the 7-position[313]. This is believed[314] to be an indication that the minimum distance between the nitrogen atoms required for antileukaemic activity must be about 18 Å. When the benzene rings in the biphenylene group are fixed by a methylene bridge



the activity disappears[313].

The study of the activity of the most effective preparations of the type under consideration against various cancer tumours showed that they do not suppress carcinoma 180 and the spontaneous cancer of mammary glands. However, a distinct suppression of the tumour was observed in the case of lymphosarcoma induced by methylcholanthrene[311].

The activity of many quinolinium salts was studied by the method involving the suppression of the growth of a KB tissue culture[265,266,268,269,272,273,288,314,315].

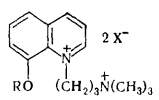
c. Other Radiomimetic Properties

Other radiomimetic properties of quinolinium salts have been investigated very little. There are reports of a mutagenic activity by compound (XXXIII), which is also known to be carcinogenic. It induces the mutation of strain B of *E. coli*[316] and *Saccharomyces cerevisiae*[317-319]. When the embryos of *Tritonia alpestris* and *Caenopus laevis* are treated in an early stage of development with preparation (XXXIII) at concentrations in the range 0.001 to 0.0001%, an abnormal course of development takes place (deformations, proliferation of tissues, and high mitotic activity), similar to the effect of X-rays at a dose of 120 to 500 roentgens[320].

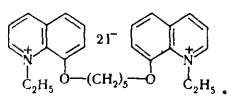
V. EFFECT OF QUINOLINIUM SALTS ON THE NEUROMUSCULAR SYSTEM AND ENZYMES

The effect of monoquaternary quinolinium salts on the neuromuscular system has been known for a long time. For example, Bamberger[321] reported in 1887 that *N*-phenylacylquinolinium bromide has a curare-like activity. However, these properties were investigated in greater detail much later. Schneider[322] and Denys and Levy[323] showed that 1-methyl-5,6-benzoquinolinium iodide is twice as active as eserine in suppressing the effect of acetylcholinesterase, but is slightly less active than Prostigmine;

it inhibits pseudocholinesterase more than the specific enzyme. The isomeric 1-methyl-7,8-benzoquinolinium iodide inhibits equally both acetylcholinesterases. High concentrations of the first preparation suppress the effect of acetylcholine on muscles. 1-(2'-Phenylcarbamoyloxyethyl)quinolinium iodide[324], 3-(diethoxyphosphinyloxy)-1-methylquinolinium methosulphate[325], and acetoxyquinolinium salts[326] also exhibit an antiacetylcholinesterase activity, 3-acetyl-1-methylquinolinium iodide being more active than the isomer containing the acetoxy-group in the 8-position of the quinoline ring. In a study of the effect of various quaternary ammonium salts on the rectus abdominis muscle, Iordache[327] found that 1-allylquinolinium bromide sensitises it with respect to acetylcholine. Quaternary salts of 8-alkoxyquinolinium have an analgesic effect[328]. In experiments on animals, 1-allyl-8-ethoxy- and 1-allyl-8-propoxy-quinolinium bromides showed a very satisfactory activity. 8-Hydroxy-1-methylquinolinium methosulphate has an analgesic effect in the treatment of the eye, associated with its ganglion-blocking activity[329]. Austin et al.[162] studied the curare-like activity of compound (X). It proved to be only twice as weak as (+)-curarine. Werner[330] suggested the use of quaternary quinolinium salts with a dioxanylalkyl residue at the nitrogen heteroatom as sympathomimetic preparations. Surrey and coworkers[331,332] synthesised mono- and di-quaternary salts of 4-dialkylaminoalkylquinolinium with hypotensive activity. Among other diquaternary quinolinium salts with hypotensive activity, mention should be made of the trypanocidal preparation antrycide (XVIII), which reduces blood pressure when administered in doses considerably below the therapeutic amount[333] and also causes the secretion of histamine[334]. The effect of compound (XVIII) on the cardiac activity of healthy cattle and cattle suffering from piroplasmosis has also been studied[335]. Gray and coworkers[336,337] synthesised and investigated diquaternary salts of type (LXXVIII).



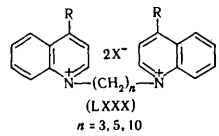
(LXXVIII)
(R = H, CH_3)



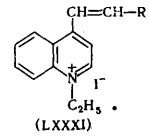
(LXXIX)

Many of these also exhibit a hypotensive activity. Quininebis(allyl bromide), which is also a diquaternary quinolinium salt, has an antiacetylcholine activity of the type of curare[337].

Bovet and coworkers[338,339] began an intensive study of the pharmacodynamic properties of bisquinolinium salts and in 1946 published data on the curare-like activity of compound (LXXIX) (RP-3381). Eserine and Prostigmine are antagonists of this preparation. Apart from the curare-like activity, compound (LXXIX) exhibits only physostigmine-like activity[340-342], inhibits pseudocholinesterase (but not the specific enzyme)[343,344], causes the contraction of the bronchi in guinea-pigs[345], and lowers the blood pressure in dogs[346]. Huidobro and Ugarte[347,348] studied the mechanism of the curare-like activity of the preparation. A number of patents have been obtained for preparations similar to compound (LXXIX)[349,350]. Barlow and coworkers[351,352] studied the curare-like activity of bisquinolinium salts of type (LXXX, R = H) with 3, 5, and 10 ethylene groups.



(LXXX)
n = 3, 5, 10



(LXXXI)

All three homologues exhibit a moderate curare-like activity and the highest member of the group shows in addition a considerable antiacetylcholinesterase activity. Reduction of the quinoline ring and the introduction of more than one OCH_3 group enhance the curare-like activity of the preparation[353-355]. Bhattacharya and Sen[356] studied compound (LXXX) with 20 methylene groups (n = 20). The preparation is antigonistic to acetylcholine but does not eliminate the effect of histamine and nicotine. Vyrbanova and Ivanov[357] studied the curare-like and anticholinesterase activity of compounds of type (LXXX, R = CH_3, n = 3–6, 8, or 10, X = Br). It was established that at a concentration of 10^{-6} M the anticholinesterase activity increases with the length of the polymethylene chain, but members with an odd number of CH_2 groups (n = 3 or 5) are somewhat more active. At the same time the curare-like activity is most pronounced in compounds with n = 4 and 6, i.e. those with the lowest anticholinesterase activity[358].

In a study of the effects of these compounds on the control of movement in rabbits, it was found that at a dose of 1 mg kg^{-1}, compounds with n = 3 and n = 10 enhance the control, while all other homologues lower it. The maximum decrease is observed with n = 5.[359]

The toxicity of polymethylenebislepidinium bromides (LXXX, R = CH_3, X = Br) is insignificant[360] and varies in parallel with their effect on subordination, reaching a maximum at n = 5. The compounds do not exhibit a local irritant activity when introduced into the conjunctival sac and also on subcutaneous and intramuscular administration.

Tarakhovs'kii and coworkers[361,362] showed that pentamethylenebisquinolinium bromide (pentaquinomethonium) (LXXX, R = H, n = 5, X = Br) lowers the blood pressure in experiments on cats and dogs in doses of 1–10 mg kg^{-1} and blocks the transmission of nerve impulses both via the sympathetic and parasympathetic ganglia of the vegetative nervous system. The preparation also exhibits a central cholinolytic activity. Kimenis[363,364] studied the effect of the quinolinium analogue of ditilin (preparation DS-3) on the neuromuscular system of warm-blooded animals. In its curare-like activity the compound is inferior to ditilin, but the duration of its action is longer. The antiacetylcholinesterase activity of compound DS-3 exceeds by severalfold that of proserene and is less toxic by a factor of 8.

At attempt has been made to establish a relation between the curare-like activity and the magnitude of the cationic charge of the nitrogen atoms. The ability of conjugated system to distribute the charge associated with the nitrogen atom leads to a decrease of the curare-like activity[365]. Maximum curare-like activity is observed with compounds in which the distance between the two positively charged nitrogen atoms is 15 Å.[366]

Certain quinolinium dyes also exhibit an appreciable activity. Although Brooker and Sweet[71] reported that cyanine dyes do not have an appreciable effect on α-amino-acid oxidase, cytochrome oxidase, succinate dehydrogenase glucosedehydrogenase, and glyoxalase and Ciaccio et al.[367] found that (LXX) and (LXX) are inactive in relation to lactate dehydrogenase and α-glycerolphosphate dehydrogenase and do not inhibit glycolysis, Hase and coworkers[368,369] showed that many cyanine and styryl dyes of the quinolinium series inhibit acetylcholinesterase.

It has also been established that the non-purified preparation (XVII) (the so called Lumin) has a marked influence on the respiration of animals[370-372]. Fuzimoto[373] investigated quinolinium dyes of type [LXXXI, R = piperidyl, $N(CH_3)_2$, $N(CH_3)C_6H_5$]. The preparations cause a dilatation of blood vessels and accelerate the peristalsis of the intestine. Many quinocyanine and quinostyryl dyes inhibit aerobic glycolysis[293,374]. Ogura et al.[375] made a kinetic study of the mechanism of the inhibition of catalase by compound (XVII).

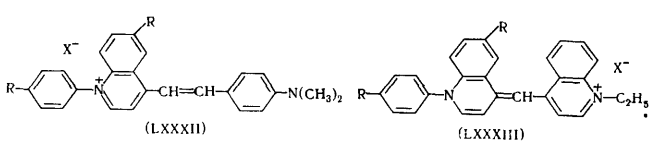
Recently styrylquinolinium compounds have also been investigated as inhibitors of choline acetyltransferase[376] and monoamine oxidase[377].

Among the numerous reviews dealing with the effect of quaternary ammonium salts on the neuromuscular system, only two[378,379] consider briefly bisquinolinium salts in this respect, on the basis of the literature between 1946 and 1951.

VI. QUINOLINIUM SALTS AS REGULATORS OF PLANT GROWTH AND DEVELOPMENT

The properties of quinolinium salts as regulators of plant growth began to be studied only 20 years ago by Japanese investigators. In 1949 Fujisawa and Ohba[380,381] made patent applications for the use of monomethinecyanine dyes, and particularly bis-(1-ethylquinolin-2-yl)-monomethinecyanine iodide, as stimulators of seed germination; Ogata and Shingu[382] studied the activity of a number of quaternary heterocyclic salts and cyanine dyes synthesised from them in tests on peas. The trinuclear quinocyanine dye (XVII) was investigated as a regulator of fungal growth[383]. The growth of fungi is stimulated when the preparation is diluted to 1 : 100 000–1 : 10 000 000 and is inhibited at a dilution of 1 : 10 000. The stimulation of the growth of certain medicinal plants by purified compound (XVII) was also investigated[384]. In the middle 1960's the work of Soviet scientists in this field was published. A method was proposed for increasing the crop of peas (to the extent of 117%) by soaking the seeds before sowing in 0.001% aqueous solution of (1,2-diphenylquinolin-4-yl). (1'-ethylquinolin-4'-yl)monomethinecyanine perchlorate[385]. Wheat grains treated with 0.001% solution of 4-*p*-dimethylaminostyryl-1,2-diphenylquinolinium perchlorate resulted in an increase of the growth of the green mass of wheat by the hydroponic method by 124%,[386] and treatment with a solution of 4-*p*-dimethylaminostyryl-1-β-naphthyl-5,6-benzoquinolinium perchlorate gave an increase of 117%.[387]

In a study of the activity of monomethinecyanine and styryl dyes derived from *N*-aryl-lepidinium on the growth of cucumbers and hemp[388], it was found that the dyes at a concentration of 0.01% inhibit the germination of the seeds or do not have an appreciable effect. The optimum concentrations proved to be 0.0001 and 0.00001% for cucumbers and 0.00001% for hemp. Experiments showed that lepidinium derivatives have unequal effects on the growth of various plant species.



(LXXXII) (LXXXIII)

Here R = H (a), CH_3 (b), OH (c), $OCOCH_3$ (d), or OCH_3 (e).

Thus in the case of cucumber seeds the best growth stimulating activity was shown by compounds (LXXXII, e), and (LXXXIII, b) and satisfactory activity was also shown by compounds (LXXXII, a, d) and (LXXXIII, a, c, e). In an identical experiment with hemp, the best stimulators proved to be (LXXXII, c, d) and (LXXXIII, a, c, d,). It is interesting to note that in experiments with cucumbers the preparations showed a somewhat lower activity than potassium heteroauxinate. However, in experiments with hemp, the latter proved less active than the lepidinium derivatives. Field tests on hemp showed that certain preparations increase the length of the internodal sections, enhance the saturation of tissues with water, and promote the accumulation of protein[388,389].

Preparations of type (LXXXII) and (LXXXIII) were also tested in the growth of tree seedlings, in particular fir seedlings[390]. Compounds (LXXXII, a, c, e,), (LXXXIII, a, c,), certain styryl derivatives, and monomethines synthesised from 1-aryl-5,6-benzolepidinium salts, and also Pinacyanol iodide [bis-(1-ethylquinolin-2-yl)trimethylcyanine iodide] proved to be the most active. It is interesting that, in order to stimulate the growth of tree seedlings, it is necessary to employ more concentrated solutions (0.005 and 0.001%). More water-soluble preparations (LXXX, LXXXII, a, X = Cl) and Pinacyanol chloride were tested *in vitro* on Belotserkovskaya 23 and Meris Widgen [spelling uncertain (Ed. of Translation)] wheat grains. The experiments showed that the activity of the preparations is almost equal to that of (LXXXIV) as regards the enhancement of the growth of the part of the plant above ground but is somewhat inferior as regards the stimulation of root growth[391]. The growth stimulating activity of compound (LXXXV) was also tested on leguminous plants[392]. In field tests the preparation increased the content of chlorophylls, reducing sugars, and the dry matter in the plant leaves during the flowering phase. The preparation is somewhat more active than (XXXIV). It increased the crop of broad beans by 108% and that of French beans by 114.6%.

In studies of the growth stimulating activity of dyes synthesised from 6-hydroxy-1-methyllepidinium chloride[393] in the initial phase of the growth of Belotserkovskaya 23 wheat and Nadezhnyi oats, a high activity of 1-methyl-4-*p*-dimethylaminostyryl- and 4-*p*-hydroxy-*m*-methoxystyryl-1-methyl-substituted 6-hydroxylepidinium chlorides was noted, being equal to that of compound (XXXIV).

Determination of the Number of Active Centres and Growth Rate Constants in the Catalytic Polymerisation of α-Alkenes

Yu.I.Ermakov and V.A.Zakharov

The reliability of different methods for determining the number of active centres (n) and calculating the growth rate constants (k_g) in the catalytic polymerisation of α-alkenes is discussed. The values of n and k_g obtained for different catalytic systems are given. Information on the dependence of the number of growth centres and the rate constants of the separate steps (primarily the growth rate constants) on the composition of the catalyst, its method of preparation, and the conditions of polymerisation can yield important conclusions regarding the mechanism of polymerisation and the composition of the active centres. The bibliography contains 113 references.

I. INTRODUCTION

In the study of radical polymerisation, the rate constants of the elementary steps are now being measured. The problem of determining the kinetic characteristics of the elementary steps of catalytic polymerisation is only just being tackled. The complexity of the study of the elementary steps in this instance is associated with the fact that the separate reactions involved in catalytic polymerisation are not in general elementary steps in the sense in which this term is used in the theory of absolute reaction rates, but consist of many elementary steps. The study of the kinetics of polymerisation in the presence of homogeneous and heterogeneous catalysts is still at the stage where the rate constants of the separate reactions making up the overall process (chain growth, chain transfer, etc.) are being determined.

Since in the description of catalytic polymerisation, slight differences are noted in the interpretation of a number of terms, it is appropriate to explain the terminology used in the present paper.

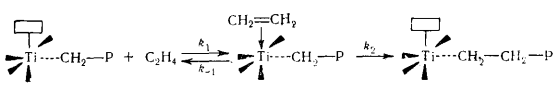
Catalytic polymerisation can be defined as a process in which a catalyst takes part in the formation of the activated complexes for the elementary steps of growth. The growth centre in catalytic polymerisation can be defined as the active bond between the catalyst and the growing polymer molecule, through which the monomer molecule is brought into the chain growth reaction, together with those atoms of the catalyst which take part in the formation of the activated complexes during growth. In heterogeneous catalysts, the growth centre is a surface compound.

In contrast to the situation in heterogeneous-catalytic reactions involving the production of non-polymeric products, the concept of active centres acquires particular

importance in heterogeneous catalytic polymerisation. All stages in the polymerisation involve the participation of localised growth centres; the rates of the elementary steps should thus be influenced primarily by the local properties of the growth centre—the properties of the active bond and the atom or group of atoms joined to the terminal atom of the growing polymer chain and the properties of the immediate environment of the growth centre. Early suggestions[1,2] regarding the mechanism of heterogeneous catalytic polymerisation, in which it was assumed that the end of the growing polymer chain is able, during growth, to move over the surface, which was assumed to have a regular structure, were not confirmed by detailed study of the mechanism of polymerisation on heterogeneous catalysts.

For homogeneous polymerisation, in some instances it is difficult to draw a clear distinction between a catalytic process and a process taking place by an ionic polymerisation mechanism. In general, the reactivity of the growth centre and the structure of the polymer are influenced by the composition of the catalytic complex; a free-ion mechanism may be realised in polymerisation in polar media[3].

A characteristic feature of catalytic polymerisation, which distinguishes it from radical polymerisation, is that the individual reactions are generally complex and consist of several successive elementary steps (in other words, more than one activated complex is formed in the reaction). For example, it is usually postulated that in the catalytic polymerisation of alkenes, growth takes place in two stages: in the first, an unstable π-complex of the alkene with a metal with variable valency is formed, and in the second a *cis*-insertion reaction takes place; for the polymerisation of ethylene on Ziegler–Natta catalysts, this scheme can be represented as follows (the rectangle represents a vacant coordination position, and P the polymer chain):



The catalytic polymerisation of alkenes has been most extensively studied for the determination of the kinetic parameters of the individual steps. The rate constants obtained for the individual reactions, however, are usually not the absolute rate constants of the elementary steps, and their physical significance depends on the way in which the individual reaction takes place. For example, for a growth reaction in which two activated complexes are formed (see above scheme), the growth rate constant k_g depends on the rate constants of these steps:

$$k_g = \frac{k_1 k_2}{k_2 + k_{-1} + k_1 \cdot [M]} \qquad (1)$$

where [M] is the concentration of the monomer, and k_1, k_{-1}, and k_2 the rate constants of the corresponding elementary steps.

In this connection, care must be taken when applying the theory of absolute reaction rates to the interpretation of the rate constants of the separate stages of catalytic polymerisation, and also when examining various correlations between these constants and the physical characteristics of the catalyst. Despite this, however, the determination of the rate constants of the separate reactions in polymerisation is of considerable importance in connection with the problem of predicting catalytic activity.

The activity A of a polymerisation catalyst is proportional to the number of growth centres n and the growth rate constant k_g:

$$A \sim k_g \cdot n$$

In catalytic polymerisation it is possible and necessary to distinguish clearly two factors influencing the catalytic activity: a) the number of growth centres, which is determined by the original state of the catalyst and the reactions taking place in the formation of the growth centres (separated from possible reactions involving subsequent deactivation of the growth centres by reaction with components of the reaction medium); and b) the growth rate constants, that is the reactivity of a single growth centre.

To develop methods for controlling catalyst activity, it is necessary to study the influence of these factors separately. The determination of the rate constants of reactions limiting the growth of a polymer chain is related to the problem of controlling the molecular weight of the polymer.

The determination of the kinetic characteristics of the growth centres also makes it possible to reach a number of important conclusions regarding the mechanism of catalytic polymerisation. The direct use of such quantities as the rate of polymerisation (V) and the degree of polymerisation ($\bar{P}$), cannot give unambiguous information regarding the nature of the individual elementary reactions, since V and $\bar{P}$ are complex quantities which depend on the ratio of the rates of initiation, growth, transfer, and termination of the chains.

The results of the determination of the number of growth centres in catalytic polymerisation have been reviewed briefly by Boor[4]. At the Budapest Symposium on Macromolecular Chemistry (August 1969), Kern[5] described the determination of the number of growth centres for Ziegler–Natta catalysts (chiefly by a method involving the termination of the polymerisation by a radioactive alcohol), but this paper similarly does not contain a sufficiently complete review of the results obtained in the important field of the determination of the kinetic characteristics of growth centres in catalytic polymerisation.

It is possible to distinguish three basic groups of methods used for the determination of the kinetic characteristics of growth in catalytic polymerisation.

1. Methods based on the determination of the dependence of V and $\bar{P}$ on the duration and conditions of the reaction. These will subsequently be referred to conditionally as kinetic methods.
2. The inhibition method, in which the number of growth centres is calculated from the quantity of added inhibitor which brings about complete termination of polymerisation.
3. Methods based on the labelling of the growing polymer molecule.

II. KINETIC METHODS

These methods are based on the study of the dependence of the rate of polymerisation and the molecular weight of the polymer on the conditions of polymerisation. For processes in which the number of growth centres is independent of time (steady-state polymerisation), methods based on the use of the dependence of V on the concentrations of the reagents and the dependence of $\bar{P}$ on time and the concentrations of the reagents have been proposed for the calculation of the rate constants. For processes in

which the number of growth centres changes with time (non-steady-state polymerisation), the time dependence of V is also used in the calculation of rate constants.

1. Steady-state Polymerisation Kinetics

The method of calculating the rate constants of the separate reactions from the dependence of V and $\bar{P}$ on the concentrations of the reagents has been described by Chirkov and coworkers [6] and Natta and coworkers [7]. These authors used a comparatively simple kinetic scheme, based on the following assumptions: a) the total number of active centres remains constant throughout the process; b) the initiation involves the attachment of the first monomer molecule to the active centre; c) transfer takes place with the participation of the monomer, impurities, components of the catalyst, and spontaneously; d) transfer is followed by regeneration of the active centre.

In accordance with the foregoing:

$$n_0 = n_g + n_i \qquad (2)$$

where n_0 is the total number of active centres in the catalyst, n_g the number of active centres joined to a growing polymer molecule, and n_i the number of centres in a state of temporary deactivation. The steady-state conditions for this scheme gave the dependence of V and $\bar{P}$ on the concentrations of the reagents:

$$\frac{[M]}{V} = \frac{1}{k_g \cdot n_0} + \frac{k_M}{k_g \cdot k_i \cdot n_0} + \frac{\sum_{j-1} k_j \cdot c_j^a}{k_g \cdot k_i \cdot n_0} \cdot \frac{1}{[M]} \qquad (3)$$

$$\frac{1}{\bar{P}_n} = \frac{V_0}{V_g} = \frac{k_M}{k_g} + \frac{\sum_{j-1} k_j \cdot c_j^a}{k_g} \cdot \frac{1}{[M]} \qquad (4)$$

where V_g is the rate of growth, V_0 the rate of transfer, k_j the rate constant for transfer involving the agent j, k_M the rate constant for transfer involving the monomer, k_i the initiation rate constant, c_j the concentration of transfer agent j; [M] the concentration of monomer, and n_0 the total number of active centres.

The experimental dependence of V and $\bar{P}$ on the concentrations of the reagents can be used to calculate products of the rate constants of the separate reactions and the concentrations of the active centres, but this method does not yield absolute values of the rate constants. This method has been used to study the polymerisation of propene on heterogeneous catalytic systems based on $TiCl_3$ and VCl_3 combined with various organometallic components [3-17] (see Table 1). It should be noted that the correct application of this method requires the use of the experimental values of the number-average degree of polymerisation ($\bar{P}_n$). In the calculations, however, the weight-average factor ($\bar{P}_w$) is usually employed, with the assumption that the polydispersion factor γ ($\gamma = \bar{P}_w/\bar{P}_n$) remains constant over the range of values of the parameters studied. The applicability of this assumption will be discussed below. Because of the assumptions made in the derivation of the kinetic equations and the calculation, the results of the calculation are approximate and suitable only for the comparative estimation of the efficiency of chain transfer agents for catalytic systems with similar compositions.

A method for calculating the rate constants of the separate reactions for steady-state polymerisation, based on an analysis of the dependence of the molecular weight

on the duration of polymerisation, was proposed by Natta and coworkers [8,9,31,35]. This method uses the following expression for the number-average degree of polymerisation:

$$\overline{P}_n = \frac{Q}{N} = \frac{\int_0^\tau k_g \cdot n \cdot [M] \cdot d\tau}{n + \int_0^\tau \sum_j k_j \cdot n \cdot c_j^a \, d\tau} \qquad (5)$$

where N is the number of polymer molecules formed in polymerisation for time τ, Q the yield of polymer, k_j the rate constant for transfer involving agent j, and [M] the concentration of monomer.

For steady-state systems (n = const), the rate constants can be calculated from the linear dependence of $1/\overline{P}_n$ on $1/\tau$, which follows from Eqn.(5). With values of the polymerisation factor $\overline{P}_V$, calculated from measurements of the characteristic viscosity, the authors cited [8,9] used the equation

$$\frac{1}{\overline{P}_V} = \frac{1}{k'_g[M]} \cdot \frac{1}{\tau} + \frac{\sum_j k_j \cdot c_j^a}{k'_g \cdot [M]} \qquad (6)$$

where k'_g is the viscosimetric-average rate constant for chain growth, taken as a measure of the activity of one growth centre, and $k'_g = k_g/\gamma$, where γ is the polydispersion factor. The method based on Eqn.(5) makes it possible in principle to determine the absolute values of the kinetic parameters of growth.

Table 2. Determination of the kinetic parameters of growth for the catalytic polymerisation of α-butene at 0° (method of calculation I-3, see Table 1).

Catalytic system	k'_g[M], s^{-1}	E^*_g, kcal $mole^{-1}$	Catalytic system	k'_g[M], s^{-1}	E^*_g, kcal $mole^{-1}$
VCl_3 + $AlEt_3$ / $BeEt_2$	3100	2.3	$TiCl_3$ + $AlEt_3$	280	—

*E_g is the activation energy of growth, calculated from the temperature dependence of k_g.

This method has been used [8,9] to determine k_g for the polymerisation of α-butene on catalytic systems based on VCl_3 and different crystalline modifications of $TiCl_3$ (see Table 2). The dependence of P_V on τ was determined for comparatively small polymerisation times (30–600 s). The value of k_g depended on the form of the compound of the metal with variable valency, but was almost independent of the organometallic co-catalyst, although the replacement of the co-catalyst influenced the overall rate of the process, the stereoregularity, and the molecular weight of the polymer.

The Italian authors [9] used the same method to study the polymerisation of propene into a syndiotactic polymer on the VCl_4 + $AlEt_2Cl$ catalytic system in the presence of anisole. The graphs giving the dependence of the stereospecificity of the catalysts and the rate of polymerisation on the concentration of anisole showed maxima; the value of k'_g decreased considerably when anisole was added and was independent of its concentration in the system. The Italian authors [9] introduced into the expression for the "viscosimetric-average" growth rate constant a coefficient making allowance for the change in the number of growth centres during the polymerisation, but the choice of value for this coefficient was somewhat arbitrary.

A method for determining the kinetic parameters for steady-state catalytic systems, based on an analysis of the dependence of $\overline{P}_V$ on τ, was used [36,37] for the polymerisation of ethylene (the γ-$TiCl_3$ + $AlEt_2Cl$ system) in the presence and absence of hydrogen (see Table 3). After the initial non-steady-state period, the duration of which was not correlated with any of the parameters of the reaction, the rate of polymerisation remained stable for a prolonged period. Determination of the polydispersion of several polymers obtained under different conditions showed that the value of γ varies from 7 to 16. A constant value of γ equal to 10 was taken for the calculations. It was recognised [37] that the numerical values obtained for the rate constants are only approximate, because of the assumptions made and the limited accuracy of the measurement of the characteristic viscosity for polymers with high molecular weight. This method was also used [27,28] for the polymerisation of propene in the presence of the α-$TiCl_3$ + $AlEt_3$ system, although this system is not a steady-state system: the rate of polymerisation in the initial period increased until a constant value was established. The calculation based on the dependence of $\overline{P}_V$

and $\bar{P}_n$ on τ showed a decrease in the concentration of active centres during the polymerisation. The probable reason for this contradiction is that in this instance the condition for applicability of the method used to calculate the rate constants (n = const) was not satisfied.

2. Non-steady-state Kinetics

A number of authors have examined methods for calculating n and k_g for catalytic systems with variable activity from the dependence of the rate of polymerisation and the yield of polymer (Q) on time (τ). The dependence of V and Q on τ for one of the possible kinetic schemes for non-steady-state polymerisation has been derived [50]. For the interpretation of the time dependence of the number of growth centres in the kinetic scheme, the deactivation of the active centres in their reactions with monomers, with one another, and spontaneously were examined. The rate constants for the separate reactions involved in the polymerisation of propene were calculated [17] from the dependence of V on τ for the $VCl_3 + AlR_3$ system. In the interpretation of the non-steady-state behaviour of the system at elevated temperatures and high Al/V ratios, the kinetic scheme for steady-state polymerisation, examined earlier [14-16], was supplemented by deactivation of the catalyst, which, in the opinion of the authors cited, is associated with the extensive reduction of vanadium by the organoaluminium compound. By assuming that the period of accelerating rate of polymerisation is due to slow initiation with rate constant k_i, the product $k_i k_g n$ was calculated. Comparison of this quantity with the values of $k_i n$ and $k_g n$ found under conditions of steady-state behaviour of the system [16], made it possible to calculate n and the values of the rate constants for the separate reactions (Table 1) with an accuracy equal to that of γ.

A variant of the kinetic method of determining the constants of the elementary steps in non-steady-state catalytic polymerisation from the dependence of the rate of polymerisation on the conditions of the process was described by Ermakov and coworkers [51]. Its unique feature is that the description of the kinetics is not taken as far as the overall kinetic equation in integral form, which either includes a considerable number of variables, or requires for its simplification a large number of assumptions, but is represented in the form of a system of differential equations, derived from the kinetic scheme adopted for the process. This mathematical description is studied by means of an electronic computer. The mathematical description of the polymerisation of ethylene on a chromium oxide catalyst, compiled on the basis of a kinetic scheme involving initiation, growth, transfer, and deactivation of the catalyst was studied [51]. This kinetic scheme was proposed on the basis of data obtained in a study of the kinetics of the process [52]. The rate constants for the separate reactions were adjusted to obtain a dependence of V on time, the concentration of the catalyst, and the monomer which agreed with experiment. The chief limitations of this method are the indefinite nature of the choice of kinetic scheme and the ambiguous nature of the numerical solution of the system of equations. Considerable difficulties also arise in the selection of the initial conditions: the concentrations of the active component, the chain transfer agent, and the catalyst deactivator.

A method for determining the rate constants of the separate reactions from the dependence of $\bar{P}_V$ on τ for non-steady-state polymerisation was proposed by Matkovskii [41]. In order to apply this method it is necessary to establish, in a reaction vessel with ideal mixing, a constant concentration of active centres by selection of the rates of supply of catalyst and removal of polymer and catalyst. Under steady-state conditions, the rate constants can in principle be calculated by the methods proposed for steady-state catalytic systems [6,7,13]. For one of the probable kinetic schemes, equations relating V to the rate constants of the separate reactions, the concentrations of the reagents, and the amount of material exchange with the external medium, and also equations relating the mean time (τ_{mean}) for which the reaction mixture is in the reaction vessel to the concentration of the active centres and the rate constants of the deactivation processes, were derived. For a certain intensity of mass exchange, a linear relationship is observed between τ_{mean} and $\bar{P}_V$; this dependence was used to calculate n and k_g for the polymerisation of ethylene in the presence of the $VOCl_3 + Al(i\text{-}Bu)_3$ system (see Table 3).

An approach to the determination of the rate constants of the separate reactions on the basis of data on the dependence of V, Q, and $\bar{P}_n$ on the duration of polymerisation has been described [46,53,54]. For non-steady-state polymerisation, when chain transfer involving the monomer and spontaneous chain transfer take place, Eqn.(3) can be rewritten in the form [53]

$$\frac{1}{\bar{P}_n} = \frac{1}{k_g \cdot [M]} \cdot \frac{V}{Q} + \frac{k_M}{k_g} + \frac{k_S}{k_g \cdot [M]} \qquad (7)$$

(k_S is the rate constant for the spontaneous transfer).

Expression (7) has a relatively simple form, since it does not include the rate constants for initiation and deactivation of the growth centres. The change in the number of growth centres with time as a consequence of these reactions is included in implicit form in the ratio V/Q. Thus Eqn.(7) gives the dependence of the molecular weight on the duration of polymerisation, resulting from the change in the number of growth centres. This method can be used to determine the values of k_g (with an accuracy equal to that of the coefficient γ), k_M, and k_S. When this method was used to study the polymerisation of ethylene on a chromium oxide catalyst [46,53], a decrease in the quantity $\gamma . k_g$ with decrease in the temperature of polymerisation was observed, and this was attributed to a decrease in the polydispersion of the polymer (data on the possibility of narrowing the molecular weight distributation of a polymer by decreasing the temperature of polymerisation on oxide catalysts have been published [55]). This method is also used for the polymerisation of ethylene in the presence of a soluble catalytic system [44].

3. Applicability of Kinetic Methods

The following possible sources of error in the determination of the absolute values of n and k_g by kinetic methods may be noted.

1. Lack of correspondence between the kinetic scheme adopted and the actual mechanism of the process. For non-steady-state polymerisation, when a method based on the analysis of the dependence of V and $\bar{P}$ on τ is used, the choice between different mechanisms of chain transfer and termination is somewhat arbitrary; different authors have

proposed different transfer and termination reactions for catalytic systems with similar compositions [13,18,24,30,42,56-60]. For steady-state polymerisation, k_g can be calculated on the basis of the linear dependence of $1/\bar{P}_V$ on $1/\tau$ if the catalytic system is suitable from the start of polymerisation. Most authors who have used this method, however, do not give kinetic curves justifying the assumption that the number of active centres is constant in the initial period of polymerisation for which the dependence of $\bar{P}_V$ on τ is determined. When methods based on the analysis of the dependence of $\bar{P}_V$ on τ are used, errors may arise because processes involving the temporary deactivation of active centres, not associated with rupture of the active chain, are not taken into account in the derivation of the equations (6) and (7) used in the calculations. When these processes take place, the growth of an individual molecule is interrupted periodically; the temporary interruption of growth ("falling asleep") leads to a decrease in the overall rate of polymerisation, but does not increase the number of polymeric molecules.

2. Use of $\bar{P}_V$ instead of $\bar{P}_n$. Most authors who have used kinetic methods have calculated the number-average polymerisation factor ($\bar{P}_n$) from the results of the measurement of the characteristic viscosity (η). In this instance, errors may arise as a consequence of errors in the determination of η for polymers with high molecular weight, and also because of the arbitrary nature of the selection of the method for calculating $\bar{P}_V$ from η. It is known that even for narrow fractions of linear polyethylene [61], the equations proposed by different authors, for the same values of the viscosity, give molecular weight values which differ considerably. Moreover, it appears that one of the fundamental assumptions which is usually made when kinetic methods are used—the assumption that the polydispersion of the polymer (the factor $\gamma = \bar{P}_V/\bar{P}_n$) is independent of the conditions of the process—is not always satisfied. It should be noted that the experimental determination of the quantity γ for polyalkenes with high molecular weight involves considerable difficulty, and published data on this topic are somewhat contradictory. For soluble catalytic systems, a narrower molecular weight distribution is observed, but even for these systems, the values of γ given by different authors [20,62-64] vary from 1.5 to 6, and Chien [62] points out that the quantity γ shows a complex dependence on τ, increases with decrease in temperature, and changes with change in the catalyst concentration and the Ti/Al ratio. It has been noted [63,64] that γ depends on the concentration of the catalyst and monomer, and the nature of the solvent. For heterogeneous catalysts, the polymers obtained have a wider molecular weight distribution; according to the data of various authors [20,27,37,62,65,66], the value of γ may vary for a given catalytic system with change in the duration and conditions of polymerisation. A change in the width of the molecular weight distribution is even more probable with change in the chemical composition of the catalyst (either the metal with variable valency [66,67] or the organometallic component [68]). According to some authors [69], the polydispersion decreases considerably when hydrogen is used to control the molecular weight of polyethylene obtained on Ziegler–Natta catalysts.

Thus the absolute values of the rate constants of the separate reactions and the number of active centres determined by kinetic methods cannot be taken as sufficiently reliable. Particularly large errors may arise when catalysts with different chemical compositions are compared.

III. INHIBITION METHOD

A number of authors [29,30,45,70], for the estimation of a number of active centres on heterogeneous catalytic systems in the polymerisation of α-alkenes, have used the inhibition method, which is often used for radical polymerisation. In this method, the concentration of growth centres is estimated from the quantity of inhibitor required for the complete or partial termination of polymerisation.

Carbon tetrachloride [45] and allyl alcohol [70] have been used to inhibit polymerisation on chromium oxide catalysts; the inhibiting action of CCl_4 was found to be much stronger. The inhibition method has also been used [29] to determine the concentration of active centres in the polymerisation of propene on an α-$TiCl_3$ + $AlEt_3$ catalyst. Before the polymerisation, the titanium trichloride was treated with ethanol, and this led to the production of an induction period during polymerisation. Comparison of the initial rates of polymerisation in the "pure" experiments and the experiments in the presence of different quantities of alcohol and catalyst makes it possible, in the opinion of the authors cited, to calculate the concentration of growth centres (Table 1). As in the work with CCl_4, [45] it is assumed that the inhibition of one active centre requires one molecule of alcohol, and allowance is not made for the consumption of alcohol in possible side reactions or as a result of adsorption on the surface of the catalyst, not associated with the catalytic activity. This may lead to high values for the measured number of active centres.

In general it may be noted that the inhibition method in catalytic polymerisation provides only limited possibilities, since it is difficult to select an inhibitor which is used up only in deactivation of the growth centres and which is not used up in reaction with the surface of the catalyst or with components of the reaction system.

IV. METHODS BASED ON LABELLING OF THE POLYMERIC MOLECULE

A tracer can be introduced into a polymeric molecule either at the initiation stage (the use of labelled catalyst components) or during the termination of growth (the stopper method). In the formation of a polymer with high molecular weight, in order to attain the necessary sensitivity in the determination of the number of labelled polymer molecules, it is best to use radioactive isotopes as tracers. Iodine has been used as a non-radioactive tracer for the termination of catalytic polymerisation [6,30,71]. Compounds labelled with carbon-14 and tritium are most frequently used in the study of catalytic polymerisation. Chlorine-36, iodine-131, and zinc-65 have also been used.

1. Use of Labelled Catalyst Components as Tracers

Natta's school [26,31,78] and Chien [24,42] determined the kinetic parameters of growth and initiation from the radioactivity of a polymer obtained in the presence of a labelled catalyst. For heterogeneous systems based on $TiCl_3$, the number of active centres [26,31,72] was determined by two methods: a) by adsorption of labelled alkylaluminium on $TiCl_3$ with subsequent analysis of the reaction products for radioactivity; and b) by carrying out the polymerisation in the presence of labelled trialkylaluminium.

The use of the adsorption method made it possible to establish that the number of labelled alkyl groups on the

surface of titanium trichloride depends on the temperature of adsorption, the conditions of the subsequent washing of the catalyst with a hydrocarbon solvent, and the nature of the organometallic compound. The radioactivity of polypropene obtained on a catalyst treated with labelled alkylaluminium was used to calculate the number of alkyl groups transferred to the polymer; this was taken to be equal to the number of active centres. The value found in this way for the number of active centres was less than or equal to the number of alkyl groups initially combined with the $TiCl_3$ surface. The adsorption method gives the number of active centres initially present on the catalyst surface (n_0). It may not correspond to the steady-state value of the concentration of active centres; this may change after the start of polymerisation and reach a certain constant steady-state value. To estimate the steady-state number of growth centres, use has been made of a method [31] based on the determination of the number of labelled ethyl groups in a polymer, obtained after polymerisation for different periods of time in the presence of free triethylaluminium labelled with ^{14}C. The calculation of the number of active centres from the concentration of labelled ethyl groups in the polymer was based on the assumption that the rate of chain transfer by triethylaluminium and the rate of growth are independent of the duration of polymerisation. Table 1 gives data on the determination of the kinetic parameters of growth [26,31] obtained by both methods.

In an evaluation of the results obtained by the two methods for determining n with a labelled catalyst, it was assumed [31] that the results obtained by the introduction of a labelled co-catalyst into the polymerisation system are more accurate, since when this method is used the influence of foreign radiochemical contamination is smaller and more effective allowance is made for the effect of transfer processes.

A labelled catalyst was also used by Chien [24] to study the kinetics of the polymerisation of propene. Before the reaction, titanium trichloride was treated with diethylaluminium chloride labelled with ^{14}C. An increase in the number of active centres with increase in the $TiCl_3$ concentration at a constant ratio of the titanium and aluminium components was observed; the number of active centres increased with increase in the concentration of $AlEt_2Cl$ at constant concentration of $TiCl_3$, and decreased with increase in temperature in the range 30–90°. Change in the pressure of the monomer had no influence on the concentration of the active centres. The calculated values of k_g were constant in experiments with different concentrations of the monomer, titanium trichloride, and diethylaluminium chloride, and for different yields of polymer (see Table 1).

2. Introduction of Tracers on Termination of Polymerisation

This method is based on the introduction, into the reaction system, of substances (stoppers) which terminate the polymerisation in such a way that a molecule of the substance, or part of it, is attached to the growing polymer chain. If the stopper reacts quantitatively with the growing polymer chains, the number of growth centres can be calculated from the concentration of tracer in the polymer. If however the polymerisation takes place in the kinetic range, the growth rate constants can be calculated from data on the number of growth centres, the rate of polymerisation, and the concentration of monomer.

The stoppers which have been used in anionic and anionic-coordination polymerisation include carbon dioxide labelled with ^{14}C, [73–76] acetic acid in which the active hydrogen was replaced by tritium [77,78], alcohols labelled with tritium in the hydroxyl group [18,19,23,25,38,73,74,79,80], and radioactive iodine [42]. Alcohols labelled with ^{14}C in the alkoxy group [73,81] have been used for cationic polymerisation.

The stopper method has been widely used to determine the number of growth centres in the polymerisation of α-alkenes on complex organometallic catalysts. In most instances, alcohols in which the hydroxyl hydrogen was replaced by tritium were used. This was first done by Feldman and Perry [38] in a study of the polymerisation of ethylene in the presence of the $TiCl_4 + AlEt_3$ system. This work was based on the assumption that if the active catalyst–carbon bond is polarised in such a way that the carbon atom carries a negative charge, as should be the case for a metal–carbon bond, the hydroxyl group should combine with the negatively charged carbon on rupture of the active bond, and the polymer should become radioactive:

$$\text{Cat.}^{+\delta}\!-\!-\!-\overset{-\delta}{\underset{|}{\text{C}}}\!-\!\text{P} + \text{ROT} \rightarrow \text{Cat.}\!-\!\text{OR} + \text{T}\!-\!\underset{|}{\text{C}}\!-\!\text{P}$$

where P represents the polymer chain.

Quantitative reactions of this kind are known for organotitanium compounds of low molecular weight [82]. When CH_3OT is introduced in the polymerisation of alkenes on Ziegler–Natta catalysts, a radioactive polymer is obtained, whereas when methanol $^{14}CH_3OH$ is used as inhibitor, radioactivity is not detected in the polymer [38]. These results indicate that growth takes place at a catalyst–carbon bond, polarised as follows:

$$(\text{catalyst})^{+} \cdots {}^{-}\text{CH}_2\!-\!\text{P}$$

This result corresponds to the anionic-coordination mechanism of the polymerisation of α-alkenes, accepted for Ziegler–Natta catalysts.

The method involving the introduction of a tracer into a polymer on termination of the polymerisation by stoppers (chiefly by alcohols labelled with tritium in the hydroxyl group [19,23,25,38,42,79,80] and less frequently by radioactive or non-radioactive iodine [30,42,71]) has been used to obtain the kinetic characteristics of growth in the polymerisation of α-alkenes on many Ziegler–Natta catalytic systems; the results are given in Tables 1 and 3.

The method involving termination by radioactive alcohol has been used to study the polymerisation of ethylene on oxide catalysts [83–89]. In the termination of polymerisation by alcohol in which the hydroxyl hydrogen was replaced by tritium, radioactivity was not detected in the polymer. A radioactive polymer was obtained when methanol labelled with ^{14}C was used for the termination. From these results it was concluded [83,84] that in oxide catalysts the terminal atom of the growing polymer chain carries a positive charge:

$$(\text{catalyst})^{-} \cdots {}^{+}\text{CH}_2\!=\!\text{P}$$

Thus polymerisation on oxide catalysts can be classified as belonging to the "cationic-coordination" type of catalytic polymerisation. To explain the nature of the polarisation of the active bond, it was suggested that in this bond the carbon is joined to a more electronegative element; for oxide catalysts, this element may be oxygen [83,86]. The possibility that an active M–C bond with an unusual type of polarisation is formed cannot however be excluded.

Data on the number of growth centres and the growth rate constants for the polymerisation of ethylene on oxide catalysts with different compositions, obtained by terminating the polymerisation by the introduction of $^{14}CH_3OH$, are given in Table 4.

Table 4. Determination of the kinetic parameters of growth for the polymerisation of ethylene on deposited oxide catalysts, by the radioactive stopper method [81-89].

Evaluation of methods based on the introduction of a tracer. One of the chief difficulties in the quantitative determination of the number of growth centres by the introduction of a tracer into a polymer when complex organometallic catalysts are used is associated with the formation of inactive metal-polymer bonds (MPB) during polymerisation. These bonds arise as a result of chain transfer involving the organometallic co-catalysts. The reaction of inactive MPB with a stopper (alcohol or iodine) also leads to the introduction of a tracer into the polymer, as with active catalyst–carbon bonds. A direct indication of the formation of inactive MPB in a polymerisation system was obtained, for example, by Kohn and coworkers [18], who found that with increase in the duration of polymerisation the number of labelled polymer chains gradually increased, whereas the rate of polymerisation decreased (polymerisation of propene in the presence of $TiCl_3 + AlEt_2Cl$). A sharp increase in the number of labelled chains at constant rate of polymerisation was observed by Coover and coworkers [19].

Different authors have used different methods to introduce corrections for the formation of inactive MPB. The assumptions regarding the mechanism of polymerisation on which these calculations have been based have not always been sufficiently well-founded. According to the results obtained by Coover and coworkers [19], the rate of formation of MPB does not remain constant during the polymerisation—it is much greater in the initial stage than in later stages. In the opinion of the authors cited [19], this result casts doubt on data on the number of growth centres obtained by Natta and coworkers [31], Kohn and coworkers [18], and Chien [42], where the rate of transfer involving the organometallic compound was assumed to be constant, and the analysis for the concentration of tracer was carried out with a polymer obtained after polymerisation for a considerable period of time, as a result of which high values were obtained for the calculated number of active centres. In the calculation of the number of inactive MPB, [18,19] it was assumed that tracers enter all the polymeric molecules; the possibility that polymeric molecules are formed as a result of transfer involving the monomer or spontaneous termination was not taken into account. Coover and coworkers [19] recognise that, because of the difficulty of making allowance for inactive MPB, the accuracy of the determination of n and k_g is insufficient to permit the comparison of catalytic systems with different compositions.

The results obtained by Bier and coworkers [20,80] in a study of the polymerisation of propene on the catalytic system α-$TiCl_3 + AlEt_2Cl$ (or $AlEt_3$) with termination of the reaction by labelled alcohol, differ in many respects from the results of the study of analogous catalytic systems published by other workers [18,19,24,26,31]. In the opinion of Bier and coworkers, reactions involving transfer and termination of the chain with the formation of inactive MPB play a very small role for these catalytic systems, since they found that the molecular weight of the polymer was not influenced by the concentration of organoaluminium compound. The number of growth centres was therefore calculated directly from the concentration of tritium in a polymer obtained after termination of the polymerisation by butanol-^{3}H. These results were criticised by Kohn [30] and Medvedev and coworkers [90], who found for the same catalytic systems that the molecular weight of the polymer depends on the concentration of organometallic co-catalyst, indicating chain transfer, in which the formation of inactive MPB is possible.

The difficulties associated with the formation of inactive MPB can apparently be avoided by using catalytic systems which do not contain free metal alkyls. Youngman and Boor [25] tried to use this system as a model for the determination of the kinetic characteristics of the growth centres (see Table 1), but the results of the determination of k_g obtained by these workers cannot be regarded as unambiguous, since an increase in the number of metal–polymer bonds with time was observed, together with a decrease in the rate of polymerisation.

Oxide catalysts have been found to be more convenient when the method of radioactive stoppers is used, since these catalysts are one-component catalytic systems, which exhibit activity without the addition of organometallic compounds. All the catalyst–polymer bonds present in the system are active, and this makes it possible to calculate the number of growth centres directly from the radioactivity of the polymer [86,88]. For catalysts with the same chemical composition, within the limits of possible experimental error, the value of k_g was not affected by the quantity of inhibitor introduced, the concentration of catalyst in the solvent, the duration of polymerisation up to the moment of termination, the rate of polymerisation, and the porosity and original particle size of the catalyst. The value of k_g was also found to be independent of whether the polymerisation was carried out with or without

a solvent. The fact that the values of k_g were found to be constant provides evidence that the number of growth centres for this catalytic system is determined quantitatively, and that there is no diffusion retardation under these conditions.

The unsatisfactory features of methods in which tritium is used as a tracer include the difficulty of making allowance for the kinetic isotope effect. The magnitude of the isotopic effect in work in which alcohols labelled with tritium were used as stoppers has been estimated from the change in the radioactivity of the polymer on termination of the polymerisation by different quantities of stopper [18,80] or by altering the time interval within which the stopper is introduced into the reaction medium [38]. Considerable differences were observed in the values found for the kinetic isotope effect, the values obtained by different authors [18,19,38,79,80,91] varying from 1 to 4.5.

When iodine is used as stopper, the results of the determination of the number of active centres may be distorted by side reactions leading to a change in the concentration of the tracer in the polymer. One such reaction may be, for example, the formation of terminal vinylidene groups in polypropene with the liberation of hydrogen iodide [15].

In a number of instances, the possibility that the results of the determination of the number of active centres and the calculation of k_g may be distorted because of the influence of the rate of diffusion of the stopper and monomer to the growth centres cannot be excluded. The possibility that the formation of solid polymer during the reaction affects the kinetic relationships has been examined by many authors [23,80,92,93] in studies of the kinetics of the polymerisation of alkenes on Ziegler–Natta catalysts. Coover and coworkers [19] regarded the decrease in the concentration of aluminium alkyl on the catalyst surface due to slow diffusion through the layer of polymer formed as the reason for the decrease in the rate of formation of metal–polymer bonds during polymerisation. Youngman and Boor [25] attributed the decrease in the calculated value of k_g during polymerisation to an increase in the diffusion retardation of the transport of monomer as result of the formation of polymer on the surface of the catalyst. The possibility that the values of k_g found from the results of analysing a radioactive polymer may be distorted by diffusion retardation was also noted by Feldman and Perry [38]. Diffusion retardation was not observed in the polymerisation of ethylene on oxide catalysts when a loose porous polymer powder was formed [94]. When the polymerisation is carried out above 90° in a solvent, a decrease in the concentration of monomer at the surface of the catalyst particles is possible as a consequence of the resistance to diffusion through the layer of partly soluble polyethylene fraction with low molecular weight. This leads to a decrease in the rate of polymerisation on going from 75° to 90° with a constant number of growth centres [88], so that the calculated value of k_g decreases.

V. MECHANISM OF CATALYTIC POLYMERISATION BASED ON MEASUREMENT OF n AND k_g

The value of k_g provides a measure of the reactivity of the active centres with respect to growth. The conclusions which may be drawn from data on the change in n and k_g are more reliable than those obtained by comparing catalysts with respect to the rates of polymerisation relative to unit weight or surface area of the catalyst. We can consider some examples of the use of data on the kinetic parameters of growth to reach conclusions regarding the mechanism of the catalytic polymerisation of alkenes.

1. Number of Growth Centres and Degree of Utilisation of the Metal with Variable Valency

By determining the relative fraction of the metal with variable valency taking part in the formation of the growth centres it is possible to reach certain conclusions regarding the state of the transition element necessary for the manifestation of catalytic activity. In the examination of the mechanism of action of catalysts based on $TiCl_3$, two contradictory viewpoints have been put forward on the question as to which of the surface titanium atoms are potential active centres. Cossee and Arlman [10–12,95–97] formulated a theory, according to which catalytic activity is exhibited by coordinatively unsaturated titanium atoms, with chlorine vacancies, situated on the lateral faces of the $TiCl_3$ crystal; according to this theory, the titanium atoms adjoining the (001) basal plane do not take part in the formation of growth centres. Rodriguez and Van Looy [91] observed the formation of patches of polymer on the surface of a $TiCl_3$ crystal, the positions of which coincided with the points of emergence of spiral dislocations. In their opinion, these results confirm the view that the active centres arise only on the lateral faces of the $TiCl_3$ crystals; active centres are not formed on the basal plane, which makes up 95% of the total surface area of the $TiCl_3$ crystal.

Chirkov and coworkers [17,39] determined the number of growth centres by a kinetic method for a system based on VCl_3 (specific surface $\sim 5\ m^2\ g^{-1}$) and found that the maximum number of active centres amounts to $\sim 5 \times 10^{14}$ centres per cm^2, the order of magnitude of which corresponds to that of the total number of surface vanadium atoms. Thus according to these results, active centres should form on the basal plane of the crystals of the halides of the metals with variable valency.

It should be noted that when the fraction of the metal with variable valency taking part in the formation of growth centres is compared with the total number of surface atoms of the transition metal halides, it is necessary to consider the possibility that reversible deactivation (transfer processes) and irreversible poisoning of the growth centres take place. In general, the following relationship applies for catalytic polymerisation:

$$N = n_g + n_x + n_y \qquad (8)$$

where N is the total number of transition metal atoms capable of taking part in the formation of growth centres ("potentially active centres" or "active component" of the catalyst), n_g the centres joined by an active bond to the growing polymer molecule (actual growth centres), n_x the centres in a state of reversible deactivation as a result of transfer processes ("initiation centres"), and n_y the irreversibly deactivated centres.

Data on the value of n_g, which usually depends markedly on the purity of the polymerisation system and the conditions of preparation of the catalyst, cannot provide an unambiguous basis for obtaining information as to the number of potentially active transition metal ions (the value of N). Analysis of data on the fraction n_g relative to the total number of transition metal atoms in Ziegler–Natta catalysts is made difficult by the fact that most authors do not give data on the surface area of the heterogeneous component of the catalytic system. It may be noted that most papers on catalysts based on $TiCl_3$

($AlEt_2Cl$ and $AlEt_3$ co-catalysts) give similar values for n_g ($0.5\times10^{-2}-5\times10^{-2}$ mole per mole $TiCl_3$ for temperatures in the range 50–70°, which for $TiCl_3$ specimens with a surface area of 5–25 $m^2\,g^{-1}$ corresponds to 10–100% of the surface atoms). Some authors [28] have obtained values of n_g which are clearly greater than the number of titanium atoms adjoining the surface. For systems based on $TiCl_4$ and VCl_4, used for the polymerisation of ethylene (see Table 3), a higher fraction n_g is observed, probably due to the high degree of dispersion of the heterogeneous component.

For oxide catalysts, the fraction of growth centres relative to the total concentration of deposited metal with variable valency depends on the composition of the catalyst (see Table 4). The maximum degree of utilisation of the metal with variable valency, observed for a chromium oxide catalyst on an Al_2O_3 base, amounted to 1.5%. It should however be noted that these results were obtained for comparatively low rates of polymerisation. By decreasing the concentration of impurities in the reaction medium, in particular by carrying out the polymerisation in the gaseous phase, when there is no deactivation of the growth centres by impurities in the solvent, a high rate of polymerisation is achieved on chromium oxide catalysts (up to 1.5×10^5 g polyethylene per g of chromium per hour). Under these conditions, up to 25% of the deposited chromium is present in growth centres. From these results it was concluded [98] that all the chromium with oxidation state +6, present in the deposited oxide catalysts in the form of surface compounds of the chromate type [99], can act as active centres. The formation of growth centres is accompanied by the reduction of Cr^{6+} to compounds of chromium in one of its lower oxidation states (Cr^{2+} and Cr^{3+}). The decrease in the number n_g relative to N is due both to reversible deactivation [100] as a result of transfer involving impurities such as CO, CO_2, and C_2H_2, and to irreversible poisoning (for example as a result of the action of water [51,52]).

The dependence of the number of growth centres on the conditions of polymerisation can give information on the mechanism of their formation. The most detailed results have been obtained by studying the dependence of the number of growth centres on the temperature of polymerisation. If the number of growth centres changes with change in temperature, the total activation energy (E_{form}), determined from the temperature dependence of the rate of polymerisation, differs from the activation energy of growth (E_g), which can be determined from the temperature of k_g. A large amount of published information indicates that the number of growth centres depends on the temperature of the catalytic polymerisation [18,23,24,31,38,42,80,101]. It has been shown [81,101,102] that for systems based on $TiCl_3$ the number of growth centres is inversely proportional to the temperature of the process. The explanation is that the reaction involved in their formation, which takes place when $TiCl_3$ reacts with the metal alkyl, is reversible and reaches equilibrium under the conditions of polymerisation. A characteristic feature is the marked scatter in the values of E_{form} obtained by different authors for catalytic systems with similar compositions [36,38,103–105]. Data on the dependence of E_{form} on the composition of the catalyst are equally contradictory [65,103,105–109].

There is comparatively little published information on the direct determination of E_g from the change in k_g with temperature for complex organometallic catalysts (see Tables 1–3). The values of E_g differ considerably from the values of E_{form} [5,8,18,53,38].

For oxide catalysts it has been shown by the radioactive stopper method that the number of growth centres changes with change in the temperature of polymerisation [88,101]. The nature of this dependence (and hence the value of E_{form}) varies with the composition of the catalyst. From data on the influence of preliminary reduction of the catalyst on the temperature dependence of the number of growth centres, it was concluded that the formation of growth centres in chromium oxide catalysts involves the reduction of sexavalent chromium and is irreversible.

2. Composition of Growth Centres

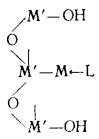
Data on the influence of the composition of a catalyst and the conditions of its preparation on the value of k_g can be used to reach a number of conclusions regarding the composition of the active centres. Unfortunately, for Ziegler–Natta catalysts, different methods for determining k_g for a given catalytic system give values which differ considerably (for example, by a factor of 30 at 70° for the simplest system studied—the polymerisation of propene in the presence of $TiCl_3 + AlEt_2Cl$) (see Table 1). There is little published information on the comparison of catalysts with different compositions using values of k_g obtained by the same method. Natta and coworkers [8,35] compared the "viscosity-average" growth rate constants (k_g) for the polymerisation of but-1-ene in the presence of different catalytic systems. They found (Table 2) that k_g is independent of the form of organometallic compound used, but depends on the compound of the metal with variable valency. On the basis of these results, it was concluded [8,35] that for systems based on the same transition metal halide, the growth centres are kinetically equivalent, and their reactivity is independent of the alkylating compound. The difference in the rate of polymerisation for different organometallic components, which in some instances amounts to more than two orders of magnitude, is due entirely to the difference in the number of active centres. Change in the metal with variable valency leads to a change in both the growth rate constant and the number of active centres. The stereoregularity of the polymer was found to depend on the type of metal alkyl, from which it was concluded [8,35] that the active centres are "bimetallic" (include both the metal with variable valency and the metal of the alkylating compound). Cossee and Arlman [10,95–97] formulated the theory that the active centres of the Ziegler–Natta catalysts are "monometallic". Unfortunately, the change in k_g for catalysts not containing alkyls [25], prevents unambiguous results on the influence of the organometallic compound on the kinetic properties of the growth centre being obtained.

Data have been published on the change in the kinetic properties of the growth centres when electron-donor additives are introduced into a catalytic system [9], when hydrogen is introduced into the system [110], and with change in the ratio of the organometallic co-catalyst to the compound of the metal with variable valency [9,38,42,111].

Interesting results were obtained [31] by comparing the radioactivity of the atactic and isotactic fractions of polypropene with their concentration in the polymer; from these results it was concluded that the rate constant for the centres on which the atactic polymer is formed is smaller by a factor of 6 than that for the centres on which the stereoregular polymer is formed.

In a study of the effect of the composition and conditions of preparation of oxide catalysts on the value of k_g, it was

established that k_g is influenced by change in the metal with variable valency (M), the cation of the oxide carrier (M'), the agent used for the preliminary reduction of the catalyst, and the temperature of activation of the catalyst. On the basis of these results, the following scheme [89], giving the composition of the immediate environment of the metal with variable valency in the growth centre of oxide catalysts was proposed:



Here, L represents the ligand which forms part of the growth centre after treatment of the catalyst with an agent capable of forming coordination compounds. The rate constants for transfer (involving the monomer and the spontaneous process), determined from the dependence of the molecular weight on the conditions of polymerisation, depend on the same factors as the value of k_g. [112]

3. Mechanism of Growth

The number of growth centres for different concentrations of monomer has been measured, and it has been shown that the reaction involved in growth is first order with respect to the monomer for catalysts based on transition metal halides [8,18,24,35] and for chromium oxide catalysts [88].

In most schemes proposed to explain the mechanism of the catalytic transformation of alkenes in the presence of transition metal compounds, it is considered that a necessary stage is preliminary complex formation by the alkene (the so-called coordination mechanisms [109,113]), as a result of which the double bond is weakened and its reactivity increases. For a two-stage mechanism of polymerisation, including as first stage the formation of a π-complex [9-12], the first order kinetics of the reaction with respect to monomer may correspond to case 2 [see Eqn. (1)]:

1. $k_g = k_1$; in this instance, E_g corresponds to the activation energy of the formation of the π-complex;
2. $k_g = K_a.k_2$; in this instance, $E_g = E_2 - Q$, where E_2 is the activation energy of the introduction of ethylene at the active bond; Q the heat of formation of the π-complex, and $K_a = k_1/k_{-1}$ the equilibrium constant for the formation of the π-complex.

In the opinion of Natta and coworkers [8], the limiting stage in the polymerisation of alkenes on catalysts based on transition metal halides is the first stage (the formation of the π-complex). In a number of instances, low values were found for E_g (2.5 kcal mole^{-1} for a catalyst based on VCl_3; 4.5 kcal mole^{-1} for a catalyst based on $TiCl_3$; and 4–5 kcal mole^{-1} for chromium oxide catalysts). In these instances the pre-exponential factors have anomalously low values (10^5–10^6 litre mole^{-1} s^{-1}). A possible reason is that the formation of the surface π-complexes is accompanied by a marked decrease in entropy. At the present time, however, there are no unambiguous data which exclude the possibility that for the catalytic polymerisation of alkenes the second situation is realised ($k_g = K_a.k_2$), and the value found for E_g is not the activation energy of the elementary stage.

---o0o---

After the present review had been written, a number of new papers were published [32-34,47-49], giving results of the determination of the number of growth centres and the growth rate constants for the catalytic polymerisation of alkenes. These results are included in Tables 1 and 3.

Papers [32,33] based on previously developed kinetic methods and the inhibition method give new data on the values of n and k_g for the polymerisation of alkenes in the presence of complex catalysts based on $TiCl_3$ and VCl_3. The values obtained for n correspond to almost complete coverage of the catalyst surface, from which it follows that the active centres are situated chiefly on the basal planes of the $TiCl_3$ and VCl_3 crystals. These results were used to provide a basis for a model of a stereospecific active centre, which is localised on the basal plane and which has two vacancies per transition metal ion in the growth centre.

Radioactive inhibitors have been used [48,49] to determine the kinetic parameters of growth in the polymerisation of ethylene on titanium dichloride, which is active in the polymerisation of alkenes without the addition of organometallic compounds. In addition to the labelled alcohol which is usually employed for this purpose, $^{14}CO_2$, ^{14}CO, and $^{14}CH_3CH_2CH_2I$ were used. For this one-component heterogeneous catalytic system, since there are no inactive aluminium–polymer bonds, the method of radioactive inhibitors makes it possible to determine reliably the number of growth centres. The results obtained show that the value of n amounts to not more than ~0.1% of the number of surface titanium atoms in the $TiCl_2$ specimens used. The probable explanation is that the alkylation of titanium by ethylene under mild conditions takes place on surface defects of the $TiCl_2$ crystals. The value of k_g found in these experiments is greater by about two orders of magnitude than the values of k_g obtained for the polymerisation of ethylene on catalysts based on $TiCl_3$. [32,37,38]

The use of radioactive inhibitors of different types to study one-component heterogeneous catalysts (chromium oxide and titanium dichloride) also gave results [49] confirming the coordination mechanism of growth in the catalytic polymerisation of alkenes.

A number of papers published in recent years have been devoted to the study of the morphology of polyalkene crystals formed directly during polymerisation ("primordial morphology"). These results can be used to reach an understanding of the mechanism of formation of a solid polymer on the surface of a solid catalyst. In particular, values of the growth rate constants have been calculated [34,47] from the results of an electron-microscope study of polyalkene crystals produced in the initial stage of polymerisation. The value of k_g found [47] for the polymerisation of ethylene on a chromium oxide catalyst is close to the value of k_g obtained for catalysts with the same composition by the radioactive inhibitor method. The value of k_g obtained [34] for the polymerisation of propene on the $TiCl_3 + Al(CH_3)_3$ catalytic system is smaller by two orders of magnitude than the values given above for analogous systems (see Table 1).

Conformational and Thermodynamic Properties of Macromolecules in Ternary Polymeric Systems

A.V.Gevorkyan

An account is given of the present state of knowledge on the properties of solutions of homopolymers and copolymers (having different distributions of monomer units in the chain) in binary mixtures of solvents. Several specific features of the hydrodynamic behaviour of macromolecules in such systems are discussed. Selective adsorption, which develops in mixed solvents, cannot be responsible for the lack of agreement between theory and experiment. Results reported here indicate that macromolecules retain a Gaussian structure ($[\eta]_\theta \propto M^{1/2}$) in several polymer-binary mixture systems. Conformational properties and transitions of macromolecules from a "segregated" to a random form are examined as functions of the composition of the mixed solvents. A list of 61 references is included.

3. Ternary polymeric systems in good solvents 218

1. Introduction

Considerable attention has been paid during recent years [1-8] to investigating the properties of solutions of polymers involving ternary systems†. However, experimental information on this question is still inadequate and contradictory, perhaps owing to specific features of the hydrodynamic behaviour of copolymers in solution [9,10] or to the development of selective interactions (selective adsorption) in ternary systems comprising a polymer plus a binary mixture [11]. A final solution to the problem may be obtained from further special investigations, for the correlation of theory with experiment in ternary systems is still mainly qualitative.

The present paper gives a brief account of modern views on the thermodynamics of solutions of polymers in ternary systems. It considers also certain results obtained by the Reviewer when investigating the structure and the hydrodynamic behaviour of molecules of random chloroprene–isoprene and chloroprene–dichlorobutadiene copolymers and of the corresponding homopolymers in ideal mixed solvents [12-18]. In contrast to homopolymers, copolymers are inhomogeneous with respect not only to conformation but also to composition, but we shall not deal with the latter type of variability, and refer merely to the survey by Litmanovich and Izyumnikov [19].

2. θ-Conditions and Unperturbed Dimensions of Macromolecules in Ternary Polymeric Systems

According to modern views, "equilibrium dimensions" of macromolecules, whose structure is unperturbed by the solvent, are established under θ-conditions, when the osmotic forces of repulsion between the dissolved polymer macromolecules and the solvent molecules are balanced by coiling of the molecular chains because of the energetic unfavourability of the contacts between polymer and solvent [20]. In other words, the condition of zero second virial coefficient A_2 in the expansion of the osmotic pressure should correspond unambiguously to the absence of swelling of the molecular coil ($\alpha = 1$) and maintenance of the conditions $[\eta]_\theta \propto M^{\frac{1}{2}}$. However, recent results indicate that the Gaussian distribution may break down in ternary systems ($[\eta]_\theta \neq K_\theta M^{\frac{1}{2}}$).[9] Furthermore, the very concept of θ-point (and also α-point) now requires some elaboration, as indicated by results on the conformational transitions of macromolecules in the critical region of polymer–solvent mixing [21-23]. Attention must be paid also to the existence of both upper and lower critical temperatures for several rigid and semi-rigid macromolecules [24,25]. The Reviewer [26] has also observed phase separation with rise in temperature for aqueous solutions of poly(methyl vinyl ether)—"thermal denaturation" of the macromolecules—caused by rupture of polymer–solvent intermolecular hydrogen bonds [27].

It is noteworthy that Benoit and Dondos have recently suggested [28] that solutions of polymers in binary mixtures may have two θ-points, owing to the development of selective interactions (selective adsorption), which distort the Gaussian structure of the macromolecules even when $A_2 = 0$. From investigations of the temperature dependence of the unperturbed coil dimensions of several polymers in binary mixtures these workers concluded further that the present classical theory of solutions is unsuitable for strongly associated solvents [29]. It was found that K_θ in such solvents was smaller than $K_{\theta,\text{ideal}}$ and increased with rise in temperature (Fig. 1). Extrapolation of K_θ to the boiling point of the solvent, when association of solvent molecules disappears, yields the ideal value of K_θ. The decrease in the unperturbed dimensions of the macromolecules in associated solvents is explained [29] by intermolecular polymer–solvent interaction, leading to the formation of cyclic structures bound by hydrogen bonds of the solvent, which in turn produces a decrease in $(\overline{h^2})_\theta^{\frac{1}{2}}$ of the macromolecules.

However, the conclusions reached in the above papers are open to question, since they are based not on direct experiment but on extrapolation by the Stockmayer–Fixman method [30] far from the θ-point:

$$[\eta] \cdot M^{-1/2} = K_\theta + 0.51 \cdot \Phi_0 \cdot BM^{1/2}; \quad B = \bar{V}^2(1-2\chi_1)/V_1 N_A \qquad (1)$$

† We shall hencefore take a ternary polymeric system to imply solutions of copolymers (with different types of distribution of monomer units in the chain–random, block, and graft copolymers) and of homopolymers in binary mixtures of solvents.

where $\bar{V}$ is the partial specific volume of the polymer, V_1 the molar volume of the solvent, and χ_1 a thermodynamic parameter of intermolecular polymer–solvent interaction. Although Eqn. (1) is regarded as soundly enough based for estimating the unperturbed dimensions of macromolecules in solution [31], it is premature to consider that calculations using this equation establish a specific effect of the solvent.

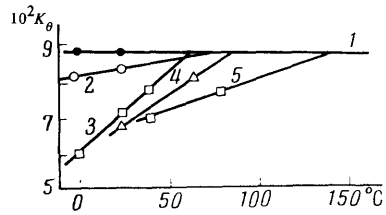

Figure 1. Temperature dependence [29] of K_θ for poly-2-vinylpyridine in dilute solution in: 1) chloroform; 2) ethanol; 3) methanol; 4) propan-2-ol; 5) cyclohexane.

On the other hand, Cowie [32], who investigated the unperturbed dimensions of a polystyrene fraction ($\bar{M}_w = 2.2 \times 10^6$) in binary solvent mixtures, demonstrated that selective adsorption cannot be responsible for the dependence of $(\overline{h^2})_\theta^{\frac{1}{2}}$ on the composition of the θ-solvent, since a unique relation between $(\overline{h^2})_\theta^{\frac{1}{2}}$ and the selective adsorption parameter λ' was not observed.

Several new results have been obtained [33,34] on selective adsorption in ternary polymeric systems, its thermodynamic interpretation, and also the effect on the conformation of the macromolecules. These workers state that a definite correlation exists between the swelling α of a macromolecule and selective adsorption in ternary systems, the change in the radius of inertia of the macromolecules $(R^2)^{\frac{1}{2}}$ being $\leq 10\%$ for solutions of non-polar polymers. Nevertheless, a quantitative relation is observed in the well known dependence on composition of the dimensions: $[\eta]_\theta$ and $(\overline{h^2})_\theta^{\frac{1}{2}}$ pass through a sharp maximum (this change in these parameters amounts to ~30% and 10% respectively).

Conformational transitions of cooperative character have been observed also for molecules of unionised polymethacrylic acid with change in composition of the θ-solvent [35,36].

The specific effect of θ-solvents on the structure of macromolecules observed by Poddubnyi et al. [37] in ternary systems was explained mainly by the considerable polarity of the copolymer examined. Other workers [11,38] attribute this effect to the thermodynamic interaction parameter χ_{AB} of the copolymer components in the given solvent. A linear relation is reported [38] between the values found for K_θ (extrapolated as in Ref. 30) and χ_{AB}, so that extrapolato $\chi_{AB} = 0$ (Fig. 2) will give the additive value of K_θ. The temperature variation in the parameter χ_{AB} is due also to the strong temperature dependence of the unperturbed dimensions.

Incidentally, analysis of the unperturbed coil dimensions of styrene–acrylonitrile and styrene–methyl methacrylate copolymers and of the corresponding homopolymers in solution shows that freedom of rotation about a single bond between unlike monomers is more strongly temperature-dependent than is that about similar bonds between units of the same type [39]. Considerable sensitivity of short-range action to variation in the θ-temperature has been established also by the Reviewer [15,16] for molecules of a random chloroprene–dichlorobutadiene copolymer, although additional short-range interactions between unlike monomer units in copolymer chains have a quite insignificant effect of $(\overline{h^2})_\theta^{\frac{1}{2}}$. [12,13] Fig. 3 shows that increase in the θ-temperature (by ~50 deg) leads to an average decrease of 15% in the unperturbed dimensions.

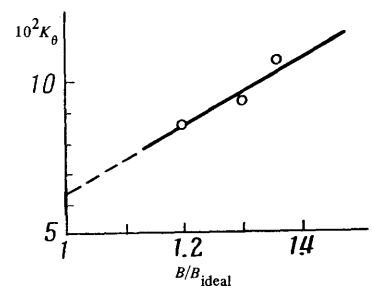

Figure 2. Variation in K_θ with the ratio of B to its "ideal" value: this relation represents the incompatibility of the components of the copolymer chain in solution [38].

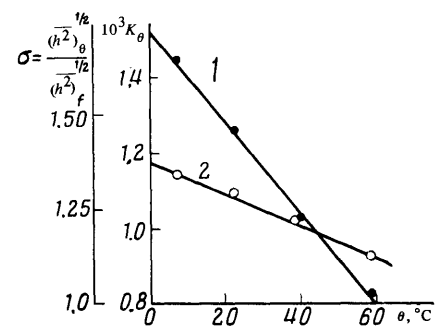

Figure 3. Variation with the θ-temperature, for a random chloroprene–dichlorobutadiene copolymer in solution, of the conformational parameters: 1) $K_\theta = \Phi_0(\overline{h_\theta^2}/M)^{\frac{3}{2}}$; 2) $\sigma = (\overline{h^2})_\theta^{\frac{1}{2}}/(\overline{h^2})_f^{\frac{1}{2}}$.

The above considerations do not exclude the possible preservation of the Gaussian structure of molecular coils in binary mixtures. In fact, the Reviewer has shown [18] (Fig. 4) that the nature of the θ-solvents (in this case their polarity) neither changes the Gaussian distribution in the chloroprene–dichlorobutadiene copolymer nor affects the values of $[\eta]_\theta$, although the influence of electrostatic

polymer–binary mixture interaction of $[\eta] \propto (\overline{h^2})_\theta^{\frac{3}{2}}$ is quite appreciable for molecular chains comprising monomer units of the same type[14]. The fact that it is not apparent in the above copolymer chains can probable be explained by the lower polarity of the dissolved copolymer molecules, caused by the predominance of *trans*-1,4-dichlorobutadiene units. An analogous dependence of unperturbed macromolecular dimensions on molecular weight (i.e. $[\eta]_\theta \propto M^{\frac{1}{2}}$) was obtained[40] for butadiene–nitrile copolymers, and was attributed to the impossibility of forming sufficiently long microblocks of units of the same type in the copolymer chains.

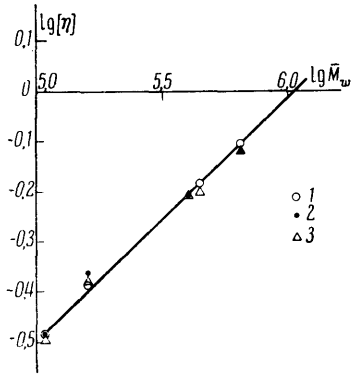

Figure 4. Dependence of $\lg[\eta]$ on $\lg\bar{M}_W$ for chloroprene–dichlorobutadiene copolymer fractions at $\theta = 25.4°C$ in binary solvent mixtures (by volume): 1) 1.33 : 1 chloroform + acetone; 2) 5.18 : 1 benzene + methanol; 3) 1 : 1 carbon tetrachloride + n-octane.

Nor is the Gaussian structure of the copolymer macromolecules distorted in the θ-state if the polymer–solvent interaction is almost the same for the chain components[10,41]. Results obtained by Inagaki et al. in a detailed study of the properties of solutions of block and random copolymers of styrene with methyl methacrylate show[41] that in cyclohexanol the θ-temperatures differ very little for block copolymers (with different styrene contents) and for the corresponding homopolymers, whereas for random copolymers the θ-temperature varies appreciably with different styrene contents, passing through a minimum in the vicinity of the equimolecular copolymer (Fig. 5). In 2-ethoxyethanol block copolymers have higher θ-temperatures than random copolymers of similar composition, probably as a consequence of intramolecular interaction between styrene and methyl methacrylate units. Nevertheless, the closeness of the conformational and thermodynamic properties of block copolymers to the average properties of homopolymers somewhat contradicts existing views[3].

Conformational analysis of macromolecules for a large number of copolymers differing in structure shows[42–46] that the unperturbed coil dimensions follow (with insignificant deviations) a simple additivity rule (i.e. short-range interactions in the copolymer chains are the same as in the corresponding homopolymers). A clear exception to this rule is provided by graft (particulate and block) copolymers, in which interactions between unlike units have a substantial effect of $(\overline{h^2})_\theta^{\frac{1}{2}}$ (or the thermodynamic flexibility). For example, the optical and hydrodynamic properties of solutions of graft poly(methyl methacrylate)–polystyrene copolymers show[47] that the rigidity of such a macromolecule, regarded by Tsvetkov and his coworkers as a persistent chain, exceeds the value usually obtained for carbon-chain macromolecules[20] by an order of magnitude. The greater rigidity of the graft copolymer chains is assumed[47] to be due to the interaction of side-groups, which form intramolecular structures, having a high degree of orientational order, this being responsible for the great optical anisotropy of the macromolecule.

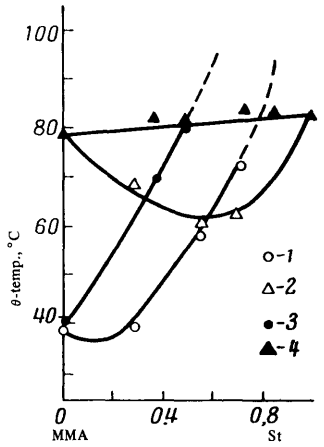

Figure 5. Dependence of θ-conditions on styrene (St) content for copolymers with methyl methacrylate (MMA):[41]
1) random copolymers in 2-ethoxyethanol;
2) random copolymers in cyclohexanol;
3) block copolymers in 2-ethoxyethanol;
4) block copolymers in cyclohexanol.

3. Ternary Polymeric Systems in Good Solvents

Several studies of ternary polymeric systems have demonstrated[50–53] that an intrachain phase separation of the copolymer (a "segregated conformation" of the coil) occurs in selective solvents, when the insoluble portion "settles out", being twisted "on itself", which diminishes to a minimum the interaction between unlike chain units (or the number of "heterocontacts"). In such a solution, therefore, intrachain and interchain interactions between segments differ markedly.

It has been reported[54] that the transition from the "segregated" to the random form corresponds to a definite composition of the binary solvent mixture: the "segregated conformation" exists above this transition composition (or temperature), and a random conformation below it, the former excluding and the latter permitting contact between unlike monomer units of the copolymer. These transitions are, of course, accompanied by great conformational changes (the dimensions of the copolymer chain and hence the viscosity of the solution either decrease or increase sharply). The presence of selective interactions in solutions of copolymers is responsible for their specific

thermodynamic and hydrodynamic behaviour. Fig. 6 [40] illustrates a peculiar effect associated with the development of such interactions for solutions of fractions of a random butadiene–acrylonitrile copolymer.

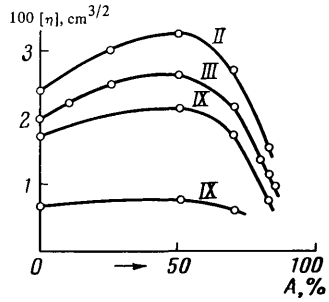

Figure 6. Dependence of intrinsic viscosity of butadiene–acrylonitrile copolymer fractions on composition of butan-2-one–cyclohexane mixtures (numbering of curves indicates that of the fractions [40]).

If we extend to solutions of copolymers the usual concepts applicable to homopolymers, and characterise the hydrodynamic behaviour of a molecular coil by the excluded segment volume

$$Z = \int_0^\infty \{1 - \exp[-U(r)/kT]\}\, 4\pi r^2\, dr \qquad (2)$$

where $U(r)$ is the potential interaction energy of two segments distant r apart, we obtain for a random copolymer [55]

$$\langle Z\rangle_{rand} = X^2 Z_{AA} + (1-X)^2 Z_{BB} + 2X(1-X) Z_{AB}, \qquad (3)$$

in which X is the proportion by weight of component A in the chain. The parameters representing interaction between A, B, and AB units are respectively

$$Z_{AA} = 2V_1\left(\frac{1}{2} - \chi_{A_1}\right);\ Z_{BB} = 2V_1\left(\frac{1}{2} - \chi_{B_1}\right);$$
$$Z_{AB} = \frac{Z_{AA} + Z_{BB}}{2} + V_1\chi_{AB}. \qquad (4)$$

(The subscript "1" denotes the solvent). Analogous deductions were made [55] for graft and block copolymers, but the formulae are too cumbersome to be considered here.

The above relations show that, when the θ-conditions are satisfied for a random copolymer and one of the corresponding homopolymers A (i.e. $\langle Z\rangle_{rand} = 0$ and $Z_{AA} = 0$), and χ_{AB} is positive, the other component may be somewhat below its θ-temperature ($Z_{BB} < 0$). This represents the so called "negative volume effect", which has actually been observed by several workers [9,53]. However, experimental results [9] show that Z_{BB} for the copolymers investigated is still so small that there is no appreciable "settling out" of monomer units of B, and hence no distortion of the Gaussian structure. In selective solvents, however, when the coefficients of Z_{AA}, Z_{BB}, and Z_{AB} become functions of the selectivity, the probability of contacts between units of the insoluble component is increased, which obviously leads to distortion of the conformation of the coil and ultimately its "stratification" [48–52,54]. With solvents and mixtures of cross selectivity (for a random copolymer of methacrylic acid with methyl methacrylate [53]) it becomes possible to trace a continuous transition from a secondary structure of one type to a structure of another type, through a stage involving the most uncoiled conformation, as a consequence of non-selective solvation of both types of monomer unit in the binary mixtures (Fig. 7).

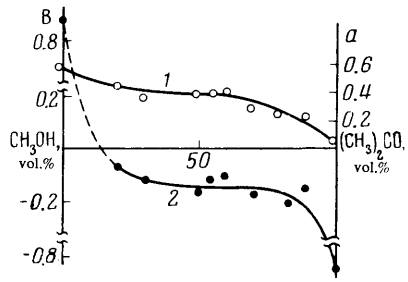

Figure 7. Effect of composition of mixed solvent (methanol + acetone) [49] on: 1) power of a in the Mark–Houwink equation; 2) the parameter B.

Since the literature frequently reports attempts to link the swelling coefficient α of copolymer molecules in solution with the thermodynamic parameter χ_{AB} of interaction between unlike monomer units of the copolymer one with the other and with the solvent [38,56], we must note a specific aspect of the thermodynamic properties of solutions of graft copolymers which was observed by Eskin and Baranovskaya [57,58]. These workers established that the second virial coefficient $A_2 \simeq 0$ for graft copolymers of polystyrene with poly(methyl methacrylate) ($X_A = 0.9$) having sufficiently high molecular weights ($\bar{M}_w > 10^6$). In fact calculation based on Flory's theory of polymer solutions [59]

$$A_2 = \frac{N_A Z}{2M^2} F(Z), \qquad (5)$$

(where $F(Z)$ is a function of the thermodynamic parameters of intermolecular polymer–solvent interaction), allowing for the hydrodynamic "non-flowability" of the coils [47], shows that the second virial coefficient A_2 for solutions of such graft copolymers [57] is of the order of 10% of that for solutions of the homopolymers, and decreases considerably more rapidly with molecular weight. This property of solutions of graft copolymers must, of course, be taken into account in determining the θ-conditions (e.g. by interpolating the temperature dependence of A_2 found by light scattering).

Experimental facts reported by Inagaki et al. [42] indicate, however, that long-range interactions between unlike monomer units do not disappear under any conditions, even when such interactions between units of the same type have absolutely no effect on the conformation of the macromolecules.

In conclusion we note that Dondos and Patterson [60] have examined the intrinsic viscosity of polymers in mixed solvents using theoretical results [61] on the effect of selective adsorption on the thermodynamic properties of polymer solutions. They find that the difference in the intrinsic viscosity of solutions of polymers in binary mixtures produced by taking selective adsorption into account is

$$\Delta[\eta] = \frac{1.02\bar{V}^2\Phi_0 M G^E(\varphi_2^0)}{N_A V R T}, \qquad (6)$$

where V is the molar volume of the mixed solvent, φ_2^0 the fraction by volume of the second component in the solvent, and G^E the excess free energy of mixing of the component with the solvent. Only qualitative agreement was obtained when this equation was tested on various ternary polymeric systems: the quantitative results differed by factors of $10-10^2$, a discrepancy between theory and experiment which could hardly be explained by selective adsorption, as the authors pointed out. Nevertheless, the theoretical slight temperature dependence of intrinsic viscosity in binary mixtures

$$-T\frac{\partial(\Delta[\eta])}{\partial T}=\frac{1{,}02\bar{V}^2\Phi_0 M H^E(\varphi_2^0)}{N_A V R T}, \qquad (7)$$

where H^E is the heat of mixing of the binary solvent mixtures, agrees quite satisfactorily with experiment.

Separation of Isotopes by Electrical Migration and Determination of Ionic Mobilities in Molten Salts

V.N.Lyubimov

Problems of the use of ionic migration for the separation of stable isotopes under laboratory conditions and in large-scale plant are considered. The phenomenological theory of the process, the apparatus, the mode of operation, experimental conditions, and results obtained for twenty elements are discussed in detail. Results obtained by countercurrent and zone electrical migration for the structure of molten salts and the mechanism of the migration of ions in an electric field are examined. A list of 341 references is included.

IV. Application of electrical migration to the study of the structure and transport properties of molten salts 239

I. INTRODUCTION

Electrical migration is the directed movement of ions in an electric field, which is superimposed on the random thermal motion of the particles. Study of the motion of ions in an electric field is important both for elucidating the internal structure of a substance and the actual mechanism of such motion and, in application, for separating mixtures of substances in an ionised state, in particular for the separation of isotopes.

Electrical migration has been the subject of several reviews [1-25], some of which have become out of date. Yet many experimental and theoretical papers are continually being published on this method, which indicates the unflagging interest of research workers. It therefore appears useful to review the present-day state of the problem.

Electrical migration can be accomplished in solids, liquids, and gases possessing ionic conduction. The present review considers aspects of the migration of ions in molten salts. Information on analogous processes in other media—solid salts, solutions, liquid metals—is given only in the historical survey or for comparison with corresponding data for molten salts. Reviews have been published fairly recently on the movement of ions in aqueous solutions [26,27] and in liquid metals [28,29].

II. HISTORICAL SURVEY

The separation of isotopes by the migration of ions in an electric field is based on the fact that the mobility of isotopic ions is greater the smaller their mass. This idea was first put forward in 1921 by Lindemann [30]. Milliken and Harkins [31], however, then expressed doubt concerning the feasibility of the process owing to possible masking of the isotopic effect by diffusion and convection. These misgivings appeared to be confirmed by a series of experimental papers [32-37], for no change could be observed in the isotopic composition of lithium, magnesium, or chlorine in attempts to effect the electrical migration of their salts in aqueous solution, and Eilert's experiment [38] evidently passed unnoticed. And although rare-earth metal ions were successfully separated by this method [37,39-42], Jette [43] concluded, from a comparison of deductions from hydrodynamic and kinetic theories, that "differences in the mobilities of isotopic ions are extremely small, and cannot be detected by existing methods". Attention was therefore switched to other processes, and even in 1942 Kendall [44] still asserted that the method was powerless to effect the separation of isotopes.

These failures are explained by the low sensitivity of the method of isotopic analysis—determination of the atomic weight of the element undergoing separation—employed at that time. An isotope effect was, of course, present, but it was too small. This was proved later, when mass-spectrometric and activation methods of analysis became generally available, and radioactive isotopes began to be used as tracer atoms: when the experiments were repeated under identical conditions, a change in isotopic composition was not only observed qualitatively but also measured quantitatively [45-49].

In the initial attack on problems of producing an atomic bomb a detailed study was made of many methods—including electrical migration—suggested earlier for separating isotopes. As early as 1942 several groups of investigators in the U.S.A. were developing this method [50-58], but the first publication appeared only in 1946. [59] Accounts appeared later of the method of operation based on the countercurrent principle, and experimental results on the separation of the isotopes of potassium [60,61], chlorine [62], copper [63], and uranium [64,65], as well as the theory of the process [66,67]. During the War interest in this method was taken also in Germany [68-72].

In the postwar period the method of electrical migration was developed in several directions. Countercurrent electrical migration in aqueous solution applied to the separation of isotopes was studied in the Soviet Union [73-84], the Federal Republic of Germany [4,85-90], Switzerland [91-100], West Berlin [27,101-114], and Israel [115,116]. Electrical migration combined with ion exchange in resin-filled columns or with the use of ion-exchange membranes has been studied in Japan [117-130] and in the Soviet Union [131-137]. The electrical migration of ions on a paper strip impregnated with an aqueous salt solution has been studied in France by the use of radioactive and stable isotopes [13,14,138-144].

Study of the diffusion of ions in salt crystals by means of a radioactive tracer [145-148] suggested conducting this

process with a superimposed constant electric field: in this way electrical migration was effected in single crystals or compressed powders of salts[148-155]. The production of high-temperature fuel cells with solid electrolytes enabled them to be used to enrich oxygen isotopes by the electrical migration method[156-158].

Molten salts, which, like aqueous solutions, permit the countercurrent principle to be applied and thereby the effect of the difference in mobility between isotopic ions to be magnified many times, have attracted great attention from research workers. Following the successful enrichment in 1947 of lithium and potassium isotopes in a mixture of their molten chlorides[159], more than a hundred theoretical and experimental papers have appeared on countercurrent electrical migration in molten salts: studies have been made of the separation of the isotopes of lithium[20,21,159-197], sodium[192,198], potassium[20,21,159,191,192,199-201], rubidium[178,192,200,202,203], caesium[192], copper[204], silver[205], magnesium[191,206,207], calcium[21,206-214], strontium[206,207], barium[206,207], zinc[215,216], cadmium[214,217,218], thallium[219-222], tin[223-225], lead[214,225-227], uranium[228], chlorine[166,167,200,229-233], and bromine[200,234,235]. The technique developed for molten salts has been used to investigate electrical migration in solid salts of lithium[236-239]. The electrical migration of isotopic alkali-metal ions has been examined also in their molten nitrates impregnating a strip of asbestos[10-14,240-243].

In 1953 Haeffner[244] detected a slight change in isotopic composition when a current was passed through a capillary filled with mercury. This phenomenon, named after him the Haeffner effect, was investigated not only in mercury[245-247] but also in molten lithium[248,249], potassium[250-252], rubidium[251-254], zinc[255], cadmium[255], gallium[256-259], indium[252,258,260], tin[255,258], and lead[258] and in solid uranium[245]. Sharp differences were observed in the behaviour of isotopic ions in metals and in salts. The fact alone that in metals light isotopes accumulate at the anode—not at the cathode as in all other media—suggests that the migration of ions takes place by different mechanisms in metals and in salts. Many theoretical papers have been published[263-277] on isotope effects in the electrical migration of ions in liquid metals.

III. SEPARATION OF ISOTOPES BY COUNTERCURRENT ELECTRICAL MIGRATION

1. Principles and Phenomenological Theory of the Method

The underlying principle of countercurrent electrical migration consists in producing a flow of electrolyte in the opposite direction to the movement of the isotopic ions in the separating apparatus. The velocity of the electrolyte is adjusted so that the faster light isotopes overcome the countercurrent and accumulate in the "head" electrode compartment and in the adjacent portion of the separating tube joining the two electrode compartments, while the slower heavy isotopes are washed back by the counterflow of liquid. If isotopic cations are being separated, the cathodic compartment is the head electrode compartment in this sense.

The mathematical description of countercurrent electrical migration is based on the assumptions[67,96,278] that the velocities v of the ions, their diffusion coefficients D, and the electric field strength E are in general constant at any point in the system at any instant t. A one-dimensional process is considered: i.e. the variables change only along the x-coordinate in the direction of the axis of the separating tube, whereas all parameters are invariable in a radial direction, perpendicular to x. All non-kinetic factors which may affect the separation (degree of dissociation of the electrolyte, association and complex formation by the ions, reactions involving precipitation of a solid phase or the evolution of gases, etc.) are disregarded by the general theory; if one or more such processes are superimposed on electrical migration, this is regarded as a more complex particular case and is considered specially. Electrode reactions are assumed not to affect the separation of isotopes, and the electrolyte in the electrode compartments is perfectly mixed.

Such idealisation of the conditions of the process makes the problem much simpler to solve, while introducing only minor errors into the final results. Furthermore, if particular details of this method are disregarded, other methods of separation—gaseous diffusion, thermal diffusion, chromatography, etc.—can be described by the same mathematics. The phenomenology of the countercurrent electrical migration of ions is the same, of course, in molten salts, aqueous solutions, and liquid metals.

Let the mixture of isotopes to be separated consist of mole fractions ${}^i\gamma$ of n components:

$$\sum_i^n {}^i\gamma = 1.$$

When the current is switched on, the components acquire velocities ${}^iv$ in the direction of the x-coordinate, the speed of each component being inversely proportional to the square root of its mass[279]. Thus directed movement in the electric field—electrical migration—is superimposed on the random thermal motion of the molecules of the liquid. The transport of components along the separating tube results in a concentration gradient $\partial {}^i\gamma/\partial x$, which leads to diffusion in the opposite direction to the movement of the ions. The relation between these two factors—migration in the electric field and diffusion and in the opposite direction—determines the total flux ${}^i\varphi$ of the component along the separating tube:

$${}^i\varphi = {}^i\gamma {}^iv - {}^iD\frac{\partial {}^i\gamma}{\partial x}. \quad (1)$$

The more mobile components, overcoming the countercurrent of liquid, accumulate at the head of the tube, while the less mobile components are washed towards the other end. Since the rate of the countercurrent is equal to the mean speed of the ions, the mixture as a whole remains stationary with respect to the walls of the tube:

$$\sum_k^n {}^k\gamma {}^kv = 0. \quad (2)$$

The concentration of the components undergo redistribution along the separating tube at the rates

$${}^iv = \sum_k^n {}^k\gamma ({}^iv - {}^kv). \quad (3)$$

From the condition of continuity we can set up the differential equation

$$\frac{\partial {}^i\gamma}{\partial t} = -\frac{\partial {}^i\varphi}{\partial x} = -\sum_k^n ({}^iv - {}^kv)\frac{\partial {}^i\gamma {}^k\gamma}{\partial x} - \sum_k^n {}^i\gamma {}^k\gamma \frac{\partial ({}^iv - {}^kv)}{\partial x} + {}^iD\frac{\partial^2 {}^i\gamma}{\partial x^2}. \quad (4)$$

for the process of countercurrent electrical migration.

Since the strength of the electric field and the speeds of the components are everywhere constant, the second term on the right-hand side of Eqn. (4) vanishes. The inevitable

mixing of the liquid in the cell as a result of convection and electro-osmosis can usefully be allowed for by introducing, instead of the molecular diffusion coefficients ${}^{i}D$, an effective diffusion coefficient or coefficient of intermixing $D' > {}^{i}D$. There is then no need to distinguish between the diffusion coefficients of the components, and Eqn. (4) simplifies to

$$\frac{\partial {}^{i}\gamma}{\partial t} = -\sum_{k}^{n} ({}^{i}v - {}^{k}v)\frac{\partial {}^{i}\gamma {}^{k}\gamma}{\partial x} + D'\frac{\partial^2 {}^{i}\gamma}{\partial x^2}. \quad (5)$$

For a system of n components we have thus established a set of n differential equations of type (5), which are mutually dependent.

No general method has been found for solving this set of equations, and therefore simplifying artifices are used. A particular case of an actual n-component system—a binary mixture of isotopes—is usually considered. Since a two-component model can be used to describe the separation of isotopes of polyisotopic elements [280], the method of solution is evidently applicable also in the general case. Denoting light and heavy components by the affixes "l" and "h", we obtain ${}^{h}\gamma = 1 - {}^{l}\gamma$, ${}^{l}\gamma = \gamma$, and ${}^{l}v - {}^{h}v = \Delta v$; and Eqn. (5) becomes [74,281]

$$\frac{\partial \gamma}{\partial t} = -\Delta v(1-2\gamma)\frac{\partial \gamma}{\partial x} + D'\frac{\partial^2 \gamma}{\partial x^2} \quad (6)$$

It can also be assumed [8,282] that all the isotopes in the mixture, with one exception, are so rare that their mole fractions remain very small at any instant, and we then have a set of n independent equations. When in particular $\gamma \ll 1$, we have instead of (6) the linear differential equation

$$\frac{\partial \gamma}{\partial t} = -\Delta v\frac{\partial \gamma}{\partial x} + D'\frac{\partial^2 \gamma}{\partial x^2} \quad (7)$$

Mason and Weaver [283] discovered a method for solving an equation of the type (7) in a study of the distribution of fine particles, suspended in a liquid, in a gravitational field. Konstantinov and Fiks [74] suggested a direct solution for countercurrent electromigration. A general solution of Eqn. (6) was first given by Majumdar [284] when developing a theory of the thermal diffusion column. The general principle of the solution of such equations, which has since been used by all authors, consists in introducing the dimensionless variables

$$\xi = \frac{\Delta v}{D'}x, \quad \tau = \frac{(\Delta v)^2}{D'}t \quad (8)$$

whose physical meanings correspond to a coordinate along the separating tube and the time, both expressed in terms of the process parameters Δv and D'. For example, substituting (8) in (6) and replacing variables

$$\gamma = \frac{1}{2} + \frac{1}{q}\frac{\partial q}{\partial \xi}, \quad (9)$$

where q is some function [281,284], will give an equation of the type

$$\frac{\partial q}{\partial \tau} = \frac{\partial^2 q}{\partial \xi^2}, \quad (10)$$

the method of whose solution is well known.

Solutions of equations of the type (6), (7), and (10) have been published for several actual cases of countercurrent electromigration. If the salt containing the separable isotopes is located entirely inside the separating tube and is bounded by other salts at both ends, the system is simulated by the problem of a tube of finite length L closed at both ends [67,74,265,266,283,284]. The initial condition represents uniform distribution of the components throughout the length of the separation zone $0 \leqslant x \leqslant L$ at $t = 0$. The boundary conditions correspond to the fact that the components remain within the separation zone throughout the experiment, i.e. that their fluxes are zero at both boundaries of the zone, which can be written e.g.

$$\gamma(x, 0) = \gamma_0, \ \varphi(0, t) = 0, \ \varphi(L, t) = 0, \quad (11)$$

where γ_0 is the mole fraction of the component in the initial isotopic mixture.

If one end of the separation zone is bounded by another salt inside the separating tube, while the other end expands into a sufficiently large electrode compartment, the zone can be simulated by the problem of a tube of finite length with one end closed and a reservoir of infinite capacity at the other end [246,284] or by the problem of a tube of semi-infinite length with one end closed [67,74,265,266,281,282]. In such a system the second boundary condition is that the isotopic composition of the salt at the point $x = L$ or ∞ respectively should at any time t be equal to the initial composition.

If the separation zone occupies the whole separating tube, terminating at one end in an electrode compartment of small capacity (from which an enriched product can be withdrawn), while the other end is joined to a large electrode compartment, as in the preceding case, the model problem involves a tube of semi-infinite length with a reservoir of finite volume at one end [67,285]. Initial and boundary conditions are the same as in the preceding system, but with the refinement that zero flux of the component occurs at the point $x = -L'$:

$$\gamma(x, 0) = \gamma_0, \ \varphi(-L', t) = 0, \ \gamma(L, t) = \gamma_0 \quad (12)$$

where $L' = V/A$ is the reduced length of the reservoir (electrode compartment) of finite volume V, and A is the cross-sectional area of the separating tube (if the tube is filled with a packing, A is the free cross-section). These problems in effect cover all concrete cases of the separation of isotopes in an electromigration cell.

A solution to the differential equation is in general found as a more or less rapidly converging series suitable for practical calculations:

$$\gamma = \gamma_0 f(\xi, \lambda, \eta, \tau), \quad (13)$$

where ξ and τ are defined by formulae (8), while λ and η are also dimensionless variables. Their physical meanings correspond to the length of the separating tube and the reduced length of the reservoir:

$$\lambda = \frac{\Delta v}{D'}L, \quad \eta = \frac{\Delta v}{D'}L' \quad (14)$$

For a tube of finite length terminating in a reservoir, for example, the solution is [67]

$$\gamma = \gamma_0 \exp\xi - \frac{8}{\lambda}\gamma_0\left(\exp\frac{\xi-\lambda}{2}\right)\sum_{s=0}^{\infty}\frac{\sinh\frac{r_s\lambda}{2}\sinh\frac{r_s\xi}{2}\exp\left[-\frac{1}{4}(1-r_s)^2\tau\right]}{\frac{2}{\lambda}-1+r_s+\frac{2}{\lambda}\frac{\frac{\eta}{2}\left(1+\frac{\eta}{2}\right)(r_s^2-1)}{\left(1+\frac{\eta}{2}\right)^2-\eta^2\frac{r_s^2}{4}}}, \quad (15)$$

where the rs are the roots of the equation

$$\tanh\frac{r\lambda}{2} = \frac{r}{1+\frac{\eta}{2}(1-r^2)} \quad (16)$$

Equation (15) enables the distribution of the isotopic components along the tube to be calculated for any instant. A similar type of solution is obtained for the other problems enumerated above.

It is sometimes convenient to choose the separation factor of two isotopes

$$S = \frac{\gamma(1-\gamma_0)}{\gamma_0(1-\gamma)} \qquad (17)$$

instead of the mole fraction γ of a component of the isotopic mixture, as the variable for which a solution to the differential equation is sought [281]. Equation (17) has been written for a binary mixture. If an element consists of more than two isotopes, the separation factor for any pair is a linear function of the difference between their masses [215-217,226,246]. A method has been given [280] for calculating the separation factors of all pairs of isotopes provided that the value of S for any one pair of the mixture is known. Solutions analogous to (15) are found for S.

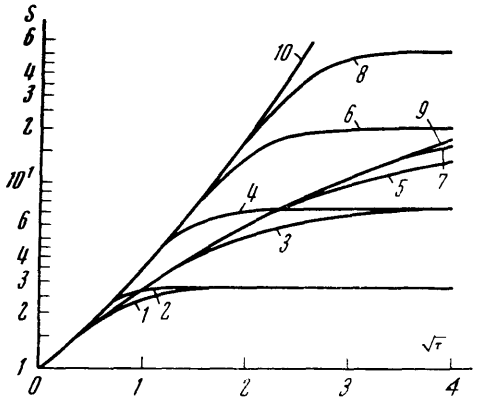

Figure 1. Dependence of separation factor S on time τ for separating tubes of different lengths λ with different initial mole fractions γ_0 of enrichable isotope [281]: 1) $\lambda = 1$, $\gamma_0 = 0$; 2) 1, 1; 3) 2, 0; 4) 2, 1; 5) 3, 0; 6) 3, 1; 7) 4, 0; 8) 4, 1; 9) ∞, 0; 10) ∞, 1.

Examination of expressions of the type (15) will give a theoretical description of the behaviour of an isotopic mixture during separation. Fig. 1 shows an example of such behaviour in separating tubes of various lengths, with one end closed and the other connected to an infinite reservoir [281]: it illustrates the dependence of S on $\tau^{1/2}$ for various reduced tube lengths λ. Initially enrichment follows an almost parabolic curve (Breit and Friedman [67] confirmed this by numerical calculations), and then it approaches a horizontal straight line asymptotically: it reaches a steady state.

For low values of τ the curve is described by the simple formula [281]

$$S = e^{2\sqrt{\tau/\pi}} \qquad (18)$$

i.e. initially the separation of an isotopic mixture is independent of the length of the separating tube. This holds provided that $L \geqslant 1.8(D'/|\Delta v|)\ln S$. Thus when τ is small we can put $\lambda = \infty$ in formulae of type (15), which greatly simplifies the calculations.

Fig. 1 shows that the rate of separation of the isotopes begins to diminish sooner the smaller is λ, i.e. the shorter the separating tube. If the closed end of the tube is replaced by a reservoir of limited volume, the overall rate of separation decreases: i.e. the corresponding $S-\tau^{1/2}$ curve is inclined at a larger angle to the horizontal axis than is the curve in Fig. 1. At $\tau = 0.002$, for example [67], the rates of accumulation of enriched isotope in the reservoir with $\eta = 0.1$ and 1 respectively are only one-third and one-tenth of the rate for $\eta = 0$.

An interesting feature is the dependence of the separation factor on the content of the enrichable isotope in the initial mixture: this is apparent in Fig. 1 in a "bifurcation" of the $S-\tau^{1/2}$ curves at quite large τ, but with the system still far from a steady state. Under otherwise similar conditions a given separation factor is attained more rapidly the richer was the initial mixture in the enrichable isotope [281,282]. For example, the time required to reach $S = 10$ with $\gamma_0 = 1$ is only one-third of the time required when $\gamma_0 = 0$. These are obviously limiting cases for the isotopic composition of a mixture, for in real materials $0 < \gamma_0 < 1$.

The "mean time" t_S required for a steady state to be established is given by the formula [74]

$$t_s = \frac{L^2}{\left(\pi^2 + \frac{\lambda^2}{4}\right)D'} \qquad (19)$$

Since $\frac{1}{2}\lambda \ll \pi$, we have [68,74] $t_S = L^2/\pi^2 D'$; a steady state is actually established [74,246] in the time $t \simeq 4t_S$. The maximum separation factor which can be achieved in the steady state is determined solely by the length of the tube [281]:

$$S_{st} = e^{\lambda}. \qquad (20)$$

Equations (18) and (20) are valid in the absence of withdrawals. If enriched material is removed at a rate p (in $cm^3\ s^{-1}$) from the head of the cell, the separation factor S_p is given by the formula [96]

$$\ln\frac{S_p}{S} = -\frac{v_p}{v_{cc}}(S-1)\frac{\gamma(0,t)}{\gamma(L,t)}, \qquad (21)$$

where $v_p = p/A$ (cm s^{-1}) is the speed of withdrawal, d_{cc} is the speed of the countercurrent of electrolyte in the separating tube, and $\gamma(0, t)$ and $\gamma(L, t)$ are the mole fractions of enriched isotope at the instant of withdrawal t at the head and at the opposite end of the tube. By integrating the equation of transport with continuous withdrawal

$$v_p\gamma_p = v'\gamma - D'\frac{d\gamma}{dx}, \qquad (22)$$

where γ_p is the mole fraction of the isotope in the product, while the rate of withdrawal of the isotope is related to its actual speed v' along the separating tube (i.e. v' is the rate of electrical migration minus the rate of diffusion in the opposite direction) by the expression

$$v_p = v'\gamma + (v' + \Delta v')(1-\gamma) \qquad (23)$$

(it is obvious $\Delta v' = \Delta v$), Klemm [167] obtained the formula

$$L = \frac{D'}{2\Delta v\sqrt{b^2 + \frac{v_p\gamma_p}{\Delta v}}}\ln\left[\frac{\gamma_p - b - \sqrt{b^2 + \frac{v_p\gamma_p}{\Delta v}}}{\gamma_p - b + \sqrt{b^2 + \frac{v_p\gamma_p}{\Delta v}}}\cdot\frac{\gamma_0 - b - \sqrt{b^2 + \frac{v_p\gamma_p}{\Delta v}}}{\gamma_0 - b + \sqrt{b^2 + \frac{v_p\gamma_p}{\Delta v}}}\right], \qquad (24)$$

where $b = \frac{1}{2}(1 - v_p/\Delta v)$. Substituting selected values for γ_p and v_p in Eqn. (24), together with values of Δv and D' determined by the actual conditions under which the process is conducted, we can find the length of tube L which is necessary for the withdrawal at a rate v_p of a product enriched to γ_p.

Accumulation of the enriched isotope is most rapid in the absence of withdrawal at the closed end of the separating tube or—rather slower—in a small reservoir. The content of the isotope also increases with time in the adjacent region of the tube, but a specified separation factor is reached here with some delay, which is greater the further the point from the end of the tube. In other words, the region of enrichment gradually extends from the end of the tube to its midpoint, reaching the latter in time $t_{1/2} = L^2/\pi D'$; at the same time impoverishment of the mixture with respect to this isotope takes place in the other half of the tube. The distribution of isotopes along the tube at time t is given by formulae of type (15). In particular, in the steady state

$$\gamma(\xi, \infty) = \gamma_0 e^{\xi} \tag{25}$$

It is easily seen that Eqn. (20) is a particular case of (25).

By time t the region of enrichment has extended to a distance

$$x' = \sqrt{\pi D' t}, \tag{26}$$

from the end of the tube[281,282], provided that the tube has no reservoir at its head. The presence of a reservoir of reduced length L' has little effect[285] on x', which remains proportional to $(D't)^{1/2}$, the coefficient of proportionality being $\pi^{1/2} = 1.77$ or $8/3\pi^{1/2} = 1.5$ according as $L' \ll$ or $\gg (D't)^{1/2}$.

Expanding Eqn. (18) as a series and neglecting powers higher than the first, we obtain for small values of τ the relation[278]

$$\gamma = \gamma_0\left(1 + 2\frac{\Delta v}{v} \cdot \frac{vt}{\sqrt{\pi D' t}}\right) \tag{27}$$

where v is the mean velocity of ions of the element in an electric field of strength E. Thus in the initial stage of the process the accumulation of the isotope $N(\gamma - \gamma_0)$ over the initial quantity, where N is the total number of equivalents of the element in the region of enrichment x', is proportional to the migration path vt and inversely proportional to the diffusion path $(\pi D't)^{1/2}$.

The quantity $\Delta v/v$ in Eqn. (27)—the relative difference in rates of migration of the isotopic ions—is independent of the operating parameters of the process and is directly related to the mechanism of separation. It represents the theoretical efficiency of countercurrent electrical migration, and determines the single-stage separation factor by this method

$$1 + \frac{\Delta v}{v} = 1 + \frac{\Delta w}{w} = 1 + \varepsilon = \alpha, \tag{28}$$

where $w = v/E$ is the mobility of the ions, i.e. their velocity in an electric field $E = 1$ V cm^{-1}.

Expressing the enrichment factor ϵ in terms of the relative difference between the mobilities of the isotopic ions $\Delta w/w$—not the difference in their speeds $\Delta v/v$—makes it unnecessary to allow for the effect of the variable E and enables an objective characteristic of the method ϵ to be assigned to standard conditions. In this respect a still more useful characteristic is the mass effect suggested by Klemm[68,282]

$$\mu = \frac{\Delta w / w}{\Delta m / m}, \tag{29}$$

where $\Delta m = {}^{j}m - {}^{k}m$ and $m = \frac{1}{2}({}^{j}m + {}^{k}m)$, which enables the efficiency of the method to be assessed independently of the number of atomic mass units distinguishing the isotopes j and k. If j and k are respectively a light and a heavy isotope, we have $\Delta w = {}^{l}w - {}^{h}w > 0$ and $\Delta m = {}^{l}m - {}^{h}m < 0$, so that the mass effect is always negative.

Taking into account the quantity of electricity transported in time t through a cross-section of the separating tube

$$Q = \frac{NF}{x'} vt, \tag{30}$$

where F is Faraday's constant, we obtain from Eqns. (26) and (27) the expression

$${}^{jk}\varepsilon = \frac{\Delta^{jk} w}{w} = -\left(\frac{{}^{l}\gamma}{{}^{l}\gamma_0} - \frac{{}^{h}\gamma}{{}^{h}\gamma_0}\right)\frac{FN}{Q} \tag{31}$$

for the relative difference in the mobilities of the two isotopes[282]. A method has been published[8,192] for assessing the accuracy of the calculation of ϵ by means of Eqn. (31).

Equation (31) is easily converted into a form which is convenient for practical calculation of the mass effect[200]:

$$\mu = \frac{Fz}{MQ} \cdot \frac{m}{\Delta m} \cdot \frac{1}{\gamma_0(1-\gamma_0)} \sum_r G_r(\gamma_r - \gamma_0), \tag{32}$$

where z is the valency of the isotopic ions, M the molecular weight of the salt, r the serial number of one of the specimens into which the separating tube is cut after electrolysis has ceased and the melt has solidified (see subsection 2), G_r is the weight of salt in the rth specimen, and the summation is made over all specimens r in which isotopic analysis has detected enrichment with a given isotope. This formula (32) applies to elements consisting of two isotopes. If an element comprises n isotopes, the mass effect can be calculated for the jth and kth isotopes by means of the equation[214]

$${}^{jk}\mu = \frac{Fz}{MQ^{j}\gamma_0} \cdot \frac{m}{\Delta m} \sum_r \frac{G_r({}^{jk}R_r - {}^{jk}R_0)}{\sum_i^n {}^{ik}R_r}, \tag{33}$$

where ${}^{ik}R_r = ({}^{j}\gamma/{}^{k}\gamma)_r$ is the ratio of the contents of these isotopes in the rth specimen, and

$$[m = \sum_i^n {}^{i}\gamma_0 {}^{i}m --$$

is the atomic weight of the element.

The overall and the single-stage separation factors, S and α, are related by the formula

$$S = \alpha^q \tag{34}$$

where q is the number of theoretical plates realised in the region of enrichment. The function q in Eqn. (9) has this physical meaning. The quantities x' and q are interrelated by the height of an equivalent theoretical plate:

$$h = \frac{x'}{q} \tag{35}$$

According to Westhaver[66] the physical meaning of h in countercurrent electrical migration is the length of the separating tube in which the isotopic ratio ${}^{jk}R$ changes by a factor α. This author discussed in detail[66] theoretical methods for estimating h and D'. The practical calculation of h can be based on data obtained when a steady-state is reached. Since α differs very little from unity, it follows from Eqn. (34) that $\ln S = q\ln(1+\epsilon) = q\epsilon$, when substitution for q in (35) yields for the steady state

$$h = \frac{L\varepsilon}{\ln S_{st}} \tag{36}$$

It follows from Eqns. (14) and (20) that $L/\ln S_{st} = D'/\Delta v$, and substitution in (36) gives

$$h = \frac{D'\varepsilon}{\Delta v} = \frac{D'}{v} \tag{37}$$

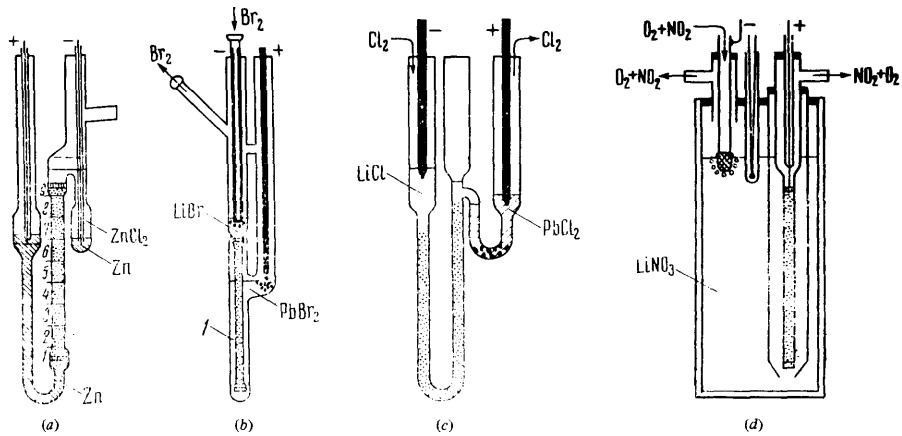

Figure 2. Cells used in the application of countercurrent electrical migration to the enrichment of: *a*) ^{35}Cl in molten $ZnCl_2$ (the numbering 1–9 indicates the specimens into which the separating tube is cut for chemical and isotopic analyses after the experiment)[8]; *b*) ^{7}Li in molten LiBr (*1* = boundary between LiBr and $PbBr_2$)[164]; *c*) ^{7}Li in molten LiCl;[162] *d*) ^{7}Li in molten $LiNO_3$.[192]

i.e. the height of an equivalent theoretical plate is smaller the smaller is D' and the greater the rate of migration of ions in the separating tube.

2. Apparatus and Method of Operation under Laboratory Conditions

Fig. 2 shows typical designs of cells for electrical migration under laboratory conditions. The cell is made of quartz or heat-resistant glass (Vycor, Supremax, Pyrex), the choice of material depending on the operating temperature and the corrosiveness of the molten salt. It consists mainly of a vertical cylindrical (*a*, *b*, *d*) or U-shaped (*c*) separating tube. Conical separating tubes have been suggested[192,203] to provide a better countercurrent and a higher current density transported by the enriched isotope; this increases the efficiency of separation of the isotopes provided that $(r_1r_2)^{1/2} < r$, where r_1 and r_2 are the radii of upper and lower portions of the conical tube, and r is the radius of a cylindrical tube of the same volume.

The separating tube is filled with a packing satisfying certain requirements—mechanical and thermal stability, chemical resistance to the molten salt, and the maximum possible thermal conductivity—in order to prevent mixing of the melt by convection currents. The packing materials usually employed are ground glass or quartz, from which the cell itself is made, and also alundum, steatite, zirconium oxide, zircon, and zirconyl phosphate. The packing should first have been carefully freed from traces of organic compounds and metallic particles by being boiled in acid or heated in a current of chlorine, washed with water, and dried. The free volume of a packed separating tube is 35–45% of the volume of the empty tube and depends on the uniformity of the particles with respect to shape and size, not on their coarseness. The "electrical free space" constitutes 70–80% of the geometrical free space, since the ions are unable to move in straight lines, but have to pass through pores between packing grains ("labyrinth effect"): in ignited asbestos, for example, the path traversed by the ions is on the average 30% longer than the straight line between the electrodes[14]. The efficiency of separation is independent of the material of the packing, but becomes higher as the latter becomes finer. Since at the experimental temperature the density of the packing may be comparable with that of the melt, the packing is placed between porous glass or quartz filters (frits) sealed into both ends of the separating tube, in order to prevent the packing from floating to the surface or being loosened by gases evolved from the melt with the formation of longitudinal channels. Details of the design of the cells and of the part played by the packing have been fully discussed by Lundén[8]. A theoretical analysis of the hydrodynamic flow of an electrolyte through a packed separating tube and of various effects on the separation factor was made by Westhaver[66].

A fundamentally different design of cell has also been proposed and studied for work with molten salts[20]: a horizontal separating tube without packing is divided by frits into a series of successive compartments, in which the melt mixes freely (Fig. 3). The advantages of such a design have been considered for aqueous solutions[27,91–93], and the conclusions reached are valid also for molten salts.

Intense movement of the liquid takes place in the separating tube during electrolysis. This results in a shift in the levels of the melt in the electrode compartments relative to their original position (Fig. 2*a*), and may even cause a break in contact between the salt and the anode[163]. Various methods are used to control the levels of the melt in the electrode compartments: the initial salt may be added to the anode compartment and excess of the melt overflows from the cathode compartment[200,219,233]; excess pressure is produced in the cathode compartment by means of an inert gas[160,214]; etc. With a correct choice of current density and in the absence of breaches in the packing, no displacement of the electrolyte relative to the cell is observed, although the components of the mixture undergo continuous separation as a consequence of mutual displacement of the molecules. This constitutes one of the advantages of the countercurrent method over

movement of a zone, e.g. in electrophoresis on a paper support: with a short distance between the electrodes the separable species, in overcoming the counterflow of electrolyte, traverse a very long path, which ensures high separation factors. Thus in an experiment with cadmium chloride in a tube ~ 20 cm long the displacement of the cations relative to the anions was estimated[217] to be 3 m, and in a prolonged experiment with thallium(I) chloride about 18 m[219].

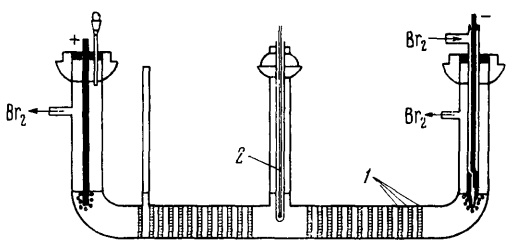

Figure 3. Horizontal cell[20] without packing: 1) porous sintered-glass discs; 2) thermocouple.

Electrical migration must be arranged in such a way that the components do not leave the separation zone, e.g. as a result of electrode reactions. This is ensured in two ways. The first method consists in neutralising the products of the electrode reaction and regenerating the original salt in the electrode compartment. Metals deposited on the cathode in molten halides are continuously oxidised by gaseous chlorine or by bromine or iodine vapour in a current of argon, entering the cathode compartment through either a special tube or a hollow cathode (special investigations have been made[8,20,163,184] to elaborate a cathode); a current of nitrogen dioxide, alone or mixed with oxygen, or of the vapours from fuming nitric acid is used for this purpose in molten nitrates. The quantity of oxidising gases supplied should always be considerably larger than stoichiometric to ensure saturation of the melt in the cathode compartment; otherwise, corrosive metals, especially alkali metals, will rapidly put the electrodes and the walls of the cell out of action. The results of many experiments have shown that the most corrosion-resistant materials for cathodes are graphite and carborundum with halides, and aluminium and stainless steel with nitrates; the most corrosion-resistant anodes are made of carbon and graphite for halides, and of platinum for nitrates, while gold anodes have been used with sulphates[193,236-238]. Data on the stability of various materials in molten salts and metals have been compiled in Ref. 286 and in standard tables[287].

Molten metal anodes can be used in the separation of isotopic anions, with tungsten wires as conducting electrodes (leads). Thus in the separation of chlorine isotopes[9,229,230] molten lead or zinc dissolves to form the corresponding chloride, so that chlorine does not leave the separation zone, and enrichment with the light isotope ^{35}Cl takes place gradually at the salt–metal interface. The same procedure is used in the separation of bromine isotopes[234,235]. If the opposite process—deposition of metal from the salt—takes place at the cathode, the molten salt remains held between two regions of molten metal—cathodic and anodic—and the only apparent result is the transport of metal from anodic to cathodic compartments (Fig. 2*a*), with no evident separation of isotopes. Liquid metals—lead, zinc, mercury—have sometimes been used as cathodes also in the separation of alkali-metal isotopes[8,193], but the alkali metal then underwent reduction and formed an alloy with the metal of the cathode, so that ions were removed irreversibly from the separation zone, and played no part in the subsequent process. Lundén has made a detailed study of this method[238,288,289].

The second method of retaining the components in the separation zone is to exclude any contact between the separable species and the electrode. This is accomplished by placing an ancillary salt, having the same gegenion as the working salt, between the latter and the electrode (Fig. 2*b*). A sharp boundary is formed between the two salts, which is especially noticeable when the salts differ in colour or have sufficiently differing refractive indices. The relative positions of the salts in the separating tube are determined by the ratio of their densities at the temperature of the experiment (to avoid mechanical mixing the denser salt should be below the boundary, which is the main factor governing the form of tube chosen) and by the relative mobilities of unlike ions (e.g. the salt having the more mobile cation should be located closer to the cathode). The common ion passes freely through the boundary, which is the only obstacle to the unlike ions: in fact, the more mobile the ions of the salt the higher its conductivity and the weaker the electric field on that side of the boundary; when, therefore, the "foreign" ion, which may be e.g. less mobile, penetrates the boundary into the zone occupied by the salt, it immediately begins to move more slowly than in its "own" salt, lags behind the ions of the first salt, and returns back through the boundary. However, this mechanism is not sufficiently effective with small differences in mobility between the ions, and the boundary between the salts remains blurred or "diffuse". If necessary the working salt can be bounded by other salts at both ends: relative densities and conductivities must satisfy the above requirements for both salt pairs forming the two boundaries. Conditions for the production of a boundary between molten salts and its behaviour have been surveyed[165]. A boundary is an excellent indicator of movement of the salts along the separating tube, and is often used to measure various characteristics of the salt systems.

Special precautions are necessary when filling the cell with the salts: no bubbles of air or other gases should remain in the separating tube; hygroscopic salts should absorb as little moisture as possible during filling; and the free surface of molten metal electrodes should not be oxidised before contact has been established with the molten salt. Filling is therefore conducted either under a vacuum or in an atmosphere of an inert gas; if necessary the initial position of the zone of the working salt in the separating tube is controlled by producing a difference in gas pressure between the electrode compartments.

The choice of conditions of electrolysis is dictated by the aims of the experiment. The design of the furnace should ensure that the thermal field inside it is as uniform as possible and is constant with time. The minimum working temperature is determined by the melting point of the most refractory of the salts used, and the maximum working temperature by the volatility of the salts and the temperature at which the glass of the cell begins to soften. In practice a vertical temperature gradient along the cell cannot be avoided, especially if the separating tube is not

immersed in a melt but is surrounded by air. Furthermore, the heating effect of the electric current produces a radial temperature gradient in the tube: special measurements have established that the difference in temperature between the centre of the tube and its outer wall may reach 200 deg in individual cases[231]. The electric field in the separating tube should be as strong as possible, but there is always an upper limit to the current, depending on the thermal conductivity of the salts and the materials of the cell: if the current density is too high, regions of local overheating appear in the packing, which may cause serious disturbances of the process and even the need to discontinue the experiment. In measurement of the electrical transport characteristics of salts the duration of an experiment is usually a few days, but with lithium salts 10–12 h is sufficient for isotopic effects to be measured by modern methods of analysis. Nevertheless, reliable means of measurement and automatic control have been developed which enable the process to be conducted continuously for several months or years in order to obtain the necessary quantity of enriched material.

The progress of electrical migration is monitored by means of electrical measuring instruments and also visually, by observing that no visible disturbances occur in the cell (a stationary boundary between the salts in the separating tube is often a convenient indication of the steady occurrence of the process), for which purpose the cell is placed in a vertical tubular electric furnace made of transparent fused quartz. The results of the separation are evaluated by studying the distribution of the components along the tube after the experiment. For this purpose the cold separating tube is divided into lengths of 1–1.5 cm, and chemical and isotopic analyses are made on every sample. Sometimes the accumulation of an isotope in the electrode compartment is observed by withdrawing after a certain time a sample of the molten salt for analysis.

3. Experimental Conditions for and Results of the Separation of Isotopes

Data on all published molten salt systems in which countercurrent electrical migration has been studied are compiled in Table 1. Certain data on electrical migration in solid salts, aqueous solutions, and liquid metals are included for comparison.

Table 1 shows that, for isotopes of the same element, the mass effect depends on the medium in which electrical migration is conducted: in solid and molten salts $\mu \simeq 10^{-2}$; in aqueous solutions it is usually 20–30% of its value in melts (for uranium isotopes the mass effect is larger in solutions than in melts, apparently because of the superimposition of the isotope effect of exchange between different species present in solution); in liquid metals $\mu \simeq 10^{-5}$; and in solid metals the mass effect is extremely small. Metals are clearly of no interest as media for the practical separation of isotopes. Solid salts will evidently also find no application, for it is impossible to accomplish a countercurrent process (but see Ref. 156 to 158). Solutions of salts in water and other solvents continually attract attention by the convenience and safety of their use for enrichment and by the simplicity of the apparatus, but a substantial defect is the considerable consumption of energy in the "useless" transport of the solvate sheaths together with the ions. Thus molten salts are the most suitable media for the separation of isotopes by the electrical migration of ions.

Despite several experimental difficulties (high temperature, restricted choice of materials resistant to the corrosive action of melts, and with several elements the absence of salts of sufficiently high electrical conductivity which do not undergo thermal decomposition), electrical migration in molten salts has definite advantages: maximum mass effects are accompanied by a far wider temperature range for molten salts, which makes artificial cooling of the separating tube unnecessary (with aqueous solutions this is required to avoid their boiling), while the heat produced by the passage of the electric current through the melt makes a substantial contribution to the thermal balance and may completely eliminate the need for additional heating of the melt[167]; a countercurrent of electrolyte is far easier to provide in molten salts than in solutions; and molten salts are liquids having the maximum concentration of separable isotopes (apart from liquid metals), which ensures a higher yield of product from apparatus of a given size.

4. Separation of Isotopes in Large-scale Plant

In laboratory apparatus, where working with small quantities of material involves a small consumption of energy, the tendency is to achieve maximum enrichment is as short time as possible, which determines the design of cells and the choice of experimental conditions. The organisation of large-scale production involves the solution of a large complex of engineering problems, consideration of which is beyond our scope, as well as economic problems. In the present subsection we shall deal only with a few questions of principle.

The design of industrial equipment is similar to that shown in Fig. 2*d*: vertical separating tubes, into which electrodes are inserted from above, are lowered into a molten-salt bath. The advantages of this design[192] are that the separating tube can be moved vertically to control the countercurrent of electrolyte (e.g. with very compact packing, of grain diameter < 0.1 mm, the rate of flow of the melt in the tube is so diminished that its level in the anode compartment should be 3–5 cm below the level of the melt in the bath in order to create additional hydrostatic pressure), the temperature gradient along the separating tube becomes negligible owing to the intense convection in the bath, and the separating tubes are easily replaceable and simple in construction. A substantial disadvantage, however, is the unavoidable diffusion of ions through the walls of the tube, intensified by the electric field (direct experimental evidence of such a process has been provided[101]), which may considerably diminish or even eliminate altogether the effect of separation of the isotopes, so that the choice of material for the separating tube and the thickness of its walls are of decisive importance. Thus in the separation of calcium isotopes the necessary enrichment was ensured only by use of tubes made of several varieties of alumina[213].

If light isotopes are to be concentrated, a cathode of suitable design is immersed in the electrode compartment of the separating tube, and several anodes are arranged symmetrically around the tube, in such a way that the bath forms the anode compartment of the installation[184]. When a steady state is reached, enriched material is withdrawn regularly from the cathode compartment of the tube, and an equivalent quantity of the initial salt is added to the

[1]Isotopes for which the mass effect has been calculated. The abbreviations have the following significance: MS = molten salts; SS = solid salt; AQ = aqueous solution; LM = liquid metal; SM = solid metal.

[2]The structural characteristics of the cell are given in the sequence—form and material of separating tube, dimensions of tube (length (cm) in numerator, internal diameter (mm) in denominator) and material and grain-size (mm) of packing. Abbreviations: U = U-shaped tube of type illustrated in Fig. 2*c*; V = vertical tube as shown in Figs. 2*a*, 2*b*, and 2*d*; H = horizontal cell as in Fig. 3; Supr = Supremax glass; ZrPh = zirconyl phosphate.

[3]"Head" electrode on left-hand side (negative in the separation of isotopic cations, positive in the separation of anions). The salt containing the isotopes to be separated is printed in bold type; its content in the initial mixture or the concentration of the solution is indicated underneath.

[4]Results of isotopic analysis before → after experiment (in the numerator for the cathodic end of the separation zone, in the denominator for the anodic end): the values given are those which differ to the maximum extent from the initial values (for example, if maximum enrichment with a given isotope is observed not in an electrode compartment but in the adjacent portion of the separating tube, the latter value is cited). The quantity of enriched salt (in g or cm^3) is given in parentheses if electrical migration was conducted for preparative purposes.

bath. When heavy isotopes are to be concentrated, on the other hand, the bath forms the cathode compartment, and enriched material is withdrawn from the upper space, not occupied by the packing, of the tube (the anode compartment)[20,213]. If, however, both cathodic and anodic separating tubes are immersed in the bath, both light and heavy isotopes can be concentrated in the same installation; an electrode at zero potential should be lowered into the bath to prevent disturbance of the electrical conditions in the individual tubes and the bath as a whole. Klemm[172] described the mode of operation of such an installation for separating the isotopes of lithium, in which the ratio of the numbers of cathodic and anodic tubes was 1 : 2, the quantity of material enriched with the light isotope ^{6}Li to 90 at.% was 8.2% of the total quantity of salt removed from the separating tubes, whereas 91.8% of the whole salt was enriched to 99.974 at.% with the heavy isotope ^{7}Li.

The choice of optimum dimensions for the separating tube is governed by the relation between the required separation factor S and the rate v_p of removal of the product from the plant, together with the mechanical and thermophysical properties of the materials of which the plant is made. Thus S is proportional to the current density, i.e. inversely proportional to the diameter of the tube; and the permissible rate of withdrawal, which is still insufficient to cause serious disturbance of the steady state, is directly proportional to the diameter of the separating tube. In the separation of lithium isotopes in the molten chloride with $S = 3-4$ and a very small withdrawal the optimum tube diameter has been estimated[184] as 10–15 mm; but with considerable withdrawal (several grams of lithium chloride per day) and $S = 2$, the diameter must be increased to 30 mm.

From Eqn. (24) and the requirement of minimum energy consumption Klemm[167] found that the optimum conditions for the concentration of ^{7}Li from 92.7% to 99.974% ($S = 310$) were a separating tube 22.8 cm long with the product removed at a rate of 2.8 cm day^{-1}. The electrical energy consumed was 11 kW h per gram of lithium enriched with ^{7}Li. The energy consumption for the concentration of ^{6}Li from 7.3% to 90% was[172] 60 kW h g^{-1}. Neubert and Klemm[208] calculated the energy consumption and the cost for calcium chloride enriched with the ^{48}Ca isotope: a single value of the separation factor, which must be achieved by electrical migration in order that the total cost of the product should be a minimum, corresponds to each value of the sum of overhead expenses in preliminary enrichment with ^{46}Ca by electrical migration followed by complete enrichment on an electromagnetic separator. In the equipment of Ménès et al.[211] 25 kW h of electrical energy was consumed per gram of calcium in which the initial content of ^{46}Ca had been doubled. Westhaver[66] estimated energy consumptions in the separation of potassium isotopes in aqueous solution: enrichment with ^{41}K from 14.2% to 21.3% in a tube 4.6 cm long requires 14 kW h g^{-1} potassium.

Equation (37) shows that the chief parameter of an actual tube as a separating device[74] is the ratio D'/v, so that its diminution is one of the most important engineering problems. Experience of the operation of large-scale installations[20,167,184,192] shows that under optimum conditions D' does not exceed D more than 3–4 fold: i.e. it is of the order of 10^{-4} cm^2 s^{-1}. Since the mobility of ions in a molten salt is $\sim 10^{-4}$ cm^2 V^{-1} s^{-1}, the quantity h is around 2–3 mm with a field of 3–5 V cm^{-1} in the tube: i.e. the dimensions of separating devices of this kind can be considerably smaller than in other methods for the separation of isotopes.

IV. APPLICATION OF ELECTRICAL MIGRATION TO THE STUDY OF THE STRUCTURE AND TRANSPORT PROPERTIES OF MOLTEN SALTS

1. Measurement of Ionic Mobilities by Countercurrent Electrical Migration

A cell with a separating tube can be used not only for applied purposes—for the separation of isotopes—but also as a scientific research tool. A large proportion of the experiments reflected in Table 1 were undertaken with the aim of measuring the relative difference in mobility between isotopic ions, a quantity which is necessary for theoretical conclusions and generalisations with respect to both the structure of the medium in which the ions move, in particular molten salts, and the mechanism of the actual movement of the ions.

Table 1 shows that the mass effect has a tendency to decrease with increase in the atomic weight of the separable element, which can be expressed by the empirical formula[290]

$$\mu_+ = \mu' \left(1 + \frac{m_+}{M}\right)^{-1} \qquad (38)$$

where μ' is a constant, $M = km_-$, and m_+ and m_- are the masses of the cations and anions forming the salt. Klemm[279,208], having published a summary of measurements of μ_+ for seventeen metal halides in the molten state, noted an interesting regularity: the mass effects of isotopic cations of salts having a layer lattice in the solid state conformed closely to the curve described by Eqn. (38) with $\mu' = -0.15$ and $k = 2.1$; but for cations of salts not having a layer lattice the appropriate values were -0.079 and 2.1 respectively. Both curves are shown in Fig. 4, from which it is evident that all halides have values of μ_+ grouped about these curves. Attempts to select other values of μ' and k had only partial success[8,200,227].

Klemm's suggestion[208]—that if the above rule is valid magnesium and cadmium bromides, the corresponding iodides, and the iodides of calcium, zinc, and lead, which have a laminar structure in the solid state, should when molten have values of μ_+ close to curve A, while those of strontium and barium bromides should be close to curve B—has since been verified for CaI_2, CdI_2, PbI_2,[214] and $CdBr_2$,[218] and also for $SnCl_2$,[223] $SnBr_2$,[223] and SnI_2.[224] The results made a more careful formulation of the rule necessary[214], the two types of salts being delimited by an empirical curve (the broken curve C in Fig. 4), for which an analytical expression was not found.

Experimental values of μ_+ for alkali-metal and thallium nitrates are also plotted in Fig. 4. Lundén and Ekhed[196] found that the variation in μ_+ for the alkali-metal nitrates is best represented by the equation

$$-\mu_+ = 0.0848\,(1 + m_+/46)^{-1}, \qquad (39)$$

provided that values of μ_+ are taken at temperatures 5% above the absolute melting points of the corresponding nitrates. It is evident that μ_+ for thallium(I) nitrate does not obey the rule. It is noteworthy that values of μ_+ for solid lithium sulphate and lithium hydride fit well on curve A.

Attempts to find a similar relation for isotopic anions were undertaken[229,235] in the absence of sufficient experimental results. Similar series of salts in the order of diminishing μ_-—RbCl > TlCl > KCl > $PbCl_2$ > $CdCl_2$ > > $ZnCl_2$ and RbBr > $PbBr_2$ > $ZnBr_2$—can be distinguished from the results in Table 1. If this type of relation does

exist for anions, it is obviously more complicated. In any case, the rule formulated by Herzog and Klemm[231]—that the isotope effect in ionic mobilities is larger the greater the number of the heaviest possible gegenions surrounding the separable isotopic ions in the melt—is well satisfied for cations, and with large exceptions for anions.

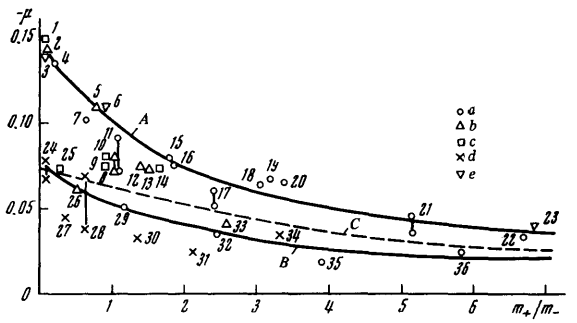

Figure 4. Graphical expression of Klemm's "halide rule"[279,208], where the curves represent: *A*) $\mu = 0.15(1 + m_+/2.1m_-)^{-1}$; *B*) $\mu = 0.079(1 + m_+/2.1m_-)^{-1}$; *C*) boundary between salts having layer and coordinated lattices in the solid state. The experimental points correspond to: *a*) molten chlorides; *b*) molten bromides; *c*) molten iodides; *d*) molten nitrates; *e*) solid salts: 1) LiI; 2) LiBr; 3) Li_2SO_4; 4) LiCl; 5) $ZnBr_2$; 6) α-AgI; 7) $MgCl_2$; 8) RbBr; 9) CdI_2; 10) SnI_2; 11) KCl; 12) $CdBr_2$; 13) $SnBr_2$; 14) PbI_2; 15) CuCl; 16) $ZnCl_2$; 17) RbCl; 18) AgCl; 19) $CdCl_2$; 20) $SnCl_2$; 21) TlCl; 22) UCl_4; 23) LiH; 24) $LiNO_3$; 25) CaI_2; 26) $CaBr_2$; 27) $NaNO_3$; 28) KNO_3; 29) $CaCl_2$; 30) $RbNO_3$; 31) $CsNO_3$; 32) $SrCl_2$; 33) $PbBr_2$; 34) $TlNO_3$; 35) $BaCl_2$; 36) $PbCl_2$.

Correlations of μ_+ with ionic radii are clearer than with ionic masses. For nitrates Okada and Saito[192,222] suggested a linear relation between μ_+ and r_+, but the empirical formula

$$-\mu_+ = 1/(20.9r_+ - 2.4) \qquad (40)$$

derived by Lundén and Ekhed[196] is a far better description of such correlation, which applies also to thallium(I) nitrate. With nitrates this formula (40) is satisfied better than (39)[196], and a still better correlation

$$-\mu_+ = 1/(9.91 + 1.51V_+) \qquad (41)$$

exists between μ_+ and the volume V_+ of the cation: thus the deviation in experimental values of μ_+ for the lithium isotopes from those calculated by means of Eqns. (39)–(41) is respectively 53%, 1%, and 0.4%. For halides Klemm[279] found that μ_+ is correlated more closely with r_+/r_- than with m_+/m_-.

The temperature variation of the mass effect has been studied for several salts. A linear relation is obtained in all cases, expressed by empirical formulae of the type

$$-\mu = a[1 + b(t - t_0)] \qquad (42)$$

where a and b are constant coefficients and t_0 (°C) is a fixed temperature. Table 2 gives values of these three parameters together with the temperature range for which formulae (42) have been derived. The mass effect is seen to decrease with temperature for thallium and chlorine isotopes in thallium(I) chloride and for tin and lead isotopes in tin(II) and lead(II) chlorides respectively; it is almost independent of temperature for lithium isotopes in solid lithium sulphate, chlorine isotopes in rubidium chloride, and bromine isotopes in the bromide; and in the remaining cases it increases with temperature. There are several discrepancies in the results of different workers: for example, μ_+ for lithium isotopes in the nitrate has been found to increase[196] and to decrease[14,172] with temperature (in Ref. 14 the coefficients in Eqn. (42) were not calculated). Lundén and Ekhed[196] suggested several reasons for such discrepancies, but also emphasised the strong influence of difficulty controllable parameters on experiments, which diminished reliability of the results.

Table 2. Values of the constant a, b, and t_0 in Eqn. (42). Elements for whose isotopes this relation has been found are indicated by **bold type** in the formulae of the salts.

*Calculated by authors from measurements of ratio of electrical conductivities for isotopically pure lithium salts.
**Calculated by Reviewer from results of Expts. 96–98 and 100 in Table 1.
***Calculated by Reviewer from results of Expts. 228 and 229 in Table 1.

Mass effects for the isotopes of five elements (shown in **bold type**) have been measured in the molten salt mixture **Li**Cl–KCl,[159] **Li**Br–NaBr and **Li**Br–KBr,[20,178,180,182,183,186,197] Li_2SO_4–K_2SO_4,[193,194] **Li**NO_3–Li_2SO_4,[192] **Li**Cl–$PbCl_2$,[165] $SnCl_2$–$PbCl_2$,[225] $CdBr_2$–Cd,[218] and $CdCl_2$–Cd.[232] In most cases measurements were made in a narrow range of compositions, which is probably why no clear dependence of μ on the chemical composition of the melt could be detected. The work of Chemla et al. showed that variation in the content of lithium and potassium bromides in the separating tube during electrical migration had no apparent effect on the separation of lithium and potassium isotopes. On the other hand, Klemm and Monse[165] studied the composition variation of μ in the **Li**Cl–$PbCl_2$ system, and showed that the mass effect of lithium isotopes remains almost unchanged over the range 100–25 mole % of lithium chloride, but increases sharply at lower contents of this

salt (Table 1, Expts. 4–9), and $-\mu_+ = 0.296$ at 5.3 mole % LiCl. This rule is fully consistent with the value $-\mu_+ = 0.32$ for potassium isotopes in a mixture of 2 mole % of the chloride with lithium chloride[159] (Expt. 109). The abnormally high value of $-\mu_+ = 0.261$ obtained by Lundén[164] for lithium isotopes in the bromide (Expt. 19) is explained by considerable contamination of the lithium bromide melt with other salts, as has been established by control experiments[173,174] (Expts. 20–25). This relation is probably widespread: Klemm[216] showed that the mass effects in the diffusion of hydrogen in solid palladium, of lithium in molten lead, and of copper in solid silver sulphide are respectively −0.45, −0.47, and −0.44, of the order of ten times the values of μ for these cations in molten salts. A common feature of all these processes is the dilute state of the separable species. Nevertheless, over the range 10–80 mole % of tin(II) chloride in lead(II) chloride the tin isotopes have[225] $-\mu_+ = 0.012$ (Expts. 224–226), which is one-fifth of the mass effect in pure tin(II) chloride.

Klemm and Monse[165] proposed a method for measuring the absolute difference in mobility between the isotopic lithium ions in the $LiCl-PbCl_2$ system. The formula used for the calculations was

$$\Delta^{lk}w = -\frac{\varkappa}{Q}\left(\frac{{}^{l}N}{{}^{l}c} - \frac{{}^{k}N}{{}^{k}c}\right) = -\frac{\varkappa x' A}{Q}\left(\frac{{}^{l}\gamma}{{}^{l}\gamma_0} - \frac{{}^{k}\gamma}{{}^{k}\gamma_0}\right) \qquad (43)$$

where $\varkappa$ is the electrical conductivity, ${}^{j}c$ and ${}^{k}c$ are the molar concentrations of the components in the initial molten salt, and ${}^{j}N$ and ${}^{k}N$ are the numbers of moles of the components in the enrichment zone x' after the passage of Q coulombs of electricity through it, the remaining symbols having the same significance as in Eqn. (31). Variation in the mole fraction of lithium chloride from 1.0 to 0.053 is accompanied by an increase in $\Delta^{67}w$ from 3.93×10^{-5} to 7.10×10^{-5} $cm^2\ V^{-1}\ s^{-1}$.

Countercurrent electrical migration has proved extremely fruitful in studies of the transport properties not only of isotopic ions but also of ions of different elements in mixtures of molten salts. It has been used to measure the relative mobilities of Li^+ and Pb^{2+} in $LiCl-PbCl_2$;[165] Li^+, Na^+, and K^+ in various mixtures of their bromides[20,23,178,180] and nitrates[23,188,190,292,293]; Na^+, K^+, and Rb^+ in mixtures of their nitrates[294]; Li^+ and K^+ in $Li_2SO_4-K_2SO_4$;[193] Li^+, K^+, and Ag^+ in $LiNO_3-KNO_3-AgNO_3$;[294] Li^+ and Ca^{2+} in $LiNO_3-Ca(NO_3)_2$;[294] Li^+ and Ag^+ in $Li_2SO_4-Ag_2SO_4$;[193] Ca^{2+}, Sr^{2+}, and Ba^{2+} in mixtures of their bromides[211,295]; Li^+, K^+, and Ca^{2+} in mixtures of their bromides[211]; Sn^{2+} and Pb^{2+} in $SnCl_2-PbCl_2$;[225] Cl^- and NO_3^- in $AgCl-AgNO_3$;[296] NO_3^- in $LiNO_3-KNO_3$;[297] Cd dissolved in $CdCl_2$[232] and in $CdBr_2$;[218] and also Pb dissolved in $PbCl_2$.[298] The technique of measuring transport numbers of ions in individual melts was developed by Fischer and Klemm[299], and their temperature dependence in thallium(I) chloride and zinc chloride was measured. A general phenomenological theory of the measurement of transport in molten salts by this method was put forward by Klemm[300].

2. Measurement of Ionic Mobilities by the Electrical Migration of a Zone

The electrical migration of ions can be investigated also without production of a countercurrent of electrolyte, by the use of the classic principle of paper electrophoresis[301]. Fig. 5 illustrates the experimental arrangement[14] for molten salts: inside a tubular electric furnace *1* is fixed, in an exactly horizontal position, an asbestos strip *2* (typical dimensions 600 × 12 × 0.3 mm), the ends of which dip into small baths *3* and *4* containing melts of the same salt together with conducting electrodes *5* and *6*. The asbestos strip has previously been washed in acids, ignited, and impregnated with the molten salt solvent.

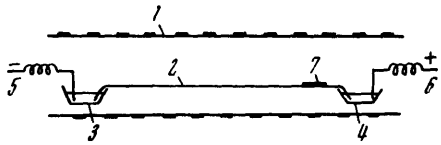

Figure 5. Experimental arrangement for studying electrical zone migration[14].

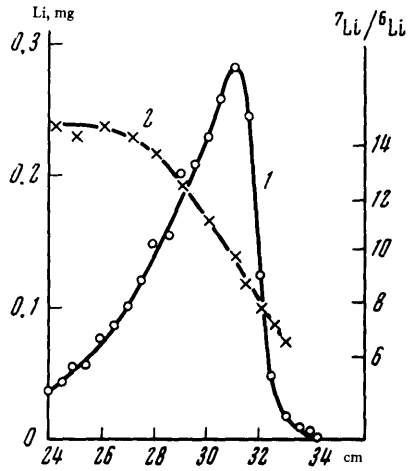

Figure 6. Distribution along migration path of zone after completion of experiment[12] for: 1) concentration of lithium; 2) isotope ratio $^7Li/^6Li$.

The method of investigation consists in applying to one end of the asbestos strip a few milligrams of the salt containing the isotopes, and passing through the system a constant current, under whose influence the initial spot (zone) of the salt *7* moves along the strip. If the zone contains radioactive isotopes, its movement can be followed conveniently by means of a counter. Owing to the difference between the mobilities of isotopic ions, their concentrations within the zone undergo redistribution in the direction of migration: the more mobile light isotopes accumulate at the forward edge of the zone, and the slower heavy isotopes at the rear. The experiment is continued for 2–4 h, after which the asbestos strip with the solidified salts is cut, in the region occupied by the zone, into transverse bands about 5 mm wide, in each of which the isotopic composition of the test element is determined, and if necessary a chemical analysis of the salt mixture is made. Typical results for the electrical migration of a zone in molten salts are illustrated in Fig. 6.

The phenomenological theory of electrical zone migration is simpler than that of countercurrent migration.

Chemla[10,13] showed that movement of the zone in the direction of the electrical field and extension of its boundaries by diffusion can be regarded to a first approximation as mutually independent processes. Substitution of variables $y = x - t\Delta v$ in Eqn. (7) then leads to the equation of Fick's law

$$\frac{\partial \gamma}{\partial t} = D\frac{\partial^2 \gamma}{\partial y^2}, \qquad (44)$$

in which the coefficient of molecular diffusion D (not the coefficient of mixing D') is used. In fact diffusion and electrical migration are not independent processes: Arnikar[48,49,302] showed that the final distribution of the components in electrical zone migration is not identical with their distribution in pure diffusion. The difference between the actual distribution curve for lithium isotopes along the zone and the symmetrical Gaussian curve is readily seen from Fig. 6. In order to calculate the relative difference between the mobilities of the isotopic ions we construct concentration distribution curves for each isotope along the zone, using curves *1* and *2* in Fig. 6. The curves obtained for the distribution of the isotopes are similar to curve *1* for the distribution of the element, but their maxima are displaced a distance $\Delta x'$, and it is easy to show that

$$\frac{\Delta w}{w} = \frac{\Delta x'}{x'} \qquad (45)$$

where x' is the distance traversed by the whole zone. This formula has been discussed critically[14,303]. Experimental conditions and measurements of the mobilities of isotopic ions by electrical zone migration in molten salts are collected together in Table 3, which includes for comparison some data on aqueous solutions with various kinds of paper as support.

Like countercurrent migration, zone migration is widely used to measure the electrical transport parameters of ions in molten salts. Besides asbestos, glass-fibre cloth and plates of sintered alumina powder are employed as substrates. This method has been used to measure the mobilities and the transport numbers of ions of alkali metals, silver, and thallium in pure alkali-metal nitrates[11,12,243,303-312] and in their mixtures[313-315], alkaline-earth metal ions in alkali-metal nitrates[11,12,303,313,314,316] and their mixtures with alkaline-earth metal nitrates[317,318], ions of multivalent metals—copper, zinc, cadmium, cobalt, chromium, cerium, lead, and thorium—in alkali-metal nitrates[313,314,319], in potassium thiocyanate[319], and in LiCl–KCl eutectic[313,320], and chloride, bromide, and nitrate anions in alkali-metal nitrates[11,12,243,303,306,315]. Radioactive isotopes have been widely used in these investigations as tracers in following the movement of the zone along the migration path.

3. Comparison of the Two Methods of Electrical Migration —Frame of Reference

Comparison of Tables 1 and 3 shows fairly close agreement between values of the mass effect determined by electrical zone and countercurrent migration for isotopes in the same salt. Lundén[321] made a detailed comparison of results obtained by the two methods for molten nitrates. Nevertheless, Table 3 shows that the mass effect varies in complicated fashion with the mass of the element, with the composition of the solvent medium impregnating the asbestos support, and also with the temperature. The effects of all these factors on the mobility of isotopic ions are closely interrelated, so that all the experimental results accumulated up to the present time (Tables 1–3) must be taken into account in order to establish general rules. Attempts at the interpretation of experimental results in the light of individual measurements (often only the interpreter's own) are considered below.

Table 3. Experimental conditions of and results obtained by electrical zone migration.

*The $NaNO_3$ + KNO_3 mixture always contains 45 wt.% $NaNO_3$.
**The mixture contains 75 wt.% $NaNO_3$.
***The mixture contains 25 wt.% $NaNO_3$.

In the comparison of mass effects obtained by different methods and the assessment of their reliability, it must be borne in mind that any determination of a velocity presupposes agreement on the frame of reference: in the present case this is an object, selected inside or outside the electrolyte, relative to which the speed of the ion is measured. A "convenient"[295] system is one in which the separation factor α is independent of the electric field strength in the electrolyte. Different frames of reference are chosen[279] depending on the medium in which the ions migrate: in solids the surface or the stationary crystal lattice is selected, in solutions the solvent, in molten salts the centre of gravity of the oppositely charged ions, and in liquid metals the flux of conduction electrons. In pure molten salts the choice is a fundamental question, involving controversy about the advisability of applying the concept of transport number to such salts[18,300,322-324]. If the gegenions are chosen as reference, the transport number of the test ions is unity: i.e. they alone are regarded as current carriers and move within the melt, while the gegenions are at rest (this gives rise to the concept of a quasi-crystalline lattice in molten salts).

Physically, however, it is also possible that both cations and anions may move relative to the walls of the vessel, which may also be chosen as stationary frame of reference: in such case both types of ions have fractional transport numbers. The possibility of displacement of the melt as a whole relative to the walls makes incorrect measurement of these quantities highly probable. The use of a porous diaphragm—packing in the separating tube or an asbestos support—tends to diminish the probability of such displacement, in the ideal case to zero (Eqn. 3).

Measurement of transport numbers and ionic mobilities relative to these two frames of reference—gegenions inside the molten salt and a porous diaphragm outside the salt—yields different values for these quantities, which Klemm [19,300] proposed calling "internal" and "external" respectively. Formula (29), which is a definition of the mass effect, shows that the choice of frame of reference affects only the one quantity

$$w = \frac{\sum_i {}^i w {}^i\gamma}{\sum_i {}^i\gamma} \qquad (46)$$

the mean mobility of the isotopic ions to be separated. According to this the internal mobilities of ions should exceed in absolute magnitude the external values, and therefore the internal mass effects, measured by counter-current electrical migration, should be smaller than the external mass effects, measured by electrical zone migration under identical conditions. Comparison of the values of μ for alkali-metal nitrates in Tables 1 and 3 shows general conformity to this principle.

4. Structure of Molten Salts and Mechanism of Ionic Migration

Among the numerous theoretical papers on the inner structure of molten salts and the mechanism of the movement of ions in them under the influence of an electric field, we shall consider only those relating to the problem of the mobility of isotopic ions and their separation. The reasons for the occurrence of an isotope effect in electrical migration have not been established unambiguously. Investigators usually choose the most soundly based (in their opinion) model for the structure of a molten salt and for intermolecular interaction, and compare with experimental results the macro-values calculated on the basis of this micro-model.

To explain the differences in the mobilities of isotopic ions in molten salts we suppose that the element can exist in several states (as free ions, ion-pairs, etc.). The mole fraction of the element in state l is $\Gamma_l = C_l/C$, where C is the molar concentration of the element in the melt, C_l is the concentration of a species in state l, and $\sum_l \Gamma_l = 1$. The mole fraction of the ith isotope in this state is ${}^i\gamma_l = {}^iC_l/C_l$, and $\sum_i {}^i\gamma_l = 1$. The mobility of the ith isotope in the electric field is

$${}^i w = \frac{\sum_l \Gamma_l {}^i\gamma_l {}^i w_l}{\sum_l \Gamma_l {}^i\gamma_l}. \qquad (47)$$

If the equilibrium constant for the exchange of isotopes j and k between states l and m

$${}^{jk}K_{lm} = \frac{{}^i\gamma_l {}^k\gamma_m}{{}^i\gamma_m {}^k\gamma_l} \qquad (48)$$

differs from unity, the difference between the mobilities of the two isotopes in the electric field is [325]

$$\Delta^{jk} w = {}^j w - {}^k w = \sum_l \Gamma_l \left[{}^j w_l - {}^k w_l + \left(w_l - \sum_r \Gamma_r w_r \right) ({}^{jk}K_{lm} - 1) \right]. \qquad (49)$$

Since the mobility of the element as a whole is composed of the mobilities of its species in different states $w = \sum_r \Gamma_r w_r$, it follows from formulae (29) and (49) that [290]

$$\mu \frac{\Delta_m}{m} = \frac{\Delta w}{w} = \sum_l \Gamma_l \frac{\Delta w_l}{w} + \sum_l \Gamma_l \left(\frac{w_l}{w} - 1 \right) ({}^{jk}K_{lm} - 1). \qquad (50)$$

Numerical estimates showed Klemm [215,231,290] that the effect of the isotope exchange equilibrium between different states is not significant in molten salts: i.e. the second summation in Eqn. (50) could be neglected. However, the precisely opposite view is also held [243]: isotopic exchange actually makes the chief contribution to $\Delta w/w$, and the first summation in formula (50) is negligible in comparison with the second.

If the "self-transport number" T is defined as the ratio of external u to internal w ionic mobilities of the element [19]

$$T = \frac{u}{w}, \qquad (51)$$

we can rewrite Eqn. (50), on the assumption that the second summation is close to zero, in the form

$$\mu = T \sum_l \frac{\gamma_l u_l}{\gamma u} \cdot \frac{\Delta u_l}{u_l} \cdot \frac{m}{\Delta m}, \qquad (52)$$

since $\Delta u_1 = \Delta w_1$. Only two states of the species—mobile and stationary—need be distinguished in ionic liquids [261,262]. In terms of the theory of rate processes, activated ions—i.e. those occupying interstitial sites, sites adjacent to holes, etc. in the quasi-crystalline lattice—can be regarded as mobile [167]. Thus mobile ions migrate through the quasi-crystalline lattice formed by the stationary species, by making spontaneous jumps between adjacent equilibrium positions with an average frequency z_S (s^{-1}). [216] This is proportional to the thermal vibration frequency ν of the ions, which is in turn proportional to $m'^{-1/2}$, where $m' = mM/(m+M)$, in which m is the mass of the ion making a jump and M is the total mass, arbitrarily concentrated at a point and vibrating together with the ion, of particles which surround this ion immediately before the jump [290]. Since the summation in Eqn. (52) is made only over the mobile states $l = b$, it follows that

$$\Delta u_l/u_l = \Delta u_b/u_b = \Delta\nu/\nu = -\tfrac{1}{2}\Delta m'/m',$$

and formula (52) becomes

$$\mu = -\frac{1}{2} T \frac{\Delta m'}{m'} \cdot \frac{m}{\Delta m} \sum_b \frac{\gamma_b u_b}{\gamma u}. \qquad (53)$$

The mean rate of migration u_b of mobile ions is proportional to their total number of jumps per second: $z = z_S + z_i$, where z_i is the frequency of jumps induced by processes in the immediate environment of the ion, e.g. by jumps by adjacent ions. Therefore

$$\sum_b \frac{\gamma_b u_b}{\gamma u} = \frac{\gamma_s u_s + \gamma_i u_i}{\gamma u} = \frac{z_s + z_i}{z}.$$

If we bear in mind that the frequency of induced jumps is independent of the mass of the isotopic ions and, passing from finite differences Δm and $\Delta m'$ to infinitesimals dm and dm', differentiate Eqn. (53), we obtain

$$\mu = -\frac{1}{2} T \frac{z_s}{z} \left(1 + \frac{m}{M} \right)^{-1}. \qquad (54)$$

Thus a theoretical basis has been found for formula (38), and the constant it contains μ' is interpreted as $-\frac{1}{2}Tz_S/z$.

It is also useful to introduce the concept of the intrinsic mobility w_0 of an isotopic ion—its mobility in the isotopically pure compound—when the molten salt contains only this isotope of the given element. Since $w = \Lambda/F$, where Λ is the equivalent conductance of the molten salt and F is Faraday's constant, the ratio of the intrinsic mobilities of two isotopic ions is equal to the ratio of the equivalent conductances of the isotopically pure molten salts, and since the difference between the molar volumes of such salts can be neglected[195], this ratio is equal to the ratio of their conductivities κ, which can be found experimentally. Values of this parameter have now been determined for the systems $^6LiCl-^7LiCl$,[195,291] $^6LiNO_3-^7LiNO_3$,[195] and $^6Li_2SO_4-^7Li_2SO_4$.[326]

In the absence of any interaction between the moving ions the mass effect attains the limiting value[279] of $\mu = -0.5$. But in an actual substance this interaction cannot be neglected. Even in an ionic gas, which may be so degenerate that only two-body collisions need be considered, and the effect of the charges of surrounding ions, i.e. the ionic atmosphere, can be neglected, the intrinsic mobility of the ions depends on the reduced mass of the component cations and anions of this gas[25,200]:

$$w_0 = A\left(\frac{m_+ \cdot m_-}{m_+ + m_-}\right)^{-1/2}, \qquad (55)$$

where A is a factor which is independent of the masses. The intrinsic mass effect then becomes

$$\mu_0 = \frac{\Delta w_0}{w_0} \Big/ \frac{\Delta m}{m} \approx \frac{\partial \ln w_0}{\partial \ln m} = -\frac{1}{2}\left(1 + \frac{m_+}{m_-}\right)^{-1}. \qquad (56)$$

Calculation by means of Eqn. (56) of μ_0 for lithium chloride, nitrate, and sulphate yields respectively −0.42, −0.45, and −0.47, whereas the corresponding values measured in the molten salt are −0.35, −0.18, and −0.28.[195,326] This indicates that the mass of the anions has a stronger effect on the intrinsic mobility of the cations in molten salts than in an ionic gas. The ratio $n = \mu_0/\mu$ is interpreted[195,326,327] as the mean number of cations involved in the elementary step of electrical migration by being bound into a single group. For the above lithium salts it has the values 2.39, 2.56, and 2.0. Whether these numbers can be linked with the number of spontaneous and induced jumps by ions and in what way is still being examined more closely; in any case these results reflect the fact that the ions in molten salts cannot move independently of each other.

Ionic conductivity, migration, and diffusion data do not yet enable us to suggest a more detailed model for the structure of molten salts. Thus Klemm[300] showed, when considering the phenomenology of the transport of ions in pure molten salts, that it was impossible to choose the best among models presupposing that a molten salt consists of two components (cations and anions), three components (cations, anions, and a quasi-crystalline lattice), or four components (cations, anions, lattice, and neutral complexes). Lundén[328] found that parameters calculated specially for molten alkali-metal nitrates on a basis of all three models agreed qualitatively with the experimental results. Attempts to apply similar models to solutions of cadmium in cadmium chloride[232] and of lead in lead(II) chloride[298] also showed the impossibility of selecting one of them unambiguously on the basis solely of data on the transport properties of the molten salts.

The theoretical concepts used to explain the temperature dependence of the mass effect have been modified and refined as experimental data have accumulated[25,167,200,231,279,303]. A model was suggested[25] taking into account the most recent measurements of the mass effect at different temperatures. With rise in temperature the structure of an ionic melt passes successively through three different stages (Fig. 7): a quasi-crystalline structure—a lattice with a few free ions within—predominates at low temperatures (stage I); then the lattice breaks down into electrically charged polyionic groups (stage II); and at very high temperatures the melt consists mainly of neutral ion-pairs with a small proportion of free ions (stage III). The situation is less favourable for a large mass effect in the second stage than in stages (I) and (III), in which a larger number of mobile groups of ions are present. Experimental results show larger mass effects in solid than in molten salts, and the above estimates indicate that they should also be larger in an ionic gas than in a melt. Thus on passing from a solid through the melt to the gas the mass effect has a tendency to pass through a minimum (the smooth variation in the function may be disturbed abruptly at the melting point and the boiling point[200]).

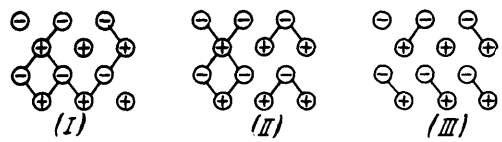

Figure 7. Model of change in structure of molten salt with rise in temperature[25].

From a comparison of this model with Table 2 it may be supposed that, for example, molten thallium(I) and lead(II) chlorides are located somewhere between stages (I) and (II), and molten alkali-metal halides somewhere between stages (II) and (III). The contribution of quantum-mechanical effects to isotopic differences in the mobilities of light elements such as lithium can be neglected at high temperatures[195,200], but in lithium nitrate electrical migration takes place at relatively low temperatures, and these effects may be appreciable: hence the difference between the temperature dependence of μ_+ for this salt and for other alkali-metal salts. The variation of the mass effect for sodium isotopes in the $NaNO_3-KNO_3$ eutectic (Expts. 16–21, Table 3), which is "unusual" in terms of this model, is explained[243] by the predominant effect at low temperatures of the proportion of combined displacements of ions, which increases with temperature, and by the predominant effect at high temperatures of the isotopic exchange constant (48) between ions and neutral complexes, which decreases with temperature. On the whole these views evidently do not contradict a three-stage model, and the above categorical statements on the relative contributions of the first and second summations in Eqn. (50) to the mass effect are refined. The most correct hypothesis is apparently that the separation of isotopes in the electrical migration of ions takes place by several parallel mechanisms[279], whose relative contributions to the overall effect varies with temperature.

APPENDIX

Since this paper was submitted for publication a monograph [329] and several papers have appeared on the electrical migration of ions in molten salts [330-339], aqueous solutions [340], and solid salts [341].

Thermogalvanic Cells with a Single Fused Salt

B.F.Markov and E.B.Kuzyakin

This paper reviews the theory of thermogalvanic cells with metal or halogen electrodes and a single fused salt, and analyses the results of experimental studies of thermogalvanic cells (including those obtained in the author's laboratory). Some examples of the application of thermopotentials in studies of the physical chemistry of fused salts are discussed. 47 references.

1. INTRODUCTION

Two identical reversible electrodes held at different temperatures and connected by a fused electrolyte containing the potential-determining ions will generate a thermo-e.m.f whose magnitude depends first and foremost on the temperature difference and on the nature of the element. A thermogalvanic element of this type is usually characterised by the temperature coefficient of its thermo-e.m.f., for which we shall use the term "thermopotential". Equivalent terms often used in the literature include "thermo-electric power" and "Seebeck coefficient". When a cell of this type is short-circuited, current flows in a direction such that the electrode reaction at the hotter electrode is continuously absorbing heat, and vice-versa. Hence, the only driving force for the generation of electrical energy is the transfer of heat from the hotter to the cooler region.

The study of thermoelectric phenomena in fused salts includes a wide range of problems of great theoretical and practical importance. During the past decades, a great deal of work has been done on non-isothermal fused electrolyte systems because of the possibility of finding useful applications in the field of thermo-electricity and also in order to increase our understanding of the transfer of heat and electricity in ionic melts. Studies of thermogalvanic cells enable us to characterise the electrode reaction at the electrode–fused salt interface and give some insight into the structure of ionic melts. Enough experimental information on thermogalvanic cells with a single fused salt is available for a general analysis of the thermoelectric effect and its components as a function of the nature and the state of aggregation of the electrodes and the electrolyte. The thermogalvanic cells with a single fused salt which have been studied up to the present are listed in Table 1.

2. MODEL OF THE THERMOGALVANIC CELL AND LOCATION OF THE THERMOPOTENTIAL

The location of the thermopotential in a thermogalvanic cell consisting of two identical, reversible solid electrodes can be described by the model shown in Fig. 1. (The two electrodes are immersed in the same fused salt, containing ions of this metal in a single state of oxidation.) If T_2 and T_1 differ by 1°, the thermo-e.m.f. measured between the electrodes is equal to the thermopotential of the cell. The thermopotential is the algebraic sum of five quantities: the potential steps (having opposite signs) at the electrode—melt interfaces at temperatures T_2 and T_1, the potential differences in the metallic conductors due to the temperature differences $(T_2 - T_0)$ and $(T_1 - T_0)$, also having opposite signs, and the potential difference due to the temperature difference within the electrolyte.

To simplify the theoretical analysis of the thermopotential, we shall assume a temperature distribution within the cell as shown in Fig. 1: each electrode will be treated as if it were in an isothermal region. Our experiments were designed to produce a temperature distribution of this type. A thermogalvanic cell consisting of two halogen electrodes on an indifferent carrier (for example, graphite) and a suitable salt can be represented by an analogous model.

In the case of a thermogalvanic cell with two liquid metal electrodes (M_I) to which contact is made with solid electronic conductors (M_{II}), a correction must be made to the measured thermopotential for the thermopotential of the couple M_I/M_{II}. The potential gradient in the liquid metal is ignored because it is much smaller than the thermopotential for a temperature difference of the order of one degree.

3. RELATION BETWEEN THE THERMOPOTENTIAL AND THE TEMPERATURE COEFFICIENT OF THE E.M.F. OF THE ISOTHERMAL CHEMICAL CELL

Reinhold[25], in his work on thermogalvanic cells with solid electrolytes, first pointed out that the measured thermopotentials can conveniently be tested against the temperature coefficient of the appropriate isothermal chemical cell. The relationship between these quantities can easily be derived analytically[8], and it also follows from the diagram of Fig. 2.

Adding all the e.m.f.'s in this circuit, and equating to zero, we obtain the following expression:

$$\left(\frac{dE}{dT}\right)_{X_2} - \left(\frac{dE}{dT}\right)_{M} = \left(\frac{dE}{dT}\right)_{chem} - \left(\frac{dE}{dT}\right)_{M-C}. \quad (1)$$

The thermopotentials $(dE/dT)_{X_2}$ and $(dE/dT)_M$ are given a sign corresponding to the polarity of the "hot" electrode, and the thermopotential of the pair M—C is given a sign corresponding to the polarity of the metal with respect to graphite. We shall consider a few examples of the application of Eqn. (1).

For the thermogalvanic cell $Ag_{T_2}|AgCl_{melt}|_{T_1}Ag$ we have the following thermopotential: $(dE/dT)_{Ag} = -0.400 \times 10^{-3}$ V deg^{-1}; for the cell $Cl_2T_2|AgCl_{melt}|_{T_1}Cl_2$ we have $(dE/dT)_{Cl_2} = -0.695 \times 10^{-3}$ V deg^{-1}; for the

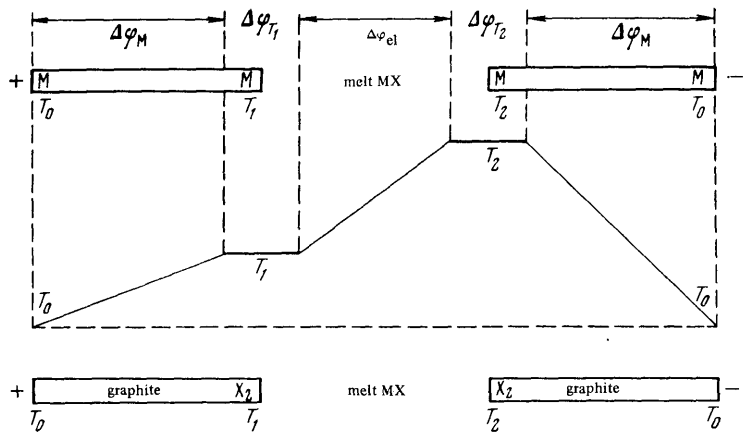

Figure 1. Model of a thermogalvanic cell and location of the thermopotential.

Ag—C thermocouple we have $(dE/dT)_{Ag-C} = +1 \times 10^{-6}$ V deg^{-1}.[8] Inserting these values into Eqn. (1) we obtain $(dE/dT)_{chem.\ calc.} = -0.285 \times 10^{-3}$ V deg^{-1}. The most reliable measurements of the e.m.f. of the chemical cell $Ag|AgCl_{melt}|Cl_2$, reported by different workers, lead to the following values for the temperature coefficient of the e.m.f.: 0.292×10^{-3} V deg^{-1},[26] 0.289×10^{-3} V deg^{-1},[27] and 0.294×10^{-3} V deg^{-1}.[8] Thus, the agreement between the measured temperature coefficient and the value calculated from the thermopotentials is within experimental error.

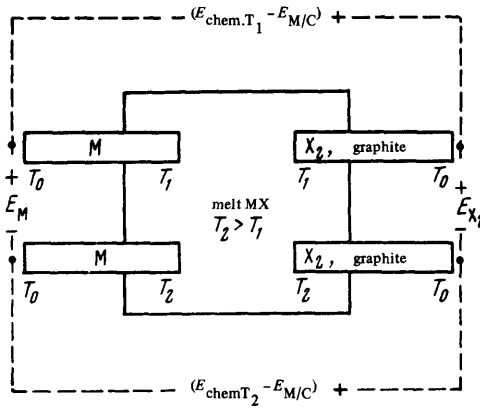

Figure 2. Relationship between the e.m.f.'s of the thermogalvanic cells and the e.m.f. of the isothermal chemical cell with a single fused salt.

The experimentally measured thermopotential for the thermogalvanic cell $Pb_{liq.}\,T_2|PbCl_2 melt|T_1\,Pb_{liq.}$ is $(dE/dT)_{Pb} = -0.008 \times 10^{-3}$ V deg^{-1}, for the cell $Cl_2T_2|PbCl_2 melt|T_1Cl_2$ we find $(dE/dT)_{Cl_2} = -0.620 \times 10^{-3}$ V deg^{-1}, and for the Pb—C couple $(dE/dT)_{Pb-C} = +0.001 \times 10^{-3}$ V deg^{-1}.[24] From Eqn. (1) we obtain $(dE/dT)_{chem.\ calc.} = -0.61 \times 10^{-3}$ V deg^{-1}. Direct measurements of the e.m.f. of the chemical cell $Pb|PbCl_2 melt|Cl_2$ gave the following values of the temperature coefficient: -0.60×10^{-3} V deg^{-1} [28] and -0.62×10^{-3} V deg^{-1}.[29]

For the thermogalvanic cell $Cd_{liq.}\,T_2|CdCl_2 melt|T_1\,Cd_{liq.}$ we find $(dE/dT)_{Cd} = -0.146 \times 10^{-3}$ V deg^{-1}; for the cell $Cl_2T_2|CdCl_2 melt|T_1Cl_2$, $(dE/dT)_{Cl_2} = -0.714 \times 10^{-3}$ V deg^{-1}; for the $Cd_{liq.}$—C couple, $(dE/dT)_{Cd-C} = -0.0075 \times 10^{-3}$ V deg^{-1}.[22] Hence $(dE/dT)_{chem.\ calc.} = -0.575 \times 10^{-3}$ V deg^{-1}, whereas the experimentally measured value[30] is -0.568×10^{-3} V deg^{-1}. For fused zinc chloride[18] the thermopotential difference[30] is -0.700×10^{-3} V deg^{-1}; the thermopotential of the $Zn_{liq.}$—C couple is $+0.005 \times 10^{-3}$ V deg^{-1}. Hence $(dE/dT)_{chem.\ calc.} = -0.695 \times 10^{-3}$ V deg^{-1}. From the measured e.m.f.'s of the cell $Zn_{liq.}|ZnCl_2 melt|Cl_2$, the temperature coefficient is given as -0.695×10^{-3} V deg^{-1},[29] -0.697×10^{-3} V deg^{-1},[31] and -0.700×10^{-3} V deg^{-1}.[32] The agreement between calculation and experiment is good.

4. THERMOPOTENTIAL EQUATION

We shall derive an equation for the thermopotential by considering the components of this potential, as shown in Fig. 1.

According to Wagner[33], the thermopotential can be divided into two components: a heterogeneous thermoelectric effect, arising from the electrochemical reaction at the electrode—electrolyte boundary, and a homogeneous thermoelectric effect, due to the temperature gradient in the electrolyte and in the electrodes.

For the thermogalvanic cell $M_{T+dT}|MX_{melt}|T^M$, the heterogeneous thermoelectric effect $(dE/dT)_M^{het}$ can be expressed as the difference between the potential steps at the electrode—electrolyte interface: $(dE/dT)_M^{het} = \Delta\varphi_{T+dT} - \Delta\varphi_T$. The passage of one Faraday of electricity through the electrode—electrolyte interface alters the free energy of the system, as a result of the reaction $M \rightarrow M^+ + e$, by an amount $\Delta G = F \cdot \Delta\varphi$. Hence, for the whole cell, $F \cdot (dE/dT)_M^{het} = \Delta G_{T+dT} - \Delta G_T = -\Delta S$, where ΔS is the entropy change attending the reaction. Expressing ΔS as the difference $\Delta S = \bar{S}_{M^+} + \bar{S}_e^M - S_M$, we obtain

$$F \cdot \left(\frac{dE}{dT}\right)_M^{het} = S_M - \bar{S}_{M+} - \bar{S}_e^M \qquad (2)$$

where S_M is the absolute entropy of the metal at temperature T, $\bar{S}_{M^+}$ is the partial entropy of the M^+ ion in the electrolyte, and $\bar{S}_e^M$ is the partial entropy of an electron in the metal.

The homogeneous thermoelectric effect, as a component of the thermopotential, can itself be expressed as the resultant of two effects: one due to the temperature gradient in the electrolyte and one due to the temperature gradient in the metal:

$$F \cdot \left(\frac{dE}{dT}\right)_M^{hom} = \overset{*}{S}_i - \overset{*}{S}_e^M \qquad (3)$$

where $\overset{*}{S}_i$ is the entropy of transfer in the electrolyte, $\overset{*}{S}_e^M$ is the entropy of transfer of an electron in the metal. By adding Eqns. (2) and (3) we obtain the equation for the thermopotential of a thermogalvanic cell with metallic electrodes:

$$F \cdot \left(\frac{dE}{dT}\right)_M = S_M - \bar{S}_{M+} + \overset{*}{S}_i - (\bar{S}_e + \overset{*}{S}_e)^M \quad . \qquad (4)$$

Similarly, for a thermogalvanic cell with halogen electrodes we obtain

$$F\left(\frac{dE}{dT}\right)_{X_2} = \bar{S}_{X^-} - \frac{1}{2}S_{X_2} + \overset{*}{S}_i - (\bar{S}_e + \overset{*}{S}_e)^c \qquad (4')$$

where S_{X_2} is the absolute entropy of the halogen, $\bar{S}_{X^-}$ is the partial entropy of the halide ion. Thermopotential equations have been derived also from irreversible thermodynamics[34,35].

5. HETEROGENEOUS COMPONENT OF THE THERMOPOTENTIAL

In the calculation of the heterogeneous component of the thermopotential of a thermogalvanic cell with metallic electrodes the partial entropy of electrons in the metal [Eqn. (2)] is much smaller than the other components and can be ignored[36].

The absolute entropy S_M of the metal at the temperature T for which the thermopotential is measured can be found in standard thermodynamic tabulations[37,38]. The difficulty arises in computing the partial entropy of the ion. In 1929 Wagner had suggested taking the partial entropy of an ion in a uni-univalent electrolyte as one-half of the entropy of the salt[33]. A more valid method, put forward by Pitzer[39], takes into account the mass (M) of both the cation and the anion: Pitzer's equation is

$$\bar{S}_{M+} = \frac{1}{2}\left(S_{MX} + \frac{3}{2} R \ln \frac{M_M}{M_X}\right) \quad (5)$$

Eqn. (5) gives the best results with alkali metal halides, but it can be used (with some reservations) with other uni-univalent electrolytes as well.

Having evaluated the heterogeneous component, we can now calculate an approximate value of the homogeneous component of the thermopotential.

Since the heterogeneous effect is the entropy of the electrode reaction, it also gives a measure of the heat of the electrode reaction when multiplied by the absolute temperature (local Peltier effect). Evidently, the magnitude and sign of the thermal effect must be determined by the difference between the entropy of the metal and the partial entropy of the metal ion.

6. ENTROPY OF TRANSFER IN THE SALT

As the diagram of the thermogalvanic cell (Fig. 1) shows, a potential gradient $\nabla\varphi_i$ arises in the electrolyte as a result of the presence of a temperature gradient. The work done by the passage of one Faraday of electricity through the electrolyte ($F \cdot \nabla\varphi$) appears in the form of heat absorbed or evolved by the electrolyte, depending on the direction of the current and on the sign of the potential gradient $\nabla\varphi_i$. This thermal effect, known as the heat of transfer, corresponds to the Thomson effect. The heat of transfer, divided by the temperature, defines a new parameter: the entropy of transfer in the salt, denoted by $\overset{*}{S}_i$. Naturally, for a given temperature gradient, the magnitude and sign of the potential gradient in the electrolyte ($\nabla\varphi_i$) must be a function of the nature of the fused electrolyte: for example, for a symmetrical electrolyte like KCl having a cation and an anion of comparable mobility the potential gradient will be small, and conversely for a unipolar cationic conductor like AgCl the potential gradient will be quite large. If the conductivity type in the fused electrolyte is a sensitive function of temperature, the potential gradient will also change with temperature.

Thus, the entropy of transfer in the electrolyte is a direct measure of the structural features of the fused salt. Since the entropy of transfer [see Eqns. (4) and (4')] is defined as a difference, its confidence limits are set by the uncertainty in the heterogeneous component of the thermopotential.

Physically, the entropy of transfer in the salt ($\overset{*}{S}_i$) is a manifestation of the migration of ions accompanying the passage of current through the electrolyte. If the heterogeneous component of the thermopotential is known with sufficient accuracy, the calculated entropy of transfer can be related to transport phenomena in the fused electrolyte (conductivity, self-diffusion, transport number), and can be treated as a structural characteristic determined by the nature of the chemical bond. The discontinuous change in transfer parameters which occurs at the melting point is reflected in a sharp change in the entropy of transfer.

The entropies of transfer of uni-univalent fused electrolytes are compared in Table 2. It can be seen that alkali metal chlorides have a small entropy of transfer: in other words, their thermopotential is determined mainly by the heterogeneous component, and only Joule heat is evolved by the passage of current through these electrolytes. For the most symmetrical of these electrolytes (KCl) the entropy of transfer is almost zero. In fused copper and silver halides the entropy of transfer is appreciable, not surprisingly since their structure is more complex than that of the alkali metal halides. In fused silver nitrate and silver sulphate the calculated $\overset{*}{S}_i$ values are +7.5 e.u. (at 550°K) and +7.7 e.u. (at 950°K) respectively, showing that the presence of a complex anion leads to anomalous $\overset{*}{S}_i$ values. This effect may be ascribed to a significant potential gradient in a direction opposite to that of the thermo-e.m.f. of the cell.

Table 2. Entropy of transfer in single fused salts.

Electrolyte	Temp., °K	Entropy of transfer, e.u.	Reference	Electrolyte	Temp., °K	Entropy of transfer, e.u.	Entropy of transfer, e.u.
LiCl	1100	—1.0	1	CuI	900	—6.0	6
NaCl	1300	—0.3	1	AgF	800	—3.5	5
KCl	1300	—0.2	1	AgCl	900	—3.4	8
RbCl	1000	—1.5	2	AgBr	900	—4.2	13
CsCl	950	—1.7	2	AgI	900	—5.4	6
CuCl	900	—3.5	4	$AgNO_3$	550	+7.5	14
CuBr	900	—5.1	6	Ag_2SO_4	930	+7.7	17

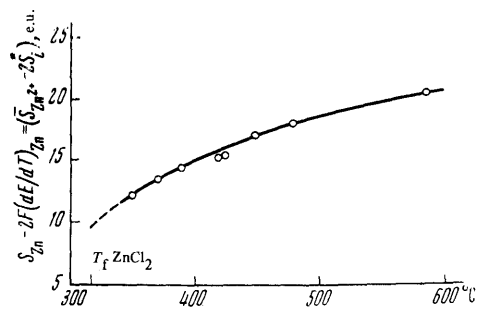

Figure 3. Variation of $(\bar{S}_{Zn^{2+}} - 2\overset{*}{S}_i)$ with temperature for the thermogalvanic cell $Zn_{T_2}|ZnCl_2|_{T_1}Zn$.

The entropy of transfer of bivalent metal salts may be discussed by considering a thermogalvanic cell with fused zinc chloride and liquid zinc electrodes. Inserting known values of S_{Zn} and $(dE/dT)_{Zn}$ into the thermopotential equation we can obtain the algebraic sum $(\bar{S}_{Zn^{2+}} - 2\overset{*}{S}_i)$: this quantity is found to increase by more than 11 e.u. over the temperature range between the melting point of $ZnCl_2$ and 600° (Fig. 3). The contribution of $\bar{S}_{Zn^{2+}}$ to this increase cannot be more than a few entropy units, since the entropy of zinc chloride increases by approximately 8.7 e.u. in this temperature range and the partial entropy of the zinc ions can only account for a fraction of this increase. It follows that the entropy of transfer in fused zinc chloride

is a fairly large quantity which decreases with temperature (in absolute value). Thus, the quantity $\overset{*}{S}_i$ may be added to the list of strongly temperature-dependent properties of fused $ZnCl_2$ (electrical conductivity, viscosity, self-diffusion[40,41]). The lack of constancy of $\overset{*}{S}_i$ is consistent with the polymeric network model of the structure of zinc chloride, which has been postulated[42] on the basis of Raman scattering studies.

At temperatures close to the melting point, the dissociation of zinc chloride with formation of simple ions is negligible, owing to polymerisation. Few current carriers are present, and fairly large potential gradients can develop. On raising the temperature the polymers are broken down and a simpler structure begins to appear, tending towards the structure of ionic melts (for which the entropy of transfer is small).

A more detailed analysis of the entropy of transfer is not justified as long as only tentative values of this parameter are available.

7. DEPENDENCE OF THE THERMOPOTENTIAL AND ITS COMPONENTS UPON THE STATE OF AGGREGATION OF THE ELECTRODES AND THE ELECTROLYTE

In the majority of thermogalvanic cells with a single fused salt (Table 1) the thermopotential has a negative sign and is almost independent of temperature. A barely significant change of thermopotential with temperature has been observed in sodium and potassium chloride[1], zinc and tin iodide[20], and lead bromide[3]. Measurements[18] on the cell $Zn_{liq.\,T_2}|ZnCl_{2melt}|_{T_1}Zn_{liq.}$, which were subsequently confirmed[20], indicate a more substantial and complicated temperature dependence of the thermopotential. Between 420 and 600° the thermopotential of fused zinc chloride changes sign (from positive to negative), showing a discontinuity at the melting point of zinc (Fig. 4).

Changes in thermopotential with temperature are due to structural changes in the fused electrolyte, and should therefore be observed in all electrolytes over a sufficiently wide range of temperature.

We shall discuss the discontinuous change in thermopotential accompanying a change in the state of aggregation of the electrodes for the particular case of the thermogalvanic cell consisting of fused zinc chloride with zinc electrodes. Applying Eqn. (4) to the cell

$$\underset{T_0}{W}\ \ldots\ W\,|\,\underset{T}{Zn}_{liq.(sol.)}\,|\,ZnCl_{2\,melt}\ \ldots\,|\,\underset{T+dT}{Zn}_{liq.}\,|\,W\ \ldots\ \underset{T_0}{W}$$

we can write

$$2F\left(\frac{dE}{dT}\right)_{Zn\,liq.} = -\Delta S + 2(\bar{\bar{S}}_e^{Zn\,liq.} - \bar{\bar{S}}_e^{W}) - 2\overset{*}{S}_e^{Zn\,liq.} + 2\overset{*}{S}_i$$

where $\Delta S = S_{Zn(liq.)} - \bar{S}_{Zn^{2+}} - 2\bar{S}_e^{Zn(liq.)}$, $(\bar{\bar{S}}_e^{Zn(liq.)} - \bar{\bar{S}}_e^{W})$ is the thermopotential of the Zn(liq.)/W couple, $\overset{*}{S}_e^{Zn(liq.)}$ is the entropy of transfer of electrons in liquid zinc, $\overset{*}{S}_i$ is the entropy of transfer in the salt.

After simplification we arrive at the expression

$$2F\left(\frac{dE}{dT}\right)_{Zn\,liq.} = S_{Zn\,liq.} - \bar{S}_{Zn^{2+}} - 2s_e^{W} + 2\overset{*}{S}_i$$

Similarly, for the cell with solid zinc, we can write

$$2F\left(\frac{dE}{dT}\right)_{Zn\,sol.} = S_{Zn\,sol.} - \bar{S}_{Zn^{2+}} - 2s_e^{W} + 2\overset{*}{S}_i$$

The difference between these equations is

$$2F\left[\left(\frac{dE}{dT}\right)_{Zn\,liq.} - \left(\frac{dE}{dT}\right)_{Zn\,sol.}\right] = S_{Zn\,liq.} - S_{Zn\,sol.} = \Delta S_{f(Zn)}$$

Thus, the difference in thermopotential between two cells measured close to and on either side of the melting point of zinc gives the entropy of melting of zinc.

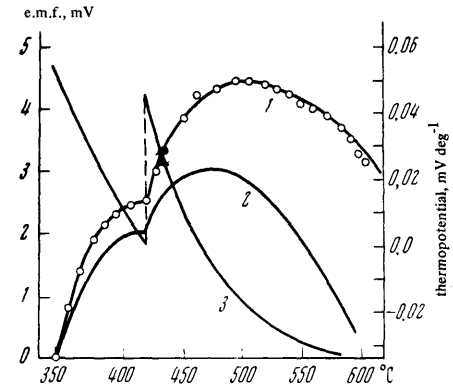

Figure 4. *1*) e.m.f. of the thermogalvanic cell $W\,|\,Zn_{T_2}\,|\,ZnCl_{2melt}\,|\,_{T_1}Zn\,|\,W$ against temperature of the "hot" electrode; *2*) ditto, for the thermogalvanic cell $Zn_{T_2}\,|\,ZnCl_{2melt}\,|\,_{T_1}Zn$; *3*) variation of thermopotential with temperature.

In our approximate, graphical determination, the jump in thermopotential at the melting point (see Fig. 4) is 0.05—0.052 mV deg^{-1}, giving an entropy of melting of 2.3—2.4 e.u. The tabulated value[43], obtained from calorimetric measurements of the heat of melting, is 2.48 e.u.

Table 3.

Electrolyte	T, °C	$F\left(\frac{dE}{dT}\right)_{Ag}$ e.u. crystal	$F\left(\frac{dE}{dT}\right)_{Ag}$ e.u. crystal	$\Delta F\left(\frac{dE}{dT}\right)_{Ag}$ e.u.	$(\bar{S}_{Ag^+})$melt − $-(\bar{S}_{Ag^+})$cryst. e.u.	$\overset{*}{S}_{i\,cryst} - \overset{*}{S}_{i\,melt}$
AgCl	455	−14.10	−9.30	−4.8	(+2.2)	(−7.0)
AgI	558	−11.30	−11.30	0	(+1.35)	(−1.35)
$AgNO_3$	210	−5.45	−7.35	+1.9	(+2.86)	(−0.96)

Writing Eqn. (4) for the liquid and the solid electrolyte, and subtracting the two expressions, we obtain

$$F\cdot\left[\left(\frac{dE}{dT}\right)_M^{liq.} - \left(\frac{dE}{dT}\right)_M^{cryst.}\right] = (\overset{*}{S}_i^{liq.} - \overset{*}{S}_i^{cryst.}) - (\bar{S}_{M^+}^{liq.} - \bar{S}_{M^+}^{cryst.})$$

Evidently, since $\bar{S}_{M^+}^{liq.} > \bar{S}_{M^+}^{cryst.}$, the second term on the right-hand side is negative. In absolute value, $\overset{*}{S}_i^{cryst.} > \overset{*}{S}_i^{liq.}$, and therefore the first term is positive (since $\overset{*}{S}_i > 0$). The combined effect of these two terms may be a decrease or an increase in thermopotential at the transition from crystalline to fused electrolyte. As a special case, the

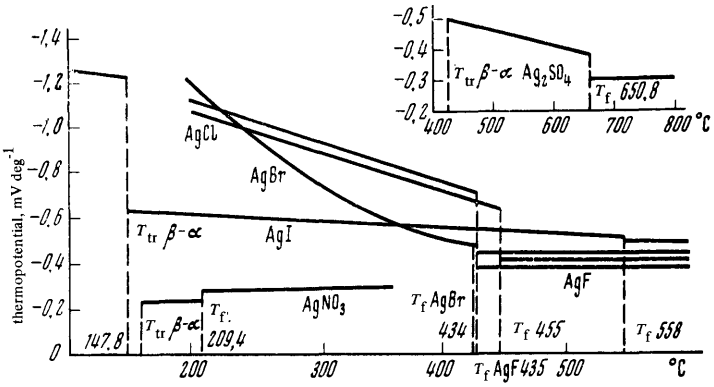

Figure 5. Temperature dependence of the thermopotential of the thermogalvanic cell $Ag_{T_2}|AgX|_{T_1}Ag$ (X = F, Cl, Br, I, NO_3, SO_4), from published data.

thermopotential may remain constant at the melting point of the electrolyte.

The measurements on thermogalvanic cells with AgCl, AgI, and $AgNO_3$ electrolytes, summarised in Table 3, provide examples of each type of thermopotential change at the melting point of the electrolyte.

Though the total thermo-effect can show different types of change at the melting point of the crystalline electrolyte, the entropy of transfer decreases in every case, because unipolar conduction (in the crystal) is replaced by mixed conduction (in the melt).

Fig. 5 shows thermopotential curves for cells with metallic (silver) electrodes and silver salt electrolytes over a wide temperature range. The curves have been compiled from published data.

New data on the entropy of transfer in solid and in fused salts are needed in order to provide more accurate values of ΔS_i^*, the change in entropy of transfer at the melting point, a very important parameter which reflects structural changes in the salt on melting. The first measurements of this type, reported by French workers[47], are consistent with a discontinuous change in the chemical bond of silver halides at the melting point.

8. APPLICATIONS OF THE THERMOPOTENTIAL

Leaving aside the possible application of thermogalvanic cells as converters of thermal into electrical energy, we can list some applications of thermo-e.m.f.'s in the study of the electrochemistry of fused salts.

Thermogalvanic corrosion. If the temperature of the surface of a reversible metal electrode is not uniform, a thermo-e.m.f. is developed between regions at different temperatures. Thermogalvanic corrosion is the result of current flow through this short-circuited thermogalvanic cell: the hotter regions are dissolved anodically, and metal is deposited on the cooler regions (usually in the form of dendrites). Thermogalvanic corrosion is often observed in practice.

Local Peltier effect. Electrolysis under isothermal conditions is accompanied by the absorption of heat in the regions where metal is dissolving anodically and heat evolution where metal is cathodically deposited. Hence, the passage of current through an isothermal electrode—fused electrolyte—electrode system converts it into a non-isothermal system: the temperature of the anode decreases, and that of the cathode increases with respect to the temperature in the bulk of the electrolyte. This phenomenon has been observed experimentally during the anodic dissolution and cathodic deposition of copper in a melt of cuprous chloride[46].

The sign and magnitude of the thermal effect accompanying, say, the anodic dissolution of a metal can be obtained from the measured thermopotential or calculated from the difference between the entropy of the metal and the partial ionic entropy of the same metal. Three cases are possible: the entropy of the metal and the partial entropy of the ion are approximately equal (resulting in a negligible thermal effect); the entropy of the metal is significantly smaller than the partial entropy of the ion (resulting in a large and positive thermal effect, i.e. heat absorption); the entropy of the metal is significantly larger than the partial entropy of the ion (resulting in a large and negative thermal effect, i.e. heat evolution). The thermal effect for cathodic reactions has the opposite sign.

Instances of all three cases are found in the calculations for systems with uni-univalent electrolytes summarised below.

$Cu_{sol.}|CuCl_{liq.}$ System

M.p. CuCl = 703°K; $S_{CuCl(liq.)}$ at 703°K is 36.9 e.u.[44]; S_{Cu} at 703°K is 13.2 e.u.[44]; $\bar{S}_{Cu^+}$ = 19.3 e.u.; ΔS = +6.1 e.u.; $T\Delta S$ = +4.3 kcal g-equiv^{-1}

$Ag_{sol.}|AgCl_{liq.}$ System

M.p. AgCl = 728°K; $S_{AgCl(liq.)}$ at 728°K is 39.8 e.u.[44]; S_{Ag} at 728°K is 15.8 e.u.[44]; $\bar{S}_{Ag^+}$ = 21.5 e.u.; ΔS = +5.7 e.u.; $T\Delta S$ = +4.15 kcal g-equiv^{-1}

$Li_{liq.}|LiCl_{liq.}$ System

M.p. LiCl = 880°K; $S_{LiCl(liq.)}$ at 880°K is 33.5 e.u.[44]; $S_{Li(liq.)}$ at 880°K is 15.7 e.u.[44]; $\overline{S}_{Li^+}$ = 14.3 e.u.; ΔS = −1.4 e.u.; $T\Delta S$ = −1.2 kcal g-equiv^{-1}

$Na_{liq.}|NaCl_{liq.}$ System

M.p. NaCl = 1073°K; $S_{NaCl(liq.)}$ at 1073°K is 40.8 e.u.[37]; S_{Na} at 1073°K is 23 e.u.[37]; $\overline{S}_{Na^+}$ = 19.8 e.u.; ΔS = −3.2 e.u.; $T\Delta S$ = −3.5 kcal g-equiv^{-1}

$K_{gas}|KCl_{liq.}$ System

M.p. KCl = 1043°K; b.p. K = 1030°K; $S_{KCl(liq.)}$ at 1045°K is 42.2 e.u.[37]; S_K at 1043°K is 44.87 e.u.[44]; $\overline{S}_{K^+}$ = 21.1 e.u.; ΔS = −23.77 e.u.; $T\Delta S$ = −24.8 kcal g-equiv^{-1}

$Rb_{gas}|RbCl_{liq.}$ System

M.p. RbCl = 995°K[45]; b.p. Rb = 952°K; $S_{RbCl(liq.)}$ at 995°K is 44.3 e.u.[45]; $S_{Rb(gas)}$ at 995°K is 48 e.u.[37,43,38]; $\overline{S}_{Rb^+}$ = 23.5 e.u.; ΔS = −24.5 e.u.; $T\Delta S$ = −24.4 kcal g-equiv^{-1}

$Cs_{liq.}|CsCl_{liq.}$ System

M.p. CsCl = 918°K; S_{CsCl} = 45 e.u.[45]; $S_{Cs(liq.)}$ at 918°K is 30.3 e.u.[37,43,38]; $\overline{S}_{Cs^+}$ at 918°K is 24 e.u.; ΔS = 5.9 e.u.; $T\Delta S$ = −5.4 kcal g-equiv^{-1}

It can be seen from these results that for solid metals the heat of anodic dissolution is appreciable, and its sign corresponds to absorption of heat; on the other hand, when the metal is in the vapour state its ionisation involves the evolution of a large amount of heat. When the state of aggregation of a metal electrode changes, a discontinuity occurs in the thermal effect. For liquid metals the thermal effect is small: this observation is consistent with the absence of chemical polarisation during the cathodic deposition of liquid metals. The small cathodic polarisation observed when solid metals are deposited is most probably a thermo-e.m.f. arising because of the difference in temperature between the polarised electrode and the reference electrode.

Electrocrystallisation of metals. The cathodic deposition of metals under non-isothermal conditions (i.e. in the presence of a temperature gradient) gives different types of deposit depending on the direction of the thermal field. In one direction, the operation of the short-circuited thermogalvanic cells assists the formation of a dendritic deposit, in the other direction it opposes dendrite formation. Of course, this effect is appreciable only when the thermopotential of the cell is fairly large.

Temperature coefficient of the electrode potential. The temperature coefficient of the e.m.f. of an isothermal chemical cell is the algebraic sum of the temperature coefficients of the two electrode potentials. Hence we can write

$$\Delta S = S_{MX} - S_M - \frac{1}{2}S_{X_2} = \left(\overline{S}_{X^-} - \frac{1}{2}S_{X_2}\right) - (\overline{S}_{M^+} - S_M)$$

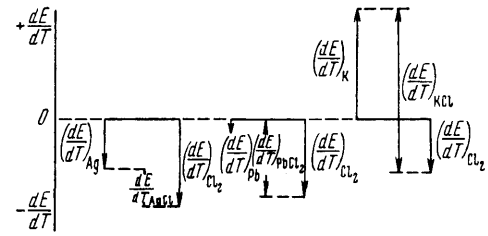

Figure 6. Temperature coefficient of the e.m.f. of a chemical cell as the algebraic sum of the temperature coefficients of the electrode potentials.

The terms in brackets (the heterogeneous components of the thermopotentials) are proportional to the temperature coefficients of the electrode potentials, which are added or subtracted (depending on their sign). Three possible cases are shown schematically in Fig. 6. For fused AgCl the temperature coefficient of the e.m.f. of the chemical cell $Ag|AgCl_{liq.}|Cl_2$ is equal to the difference between the temperature coefficients of the electrode potentials; for fused $PbCl_2$, $(dE/dT)_{PbCl_2}$ is equal to the temperature coefficient of the potential of the chlorine electrode; for fused KCl, $(dE/dT)_{KCl}$ is equal to the sum of the temperature coefficients of the electrode potentials.

---o0o---

Further work on thermogalvanic cells with one-component electrolytes should be aimed at the following objectives. The experimental measurements should be extended to salts on which no data are yet available (in particular, bromides and iodides, and also fused oxides); there is also a need for a method of direct experimental measurement of the local Peltier effect (the heterogeneous component of the thermopotential), in order to obtain more precise data on partial ionic entropies and on the entropy of transfer in the salt (the homogeneous component of the thermopotential). Only then will it be possible to seek a quantitative relationship between the entropy of transfer and other kinetic parameters of the salt. The comparative studies of thermoelectric phenomena in crystals and in their melts should also continue, in order to throw new light on the nature of the melting process in crystalline salts.

Infrared Spectroscopy of Nucleic Acids

G.P.Zhizhina and E.F.Oleinik

The review deals with infrared and Raman spectroscopic data for DNA, RNA, and their components and with the assignment of the infrared bands to the vibrations of individual bonds. An approach to a theoretical treatment of the normal vibrations of the nucleic acid skeleton is described. The applications of infrared spectroscopy to the study of the specificity of the interaction of the heterocyclic bases, the secondary structure of nucleic acids, and their interactions with proteins, metal ions, and certain biologically active substances is considered.
The bibliography includes 218 references.

I. INTRODUCTION

The vigorous development of molecular biology has been accompanied by a large-scale application of physical and physicochemical methods in the investigation of the composition and structure of biologically important compounds. Infrared spectroscopy is acquiring increasing importance among these methods. The infrared spectroscopic method has been successfully employed to solve various structural and physicochemical problems in molecular biology, including the recognition of compounds with weak structural characteristics, the determination of the structural formulae of biologically important compounds, and the study of the steric configuration of biopolymers.

The infrared spectra of biologically important compounds such as aminoacids, peptides, heterocyclic bases of nucleic acids, lipids, steroids, and vitamins and also the spectra of biopolymers—proteins, nucleic acids, and polysaccharides—are being investigated at the present time. Major advances have been achieved in the study of the structure of polypeptides and proteins with theoretical analysis of the normal vibrations. However, for nucleic acids a complete description of the normal vibrations is still lacking, most probably due to the complexity of their molecular structure. Therefore the fundamental bands in the infrared spectra of the bases, polynucleotides, and nucleic acids have been interpreted by a semiempirical method based on the study of the absorption by individual atomic groups in the low-molecular-weight components. This reduces the reliability of the conclusions arrived at and, what is most important, limits the information which may be derived from the infrared spectra.

Nucleic acids consist of highly polymerised unbranched molecules the main valence chain of which comprises alternating phosphoric acid and sugar units; purine and pyrimidine bases are attached to the sugar residues (Fig. 1)†. The molecular structure of nucleic acids and also of synthetic polynucleotides is now fairly well known, as can be seen from the numerous papers, reviews, and monographs [1-9].

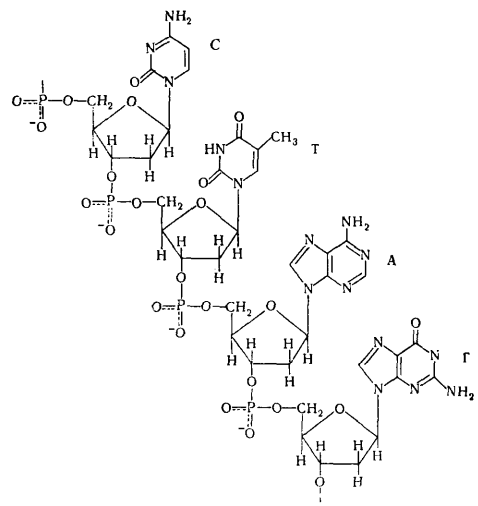

Figure 1. Schematic representation of the primary structure of the DNA chain.

There are no reviews on the infrared spectroscopy of nucleic acids in the Soviet literature. Abroad a review was published in 1965 by Shimanouchi et al. [10], in which the authors considered mainly the results of their own infrared spectroscopic studies on nucleotides, sugars, phosphates, synthetic polynucleotides, DNA, and RNA, while during the preparation of the present review Tsuboi [11] published a review on the infrared spectroscopic studies on the structure of nucleic acids. During recent years very many studies on the infrared spectra of nucleic acids, not included in the above reviews, have been published.

†The following abbreviations have been adopted: A = adenine, G = guanine, T = thymine, C = cytosine, U = uracil, I = inosine, GMP = guanosine monophosphate, poly-A = polyriboadenylic acid, poly-(G/C) = double helix of polyguanylic and polycytidylic acids.

II. VIBRATIONAL SPECTRA OF NUCLEIC ACIDS

The infrared spectrum of DNA was described for the first time in 1948–1953 by Blout and coworkers for solid specimens in the range 4000–700 cm^{-1} [12,13] and for solutions in D_2O in the range 1750–1500 cm^{-1}. [14,15] Non-oriented DNA films and non-polarised radiation were employed in these investigations. The spectra of non-oriented DNA films were first published by Fraser [16] in 1951, but he did not take into account the effect of the moisture content of the specimens on the spectra. Subsequently a number of workers [10,17-23] studied the vibrational spectra of nucleic acids in the range 4000–400 cm^{-1} using all the possibilities of the method at present available.

The infrared spectrum of DNA [10] shown in Fig. 2 is comparatively simple: it consists of a fairly "diffuse" pattern, the majority of the bands of which are diffuse and only a few are fairly distinct. Numerous bands have become appreciably broadened and overlap with those adjoining them.

Three regions may be arbitrarily distinguished among the groups of absorption bands in the spectrum: 4000 to 2000 and 1700–1500 cm^{-1}, usually attributed to the vibrations of the bases and the CH groups of deoxyribose in DNA, and 1300–1000 cm^{-1} attributed to the vibrations of the sugar and the phosphate groups in the DNA molecular skeleton. The assignment of the bands in the infrared spectrum of DNA to the individual bonds of the skeleton and the DNA bases is given in Tables 1 and 2; for the majority of the bands, with the exception of those in the region 3500–2000 cm^{-1} and at 1705, 1220, and 1084 cm^{-1}, the assignment must be regarded as only approximate.

One should also bear in mind that the vibrations of the double bonds in the rings of the bases are strongly coupled. In the spectra of deuterated DNA, a shift of the majority of the bands towards lower frequencies is observed owing to the H–D isotope exchange in the NH_2 and NH groups of the bases [10,18].

The form of the infrared spectrum of DNA changes somewhat as the moisture content of the specimen is varied (Fig. 3)—a number of bands are displaced and the spectrum becomes systematically improved with increase of the relative moisture content to 92% [17,19] (a particular moisture content is achieved usually by placing the DNA film in a hermetically sealed chamber over a saturated solution of a particular salt or by blowing through the chamber a gas with a specified moisture content). Many bands become narrower, the degree of overlapping diminishes, and the overall diffuse background of the spectrum becomes less pronounced. A similar pattern

is observed in the study of the vibrational spectra of amorphous synthetic polymers [36,37] and this suggests that the above spectroscopic behaviour is due to an appreciable structural imperfection of the test material. This conclusion is partly confirmed by an examination of the infrared spectrum of the double helix of polyriboadenylic acid (poly-A) [28] shown in Fig. 4. Simple elimination of the irregularity in the alternation of bases appreciably improves the spectroscopic pattern.

The polarisation of the infrared absorption bands of DNA also depends on the moisture content, the dichroism of the majority of the bands being shown fairly distinctly,

although it does not lead to an appreciable improvement of the quality of the spectrum (Fig. 3). The dichroic ratio of many bands usually increases with the relative moisture content of crystalline DNA specimens.

In the range 1750–1550 cm^{-1}, where the in-plane vibrations of the rings of the bases are active, all the bands of Na- and Li-DNA are polarised at right angles to the direction of the orientation of the film. An analogous polarisation is observed also for the stretching and in-plane deformation vibrations of the NH_2, NH, and CH groups in the range 1600–1300 cm^{-1}.[18,19] It is interesting that the band at 1240 cm^{-1}, corresponding to the antisymmetric vibrations of the PO_2^- groups of Na-DNA,[10] does not exhibit dichroism at a relatively low moisture content, but, on increasing the latter, it is displaced from 1240 to 1220 cm^{-1} and is split into two components. Tsuboi believes[11] that this finding implies that the antisymmetric vibrations of each PO_2^- groups are not independent and that adjacent PO_2^- groups appreciably interact with one another, generating a series of vibrations which are propagated throughout the chain. The component with a lower wave-number (1215 cm^{-1}) and parallel dichroism may be assigned to the in-phase vibrations of the PO_2^- groups and the component with a higher wave-number (1225 cm^{-1}) and perpendicular dichroism may be assigned to the vibrations of the PO_2^- groups with a phase difference of $2\pi/n$, where n is the number of nucleotides corresponding to one turn of the DNA spiral. The wave-number difference between these components (~10 cm^{-1}) may be regarded as reflecting the strength of the interaction between the PO_2^- groups in the given crystalline Na-DNA specimen.

The band due to the symmetrical vibrations of the PO_2^- groups of DNA (1089 cm^{-1}) exhibits perpendicular dichroism. An analogous polarisation is observed also for the absorption bands in the range 1100–900 cm^{-1}, which are mainly due to the vibrations of the sugar and phosphate groups. The bands in the range 900 to 700 cm^{-1}, where the out-of-plane deformation vibrations at the N–H bond are active, also show parallel dichroism[17–19].

The effect of an increase of temperature from 22° to 90°C on the infrared spectra of DNA has been discussed by a number of investigators[10,20,38,39] and has been attributed to the breakdown of the secondary DNA structure (see Section V).

The infrared spectra of RNA have now been investigated in fair detail. All the general characteristics of the spectrum indicated for DNA hold also for RNA (Fig. 5). The vibrational spectrum of RNA has a set of intense absorption bands in the regions 3500–2000, 1700–1500, and 1250–1050 cm^{-1}. However, in the range 1100 to 800 cm^{-1}, where the sugar components of nucleic acids absorb, there is an appreciable difference between the DNA and RNA spectra[10,39,40]. The RNA spectra have bands at 1120 and 810 cm^{-1}, which are absent from the DNA spectra, and conversely the 1050 cm^{-1} band is characteristic only of polydeoxyribonucleotides. The spectroscopic characteristics of various types of RNA—ribosomal, transport, and viral—are in many ways similar, but the details of the spectra in the ranges 1750–1400 and 840 to 760 cm^{-1} are somewhat different, which is probably due to the different quantitative compositions of the bases and different percentage contents of the base pairs[27,41–43]. The infrared spectra of moist films of viral RNA show a weaker polarisation than DNA, which, however, may be due to the lower degree of orientation of the films. It is important to note that the symmetrical and antisymmetrical vibrations of the double helical RNA of the dwarf rice virus shows a dichroism which differs from that of DNA (Table 8). Quantitative data on the orientation of DNA and RNA films are normally quoted with the spectra, which greatly complicates their interpretation and comparison of spectra in polarised radiation. Oriented films of transfer RNA cannot be obtained owing to their low molecular weight.

The effects of changes in moisture content and temperature on the infrared spectra of RNA have been investigated to a lesser extent than for DNA. In contrast to DNA, the infrared spectrum of a solution of double stranded viral RNA is still lacking, but the spectra of transfer RNA have been recorded both for films and for D_2O solutions[11].

Synthetic polynucleotides exist either in a single-chain state or form double or triple helices, depending on a number of conditions (concentration, ionic strength, pH of the medium, etc.[6,44,45]). The infrared spectra of films comprising the double helices of polyadenylic acid (poly-A) and poly-(G/C) and the triple helix of poly-(A/2U) have been described[11,28] and the spectra of D_2O solutions of double-helical poly-(A/U), poly-(G/C), and poly-(I/C) have been measured by Miles and coworkers[46–52].

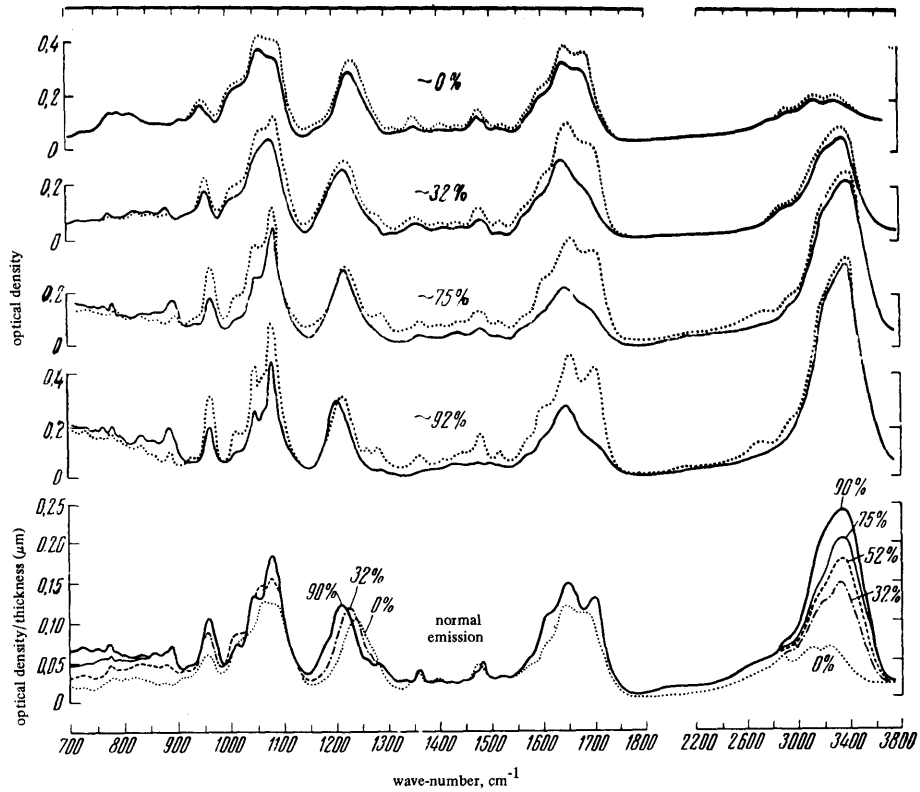

Figure 3. Polarised infrared spectra of oriented films of the sodium salt of DNA with different relative moisture contents[17]; dashed curves—emission vector perpendicular (⊥) to direction of specimen orientation; continuous curves—emission vector parallel (∥) to direction of specimen orientation.

The attempts to ob in the Raman spectra of aqueous DNA and RNA solutions remained unsuccessful for a long time. Only the Raman spectrum of polyadenylic acid in the single-chain state was known[53]. The laser Raman spectra of solutions of calf thymus DNA and the ribosomal RNA of *E. coli* were obtained by Tobin in 1969 [54] and Thomas in 1970 [55]. The positions of the bands in the Raman and infrared spectra of DNA largely coincide except for a discrepancy in the range 1700–1600 cm^{-1}, while the bands in the Raman spectrum of RNA from *E. coli* coincide satisfactorily with the bands in the corresponding region of the infrared spectrum[42].

III. VIBRATIONS OF THE MAIN VALENCE CHAIN OF NUCLEIC ACIDS

The theory of the normal vibrations of high-polymer molecules has recently developed considerably and, since nucleic acids are polymeric, it is quite reasonable to attempt a description of their vibrational spectra within the framework of the concepts formulated for polymeric systems[37,56].

A complete analysis of the vibrational spectrum of a polymer—a determination of the total number of its normal vibrations, their polarisation, and the selection rules for the infrared and Raman spectra and also the calculation of the frequencies and forms of the normal vibrations—is possible only for systems with a high degree of three-dimensional order. Despite their capacity for being packed in crystal lattices[57], neither DNA nor RNA possess such an order owing to the irregular sequence of bases. Only the molecules of synthetic polynucleotides such as poly-A and poly-C exhibit a rigorous chemical and steric (in the crystalline phase) periodicity and can be regarded as regular. Unfortunately the data for the vibrational spectra of these systems available in the literature are extremely limited[10,28], and yet they may prove to be indispensable in the interpretation of the vibrational spectra of nucleic acids. At the same time the main chains (skeleton) of the DNA and RNA molecules have an irregular chemical structure and under certain conditions also an irregular conformational structure[5,58–60], which allows an interpretation of the normal vibrations of the molecular skeleton using the periodic properties. Strictly speaking, the vibrational spectra of such helix complexes should be due to the vibrations of the atoms in both chains and to their interactions. However, one may suppose that the interaction of the chain vibrations in the double helix should be extremely insignificant, since the chains are separated by a considerable distance (the helix diameter is about 20 Å). The interactions between different double helices in the crystal phase can also be neglected. The most intense interaction between the main DNA and RNA chains occurs owing to the hydrogen bonds between the bases, but such interaction influences mainly the vibrations of the atoms in the bases, virtually without any perturbation of the atomic vibrations in the main chain.

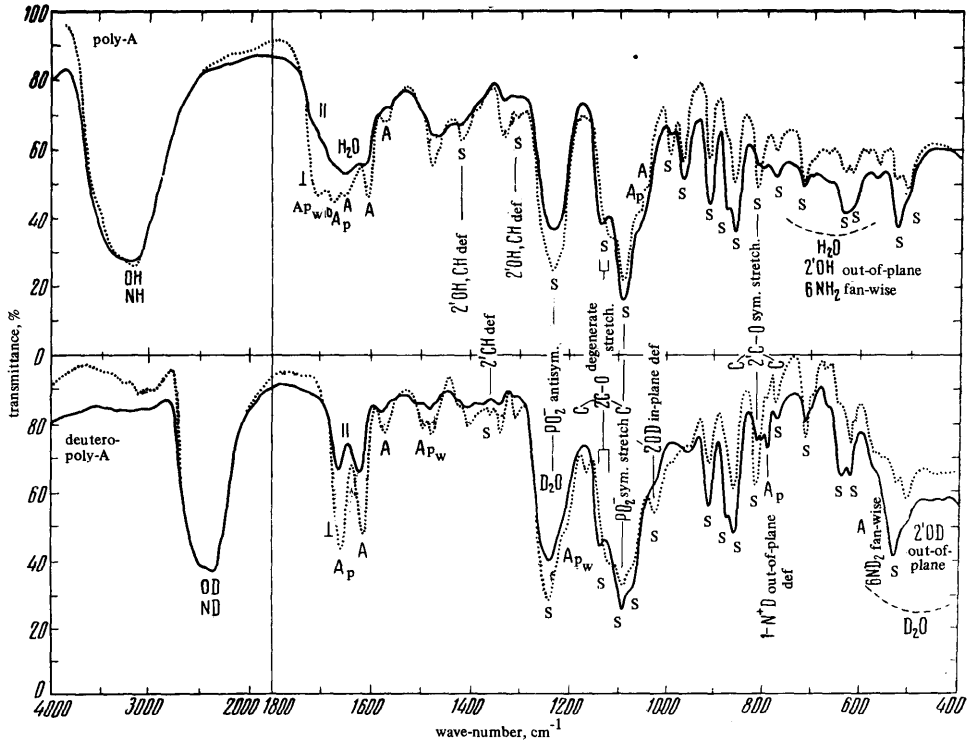

Figure 4. Polarised infrared spectrum of polyriboadenylic acid in the H- and D-forms with a 92% relative moisture content[28]; A—adenine absorption bands; A_p—bands of protonated adenine; A_{pw}—bands disappearing on drying; S—absorption bands due to the vibrations of the molecular skeleton.

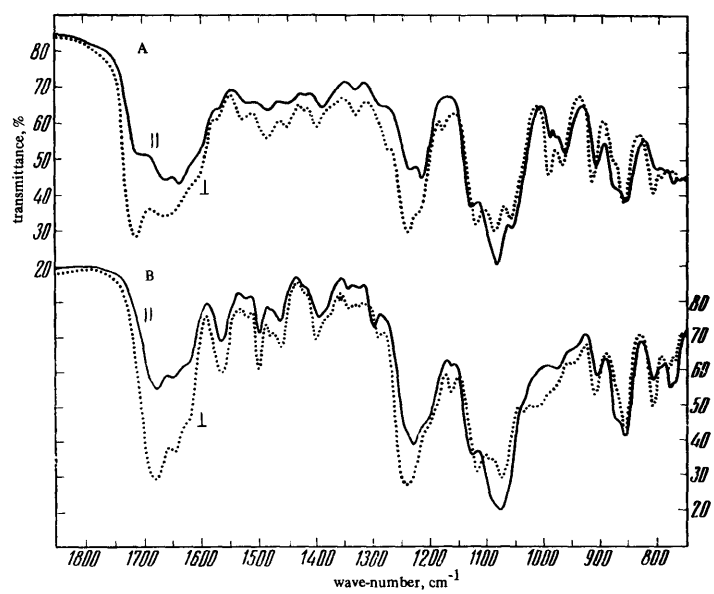

Figure 5. Polarised infrared spectrum of a film of the sodium salt of dwarf rice virus RNA in the H- and D-forms (A and B respectively) for a 75% relative moisture content[27].

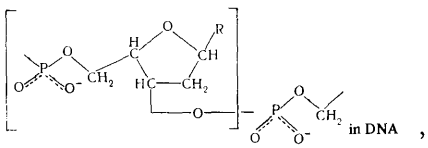
This suggests that both chains in the double helix have identical vibrational spectra and for the analysis of the latter it is sufficient to consider the vibrations of a single chain, formally assuming them to be doubly degenerate.

Summarising the foregoing, one may conclude that the expected vibration spectrum of nucleic acids as polymeric formations is obtained when a single chain of the double helix with a regular structure of the skeleton and a random sequence of the bases is considered.

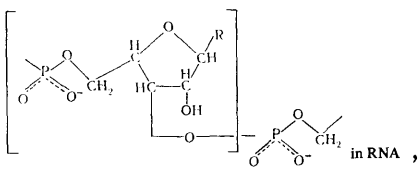
Let us consider the expected vibrational spectrum of the model

$$\underset{M}{\overset{\top}{R}\left[\overset{\top}{R}\right]\overset{\top}{R}},$$

where R is a point mass replacing any of the four bases and M is the monomeric unit which has the following structure:



M = 18 atoms (without R);



M = 19 atoms (without R).

Table 3. The characters, number of normal vibrations, and selection rules for the vibrations of the main DNA chain [rotational axis $C(\pi/5)$].

$C(\pi/5)$	E	C^1	C^2	$C^3 \ldots C^9$	N	Activity	
						i.r.	Raman
A	1	1	1	1...1	3·18—2=52 (T_π, R_π)	act. (∥)	forb.
B	1	—1	1	—1...—1	3·18=54	forb.	act.
E_1	2	$\varepsilon^{\pm1}$	$\varepsilon^{\pm2}$	$\varepsilon^{\pm3}\ldots\varepsilon^{\pm9}$	3·18—1=53 (T_σ)	act. (⊥)	»
E_2	2	$\varepsilon^{\pm2}$	$\varepsilon^{\pm4}$	$\varepsilon^{\pm6}\ldots\varepsilon^{\pm18}$	3·18=54	forb.	»
E_3	2	$\varepsilon^{\pm3}$	$\varepsilon^{\pm6}$	$\varepsilon^{\pm9}\ldots\varepsilon^{\pm27}$	54	»	forb.
E_4	2	$\varepsilon^{\pm4}$	$\varepsilon^{\pm8}$	$\varepsilon^{\pm12}\ldots\varepsilon^{\pm36}$	54	»	»

Note. i.r.—infrared spectrum; N—number of normal vibrations; act.—active vibrations; forb.—forbidden vibrations; T—pure translations of the entire chain parallel (π) and at right angles (σ) to its axis; R_π—rotation of the chain as a whole about the corresponding axis; C^K—rotation by an angle $K\omega$; $\omega = 2\pi/10$; $\epsilon = \exp[i(2\pi/10)]$.

This model probably constitutes a satisfactory first approximation, since here only those skeletal vibrations which are appreciably "mixed" with the vibrations of the bases are distorted.

Assuming the chains of the model to be infinitely long and regular macromolecules, the structure of which may be formulated as $-[M_i]_\infty-$, where M_i is a repeating chain unit, we can derive the general form of the vibrational spectra of such systems. The structure of model chains of this kind belongs to a one-dimensional space group with a $C(\pi/5)$ rotational axis, which is isomorphous with the C_5 point group [61,62]. Table 3 lists the characters, the number of normal vibrations, and the selection rules for the main DNA chain. For viral RNA containing 10 nucleotides per turn of the helix, the factor group remains the same and the characteristics of the spectra are as follows

M=20 (including R)
A=3·20—2=58 (∥) (i.r.)
B=60 (Raman)
E_1 = 59 (⊥) (i.r., Raman)
E_2=60 (Raman)
E_3 = 60, E_4 = 60 } forbidden (i.r., Raman)

The double helix of poly-A has a $C(\pi/2)$ rotational axis, M = 32 (chain unit together with adenine), and the following normal vibrations:

A=3·32—2=94
B=96
E_1=95
E_2=96

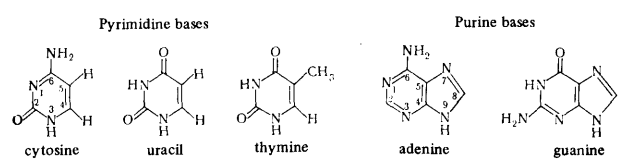
Examination of this model shows immediately that the total number of bands in the real infrared spectra of nucleic acids is less than expected. This finding may be due to several causes: (1) the low intensity of a number of bands; (2) the existence of numerous bands below 400 cm^{-1}; (3) the irregular structure of the molecules, which leads to a broadening of the bands and a pseudo-simplification of the overall pattern.

IV. VIBRATIONS OF NUCLEIC ACID BASES

As stated above, the theoretical calculation of the normal vibrations of nucleic acid bases is difficult owing to the complexity of their structures and very few studies have been made on this problem. Kanaskova [63] calculated the frequencies and the forms of the normal vibrations of free pyrimidine, imidazole, and purine on the basis of the valence force fields of these molecules.

1. Spectra of the Free Bases

The nucleic acid bases are aminoketo-derivatives of purine and pyrimidine—heterocycles containing ring nitrogen atoms.



The problem of the keto–enol and amine–imine tautomerism of the bases in the solid phase was already solved by infrared spectroscopy in the early investigations [29,64-73]. The molecules of the bases lack elements of symmetry and according to crystallographic data [74-81] have a planar configuration. The principal characteristics of the crystals are presented in Table 4.

According to the selection rules [62], all 3N-6 normal vibrations should be active in the infrared spectra of the free nucleic acid bases (30 for uracil, 33 for cytosine, 36 for adenine, 39 for thymine, and 42 for guanine).

The infrared spectra of nucleic acid bases, nucleosides, (base + sugar), and nucleotides (nucleoside phosphates), which are components of the DNA and RNA polynucleotide chains, have been quoted in a number of studies [24,30,32,33,70-72,82-96], where the absorption bands were also assigned.

In the majority of the investigations measurements were made of the spectra of these compounds in the solid phase (potassium bromide discs or mulls) in the light or deuterated forms in the range 4000–700 cm^{-1}, the spectra of the D_2O solutions having been obtained in only a few cases [14,31,35,97-101] over a narrow range (1700–1500 cm^{-1}). The spectra of the bases and nucleosides in the solid phase consist as a rule of narrow well resolved bands (Figs. 6 and 7).

For the isolated nucleic acid bases, one may expect the occurrence of intense bands due to the stretching vibrations of NH, NH_2, and CH groups in the range 3500 to 2000 cm^{-1} and intense vibration bands of the carbonyl groups, moderately intense bands of the double bond vibrations in the rings of the bases, and deformation vibration bands of the NH and NH_2 group in the range 1800 to 1500 cm^{-1}; in the range 1500–1000 cm^{-1}, one should expect bands of moderate and low intensity associated with the vibrations of the single C–C and C–N bonds, the deformation vibrations of the C–H and N–H bonds, and the skeletal vibrations of the bases; in the range 1000 to 700 cm^{-1}, there should be weak bands due to the out-of-plane deformation vibrations of the NH and CH groups. The infrared spectra of nucleic acid bases are presented in Figs. 6–8; the positions and assignments of the fundamental absorption bands are given in Tables 2, 5, and 6.

The spectrum of cytosine (Fig. 7) shows intense stretching vibration bands of the amino-group at 3367 and 3155 cm^{-1}, an N–H stretching vibration band at 2778 cm^{-1}, which is displaced on deuteration towards lower frequencies, and moderately intense bands associated with the stretching vibrations of the C–H bonds at 3081 and 2948 cm^{-1}, the positions of which are unaffected by deuteration [29,30,32,104]. Indeed, the rate of isotope exchange involving the hydrogen atoms of the DNA bases has been investigated by infrared spectroscopy and other methods and it has been shown that the H atoms in the NH and NH_2 groups are exchanged almost instantaneously, while the exchange in the CH groups is very slow [17,18,103,105-116]. The stretching vibration frequencies of the amino- and imino-groups of the bases show that in both solutions and crystals there are hydrogen bonds between the bases [76,79-81].

The stretching vibration bands of the double bonds of the bases can be conveniently observed in the spectra of the deuterated forms (Fig. 8), since the NH_2 and NH deformation vibration bands, which overlap them, are then displaced towards longer wavelengths. At the same time there is also a bathochromic shift of the band due to the double bonds, which reflects the occurrence of an interaction between the deformation vibrations of the NH and NH_2 groups on the one hand and the vibrations of the rings double bonds and the C=O groups on the other [10,31]. This type of shift is observed, for example, in the spectrum of a D_2O solution of cytosine for the bands due to the $C_{(6)}$=N and C=C bonds adjoining the amino-group (Table 5). The C=C vibrations and the NH_2 deformation vibrations in the light form of cytosine in the solid phase give rise to two bands in the form of a doublet (1655 and 1667 cm^{-1} respectively). The wave-numbers corresponding to the double bond vibration frequencies of cytosine (1655 cm^{-1} for C=O, 1630 cm^{-1} for C=N, and 1621 cm^{-1} for C=C) are reduced, probably owing to conjugation.

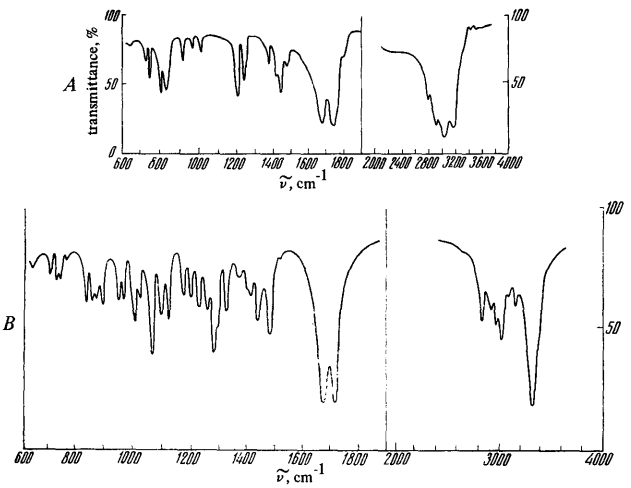

Figure 6. Infrared spectra of solid thymine (A) and thymidine (B) in a neutral medium.

The cytosine ring vibrations are reflected in the spectrum by bands at 1527 and 1365 cm^{-1}, close to the characteristic absorption bands of the pyrimidine ring (1565, 1462, and 1397 cm^{-1}) [89], which have not been assigned to the vibrations of the individual bonds in the ring. These bands and also those at 1236 and 794 cm^{-1} are active in the Raman spectra of cytosine [103].

Substituents in the N_3 position of pyrimidines and the $N_{(9)}$ position of purines in general influence the vibration frequencies of the bases. However, the addition of deoxyribose or ribose leads to only insignificant shifts in the bases. The spectra of nucleosides are complicated owing to the appearance of the sugar absorption bands: bands due to the stretching vibrations of the OH and CH bonds in the range 3700–2000 cm^{-1}, the deformation vibrations of the hydroxy-groups in the range 1350–1110 cm^{-1}, and the vibrations of the ribose ring in the range 1110–900 cm^{-1} (Fig. 6) [10,29,32]. The characteristic bands of the phosphate group (1220 and 1089 cm^{-1}) appear in the spectra of nucleotides and in the case of cytidylic and adenylic acids there are very significant displacements of the bands of the bases owing to the formation of zwitter-ions (a negative charge at the phosphate group and a positive charge at the base) [29,32].

Uracil and thymine, which have similar molecular structures, also have similar infrared spectra (Figs. 6 and 7). Each base has two carbonyl groups, the C_6=O group conjugated with the C=C bond and the $C_{(2)}$=O group

*Nucleoside.

located between the imino-groups. The effect of the environment on the carbonyl groups in both positions should lead to a lowering of their vibration frequencies compared with the characteristic vibration frequencies of the carbonyl group in ketones (in the range 1725–1705 cm^{-1}). Indeed the vibration frequency of the C=O group in imidazolone corresponds to 1684 cm^{-1}.[108] However, two bands at 1735 and 1670 cm^{-1} appear in the spectrum of crystalline uracil[29,32,33], the wave-number of the first being higher than expected. The 1670 cm^{-1} band has been assigned to the vibrations of the $C_{(6)}$=O group conjugated with the C=C bond and the 1730 cm^{-1} band has been assigned to the vibrations of the $C_{(2)}$=O group[29,31–33]. Probably there is an interaction between the carbonyl groups in the uracil and thymine molecules of the type known for dicarbonyl compounds, which leads to a displacement of the vibration frequency of one of the groups towards higher values[109]. It is also possible that the increase of the vibration frequency of the $C_{(2)}$=O group is due to its combination with the N_1H bond vibrations.

Sukhorukov et al.[33] determined the multiplicity n and the length r of the bonds of the carbonyl groups of uracil from

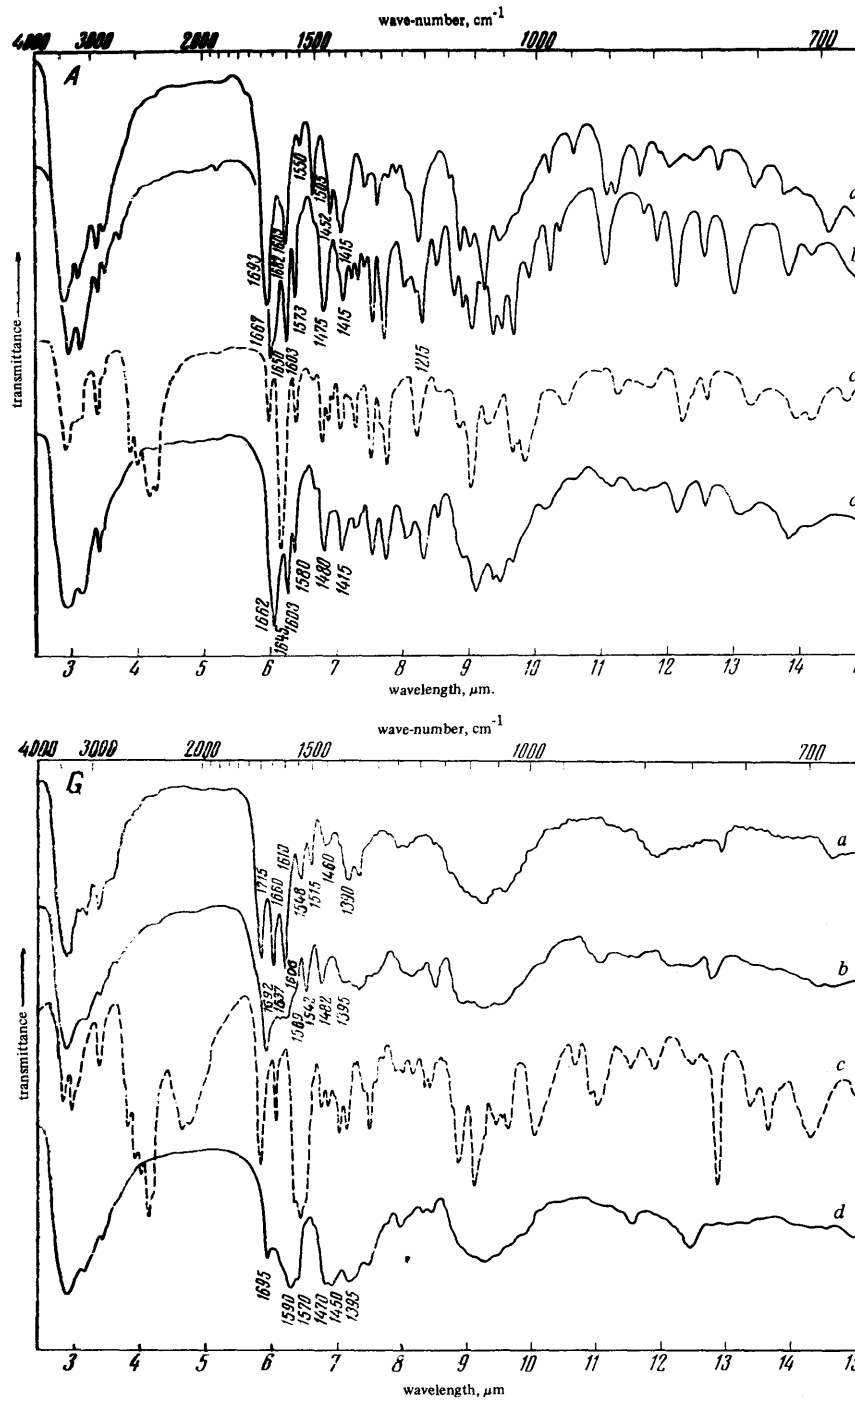

Figure 7. Infrared spectra of solid nucleosides[31]:
a) from an acid solution in H_2O; *b*) from a neutral solution in H_2O;

their vibration frequencies in the infrared spectrum and the empirical relations between these quantities quoted in the literature[110,111]. The vibration frequency of the $C_{(2)}$=O group (wave-number 1735 cm^{-1}) corresponds to $n = 2.07$ and $r = 1.225$ Å, while that of the $C_{(6)}$=O group (1670 cm^{-1}) corresponds to $n = 1.85$ and $r = 1.241$ Å; the values of r obtained agree satisfactorily with the X-ray diffraction data[80]. The intense 1451 and 1238 cm^{-1} bands and the weak 780 cm^{-1} bands have been assigned to the vibrations of the uracil rings coupled with deformation vibrations of the NH bonds.

The spectrum of thymine differs from that of uracil mainly by the presence of bands corresponding to the stretching and deformation vibrations of the methyl group.

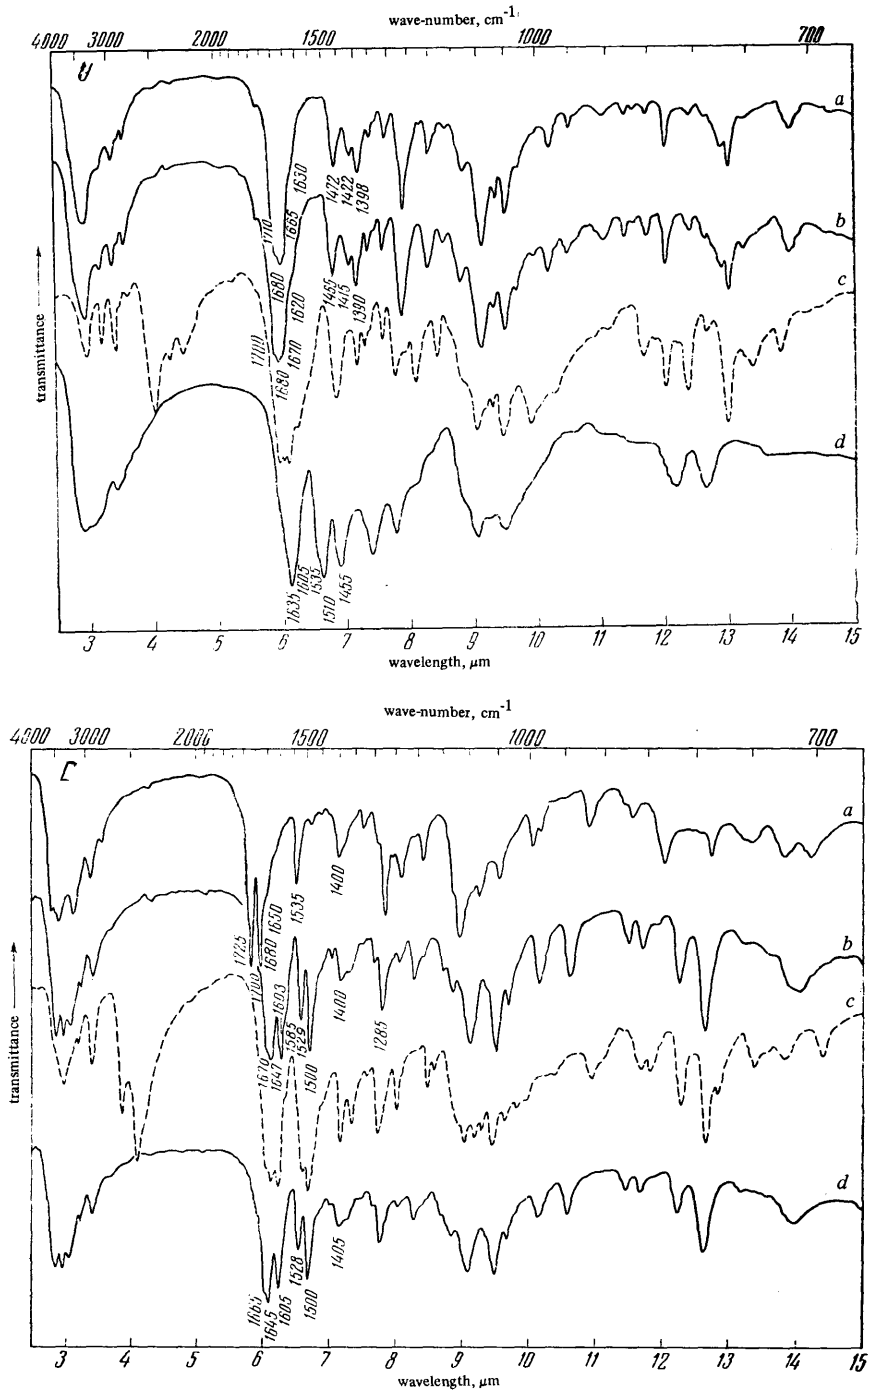

Figure 7 continued. Infrared spectra of solid nucleosides[31]:
c) from a neutral solution in D_2O; *d*) from an alkaline solution in H_2O.

In the low-frequency part of the spectrum (700 to 200 cm^{-1}), polysubstituted pyrimidines have two intense absorption bands at 525 ± 25 and 450 ± 25 cm^{-1}, corresponding to the out-of-plane and in-plane deformation vibrations of the pyrimidine ring[111-115]. The 450 cm^{-1} band can serve for identification, since its position is not affected by substituents. The position of the band due to the out-of-plane vibrations of the pyrimidine ring (525 ± 25 cm^{-1}) depends on the mass of the substituent (NH_2, OH, SH, and $S-CH_3$ groups), the relation being linear[116].

Guanine has a structure similar to that of cytosine. However, the vibration frequency of its carbonyl group

(wave-number 1700 cm^{-1}) is much higher than in cytosine (1655 cm^{-1}) and higher than the expected vibration frequency of the C=O group conjugated with the C=C double bond. Intense bands characteristic of the purine ring have been observed in the guanine spectrum[88]: 1639 (C=N), 1567 (C=C), 1518, 1477, and 1375 cm^{-1}.[29,31,32] The deuteration of guanine is accompanied by a slight decrease of the C=O and C=N bond frequencies, which may be evidence of a slight interaction of their vibrations with those of the NH and NH_2 groups.

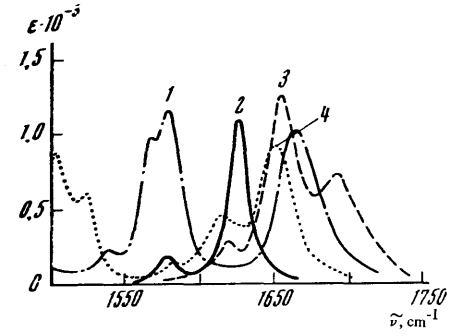

Figure 8. Infrared spectra of D_2O solutions of nucleotides: 1) guanine; 2) adenine; 3) uracil; 4) cytosine; pD 7 (Thomas[102]); ε—molar extinction coefficient.

Adenine is the only base without a carbonyl group. Its amino-group gives rise to intense bands at 3280 and 3105 cm^{-1} (ν) and at 1672, 1451, 1022, and 797 cm^{-1} ($\beta + \delta$).[29,32,65] The vibrations of the amino-group interact strongly with those of the adjacent C=N bonds, as a result of which the wave-number of the latter increases on deuteration of adenine from 1605 to 1627 cm^{-1}.[59] Since the structure of adenine differs from that of purine only by the presence of a single substituent, its spectrum shows six characteristic bands due to the skeletal vibrations of purine: at 1605 (C=N), 1575 (C=C), 1510, 1458, 1418, and 1368 cm^{-1}.[10,29,32,97] The C=C bond stretching vibration band usually has a low intensity in infrared spectra, but in the adenine spectrum it is fairly intense, possibly owing to the aromatic nature of the ring of this base.

In a study of the effect of temperature on the infrared spectra of the crystalline bases, Sukhorukov, Kanaskova, Pentin, and coworkers[33,63,117,118] observed that, in the spectra of imidazole, purine, and a number of their derivatives in the range between −160° and 100°C, the bands due to the out-of-plane NH and NH_2 deformation vibrations are the most sensitive to changes in temperature. It was shown that the temperature variation of the frequencies of the out-of-plane vibrations is in all cases linear and may be described by the equation $\nu_{o.o.p.} = A - BT$, where A and B are constants characteristic of each compound. In this connection a method was proposed for the identification of the out-of-plane deformation vibration frequencies of the NH and NH_2 groups of nitrogeneous bases, called the temperature shift method[63,117]. The author used this method to identify a number of bands in the infrared spectra of adenine and its N-methyl derivatives. On the other hand, it was shown that the frequency shift of the proton-donating NH and NH_2 groups depends on the length of the hydrogen bonds (r) formed by them: $B = 0.93 - 0.29r$ (for NH) and $B = 0.83 - 0.27r$ (for NH_2). The temperature shift method proposed makes it possible to distinguish the NH and NH_2 deformation vibration bands and, when combined with other methods, allows a more reliable determination of the structure of the bases in the crystalline state.

The Raman spectra of the free bases and nucleosides in the solid phase and in solution were measured by Lord and Thomas[103]. The frequencies in this spectra are listed in Tables 5 and 6.

The NH and NH_2 deformation vibration bands in the Raman spectra are very weak or altogether absent, but the double bond and ring vibrations give rise to more intense bands than in the infrared spectra. Ribose and phosphate give rise to very weak Raman bands. In the Raman spectra the bands due to the carbonyl groups and those in the range 800 to 750 cm^{-1} in the spectra of pyrimidines and in the range 730–680 cm^{-1} in the spectra of purines are highly polarised. Bands polarised to a moderate extent are observed in the range 1500–1200 cm^{-1}. The depolarisation ratio is determined by the local planar symmetry of the ring of the base, the in-plane deformation vibrations being polarised and the out-of-plane vibrations depolarised.

2. The Spectra of the Nitrogeneous Bases in Polynucleotides

The main problem in the study of the infrared spectra of polynucleotides is the determination of the specific spectroscopic characteristic of the interaction of the bases forming part of nucleic acids, in contrast to those of the free bases.

When the vibration bands of the bases in polynucleotides and nucleic acids are considered, one should expect shifts of certain frequencies owing to the enhancement of the interaction between the complementary bases, since it is known that the specific interaction of such bases via hydrogen bonds is much stronger than their self-association (see Section VI). Moreover, the dispersion interaction between the π electrons of the bases in the vertical "piles" within the polynucleotide chain may make a definite contribution to the change in the vibration frequencies of the bases.

Assignments of the absorption bands due to the vibrations of specific groups in the bases within nucleic acids are available in the literature only for the stretching vibrations of the NH_2 (3350 and 3210 cm^{-1}), NH (2950 cm^{-1}), and CH (3090 cm^{-1}) groups[10,17-19]. The 1705 cm^{-1} band, characteristic of the spectra of native DNA and RNA preparations, which on deuteration shift towards lower frequencies down to 1685 cm^{-1}, has also been discussed. According to Shimanouchi and coworkers[10,38,39] and also Fritzsche[20], the 1705 cm^{-1} band is associated with the stretching vibrations of the carbonyl groups of the bases interacting with the deformation vibrations of the amino-groups. The frequency of this band is higher than those associated with the vibrations of the carbonyl groups of the free bases (with the exception of one of the groups in thymine and uracil). The increase of the C=O vibration frequency of the bases forming part of nucleic acids is probably due to their involvement in hydrogen bonds between the complementary bases.

There are virtually no assignments in the literature for the remaining absorption bands of the bases in nucleic acids. On the basis of published experimental data, we attempted to make a more detailed assignment of the bands

of the bases in DNA. However, for the majority of the bands in the range 1400–600 cm^{-1} such refinement can be regarded as merely conventional. The results are presented in Table 2. Analysis of the data in Table 2 reveals certain regularities. Thus the position of the C=N band in the DNA spectrum is very close to the positions in the corresponding spectra of the individual bases.

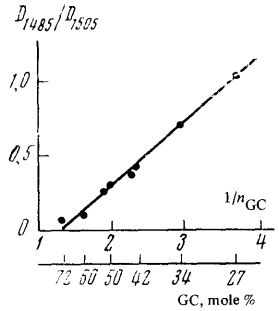

Figure 9. Variation of the ratio of the optical densities of the 1485 and 1505 cm^{-1} bands of deuterated DNA films with $1/n_{GC}$ (n_{GC} = mole fraction of G-C pairs in DNA) [22].

The vibration frequencies of the C=C bonds in the DNA spectrum and in the spectra of free guanine and adenine are almost identical, while in the spectra of free pyrimidines they are somewhat higher. However, the reasons for this effect are so far obscure. The bands due to the in-plane deformation vibrations of the NH_2 and NH groups of the bases are displaced in the DNA spectrum towards lower frequencies compared with the corresponding bands in the spectra of the free bases, which may be caused, as for the C=O groups, by the involvement of the hydrogen atoms of the NH_2 and NH groups in hydrogen bonds. In the remaining parts of the spectrum the vibration frequencies of the bases in nucleic acids are the same as those of the free bases, within the expected limits.

Fritzsche [21,22], who studied the infrared spectra of DNA specimens with different base compositions in the range 1800–1200 cm^{-1}, observed a quantitative linear relation between the intensity ratio of the 1505 and 1485 cm^{-1} bands, which are characteristic of the absorption by guanine and adenine respectively, and the percentage content of the G-C pairs (Fig. 9). He suggested that the infrared spectra of DNA be used for analytical purposes—in order to determine the content of the G-C pairs. In a further development of studies on these lines, Tsuboi et al. [23] measured the infrared spectra of DNA from different species of bacteria with different ratios of the G-C (guanine–cytosine) and A-T (adenine-thymine) base pairs and observed a correlation between the contents of the G-C and A-T pairs and the intensity of the majority of bands in the spectrum. On the basis of these data, they found spectroscopic features characteristic of the presence of the AT and GC base pairs in DNA (listed in Table 7).

Thus the infrared spectrum of DNA does indeed show shifts of certain absorption bands compared with the corresponding bands in the spectra of the free bases and also there are a number of bands characteristic of the AT and GC base pairs.

3. Effect of pH on the Spectra of the Bases

The nucleic acid bases can exist in different ionic forms, since in their molecules there are several sites for proton addition. However, in practice relatively few tautomeric forms are observed, because in many cases protonation is unfavourable on energy grounds. One of the methods for the determination of the site of addition or abstraction of a proton is infrared spectroscopy of the ionic forms of the bases.

The studies by Sukhorukov [30,32,33,119] and Angell [29] (solid phase), Tsuboi and Shimanouchi [10,31] (solid phase and D_2O solutions), and Sinsheimer et al. [35] (D_2O solutions) were devoted to the elucidation of this problem. The studies showed that, for all the nucleic acid bases, the formation of cations involves a shift of the double bond vibration frequencies towards higher values and the formation of an anion causes a shift towards lower frequencies in both infrared and Raman spectra [31–33,53].

The infrared spectrum of cytidine ($pK = 4.5$) [120] in an acid medium differs considerably from its spectra in neutral and alkaline media (Fig. 10).

The spectrum of protonated cytosine is characterised by an increase of the wave-numbers associated with the C=O bond vibrations (from 1655 to 1680 cm^{-1}) and the vibrations of the NH_2 group (from 1667 to 1725 cm^{-1}). Cytosine may be protonated in two ways: at the amino-group and at the N_1 ring atom. The shift of the absorption bands due to the multiple bonds towards higher frequencies indicates an increase of the multiplicity of the C=O and C=N bonds which is more likely to occur as a result of loss of conjugation following the addition of a proton to the N_1 atom rather than to the amino-group. An analogous shift of the absorption frequencies of the ring double bonds is observed on protonation of pyridine ($C_5H_5NH^+$) but not aniline ($C_6H_5-NH_3^+$). [10,31,32]

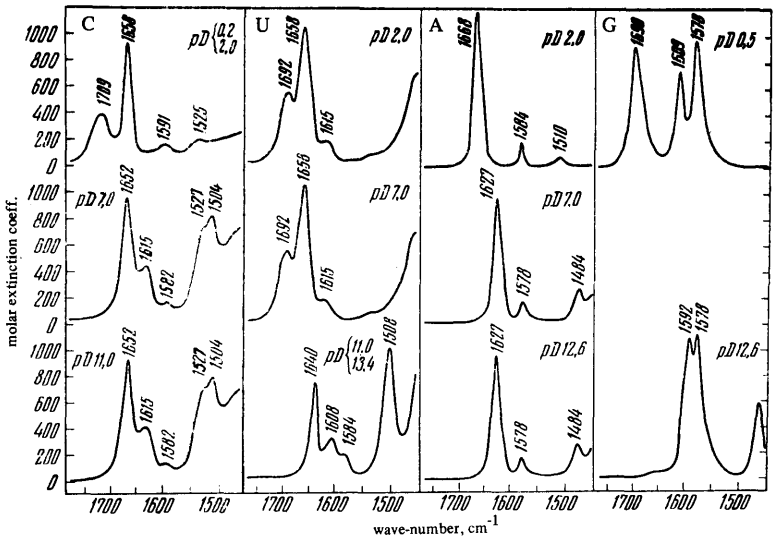

Figure 10. Infrared spectra of D_2O solutions of nucleosides at different pD. [31,100]

A decrease of the intensity of the NH stretching vibration band and a decrease of the frequency of the C=O stretching vibrations (the wave-number decreases from 1680 to 1638 cm^{-1}) are observed in the infrared spectrum of uracil in an alkaline medium ($pK = 9.5$), which is due to the abstraction of a proton from the $N_{(1)}$ or $N_{(3)}$ ring atom and the delocalisation of the electron over the system of conjugated double bonds [31,32]. An empirical relation between the frequency of the stretching vibrations of the carbonyl group and the ionisation potential I, [116]

$$\nu_{C=O} = 29.2\,I + 1409,$$

yields ionisation potentials of 9 and 11 eV for frequencies corresponding to wave-numbers of 1670 and 1735 cm^{-1} respectively; the ionisation potential of the ionic form of uracil is reduced to 7.8 eV; [33] however, all these data require confirmation by independent methods.

In highly alkaline solutions of thymine ($pK = 9.8$), one of the carbonyl groups is enolised and the corresponding band disappears from its infrared spectrum. The remaining bands are displaced towards lower wave-numbers (1735, 1670, 1640, and 1570 cm^{-1} bands in a neutral medium and 1650, 1600, and 1580 cm^{-1} bands in an alkaline medium) [14,98].

The formation of the adenine anion in an alkaline medium ($pK_2 = 9.8$) is accompanied by the disappearance from its infrared spectrum of the band associated with the $N_{(9)}H$ bond, which indicates unambiguously the site of abstraction of the proton from the imidazole ring of adenine [29,32]. In infrared spectra of protonated adenine ($pK_1 = 4.1$), in both the solid phase and in solution, the frequencies of the ring vibrations are enhanced, including the vibrations of the $N_{(1)}=C_{(6)}$ bond (the wave-number increases from 1626 to 1668 cm^{-1} in D_2O solution) [32]. This is most likely to occur as a result of the addition of a proton to the ring $N_{(1)}$ atom rather than to the amino-group. Indeed, it has been shown by X-ray diffraction that in crystalline adenine hydrochloride the proton is located at the ring $N_{(1)}$ atom [121].

As for the remaining bases, the protonation of guanine ($pK_1 = 1.6$) is accompanied by a general shift of the absorption bands in the range 1700–1400 cm^{-1} towards higher frequencies, including the NH_2 deformation vibration band (from 1681 to 1718 cm^{-1}) and resembles the frequency shift on protonation of pyridine (Fig. 10). [12,13,31,32,101] According to crystallographic [75] and NMR [122] data and Pullman's calculations [123], guanine is protonated at the ring $N_{(7)}$ atom and infrared spectroscopic data [31,101,124] are consistent with this postulate. A shift of pH to the alkaline region lowers the intensity of the absorption band due to the guanine carbonyl group ($pK_2 = 9.4$) and gives rise to new absorption bands at 1638 and 1413 cm^{-1}. [31,101] The spectrum of an alkaline solution of guanine resembles that of 2-amino-6-methoxypurine. Probably these changes in the infrared spectrum of guanine are caused by the abstraction of a proton and a redistribution of the charge, resulting in a decrease of the multiplicity of the C=O bond and in increase of electron density at the guanine oxygen atom [31].

The purine and pyrimidine bases may exist in solution in various tautomeric forms, and a different form may predominate than in the solid phase. Miles and coworkers [31,97–101,109] solved this problem by comparing the infrared spectra of D_2O solutions of the bases with those of solutions of model compounds, in which a particular structural element is fixed. For example, *N*-dimethylcytosine and 1-methyl-2-oxopyrimidine served as model compounds for cytosine and 1,9-dimethylguanine and 2-amino-6-methoxypurine were used for guanine. Thus it was shown that the aminoketo-form predominates in cytosine and guanine solutions, the amino-form in adenine solutions, and the diketo-form in uracil and thymine solutions, this being confirmed by NMR data [125].

Thus the study of the spectroscopic changes in the infrared region as the pH of the medium is varied makes it possible to determine the site of abstraction or addition of the proton in purine and pyrimidine bases. Measurements of the infrared spectra of solutions of the bases also make it possible to establish the dominant tautomeric form of the base.

V. INFRARED SPECTROSCOPIC STUDY OF THE SECONDARY STRUCTURE OF NUCLEIC ACIDS

According to the model of Watson and Crick[4,5], the secondary DNA structure consists of a double helix with antiparallel chains (stable in both the crystalline state and in solution[126,127]) stabilised by hydrogen bonds as well as van der Waals forces. The disruption of the DNA helix and the separation of its chains (denaturation) occur both on heating and under the action of acids and alkalies.

The study of the secondary structures of DNA and RNA is one of the most important tasks in molecular biology. In the study of the secondary structure of nucleic acids, X-ray diffraction has hitherto played the main role and infrared spectroscopy an auxiliary role. However, in the study of DNA and RNA structures in solutions, the infrared spectroscopic method has many advantages and yields important information when combined with other methods—hydrodynamic and optical methods and low-angle X-ray scattering[126-129].

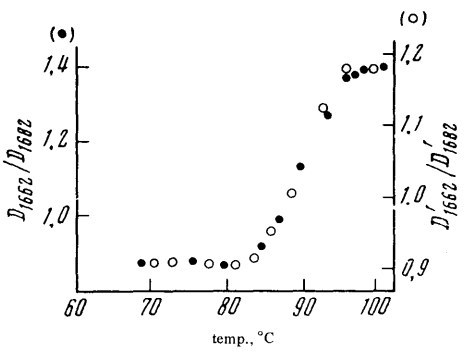

Figure 11. Temperature variation of the ratio of the optical densities of the 1662 and 1682 cm^{-1} bands of D_2O solutions of DNA; 10 mg ml^{-1} of DNA in 0.15 M KCl.[20]

In the infrared spectra of native DNA (in solution or in a film), an intense absorption band, characteristic of its secondary structure, was found; it is located at 1705 cm^{-1} for the light form and at 1685 cm^{-1} for the deuterated form of DNA.[15,20,23,38,37,130] On denaturation, the band is displaced towards lower wave-numbers, for example, from 1685 to 1660 cm^{-1}. The fact that the 1705 (1685) cm^{-1} band is characteristic of the secondary DNA structure has been confirmed by a study of the effect of temperature on its intensity. The curve relating the relative intensities of the 1662 and 1682 cm^{-1} bands to temperature (Fig. 11) resembles the melting curve for DNA in measurements of ultraviolet absorption in the region of 260 nm.[20,39] It has been shown[131] that the temperature variation of the intensity of the maxima in the difference spectra of D_2O solutions of DNA, corresponding to the DNA absorption bands in the region 1700–1550 cm^{-1}, also agrees with the melting curve. This makes it possible to follow the "helix–coil" thermal transition on the basis of the vibrational spectra of DNA solutions and to determine fairly accurately the melting point of the DNA solution (T_{fu}) and the width of the transition (ΔT_{fu}). In contrast to measurements of T_{fu}, ultraviolet spectroscopy, or measurements of the viscosity of DNA solutions, the infrared spectroscopic method makes it possible to determine the melting points of concentrated and gel-like DNA solutions.

At present it is not yet clear why the above bands are sensitive to changes in the secondary DNA structure: whether they are due to changes in the interaction between the two chains or arise in consequence of a breakdown of regularity. However, there is no doubt about the practical usefulness of such data.

Classical X-ray diffraction studies on crystalline DNA specimens[58,59,132] showed that the DNA helix can have different conformations depending on the degree of hydration. The sodium salt of DNA can exist in the B-form, which is stable when the relative moisture content is in excess of 92%, and the A-form is stable for a 75% relative moisture content[58,59,132]. The lithium salt of DNA also has two conformations: the B-form for a relative moisture content in excess of 66% and the C-form for a relative moisture content in the range 44–66%.[139] Further decrease of the water content leads to a gradual disordering of the DNA structure. These conformations of the DNA helix differ from one another in their parameters and the orientation of the bases.

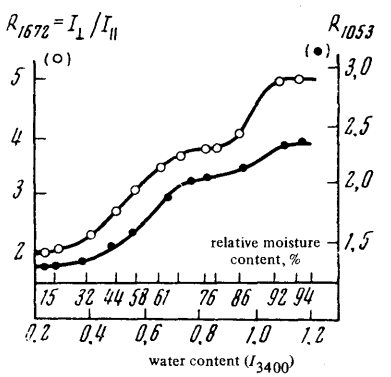

Figure 12. Variation of the dichroic ratios R_{1672} and R_{1053} with the water content in oriented DNA films[18].

The study of the infrared spectra of DNA confirmed and extended the X-ray diffraction data for the conformational transitions in DNA. Bradbury et al.[18] investigated the dependence of the polarisation of a number of absorption bands on the relative moisture content of oriented specimens of the sodium and lithium salts of DNA. A constant dichroic ratio R for the 1672 and 1053 cm^{-1} bands in the relative moisture content ranges corresponding to the stability of the B- and A-forms of DNA, namely above 90% and between 80 and 70%, has been observed for the sodium salt of DNA (Fig. 12). For the lithium salt of DNA, a plateau of this kind was observed on the curve relating R_{1670} to the relative moisture content in other ranges: above 66% and between 56 and 44% for the B- and C-forms respectively. It has been shown[18,134] that, for each conformation of the sodium salt of DNA, there is a characteristic frequency of the antisymmetric vibrations of the phosphate group (two plateaus on the frequency–moisture content curves for this band).

Sutherland and Tsuboi[17] and Falk et al.[19], who carried out similar investigations, also observed an increase of the dichroic ratio of the absorption bands due to the rings of the bases in the sodium salt of DNA with increasing water content in the specimen, but the curves are of a different type, which does not yield a clear proof of the interconversion of the A- and B-forms of DNA. Nevertheless these results show that an ordered helical DNA structure depends on the amount of adsorbed water and its partial dehydration leads to a considerable disorganisation of the molecular structure.

Quite recently Webb and Buther[135] succeeded in finding by the infrared spectroscopic method the structural characteristics of tumour DNA isolated from the tissue of Rous sarcoma and the mammary gland carcinoma in mice[135]. They observed that the tumour DNA is less hydrated for higher values of the relative moisture content and more hydrated for low values than DNA from normal tissues and that the dichroic ratio for tumour DNA is smaller than for normal DNA, remaining constant for relative moisture contents in the range 92–45%. They interpret the infrared spectroscopic data as evidence that the structure of the tumour DNA is intermediate between the B- and A-forms and does not alter for moderate degrees of dehydration.

The study of the vibrational structure of DNA spectra using polarised radiation yielded information about the orientation of its structural elements. Thus the knowledge of the dichroic ratio for the 1670 cm^{-1} band for relative moisture contents of 92 and 75% makes it possible to determine the orientation of the planes of the bases in the A-form of DNA on the hypothesis that in the B-form they are perpendicular to the axis of the helix. The results of such calculations show that in the A-form the planes of the bases deviate from the vertical orientation by 13–15°.[17,18] Measurement of the dichroism of the 1220 and 1089 cm^{-1} bands also permits the calculation of the orientation of the phosphate groups, since it is known that the transition moment of their antisymmetrical vibrations is directed along the O...O line and that of the symmetrical vibrations lies along the bisector of the OPO angle. It has been shown[17,18] that in both the A- and B-forms of DNA the O...O line is inclined to the axis of the spiral by 50–60° and the bisector of the OPO angle is perpendicular to the molecular axis. However, this conclusion is valid only when the form of the vibrations is highly characteristic. But, since the vibrations of the phosphate group are undoubtedly appreciably mixed with other skeletal vibrations, the angles of the orientation of this group in DNA must be assumed to be only approximate. The experimentally observed orientation of the PO_2^- groups in DNA contradicts the Watson–Crick model[4,5], according to which in the B-form of DNA the O...O line is perpendicular to the axis of the helix and the bisector of the OPO angle is parallel to it.

In order to investigate the hydration processes of DNA macromolecules, it is important to elucidate the sequence of the hydration of the structural elements of DNA (bases, deoxyribose, and phosphate groups), which can be achieved with the aid of infrared spectra, since changes in the relative moisture content involve shifts of the absorption bands associated with these structural elements. Thus an increase of the relative moisture content from 0 to 92% causes a shift of the carbonyl band of the DNA bases from 1705 to 1715 cm^{-1}, of the PO_2^- band from 1240 to 1220 cm^{-1}, and of the C–O band of deoxyribose from 1066 to 1053 cm^{-1}.[17,19] By studying the variation of the spectroscopic shifts with the moisture content of the DNA specimens, Falk et al.[19] established that the phosphate groups of DNA are hydrated when the relative moisture content is in the range 0–66% (six water molecules per phosphate group for a 66% relative moisture content), while above 66% the hydration of the bases begins. It has not yet been possible to elucidate the relation between the transition from the A-form to the B-form and the characteristics of the adsorption of water. The positions of the water bands in the infrared absorption spectrum of DNA show that all the adsorbed water layers except the first have a structure similar to that of liquid water[16,137]. Therefore the amount of water adsorbed by the DNA film may be calculated from the intensity of the 3400 cm^{-1} band, assuming that its molar extinction coefficient ϵ is the same as that for liquid water.

The secondary structure of RNA has been investigated much less than that of DNA, because RNA crystallises with difficulty and yields low-quality X-ray diffraction patterns. Nevertheless, it has been established by X-ray diffraction and other methods that RNA molecules consist of single coiled chains with an alternation of helical and non-helical sections[129,137]. The fraction of the A–U and G–C base pairs is different for different types of RNA. The infrared spectra of RNA films, like those of DNA, show a band at 1705 cm^{-1} (1680 cm^{-1} in D_2O), indicating the presence of paired bases in the RNA chain[38]. The variation of the intensity of this band as the temperature is raised from 22° to 90°C is represented by a gently sloping curve, resembling the melting curve of RNA in the ultraviolet region[39]. Infrared spectroscopy has been successfully employed to determine the secondary structure of RNA. The relative amounts of the A–U and G–C pairs have now been found by comparing the observed and calculated spectra for five varieties of transfer RNA: alanine, valine, methionine, formylmethionine, and tyrosine RNA[41,138,139] by the Thomas method[102] and for the ribosomal RNA of *E. coli* by the method of Cotter and Gratzer[42,43]. Both methods of calculation are based on the fact that the absorption by hydrogen-bonded bases differs from that of the free bases and on the hypothesis that the dispersion interaction between the bases in the vertical stacks does not affect the spectrum, although the latter postulate contradicts the data of Maleev and coworkers[140]. The Thomas method consists in the calculation of the RNA spectrum on the hypothesis that the RNA absorption is made up additively from the absorption by the A–U and G–C pairs and the four unpaired bases. The overall RNA spectrum is calculated from the absorption spectra of the four nucleotides and two helical polynucleotides: poly-(A/U) and poly-(G/C). The method of Cotter and Gratzer consists in the calculation of the difference spectrum of RNA (relative to the dialysate) with the aid of the analogous spectra of poly-(A/U) and poly-(G/C), which take into account only the contribution by the paired bases. An advantage of this method over the Thomas method is that of a greater simplicity of the calculation of the spectra, since it involves the analysis of a two-component and not a six-component system.

The data for the secondary structure of RNA obtained from infrared spectra are consistent with the results of other methods, for example the method of optical rotatory dispersion, ultraviolet, spectroscopy, acid–base titration, and the "clover leaf" model of transfer RNA proposed by Dube[141].

It has been shown by X-ray diffraction that the RNA of dwarf rice virus has a secondary structure resembling that of DNA. However, the infrared spectrum of the RNA exhibits a weaker polarisation than the DNA spectrum

(Fig. 5).[27] The bands of the in-plane vibrations of the bases are polarised at right angles to the direction of orientation, as in the DNA spectrum, but the polarisation of the absorption bands of the RNA and DNA phosphate groups is different and hence there is a difference between the orientations of the PO_2^- groups. In the dwarf rice virus RNA helix, the O...O line makes an angle of 70° with the axis and the bisector of the OPO angle makes an angle of 40° (Table 8).

Table 8.

Double helix	1220 cm^{-1} band		1085 cm^{-1} band	
	dichroism	θ, deg*	dichroism	θ, deg*
DNA	nil	55	$\perp$	65
RNA	$\perp$	70	$\parallel$	40
DNA-RNA hybrid	$\perp$	68—78	nil	53—57

*θ—angle between the axis of the helix and the O...O line for the 1220 cm^{-1} band or the angle between the axis of the spiral and the bisector of the OPO angle for the 1085 cm^{-1} band.

The infrared spectrum of the DNA–RNA hybrid contains intense absorption bands characteristic of both DNA and RNA.[142] The dichroism of the absorption bands of the phosphate groups is evidence that the orientation of these groups relative to the axis of the helix of the hybrid is not completely identical with their orientation either in the double-helical DNA or in the double-helical RNA. It has been suggested[142] that the observed dichroism can be explained by the fact that in the hybrid molecule the PO_2^- groups of the DNA chain retain the same orientation as in the double-helical DNA, while in the RNA chain the orientation is the same as in the double-helical RNA.

DNA molecules are known to form nucleoprotein complexes with histones and with polypeptides, for example with poly-L-lysine. Information about the structures of DNA and the histone in deoxynucleoprotein (DNP) is important for the determination of the structure of chromosomes. The spectrum of the DNP film in the range 3500–1400 cm^{-1} resembles more closely the spectrum of the histone than that of DNA, since the bands of the protein are more intense than those of DNA. Below 1400 cm^{-1}, the spectrum of the nucleoprotein is identical with that of DNA[143]. The histone in DNP has an intense band at 3300 cm^{-1} (stretching vibrations of the NH bonds), an Amide I band at 1660 cm^{-1} (stretching vibrations of C=O groups), an Amide II band at 1545 cm^{-1} (deformation vibrations of the NH group), and also weak bands at 1450, 1400, and 1320 cm^{-1}.[144] The absorption bands of the histone are weakly polarised even for high moisture contents. The study of the infrared spectrum and also of the optical rotatory dispersion of DNP in the normal and deuterated states showed that in DNP part of the protein (50%) is in the α-helical form, the conformation of the protein varying with time. Measurement of the dichroism of the absorption bands of DNA for high relative moisture contents of DNP films showed that DNA in the nucleohistone is in the crystalline B-form, in agreement with X-ray diffraction data[134].

The stoichiometric complex of DNA with poly-L-lysine consists of fibres giving rise to distinct X-ray diffraction patterns, resembling that of the B-form of DNA when the relative moisture content is 75 and 66%.[145] The infrared spectrum of this complex is similar in broad outline to that of DNP, the band due to the phosphate groups undergoing only an insignificant shift (from 1224 to 1233 cm^{-1}) as the relative moisture content is reduced to zero, compared with the shift for DNA (from 1225 to 1240 cm^{-1}). In the spectrum of the DNA–histone complex, this shift is somewhat greater than for the DNA–poly-L-lysine complex.

The authors regard the shift of this band on dehydration of DNA as evidence of the liberation of phosphate groups from hydrogen bonding. From this point of view, the slight shift of the band due to the asymmetric PO_2^- vibrations on dehydration of the DNA–poly-L-lysine complex may imply that in this complex there are hydrogen bands between the PO_2^- groups of DNA and the NH_3^+ groups of the poly-L-lysine side chains. However, the details of the molecular environment of the phosphate groups have not been elucidated and therefore such interpretation cannot be regarded as unambiguous.

VI. INFRARED SPECTROSCOPIC STUDY OF THE INTERACTION OF NUCLEIC ACID COMPONENTS WITH ONE ANOTHER AND WITH OTHER SUBSTANCES

The interaction of the complementary bases of nucleic acids via hydrogen bonding, postulated by Watson and Crick in 1953,[5] is fundamental in biological systems. The linear sequence of nucleotides in DNA molecules stores the genetic information about the cell (the triplet code). An important process in the reading and transmission of this information is the formation of complementary structures with the aid of specific hydrogen bonds. It has been suggested that this type of interaction occurs when DNA controls the synthesis of RNA and also in the interaction between nucleic acids during the synthesis of protein. Therefore it is necessary to find physical and chemical criteria of the specificity and stability of the pairing of the bases in helix nucleic acids, a problem which can be successfully solved by infrared spectroscopy.

The formation of association complexes in aqueous purine and pyrimidine solutions has been observed by measuring the concentration variation of their water vapour pressure[146,147] and also by a chromatographic method in which one of the bases is attached covalently to a column and then eluted by a solution of the other base[148,149]. However, it has been shown by NMR that in aqueous solutions association complexes of the bases can be formed both via hydrogen bonding and via π-electron interaction between the heterocyclic rings and the formation of vertical stacks of the bases[150,151]. On the other hand, Raman spectroscopy failed to show the formation of hydrogen bonds between the complementary bases in aqueous solutions[152]. In water the hydration effect is too large, i.e. the degree of hydrogen bonding between water and the solutes is too high for the interaction between the solutes to be investigated.

It proved possible to demonstrate by infrared spectroscopy the formation of hydrogen bonds between the complementary bases of nucleic acids, initially in the solid phase for mixed crystals of the bases. A new absorption band at 1710 cm^{-1} was observed in the infrared spectrum of a mixed crystal of adenosine and uridine and a 1720 cm^{-1} band was found in the spectrum of a mixed crystal of guanosine and cytidine, both being absent from the spectra of the components[41,153]. Miles[154] failed to reproduce these results, but X-ray diffraction confirmed the presence of hydrogen bonds in mixed A–U and G–C crystals[155–170]. These observations are of fundamental

importance, because they revealed the possibility of determining the ratio of the specific base pairs from infrared spectra.

The study of the hydrogen bonding of nucleic acid bases in a pure form in solution can be conveniently carried out in non-polar solvents such as carbon tetrachloride or weakly polar solvents of the type of chloroform, which form weak hydrogen bonds with the solutes and rule out hydrophobic and electrostatic interactions between the bases and hence the formation of vertical stacks[161-165]. The study of the interaction of the bases in non-aqueous solvents is also important because it may resemble the interaction between the bases within the DNA double helix, where the bases are hardly in contact with water molecules. Such investigations became possible owing to the synthesis of *N*-derivatives of the bases and derivatives substituted in the nucleoside sugar residues, which are soluble in organic media.

Table 9. Vibration frequencies (wave-numbers) of the free NH groups of the bases and the bound NH groups of the homo- and hetero-association complexes.

Compound	$\tilde{\nu}_{NH}$(free), cm^{-1}	$\tilde{\nu}_{NH}$(self-assoc.), cm^{-1}	$\tilde{\nu}_{NH}$(hetero-assoc.), cm^{-1}
Adenine	3530—3527 3415	3485, 3250 3312, 3200	3490 3330
Uracil	3400—3395	3210—3185 3110, 3050	3260 2800
Guanine	3515—3510 3408	3480, 3305 3355	 3490
Cytosine	3531, 3418	3485 3320	3472

The interaction of the bases in solution may be studied on the basis of the infrared spectra in the range 3500 to 2800 cm^{-1}, since the stretching vibration frequencies of the NH_2 and NH groups decrease on formation of hydrogen bonds. The formation of association complexes of the bases is accompanied by a decrease of the intensity of the bands due to the free bases and the appearance of a series of new bands due to the bound NH and NH_2 groups (Table 9). Self-association of the bases in fairly concentrated (10^{-2} M) solutions and association in mixed dilute (10^{-4} M) solutions of the complementary bases of nucleic acids was observed from these spectroscopic changes[161-166] (Fig. 13). Infrared spectroscopy has provided direct proof of homo- and hetero-association of purines and pyrimidines via hydrogen bonding. It also revealed the specificity of this interaction, since, among all possible combinations of the four bases, the G–C and A–U (A–T) combinations proved to be the most stable, the G–C complex being more stable than the A–U complex, probably owing to the formation of three hydrogen bonds. These results have been fully confirmed by studies on the association of the bases and nucleosides by the NMR method[168,169].

In a number of studies[163,170-173] on the concentration variation of the intensity of the NH bands of the monomers, self-association and heteroassociation complexes were obtained for different bases (Table 10). The results of different workers for association in chloroform are satisfactorily consistent with one another and the high values of the constants obtained by Küchler and Derkosch[163] are probably due to the use of carbon tetrachloride as a solvent (see also Drozdova et al.[172]). The values of the constants confirm that the association of adenine with uracil and particularly of guanine with cytosine is much stronger than the self-association of these bases.

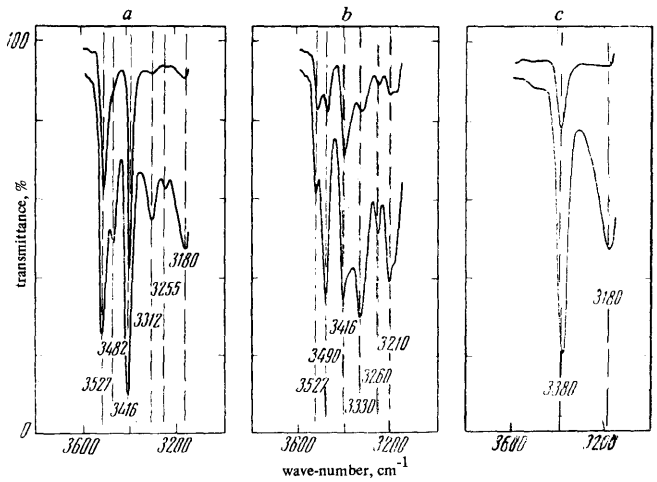

Figure 13. Infrared spectra of solutions in $CDCl_3$: *a*) 9-ethyladenine; *b*) 5-bromouracil; *c*) 1 : 1 mixture of 9-ethyladenine and 5-bromouracil; upper curves—0.019 M; lower curves—0.077 M.

The thermodynamic parameters of the association of the bases in different solvents were calculated from the temperature variation of the association constants. These data are presented in Table 10, which shows that the heats of formation of the association complexes are higher by a factor of 2–3 than the heat of formation of a hydrogen bond of the type H...O–C,[174] which may be due to the cyclic structure of these complexes.

The calculations of the association constants in all the studies mentioned above were made on the hypothesis of dimeric association of the bases, which is supported by the finding that the intensity of the absorption at all the bands of the heteroassociation complexes for a constant overall concentration of the components but with a variable ratio of the latter has a maximum corresponding to a 1 : 1 concentration ratio[161-164,167,170] (Fig. 14). This has been demonstrated[163] by determining the degree of association *n* from the variation of the concentration of the association complex with that of the monomer. For the association of adenine with uracil in their equimolar mixture and for the self-association of adenine and uracil, $n = 2$ was obtained in all cases. The infrared spectroscopic data have also been confirmed by the cryoscopic method.

Another argument in favour of the dimerisation of the bases is the constancy of the ratio of the intensities corresponding to the free NH and NH_2 groups of uracil and adenine in their mixture with variable concentrations of the components[164]. The heats of formation of the dimers, which are 4–6 kcal $mole^{-1}$, indicate the possibility of a cyclic structure maintained by two hydrogen bonds. X-Ray diffraction showed that in the crystalline state the A–U and G–C dimers have a cyclic structure[155,158].

The majority of the investigators of the specific pairing of nucleic acid bases suggest that one of the several

possible cyclic structures of the dimers predominates in solution, although so far no-one has succeeded in establishing the structure which actually exists. However, the formation of dimers of only one kind has been questioned[172] on the basis of the following facts. Firstly, on dimerisation of the bases a larger number of new bands appear in the infrared spectra than might have been expected for dimers of only one type. Secondly, calculation of the association constants based on the bands of the monomers and dimers leads to different results. The authors of this study believe that the results can be accounted for either by the formation of dimers of different kinds or of trimers of the type A + 2U. The possibility of the formation of trimers in solutions of adenine and a mixture of adenine and uracil is also indicated by NMR data[168,176].

Table 10. Association constants of different bases.

Association complex	Solvent	Association constant, litre mole^{-1}	Temp., °C	ΔH, kcal mole^{-1}	Ref.
A-A	$CHCl_3$	13±2	25	1.3±0.1	173
	$CDCl_3$	3.1±0.3	25	4.0±0.8	170
	CCl_4	83±7	20		163
U-U	$CHCl_3$	11.6±2.0	25		172
	$CHCl_3$	19±4	25	2.0	173

The study of the effect of various substituents (CH_3, SH, Br, and I) on the degree of association of uracil with adenine reveals that substituents which decrease pK_{ass} for uracil or increase electron density in the N(7)-position of adenine also increase their capacity for association. Thus, complexes of 2,6-diaminopurine with uracil and of 5-bromouracil with adenine are the most stable. On the other hand, substitution of the hydrogen atoms in the amino-group of adenine lowers its association constant, for example 6-dimethylaminopurine is completely incapable of association[175].

Miles and coworkers[47-49,52,99] used the infrared spectroscopic method to investigate various structural complexes of synthetic polynucleotides in solution. Polycytidylic (or poly-5-bromocytidylic) and polyinosinic acids are known to interact in solution, forming helices with a structure resembling that of DNA, and polyuridylic and polyadenylic acids form a double or triple helix depending on the experimental conditions[6,45,177-181]. The formation of helical complexes in the interaction between polynucleotides is accompanied by considerable and characteristic changes in the infrared spectra owing to the formation of hydrogen bonds and the change in the chemical environment of the bases (Fig. 15). The bands due to the vibrations of the carbonyl groups are then displaced towards higher frequencies, as for DNA. When the double helix of poly-(A/U) is formed, the infrared spectrum of the complex reveals a shift of the carbonyl band from 1660 to 1672 cm^{-1}.[49,99,154] The spectrum of a solution of the helical poly-(I/2C) complex reveals a shift of the absorption band of polyinosinic acid from 1678 to 1697 cm^{-1} and a decrease of the intensity of the 1651 cm^{-1} band of polycytidylic acid[47,49,50,154]. The 1710 cm^{-1} band, which is characteristic of the secondary structure of double helices, appears in the spectrum of the double-helical polyadenylic acid. A similar increase of the vibration frequency of the carbonyl group of guanine (the wave-number increases from 1666 to 1680 cm^{-1}) occurs on formation of the spirals of 3'- and 5'-guanylic acids.

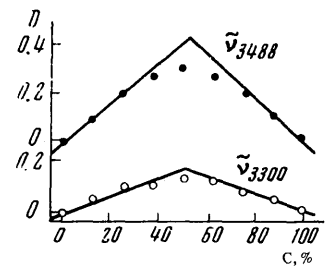

Figure 14. Variation of the optical densities of the 3300 and 3488 cm^{-1} bands of the association complexes with the percentage content of cytosine in a mixture of guanine and cytosine derivatives (overall concentration 1.6×10^{-3} M)[162].

Guanylic acid is known to be capable of forming helical macromolecular complexes which are stable at reduced temperatures[182]. The melting of these helical aggregates has been investigated[48] in the temperature range 10 to 60°C by measuring the intensities of the carbonyl bands.

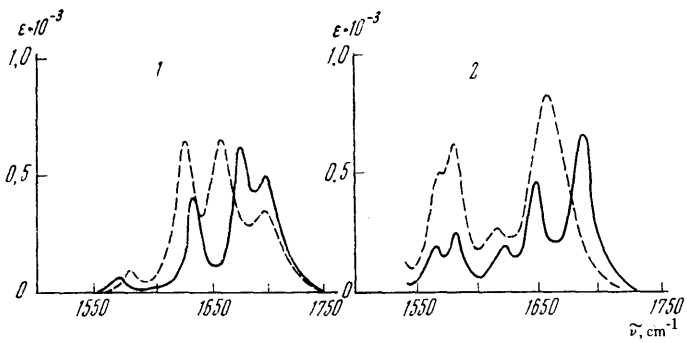

Figure 15. Infrared spectra of D_2O solutions (pD 7.0) of complexes: 1) poly-(A/U); 2) poly(G/C); dashed curves—sum of the spectra of the corresponding mononucleotides[102].

The formation of a helical secondary structure has been observed on the basis of infrared spectra not only in the interaction between complementary polynucleotides but also in the interaction of mono- and oligo-nucleotides with a polynucleotide, for example of guanosine 5'-phosphate or the trimer of guanosine phosphate with polycytidylic acid, of adenosine with poly-(U/C), etc.[51,52] The infrared spectra of these complexes also differ from the sum of the

spectra of the components. However, the complexes are stable only below 40°C (m.p. about 40°C). The parallel variation of the melting curves for the characteristic frequencies of the purine and pyrimidine bases is evidence of the specificity of the pairing of the bases in the complexes of polynucleotides with mono- and oligo-nucleotides.

A number of studies on complexes of nucleic acids and their components with metal ions by different procedures, including the infrared spectroscopic method, have been published recently [183-192]. The physicochemical properties of nucleic acids (intrinsic viscosity, sedimentation rate, and melting point) are known to alter under the influence of metal ions or the acids undergo degradation.

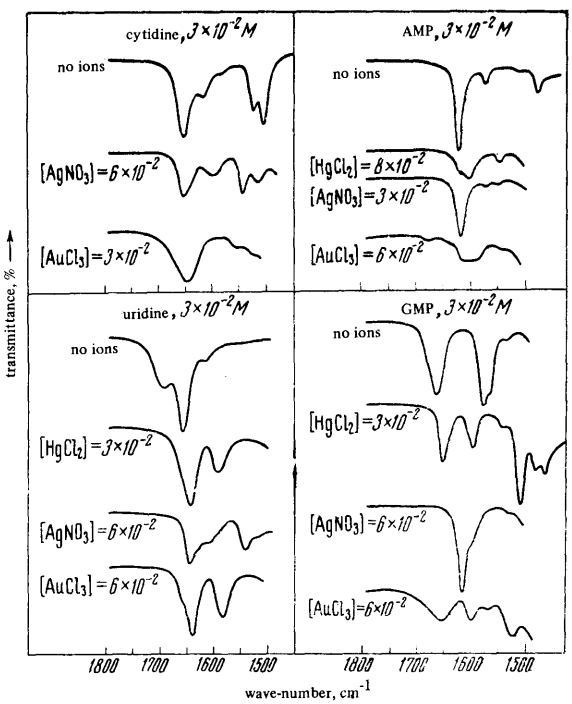

Figure 16. Infrared spectra of D_2O solutions of cytidine, uridine, GMP, and AMP (3×10^{-2} M) in the absence and presence of metal ions [198].

For example, alkali metal, alkaline earth metal, and transition metal ions increase the melting point of DNA and Cu^{2+}, Cd^{2+}, Ag^{2+}, and Fe^{3+} ions reduce it [193,194].

Metal ions can interact with the phosphate groups of nucleic acids (an ion–ion type of interaction) or with the dipoles of the rings of the bases (ion–dipole type of interaction). Therefore in a study of metal complexes of nucleic acids it is important to discover the site of binding of the ion. It has been shown by conductimetric titration that metal ions stabilising the DNA structure combine with its phosphate groups [195,196], while ESR, [197] NMR, [198] and spectrophotometric measurements [193,199-201] showed that destabilising ions (Cu^{2+}, Cd^{2+}, Pb^{2+}, Ag^{+}, and Hg^{2+}) are bound to the DNA bases at the sites of formation of hydrogen bonds. In agreement with these data, it has been observed that Na^{+}, Ca^{2+}, Mg^{2+}, Zn^{2+}, Fe^{2+}, Co^{2+}, and Ni^{2+} do not cause a displacement of the bands in the infrared absorption spectra of nucleic acid bases, while Ag^{+}, Hg^{2+}, and Au^{3+} ions do give rise to a displacement of this kind [202-204]. Shifts of the phosphate bands but not of the bands due to the bases have been observed in the infrared spectrum of a DNA–Fe^{2+} complex [203,204]. Hg^{2+} and Ag^{+} ions lead to considerable shifts of the bands in the region 1800–1500 cm^{-1} in the infrared spectra of all the nucleic acid bases for a metal : base ratio of 2 : 1 (Fig. 16). [202] In the region of the double bond vibrations of the bases, the spectrum of the DNA–Hg^{2+} complex is also appreciably different from that of DNA, which is evidence of the addition of mercury ions to the bases in the macromolecules [202,205,206].

The infrared spectroscopic data concerning the interaction of copper ions with nucleic acid bases are extremely contradictory: some investigators [207] have observed band shifts in the spectra of certain bases in the presence of Cu^{2+} ions, while others [202] failed to observe such shifts. Indeed, Drozdova-Tikhomirova and Kikoina showed [208] that, in the absorption spectrum of solid guanosine and its solution in dimethyl sulphoxide (DMSO) with added copper, the positions of the maxima in the region 1700–1600 cm^{-1} remain unchanged. Changes in the intensities of the carbonyl, amino-group, and double bond bands have been observed in the spectrum of solid guanosine in the presence of Cu^{2+} ions, the changes reaching a maximum for an equimolar ratio of the Cu^{2+} and guanosine concentrations, which is evidence of the formation of a 1 : 1 complex. The existence of a complex in a guanosine solution in DMSO was demonstrated with the aid of a differential spectrum in which analogous changes were observed. The authors postulate that the formation of the G.Cu^{2+} complex is associated with the shift of the tautomeric equilibrium of guanine towards its enolic form, and that this shift may be the reason for the lowering of the melting point of DNA. Uranyl ions form an insoluble complex with DNA, the stoichiometry of which depends on the pH of the medium and the concentration of the ions. Uranyl ions combine with the phosphate groups of DNA, since the spectrum of its complex shows a displacement of the phosphate absorption bands [107]. Thus infrared spectroscopy may be useful for the determination of the location of metal ions in their complexes with nucleic acids.

The interaction of DNA with various compounds, which are of interest from the standpoint of biochemistry or the protection of DNA molecules from various effects, can also be investigated by infrared spectroscopy. One of such compounds is myoinositol, which prevents the destruction of bacterial cells on dehydration and protects them when they are irradiated with ultraviolet light. A considerable increase of the sensitivity of micro-organisms to irradiation and dehydration occurs in the range of relative moisture content between 75 and 50%, i.e. in the region where the packing of the bases in the DNA helix becomes disorganised [209-213]. Preliminary physicochemical studies led to the hypothesis that compounds similar to inositol play the role of combined water on partial dehydration or irradiation of the cells and their components [214,215]. A study of the variation of the polarisation of the infrared spectrum of DNA yielded a direct proof of this hypothesis [206]. As stated above, a decrease of the relative moisture content of DNA films from 75 to 30% is accompanied by a considerable decrease of the dichroic ratio for the 1670 cm^{-1} band. Inositol keeps R_{1670} constant when the DNA film is dehydrated in the relative moisture content range 84–10%. These results may mean that myoinositol replaces the water molecules in the DNA

structure when it is dehydrated and thus stabilises its helical configuration[216]. Unfortunately so far this is the only study of this kind. Nevertheless infrared spectroscopy may prove very promising in the study of the interaction of nucleic acids with agents protecting against radiation, mutagenic and carcinogenic agents, and other biologically active substances.

Measurement of the intensity of the infrared bands of DNA and its components is extremely important in the study of the damage of DNA and various interactions, which has been convincingly demonstrated in the investigation of the specific interactions of DNA bases in solution, discussed in this Section.

In addition, using the area of the absorption bands as a measure of intensity (after Ramsay)[218], Miles[217] showed that the integral intensity of the bands in the range 1700 to 1600 cm^{-1} in the spectra of D_2O solutions of certain nucleotides and polynucleotides is proportional to their concentration. Thus Miles succeeded in demonstrating quantitatively that, when solutions of polyadenylic and polyuridylic acids are mixed, an appreciable deviation from the additivity of the band intensities is observed in the above range as a result of the formation of hydrogen bonds, while for a mixture of mononucleotides additivity is found to hold.

Measurements of the intensity of the absorption bands for DNA solutions and nucleotides apparently make it possible to follow the changes in the structure of the bases in shifts of the tautomeric equilibrium or under the influence of various factors.

Spin-Spin Coupling between Geminal and Vicinal Protons

V.F.Bystrov

The geminal (HCH) and vicinal (HCCH) proton spin-spin coupling constants are of fundamental importance in the applications of nuclear magnetic resonance (NMR) spectroscopy in structural and conformational analysis, since they are extremely sensitive to fine details of steric and electronic molecular structure. The nature of the dependence of the constants on individual structural factors (bond length, valence and dihedral angles, electronic structure of the substituents and their orientation, etc.) has been examined in detail. At present *a priori* theoretical calculations do not allow an exact description of these relations and therefore a semiempirical approach, based on general qualitative relations found by quantum-mechanical calculations, is very promising.
The bibliography includes 293 references.

III. The vicinal constant $^3J_{HH}$ 290

I. INTRODUCTION

Spin–spin coupling between protons observed in the NMR spectra of liquids and gases has been attracting attention for many reasons. From the theoretical standpoint, this is one of the simplest cases of the transfer of nuclear spin polarisation via the electron cloud, which depends in the most critical way on the electronic structure of the molecule. From the practical standpoint, the H–H constants in fact constitute the basis of the study of molecular structure, conformation, and configuration—one of the most important applications of NMR spectroscopy in chemistry. Moreover, H–H constants (J_{HH}) are important for structural analysis and the study of the electronic structure of molecules and kinetic processes, such as internal rotation, inversion transitions, and hydrogen exchange [1].

In the present review attention has been concentrated on the relation between the H–H constants and the steric and electronic structures of molecules. On the basis of the extensive data which have accumulated, a number of correlations have been obtained, in particular with the relative steric positions of hydrogen atoms. Some of these relations have found wide application in the solution of chemical structural problems, while others are not so well known. Many of the correlations have a firm theoretical basis. In order to employ such correlations, it is important to bear in mind the limits of their applicability and also the deviations caused by certain structural factors. One must also emphasise that the ranges of the possible values of the H–H constants for the fundamental structural fragments overlap significantly:

		+280 HZ
^1J	H—H	(Carr and Purcell) (Ref.2)*
^2J	H—C—H	from −22 to +40 Hz
^3J	H—C—C—H	from 0 to +19 Hz
^4J	H—C—C—C—H	from −2 to +18 Hz

* The sign of the constant was established for HD molecules by the molecular beam method [3].

This makes it necessary to analyse thoroughly the causes of the variation of the constants by both theoretical and empirical procedures.

Spin–spin coupling in molecules with saturated valences is due to slight unpairing of the electron pair spins (i.e. a contribution by excited electronic structures), induced by the magnetic moment of the nucleus. It has been reliably established [4-6] that the principal mechanism (which can actually be said to be dominant) of the transfer of interaction between protons is Fermi contact interaction. The extent of this interaction is proportional, to a first approximation, to the probability $S(0)$ that the orbital electrons are located at the sites of the protons A and B (Fig. 1):

$$J \propto S_A^2(0) S_B^2(0).$$

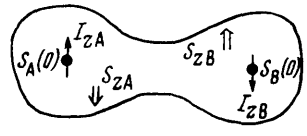

Figure 1. Schematic representation of the electronic properties of the spin–spin contact interaction between protons. I_{zA} and I_{zB} are the spin moments of electrons.

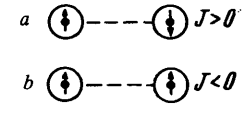

Figure 2. Illustration of the physical significance of the sign of the spin–spin coupling constant.

The sign of the coupling constant, which characterises the relative distribution of the spin energy levels of the nuclear system, is a characteristic no less important than J itself. If the lowest level corresponds to a state with an antiparallel arrangement of nuclear spins (Fig. 2*a*), a positive sign is attributed to the constant, a negative sign corresponding to a parallel arrangement (Fig. 2*b*).

The signs of the coupling constants are established by special methods. The absolute signs are determined from spectra in nematic solvents [7,8], from the changes in splitting in a strong electrostatic field [8], and from the relaxation parameters of multispin systems [9]. The relative signs of the constants are determined by double resonance methods [10], by analysing spectra with strong interaction [11], and from the positions of the signals due to two-quantum transitions [12].

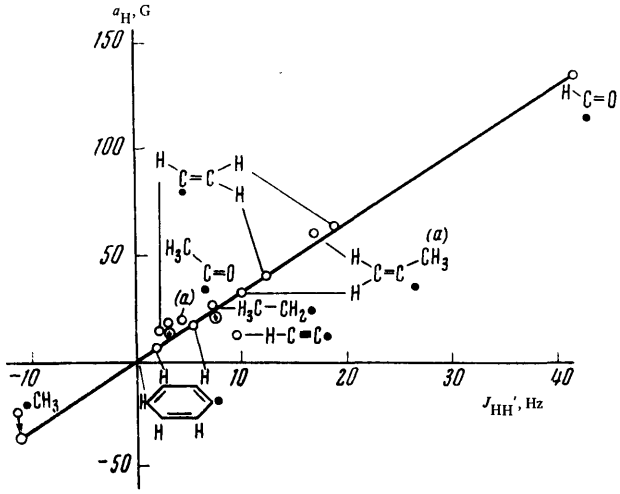

Figure 3. Relation between the spin–spin proton coupling constant $J_{HH'}$ (NMR) and hyperfine coupling constant a_H (ESR). The values of a_H for the radicals $\dot{C}H_3$, $\dot{C}H_2CH_3$, and $\dot{C}OCH_3$ have been corrected for the structure factor; the corrected values are designated by an arrow [15].

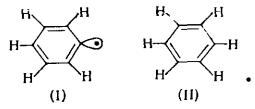
The problem of the relations governing the transfer of unpaired-electron density is of considerable interest for theoretical chemistry. Together with the widely familiar delocalisation over a system of conjugated bonds, the methods of magnetic microwave spectroscopy made it possible to investigate finer details of the perturbing influence of the unpaired electron, largely localised at a single atom. The delocalisation of spin density caused by such perturbation may be reflected in various molecular parameters—such as the spin–spin coupling constant J in molecules with saturated valences and the contact chemical shift in the NMR spectra of paramagnetic complexes as well as the isotropic hyperfine coupling constant (a) in electron spin resonance spectra. The most typical example demonstrating the general properties of delocalisation is provided by a comparison of the constants a for free radicals with a localised valence [for example the phenyl radical (I)] and the constants J_{HH} of the corresponding molecules [benzene (II)] in which the free valence is saturated by a hydrogen atom (H) [13–17].



(I) (II)

The linear relation obtained (Fig. 3) [15],

$$J_{HH'} \simeq 0{,}3\,a_H,$$

where J_{HH} and a_H are expressed in Hertz and Oersted units respectively, shows that the non-compensated electron density at the σ orbital of the carbon atom, induced by the magnetic moment of the H′ proton, plays a fundamental role in the spin–spin interaction. Therefore the perturbing effects in the molecule and the free radical obey the same relation. Recent theoretical calculations [17] by the valence bond method confirmed the existence of a linear relation:

$$J_{HH'} = 4.1\,a_H/\Delta E,$$

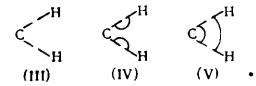
where ΔE is the average energy of the perturbed state in electron-volts. With the usually adopted value ΔE = 10 eV, the proportionality coefficient (0.41) agrees satisfactorily with the empirical value. A linear relation has also been found between the J_{HH} constants and contact chemical shifts [15]. Thus the data obtained by different methods for similar systems with identical structures can significantly complement one another. For example, the sign of a_H may be established from that of J_{HH} or from the sign of the contact chemical shift.

We shall now pass to a discussion of the dependence of the H–H interaction constants for HCH and HCCH structural fragments in organic compounds on various factors associated with steric and electronic structures.

II. THE GEMINAL CONSTANT $^2J_{HH}$

The simplest fragment (apart from the hydrogen molecule) is H–C–H, where the hydrogen atoms occupy *gem*-positions (with the geminal constant $^2J_{HH}$). As already mentioned, the values of ^2J are in the range between −22 and +40 Hz, i.e. not only their magnitude but also their sign can vary.

In the calculation of ^2J by the valence bond method, the geminal fragment is regarded as a four-electron system (III), consisting of two 1s orbitals of the hydrogen atoms and two hybridised sp orbitals of carbon [18,19]. The ground electronic state (IV) corresponds to complete pairing of bond electrons. Since there is then no interaction between the electron pairs, no spin–spin coupling between protons is shown. For H–H interactions to occur, it is necessary to mix the ground state (IV) with an excited state (V).



(III) (IV) (V)

The degree of such mixing is determined by the energy difference between the ground and excited states, which is as a rule estimated very approximately. In terms of the mean excitation energy approximation, it has been found [18,19] that

$$^2J \propto \frac{K(HH') + K(\sigma\sigma') - 2K(\sigma H')}{K(\sigma H)}, \qquad (1)$$

where K are exchange integrals between the corresponding atomic orbitals (Fig. 4). The values of these integrals are difficult to estimate quantitatively. One can only assume with a degree of certainty [20] that $K(\sigma H) < 0$, $K(HH'') < 0$, and $K(\sigma\sigma') > 0$. It then follows from Eqn. (1) that the contribution by the $K(HH')$ integral to ^2J is positive and that of $K(\sigma\sigma')$ is negative. However, calculations show that the absolute values of $K(HH')$ and $K(\sigma\sigma')$ are approximately the same and cancel out. $K(\sigma H')$ is even more

difficult to calculate. Its sign may be both positive or negative. In the first case $^2J < 0$ and in the second $^2J > 0$. The error in the estimation of the integrals (about ±10%) can lead to discrepancies between the values of $^2J_{HH}$ up to ±6 Hz.[6]

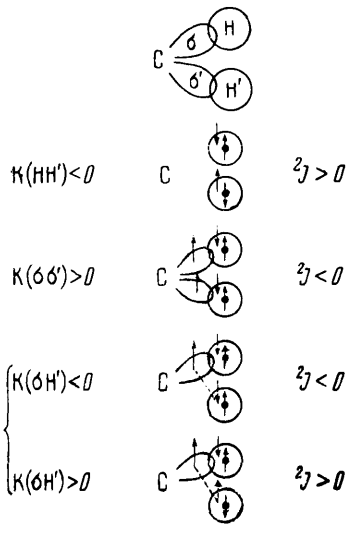


Figure 4. The H–H geminal constant within the framework of the valence bond method and a schematic representation of exchange integrals. In this and other figures the arrows denote energetically favourable relative orientations of the spin moments of protons and orbital electrons.

Numerical calculations by both the valence bond method[20-23] and by the molecular orbital method[24-36] in different modifications show significant discrepancies with experimental data (Table 1)†. This applies not only to the absolute values but even to the sign. Therefore analysis of the empirical relations becomes important. The theoretical justification and prediction of the relation between ^2J and molecular structure probably should not be based on the calculation of the overall values of the constants but should consist in isolating the additional contributions due to specific structural factors.

Significant advances on these lines have been achieved by the molecular orbital method taking into account the excitation energies of the triplet states[20,36,39,40]. For a qualitative examination[39] of an isolated four-electron CH_2 fragment, one may restrict the treatment to four molecular orbitals ψ_i (Fig. 5) constructed by a linear combination of the atomic orbitals φ_k:

$$\psi_i = \sum_k c_{ik}\varphi_k.$$

Table 1. Theoretical calculations of the $^2J_{HH}$ geminal constant (Hz) by the valence bond method (VB), the molecular orbital method without allowance for overlapping (MO), with allowance for overlapping (MO–O), with allowance for delocalisation (MO–D), by the self-consistent field method with complete and partial neglect of differential overlapping (CNDO and INDO), and the complete self-consistent field method (SCF).

Compound	Experiment	VB (Ref.20)	MO (Ref.25)	MO–O (Ref.26)	MO–D (Ref.27)	CNDO (Ref.27)	INDO (Refs.28 & 36)	SCF (Ref.32)
CH_4	−12.4[37]	+12.5	+20.7	−16.5	−2.1	+1.17	−6.13	−7.0
$CH_2=CH_2$	+2.5[38]	+3.05	+32.5	−15.2	+1.5	+8.48	+3.24	+9.6

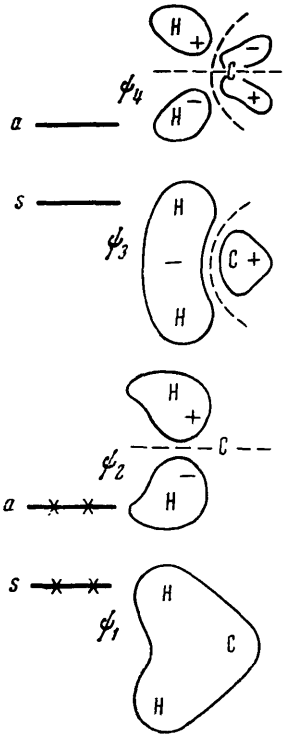

Figure 5. Molecular orbitals of the CH_2 fragment.

Two of the molecular orbitals are bonding and populated (ψ_1 and ψ_2) and two are non-bonding and unpopulated (ψ_3 and ψ_4). These orbitals are delocalised over both C–H bonds and can be divided into symmetrical (s) and antisymmetric (a) orbitals in relation to the plane bisecting

†The geminal constant $^2J_{HH}$ for the magnetically equivalent CH_3 protons is found from the $^2J_{HD}$ constant for the CHD fragment in the spectra of the corresponding deuterated compounds[37]: $^2J_{HH} = (\gamma_H/\gamma_D)\ ^2J_{HD} = 6.5144\ ^2J_{HD}$, where γ_H and γ_D are the gyromagnetic ratios for the proton and deuteron respectively. $^2J_{HH}$ for CH_2CH fragments with magnetically equivalent CH_2 protons may be determined from the satellite spectra due to ^{13}C.[38]

the H–C–H angle. The symmetrical bonding orbital ψ_1 includes the 2*s* orbital of the carbon atom and therefore has a lower energy than ψ_2 which includes the 2*p* carbon orbital. The proton spin–spin interaction constant is expressed as follows in perturbation theory:

$$^2J_{HH'} \propto S_H^2(0)\, S_{H'}^2(0)\, \pi_{HH'}, \quad (2)$$

$$\pi_{HH'} = -4 \sum_k \sum_l (E_l - E_k)^{-1} c_{kH} c_{kH'} c_{lH} c_{lH'}, \quad (3)$$

where $S_H(0)$ and $S'_H(0)$ are the densities of the 1*s* atomic orbitals at the H and H′ protons, $\pi_{HH'}$ is the mutual polarisibility coefficient of the hydrogen 1*s* orbitals of H and H′, the index *k* corresponds to populated states and *l* to unpopulated states.

Table 2.

Transition	Sign of contribution to $^2J_{HH}$
$\psi_1 \rightarrow \psi$	−
$\psi_1 \rightarrow \psi$	+
$\psi_2 \rightarrow \psi_3$	+
$\psi_2 \rightarrow \psi_4$	−

The $\psi_k \rightarrow \psi_l$ electronic transitions make contributions of different signs (Table 2), which are determined by the coefficients c_{kH}, $c_{kH'}$, c_{lH}, and $c_{lH'}$. The effect of different factors on $^2J_{HH}$ is treated as a change in the relative contribution caused by a given electronic transition, taking into account the energy difference of the transition $(E_l - E_k)^{-1}$. A number of qualitative conclusions based on this theory[39] and the results of calculations by the INDO method[36] will be discussed below.

One can regard it as established that the H–H geminal constant for the H_2C–X–Y system depends on the following fundamental factors[6,41–45]: (1) hybridisation of the carbon atom; (2) electronegativity of the substituent X; (3) the presence of a π-electron system at the atom X; (4) the presence of a lone electron pair at the atom X; (5) the nature of the β-substituent Y; (6) the nature of the solvent‡. These factors will be considered separately.

1. Hybridisation of the Carbon Atom

Experimental data for hydrocarbons show that, as the contribution by the *p* orbital of the carbon atom diminishes, $^2J_{HH}$ increases (Table 3).

A more detailed relation can be more conveniently derived[43] on the basis of the valence angle α as the parameter determining the hybridisation of carbon (Fig. 6). The relation is of course significant only for systems where the effect of the other factors mentioned above is fairly weak§. However, as a rule such "pure" systems are encountered rarely and therefore in the general case the determination of valence angles from the constant $^2J_{HH}$ is invalid. It is remarkable that the first calculation of $^2J_{HH}$ by the valence bond method[18,19] predicted an approximately the same relation but with the opposite sign of the constant (Table 1). Recent calculations by the molecular orbital method[26,36] yielded the correct sign of $^2J_{HH}$ and the correct overall relation with the valence angle, but for specific molecules (ethylene, cyclopropane, cyclohexane, and methane) there was no agreement with experiment (Table 1).

Table 3.

Molecule	CH_4		$H_2C{=}CH_2$
Hybridisation	sp^3	$sp^{2,3}$	sp^2
HCH angle	109°	116°	120°
^2J, Hz	−12.4[37]	−4.31[55]	+2.5[38]

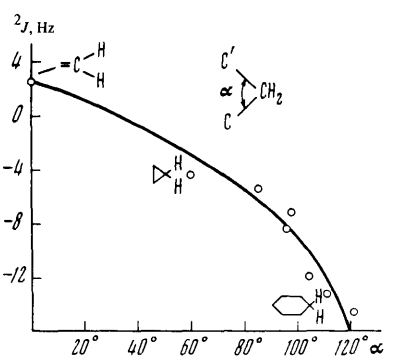

Figure 6. Variation of the H–H geminal constants with the C–CH_2–C valence angle for hydrocarbons[43].

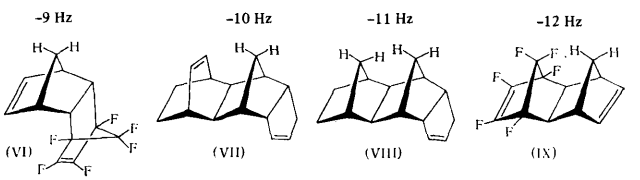
One of the features of the relation between $^2J_{HH}$ and the H–C–H angle is the effect of the steric factor. For example, the constant for the bridge protons in the bicyclo[2,2,1]heptane system decreases with increasing degree of steric hindrance in the series (VI)–(IX).[57–59] We may suppose that the H–C–H angle decreases in the same series.



‡A change in temperature is reflected in a redistribution of the populations of the torsional vibrational levels of the HCH fragment, which should lead to a change of the H–H geminal constant. Experimental data[46–54] and theoretical calculations[46,47,49,50] show that, with increase of temperature, the absolute value of $^2J_{HH}$ increases only slightly (the relative change is about 3×10^{-4} per degree).

§The lack of the $^2J_{HH}$ constants for cyclobutane makes it difficult to decide whether four-membered rings obey this relation. For cyclobutane derivatives, values of ^2J ranging from −11.0 to −14.0 Hz have been observed[43,45,56].

2. Effect of the α-Substituent

In the presence of a substituent X at the carbon atom ($X-CH_2$), one can postulate intuitively that, since the electron-accepting inductive effect of X leads to a decrease of electron density at H atoms, the absolute value of $^2J_{HH}$ should diminish. Such a relation is in fact observed experimentally (Table 4).

Table 4. Variation of $^2J_{HH}$ with the electronegativity of the α-substituent.

Compound	$^2J_{HH}$, Hz	X	$^2J_{HH}$, Hz
$(CH_3)_4C$	−14.1[60]	CH_2	−4.31[55]
CH_4	−12.4[37]	S	−1.4[62]
$(CH_3)_3N$	−11.7[44]	NCH_3	+1.0[63, 64]
CH_3OH	−10.8[61]	O	+5.4[65]
CH_3F	−9.6[61]	N^+	+5[66]

A qualitative explanation of the effects of electronegative α-substituents on $^2J_{HH}$, based on the molecular orbital method[39], involves an inductive withdrawal of electrons from the symmetrical orbital ψ_1 (Fig. 5). As a result, the orbital becomes less "hydrogen-like" and the coefficients c_1H and c_1H' in Eqn. (3) diminish. Since the molecular orbitals are made up of a complete orthogonal set of atomic orbitals, the other symmetrical orbital ψ_3 becomes more "hydrogen-like" and the coefficients c_3H and c_3H' increase. In view of the fact that the antisymmetric orbitals do not change under the influence of the inductive effect of the substituent, the product of the coefficients in Eqn. (3) for the $\psi_1 \rightarrow \psi_4$ transition will be more negative and for the $\psi_2 \rightarrow \psi_3$ transition less negative. Since a lower excitation energy $E_3 - E_2$ corresponds to the latter transition than to the $\psi_1 \rightarrow \psi_4$ transition (Fig. 5), the overall contribution to the change in $^2J_{HH}$ is positive. Thus theoretical considerations are consistent with experimental data (Table 4): electronegative substituents (for example F) in the CH_3X series leads to an increase of $^2J_{HH}$ and electropositive substituents (for example Si) lead to a decrease of the geminal constant relative to methane. Theoretical calculation by the MO–INDO method[36] indicated an increase of $^2J_{HH}$ for CH_3F by 4.28 Hz compared with methane (Table 1).

In the valence bond method, the inductive effect of the substituent on $^2J_{HH}$ is taken into account by including polar structures reflecting the ionic character of the C–X bond[21,22]. These calculations yield an incorrect sign of the geminal H–H constant, but correctly predict a decrease of $|^2J_{HH}|$ with increasing amount of ionic character of the C–X bond.

However, the electronic properties of the substituent X are not restricted to electronegativity. For example, a relation has been derived between $^2J_{HH}$ for compounds of the type $(CH_3)nX$ and the number of the Period of the atom X (Fig. 7), which makes it possible to predict the constant for compounds not hitherto investigated[67].

3. Effect of the π-Electron System of the Substituent X

If the electronic system of X includes a π orbital, an additional contribution to the constant $^2J_{HH}$ for the $X-CH_2$ fragment is generated. In the valence bond method this contribution is proportional to the product of the overlap integrals of the C–H orbitals and the π orbital of the atom X:[19,68]

$$\Delta^2 J^\pi \sim -K(\sigma\pi)\, K(\sigma'\pi).$$

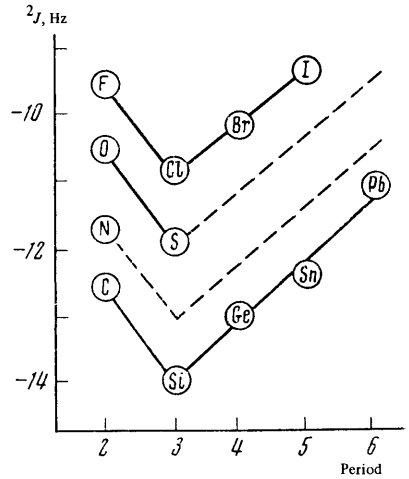


Figure 7. Variation of the H–H geminal constants for compounds of the type $(CH_3)_nX$ with the number of the Period of the atom X.[67]

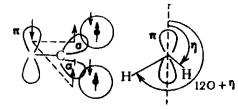
Its negative sign is due to the preferential antiparallel orientation of proton spins when the interaction is transmitted via the π orbital of the atom X (X). Indeed the $^2J_{HH}$ constant for the methyl group decreases in the series CH_4 (−12.4 Hz)[37] > CH_3Ph (−14.6 Hz)[19] > $CH_3C{\equiv}N$ (−16.9 Hz)[19]. In acetonitrile the first atom of the substituent has two π orbitals, which results in a doubling of the contribution $\Delta^2 J^\pi$.



Since the integral $K(\sigma\pi)$ is proportional to $\cos^2\eta$, where η is the dihedral angle between the C–H bond at the direction of the π orbital (XI), it follows that, for molecules with fixed positions of the C–H bonds, the contribution by the π-electron system depends on the angle η:[68]

$$\Delta^2 J^\pi \propto \cos^2\eta \cos^2(120 + \eta).$$

This theoretical relation (Fig. 8) is satisfactorily confirmed by experiment[43,68] (almost quantitatively), which makes it possible to employ it for the determination of molecular structures and conformations.

Qualitative[39] and quantitative[36] treatment by the molecular orbital method leads to similar conclusions concerning the sign of the contribution of the π orbital or the α-substituent to the geminal H–H constant and its dependence on

stereochemical factors. The effect of the π orbital is treated as involving a withdrawal of electron density from the antisymmetric populated orbital ψ_2 of the CH_2 fragment (Fig. 5).

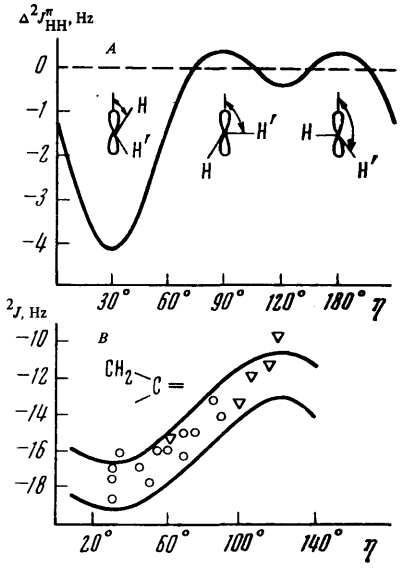


Figure 8. Theoretical [68] (*A*) and experimental (*B*) [43] dependence of the contribution by the π-electron system to the constant $^2J_{HH}$ on the projection angle η.

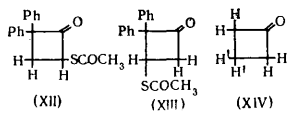
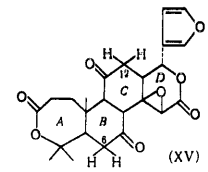
As an example of structural studies, one may quote the determination of the position of the acetylthio-group in a derivative of cyclobutane [69]. For structure (XII), $^2J_{HH}$ should not differ markedly from the usual value for cyclobutanes, i.e. −(12–15) Hz. [42,56] On the basis of the theoretical relation (Fig. 8), −4.2 Hz (η ≃ 30°) should be added for structure (XIII) because of the neighbouring π-electron system of the carbonyl carbon atom: $^2J \simeq -(16–19)$ Hz. Experiment yielded −18.4 Hz, which proved structure (XIII). For unsubstituted cyclobutanone (XIV), it has been found that $^2J_{HH} = -17.5$ Hz and $^2J_{H'H'} = 11.1$ Hz. [70]

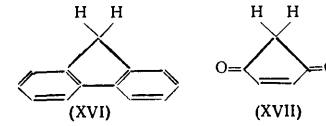


The angular variation of the contribution by the π orbital may be used, for example, to determine the conformation of the cyclohexane ring. In the chain conformation (η ≃ 86°) the geminal constant has the normal value for cyclohexanones (−13 Hz). In the boat conformation (η ≃ 30°), a decrease of the constant by 4–5 Hz is to be expected. For zapoternone (XV) [71], $^2J_{HH} = -13$ Hz for the $C_{(6)}H_2$ methylene group, which indicates a chair conformation of the *B* ring, while −19 Hz was found for the $C_{(12)}H_2$ group, which corresponds to a boat conformation of the *D* ring:



(XV)

The effect of the π-electron system leads to values of $^2J_{HH}$ which constitute the lower limit of the known geminal constants. For fluorene (XVI) [72] and cyclopenta-3,5-dione (XVII) [68], in the molecules of which the methylene group is linked to two carbon atoms involved in a double bond, $^2J_{HH} = -22.3$ and −21.5 Hz were found respectively.



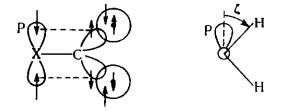
(XVI) (XVII)

These values agree well with $^2J_{HH} \simeq -12.5-4.2-4.2 = -20.9$ Hz calculated for η = 30°.

The lower value of $^2J_{HH}$ for 1,1-dimethylallene (−9.0 Hz) [73] compared with ethylene (+2.5 Hz) [38] can also be attributed to the effect of the additional π orbital of the atom X. For keten $H_2C=C=O$ ($^2J_{HH} = -15.8$ Hz) [73], the effect of the electronegativity of the β-substituent is also important (see Section II, 5).

Effect of the Lane Electron Pair of the Substituent

According to theoretical considerations based on the valence bond [6] and molecular orbital [36,39] methods, the contribution by the lone pair to the geminal constant should be positive [formula (XVIII)] and should depend on the dihedral angle ζ [formula (XIX)] between the C–H bond and the axis of the lone pair. In the qualitative molecular orbital theory [39], this effect is regarded as due to the supply of electron density to the antisymmetric populated orbital ψ_2 (Fig. 5). The effect is opposite in sign to that of the π orbital of the α-substituent.

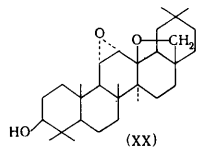


(XVIII) (XIX)

A confirmation of the effect of the lone pair can be found by comparing the $^2J_{HH}$ constants in the series of six- and five-membered heterocyclic compounds (Table 5). Two factors are noteworthy. Firstly, the monotonic increase of $^2J_{HH}$ with increasing electronegativity breaks down at the piperidinium and pyrrolidinium cations. Although the electronegativity of N^+ is higher than that of N, the latter has a lone electron pair, the positive contribution $\Delta^2 J^P$ of which increases $^2J_{HH}$, which leads to the breakdown of the sequence. Secondly, the introduction of the heteroatom has a much greater effect on $^2J_{HH}$ in five-membered rings than in six-membered rings. One must assume that this is due to the difference between the angles ζ in the two types of rings.

Theoretical calculation by the MO–INDO method showed [36] that the geminal constant for methanol depends on the orientation of the O–H bond. However, the numerical result, in particular −2.12 Hz for the average value of

$^2J_{HH}$, differs significantly from the experimental constant (Table 4). The actual variation of the geminal constant for the CH_2 group with the orientation of the lone pairs of α-oxygen can be found from the experimental data taking into account the form of the theoretical curve. Tetrahydropyran ($\zeta \simeq 180°$ and 300°), tetrahydrofuran ($\zeta \simeq 210°$ and 270°), oxetane (−6.02 Hz, [182] $\zeta \simeq 240°$) and a steroid (XX) [45] (−6.0 Hz, [83] $\zeta \simeq 240°$) were chosen (Table 5) as the reference points in the above relation (Fig. 9).



(XX)

Table 5. Values of $^2J_{HH}$ (Hz) for five- and six-membered heterocyclic compounds [43,44,74,75].

X	Y

O	O	−6.18 [79,80]	+0.8 [81]

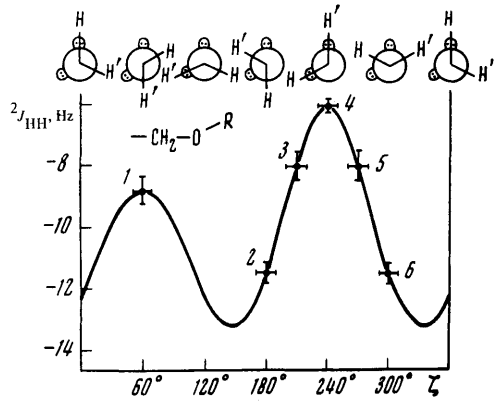

Figure 9. Variation of the H_2C-O geminal constant with the orientation of the orbitals of the lone electron pairs of oxygen: 1) calculated from the average $^2J_{HH}$ for $(CH_3)_2O$ (see text); 2) and 6) tetrahydropyran; 3) and 5) tetrahydrofuran; 4) steroid (XX) and oxetane.

The value for $\zeta \simeq 60°$ was calculated from $^2J_{HH} = -10.6$ Hz for $(CH_3)_2O$, [44] assuming rotational averaging:

$$\langle {}^2J_{HH} \rangle = \frac{1}{3}(J_{60°} + J_{180°} + J_{300°}),$$

where $J_{180°} = J_{300°} = -11.5$ Hz, as for tetrahydropyran.

Fig. 9 shows that the maximum contribution by the lone pair orbitals of α-oxygen is +7.8 Hz when both C−H bonds are eclipsed¶. The minimum value in Fig. 9 (−13.3 Hz) is confirmed indirectly by the minimum recorded value $^2J_{HH} = -14$ Hz for the CH_2-O fragment [45,84].

An empirical analysis of the effect of the orientation of the lone pair on the geminal constant has been carried out for nitrogen-containing cyclic compounds with a fixed conformation [86]. Table 6 lists the values of $^2J_{HH}$ for six-membered rings. Comparison of the geminal constants for five- and six-membered nitrogen-containing rings with known steric structures made it possible to derive a relation between $^2J_{HH}$ and the dihedral angle ζ (Fig. 10).

N (a)	N (a)	−8.5	91

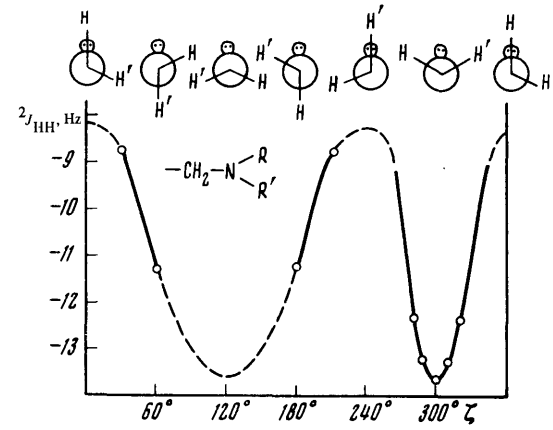

Figure 10. Variation of the H_2C-N geminal constant with the orientation of the lone electron pair of nitrogen in cyclic systems with a fixed conformation [86].

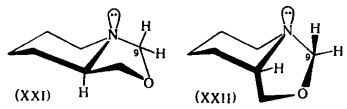
¶Empirical analysis of data for oxygen-containing ring systems showed [84,85] that, when one of the C−H bonds is eclipsed by the lone pair of the α-substituent X, the geminal constant for the H_2C-X fragment increases by 1.8 Hz. Theoretical calculation [40] by the molecular orbital method gave a maximum contribution of +12.6 Hz by the p^π orbital of the lone pair, +5.3 Hz by the sp^2 orbital, and a negative contribution by the σ orbital.

As an example of the use of the lone pair effect in conformational analysis, one may quote the determination of the configuration of the isomers of 1-aza-8-oxabicyclo-[4,3,0]nonane with *trans*- (XXI) and *cis*-junctions (XXII) between the six- and five-membered rings [92]. In the *trans*-isomer the C_9–H bond is virtually eclipsed by the lone pair of electrons of nitrogen ($\zeta \simeq 210°$) and oxygen, while in the *cis*-isomer the projection of the axis of the nitrogen lone pair bisects the H–C_9–H′ angle ($\zeta \simeq 300°$). In the first case there is a possibility of a considerable positive contribution to the H–C_9–H′ geminal constant (Fig. 10). In fact the constant for isomer (XXI) is less negative (−0.8 Hz) than for isomer (XXII): −5.0 Hz.



The effect of the lone pair together with that of the electronegativity of the α-atom explains [36,39] the very high positive values of the H–H geminal constants for formaldehyde O=CH_2 (+42.4 Hz) [93] and *N*-alkylmethyleneimines RN=CH_2 [up to +16.5 Hz, R=$C(CH_3)_3$]. [94,95] The formaldehyde value is the upper limit of the known range of $^2J_{HH}$ constants.

A non-linear relation between $^2J_{HH}$ and the electronegativities of the substituents (E_X and E_Y) was found [103] for compounds of the type H_2C=CXY:

$$^2J_{HH} = \frac{61.6}{E_X + E_Y} - 12.9 . \quad (4)$$

The form of this relation differs significantly from the linear relation proposed previously [99] on the basis of limited data:

$$^2J_{HH} = 8.7 - 2.9(E_X + E_Y). \quad (5)$$

In order to refine the relation between $^2J_{HH}$ and electronegativity, theoretical calculations are probably necessary. Nevertheless, the available data [39,43,44,99,103,104] make it possible to employ the value of $^2J_{HH}$ in order to obtain information about the structure of olefins.

The effect of the β-substituent in saturated fragments depends on its orientation relative to the geminal protons. Theoretical considerations [39] lead to the qualitative conclusion that, when the β-substituent X is within the H–C–H′ geminal angle on the Newman projection (XXIII), the contribution to the $^2J_{HH'}$ constant is positive, but, if the β-substituent is outside this angle, the contribution is negative, i.e. $^2J_{HH'} > {}^2J_{H'H''}$. In contrast to ethylenes, the H–H geminal constants for *endo*-substituted hexachlorobicyclo[2,2,1]heptenes are seen to decrease (Table 8).

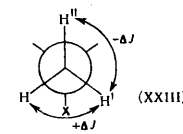
5. Effect of the β-Substituent

The H–H geminal constant is influenced not only by the α-substituent but also by the more remote β-substituent. The general tendency, observed for substituted ethylenes, indicates a decrease of $^2J_{HH}$ with increasing electronegativity of the β-substituent (Table 7). The tendency is opposed to that observed for the effect of the α-substituent, which is consistent with the intuitive hypothesis concerning the influence of the inductive effect. This example clearly illustrates the limitations of such intuitive considerations concerning the influence of the inductive effect in NMR.

In the molecular orbital method [39] the effect of the electronegative β-substituent is treated as a result of the withdrawal of electron density from the antisymmetric bonding orbital ψ_2 of the CH_2 fragment (Fig. 5). In contrast to the effect of the α-substituent, in this case theory predicts a negative contribution to $^2J_{HH}$ with increasing electronegativity.

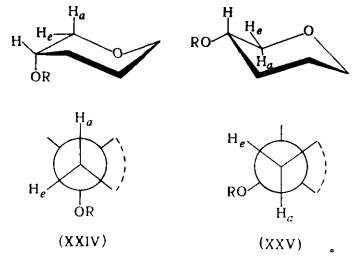
In this case the substituent is at the limit of the H–C–H geminal angle.



(XXIII)

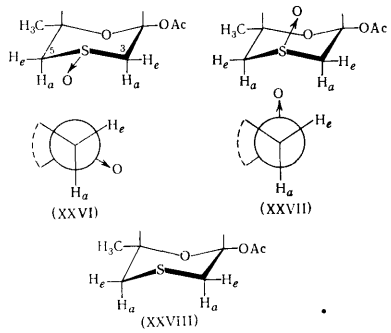
The geminal H–H constants for the inversion conformations of a number of heterocyclic compounds provide an experimental confirmation of the theoretically predicted orientation effect of the substituent. For example, among pentopyranose derivatives [111,112] a lower constant $^2J_{5e,5a}$ = −13.3 Hz is observed for the axial orientation of the substituent C_4OR (XXIV) (the electronegative β-oxygen atom is outside the $H_eC_5H_a$ geminal angle) than for the equatorial orientation (XXV): $^2J_{5e,5a}$ = −11.2 Hz (the oxygen atom is

within the $H_eC_5H_a$ angle). Similarly among 2-deoxy-D-arabohexapyranose derivatives[112], $^2J_{2e,2a} = -13.8$ Hz for the axial C_1–OR orientation is lower than for the equatorial orientation: $^2J_{2e,2a} = -12.4$ Hz.



(XXIV) (XXV)

The orientation effect of the β-atom has been used in the determination of the absolute configuration of the sulphoxide group in derivatives of 1,4-oxathian *s*-oxide[113]. For the equatorial orientation of the oxygen atom in the S → O group (XXVI), the $^2J_{5e,5a}$ and $^2J_{3e,3a}$ constants should be higher than for the axial orientation (XXVII), since in the first case the β-atom is within the H_eCH_a geminal angle. Therefore the isomer with constants of −12.0 and −11.3 Hz can be regarded as having an equatorial S → O bond, while the isomer with constants of −14.2 and −13.8 Hz should have an axial S → O bond. For comparison, we may point out that the corresponding sulphide (XXVIII) has $^2J_{5e,5a} = -13.1$ Hz and $^2J_{3e,3a} = -13.5$ Hz.



(XXVI) (XXVII)

(XXVIII)

After a suitable detailed development, the orientation effect of the β-substituent may find large-scale application in conformational analysis.

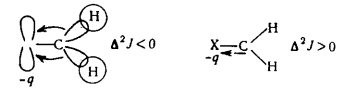
The γ-substituent (the substituent in the 4-position) has been found to influence the coupling constant of the $O-CH_2-O$ *gem*-protons in 1,3-dioxans, the effect depending on the electronic nature and orientation of the substituent[114].

6. Effect of the Medium

Careful investigations[50,51,81,93–95,115–122] showed that the H–H geminal constant clearly depends on the dielectric constant of the medium ϵ (Fig. 11). With increase of the polarity of the medium, the negative contribution to $^2J_{HH}$ also increases, the direction of the effect having an equal influence on positive (formaldehyde[93]) and negative (phenylthi-iran[81]) H–H constants (Fig. 11). The experimental data show that the effect may be used to determine the sign of ^2J: if $^2J > 0$, an increase of ϵ should entail a decrease of the absolute value of the H–H constant; if $^2J < 0$, the constant should increase.

The reason for the variation of $^2J_{HH}$ under the influence of the medium is the effect of the reaction field, induced by the solvent molecules, on the molecular dipole of the test compound[81]. Under the influence of this field, the local dipole moment of the molecule increases in two possible ways.

a. By pseudoconjugation [formula (XXIX)] in which the effect of the lone electron pair of the α-atom diminishes (see Section II, 4), resulting in a positive contribution to $^2J_{HH}$. Consequently when this effect is weakened under the influence of the medium, $^2J_{HH}$ decreases owing to the withdrawal of electrons from the antisymmetric orbital ψ_2 (Fig. 5).



(XXIX) (XXX)

b. By an inductive effect [formula (XXX)] involving the C–X σ bond, which is equivalent to an increase of the electronegativity of X. This should entail a positive contribution to $^2J_{HH}$ in consequence of the withdrawal of electrons from the symmetrical orbital ψ_1 (Fig. 5).

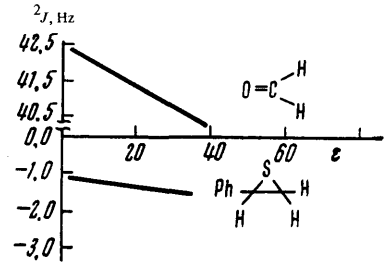


Figure 11. Effects of the polarity of the medium on the H–H geminal constants of formaldehyde[93] and phenylthi-iran[81].

Experimental data have shown that the main contribution comes from pseudoconjugation. Evidently the higher the dipole moment of the molecule, the greater the influence of the solvent. This has been confirmed experimentally: the slope of the plot of $^2J_{HH}$ against ϵ is higher for formaldehyde than for phenylthi-iran (Fig. 11).

7. H–X–H Heteroatomic Fragments

H–H geminal coupling is transmitted not only via the carbon atom but also via any other atom X of the H–X–H fragment (Table 9).

Certain evident analogies with the $^2J_{HCH}$ constant (for example the identity of the sign and the similarity of the magnitudes of the $^2J_{HH}$ constants for CH_4, NH_3, N^+H_4, PH_3, $RCONH_2$, and $CH_2{=}CH_2$) suggest that many relations found for the H–C–H fragment are valid also for H–X–H. The increase of $^2J_{HH}$ in the series $CH_4 < SiH_4 < GeH_4 < SnH_4$ can be explained qualitatively by an increase in the difference between the energies of the bonding and antibonding orbitals of the H–X–H fragment (Fig. 5), as a result of which the positive contribution by the $\psi_2 \rightarrow \psi_3$ transition becomes dominant[134]. The relatively high value of $^3J_{HH}$ for interaction between the bridge and "window" hydrogen

atoms in diborane indicates the presence of a stable three-electron bond[134]. Unfortunately the sign of this constant has not been determined, which makes comparison with theoretical calculations difficult[33].

Table 9. Geminal interactions between the protons of the H–X–H heteroatomic fragments.

There is no doubt that more extensive studies and theoretical calculations of $^2J_{HXH}$ are of considerable importance for the understanding of the nature of geminal coupling.

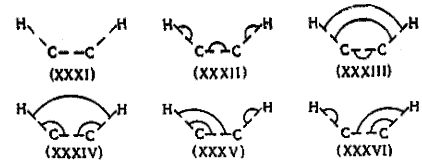
---o0o---

In conclusion of the discussion of the H–H geminal constant, we may note that the constant contains information not only about the electronic structure of the molecule but also about the conformation of adjacent atomic fragments. Although the use of $^2J_{HH}$ for conformational analysis is at present limited by the inadequate knowledge of the orientation effect and the insufficiently clear separation of the contributions by different factors, one can reasonably suppose that these limitations will be overcome by systematic accumulation of experimental data and theoretical calculations. Then NMR spectroscopy will acquire a new parameter for the conformational analysis of molecules.

III. THE VICINAL CONSTANT $^3J_{HH}$

One can claim without exaggeration that spin–spin interaction between the vicinal protons of the H–C–C–H fragment deservedly attracted most attention. The $^3J_{HH}$ constants are widely and very successfully employed in structural analysis (in the determination of the number of adjacent protons and the nature of substitution in molecules), in the study of exchange processes (based on the "obliteration" of the multiplet structure of the spectra), and particularly in configurational and conformational analysis.

Calculation by the valence bond method of the constant for the interaction between vicinal protons in the six-electron system (XXXI) takes into account the mixing with the ground state (XXXII), in which electron pairing is complete, of the four excited states (XXXIII)–(XXXVI).

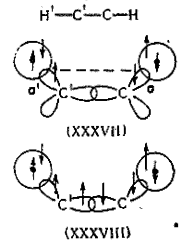


(XXXI) (XXXII) (XXXIII) (XXXIV) (XXXV) (XXXVI)

The electronic mechanism of the vicinal interaction is determined mainly by the polarisation of the "quasi-π" orbitals of the C–H and C–H bonds [(XXXIII) and (XXXVII)], which makes a positive contribution[136]:

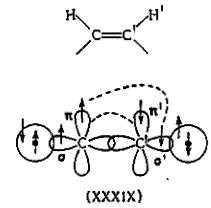
$$^3J \propto 3K(\sigma\sigma')/K(\sigma H)\,, \qquad (6)$$

where $K(\sigma H)$ is an integral with a constant value and $K(\sigma\sigma')$ depends on the relative positions of the σ and σ' orbitals. The mechanism of the consecutive transmission of spin–spin polarisation via the chain of atoms—Hund's mechanism[137] [formula (XXXVIII)]—also makes a positive, but probably very small, contribution.



(XXXVII) (XXXVIII)

Therefore, in contrast to the geminal constant, in the case of the H–H vicinal constant there is no competition between mechanisms with different signs. All the experimental $^3J_{HH}$ values available are positive.



(XXXIX)

If the carbon atoms of the vicinal fragments are separated by a double (or triple) π bond, additional contributions[138] [formula (XXXIX)] to the $^3J_{HH}$ constant are produced and are transmitted via a σ–π interaction mechanism—from the hydrogen atom to the carbon π orbital:

$$\Delta^3J(\sigma\pi) \propto K(\sigma\pi')K(\sigma'\pi)[K(\sigma H) + K(\pi\pi')]\,.$$

This contribution depends on the relative orientations of the C–H bond and the π orbital and is independent of the configurational orientation of the C–H bonds (*cis*- or *trans*-). Comparison of the theoretical relations for the contribution by the σ–π interaction to the vicinal coupling constant and for the hyperfine structure constant in the ESR spectra shows that the contribution by π electrons may be expressed in terms of experimental parameters[138]:

$$\Delta^3J_{HH'}(\sigma\pi) = h a_H(T) a_{H'}(T)/2\Delta E\,,$$

where $a_H(T)$ and $a_{H'}(T)$ are hyperfine coupling constants for the radical fragment H–Ċ=C and ΔE is the average singlet–triplet excitation energy. With $a_H(H{-}C_{sp^2}) = -65 \times 10^6$ Hz and $\Delta E = 6$ eV, +1.5 Hz was found for ethylene, and with $a_H(H{-}C_{sp}) = 95 \times 10^6$ Hz and $\Delta E = 8$ eV, +4.6 Hz was found for acetylene[138].

1. Dependence of $^3J_{HH}$ on the Stereochemical Factor

The $K(\sigma\sigma')$ exchange integral in Eqn. (6) depends on the dihedral angle θ between the H–C–C and C–C–H planes [139]. Hence follows the familiar Karplus relation [136] (Fig. 12), which constitutes the basis of the configurational and conformational analysis in NMR spectroscopy. Since the function $K(\sigma\sigma') = f(\theta)$ does not have an [exact] analytical expression, several versions of an analytical equation have been proposed to describe the variation of $^3J_{HH}$ with the stereochemical factor:

$$^3J_{HH} = k_i \cos^2\theta + C \begin{cases} k_1 & \text{for } 0° < \theta < 90° \\ k_2 & \text{for } 90° < \theta < 180°; \end{cases} \quad (7)\ [136]$$

$$^3J_{HH} = A\cos^2\theta - B\cos\theta + C; \quad (8)\ [6]$$

$$^3J_{HH} = \alpha\cos 2\theta - \beta\cos\theta + \gamma. \quad (9)\ [141]$$

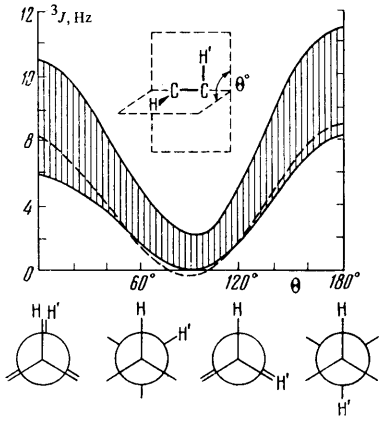


Figure 12. Variation of the vicinal constant $^3J_{HH}$ with the dihedral angle θ for the HC–CH saturated fragment. The dashed curve represents Karplus's theoretical calculation [138,141]. The shaded band corresponds to the most probable values of $^3J_{HH}$. Its upper limit is the curve for ethane [140].

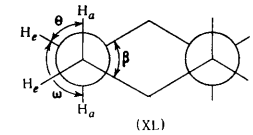
With appropriate values of the constant coefficients (all positive), these equations yield virtually coincident curves, so there is no fundamental difference between them. The choice of the equation is dictated by the suitability of its formulation. Eqns. (7) and (8) are usually employed.

The coefficients of Eqns. (6)–(8) have been evaluated theoretically [6,136,141], but these differ significantly from the experimental values (see Section III, 4). Therefore in the analysis of the conformational states of a particular series of compounds, it is recommended that these coefficients be determined empirically on the basis of models for the given series.

As an example, one may quote the determination of the HCCH dihedral angle in cyclohexane. At –100°C the rate of the "chair–chair" inversion is retarded so much that the individual signals due to the axial and equatorial protons are observed in the NMR spectrum of cyclohexane (5% solution in CS_2). The vicinal constants of these protons have been measured for 1,1′,2,2′,3,3′,4,4′-octadeuterocyclohexane: $^3J_{aa}$ = 13.12 Hz, $^3J_{ae}$ = 3.65 Hz, and $^3J_{ee}$ = 2.96 Hz [formula (XL)]. [76] These data made it possible to determine by Eqn. (8) with $C = 0$ the $H_aC–CH_e$ dihedral angle ($\theta = 57°$) for $\omega = 118°$. The stereochemical relation for cyclohexane then becomes:

$$^3J_{HH} = 12.95\cos^2\theta - 0{,}26\cos\theta.$$

The value of θ obtained agrees extremely well with electron diffraction data for cyclohexane in the gas phase (CC–CC dihedral angle $\beta = 55.9°$). [142]

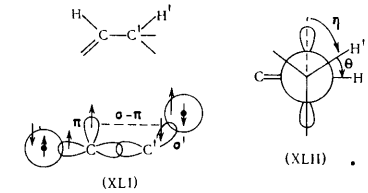


(XL)

When the values of $^3J_{HH}$ and the corresponding angles θ are plotted for compounds of different classes, a fairly broad band is obtained (Fig. 12). The scatter is due to the effect of a number of electronic and geometrical structural properties of the molecules, which are discussed below.

When vicinal protons interact in a system with an allylic double bond =CH–CH, an additional contribution by the interaction of the σ and π orbitals appears together with the interaction between σ orbitals (which depends on the orientation of the C–H bonds) [138,143,144] [formula (XLI)]:

$$\Delta^3J^{\sigma\pi}_{HH} \sim K(\sigma'\pi),$$



(XLI) (XLII)

The contribution is positive and depends on the projection angle η between the direction of the π orbital and the C–H bond [formula (XLII)]:

$$\Delta^3J^{\sigma\pi}_{HH} \propto \cos^2\eta \equiv \sin^2\theta.$$

The overall stereochemical relation for the vicinal interaction constant $^3J_{HH}$ for the =CH–CH fragment is (Fig. 13)

$$^3J_{HH} = {}^3J^{\sigma\sigma}_{HH} + {}^3J^{\sigma\pi}_{HH} = A\cos^2\theta - B\cos\theta + D\sin^2\theta. \quad (10)$$

The coefficients were determined empirically from data for a set of compounds with a fixed geometry: A = 9.1 Hz, B = 2.5 Hz, and D = 2.6 Hz. [145] D = 3.4 Hz was calculated theoretically [138]. Owing to the contribution by $^3J^{\sigma\pi}_{HH}$, the above stereochemical relation is smoother than the analogous relation for the saturated HC–CH fragment.

The coefficients in the stereochemical relations [Eqns. (7)–(9) and (10)] depend significantly on the nature of the compound containing the given CH–CH fragment. The most important factors are the geometry of the fragment (the H–C–C valence angle and the C–C bond length and also the nature and orientation of the X–CH–CH substituent.

2. Effects of the H–C–C Valence Angle and the C–C Bond Length

An increase of $^3J_{HH}$ for the CH=CH fragment of cycloolefins with increasing ring size has been observed experimentally [148,149] (Table 10). The H–C–C valence angle decreases in the same sequence, from about 150° for cyclopropene and about 135° for cyclobutene to the

normal value of about 120°. A similar tendency has been noted for $^3J_{HH}$ in aromatic systems. For example, the constant is ≤ 0.25 Hz for the three-membered cyclopropenium ring[152], 4.0 Hz for the five-membered azulene ring[153], 7.54 Hz for benzene[154], and 9.5 and 10.3 for the seven-membered azulene ring[153]. Possibly the reason for the variation of the vicinal constant with ring size arises from a number of factors, including the hybridisation of the carbon atoms, the degree of strain in the ring, and geometrical parameters of the CH=CH fragment. The above tendency may be represented[155] by a relation between $^3J_{HH}$ and the C–CH=CH valence angle (Fig. 14), which has been determined for many compounds by X-ray diffraction analysis.

Table 10. The $^3J_{HH}$ constants in the series of cycloolefins

n	1	2	3	4	5	6	7	8	9
$^3J_{HH}$, Hz	1.3 [149]	2.87 [150]	5.57 [151]	10.11 [151]	10.8 [146]	10.3 [146]	10.7 [146]	10.8 [146]	10.7 [146]

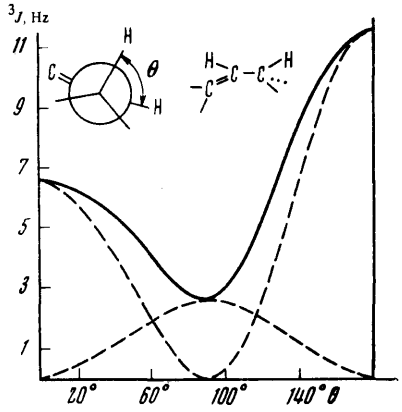


Figure 13. Variation of $^3J_{HH}$ for a vicinal fragment having an allylic double bond with the stereochemical factor[145]. The dashed curves represent the contributions by $^3J(\sigma\sigma)$ and $^3J(\sigma\pi)$.

The observed variation of $^3J_{HH}$ with the valence angle has been given a theoretical basis[27,141,161]. With increasing ring size, the distance between the hydrogen atoms diminishes and consequently the contribution by the canonical structures (XXXIII) and (XXXIV) increases, which leads to a higher vicinal constant. However, the theoretical values[141], 2.1 Hz for an H–C–C angle of 130°, 6.1 Hz for 120°, and 16.0 Hz for 110°, agree with the experimental data only qualitatively. The molecular orbital method gives a less critical sequence, namely 2.4, 5.7, and 10.1 Hz respectively[27] (see the dashed curves in Fig. 14).

It has also been shown theoretically[141] that the vicinal constant for the ethylene fragment *cis*-CH=CH decreases with the length R (Å) of the C=C bond:

$$^3J_{cisHH} = J_0[1 - 2.9(R - 1.35)], \quad (11)$$

where J_0 is the interaction constant for R = 1.35 Å.

The experimental data for carbocyclic compounds (cyclohexene, cyclohexa-1,3-diene, 1,2-dihydronaphthalene, benzene, and condensed aromatic compounds) also yield a linear relation[151]:

$$^3J_{cis} = -36.40R + 58.46,$$

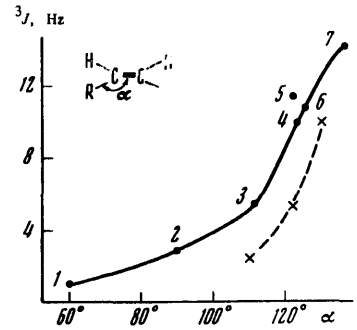

Figure 14, Variation of the vicinal constant $^3J_{cis}$ for an olefinic fragment with the valence angle α.[155] Experimental points: 1) cyclopropene[149]; 2) cyclobutene[150]; 3) cyclopentene[151]; 4) cyclohexene[151]; 5) ethylene[19]; 6) *cis*-but-2-ene[156]; 7) *cis*-di-t-butylethylene[155]. The X-ray diffraction data for compounds *3–7* were taken from Refs. 157–160. The dashed curve represents the theoretical calculation[27].

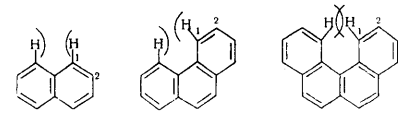
which agrees fairly well with the theoretical Eqn. (11): the ratio of the constants for bond lengths of 1.35 and 1.45 Å is 1.63, whereas Eqn. (11) predicts 1.41. For compounds of the type $R(CH{=}CH)_nCH{=}R'$ with a *trans*-configuration of the double bonds, it has been found that[162]

$$^3J_{transHH} = -81.85R + 127.86,$$

which yields the ratio $^3J_{1.35Å}/^3J_{1.45Å} = 18.4$, also in satisfactory agreement with theory.

It is noteworthy that the constants $^3J_{HH}$ for the above series of compounds[151,161] and also for a series of aromatic compounds[163,164], including charged five-membered rings[165], are linearly correlated with the C=C bond order calculated by the simple Hückel method.

When the vicinal protons come closer together in space in a series of condensed aromatic molecules, $^3J_{HH}$ deviates from the linear relation with the length and order of the bond[151].



The steric contraction effect leads to an increase of the $^3J_{1,2}$ constants by 0.08 Hz for naphthalene (XLIII), 0.30 Hz for phenanthrene (XLIV), and 0.50 Hz for benzo[*c*]phenanthrene (XLV). It has been suggested that the reason for the deviations is distortion of molecular geometry, and in the first place a decrease of the $H-C_1=C_2$ valence angle [151].

3. Effect of the Electronegativity of the Substituents

Many experimental data show that the constant $^2J_{HH}$ for the X–CH=CH fragment as a rule decreases with increasing electronegativity of the substituent **X** (Tables 11 and 12).

Table 11. Effect of the α-substituent **X** on the vicinal constant $^3J_{HH}$ (Hz).

*R=CH_3;
**R=H.

It has been established [41,42,99,166] that the relation is as a rule described by the additive equation

$$^3J_{HH} = {}^3J_0\left(1 + k\sum_i \Delta E_{X_i}\right), \qquad (12)$$

where $^3J_0$ is the interaction constant for the unsubstituted fragment (X=H), k a coefficient which depends on the class of compound (usually $k < 0$), and $E_X = E_X - E_H$ the difference between the electronegativities of the first atom of the substituent and hydrogen. The coefficients k found experimentally for substituted ethanes and ethylenes† (Table 11) agree satisfactorily with the values calculated theoretically [141] by the valence bond method taking into account ionic structures [175,176]. The dependence of $^3J_{HH}$ on the substituent is used to determine the mutual influence of the electronegativities of the groups of disubstituted ethylenes [177].

†On the basis of a set of disubstituted ethylenes XCH=CHY with a wider range of electronegativities of the substituents, non-linear relations of the type of Eqn. (4) have been found [71]:

$$^3J_{cis} = 91.2/(E_X+E_Y)-9.7,$$
$$^3J_{trans} = 75.0/(E_X+E_Y)+0.3.$$

It is striking that the electronegativity of the substituent in the ethylene fragment affects the constant $^3J_{HH}$ for *cis*-protons much more than for *trans*-protons. The influence of the orientation of the substituent **X** must also be taken into account for the saturated fragments X–CH–CH, [178] otherwise erroneous conclusions concerning the conformation of the compound may be arrived at.

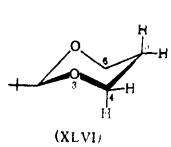
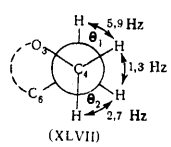
*$^3J_{endo\text{-}endo}$ = 9.17 Hz. [105]

We shall now consider an example of such influence. For 2-t-butyl-1,3-dioxan (XLVI), the dihedral angles θ_1 and θ_2 in the C_5–C_6 fragments (XLVII) should be identical (regardless of the distortion of the ring conformation) in consequence of their symmetrical disposition relative to the symmetry plane of the ring. The different values of $^3J_{HH}$ corresponding to these dihedral angles (5.9 and 2.7 Hz) [85] are due to the orienting influence of the electronegativities of the O_3 and C_6 atoms. Protons with θ_1 and $^3J_{HH}$ = 5.9 Hz have hydrogen and carbon atoms in the *trans*-position (the oxygen atom is in the *gauche*-position), while protons with θ_2 and $^3J_{HH}$ = 2.7 Hz have a hydrogen atom and an oxygen atom (which is more electronegative than the carbon atom) in the *trans*-position (the carbon atom is in the *gauche*-position). An even lower value $^3J_{HH}$ = 1.3 Hz corresponds to protons with carbon and oxygen atoms in the *trans*-position.



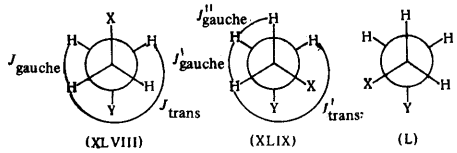
(XLVI)



(XLVII)

A systematic study of the orienting effect of substituents on the vicinal constants has been made for 1,2-disubstituted ethanes XCH_2CH_2Y. [179–186] A special technique for the interpretation of the variation of the observed constants, which have been averaged over the rotational states [formula (XLVIII)–(L)], with the polarity of the medium makes it possible to determine the constants J_{trans} and J_{gauche} for the *trans*-isomer (XLVIII) and the

constants J'_{gauche} and J''_{gauche} + J'_{trans} for the *gauche*-isomers (XLIX) and (L).[181,185]



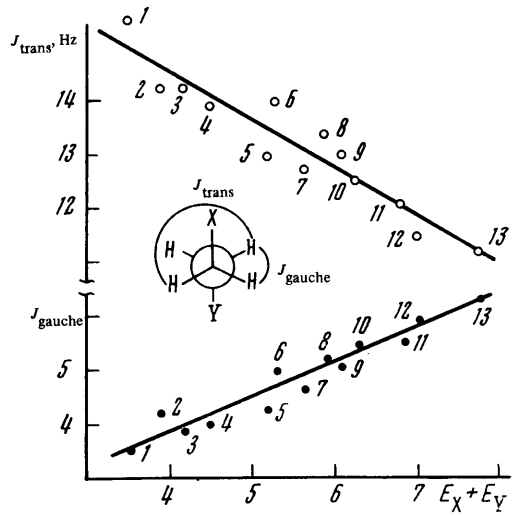


Figure 15. Variation of the vicinal constants for the *trans*-isomers of 1,2-disubstituted ethanes with the electronegativity of the substituents[185]. Substituents X and Y: 1) $C(CH_3)_3$, Li; 2) $C(CH_3)_3$, MgR_2; 3) $C(CH_3)_3$, AlR_3; 4) $C(CH_3)_3$, $Si(CH_3)_3$, 5) $C(CH_3)_3$, $C(CH_3)_3$; 6) I, I; 7) $C(CH_3)_3$, $N^+(CH_3)_3$; 8) Br, Br; 9) Cl, Br; 10) Cl, Cl; 11) F, Br; 12) F, Cl; 13) F, F. The data were taken from Ref. 1.79 for points *1*, *3*, and *4*, from Ref. 180 for point *2*, and from Ref. 185 for points *5–13*.

Fig. 15 shows the variation of J_{trans} and J_{gauche} for the *trans*-isomers with the sum of the electronegativities of the substituents X and Y. In agreement with the theoretical calculations[141], the J_{trans} constant decreases with increasing E_X and E_Y:[185]

$$J_{trans} = 14.28\,[1 - 0.062\,(\Delta E_X + \Delta E_Y)]\,. \qquad (13)$$

However, J_{gauche} increases with the electronegativity ($k > 0$):

$$J_{gauche} = 3.99\,[1 + 0.16\,(\Delta E_X + \Delta E_Y)], \qquad (14)$$

which is inconsistent with the theoretical prediction. The constant J_{ee} for *trans*-1,2-disubstituted 4-t-butylcyclohexanes[187], which corresponds to the same orientation relative to the substituents as J_{gauche} in 1,2-disubstituted ethanes, behaves in the same manner.

The coefficients J_0 in Eqns. (13) and (14) may be assumed to be identical with J_{trans} and J_{gauche} for unsubstituted ethane, if one postulates that in the *trans*-isomer the H–C–C–H dihedral angles are not distorted by substituents. In agreement with theory, the constants for the *gauche*-isomers are found to decrease as $E_X + E_Y$ increases[185]:

$$J'_{gauche} = 4.99\,[1 - 0.24\,(\Delta E_X + \Delta E_Y)], \qquad (15)$$

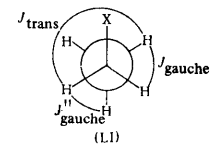
$$J''_{gauche} = 4.45\,[1 - 0.32\,(\Delta E_X + \Delta E_Y)], \qquad (16)$$

$$J'_{trans} = 13.95\,[1 - 0.043\,(\Delta E_X + \Delta E_Y)]. \qquad (17)$$

It is quite likely that the inconsistency between the coefficients J_0 for the *trans*- and *gauche*-oriented protons in the relations for the *trans*- and *gauche*-isomers [Eqns. (13)–(17)] indicates different dihedral angles, which may be due, in particular, to steric and electrostatic interactions between the substituents in the *gauche*-isomer. Moreover, the changes in the C–H and C–C bond lengths and in the H–C–C valence angles under the influence of substituents may play a definite role.

Nevertheless the coefficients $J_0 = 7.9$ Hz and $k = -0.074$ for the averaged vicinal constant $\langle J \rangle$ for monosubstituted ethanes (LI), calculated by the equation

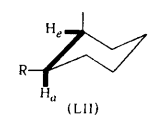
$$\langle J \rangle = (1/3)(J_{trans} + J_{gauche} + J''_{gauche}),$$



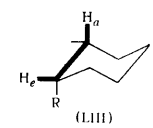
(LI)

and Eqns. (13), (14), and (16), agree satisfactorily with the experimental data (Table 11).

One must assume that the orienting effect of the substituent is in fact responsible for the observed inequality $^3J_{ae} > {}^3J_{ea}$ of the vicinal constants for six-membered rings (cyclohexanes[178,187], steroids[188]), while the dihedral angle is the same ($\theta \simeq 60°$). For example, in the series of 5β-steroids with a 3α-hydroxy- or acetate group (occupying an equatorial position), $J_{ae} \simeq 5.5$ Hz is observed [compound (LII)] and in the series of 5α-steroids with 3β-substituents (in the axial position), $J_{ae} \simeq 2.5$–3.2 Hz has been found [compound (LIII)].[189] In the first case the electronegative substituent has the *gauche*-orientation relative to the vicinal proton H_e and has virtually no effect on $^3J_{HH}$. In the second case the substituent occupies the *trans*-position relative to the proton H_a and therefore a significant effect of its electronegativity appears.



(LII)



(LIII)

The angular variation of $^3J_{HH}$ with the orientation of the substituent can be conveniently represented by a schematic relation between the coefficient k in Eqn. (12) and the dihedral angle ξ between the substituent X and one of the protons (Fig. 16). The greatest effect of the substituent is to be expected with the C–X and C–H bonds in the eclipsed and *trans*-positions.

Another type of orientation relation has been proposed[193] on the basis of an empirical treatment of a large number of experimental data for fragments of the type $X_1X_2CH–CHX_3X_4$:

$$^3J_{HH} = 11.3\cos^2\theta - 2.5\cos\theta + 1.8 - \left(0.4 + 1.2\cos^2\frac{3}{2}\theta\right) \cdot \sum_{i=1}^{4} \frac{1}{i}\,\Delta E_{X_i}.$$

Appropriate recalculation shows that this equation yields a result which differs significantly from the $k-\xi$ plot in Fig. 16. There is no doubt that the orientation effect of the substituent on the H–H vicinal constant requires further detailed experimental and theoretical study.

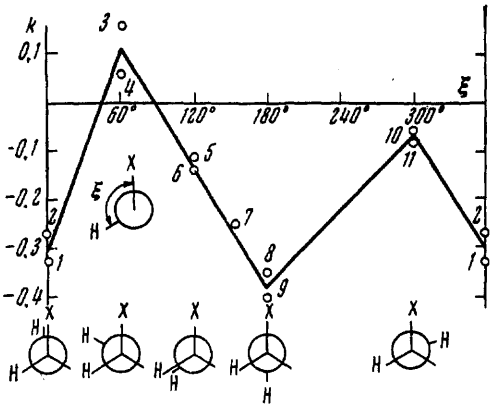


Figure 16. Variation of the effect of the electronegativity (k) of the substituent X on the $^3J_{HH}$ constant with the orientation of X relative to the interacting protons of the X–CH–CH fragment: 1) and 6) hexachlorobicyclo[2,2,1]-heptenes[109] ($\theta \simeq 120°$ and 0°); 2) and 7) cyclopropanes[190] ($\theta \simeq 147°$ and 0°); 3) and 10) *trans*-isomers of 1,2-disubstituted ethanes[185] ($\theta \simeq 60°$ and 180°); 4) and 8) *trans*- and *cis*-isomers of 1,2-disubstituted 4-t-butylcyclohexanes[187] ($\theta \simeq 60°$ and 180°); 5) bicyclo[2,2,1]heptenes[191] ($\theta \simeq 120°$); 9) and 11) 6β- and 6α-substituted 5α-cholestan-7-ones[192] ($\theta \simeq 60°$ and 180°).

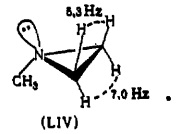
An additional complication in the analysis of the effect of the electronegativity of the substituent on the vicinal constant arises from the fact that substituents do not have axial symmetry as a rule. The orientation of the C–X bond is especially significant for substituents having a lone electron pair. In particular, $^3J_{HH}$ in the series of five-membered heterocycles with X = S and O and also $^3J_{trans}$ in the series of four-membered ring compounds have high values, contrary to the expected low values (Table 13), while for three-membered heterocycles the usual tendency towards a decrease of $^3J_{HH}$ with increasing electronegativity of the atom X is observed. It has been suggested[86,198] that the lone electron pair of the heteroatom makes a positive contribution to the constant $^3J_{HH}$, which reaches 2.3 Hz[88] for the transoid orientation of the C–H bond relative to the axis of the lone pair atomic orbital. The higher value of the constant $^3J_{cis}$ for protons with *cis*-orientation relative to the substituent in *N*-methylaziridine (LIV) compared with $^3J_{cis}$ for protons with *trans*-orientation relative to N–CH_3 serves as a clear illustration[94]. In the first case the lone electron pair of the nitrogen atom occupies the transoid position relative to the C–H bonds of the interacting protons.



(LIV)

The orientation effect of the substituent gives rise to significant difficulties in the employment of H–H vicinal constants for the investigation of conformational equilibrium processes[200]‡. Even when a Karplus curve is plotted for the given class of compounds, the required accuracy in the determination of the statistical weight of the conformers from the average constant ^3J is not secured under conditions of a rapidly attained equilibrium[204].

Table 13.

X		CH_2	References	C=O	References	S	References	NH	References	O	References

	J_{cis}	10.4	194	10.4	70	8.93	195	—		8.65	196
	J_{trans}	4.9	194	6.4	70	6.27	195	—		6.87	196
	J_{cis}	7.4	197,198	7.2	197,198	10.0	199	8.83	199	10.7	197,198
	J_{trans}	4.6	197,198	2.2	197,198	7.5	199	8.85	199	8.3	197,198

There are certain data showing that the sign of the effect of electronegativity alternates with increase of the number of chemical bonds between the substituent and the fragment with vicinal protons[205]. The $^3J_{12}$ vicinal constant for the $XC_1H-C_2H-C_3H-C_4H$ chain decreases with the electronegativity of the substituent X ($k < 0$, see above), the constant $^3J_{23}$ increases ($k > 0$), and $^3J_{34}$ again decreases. A number of examples are presented in Table 14. It is noteworthy that the magnitude of the effect decays rapidly as the substituent becomes more remote. For example, the following formula has been found to represent the constant for the interaction of *ortho*-protons of monosubstituted benzenes[212]:

$$^3J_{23} \equiv {}^3J_{ortho} = 7.56(1+0.065\ \Delta E_X),$$

where k is smaller by a factor of 5 than for the *cis*-protons of monosubstituted ethylenes (Table 11). In order to observe the expected changes in $^3J_{34}$, a very high experimental accuracy is required.

4. Theroetical Calculations of $^3J_{HH}$

A complete *a priori* calculation[6] of vicinal constants has been made both by the valence bond[136,138,141,175,176,218] and molecular orbital[25–27,29–33,35,219,220] methods. However, the calculated values agree with experiment only qualitatively (Table 15). The difficulties encountered in the calculations apply generally to the quantum-chemical theory of complex chemical compounds. This is primarily

‡In the absence of conformational transitions or when the energy parameters of the conformations with respect to which $^3J_{HH}$ is averaged are equal, temperature has a very weak effect on the vicinal constant[46,48,52–54]. The solvent may be responsible for changes in $^3J_{HH}$ for polar molecules[201–203], but as a rule this effect is much weaker than the effect on the H–H geminal constant[121].

due to the approximate nature of the mathematical expressions for the physical quantities and the low accuracy of the estimates of the parameters entering into the equations.

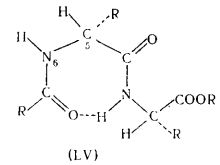
Therefore a semiempirical approach is promising. When an equation giving a correct description of the qualitative aspect of the spin–spin interaction (for example, the stereochemical relation) is available, it is possible to determine from the experimental data a number of parameters (for example, the overlap integrals, the exchange integrals, and the average excitation energies) of the theoretical equations. The values may be used to calculate other interaction constants or may be employed in other types of quantum-chemical calculations. In particular, the spin–spin interaction constants may serve as a basis for the calculation of the contribution by the spin–polarisation mechanism to the hyperfine structure constant of ESR spectra [13–17] and also the reactivities of compounds in scission [221] and bimolecular nucleophilic [222] reactions.

5. Vicinal Interaction in Heteroatomic Fragments

Experimental data show that, when the vicinal interaction is transmitted via the heteroatom (H–X–C–H), the sign of the $^3J_{HH}$ constant persists (Tables 16 and 17). It is quite likely that the properties of the vicinal interaction examined above for the HC–CH fragment hold also (at least qualitatively) for the HX–CH heteroatomic fragment. In particular, the higher value for the H–H *trans*-configuration relative to the *cis*-configuration is maintained (Table 16).

The variation of the HX–CH vicinal constant with the dihedral angle is particularly important for conformational analysis. For the $CONH-C^{\alpha}HRR'$ peptide fragment, a relation of this kind has been derived by analysing data for dipeptides with *trans*-amide bonds [240–244]. Since the N–CO bond has partial double bond character, a contribution to $^3J_{NHCH}$ by the π orbital of the nitrogen atom should be expected. Therefore the analysis was based on Eqn. (10). Positive values of its coefficients were chosen, since it is known that $^3J_{NHCH}$ for amide fragments is positive [135]. Since it has been pointed out that $^3J_{NHCH}$ for substituted N-methylanilines decreases with the electronegativity of the ring substituent [245], the effect of the substituent at C^{α} was taken into account by means of Eqn. (12). The coefficient $k = -0.1$ was chosen on the basis of experimental data for ethanes (Table 11 and Ref. 246).



(LV)

Table 15. Comparison of the experimental constants $^3J_{HH}$ (Hz) for the interaction of vicinal protons and the values calculated by the valence bond method (VB), the molecular orbital method without allowing for overlapping (MO) with allowance for overlapping (MO–O), with allowance for delocalisation (MO–D), and by the self-consistent field method with complete and partial neglect of differential overlapping (CNDO and INDO).

a. Found for 1,2-disubstituted ethanes taking into account the effect of electronegativity of the substituents [140].
b. The coefficients in Eqn. (8).
c. Taking into account the contributions of the π-electron systems for ethane (1.5 Hz) and acetylene (4.6 Hz) [138].
d. Application of the complete self-consistent field method showed that $J_{cis} = 9.6$ Hz and $J_{trans} = 20.1$ Hz. [32]

In view of the planarity of the group $\backslash N-C^{O}/$, there is no reason to expect in this case an orientation effect of the substituents R and R′ (see Section III, 3). Infrared spectroscopic data show that in a non-polar medium dipeptide molecules exist predominantly in the coiled form (LV) [246, 248], which limits significantly the range of permissible dihedral angles for the N_6H-C_5H fragment. The rotational states of this bond have been examined for two models

using the constants averaged with respect to the dihedral angles (*N*-methylformamide, Table 17). The model with the discrete angles $\theta = 0°$, 60°, 120°, 240°, and 300° led to the following ranges of allowed values (in Hz) of the coefficients of Eqn. (8):

$$8.0 \leqslant A \leqslant 9.8;\ 0.0 \leqslant B \leqslant (A - 8.0) \text{ and } C = 9.8 - A.$$

The free rotation model with allowance for the maximum values of the constants $^3J_{NHCH}$ for the angle $0° \leqslant \theta < 90°$ (8.9 Hz for 5,6-dihydrouracils [254] and 8.0 Hz for valinomycin [250]) yielded narrower ranges of the coefficients:

$$8.9 \leqslant A \leqslant 9.8,\ 0 \leqslant B \leqslant (A - 8.9), \text{ and } C = 9.8 - A,$$

represented by the shaded region in Fig. 17. The equation corresponding to the average values for this region is of the form [242]:

$$^3J_{NHCH} = 9.6\cos^2\theta - 0.3\cos\theta + 0.5\sin^2\theta. \quad (19)$$

Comparison of Eqns. (18) and (19) shows that the result is almost independent of the choice of model for rotation relative to the N–C$^\alpha$ peptide bond.

The $^3J_{NHCH}(\theta)$ stereochemical relation has served as a basis of the conformational analysis of peptides and depsipeptides [240–244,255–258]. The dihedral angle θ determines the rotational state of the N–C$^\alpha$ bond, one of the two single bonds in the peptide fragment –CON–C$^\alpha$–CO.

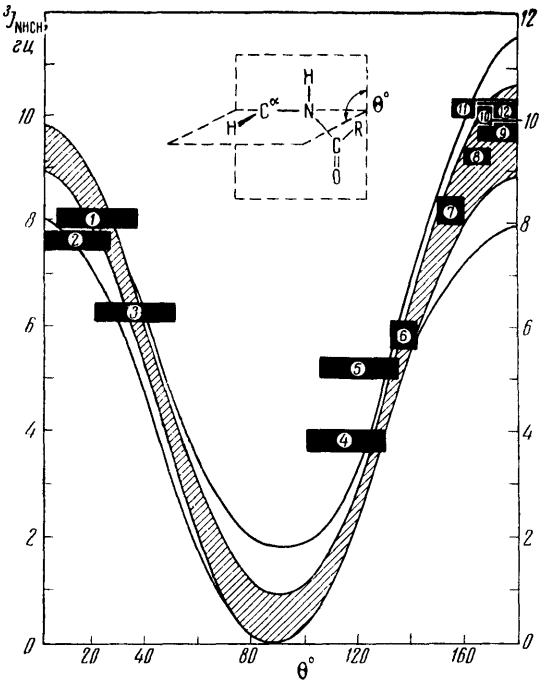

Figure 17. Stereochemical relation between the vicinal constant for the NH–CH peptide fragment and the dihedral angle θ. [240–244] The extreme curves bound the region calculated for the discrete-rotation model. The shaded region corresponds to the free-rotation model. The filled rectangles denote the experimental data for aminoacid residues: 1) D-valine of valinomycin in a non-polar medium [249]; 2) L-valine of valinomycin in a polar medium [249,250]; 3) L-valine of valinomycin in a non-polar medium [249]; 4) D-phenylalanine of gramicidin S in a polar medium [251]; 5) L- and D-valine of lincomycin in a complex with K^+ ion [249,250]; 6)–8) L-ornithine (1, 2, and 3) of alumichrome A in water [252] (X-ray diffraction analysis of ferrichrome-A) [253]; 9) L-ornithine of gramicidin S in a polar medium [251]; 10) D-valine of valinomycin in a polar medium [249,250]; 11) and 12) L-valine and L-leucine of gramicidin S in a polar medium [251].

The angle θ may be converted into the conventional angle [259] φ for the N–C$^\alpha$ bond by means of the following relations:

for L-aminoacid residues, $\varphi = 240 \pm \theta$.
for D-aminoacid residues, $\varphi = 120 \pm \theta$.

The preferred rotational states found from the $^3J_{NHCH}(\theta)$ relation have served as a basis for the determination of the conformations in solution of important biologically

active peptides and depsipeptides such as valinomycin[249,250,258], enniatin B[258,260], gramicidin S[251,258], antamanide[258,261], actinomycin D[262], oxytocin[263], alumichrome A[252], α-chymotrypsin substrates[264], and complexes of valinomycin and enniatin B with alkali metal cations. The data for valinomycin, gramicidin S, and alumichrome A, which have been reliably confirmed by data obtained by other methods, in particular by theoretical conformational and X-ray diffraction analysis, are plotted in Fig. 17.

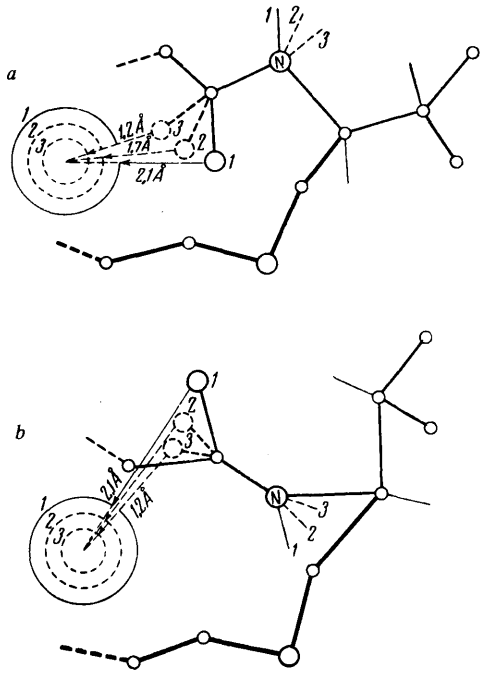

Figure 18. Effect of the dimensions of the complex cation on the orientation of the amide group of (tri-*N*-desmethyl)enniatin B in conformations P_1 (*a*) and P_2 (*b*).

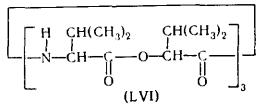
As an example of studies on the conformations of cyclic antibiotics, one may quote the determination of the conformation of an analogue of enniatin B—(tri-*N*-desmethyl)-enniatin B (LVI)—in the formation of complexes with alkali metal cations[260].



(LVI)

Examination of molecular models showed that complexes may be formed when the cation enters the cavities in two conformations P_1 and P_2. With increasing diameter of the cation, an increase of the size of the inner cavity, formed by the carbonyl groups involved in ion–dipole interaction with the cations, may be expected (Fig. 18). Evidently the effective size of the cavity for a given ring size is determined by the orientation of the carbonyl groups. In a complex with a cation having a smaller diameter, the carbonyl oxygen should be closer to the centre of the molecule than in a complex with a larger cation. The change in the conformation of the complex with increasing size of the cation may be compared with the opening of a flower bud. Fig. 18 shows that such a change in the orientation of the carbonyl groups inevitably leads to the rotation of the CONH plane, which causes a change in the orientation of the N–H and C^{α}–H bonds, i.e. in the angle θ.

Table 18. The dihedral angles and the constants $^3J_{NHCH}$ for the complexes of (tri-*N*-desmethyl)enniatin B with univalent cations[260].

Calculation					Experiment		
	P_1		P_2				
diameter of cavity, A	θ,°	J, Hz	θ,°	J, Hz	cation	diameter of cation, A	$^3J_{NHCH}$, Hz
1.7	120	2.9	0	8.9	Li^+	1.40	4.9
2.7	130	4.6	10	8.6	Na^+	1.96	6.4
3.2	140	6.2	20	7.8	K^+	2.66	7.9
3.7	150	7.4	30	6.6	Rb^+	2.98	7.9
4.2	165	9.0	45	4.3	Cs^+	3.30	8.5

Analysis of molecular models shows that, with increase of the size of the inner cavity, the angle θ increases in the range 120–170° for conformation P_1 and in the range 0–60° for conformation P_2 (Table 18). It follows from the stereochemical relation for $^3J_{NHCH}$ that, with increase of the diameter of the cation, the constant should increase in the first case and decrease in the second. The experimental data for the complexes (LVI) with Li^+, Na^+, K^+, Rb^+, and Cs^+ demonstrate reliably that conformation P_1 obtains (Fig. 19). The knowledge of the steric structure of biologically active substances permits a more profound study of the mechanism of the action of these compounds, in particular the mechanism of the selective transport of cations across cell membranes.

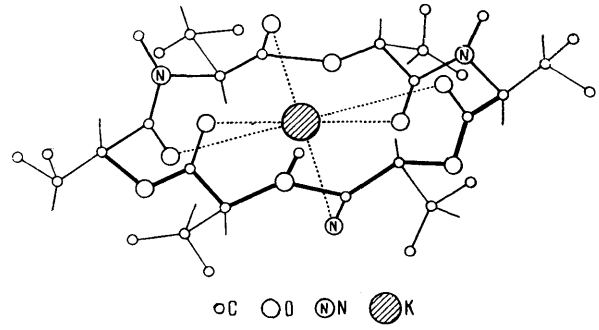


Figure 19. Conformation of the complex of enniatin B with the potassium ion.

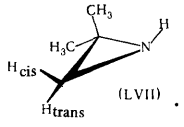
The following relation has been found for six- and five-membered rings with a *cis*-amide bond (in contrast to compounds with a *trans*-amide bond)[265]:

$$^3J_{NHCH} = 9.3\cos^2\theta - 3.5\cos\theta + 0.3\sin^2\theta\ .$$

It differs appreciably from Eqns. (18) and (19), particularly in the range $0° < \theta < 60°$. Possibly the difference can be accounted for by the specificity of the electronic structure of the nitrogen atom, which is reflected in the value of the overlap integral $K(\sigma\sigma')$ for an electronic structure of type (XXXIII), in the *trans*-amide bond and in relatively strained systems with a *cis*-amide bond.

The measurement of the ^3J(NH–CH) constants for amines is very difficult owing to the high mobility of the NH proton and requires careful elimination of catalytic acid and basic impurities. The data for 2,2-dimethylaziridine (LVII), $^3J_{cis} = 7.5$ Hz and $^3J_{trans} = 10.2$ Hz,[266] which indicate a dependence of the constant on the dihedral angle, are noteworthy. In ammonium salts the proton exchange involving the N^+H group is significantly retarded, which facilitates the measurements of the constants for the coupling of the N^+H–CH protons particularly in highly acidic media.



(LVII).

A definite indication of the dependence of this constant on the stereochemical factor has been obtained[267] for protonated benzylamines $C_6H_5CH_2N^+HRR'$. Approximate analysis showed that, for the CH–N^+H fragment, the constant $^3J_{trans,\ 180°} > 9.45$ Hz and $^3J_{gauche,\ 60°} < 3.15$ Hz.[267]

The constant for the HO–CH fragment in alcohols was found to depend on the stereochemical factor[268]:

$$^3J_{HCOH} = 10.4\cos^2\theta - 1.5\cos\theta + 0.2\ .$$

Owing to conformational factors, $^3J_{HCOH}$ for the equatorial OH group in cyclohexanols is higher by 1.0–1.5 Hz than for the axial group[230,269].

Incomplete data indicate the existence of a similar relation for the HS–CH fragment with $^3J_{gauche} < 4.03$ Hz and $^3J_{trans} > 14.9$ Hz.[270,271]

Valence bond theory predicts[17], on the basis of hyperfine structure constants of ESR spectra, the following relations for the HN–CH and HO–CH fragments:

$$^3J_{HNCH} = 12\cos^2\theta + 0.2, \qquad (20)$$

$$^3J_{HOCH} = 10\cos^2\theta - 1.0. \qquad (21)$$

The agreement with experiment for the HN–CH fragment is fairly satisfactory except that Eqn. (20) does not reflect the difference for dihedral angles of 0° and 180°. An additional discrepancy for the HO–CH fragment is that the predicted negative sign of $^3J_{HOCH}$ for $\theta = 90°$C is not confirmed by experiment.

Deviating somewhat from the subject of the review, we may mention that stereochemical relations, described by equations of type (7)–(9), have been established for the interaction of the vicinal H and ^{19}F(HC–CF) nuclei[110,272,273]:

$$^3J_{HF} \simeq 37.5\cos^2\theta - 6.5\cos\theta,$$

and H and ^{31}P(HC–CP) nuclei[274-279]:

$$^3J_{HP} \simeq 25\cos^2\theta - 9\cos\theta.$$

There are also important grounds for the expectation that analogous relations should hold for the (^{31}P–O–C–H),[277-282] (^{14,15}N–C–C–H),[276,283-285] (^{13}C–C–C–H),[286] and (^{199}Hg–C–C–H)[287] vicinal constants. Special emphasis must be laid on the importance of a future determination of the stereochemical characteristic of the constant $^3J_{15}$NCCH for the HC^{α}–CO–^{15}N peptide fragment, which would make it possible to determine the rotational conformation of the peptide chain at the C^{α}–C(O) bond (angle ψ). NMR spectroscopy would then make it possible to establish completely the conformation of peptides, since the rotational state of the NH–C^{α}H bond (angle φ) may be determined from the constant $^3J_{HNCH}$ (see above).

It has been shown theoretically for the H–C–C–X fragments, where X = B, C, N, O, or F, that the $^3J_{HX}$ interaction constants are positive because the contribution by orbitals not involved in valence bonds is decisive.

Without exaggeration, one may claim that the stereochemical relations for vicinal fragments are of the greatest importance for conformational analysis by the NMR method. The determination of the relations for new fragments leads to many possible applications of a physicochemical method as powerful as NMR spectroscopy in the study of conformational states of a wide variety of compounds.

---o0o---

Summarising the present state of the theoretical and empirical relations, one may conclude that the geminal and vicinal H–H spin–spin coupling constants are extremely sensitive to fine details of the electronic and steric structures of molecules§. In a comprehensive approach, the H–H constant constitutes an effective research tool, but this NMR spectroscopic parameter must be employed with caution, bearing in mind the complete set of effective factors involved. Probably at present the empirical approach to relations governing the interaction constants is more promising than direct theoretical calculations, which necessarily involve serious approximations. However, the theoretical approach makes it possible to find the "guide lines" for a systematic arrangement of experimental data.

§As the NMR spectroscopic technique is improved, more distant spin–spin interactions, via four and more chemical bonds, are acquiring increasing importance for structural and conformational analysis. A number of interesting reviews have been devoted to such interactions[44,289,290]. The dependence of $^4J_{HH}$ on the steric structure of the H–C–C–H fragment, determined on the basis of experimental data[10,291] significantly complements the vicinal constant $^3J_{HH}$ in conformational analysis by the NMR method[107,108,292,293].

Determination of the Effective Charges of Anions in Media of the Ionic Type by the Positron Method

G.M.Bartenev, A.Z.Varisov, V.I.Gol'danskii, E.P.Prokop'ev, and A.D.Tsyganov

The essential features of the positron method for determining the effective charges of anions in ionic solids are presented, and papers dealing with its application are reviewed. Values of the charges of the anions are given for more than 100 compounds (alkali metal halides, oxides, etc.). In contrast to earlier work, the effective charges of the anions given in this review were determined independently of other methods. Various regular features of the behaviour of the charges in the compounds studied are noted. The bibliography contains 67 references.

The experimental and theoretical study of the annihilation of positrons with the electrons of a substance has revealed a number of possible applications of the effects associated with the annihilation in the study of electronic states in solids[1-5]. Examples illustrating the fruitful nature of the application of the positron-annihilation method include the determination of the energy and topology of the Fermi surface in metals and alloys, the detection of the change in the momentum distribution of electrons in metals and alloys in their plastic deformation, the study of the magnetic structure of ferromagnetic materials, etc. In ionic media, the positron-annihilation method can be used successfully to study the nature of chemical bonds and in particular to determine the effective charges on atoms, produced on the formation of a particular compound. In this respect the positron method may provide a valuable supplement to existing methods such as Szigeti's method, the X-ray spectral method, etc. The present paper presents the essential features of the positron method for the determination of the effective charges of anions in media of the ionic type, based on the "optical" positron model of Gol'danskii and Prokop'ev[6]. To illustrate the method, the values of the charges of the anions are given for more than 100 compounds.

To determine the effective charges of the anions it is possible to use either of two fundamental characteristics of the annihilation: the angular distribution of the annihilation quanta or the lifetimes of the positrons with respect to annihilation.

The annihilation of positrons with the electrons of a substance is most commonly accompanied by the emission of two gamma-quanta at an angle of 180° to one another (in the system of the centre of gravity of the annihilating pair). If the centre of gravity of the pair is moving relative to the observer at a velocity v, the angle between the direction of movement of the photons decreases by an amount of the order of v/c, where c is the velocity of light. The experimental assembly (Fig. 1) is used to determine the deviation from 180° of the angle of separation of the photons (the angle θ). The annihilation quanta are recorded by means of two detectors including NaI(Tl) scintillation crystals with photomultipliers, the signals from which are transferred to a coincidence circuit. Between the detector and the specimen containing the source (^{22}Na or ^{64}Cu isotopes), on each side, there are placed lead screens with narrow slits, one of which—screen 1—is fixed rigidly to the movable detector. The distribution of the pairs of gamma-quanta with respect to θ is studied by measuring the count rate of coincidences in the signals from the detectors as a function of the angle of rotation of one of the detectors relative to the specimen. Since this distribution in fact lies within a small range of

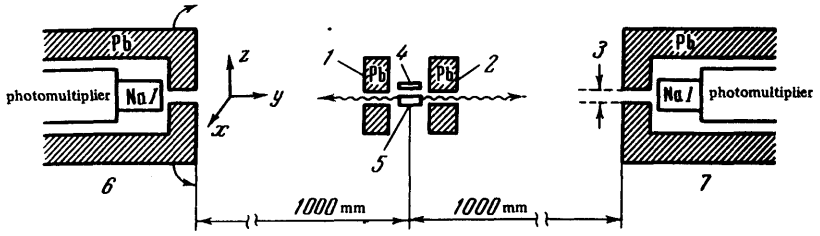

Figure 1. Typical assembly with parallel-slit geometry for the observation of the angular correlation of annihilation quanta: *1*) and *2*) screens; *3*) 1 mm slit; *4*) positron source; *5*) specimen; *6*) moveable detector; *7*) fixed detector.

angles (usually $\theta \lesssim 20$ mrad), it may be assumed that a pair of gamma-quanta moving apart at an angle $(\pi - \theta)$ has a projected momentum on the z axis (see Fig. 1) equal to $p_z = m_0 c\theta$ (m_0 is the rest mass of the electron). The typical form of the $I(\theta)$ curves giving the angular distribution of the annihilation quanta is shown in Fig. 2.

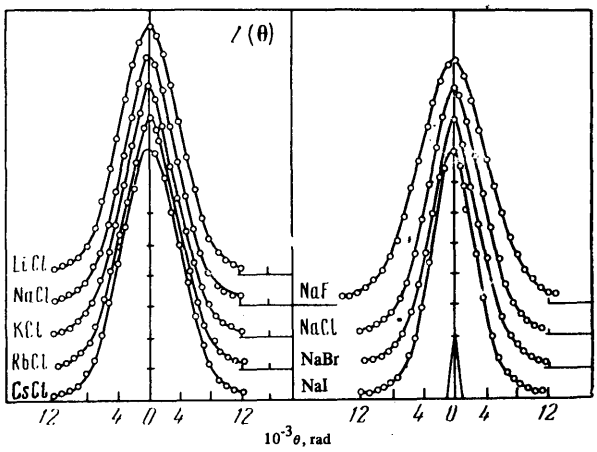

Figure 2. Curves giving the angular correlation of annihilation quanta in alkali metal halide crystals[8].

Observation of the angular correlation of the annihilation quanta gives direct information on the momentum distribution of the annihilating pairs (or electrons, if the movement of the positron can be neglected) in the substance. This is possible since the experimentally observed count rate for the coincidences of the gamma-quanta $I(\theta)$ is related to the momentum distribution density function† $\rho(p)$ for the centres of inertia of the annihilating pairs by the expression[7,8]:

$$I(\theta) = I\left(\frac{p_z}{m_0 c}\right) = \text{const} \int_{p_z}^{\infty} p\rho(p)\,dp; \quad \rho(p) \propto -\frac{1}{\theta}\frac{dI}{d\theta}. \qquad (1)$$

† The momentum distribution $N(p) = 4\pi p^2 \rho(p)$ is often considered instead of the function $\rho(p)$.

Information on the mechanisms of the interaction of a positron with the surrounding electron medium can also be obtained by measuring the lifetimes of the positrons in the substance with respect to annihilation. The lifetime is determined using an assembly (Fig. 3) including a delayed-coincidence circuit. The container with the substance being studied, surrounding the positron source—the ^{22}Na isotope—is placed between two detectors. The moment of generation of the positron is detected by recording the gamma-quantum (detector 1) with energy 1.28 MeV, the emission of which accompanies the β^+-decay of the ^{22}Na nuclei. The moment of annihilation is determined from the production of annihilation quanta with energy 0.511 MeV (detector 2). Fig. 4 gives a typical spectrum of the lifetime distribution of positrons with respect to annihilation in alkali halide crystals. The presence of several decay components with different average lifetimes in the annihilation time spectrum indicates that the mechanism of the annihilation of positrons in ionic crystals is complex. The average lifetimes of the relatively long-lived components are determined from the slope of the plot of the logarithm of the coincidence count rate against the delay time at long delay times.

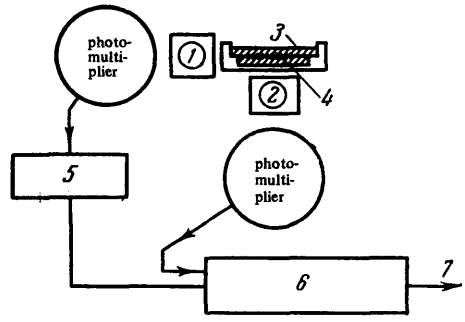

Figure 3. Basic scheme of an assembly for measuring the lifetimes of positrons in condensed media[1]: *1*) and *2*) stilbene crystals; *3*) specimen; *4*) positron source; *5*) delay line; *6*) ~ 10^{-9} s coincidence circuit; *7*) output.

A fairly large number of papers have now been published on the study of the angular distribution of the annihilation quanta and the lifetime distribution of the positrons

with respect to annihilation in different ionic media; halides, oxides, sulphides, and other metal compounds (see, for example, Refs. 1–3 and 8–26). Analysis of experimental results on the study of the annihilation of positrons in ionic crystals shows that the annihilation is preceded by the formation of combined states of the positron, the chief of which are quasi-atomic formations of the e^+–anion type and states of the positronium type (positronium formation is detected from the appearance of a narrow component in the correlation curves and long-lived components in the annihilation time spectra with decay times of the order of 10^{-9} s or more). It has also been noted that if positronium formation is not forbidden energetically, its probability is usually greatly increased by the presence in the medium of defects; of pores (gel), vacancies (irradiated crystals), regions of lower density (glass), etc. Here we shall be interested only in compounds of the e^+–anion type. The formation of these compounds in ionic crystals is preceded by the thermalisation of the positrons, that is their deceleration to thermal velocities. The thermalisation of positrons in ionic crystals is brought about as a consequence of ionisation energy losses, the excitation of electrons into the conduction zone, and by interaction with longitudinal optical phonons. Estimates[27,28] have shown that as a result of all these processes, the positrons are decelerated to thermal velocities in times of the order of 10^{-12} s. Since the shortest lifetime of positrons with respect to annihilation in ionic crystals amounts to several 10^{-10} s,[1,9,22–24,26] it may be assumed that almost all the positrons are able to undergo thermalisation before annihilation. Some of the positrons naturally enter the target and annihilate in flight, that is in the thermalisation process, but experimental results[29–32] and theoretical estimates[27] show that the proportion amounts to only 1–3%.

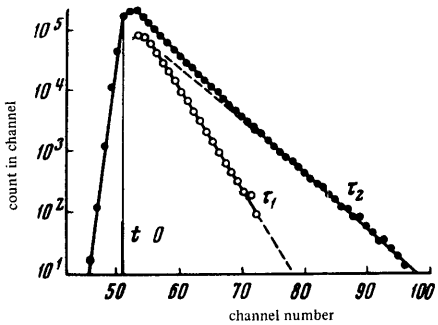

Figure 4. Positron lifetime distribution with respect to annihilation in lithium chloride[9] (one channel = 0.88×10^{-10} s, $\tau_1 = 2.36 \times 10^{-10}$ s, $\tau_2 = 4.35 \times 10^{-10}$ s).

The thermalised positron annihilates in the free state or is captured beforehand by the nearest negative ion. The probability of annihilation of free positrons in media of the ionic type is negligibly small compared with the probabilities of the two-photon annihilation of combined positrons[33]. Thus the annihilation characteristics of ionic crystals in the absence of appreciable positronium yield will be determined chiefly by the properties of the e^+–anion system.

Negative ions (F^-, Cl^-, Br^-, I^-, O^{2-}, S^{2-}, Se^{2-}, and Te^{2-}) have filled electron levels with the structure of inert gas atoms. The positron moves in the field of the nucleus and the electrons of the anion. In this instance we are dealing with a many-electron problem. If however we neglect the deforming action of the positron on the electron levels of the ion, we can regard the movement of the positron in the e^+–anion system as movement in a field of central forces; this is analogous to the model of the optical electron in alkali metal atoms. The "optical" positron model was first proposed by Gol'danskii and Prokop'ev[6]. In this model it is assumed that the positron moves in the Coulombic field of the anion, of the type $U(r) = -\eta e/r$, where $(-\eta e)$ is the effective charge of the anion in the crystal. Since the inner levels of the anion are not accessible to the positron as a consequence of the strong Coulombic repulsion by the nucleus, the wave function of the ground state of the positron in the e^+–anion quasi-atom has been given in the form[6] $r \cdot \exp(-\alpha r)$, where α is a variable parameter. For a combined positron, the correlation of the annihilation radiation is determined by the relative probability[34]:

$$P(k_z) = \frac{\int_{k_z}^{\infty}\int_0^{2\pi} \omega(k)\, k dk d\theta}{\int_0^{\infty}\int_0^{2\pi} \omega(k)\, k dk d\theta}, \qquad (2)$$

where $\omega(k)$ is the probability of annihilation, with the emission of two gamma-quanta with a total momentum $p = nk$, averaged with respect to the spins of the initial states of the electrons and the positron and summed over the polarisations of the radiated photons:

$$\omega(k) = \pi r_0^2 c \sum_{i=1}^{m} \left[h^{-\frac{3}{2}} \int e^{-ikr} \varphi_i(r)\, \chi(r)\, dr\right]^2. \qquad (3)$$

Here, r_0 is the classical radius of the electron, and $\varphi_i(r)$ and $\chi(r)$ the one-electron and positron wave functions respectively for the compound of the e^+–anion type. The summation in Eqn. (3) is carried out over all electrons involved in the annihilation.

The lifetime of a combined positron can be calculated from the equation[35]

$$\tau = 5 \cdot 10^{-10} \frac{\rho_0}{\rho}, \text{ s}, \qquad (4a)$$

where $\rho_0 = (8\pi a_0)^{-1}$ is the electron density at the positronium atom, averaged with respect to the spin states of the electron and positron, and

$$\rho = K \cdot \sum_{i=1}^{m} \int \varphi_i^2(r)\, \chi^2(r)\, dr. \qquad (4b)$$

Here, K is a factor which takes account of the change in the wave functions of the electrons not involved in the annihilation; to a good approximation, it may be assumed that $K = 1$.[33,36]

If we choose Slater exponents as the wave functions of the electrons of the anion, we can use Eqns. (2)–(4) to establish in analytical form the relationship between the chief characteristics of the annihilation of the positron with the electrons of the anion‡ and the effective charge of the anion in the crystal. Within the framework of the "optical" model of the positron, this relationship has the

‡ Usually, only the annihilation of positrons with the electrons of the outer ns^2, p^6-levels of the anions is considered.

following form[6]: the angular correlation of the annihilation quanta for the annihilation of a positron with an *nl* electron of an anion is

$$P_{nl}(k_z) = \frac{\int_{k_z}^{\infty} S_{nl}^2 k^{2l+1} dk}{\int_0^{\infty} S_{nl}^2 k^{2l+1} dk}, \quad (5)$$

where

$$S_{nl} = k^{-l} \int_0^{\infty} r^{n^*+2} e^{-(\alpha+\beta)r} j_l(kr)\, dr, \quad (6)$$

and $j_e(kr)$ represents the spherical Bessel functions (the form of various functions S_{nl} and P_{nl} has been published[6]); the half-width of the correlation curves (the total width at half the height of the curve $P_{ns,p} = 0.25\, P_{ns} + 0.75\, P_{np}$) is

$$\Gamma_{ns,p} = C^{\Gamma}_{ns,p}(\alpha + \beta), \text{ mrad} \quad (7)$$

and, finally, the lifetime of the positron (with allowance for the factor 4π omitted in Ref. 6) is

$$\tau_{ns,p} = 2{,}5 \cdot 10^{-10}\, C^{\tau}_{ns,p}\, \frac{(\alpha+\beta)^{2n^*+3}}{\alpha^5 \cdot \beta^{2n^*+1}}. \quad (8)$$

The following symbols are used in Eqns. (5)–(8): $\alpha = 3/2\eta$, $\beta = Z - \sigma/n^*$ is the Slater exponent (Z is the charge of the nucleus, σ is the screening number, and n^* is the effective principal quantum number), and $C^{\Gamma}_{ns,p}$ and $C^{\tau}_{ns,p}$ are constants, the values of which are determined entirely by the quantum number n. The calculated values of the constants $C^{\Gamma}_{ns,p}$ and $C^{\tau}_{ns,p}$ are given in Table 1.

Table 1. Calculated values of the coefficients $C^{\Gamma}_{ns,p}$ and $C^{\tau}_{ns,p}$ in Eqns. (7) and (8)*.

n	2	3	4	5
n^*	2	3	3.7	4
$C^{\Gamma}_{ns,p}$	3.52	2.86	2.59	2.48
$C^{\tau}_{ns,p}$	$\frac{1}{80}$	$\frac{3}{448}$	$\frac{1}{215}$	$\frac{1}{240}$

* The values of the constant $C^{\tau}_{ns,p}$ for $n = 2$, 3, and 5 were taken from Ref. 6.

The form of the theoretical curves for the angular correlation of the annihilation quanta and the nature of the dependence of the lifetimes of the positrons on the magnitude of the effective charge of the anion are shown in Figs. 5 and 6. The decrease in the half-width of the correlation curves and the increase in the lifetime of the positrons with increase in the number n, that is the principal quantum number of the outermost level of the anions, following from the "optical" model of the positron, and also numerical estimates of these characteristics of the annihilation, show good agreement with results of the measurement of the angular distribution of the annihilation quanta[8] and the lifetimes of the positrons[9] in alkali metal halide crystals.

The direct comparison of the theoretical and experimental curves giving the angular correlation of the annihilation quanta is of interest. The result of this comparison for the oxides of the alkaline earth metals is shown in Fig. 7.

Because of the appreciable scatter in the published values of the charges of the oxygen ion in oxides, the theoretical curves in Fig. 7 were calculated in such a way that their half-width was equal to the half-width of the experimental $I(\theta)$ curves. Comparison of the theoretical and experimental correlation curves is also necessary for the detection of the possible presence, on the curves, of a narrow component due to the annihilation decay of parapositronium atoms. When parapositronium atoms are formed, the calculated and experimental $I(\theta)$ curves do not coincide (see, for example, Fig. 8).

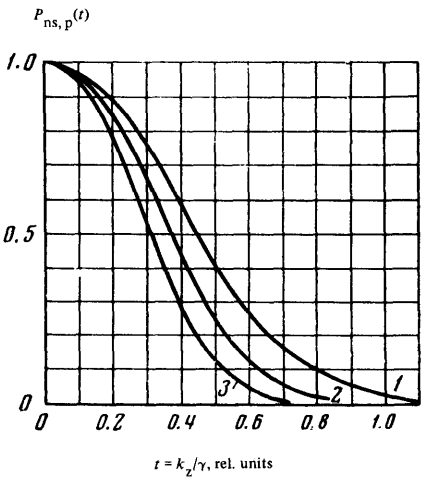

Figure 5. Theoretical angular correlation curves for annihilation quanta: *1*) $P_{2s,p}(k_z/\gamma)$, *2*) $P_{3s,p}(k_z/\gamma)$, *3*) $F_{5s,p}(k_z/\gamma)$, where $\gamma = \alpha + \beta$.

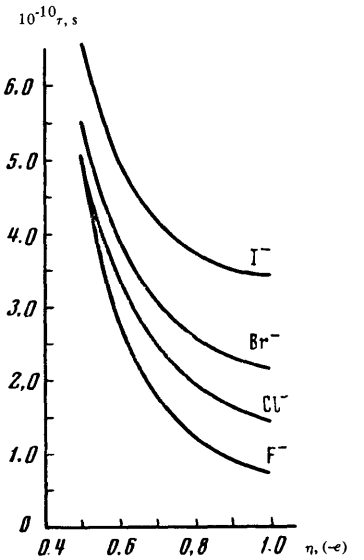

Figure 6. Dependence of the lifetimes of the positrons on the effective charge of the anion η in the "optical" positron model.

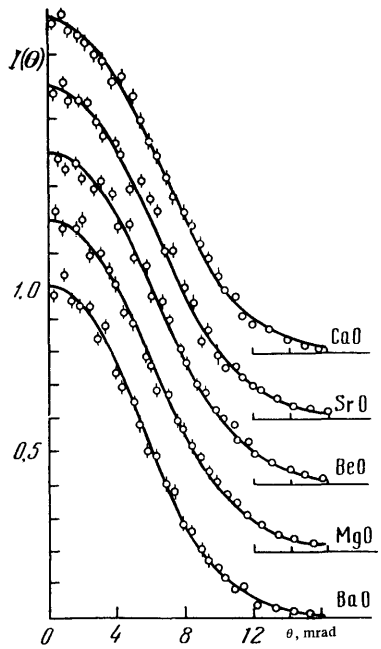

Figure 7. Theoretical (continuous line) and experimental (points) angular correlations for annihilation quanta in alkaline earth metal oxides (BeO and MgO were sintered, the others were in powder form).

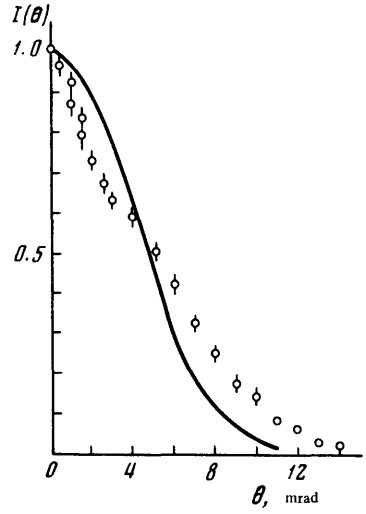

Figure 8. Theoretical (continuous line) and experimental (points) angular correlations for annihilation quanta in zirconium oxide.

We can now proceed directly to the problem of determining the effective charges of atoms from the chief characteristics of the annihilation of positrons in media of the ionic type. The possibility of determining the effective charges of anions from the half-width of correlation curves was first demonstrated for the example of metal oxides[10]. Values have been obtained for the effective charges of F^-, Cl^-, and O^{2-} ions in crystals of various alkali metal halides and quartz from the short lifetimes of positrons with respect to annihilation[37]. It may be noted that in Ref. 10, as in later papers[12,14,16-18], the constants $C^{\Gamma}_{ns,p}$ in Eqn. (7) were given empirical values chosen to give best agreement between the calculated charges and the values of the charges determined by other methods. Thus for example the semi-empirical value of $C^{\Gamma}_{2s,p}$ for the oxides is ~ 3.78,[10] which is slightly greater than the theoretical value $C^{\Gamma}_{2s,p} = 3.52$ (see Table 1). This difference is not so significant, however, if we allow for the accuracy of the determination of the effective charges and the scatter in the results obtained by different methods.

Table 2. Half-width of the correlation curves (~ ±0.2 mrad) and effective charge of the oxygen ion in metal oxides*.

* For the oxides for which the correlation curves have a narrow component, Table 2 gives the half-widths of the broad components;
** sintered;
*** single crystals; the other oxides were taken in the form of powders.

We shall use the theoretical values of the constants $C^{\Gamma}_{ns,p}$ throughout. The effective charges on the anions in various ionic crystals, calculated from the half-widths of the correlation curves (see Eqn. (7) and Table 1), are given in Table 2 (see also Table 5). In those instances where the correlation curves show the presence of a narrow component (for example La_2O_3, TiO_2, GeO_2, ZrO_2, HfO_2, and PbO), the effective charge was determined from the half-width of the broad component. The broad component from the correlation curves can be separated by the "parabola" method, based on the fact that the theoretical $I(\theta)$ curve in the "optical" positron model has the form of a parabola for angles $\theta < 4$ mrad. The narrow component lies in the part of the experimental $I(\theta)$ curve above the parabola (Fig. 9) and the part of the experimental curve remaining after the subtraction of the narrow component is the broad component. When determining the charges of ions from the half-widths of the correlation curves for those compounds in which positronium formation is possible, it should be noted that the best results can be obtained for specimens in the form of single crystals or specimens obtained by sintering powders: in this instance the correlation curves do not have a narrow component[11].

Improved results can also be achieved by carrying out the measurements under vacuum conditions; this produces a marked decrease in the intensity of the narrow component (see, for example, Refs. 11 and 38). The agreement between the effective charge of the oxygen anion, calculated from the half-width of the correlation curves, and the charges found by other methods [39-51]—Szigeti's method, the X-ray spectral method, etc. [52]—is illustrated in Table 3.

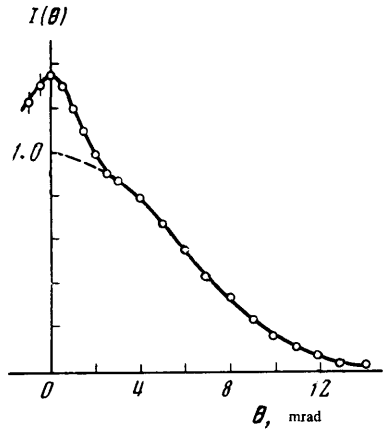

Figure 9. Separation of the broad component from the correlation curve for zirconium oxide by the "parabola" method (the parabola is given by the broken line).

The results in Table 2 lead to various conclusions regarding the magnitude of the effective charge on the oxygen ion in simple metal oxides. The effective charge of the oxygen ion in metal oxides: a) is generally much smaller than its formal value ($-2e$); b) does not change monotonically in the series of alkaline earth metal oxides; c) for the same oxidation state (transition metal oxides), it increases from the start of a period and then decreases towards its end (see, for example, the nickel group), the maximum charge corresponding to the group VI atom (for example the Cr atom); departures from this rule are shown by oxides of the A_3O_4 type (A = Mn, Fe, or Co), for which the charge increases on going from Mn to Co; d) for the same oxidation state (transition metal oxides), in a group of the Mendeleev Table, it increases or remains constant with increase in the atomic number (for example, from Ti to Hf, from V to Ta, and from Mo to W); and e) with increase in the oxidation state, the effective charges of the metal atoms in manganese and iron oxides increase, whereas in cobalt oxides they coincide, within the limits of the formal error in the measurements ($\sim \pm 0.04\ e$) (see Table 4).

Table 4. Effective charge on the metal atom in oxides of manganese, iron, and cobalt.

Manganese oxides (powders)	η, $+e$	Iron oxides (sintered)	η, $+e$	Cobalt oxides (powders)	η, $+e$
MnO	1.18	FeO	1.12	—	—
Mn_3O_4	1.68	Fe_3O_4	1.75	Co_3O_4	1.83
—	—	Fe_2O_3	2.15	Co_2O_3	1.76
MnO_2	2.36	—	—	—	—

Another interesting feature is that the values of the charges on the iron atoms correspond to the fact that the lattice of the oxide Fe_3O_4 contains iron atoms in different oxidation states Fe^{II} and Fe^{III}, in the ratio 1 : 2. The following point must be made regarding conclusion (e): according to results obtained by the X-ray spectral method [47], in compounds of "multivalent" elements the effective charges do not increase, but on the contrary decrease, with increase in the formal valency. A possible reason for this discrepancy is [12] the different physical significance attached to the concept of effective charge in the different methods (see note on p. 229 of Ref. 43).

Table 3. Comparison of the effective charges of the oxygen ion in metal oxides, determined by different methods.

As noted above, the effective charges on anions can be determined from the lifetimes of positrons (see Eqn. (8) and Table 1). The effective charges of anions in ionic crystals, determined in this way, agree well with the values found by other methods (Table 5). In the calculation of the charges given in Table 5, the lifetimes of the positrons were given the shortest value, usually denoted by τ_1, except for the bromides and iodides of copper, silver, gold, and thallium, where we used the times τ_2, since for these compounds the values of τ_1 lie much lower than the corresponding $\tau(\eta)$ curves calculated from the "optical" positron model. We used the published values of the lifetimes of the positrons for the alkali metal halides[9], the alkaline earth metal halides[22], copper, silver, gold, and thallium halides[23], crystalline and fused quartz[53], vanadium oxide[26], and nitrides[24]. The half-widths of the correlation curves were determined from published graphs for the alkali metal chlorides and sodium halides[8], LiF,[54] KI, AlN,[19] FeS, and Na_2S.[55]

* The references to the papers from which the values of τ and Γ were taken are given in the text.

The data given in Tables 2 and 5 (see also below) confirm again the view, recently developed by Syrkin and his school[56,57], that inorganic compounds do not contain multiply-charged anions; the charges of anions in compounds are generally much smaller than their formal values.

Table 6. Comparison of the half-widths of the correlation curves, the effective charge of the oxygen ion, and the melting points of molybdates and tungstates.

The positron method can be used to determine effective charges not only in binary inorganic compounds, but also in more complex compounds, for example in mixed metal oxides[17] and in multi-component inorganic glasses[13,16]. The possibility of using the "optical" positron model to determine the charges of anions in glasses is based on the fact that this model does not assume the existence of long-range order. In complex compounds, when the anion can occupy several non-equivalent positions in the lattice, the charge found for the anion will represent a value averaged over these positions. As an example of the determination of the effective charge of anions in complex compounds, Table 6 gives the charges of the oxygen ion in molybdates and tungstates, calculated from the half-widths of the correlation curves (see Eqn. (7) and Table 1). The correlation curves for these compounds, with the exception of lithium tungstate (Li_2WO_4), do not contain a narrow component. A noteworthy feature is the correlation between the change in the magnitude of the charge on the oxygen ion and the melting points of the alkali metal molybdates and tungstates and the double molybdates and tungstates of the alkali metals and scandium (in each of the four groups of compound, they change in opposite fashion in the series of atoms Li–Cs): the maximum charge corresponds to the minimum melting point in the compounds containing sodium atoms. It would appear that the compound $NaSc(MoO_4)_2$ does not obey this rule, but the study of the structure of this compound shows a polymorphic transformation at 600°. It may therefore be stated that the "melting point" of the low-temperature modification of $NaSc(MoO_4)_2$ must be lower than the melting point of the $LiSc(MoO_4)_2$ crystal. The above correlation between the relative change in the effective charge on the anion and the melting point is apparently a general characteristic of analogous compounds containing alkali metal atoms. An example confirming this conclusion is provided by the alkali metal fluorides and chlorides[17]. In this instance, in contrast to the situation for the molybdates and tungstates, the maximum melting point corresponds to the sodium halides.

Interesting results were obtained in the study of the behaviour of the effective charge on anions in the crystal–glass transition[13,16,18]. Table 7 gives the half-widths of the correlation curves and the effective charges of the oxygen ion for a number of three-component glasses, where, in contrast to the situation for one- and two-component glasses, positronium formation is not detected from the results of measurements of the angular correlation and the lifetimes of the positrons. Comparison of the values of the charges on the oxygen ion in corresponding crystalline oxides (Table 2) and glasses (Table 7) shows that the effective charge on the oxygen ion decreases systematically in the crystal–glass transition§. This conclusion is also confirmed[18] for binary compounds of the (IV–V) and (IV–VI) type. Thus the change to the vitreous state is accompanied by a redistribution of the valency electrons which increases the proportion of the covalent component in the chemical bonds.

Table 7. Half-widths of the correlation curves and effective charge on the oxygen ion in various oxygen-containing glasses.

Composition of glass, mole %	Γ, mrad	η, −e
76.2 SiO_2·19.0 Li_2O·4.8 SnO_2	10.6	0.72
76.2 SiO_2·19.0 Na_2O·4.8 SnO_2	11.2	0.84
76.2 SiO_2·19.0 K_2O·4.8 SnO_2	11.6	0.91
84.3 B_2O_3·13.7 Na_2O·2.0 Fe_2O_3	12.0	0.99
76.2 B_2O_3·19.0 Na_2O·4.8 SnO_2	11.8	0.91
63.5 CaO·31.7 Al_2O_3·4.8 SnO_2	11.5	0.89

In tin-containing glasses with the equimolar composition, an increase in the effective charge of the oxygen ion is observed when one alkali metal ion is replaced by another in the order Li–K (see Table 7). In this instance the change in the charge on the oxygen ion is confirmed[13] by measurements of the chemical shift of the Mössbauer absorption line; the chemical shift in glasses with the composition indicated is negative relative to crystalline tin(IV) oxide, and its absolute value increases on going from Li to K, indicating[58] an increase in the ionic character of the Sn–O bonds in this order. In alkali silicate glasses with the equimolar composition, as in mixed metal oxides, a correlation is observed between the change in the effective charge and various macroscopic properties. Thus the increased magnitude of the charge on the oxygen ion on going from the lithium silicate glass to the potassium silicate glass corresponds to an increase, in the same sense, in the coefficient of thermal expansion and a decrease in the micro-hardness of the glass.

Determination of the effective charge on the oxygen atom in water (the half-width of the broad component of the correlation curve is approximately 10 mrad[59]) gives the value $-0.6\,e$, which is almost twice the calculated value of $-0.26\,e$[60]; this is possibly due to the approximate nature of the "optical" positron model for the description of the characteristics of annihilation positrons in water.

§ The "positron" effective charge of the oxygen ion in alkali metal oxides is not known, but the value calculated from the heats of sublimation for Na_2O is $-1.10\,e$.[45]

The "optical" positron model cannot be used to determine the charge of the H^- ion in metal hydrides, since in the hydrides the positron is apparently present simultaneously in the field of several H^- ions; this is indicated by the dependence of the lifetimes of the positrons on the density of the hydrides[61]. A more rigorous calculation of the characteristics of the annihilation, with allowance for the distribution of electron density in the LiH molecule by the MO method, carried out[62] for the LiH crystal, gives the value $-0.60\,e$ for the charge of the H^- ion, this is fairly close to the published value of $-0.52\,e$.[63] Thus the above results indicate that the positron-annihilation method can be regarded as a new *independent* method for determining the effective charges of the anions in compounds of the ionic type.

In conclusion it may be noted that the determination of the charges of anions is not the only possible application of the positron-annihilation method in the chemistry of ionic compounds. Recent results[25,64–67] show that the annihilation characteristics of positronium atoms, for example in highly dispersed oxide powders, depend markedly on the physicochemical properties of their surfaces and the filling of the pores. It can already be stated that further studies in this direction will make it possible to use the positron-annihilation method to study adsorption phenomena.

Modern Views on the Nature of Inorganic Peroxy-compounds

I.I.Vol'nov

A general account is given of the literature data on the molecular oxygen anions O_2^{2-}, O_2^-, and O_3^- characterising the structures of simple peroxy-compounds: peroxides, superoxides, and ozonides. The principal studies published in recent years dealing with the structure of complex peroxy-compounds are briefly summarised. The nomenclature for organic peroxy-compounds proposed by other authors is critically discussed and a scheme is put forward for classification and nomenclature based on the latest data on the structures of such compounds.
The bibliography includes 93 references.

Until recently, in order to define the concept of "an inorganic peroxy-compound" it was thought sufficient to indicate compounds corresponding to this concept and containing the peroxo-group, the so called "oxygen bridge".

Detailed studies of the structures and properties of many compounds corresponding to the above concept, begun in the 1930's with active participation of Soviet scientists, showed that the term "inorganic peroxy-compounds" is applicable to a very wide class of compounds and combines at least nine groups of compounds differing in the type of bond not only between the "oxygen bridge" and the atoms of the elements constituting the peroxy-compound but also in the type of bond between the oxygen atoms in the bridge itself.

Some workers, including Hein[1], tend to regard all inorganic peroxy-compounds as complex, dividing them into three groups: polyoxides, peroxo-acids, and peroxy-hydrates. However, the authors include in the group of polyoxides, together with H_2O_2, H_2O_3, and H_2O_4, also peroxy-compounds the crystal lattices of which consist of metal ions (belonging mainly to subgroups IA and IIA of the Periodic System) and the corresponding molecular anions O_2^{2-} (peroxides), O_2^- (superoxides), and O_3^- (ozonides).

It has been shown recently[2] that compounds of this type, for example Rb_2O_2, dissociate completely in the $LiNO_3-KNO_3$ eutectic mixture into ions according to the mechanism $M_2O_2 \rightarrow 2M^+ + O_2^{2-}$ and RbO_2 dissociates[3] according to the mechanism $RbO_2 \rightarrow Rb^+ + O_2^-$.

In the neutral molecule of hydrogen peroxide H_2O_2, the peroxide ion O_2^{2-} does not exist as such. This means that hydrogen atoms are not attracted to any appreciable degree by the peroxo-group via electrostatic forces. Hydrogen peroxide is the first member of the homologous series of hydrogen polyoxides H_2O_2, H_2O_3, H_2O_4, ..., the molecules of which comprise, like sulphanes, zig-zag chains of oxygen atoms joined by single bonds with a length of about 1.5 Å.

The change in the type of bond in the peroxo-group on passing from hydrogen peroxide to other peroxy-compounds depends mainly on the change in the electronegativity of the element forming the peroxy-compound. The negative dissociation energy of the O_2^{2-} ion and the high energy required to complete the process $O_2 \rightarrow O_2^{2-}$ are the reasons why this ion can be stabilised only by highly electropositive elements (Li–Cs, Ca–Ba). To some extent this applies also to O_2^- and O_3^- ions.

To a first approximation, one may assert that the linkage between atoms of elements having an electronegativity lower than that of hydrogen and the "oxygen bridge" formed by the above molecular anions is predominantly ionic. The peroxy-compounds of elements with an electronegativity higher than that of hydrogen contain a peroxo-group (both as such and in the form of H_2O_2 molecules and HO_2 radicals). The peroxo-group may be present in the compound both as a bidentate ligand and as a "bridge".

On the basis of the differences in the structures of inorganic peroxy-compounds, it is useful to retain in their classification the subdivision into simple and complex compounds and to isolate in a special group the hydrogen polyoxides despite the clear genetic relation between H_2O_2 and metal peroxides.

For a deeper understanding of the structure of inorganic peroxy-compounds, it is necessary to examine in somewhat greater detail the electronic structure of molecular oxygen anions.

Molecular Oxygen Anions

In order to represent the electronic structure of the above molecular anions, it is necessary to recall that the oxygen molecule has an unusual structure, the details of which have still not been completely elucidated. The former representation of the double-bonded oxygen structure O=O in which the two oxygen atoms complete their stable octets by exchanging two electrons [:Ö: :Ö:] has been disproved by spectroscopic and magnetic measurements. The oxygen molecule is paramagnetic, which implies the presence of unpaired electrons. Therefore the oxygen molecule has been regarded as a kind of biradical, the structure of which may be represented by the electronic scheme [:Ö–Ö:] with an even number of electrons (twelve) but with only one single bond and two unsaturated valences. Two electrons are unpaired, which is the reason for the paramagnetism of the oxygen molecule. The low reactivity of oxygen in relation to that of free radicals is evidence against this scheme. Moreover, experimental data show that the dissociation energy of the oxygen molecule into atoms is 118 kcal mole^{-1}, which greatly exceeds the value necessary to dissociate a simple covalent bond. Hence it follows that in this case the unpaired electrons stabilise the bond between the oxygen atoms. This unusual case has been treated[4,5] as a three-electron bond. On the basis of these hypotheses, the oxygen molecule in the ground $^3\Sigma$ state can be approximately described by the formula [:O⋯O:] with one single and two three-electron bonds. The O=O bond length is 1.207 Å.[6]

The structure of the oxygen molecule may be represented as follows in terms of the molecular orbital method:

$$[KK(z\sigma)^2(y\sigma^*)^2(x\sigma^*)^2(w\pi)^4(v\pi^*)^2].$$

Consequently in the ground state of the oxygen molecule there are four bonding electrons in excess relative to the antibonding electrons and the bond order is two.

The addition of a single electron to the oxygen molecule leads to the formation of the singly-charged negative ion O_2^- which enters into the composition of superoxides. The electronic structure of the O_2^- ion may be represented by the formula $[:\ddot{O}\!\!-\!\!\ddot{O}:]$, [5,7] and in terms of the molecular orbital method by the formula

$$[KK(z\sigma)^2(y\sigma^*)^2(x\sigma)^2(w\pi)^4(v\pi^*)^3].$$

The electron adds to the antibonding orbital and the bond order diminishes by 1/2. Evidently the singly-charged negative superoxide ion has an odd number of electrons (thirteen) with one single and one three-electron bond†. This is consistent with the paramagnetism and colour of the peroxy-compounds containing this ion. More detailed information about the electronic structure of the O_2^- ion in the free state and in the lattices of alkali metal halides has been given by Zeller et al. [8]

The electron affinity of the oxygen molecule ($O_2 + e \rightarrow O_2^-$) determined by a thermochemical method [9] proved to be 0.87 ± 0.13 eV, i.e. the addition of an electron to the oxygen molecule involves an energy change of 20 ± 3 kcal mole^{-1}. However, the value of $E_{O_2^-}$ determined by other methods is much lower.

The dissociation energy of the O_2^- ion into O^- and O has been estimated from the Raman spectra of KO_2 as 2.99 eV, i.e. about 69 kcal mole^{-1}. [10] Consequently the O_2^- ion is less stable than the oxygen molecule. The O–O bond length in the O_2^- ion is greater than in the oxygen molecule. Earlier a value of 1.28 Å was adopted [10] but subsequent studies showed that it is in the range 1.82–1.35 Å. [12] The O_2^- ion has the form of an ellipsoid of rotation, the length of the major axis of which is 4.55 Å. The radius of each oxygen atom in O_2^- may be assumed to be 1.59 Å. [13] The major half-axis of the O_2^- ion is therefore 2.27 Å and the minor half-axis (or the transverse radius) is 1.52 Å. [7]

The absorption spectrum of O_2^- ions in an aprotic solvent has a maximum at 240 nm. [14]

The addition of two electrons to the oxygen molecule or of one electron to the O_2^- ion is not accompanied by evolution of energy, as in the formation of the O_2^- ion, but by its absorption,

$$O_2 + 2e \rightarrow O_2^{2-} - 110 \text{ kcal mole}^{-1},$$
$$O_2^- + e \rightarrow O_2^{2-} - 130 \pm 3 \text{ kcal mole}^{-1},$$

and the formation of the doubly charged negative O_2^{2-} ion [15,16], which forms part of peroxides‡.

In contrast to the O_2^- ion, which is known to occur in a free state [18] and which is capable of prolonged existence in aprotic solvents [19], the O_2^{2-} ion is known only in the crystal lattices of peroxides, where it is stabilised by cations with large radii. The appearance of the O_2^{2-} ion in aqueous solution is also possible: $H_2O_2(\text{liq.}) \rightarrow 2H^+ + O_2^{2-} - 56$ kcal mole^{-1}, but not in the gas phase, since in the latter case the formation of O_2^{2-} is exothermic: $H_2O_2(\text{gas}) \rightarrow 2H^+ + O_2^{2-} - 886$ kcal mole^{-1}. The electronic structure of O_2^{2-} may be represented by the formula $[:\ddot{O}\!\!-\!\!\ddot{O}:]^{2-}$, [4,20]§ and in molecular orbital terms by

$$[KK(z\sigma)^2(y\sigma^*)^2(x\sigma)^2(w\pi)^4(v\pi^*)^4].$$

The addition of two electrons to the antibonding orbital leads to a decrease of the bond order to unity. Evidently the doubly charged negative peroxide ion has an even number of electrons (fourteen) and one single bond. This is consistent with the diamagnetism and the lack of colour of peroxy-compounds containing this ion. The dissociation energy of the O_2^{2-} ion has been estimated as -125 kcal mole^{-1}, [21] while according to other data [22] it is -53.4 kcal mole^{-1}. Consequently the O_2^{2-} ion is less stable than the O_2^- ion and the oxygen molecule. The O–O bond length in O_2^{2-} is 1.40 Å, i.e. longer than in the O_2^- ion and in the oxygen molecule. Like O_2^-, the O_2^{2-} ion has the shape of an ellipsoid of rotation but with a somewhat less extended major axis, whose length is 4.19 Å. The radius of both O^- and O_2^{2-} is 1.35 Å. The major half-axis of the O_2^{2-} ion is therefore 2.09 Å and the minor half-axis (or the transverse radius) is 1.23 Å. [21,23]

The probable distribution of electrons in the three perpendicular 2*p* orbitals according to the quantum-mechanical representation of the electronic structure of the oxygen molecule and O_2^- and O_2^{2-} ions is illustrated schematically in Fig. 1. [24]

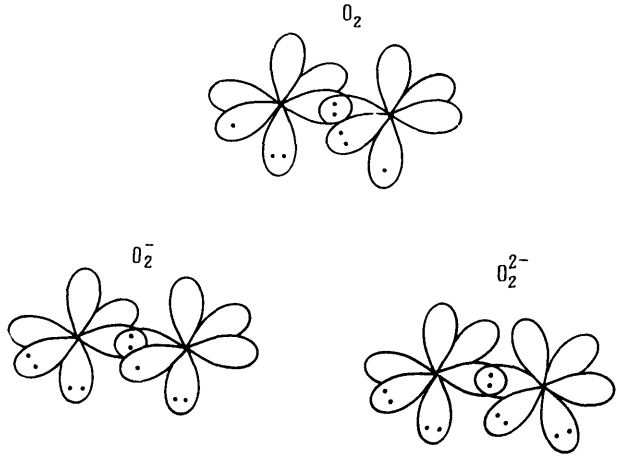

Figure 1. Schematic illustration of the probable distribution of electrons in three perpendicular 2*p* orbitals according to the quantum-mechanical representation of the electronic structure of the oxygen molecule and the O_2^- and O_2^{2-} ions.

In order to represent the electronic structure of the O_3^- ion, one must recall that the structure of ozone $:\!\overset{:O:}{\underset{:O:-:O:}{\diagup\diagdown}}$ proposed previously is in conflict with its enthalpy of formation, which amounts to +34.0 kcal mole^{-1}. If this structure is adopted, then ΔH_{298} for the formation of ozone

† The pernitride ion $[:\ddot{N}\!\!-\!\!\ddot{N}:]^{3-}$ has a similar electronic structure.

‡ The affinity of the oxygen molecule for two electrons quoted by Vedeneev et al. [17] (-175 ± 15 kcal mole^{-1}), obtained with the aid of the Born–Haber cycle on the basis of an approximate estimate of the lattice energies of alkaline earth metal peroxides, is inaccurate.

§ The O_2^{2-} has a structure which is isoelectronic with that of the fluorine molecule and is analogous to the structure of the disulphide ion $[:\ddot{S}\!\!-\!\!\ddot{S}:]^{2-}$.

should be 77.9 kcal mole^{-1}. According to Pauling [4,6], the electronic structure of the ozone molecule may be represented by a formula with eighteen electrons (Table 1). Then the structure of one of the terminal oxygen atoms in the ozone molecule resembles that of the fluorine atom; it completes its octet by sharing one electron pair with a neighbouring oxygen atom. Such an atom may be regarded as a negative ion $:\ddot{O}\cdot^-$ forming one covalent bond. The central atom may be regarded as a positive oxygen ion $:\dot{O}^+$ forming three covalent bonds: one single bond with the left-hand side oxygen atom and one double bond with the right-hand side oxygen atom. The angle at the vertex is 116°4′ according to Trambarulo [25] and 127°3′ according to Hughes [26].

Table 1. Principal characteristics of the bond types in the molecules of oxygen and ozone and their molecular anions.

Formula	Electronic structure	O–O bond length, A	Bond dissociation energy, kcal mole^{-1}	Electron affinity E, kcal mole^{-1}
O_2	:O ⋮⋮ O:	1,207	118	20±3
O_2^-	[:O ⋮⋮ O:]$^-$	1.32—1.35	69	130±3
O_2^{2-}	[:Ö–Ö:]$^{2-}$	1.49	—125	—
O_3		1.278	25.1	44±10
O_3^-		(1.19—1.22)	—	—

Table 1 presents two structures for the ozone molecule. This implies that the two terminal oxygen atoms are equivalent. Using the terminology of the resonance theory, one may say that each bond in the ozone molecule is a hybrid of a single and a double bond.

The addition of one electron to the ozone molecule results in the evolution of energy, $O_3 + e \rightarrow O_3^-$ + 66.5 kcal mole^{-1}, [25,27] or, according to later data, +44 ± 10 kcal mole^{-1}, [28] and the formation of the singly-charged negative ion O_3^- which enters into the composition of ozonides. The electron structure of the O_3^- ion may be represented by the formula quoted in Table 1. Evidently the singly-charged negative ozonide ion has an odd number of electrons (nineteen), in agreement with the paramagnetism and colour of compounds containing it. The dissociation energy of the O–O bond in the O_3^- ion is unknown, but it is probably lower than the dissociation energy of this bond in the ozone molecule itself, giving O_2 and O, which amounts to 25.1 kcal mole^{-1}. [9] Consequently in the series of molecular oxygen anions, the O_3^- anion is least stable, though, according to not altogether reliable data [29,30], its O–O bond length is smaller than in the other ions discussed above and even in the oxygen molecule itself. It is 1.19–1.22 Å, [29,30] while in ozone it is 1.278 Å [25] or, according to later data [26], 1.260 Å. The angle at the vertex of the O_3^- ion is 100°. [29]

Table 1 presents the principal characteristics of the bond types in oxygen and ozone molecules and their molecular anions.

Simple Inorganic Peroxy-compounds

Inorganic peroxy-compounds, the crystal lattices of which contain the above oxygen anions O_2^{2-}, O_2^-, O_3^- and also the hydroperoxide anion HO_2^- should be classified as simple peroxy-compounds.

Simple inorganic peroxy-compounds can be divided into four groups: (1) peroxides, the crystal lattices of which contain the peroxide ions O_2^{2-}; (2) superoxides incorporating the superoxide ions O_2^-; (3) ozonides incorporating the ozonide ion O_3^-; (4) hydroperoxides.

The crystal lattices of hydroperoxides, which have the general formula EOOH, contains the hydroperoxide ion HO_2^-. In these compounds the peroxo-group is linked by an ionic bond to the atom of the element E and by a covalent bond to the hydrogen atom. The ionic character of hydroperoxides has been demonstrated experimentally only for the compound NH_4OOH. [31,32] It is also confirmed by the fact that hydrogen peroxide is a weak acid with $K = [H^+][HO_2^-]/H_2O_2 = 2.24 \times 10^{-12}$.

It is noteworthy that certain hydroperoxides may be regarded as peroxyhydrates and others as peroxo-acids. For example, NaOOH may be represented as the peroxyhydrate $Na_2O_2.H_2O_2$, and the compound $(OH)_3TiOOH$ may be regarded as a peroxo-acid.

Compounds in which the peroxo-group is linked to the atom of the element forming the peroxy-compound by a coordinate bond involving the π bonding orbitals of the O_2^{2-} ion should be included among complex peroxy-compounds, which will be described in detail in the next section. Complex peroxy-compounds include also peroxide hydrates, adducts of peroxides and salts with hydrogen peroxide, and compounds containing in the inner sphere H_2O_2 molecules or HO_2 radicals.

A characteristic property of peroxy-compounds, both simple and complex, is their capacity to form hydrogen peroxide on interaction with dilute solutions of acids and also to evolve oxygen readily in an active form on thermal decomposition or under the influence of water and other chemical agents. The "superoxide" oxygen evolved by peroxides has come to be referred to as "active". Other inorganic compounds which can serve as sources of oxygen, for example nitrates, chlorates, perchlorates, permanganates, and certain oxides [33], do not evolve oxygen under the action of water; they do so only on heating to high temperatures and in the presence of catalysts. Potassium dichromate, manganese dioxide, and lead dioxide evolve oxygen only on interaction with concentrated sulphuric acid solutions.

The difference in the type of bond between the oxygen atoms in the "bridges" of peroxides and hydroperoxides on the one hand and in superoxides and ozonides on the other is clearly revealed on hydrolysis. Peroxides and hydroperoxides are hydrolysed according to the equations $M_2O_2 + H_2O \rightarrow 2MOH + H_2O_2$ and $MOOH + H_2O \rightarrow MOH + H_2O_2$ (where M is the metal atom) with formation of hydrogen peroxide, which is quantitatively titrated with acid permanganate. The formation of hydrogen peroxide on hydrolysis of peroxides and hydroperoxides indicates a clear genetic relation between these compounds and hydrogen peroxide. Therefore peroxides and hydroperoxides have long been regarded as salts of hydrogen peroxide with two and one metal atoms.

Superoxides are hydrolysed with formation of an intermediate HO_2 radical (the hydroperoxyl) according to the equations

$$\begin{array}{l} 2MO_2 + 2H_2O \rightarrow 2MOH + 2HO_2, \\ 2HO_2 \rightarrow H_2O_2 + O_2, \\ \hline 2MO_2 + 2H_2O \rightarrow 2MOH + H_2O_2 + O_2, \end{array}$$

Consequently two-thirds of the active oxygen, constituting the "superoxide oxygen", is evolved as O_2 and can be determined gas-volumetrically and one-third of the active oxygen, which constitutes the "peroxide oxygen", is evolved as H_2O_2 and can be titrated with acid permanganate. Ozonides are hydrolysed without the formation of H_2O_2 according to the equation $MO_3 + H_2O \rightarrow MOH + OH + O_2$.

The reactions occurring on hydrolysis of superoxides and ozonides reveal a clear genetic relation, noted by Kazarnovskii, between superoxides and the H_2O radical and between ozonides and the hypothetical radical HO_3 (the hydro-ozonyl).[34]

The term peroxide was introduced in the Russian nomenclature by D.I. Mendeleev, who wrote, emphasising the lack of similarity in the reactions of the peroxides MO_2 and the salt-forming oxides of the same composition, that "the concept of peroxides is indefinite if one includes among them not only H_2O_2, Na_2O_2, and BaO_2 but also MnO_2 and PbO_2".[35] The definitions of "peroxide" quoted in the textbook of Gess [Hess?][36] and Shcheglov[37] suffer from this lack of clear-cut significance. Unfortunately certain contemporary chemists both in the USSR and abroad continue to employ the term peroxides for quadrivalent lead and manganese oxides the molecules of which contain the oxide ion O^{2-} with the electron structure $[:\ddot{O}:]^{2-}$. The nitrogen (IV) oxide N_2O_4, in the molecule of which there is no peroxo-group and the oxygen atom is linked covalently to the nitrogen atom, is also incorrectly called a peroxide.

The principal feature distinguishing peroxide from oxides of the type MO_2 is the reaction with dilute acids. As mentioned above, the former form H_2O_2, and the latter can, for example, evolve chlorine from hydrochloric acid.

The term hydroperoxide (gidroperekis') was adopted in the Russian literature as the translation of the German term Hydroperoxyd[38].

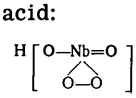
The term superperoxide (nadperekis') was introduced into the Russian nomenclature in 1948 [39] and is more apt than the term "tetroxide" adopted previously[40], since it has been shown[4,7] that there is no O_4^{2-} ion in the molecules of these compounds. The term superperoxide has become firmly established in the Russian chemical nomenclature[41-43]. In 1947 the term "dioxide" was proposed for these compounds[44], as in the German nomenclature[45], and later the term "superoxide" ["superoksid"][46], a translation of the corresponding English term, was suggested by Neuman[47]. This term was adopted[48] in 1953 in the English, French (superoxyde), German (Superoxyd), and Italian (superossido) nomenclature, but in 1957 the International Union of Pure and Applied Chemistry approved the terms hyperoxide and hyperoxyde[49,50] on the basis of the term Hyperoxyd proposed by Remy[51] for the German nomenclature. While there names are justified by the fact that in the above languages we have the terms oxide, oxyde, Oxyd, and ossido and also peroxide, peroxyde, Peroxyd, and perossido, in the Russian nomenclature the terms "superoksid" (superoxide) and "giperoksid" (hyperoxide) are in no way justified, since the terms "okis'" (oxide) and "perekis'" (peroxide)[52] have been generally adopted for the lower degrees of oxidation and not "oksid" (oxide) and "peroksid" (peroxide), as suggested by some workers[53-56]. Moreover the Russian suffix "nad" corresponds to the Latin suffix super and the Greek suffix $\upsilon\pi\epsilon\rho$. Therefore the term "nadperekis'" (superperoxide) is quite acceptable¶. Evidently, on the basis of the same considerations, the term "nadokis'" (superoxide) was proposed[52]. However, it is close in significance to the term "perekis'" (peroxide) and does not reflect the fact that the relevant compounds contain more active oxygen than a peroxide. The proposed term "superoksid" (superoxide) for peroxides of the type M_2O_2 is quite inappropriate[56].

The term "inorganic ozonide" was introduced by Kazarnovskii[57] and has been adopted by the International Union of Pure and Applied Chemistry[49,50].

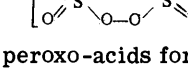
Complex peroxy-compounds may be divided into five groups.

1. Peroxo-acids and their salts, in which the peroxo-group† enters into the composition of the complex anion. Mononuclear peroxo-acids and their salts are known, for example, peroxomonosulphuric acid:

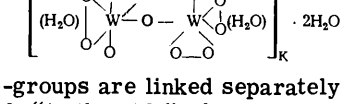
and peroxomononiobic acid:



as well as polynuclear peroxo-acids and their salts. In these compounds the atoms of elements in Groups IV–VI of the Periodic System—the non-metals carbon, nitrogen, phosphorus, and sulphur or the metals titanium, vanadium, chromium, niobium, molybdenum, tantalum, and tungsten—usually function as the coordinating species. In polynuclear peroxo-acids formed by non-metals, the atoms of the coordinating element are linked via a peroxo-group, as, for example, in peroxodisulphuric acid:



In polynuclear peroxo-acids formed by transition elements, the linkage between the atoms of the coordinating element is formed via one oxygen atom, as, for example, in potassium tetraperoxotungstate[59,60] or tetraperoxomolybdate[61]:

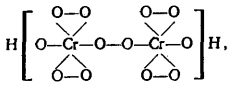


The peroxo-groups are linked separately by two covalent π bonds "to the side" of each atom of the coordinating element. The O–O bond length is 1.50 Å in the tungsten compound[60] and 1.48 Å in the molybdenum compound[61]. The peroxy-complexes of titanium[62], in which the O–O bond length is 1.45 Å, have the same structure.

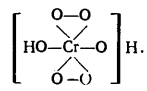
¶ If the term "oksid" (oxide) proposed by the authors of projects for the Russian nomenclature[53,54] and Kazarnovskii[55] is approved, the above remarks concerning the term "superoksid" (superoxide) will be no longer valid and the terms "perekis'" (peroxide) and "gidroperekis'" (hydroperoxide) should be replaced by "peroksid" (peroxide) and "gidroperoksid" (hydroperoxide).

† At the XXIInd Congress of the International Union of Pure and Applied Chemistry, the term "peroxido-group" was adopted instead of "peroxo-group"[58].

The presence of a linkage between the atoms of the coordinating element via an "oxygen bridge" in polynuclear peroxo-acids of certain other transition elements appeared controversial. For example, until recently [63] it was believed that there exist polynuclear peroxochromates with the composition $M_2[Cr_2O_{12}]$ to which the formula of pentaperoxodichromic acid was attributed:



However, according to later data [64,65], the mononuclear structure of oxomonohydroxodiperoxochromic acid was established for this compound:

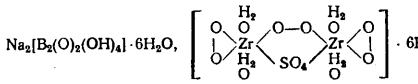


The O–O bond length in derivatives of chromium peroxo-acids is 1.40–1.47 Å. [65] The O–O bond length in peroxoacid derivatives of non-metals, for example, in the compounds $(NH_4)_2S_2O_8$ and $Cs_2S_2O_8$, is 1.46 Å. [66]

2. Peroxy-complexes which are not peroxoacids or their derivatives. These can also be divided into mononuclear and polynuclear. The mononuclear compounds may contain the peroxo-group in the inner sphere, for example $M_2[Nb(O-O)Cl_5]$, and $M_2[Mo(O-O)_2OCl_4]$, and may be combined in the subgroup of peroxo-complexes. It is noteworthy that, whereas the oxo-group always behaves as a monodentate ligand, the peroxo-group, owing to the greater length of the O–O bond, can behave as a bidentate ligand and can promote the formation of compounds with a coordination number of seven and particularly eight. This possibility diminishes in the series Cr < Mo ≃ W and V < Nb ≃ Ta. The possibility of the existence of a peroxo-ligand and other ligands around the central atom of the complex depends both on the nature of the central atom and on the conditions in the medium where the compound is synthesised. It depends on the pH of the solution and on the oxidation–reduction properties of the ions involved in the reaction.

Mononuclear peroxy-complexes also include compounds with hydrogen peroxide molecules in the inner sphere, for example $[Fe(H_2O)_5(H_2O_2)]^{3+}$. Compounds of this kind constitute the group of perhydro-complexes. Finally hydroperoxy-radicals may be coordinated in the inner sphere, as, for example, in $K_3[Co(CN)_5OOH]$. Compounds of this type constitute the subgroup of hydroperoxo-complexes.

Compounds of the type



$[(NH_3)_5Co-O-O-Co(NH_3)_5](NO_3)_5$ and others

may serve as an example of polynuclear peroxy-complexes which are not peroxo-acids.

The bond length in the first compound is 1.47 Å [67] and in the last 1.45 ± 0.06 Å. [68] In contrast to derivatives of binuclear peroxo-acid derivatives of transition elements, in these compounds the linkage between the metal atoms is formed via an "oxygen bridge".

The comparatively recently discovered complex peroxy-compounds formed by the addition of oxygen to certain reactive d^8 and d^{10} complexes of iridium, rhodium, platinum, palladium, and nickel are of some interest. For example, the iridium complex $IrO_2Cl(CO)(PPh_3)_2$, in which the O–O distance is 1.30 ± 0.003 Å, i.e. close to the O–O distance in the O_2^- anion, has been isolated [69–71]. However, this compound is diamagnetic like all other similar derivatives. It is interesting to note that the O–O bond length in iridium complexes of this kind and their capacity for combination with oxygen increase with increasing capacity of the other ligands to lose electrons.

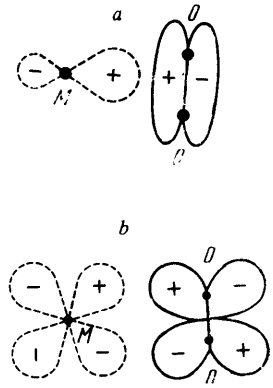


Figure 2. *a*) Transfer of π electrons from the donor (oxygen) to free *d* orbitals of the metal; *b*) transfer of *d* electrons from the metal to the antibonding orbital of the donor.

For example, in the iodide complex $IrO_2I(CO)(PPh_3)_2$, the O–O distance is 1.51 Å, i.e. close to the O–O distance in the O_2^{2-} anion, while in the phosphine chelate complex $IrO_2(PAr_2)_4$ [probably $IrO_2(P_2Ar_4)$, (Ed. of Translation)] the distance is 1.66 Å, i.e. greater by 0.17 Å than in the O_2^{2-} molecular anion. The reason for the increase of the O–O bond length should probably be sought in the fact that these compounds have a metal–oxygen bond $(L)_nM\leftarrow\overset{O}{\underset{O}{\|}}$ of the π type [72]. In this bond type, one may expect a transfer of π electrons from the donor (oxygen) to the free *d* orbitals of the metal, as shown schematically in Fig. 2*a*, and also a transfer of the *d* electrons of the metal to the antibonding orbital of the donor, as shown schematically in Fig. 2*b*. The overall effect is the transfer of electrons from the bonding to the antibonding orbital of the donor via the metal. This is reflected in a decrease of bond energy and consequently in an increase of bond length. The stronger the linkage between the donor and the metal, the greater the bond length.

The most important property of these complexes is their capacity to oxidise substrates under unusually mild conditions [73].

3. Peroxide hydrates—adducts of peroxides and water of crystallisation, for example $CaO_2.8H_2O$.

4. Peroxyhydrates—molecular compounds, resembling hydrates, containing hydrogen peroxide of crystallisation, for example $CaO_2.2H_2O_2$ and $K_2CO_3.3H_2O_2$.

The analogy between the peroxyhydrates of peroxides and their hydrates is not rigorous. In the former the hydrogen peroxide molecules are linked to O_2^{2-} ions by strong hydrogen bonds, forming infinite chains. The nature of peroxyhydrates of peroxides is close to that of compounds of the type KF.HF.[74] Molecular compounds with H_2O_2 are also formed by ammonia and certain organic compounds with basic properties.

5. Hydrates of peroxyhydrates—molecular compounds containing both water and hydrogen peroxide of crystallisation, for example $BaO_2.H_2O_2.2H_2O$ and $Na_2SO_4.0.5H_2O_2.H_2O$.

The term "peroxoacid" ("peroksokislota") is the English term recommended by the International Union of Pure and Applied Chemistry[48]. The necessity to introduce into the Russian nomenclature this term, in the place of the previously adopted "nadkislota" ("peracid") proposed by Mendeleev[75] arose due to the following considerations.

For example, the compound $H_2S_2O_8$ is at present called persulphuric acid (nadsernaya kislota) in the Russian nomenclature. The terms "sulphuric acid" ("sernaya kislota" and "sulphurous acid" ("sernistaya kislota") have been adopted for oxyacids of sulphur. They emphasise that in the first compound sulphur is in the hexavalent state and in the second in the quadrivalent state. The term "persulphuric acid" is unwittingly associated with the idea that in this compound sulphur has a valence higher than six, which is not the case. Moreover, the compound H_2SO_5 is nowadays called monopersulphuric acid (mononadsernaya kislota). It would be quite logical to assume, as rightly pointed out by Gussein-zade[76], that the prefix "mono" indicates the number of peroxo-groups in the compound, since otherwise it should be referred to as permonosulphuric acid (nadmonosernaya kislota). In fact, in the above example the prefix "mono" indicates the number of sulphur atoms. Like the preceding compound, $H_2S_2O_8$ contains one peroxo-group but two sulphur atoms, which is not reflected in its name (persulphuric acid). The use of the terms "peroxomonosulphuric" and "peroxodisulphuric" for the compounds H_2SO_5 and $H_2S_2O_8$ removes this inconsistency. If in any other peroxoacid the number of peroxo-groups is greater than unity, as, for example, in peroxochromic acid H_3CrO_8 where there are four such groups, it should be designated as a tetraperoxoacid, i.e. tetraperoxomonochromic acid.

As regards the nomenclature of peroxoacid salts, it is noteworthy that the terms persulphates, percarbonates, perborates, etc. which persist in the chemical literature, are very inapt and lead to the incorrect idea that they resemble the salts of certain oxygen-containing acids, such as perchlorates, permanganates, perrhenates, etc., where the prefix "per" indicates merely the highest degree of oxidation of the element and not the presence of the peroxo-group. Certain salts of oxygen-containing acids (for example, perchlorates and permanganates) also serve as sources of oxygen in thermal decomposition. However, in contrast to the thermal decomposition of peroxoacid derivatives, their decomposition involves a change in the valence of the elements forming these compounds. For example, whereas in the thermal decomposition of potassium peroxodisulphate according to the equation $K_2S_2O_8 \rightarrow K_2SO_4 + SO_3 + 0.5O_2$ sulphur retains a valence of six in the decomposotion products, in the thermal decomposition of potassium perchlorate or permanganate according to the equations $KClO_4 \rightarrow KCl + 2O_2$ and $2KMnO_4 \rightarrow K_2MnO_4 + MnO_2 + O_2$, the chlorine in the decomposition products has passed from the heptavalent to the univalent state and the manganese from the heptavalent to the hexavalent and quadrivalent state. The terms peroxosulphates, peroxocarbonates, etc. are correct for peroxoacid salts. According to crystal structure data[67], infrared and NMR spectroscopy[77], and magnetic measurements[78,79], "perborates" may be divided into two groups: those containing water may be referred to as diperoxodiborotetrahydroxo-salts and the anhydrous compounds may be designated by the term peroxoborates.

The general term peroxy-complexes is not open to objection. The term peroxyhydrate has also been recommended by the International Union of Pure and Applied Chemistry[48]. It is to be preferred to the terms "perhydrate"[90] and "hydroperoxate" proposed by American workers[81].

The difference in the type of bond between the "oxygen bridge" and the element forming the peroxy-linkage in peroxoacids and their salts compared with peroxides, superoxides, and ozonides is also shown in hydrolysis. For example, in the hydrolysis of peroxodisulphuric acid $H_2S_2O_8$ or peroxodisulphate salts, peroxomonosulphuric acid H_2SO_5 is formed initially without the formation of hydrogen peroxide, according to the equation $H_2S_2O_8 + H_2O \rightarrow H_2SO_5 + H_2SO_4$ and then peroxomonosulphuric acid yields hydrogen peroxide according to the equation $H_2SO_5 + H_2O \rightarrow H_2SO_4 + H_2O_2$. However, at room temperature the hydrolysis is very slow and involves considerable loss of active oxygen. Although on heating the rate of reaction does increase, there is a simultaneous increase of the amount of oxygen evolved. Consequently, the quantitative determination of active oxygen in these compounds cannot be achieved by permanganate titration and iodometric titration is employed.

Peroxy-complexes which are not peroxoacids or derivatives of peroxoacids hydrolyse in most cases with formation of hydrogen peroxide, but certain mononuclear peroxy-complexes, for example $[(NH_3)_5Co-O-O-Co(NH_3)_5]^{5+}$ are extremely stable in relation to water and give rise to H_2O_2 only in an acid medium.

When peroxyhydrates react with water, hydrogen peroxide of crystallisation passes to the solution and may be determined quantitatively by permanganate titration in an acid medium.

A new class of peroxides—organometallic peroxides—the composition of which includes one or several metal atoms, peroxy-groups, and organic residues, are of special interest[82]. For example silicon, germanium, tin, and lead are capable of forming symmetrical peroxides of the type R_3MOOMR_3, in which the linkage between the atoms of the element is achieved via an "oxygen bridge".

Table 2 presents a scheme for the classification and nomenclature of inorganic peroxy-compounds proposed by the author of this review[83-85] and supplemented by taking into account the latest data on their structure.

The methods of synthesis of each group of peroxy-compounds quoted in Table 2 are different. Hydroperoxides are synthesised mainly via alkoxides in an anhydrous medium. Peroxides are synthesised by the reaction of oxides with oxygen or via solutions of the hydroxides and hydrogen peroxide. Superoxides are synthesised mainly via the metals, by their combustion in oxygen at the normal pressure, and also by the action of oxygen on peroxides at the normal or elevated pressure. Ozonides are obtained by the reaction of ozone with hydroxides or superoxides with subsequent extraction by liquid ammonia. Peroxoacids and the peroxoacid salts of

Table 2. Classification and nomenclature of inorganic peroxy-compounds.

Type	Group			Formula
Simple	Hydrogen polyoxides			H_2O_2, H_2O_3, H_2O_4
	Hydroperoxides			M^IOOH
	Peroxides			$M^I_2O_2$
	Superoxides			M^IO_2
	Ozonides			M^IO_3
	Peroxoacids and their salts	Mononuclear		$[E^{IV}O_4]^{2-}$; $[E^VO_5]^{3-}$; $[E^{VI}O_5]^{2-}$; $[E^{VI}O_6]^{2-}$
		Polynuclear	With peroxo-bridges	$[O_2E^{IV}-O-O-E^{IV}O_2]^{4-}$; $[O_2E^V-O-O-E^VO_3]^{4-}$; $[O_2E^{VI}-O-O-E^{VI}O_2]^{2-}$
			With oxo-bridges	$[(O-O)_2OE^{VI}-O-E^{VI}O(O-O)_2]^{2-}$
Complex	Peroxy-complexes	Mononuclear	Peroxo-	$[M(O-O)_x(L)_y]^n$
			Perhydro-	$[M(H_2O_2)_x(L)_y]^n$
			Hydroperoxo-	$[M(HO_2)_x(L)_y]^n$
				$n=0,\pm1,2,3\ldots$
		Polynuclear		$[(L)_yMO-OM(L)_y]^n$
	Peroxide hydrates			$M^I_2O_2\cdot xH_2O$
	Peroxyhydrates	of peroxides		$M^I_2O_2\cdot xH_2O_2$
		of salts		$M^I_nEO_m\cdot x\cdot H_2O_2$
	Peroxyhydrate hydrates	of peroxides		$M^I_2O_2\cdot xH_2O_2\cdot yH_2O$
		of salts		$M^I_nEO_m\cdot x\cdot H_2O_2\cdot yH_2O$

		Heteroradical		$R_nMOOMR^1_n$
		Heteroelemental		R_nMOOCR_n

M = metal, E = element, L = ligand, and R = organic group.

typical elements are synthesised predominantly by the electrolytic method. The peroxoacids of transition elements and their salts are synthesised via solutions of oxygen-containing acids of these elements and of hydrogen peroxide. Peroxy-complexes which are not derivatives of peroxoacids are obtained mainly with the aid of solutions of hydrogen peroxide, but in many cases oxidation with molecular oxygen is employed. The addition of molecular oxygen to the coordinating element in compounds of certain transition metals may be represented schematically as follows:

$$M^{n+} + O_2 \xrightarrow{I} M^{n+}(O_2) \xrightarrow{II} M^{n+2}(O_2^{2-}).$$

Oxygen carriers are formed reversibly via mechanism I, while mechanism II involves the irreversible formation of peroxy-complexes where the metal passes to a higher valence state and in the case of binuclear complexes μ-peroxo-compounds are produced.

Peroxyhydrates and their hydrates are formed exclusively from hydrogen peroxide solutions. Organometallic compounds form organometallic peroxo-derivatives on reaction with peroxy-compounds or on oxidation with molecular oxygen.

The difference between the structures of inorganic peroxy-compounds is responsible for the difference between their physical properties and reactivities and hence for the possibility of employing them under a wide variety of conditions.

The above data concerning the radical differences between the molecular oxygen anions and the different states of the peroxo-group in complex peroxy-compounds demonstrate that inorganic peroxy-compounds cannot be characterised by the words "these are compounds incorporating an oxygen bridge". Additional evidence showing that this definition is not altogether satisfactory comes from the elucidation of the structure of the compound F_2O_2, which has been incorrectly called[15] fluorine peroxide. It has been established[86,87] that in the oxygen fluoride F_2O_2 the fluorine atoms are joined by the "oxygen bridge" O–O, although this compound does not exhibit the properties of peroxides. The O–O bond length in this compound (1.22 Å) differs little from the bond length in the oxygen molecule. On coming into contact with ice, F_2O_2 (m.p. 64.3°) explodes with evolution of oxygen[88]. The energy of the dissociation of F_2O_2 into 2OF is 62.3 ± 20 kcal mole^{-1}.[89]

The so called dioxygenyl compounds incorporating the O_2^+ ion, for example the compounds $O_2^+PtF_6^-$[90] and $O_2^+BF_4^-$[91] are not peroxides either. The formation of the O_2^+ ion is accompanied by the evolution of 286 kcal mole^{-1} and the energy of dissociation into $O^+ + O$ is 153.48 ± 0.05 kcal mole^{-1}.[92] The interatomic distance in the O_2^+ molecular ion, which is formed on removal of one electron from the $\nu\pi^*$ level, is reduced to 1.1227 Å compared with 1.2074 Å in the oxygen molecule, while, as stated above, on formation of peroxide anions the above distance increases owing to the introduction of additional electrons in the same level[93].

Methods for the Preparation of Refractory Compounds of Transition Metals and Prospects for Their Development

V.N.Gurin

The principal methods for preparing borides, carbides, silicides, nitrides, and oxides of transition metals in Groups IV-VI are surveyed. Distinctions between the concepts "method" and "process" of preparation are examined. The main parameters of methods and processes—temperature, time, chemical reactions, etc.—are summarised in tables. General theoretical schemes for preparation from solutions in melts and by the electrolysis of melts and solutions in melts are discussed in detail. Several prospects for the development and utilisation of the above methods of preparation are indicated. A list of 377 references is included.

I. INTRODUCTION

The refractory compounds of transition metals are their binary compounds with boron, carbon, nitrogen, oxygen, and silicon (the sulphides, selenides, phosphides, and certain other transition-metal compounds can also be included to some extent).

The vigorous development of various branches of modern technology, such as nuclear power, space technology, various direct methods of transformation into electrical energy, etc.—all this requires the application of considerable quantities of various refractory compounds. Their preparation sometimes presents considerable difficulties, for various reasons—high cost or inadequate purity of the initial products, low yield, poor reproducibility and danger of some methods of preparation, and also the poor quality of the products.

Nevertheless, modern technology demands increased reliability in objects made of refractory compounds, with stable properties (both invidivual and combined) under the most severe operating conditions. In many cases only single crystals of these compounds are able to exhibit such properties, and their production becomes an important technical problem. It can be solved in two ways—(*a*) by obtaining single crystals from the ready made compounds (by Czochralski crystal pulling, zone melting, gas transport, etc.), and (*b*) by growing them in the course of preparing the compounds (from the gas phase, from solution, etc.)—neither of which has yet been significantly investigated in its application to borides, carbides, nitrides, oxides, or silicides of transition metals. Development of the first procedure is restricted by the high temperatures of the molten compounds, their great reactivity and the lack of suitable inert materials for the crystallisers, and also the incongruent melting of several of the compounds. Development of the second procedure is made difficult by the problems of controlling the complicated mechanisms of the crystallisation of refractory compounds either from the gas phase or from solutions in and also by the absence of definite information on the structure of such solutions. The state of these procedures, especially the second, is evidence of the need for its further theoretical and experimental investigation, and the necessity of developing and improving methods for the preparation of refractory compounds.

The present Review surveys methods for the preparation of refractory compounds of transition metals in Groups IV–VI and the prospects for developing these methods both in general and in application to the growth of single crystals.

II. PRINCIPAL METHODS FOR THE PREPARATION OF REFRACTORY COMPOUNDS

The main existing methods for the preparation of refractory compounds have been quite fully classified in monographs and volumes of papers[1-26]. An analysis of these classifications suggests a somewhat modified classification—(1) direct synthesis from the elements, (2) preparation from solutions in melts, (3) electrolysis of melts and solutions in melts, (4) metallothermic reduction of metal oxides, (5) reduction of oxides and other compounds by non-metals and their compounds, and (6) gas-phase preparation.

This classification is based on combining most logically and completely the principles of adequacy of the initial components and the type (kinetic mechanism†) of the chemical reactions. Thus, for example, the state of aggregation of the reactants (gaseous, liquid, or solid) alone does not indicate the specific character of individual methods (electrolysis, preparation from molten solutions), and either of the above principles separately is an insufficient condition of classification: adequacy of the initial components does not distinguish metallothermic reduction of

† The kinetic mechanism must be taken as meaning a definite number and sequence of stages of chemical reactions, leading to the formation of definite chemical compounds.

oxides from their reduction by non-metals, and the same type of reaction identifies direct synthesis from the elements with synthesis from solutions in melts, gas-phase synthesis with reduction of oxides, etc.

It is also necessary to make a clear distinction between two concepts—method and process of preparation—which differ in extent; this distinction is by no means always made in the scientific literature. It can be concluded from the definitions [27-33] that, although in all cases "method" and "process" are actually equated, nevertheless a wider range of phenomena and even a set of phenomena are covered by a method [29-31,33]. Hence we consider the concept "method" to be more general that that of "process", which is a particular case of a "method". The mixing of these ideas, which is often met in the literature, leads to confusion and uncertainty, and does not promote a correct classification, in particular of modes of preparation. In this connection the following definitions may be suggested for these concepts.

Method of preparation is the accomplishment of a chemical reaction between elements or chemical compounds of certain classes by a definite kinetic mechanism.

Process of preparation is a particular embodiment of a method, i.e. the actual accomplishment of a chemical reaction with a definite kinetic mechanism under given specific conditions—with given reactants, a given technical operation of the method, and given state of aggregation of the reactants and products.

Let us examine the above methods for the preparation of refractory compounds, in particular information on their discovery, development, chemical reactions, conditions of preparation, industrial applications, use for the production of single crystals, virtues, defects, and development prospects. The sets of chemical reactions and the conditions of preparation in Tables 1–6 have been compiled from the original papers, in which the methods and processes were first developed. References to more than one worker as the first to discover or develop a given process are explained by significant and fundamental modifications of a process effected by subsequent investigators. It is noteworthy also that all methods of preparing nitrides and oxides are in fact variants of a semi-gaseous method (owing to the gaseous state of nitrogen and oxygen under the conditions of preparation); in view of the above conditions of classification, however, they are not included among the gas-phase preparations (Table 6), but are placed in the appropriate tables.

Tables 1–6 have been compiled not only from periodicals and special publications but also from all the available most general reviews and monographs on the preparation and technology of refractory compounds [1-26]. Among papers of the same type we have considered only those in which processes were developed for the first time, which are the most characteristic and representative, or which are concerned with the larger number of refractory compounds.

III. DIRECT SYNTHESIS FROM THE ELEMENTS

This method consists essentially in the reaction between a transition metal (M = Ti, Zr, Hf, V, Nb, Ta, Cr, Mo, W) and a non-metal (Nm = B, C, N, O, Si)

$$xM + yNm \rightarrow M_xNm_y$$

which can be effected with the components in various states of aggregation (gaseous G, liquid L, solid S). This is a redox reaction: both transition metals and non-metals can function as oxidants and reductants. Electronic processes in the formation of a chemical bond in the "molecules" of refractory compounds are especially complicated by the presence of valency d-electrons in transition metals. These and s-electrons, together with the s- and p-electrons of the non-metals, are involved in the formation of conduction bands and valency bands when the refractory compounds are formed in the condensed phase. The topography of the electron density in the solid phase of such compounds is extremely complicated: according to some workers [34,35] it is characterised by greater density either on the cores of the metal atoms, which when isolated have about 5 or 10 valency d-electrons, or on the cores of the non-metal atoms, whose electronic structure (valency electrons) is close to sp^3 or s^2p^6.

The time τ and the temperature limits T of homogenisation of refractory compounds in their direct synthesis are determined by the exponential relation $\tau^{-1} = K \exp(-Q/RT)$, where Q is the activation energy of homogenisation. The uppermost temperature limits are determined by the temperatures at which the compounds decompose, but in practice they are governed by the limit at which the materials from which the apparatus is made remain inert. Relatively little study has yet been made of the use of ultrahigh pressures in direct synthesis, but they show some promise for obtaining new modifications of such compounds, possessing more extreme properties [36,37].

Table 1 lists the main characteristics of existing processes for the direct synthesis of borides, carbides, nitrides, and silicides [38-67].

The process of melting the elements together was first used for the synthesis of silicides by Berzelius [68] and later by Moissan [40], who used it also to obtain borides [39] and carbides [38]. Sintering or saturation was first applied to the synthesis of nitrides [67,69,70] and then also for borides [42-44,46], silicides [48,54], and carbides [47]. The process of hot extrusion was first tried for the preparation of silicides [54]; carbides [52,53] and borides [51] were obtained later. The above processes were first developed in various forms by many investigators: the smelting of borides [42-45], carbides [56], and silicides [58], the sintering of borides [49], carbides [47,57], and silicides [59,60], the saturation of nitrides [57,71-77], and also the hot extrusion of borides [55], carbides [52,53], and silicides [11,14,62-66] have continued to be improved until the last decade. Oxides, which are produced from ores [78-86] and various compounds [87-92], are synthesised by the present method only under special conditions (in a plasma [93], in an electric discharge [94]) or in order to obtain special deposits (films [95]).

Application of method in industry. (1) Fusion for tungsten carbide [56,96]; with arc melting shows promise for obtaining all clasess of compounds [97]. (2) Sintering (saturation) for borides [13], carbides [16], silicides [11], and nitrides [20,98]. (3) Hot extrusion mainly for higher borides [13,55], carbides [14], and silicides [14].

Growth of single crystals. Kiessling used this method by sintering chromium boride (20 days). [42-44]

Advantages of method. (1) Possibility of obtaining large quantities of refractory compounds. (2) Production by hot extrusion of ready-made articles of borides, carbides, and silicides, including those fused to

Table 1. Direct synthesis from the elements.

Compounds	Process	Synthetic reaction	Refs	Conditions of preparation				Ref
				t, °C	time	medium	pressure	
Borides	melted together	$M_L + Nm_{L,S} \rightarrow MNm_L$ (assumed)		1200—2000	0.5 h	vacuum	—	42—44

	hot extrusion	$M_{S,L} + Nm_L \rightarrow MNm_{S,L}$ (assumed)		1000—1600	1.5—8 min	air, vacuum, H_2	~200 kg cm^{-2}	61—66
			51—54	1300—2100	2—10 min	air, vacuum, H_2	~220—250 kg cm^{-2}	11, 14
Nitrides	saturation	$M_S + N_{2,G}(NH_{3,G}) \rightarrow MN_S(+H_{2,G})$	57,67	1100—1200	2 h	N_2, N_2+H_2	—	57

100% density [99]. (3) Simplicity of apparatus for the synthesis. (4) Comparatively short times of synthesis. (5) Possibility of obtaining carbides in fibre form [100].

Disadvantages of method. Difficulty of obtaining exact composition of borides and silicides (especially the lower compounds), and limiting composition of carbides and nitrides.

Prospects for development and exploitation of method. (1) Preparation of initial components before the synthesis—pickling of powder grains of transition metals, boron, and silicon to remove oxides and activate the surface, followed by vacuum drying; thorough grinding and mixing of initial stoichiometric mixtures, and also their degasification before synthesis in a high vacuum; and selection of individual heating schedules for filled and extruded intermediate products. (2) The creation in vacuum synthesis of an attenuated inert atmosphere in the reaction apparatus to prevent dissociation of the refractory compounds [101-103]. (3) The use of plasma [104,105] and other [106,107] processes for synthesis by this method.

IV. PREPARATION FROM SOLUTIONS IN MELTS

This method consists essentially in the interaction of atoms of transition metals and non-metals or of molecules of their compounds dissolved in salt or metallic melts. Three different cases may be encountered: (1) the soluble components (elements or their compounds) do not form compounds with either salt or metallic solvents; (2) both or at least one component forms compounds with metallic solvents; (3) both or at least one component forms compounds with salt solvents. These processes can be represented by the following schemes, in which the first two stages may involve dissolution of the components, whereas the third stage (underlined) involves their interaction.

Case (1)

(*a*) Both components dissolve

For elements (partly McKenna's process, synthesis of carbides—Table 2) we have

$$\begin{gathered} M_S + Solv \rightarrow M_{diss} \\ Nm_{S,G} + Solv \rightarrow Nm_{diss} \\ \underline{M_{diss} + Nm_{diss} \rightarrow MNm_{diss}} \end{gathered} \quad (1.1)$$

For compounds (partly Gruber's synthesis of borides—Table 2) the equations are

$$\begin{gathered} MEl'_S + Solv \rightarrow MEl'_{diss} \\ NmE''_S + Solv \rightarrow NmEl''_{diss} \\ \underline{MEL'_{diss} + NmEl''_{diss} \rightarrow MNm_{diss} + El'El''_{diss}} \end{gathered} \quad (1.2)$$

Here Solv denotes the solvent, salt or metallic, in the molten, liquid state (the symbol L is omitted), diss denotes "dissolved", and El′ and El″ are elements combined with the transition metal and with the non-metal respectively.

Transition metals, non-metals, and their compounds may interact with or dissolve in the molten solvents while in any state of aggregation. However, the gaseous and liquid states of metals ($M_{L,G}$) their compounds ($MEl'_{L,G}$), and compounds of non-metals ($NmEl''_{L,G}$), as well as the liquid state of non-metals (Nm_L), are in practice unrealisable, although theoretically possible, in this method of synthesis from solutions in melts.

The state of aggregation of refractory compounds formed from solutions in melts will be determined by the state of the initial components and their behaviour towards the solvent: the products will be dissolved when both initial components either dissolve in or interact with the solvent (even if one component is in the gas phase); if, however, at least one component is insoluble, the products will also occur in the solvent in the solid phase [108].

(*b*) One component dissolves

For the elements (the zinc process, the synthesis of silicides—Table 2)

$$\begin{array}{l} M_S + Solv \rightarrow M_{diss}(M_S) \\ Nm_{S,G} + Solv \rightarrow Nm_{S,G}(Nm_{diss}) \\ \hline M_{diss}(M_S) + Nm_{S,G}(Nm_{diss}) \rightarrow MNm_{S,diss}(MNm_S) \end{array} \quad (1.3)$$

For compounds (copper silicide process, synthesis of silicides, (*a*)—Table 2)

$$\begin{array}{l} MEl'_S + Solv \rightarrow MEl'_{diss}(MEl'_S) \\ NmEl''_S + Solv \rightarrow NmEl''_S(NmEl''_{diss}) \\ \hline MEl'_{diss}(MEl'_S) + NmEl''_S(NmEl''_{diss}) \rightarrow MNm_S + El'El''_S \end{array} \quad (1.4)$$

Case (2)

(*a*) Both components interact

For the elements (zinc process, synthesis of borides and nitrides—Table 2)

$$\begin{array}{l} M_S + Solv^M \rightarrow MSolv^M_{diss} \\ Nm_{S,G} + Solv^M \rightarrow Solv^M Nm_{diss} \\ \hline MSolv^M_{diss} + Solv^M Nm_{diss} \rightarrow MNm_{diss} + Solv^M \end{array} \quad (2.1)$$

For compounds‡

$$\begin{array}{l} MEl'_S + Solv^M \rightarrow MSolv^M_{diss} + Solv^M El'_{diss} \\ NmEl''_S + Solv^M \rightarrow Solv^M Nm_{diss} + El''Solv^M \\ \hline MSolv^M_{diss} + Solv^M Nm_{diss} \rightarrow MNm_{diss} + Solv^M \end{array} \quad (2.2)$$

where $Solv^M$ is a metallic solvent.

(*b*) One component interacts while the other simply dissolves or is even insoluble

For elements (zinc process, synthesis of silicides and carbides or the copper silicide process, synthesis of silicides, (*b*)—Table 2)

$$\begin{array}{l} M_S + Solv^M \rightarrow MSolv^M_{diss} \\ Nm_{S,G} + Solv^M \rightarrow Nm_{diss}(\text{or } Nm_{S,G}) \\ \hline MSolv^M_{diss} + Nm_{diss} \rightarrow MNm_{diss} + Solv^M \\ (\text{or } MSolv^M_{diss} + Nm_{S,G} \rightarrow MNm_{S,G} + Solv^M) \end{array} \quad (2.3)$$

$$\begin{array}{l} M_S + Solv^M \rightarrow M_{diss} \ (\text{or } M_S) \\ Nm_{S,G} + Solv^M \rightarrow NmSolv^M_{diss} \\ \hline M_{diss} + NmSolv^M_{diss} \rightarrow MNm_{diss} + Solv^M \\ (\text{or } M_S + NmSolv^M_{diss} \rightarrow MNm_S + Solv^M) \end{array} \quad (2.4)$$

‡ It must be emphasised that synthesis in cases (2) and (3) requires that the refractory compound should be very stable (this can be assessed by means of the enthalpy, the energy of the chemical bond, and other parameters) in comparison with the products formed by interaction of the transition metal and the non-metal with the solvent. Transition metals and non-metals, when they interact with the solvent, function to different extents as donors and acceptors of electrons, which governs the possibility of their interaction in the melts after the compounds they form have dissociated into oppositely charged ions. For example

$$\begin{array}{l} MSolv^M \rightleftharpoons M^+ + Solv^{M-} \\ NmSolv^M \rightleftharpoons Nm^- + Solv^{M+} \\ M^+ + Nm^- \rightarrow MNm \end{array} \quad \text{or} \quad \begin{array}{l} MSolv^2 \rightleftharpoons M^+ + Solv^{2-} \\ NmSolv^1 \rightleftharpoons Nm^- + Solv^{1+} \\ M^+ + Nm^- \rightarrow MNm \end{array}$$

For compounds

$$\begin{array}{l} MEl'_S + Solv^M \rightarrow MSolv^M_{diss} + El'Solv^M_{diss} \\ NmEl''_S + Solv^M \rightarrow NmEl''_{diss} \ (\text{or } NmEl''_S) \\ \hline MSolv^M_{diss} + NmEl''_{diss} \rightarrow MNm_{diss} + Solv^M El''_{diss} \\ (\text{or } MSolv^M_{diss} + NmEl''_S \rightarrow MNm_S + Solv^M El''_S) \end{array} \quad (2.5)$$

$$\begin{array}{l} MEl'_S + Solv^M \rightarrow MEl'_{diss} \ (\text{or } MEl'_S) \\ NmEl''_S + Solv^M \rightarrow NmSolv^M_{diss} + Solv^M El''_{diss} \\ \hline MEl'_{diss} + NmSolv^M_{diss} + MNm_{diss} + El'Solv^M_{diss} \\ (\text{or } MEl'_S + NmSolv^M_{diss} \rightarrow MNm_S + El'Solv^M_S \end{array} \quad (2.6)$$

Case (3)

(*a*) Both components interact

For elements [134]

$$\begin{array}{l} M_S + Solv^1Solv^2 \rightarrow MSolv^2_{diss} + Solv^{1+} \\ Nm_{S,G} + Solv^1Solv^2 \rightarrow NmSolv^1_{diss} + Solv^{2-} \\ \hline MSolv^2_{diss} + NmSolv^1_{diss} \rightarrow MNm_{diss} + Solv^1Solv^2 \end{array} \quad (3.1)$$

For compounds [117]

$$\begin{array}{l} MEl'_S + Solv^1Solv^2 \rightarrow MSolv^2_{diss} + El'Solv^1_{diss} \\ NmEl''_S + Solv^1Solv^2 \rightarrow NmSolv^1_{diss} + El''Solv^2_{diss} \\ \hline MSolv^2_{diss} + NmSolv^1_{diss} \rightarrow MNm_{diss} + Solv^1Solv^2 \end{array} \quad (3.2)$$

where $Solv^1Solv^2$ is a salt solvent in which $Solv^{1+}$ is the cation and $Solv^{2-}$ the anion.

(*b*) One component interacts

Similarly to case (2*b*) we have for the elements

$$\begin{array}{l} M_S + Solv^1Solv^2 \rightarrow MSolv^2_{diss} + Solv^{1+} \\ Nm_{S,G} + Solv^1Solv^2 \rightarrow Nm_{diss}(\text{or } Nm_{S,G}) \\ \hline MSolv^2_{diss} + Nm_{diss} \rightarrow MNm_{diss} + Solv^{2-} \\ (\text{or } MSolv^2_{diss} + Nm_{S,G} \rightarrow MNm_{S,diss} + Solv^{2-}) \end{array} \quad (3.3)$$

$$\begin{array}{l} M_S + Solv^1Solv^2 \rightarrow M_{diss} \ (\text{or } M_S) \\ Nm_{S,G} + Solv^1Solv^2 \rightarrow NmSolv^1_{diss} + Solv^{2-} \\ \hline M_{diss} + NmSolv^1_{diss} \rightarrow MNm_{diss} + Solv^{1+} \\ (\text{or } M_S + NmSolv^1_{diss} \rightarrow MNm_S + Solv^{1+}) \end{array} \quad (3.4)$$

For compounds

$$\begin{array}{l} MEl'_S + Solv^1Solv^2 \rightarrow MSolv^2_{diss} + El'Solv^1_{diss} \\ NmEl''_S + Solv^1Solv^2 \rightarrow NmEl''_{diss} \ (\text{or } NmEl''_S) \\ \hline Msolv^2_{diss} + NmEl''_{diss} \rightarrow MNm_{diss} + El''Solv^2_{diss} \\ (\text{or } MSolv^2_{diss} + NmEl''_S \rightarrow MNm_S + El''Solv^2_S) \end{array} \quad (3.5)$$

$$\begin{array}{l} MEl'_S + Solv^1Solv^2 \rightarrow MEl'_{diss} \ (\text{or } MEl'_S) \\ NmEl''_S + Solv^1Solv^2 \rightarrow NmSolv^1_{diss} + El''Solv^2_{diss} \\ \hline MEl''_{diss} + NmSolv^1_{diss} \rightarrow MNm_{diss} + El'Solv^1_{diss} \\ (\text{or } MEl'_S + NmSolv^1_{diss} \rightarrow MNm_S + El'Solv^1_S) \end{array} \quad (3.6)$$

The above possible variants in the synthesis of refractory compounds from molten solutions are merely the simplest and relate to ternary systems. Synthesis in multicomponent systems is greatly complicated by parallel and exchange processes. Real mechanisms of synthesis are far more complicated than the schemes presented

Table 2. Formation from molten solutions.

Compounds	Process	Synthetic reaction	Ref.	Conditions of preparation					Ref.
				t, °C	time, h	protective medium	rate of cooling, deg min^{-1}	solvent	
Borides	in molten iron	$B_{diss}(BFe_{diss}) + Ti_{diss}(TiFe_{diss}) \rightarrow TiB_{diss} + (Fe_L)$ (assumed)	112	400—2000	not stated	not stated	1—100	mineral acids	112
	in molten Na (K)	$B_{diss}(BEl_{diss}) + M_{diss}(MEl_{diss}) \rightarrow MB_{diss} + El_{diss}(NaEl_{diss})$ (assumed)	113	650—1100	2—10	air	—	H_2O	113
	Zn process	$B_{S,diss} + MZn_{diss} \rightarrow MB_{S,diss} + Zn_L$	111	>907	1—4	Ar, vacuum	100—1000	HCl (1 : 1), HNO_3 (1 : 10)	111
Carbides	McKenna's	in molten Al(Na) assumed that: $C_{diss}(AlC, NiC)_{diss} + M_{diss}(AlM, NiM)_{diss} \rightarrow MC_{diss} + Al(Ni)_L$	115	~2000	not stated	not stated	Ar, vacuum	HCl, HNO_3, 3HCl+HNO_3	115
	Zn process	$C_S + MZn_{diss} \rightarrow MC_S + Zn_L$	111	>907	1—4	Ar, vacuum	100—1000	HCl (1 : 1), HNO_3 (1 : 10) NaOH (10%)	111
Silicides	Lebeau's	in molten Cu assumed that: (a) $Cu_L + Si_{diss} + MO_S \rightarrow MSi_{diss} + CuO_S + SiO_{2S}$ (b) $Si_{diss}(CuSi_{diss}) + M_{S,diss}(MCu_{diss}) \rightarrow MSi_{diss,S} + (Cu_L)$	109, 116	~1300	2	H_2	7.5	HNO_3 (10%, (warm)	109

	Zn process	$N_{G,diss} + MZn_{diss} \rightarrow MN_{diss} + Zn_L$	111	>907	1—4	N_2, Ar	100—1000	HCl (1 : 1), HNO_3 (1 : 10)	111

here, owing to reversibility of the dissolution and interaction stages with many refractory compounds, dissociation and solvation of dissolved components and products, and also the actual conditions of synthesis—composition and nature of components, technical design factors, and operating schedules.

The formation of homogeneous products and the overall yield of the reaction (provided that the products can be separated from the solvent without decomposition) are governed by the behaviour of the solvent towards the initial components: if it shows greater affinity for one of them, excess of this component is required in the melt [109]. The affinity of the solvent for the reactants can be assessed by means of thermodynamic calculations, by computing and comparing the chemical potentials of the components in the solvent and in the resulting refractory compound [109]. Furthermore, the necessary excess of one metal or non-metal in the melt, in the synthesis of refractory compounds of several transition metals or non-metals from the elements, can be established experimentally (by a series of experiments on the homogeneity of the product), and then the required excess can be calculated for other metals or non-metals by setting up the proportion $\Delta m/u_1 = \Delta m_X/u_2$, where Δm is the experimental excess of one component over the other in the melt, u_1 the total energy of the valency band of this element [110]—a quantity which is proportional to the sum of the successive ionisation potentials of the atom (this sum could also be used for these purposes, but with less accuracy)—Δm_X is the unknown excess of the other metal or non-metal, and u_2 is the total energy of its valency band. The basis of such a calculation is the dependence of all properties of the atoms of dissolved components (including their behaviour towards the solvent) on the energy characteristics of their valency electrons. The usefulness of such a calculation is confirmed in the practical synthesis of borides and silicides of transition metals from solution in molten zinc. The excess of transition metals necessary for homogeneous synthesis [109] and calculated from the above relation can be applied to the preparation of homogeneous borides and silicides (both polycrystalline powders and single crystals). In the separation of the refractory compounds from zinc this excess is easily removed by hydrochloric or nitric acid, since the intermetallic compounds which it forms with zinc (so called zincides) dissolve readily in these acids [111].

The chief characteristics of existing processes for the synthesis of borides, carbides, nitrides, and silicides by this method are given in Table 2. [109,111-117]

The first attempts to isolate carbides from steel were made in 1887. [118] The prepartion of carbides has since been improved by Williams [119], Moissan [120], and others [111,121]. Silicides were obtained long ago by Lebeau [116] using this method§; other processes for their synthesis were developed considerably later [122]. Borides [111-113] and nitrides [111,117,123] have been prepared quite recently. Development of the above processes for the synthesis of borides [112,113], carbides [115], silicides [109,114], and nitrides [117] has not yet reached industrial proportions. Oxides are not synthesised by this method because it is unprofitable; but it is possible in principle, and can be used in practice to grow single crystals [123-125].

Application of method in industry. (1) The Lebeau, McKenna, etc. processes are inapplicable because of low yield and high cost for borides and silicides, small-scale application may be possible to obtain complex and pure carbides [8,126] and nitrides [117]. (2) The zinc process is not applicable because of the low yield and the cost; in the synthesis of nitrides control of the process is complicated.

Growth of single crystals. This application is possible and promising for borides [108,111-127], carbides [128], silicides [66,108,109,127,129], and nitrides [108,127,130].

§ The variety of processes in this method is determined not only by the technical conditions of crystal growth but also by the nature of the solvent and its behaviour towards the solutes.

Advantages. (1) Comparative simplicity of synthetic processes. (2) Possibility of obtaining pure, alloyed, and complex (mixed) compounds. (3) Possibility in individual cases of regenerating easily sublimate solvent metals [111,127].

Disadvantages. (1) Low yield and high cost of production, caused by the consumption of salt and metal solvents. (2) Possibility of contamination of the products with the solvent. (3) Need for vigorous stirring of molten solutions in order to obtain homogeneous compounds.

Prospects of development and exploitation. (1) Use of vibrational agitation of solutions in melts to intensify synthetic processes. (2) Choice of solvents of low boiling point so that boiling can be used to agitate the molten solution. (3) Investigation of structure of solutions in melts in order to study the kinetics of the synthesis and the mechanism of the growth of single crystals [131] of refractory compounds. (4) Use of ultrahigh pressures (by analogy with the production of diamond) in treatment of the systems and their solutions in melts in order to grow single crystals and obtain new modifications of refractory compounds. (5) Use for the application of coatings of refractory compounds on steel, various metals, and alloys [132,133].

This method has not yet become widespread for the preparation of refractory compounds. Work on synthesis in metallic melts—(1.1), (1.2), (2.1), and (2.2)—has been concerned mainly with semiconductor and intermetallic systems [134,135]. The interesting use of amalgam metallurgy has enabled, in particular, silicides [136] and nitrides [123] of rare-earth metals to obtain at 400–600°C, although the solubility of transition metals in mercury is insignificant, and they hardly react at all with such non-metals as boron and silicon [135,137]. Furthermore, considerable theoretical and practical interest attaches also to the search for new, and the investigation of already known, low-temperature polymetallic solvents (such as Newton's, Rose's, Wood's, and Guthrie's alloys [138]) for transition metals and non-metals, that are comparatively cheap, of low viscosity, and capable of simple recovery. Salt solvents are more rarely used [139] for synthetic purposes—(1.1), (1.2), (3.1), (3.2), etc.—mainly for growing single crystals of oxides and various salts by the recrystallisation of already prepared compounds [123–125,140] and also for the application of coatings [144]. Nevertheless, synthesis in salt solvents from the elements or from compounds may be of considerable interest with appropriate selection and investigation of the systems [143,144], because of the solubility of metals in melts of their own and other salts [142].

Structural investigations on solutions in melts (both salt and metallic) are of great value for synthetic purposes, since the information obtained will provide a more detailed and a clearer picture of the processes occurring in such solutions and enable them to be controlled [134,145].

V. ELECTROLYSIS OF MELTS AND SOLUTIONS IN MELTS

This method consists essentially in the formation of refractory compounds as a result of primary or secondary electrode processes either on the cathode or on the anode. In the electrolysis of melts (only the initial one-component systems are implied) the presence of any other component in the system already represents a solution of one in the other, i.e. a solution in a melt formation of the refractory compound is always the primary¶ electrode process, but in the electrolysis of solutions in melts it may be either the primary or a secondary process.

1. Electrolysis of Melts

This form of electrolysis consists in the passage of an electric current through molten salts (or in the present case molten refractory compounds), which are strong electrolyes. It seldom finds practical application in the preparation of refractory compounds [146]. Formation of a refractory compound can take place either on the cathode, on the anode, or on both at the same time, in a single electrolytic cell, e.g. in the electrolysis of silica (silicides and oxides on the surfaces of transition-metal electrodes). The lower temperature limits are governed by the melting points of the compounds undergoing electrolysis, but in practice many factors—the possible occurrence of synthesis on the electrodes, the intensity of vaporisation or decomposition of the electrolyte, the stability of the cell towards the melt, etc—determine the temperature of electrolysis. All the classes of refractory compounds under consideration can be obtained by the present form of electrolysis. One of the components in the synthesis should form an electrode (metal or non-metal, including the possibility of gas cathodes for nitrogen and oxygen; furthermore, the non-metal cannot form the anode, since the metal which is to be discharged on it cannot have a negative charge in a melt of its binary compound, but this is hypothetical).

The following types of dissociation are undergone by salts in melts

$$MEl' \rightarrow M^{n_1^+}El'^{n_1^-} \text{ (or } n_1El^{1-}\text{), e.g. } TiS_2, VF_3, WO_3$$

$$NmEl'' \rightarrow Nm^{n_2^+} + El''^{n_2^-} \text{ (or } n_2El''^{1-}\text{), e.g. } B_4C, SiO_2, SiC$$

$$El''Nm \rightarrow Nm^{n_2^-} + El''^{n_2^+} \text{ (or } n_2El''^{1+}\text{), e.g. } CaO, K_2O, Ca_3N_2, CaC_2$$

The reactions at the electrodes (synthesis of borides, carbides, silicides, nitrides, oxides) are—at the cathode

$$\begin{aligned} Nm^{+n_2} + M_{cath}^{(n_2^-)} &\rightarrow MNm^0 \\ M^{n_1^+} + Nm_{cath}^{(n_1^-)} &\rightarrow Mnm^0 \end{aligned} \qquad (4.1)$$

and at the anode

$$Nm^{n_2^-} + M_{anode}^{(n_2^+)} \rightarrow MNm^0 \qquad (4.2)$$

where n_1 and n_2 are the valencies of metals and non-metals, EL′ and EL″ are elements with which they form compounds, and the zero denotes the electrically neutral state of molecules (atoms). The charge on an atom of the electrode (in parentheses), at which an ion of the other component is discharged, will always equal the ionic charge: $n_2 = (\pm n_2)$; $\pm n_1 = (\pm n_1)$.

The refractory compounds prepared in this way may form coatings or deposits on the electrodes or may settle as a slime at the bottom of the cell.

¶ The process is primary if it is assumed that on discharge the ions at once form lattice points of the refractory compound but, having been converted into neutral atoms, do not interact with the electrode surface, do not migrate along the surface, and also do not diffuse inside the electrode.

2. Electrolysis of Solutions in Melts

This form of electrolysis consists in passing a current through a molten strong electrolyte containing the dissolved reactants. The latter may be present either in the electrically neutral atomic or molecular state or as ions, but if one component is in a neutral state, the other must be ionised. Only the electrolysis of solutions in salt melts is used in practice for the preparation of refractory compounds (Table 3), for metallic electrolytes have not yet found widespread use.

Formation of a compound by discharge of the ion of one component on an electrode made of the other component must be regarded as the primary electrode process; in all other cases the synthesis of the refractory compound is a secondary electrode process. We shall examine possible synthetic reactions at electrodes on the assumption that both ions and complexes (complex ions) of the individual components may take part in the reactions.

(1) Reactions on cathode (borides, carbides, silicides, and nitrides)

For ions (Meerson and Smirnov's preparation of borides, Andrieux and Dodero's preparation of silicides—(Table 3) we have

$$\begin{gathered} M^{n_1^+} + n_1 e \rightarrow M^0 \\ Nm^{n_2^+} + n_2 e \rightarrow Nm^0 \\ M^0 + Nm^0 \rightarrow MNm^0 \end{gathered} \tag{4.3}$$

and for complexes

$$\begin{gathered} MEl'^{n_1^+} + n_1 e \rightarrow MEl'^0 \\ NmEl''^{n_2^+} + n_2 e \rightarrow NmEl''^0 \\ MEl'^0 + NmEl''^0 \rightarrow MNm^0 + El'El''^0 . \end{gathered} \tag{4.4}$$

It should be noted that variant (4.3), and also (4.7) and (4.11), are not applied in practice to the preparation of nitrides (these processes are possible only if ammonia dissolves and dissociates in the melts, and also nitrogen dissolves). Nitrides can be obtained on the cathode by dissolving ammonium, etc. halides, nitrates, carbonates, and other salts in the solvent melts with their subsequent dissociation to form the ammonium ion (4.4) or by simply dissolving them—(4.7) and (4.11).

Refractory compounds formed on the cathode are in the solid phase. The following possibilities can be envisaged for the synthesis.

(*a*) One component is an ion, while the other is present in a complex:

$$\begin{gathered} M^{n_1^+} + n_1 e \rightarrow M^0 \\ NmEl''^{n_2^+} + n_2 e \rightarrow NmEl''^0 \\ M_0 + NmEl''^0 \rightarrow MNm^0 + El''^0 \end{gathered} \tag{4.5}$$

$$\begin{gathered} MEl'^{n_1^+} + n_1 e \rightarrow MEl'^0 \\ Nm^{n_2^+} + n_2 e \rightarrow Nm^0 \\ MEl'^0 + Nm^0 \rightarrow MNm^0 + El'^0 \end{gathered} \tag{4.6}$$

(*b*) One component is an ion (or is present in a complex), while the other component is unionised (undissociated), i.e. occurs in the melt either in the dissolved state or in the solid state (gaseous in the case of nitrogen) as the cathode and is negatively charged (Weiss and Andrieux's preparation of carbides—Table 3): for ions

$$\begin{gathered} M^{n_1^+} + n_1 e \rightarrow M^0 \\ Nm_{diss} + M^0 \rightarrow MNm^0 \\ NmEl''_{diss} + M^0 \rightarrow MNm^0 + El''_{diss} (ZrB_2 \text{ (Ref.147)}, \end{gathered} \tag{4.7}$$

$$M^{n_1^+} + Nm_{cath}^{(n_1^-)} \rightarrow MNm^0 \tag{4.8}$$

$$\begin{gathered} Nm^{n_2^+} + n_2 e \rightarrow Nm^0 \\ M_{diss} + Nm^0 \rightarrow MNm^0 \\ MEl'_{diss} + Nm^0 \rightarrow MNm^0 + El'_{diss} \end{gathered} \tag{4.9}$$

$$Nm^{n_2^+} + M_{cath}^{(n_2^-)} \rightarrow MNm_2^0 \tag{4.10}$$

and for complexes [148,149]

$$\begin{gathered} MEl'^{n_1^+} + n_1 e \rightarrow MEl'^0 \\ MEl'^0 + Nm_{diss} \rightarrow MNm^0 + El'^0 \\ MEl'^0 + NmEl''_{diss} \rightarrow MNm^0 + El'El''_{diss} \end{gathered} \tag{4.11}$$

$$MEl^{n_1^+} + Nm_{cath}^{(n_1^-)} \rightarrow MNm^0 + El'^{n_1^-} \tag{4.12}$$

$$\begin{gathered} NmEl''^{n_2^+} + n_2 e + NmEl''^0 \\ NmEl''^0 + M_{diss} \rightarrow MNm^0 + El''^0 \\ NmEl''^0 + MEl'_{diss} \rightarrow MNm^0 + El'El''_{diss} \end{gathered} \tag{4.13}$$

$$NmEl''^{n_2^+} + M_{cath}^{(n_2^-)} \rightarrow MNm^0 + El''^{n_2^-} \tag{4.14}$$

Variants (4.11) and (4.13) are possible also as parallel reactions near the cathode. Furthermore, parallel processes are possible also in the bulk electrolyte, such as interaction between ions (complexes) and dissolved atoms (compounds) with the formation of refractory compounds:

$$\begin{gathered} M^{n_1^+} + NmEl''_{diss} \rightarrow MNm_{diss} + El''^{n_1^+} (\text{or } n_1 El''^{1+}) \\ MEl^{n_1^+} + NmEl''_{diss} \rightarrow MNm_{diss} + El'El''^{n_1^+} \\ MEl^{n_1^+} + Nm_{diss} \rightarrow MNm_{diss} + El'^{n_1^+} (\text{or } n_1 \times El'^{1+}) \end{gathered} \tag{4.15}$$

$$\begin{gathered} Nm^{n_2^+} + MEl'_{diss} \rightarrow MNm_{diss} + El'^{n_2^+} (\text{or } n_2 \times El'^{1+} \\ NmEl''^{n_2^+} + MEl'_{diss} \rightarrow MNm_{diss} + El'El''^{n_2^+} \\ NmEl''^{n_2^+} + M_{diss} \rightarrow MNm_{diss} + El''^{n_2^+} (\text{or } n_2 \times El''^{1+}) \end{gathered} \tag{4.16}$$

(2) Reactions on anode (nitrides and oxides)

Here the following possibilities arise in connection with the synthesis.

(*a*) The transition metal is the anode, on which both ions and complexes of the non-metal can be discharged [150]:

$$\begin{gathered} Nm^{n_2^-} + M_{anode}^{(n_2^+)} \rightarrow MNm^0 \\ NmEl''^{n_2^-} + M_{anode}^{(n_2^+)} \rightarrow Mnm^0 + El''^{n_2^-} (\text{or } n_2 \times El''^{1+}) \end{gathered} \tag{5.1}$$

(*b*) Synthesis may occur in the anolyte, with atoms (compounds) of the metal dissolved in the melt, after discharge of an ion (complex) of the non-metal. For ions we have

$$\begin{gathered} Nm^{n_2^-} - n_2 e \rightarrow Nm^0 \\ Nm^0 + M_{diss} \rightarrow MNm^0 \\ Nm^0 + MEl'_{diss} \rightarrow MNm^0 + El'_{diss} \end{gathered} \tag{5.2}$$

and for complexes

$$NmEl''^{n-}_3 - n_2e \rightarrow NmEl''^0$$
$$NmEl''^0 + M_{diss} \rightarrow MNm^0 + El''_{diss} \quad (5.3)$$
$$NmEl''^0 + MEl'_{diss} \rightarrow MNm^0 + El'El''_{diss}$$

(*c*) Parallel reactions are possible in the bulk electrolyte between ionised and dissolved components (variants analogous to (4.15) and (4.16) follow here, but in the latter case the signs of the ions should be changed).

The above alternative schemes representing the synthesis of refractory compounds at an electrode show neither secondary processes nor processes occurring at the opposite electrode. Furthermore, purely chemical redox processes (other than formation of the refractory compound) occurring at the electrodes are also omitted. Consideration of all these processes would introduce considerable complications into the already numerous schemes. Actual examples of several of these processes (both main and secondary processes) are given in Table 3.[10,151-157]

This method was first used by Andrieux[151,152] to prepare borides, after which he and other investigators employed it to obtain carbides[151,152,154] and silicides[158]. Following this, the method was developed for the preparation of borides[153,154,156], carbides[154,156], and silicides[157,159]. Nitrides have not yet been obtained by this method, but their synthesis is theoretically possible both on the cathode and on the anode. With regard to oxides, papers have appeared on the surface passivation of titanium and niobium in molten alkali-metal carbonates and nitrates[150,160] (corresponding to (5.1), second case). Such passivation leads to the production of oxide and nitride deposits possessing specific properties.

It should be noted that the preparation of refractory nitrides and oxides by this method is inefficient, and can be of value only for the application of oxide and nitride films and coatings[161,167]. In the view of several workers[10,153] this method may be of intrinsic interest for borides, carbides, and silicides (while it retains its value for the application of coatings[133,162,163]), especially with continuous electrolysis.

Industrial application. This has been prevented by the low yield and by the complexity of the electrolysis and of the separation of the products from the electrolyte. Application is promising especially for borides[10] and silicides[148].

Growth of single crystals. The process has not been used for this purpose. Coarsely crystalline deposits can be obtained[148].

Advantages. (1) Simplicity of equipment and availability of starting materials; (2) low temperatures; (3) possible use to obtain refractory coatings[133,162-164] and films[150].

Disadvantages. (1) The impurity of the products and the laboriousness of purifying cathodic deposits; (2) difficulty of obtaining either higher or lower (with respect to the non-metal) compounds of strictly defined composition; (3) uneconomic.

Development and use prospects. (1) Development of continuous processes of electrolysis; (2) selection of easily fusible, cheap, and technically pure electrolytes and initial components; (3) investigation of structure of electrolyte and processes of electrolysis.

Further development of this method of synthesis will depend in considerable measure on investigations of the structure of melts and solutions in melts and also on investigations of the mechanism of the processes involved in synthesis on electrodes and in the electrolyte. Such researches have recently become increasingly widespread[143,144,155].

VI. METALLOTHERMIC REDUCTION OF METAL OXIDES

This method consists in reduction of metal and nonmetal oxides (or of metal oxides in the presence of nonmetals) with aluminium (magnesium and other metals in

Table 3. Electrolysis of alloys and molten solutions.

Compounds	Electrolytic bath	Ref.	Synthetic reaction	Ref.	Conditions of preparation					Ref

the presence of compounds that evolve oxygen) to form refractory compounds:

$$MO + NmO(Nm + Al(Mg, Ca; + BaO_2, + NaNO_3) + S \rightarrow MNm_{molt} + Al(Mg)_x S_y O_z (Al_2O_3, MgO, etc.)$$

where the product MNm is in the molten state. The products of the reaction are also multicomponent compounds—slags (sulphur, etc. is sometimes added to the initial mixture to improve their fusibility)—together with oxides of the reducing metals (aluminium, magnesium, etc.).

This method of preparation involves a set of typical redox reactions, in which the starting materials always take part in the solid phase, whereas the products often melt at the resulting high temperatures (3000°C and above, especially when aluminium is used). It is the most explicit and simplest of all the methods of preparation, but the poor quality of the products and their lack of uniformity of composition, together with the difficulty of isolating them from the slags, prevent its widespread practical application for the production of refractory compounds. Furthermore, not all classes of these compounds can be obtained by this method, and carbides have been obtained only recently [165,166]. Nitrides and oxides cannot in principle by prepared by this method: nitrogen can occur only in the gas phase under the given conditions, and nitrides can therefore be formed only on the surface of the reduced metal (usually molten) in an atmosphere of pure nitrogen. In the presence of oxygen the reducing metal will burn in its atmosphere, almost without interacting at all with the metal oxides.

The main characteristics of the processes for the metallothermic preparation of borides, carbides, and silicides are set out in Table 4. [166,168-178] This method was first applied to the preparation of borides and silicides in 1905, [168,169] and only quite recently has it been used for carbides [165,166]. Many investigators have developed the method for the preparation of borides [170-173], silicides [174-176], and carbides [166].

The high temperatures make this method quite specific and industrially hazardous [24], and the impossibility of controlling the process results in compounds of variable composition. Nevertheless, several papers indicate that this is a promising method for the production of refractory compounds [24,172,173,176,179]. Further improvement is evidently possible by working very accurately through all the fine details of technology for each particular compound on both laboratory and manufacturing scales.

Industrial application. None, but promising [166,172,173,176,180].

Growth of single crystals. It has not been used for this purpose. But crystals are obtained as a consequence of the dissolution of the resulting borides, silicides, and carbides in the slags or aluminium and their subsequent crystallisation (up to 1 mm with silicides). [166,170,171,177]

Advantages. (1) Economical—little or no external supply of energy required for the process; (2) technology simple, raw material cheap [172,173]; (3) possibility of obtaining large quantities of the compounds [172,173,176].

Disadvantages. (1) Heavy contamination of the compounds with difficultly removable impurities (aluminium and magnesium borides and silicides, the monoxide of the metal, silica, etc.); (2) uncontrollability of the process and its well known danger with large quantities of reactants; (3) comparatively high cost of reducing metals.

Development and use prospects. (1) Accurate calculation of proportions of components in the initial charge and precise working out of industrial schedules for each specific compound [179]; (2) development of continuous cycles of preparation and utilisation of the energy evolved (heat and light).

VII. REDUCTION OF OXIDES AND OTHER COMPOUNDS BY NON-METALS AND THEIR COMPOUNDS

This method consists in reducing oxides (or other compounds) of transition metals by non-metals and their compounds:

$$MO(MEl', MEl'O, MEl'El'') + Nm(NmEl', NmO, NmEl'El'') \rightarrow MNm_S + NmO(El'_2, El'O, El''O, El'El''),$$

where El′ and El″ may be either metals or non-metals, MEl′ may represent a hydride, carbide, sulphide, chloride, or other compound of the metal, MEl′El″ and MEl′O are salts, NmEl′ is a hydride, carbide, or other compound of the non-metal, and NmEl′El″ is a hydrocarbon derivative, a complex, etc. (Table 5). As in the preceding method (Table 4) the preparation involves a set of redox reactions (in individual cases also exchange

Table 4. Metallothermic reduction of metal oxides.

Compounds	Synthetic reaction	Ref.	Conditions of preparation				Ref.

reactions). The reactants and products may be in different states of aggregation, but are predominantly in the solid phase.

Several specific processes may be encountered depending on the reactants used in this method. The chief characteristics of the most important processes are listed in Table 5.[12,16,47,48,55,57,60,130,181-209].

This method was first applied by Johnston in 1831,[210] when silicides were obtained by reducing oxides by non-metals. These products were prepared later also by Moissan[211]. Carbides[38,212,213], nitrides[201,202], and borides[181,184,214] have since been obtained by this process. Reduction of oxides by compounds of the non-metals with carbon and other elements was first applied to the preparation of nitrides[205], and then of silicides[1,215], borides[216,217], and carbides[190,191,218]. The process of reduction or reaction of other compounds was employed initially to obtain nitrides[203,204,207-209,219-222], and then carbides[192,213], silicides[48,199,200], and borides[55,223,224]. Credit for developing the above processes is due to many workers. Thus the reduction of metal oxides was developed initially for nitrides[203,204] and carbides[47,57], and later for silicides[60,196] and borides[182,183,185-187]. The reduction of oxides by compounds of non-metals with carbon and other elements was also elaborated for the above classes of compounds—silicides[197,198], nitrides[130,204], carbides[191], and borides[188,189]. All these classes of compounds have been obtained also by developing the reduction or reaction of other compounds—borides[55] carbides[195,225], silicides[195], and nitrides[209,226].

Industrial application. (1) Reduction of oxides by non-metals applicable to the preparation of borides[227-230], carbides[231-233], silicides[234,235], and nitrides[8-14]; (2) reduction of oxides by compounds of non-metals with carbon and other elements applicable to the preparation of borides[12,13,189,227,236] and nitrides[8,10,12,14,237,238], and promising for carbides[191,239] and silicides[197,198]; (3) reduction or interaction of other compounds promising for the production of all classes of refractory compounds, especially for carbides[225,240,241], silicides[195,200], and nitrides[206,226].

Growth of single crystals. The method has not been applied and is not applicable owing to the solid-phase mechanism of the formation of borides, carbides, and silicides, However, it is theoretically possible to obtain crystalline powders of these compounds[242].

Advantages. (1) Possibility of obtaining large quantities of refractory compounds; (2) use of oxides and other readily available compounds of metals and non-metals for the preparation[243-252].

Disadvantages. (1) Contamination of products by metal and non-metal oxides and also by other compounds; (2) impossibility of preparing molybdenum and tungsten compounds in a vacuum owing to the volatility of their oxides.

Development and use prospects. Improvement of individual stages of the preparation in actual processes and their variants, e.g. for borides[253,254], carbides[231,255], silicides[235,256], and nitrides[257]; possibility of obtaining new materials[258-260].

Borides, carbides, nitrides, and silicides can be obtained by this method. Oxides are prepared only by the decomposition or interaction of complex compounds[261-273], when oxide coatings can be produced[274].

The availability and cheapness of the initial components make this method, together with direct synthesis from the elements, the most widely used and generally applicable in industry[88,227,231,275].

Further development of the method will be concerned mainly with improving the technical conditions in each process or with modifying the processes to yield products of higher quality, as has been done e.g. in the preparation of borides by reducing oxides with non-metals [276].

VIII. GAS-PHASE PREPARATION

This method consists essentially in the decomposition of chemical compounds followed by interaction of their constituent parts in the gaseous (vapour) state (both the ions and radicals and the atoms and molecules to which they are reduced) to form the refractory compounds. Preparation is possible also by the decomposition of one compound containing either one or both components of the reaction. In the former case the second component (this applies more to metals than to non-metals) should be present in the reaction volume in the elementary state, usually in the solid phase. In all cases a reducing atmosphere is necessary in the apparatus, for both the reduction and the removal of pyrolysis products. The general process can be represented

$$MHal_n\,[M, M(NmEl)_n, M(C_xH_yO_z)_n] + NmHal_n\,(Nm, NmEl) + H_2 \rightarrow$$
$$\rightarrow MNm_{G,S} + HHal\ (+ NmEl, C_xH_yO_z)$$

where Hal = F, Cl, Br, I; NmEl = CO, and also CO_2, NH_3, hydrocarbons, etc.; and $C_XH_yO_Z$ is a carbohydrate.

Gas-phase formation consists of a series of mainly ionic and atomic (molecular) reactions in the gas phase, although in individual cases (when one component is present in the solid phase) the reaction may have a topochemical mechanism.

The main characteristics of the gas-phase method for borides, carbides, silicides, nitrides, and oxides are listed in Table 6, [218,277-288] which shows that all the classes of refractory compounds under consideration can be prepared by this method.

The gas-phase method was first used to obtain silicides [277,282,283], and other classes of compounds—carbides [218,278,280-282], nitrides [278,281,282], borides [277,278], and oxides [278]—were obtained later. Campbell, Powell, et al. [279] must be regarded as the first workers to develop the method for all classes of compounds. It may be remarked merely that an attempt to develop this method for the preparation of borides was made somewhat earlier [289]. The necessary conditions for the deposition of refractory compounds from the gas phase can be formulated from the results in Ref. 290.

Industrial application. The method is used, and is promising for borides [291], carbides [290,292-297], silicides [298-303], nitrides [304], and oxides [305-316].

Growth of single crystals. Used for borides [317], carbides [318], silicides [319], nitrides [320], and oxides [321,322].

Advantages. (1) Possibility of obtaining single crystals; (2) possibility of obtaining coatings (including multicomponent coatings) on various materials; (3) possibility of relatively easy study of the kinetics of gas-transport reactions [323,324], etc. and the mechanism of the growth of single crystals.

Disadvantages. (1) Non-uniform phase composition of products; (2) complexity of apparatus and processes involved; (3) difficulty of obtaining large quantities of single-phase products.

Development and use prospects. (1) Possibility of obtaining especially pure and alloyed single crystals [325]; (2) possibility of obtaining articles having a complicated shape [326] and also articles from monocrystalline deposits; (3) development of continuous processes of preparation.

The gas-phase method, together with the reduction of metal oxides, is now undergoing very vigorous development. Most studies of these classes of compounds have been devoted to oxides, with very close attention paid to the production of pigment titanium oxide (Refs. 327–338 and many others).

The possibility of obtaining single crystals and finished articles (with the prospect of articles from monocrystalline deposits) of borides, carbides, nitrides, silicides, and oxides makes this method one of the most promising

Table 6. Gas-phase preparation.

Compounds	Gas mixture or decomposable cpds.*	Ref.	Synthetic reaction	Ref.	Conditions of preparation				Ref.
					t, °C	time	rate of deposition	v.p. of mixture components	
Borides	$MHal_n(M) + BHal_3(B) + H_2$	277—279	$MCl_n(M)+BCl_3+H_2\rightarrow MB+$ $+HCl$	279	900—2700	a few min to a few h depending on thickness of deposited layer	7.5-65 $\mu m\ min^{-1}$	total = 1 atm provided that v.p. MHal > NmEl (El)	278, 279

Oxides	$MHal_n(M)+CO_2+H_2$; CO_2+ $+[C_6H_7O_2]_nM([C_xH_yO_z]_nM)$ $M(OH)$; $M(OH)El$; $MOCl$	279	$MCl_n+CO_2+H_2\rightarrow MO+$ $+CO+HCl$	279					
		286—288	$[C_5H_7O_2]_3Cr+CO_2\rightarrow$ $\rightarrow Cr_2O_3+(C, H, O)$	279	800—1000	ditto			278, 279

*Hal usually Cl, more rarely Br; El = element.

for use in industry, especially when pyrolysis and synthesis are conducted in plasma systems. The main problems involved in developing this method will consist in working out very precise conditions for the deposition of individual refractory compounds, their various modifications, solid solutions, and mixtures.

---o0o---

Comparison of the above methods for the production of refractory compounds shows that synthesis from solutions in melts, electrolysis, and the metallothermic reduction of oxides are the least developed. Nevertheless, they show considerable promise. Thus the metallothermic reduction of oxides is the most rapid method, not only requiring no external supply of energy but even evolving considerable amounts of energy, which can be utilised technically to produce large quantities of refractory compounds by this method. Preparation from solutions in melts at ultrahigh pressures may reveal several new modifications of such compounds, possessing valuable new properties. The electrolysis of melts and solutions in melts enables pure products to be obtained from greatly contaminated starting materials. These last two methods, together with the gas-phase method, can be used for continuous preparation (with a cyclic process). Furthermore, they enable uniform protective coatings to be applied to articles of complicated shape made of metals and various materials, for which purpose direct synthesis from the elements is considerably less suitable. Finally, these methods—especially formation from molten solutions and in the gas phase—are promising for growing single crystals of refractory compounds, being irreplaceable, as already mentioned, when the latter melt incongruently. Apart from this, single crystals grown by these methods may differ considerably in their physicochemical properties from similar single crystals pulled from the melt: the former possess faces of natural (spontaneous) growth, whereas the faces of the latter are formed under the influence of various seeds and other factors. The fine point still remains to be settled of how greatly such processes influence the difference in surface and bulk physicochemical properties of single crystals of the compounds. The small size of the crystals when grown from solutions in melts may also be significant here: the tendency to miniaturisation in instrumentation and technology makes the use of such single crystals considerably more advantageous and convenient than larger crystals obtained from their own melts, which require appropriate machining [339].

From the above considerations we may conclude that at the present time the main lines of development of methods for the production of refractory compounds are the following.

1. Further investigation of metal–non-metal systems [340-347] in order to complete the development of one [276] or a combination of several already known processes and methods [165,166,228].

2. A considerable expansion of research on preparation from solutions in melts [117,134,139,140,348] and the electrolysis of solutions in melts [148-150,162,163].

3. Preparation by the thermal decomposition of chemical compounds, including organoelementary compounds [258,259,265,349-351].

4. The development of fundamentally new processes [352,353] and the production of new forms and modifications of the compounds [100,150,260,354,355].

5. Direct production from ores [90-92,275,356] and initial components of technical purity [88,179,357], and the development of continuous processes [350] with the aim of intensifying and cheapening production.

6. Vigorous development of work on production in plasma installations having high output and offering great opportunities for the development and application of synthetic processes [104,105,357-367].

7. Broad and intense research on the production of single crystals [127,317,319,321,368-377].

In conclusion it should be noted that several major problems—such as the production of compounds of high purity throughout their ranges of homogeneity, and also the growth of especially pure and alloyed single crystals—remain to be solved in the preparation of refractory compounds of transition metals.

The Principle of Hard and Soft Acids and Bases and the Problem of Competitive Coordination in Complex Compounds

A.D.Garnovskii, O.A.Osipov, and S.B.Bulgarevich

A systematic and general account is given of data on the location of the coordinate bond in systems with several potential electron-donating centres (competitive coordination). The problem is examined from the standpoint of the principle of hard and soft acids and bases.
The biliography includes 441 references.

CONTENTS

I. Introduction 341
II. The fundamental concepts of the principle of hard and soft acids and bases 341
III. The location of the coordinate bond in systems with several electron-donating centres: competitive coordination 342

I. INTRODUCTION

The principle of hard and soft acids and bases (HSAB), put forward by Pearson[1] in 1963 has been recently widely adopted in chemistry not only as a result of the author's own efforts[2-6] but also due to the publication of monographs[5,7-9], reviews[10-16], and original papers[17-25] in which certain problems of inorganic, organic, and coordination chemistry as well as the chemistry of organic derivatives of the elements have been discussed from the standpoint of hard and soft acids and bases.

The HSAB principle is based on three fundamental postulates: (I) the majority of chemical reactions may be regarded as of the acid–base type[1-6] and compounds can be treated as complexes of Lewis acids and bases[4]; (2) all acids (A) and bases (B) can be classified as hard (H), soft (S), and intermediate (I);[1-6,11] (3) acid–base reactions take place in such a way that hard acids (HA) are preferentially coordinated to hard bases (HB) and soft acids (SA) are preferentially coordinated to soft bases (SB).[1,4,5] The reactivities of the intermediate acids (IA) and bases (IB) require a specific consideration.

The above postulates, combined in the HSAB principle, are not new to chemists, since (1) the possibility of assigning chemical reactions to the acid–base category follows directly from the Usanovich theory[26], as rightly pointed out by Yatsimirskii[13], Day and Selbin[27], Evans[18], and Denes[28]; (2) the classification of acids which follows from the HSAB principle is identical with the classification of metal ions into classes A and B (Schwarzenbach[29]) or a and b (Ahrland, Chatt, and Davies[30]), as was emphasised by Pearson himself[4,5] and also in monographs[31,32] and reviews[10,33]; an approach to the estimation of softness and hardness of bases was suggested by Schwarzenbach[34,35]; (3) the preferential coordination of hard acids to hard bases and of soft acids to soft bases has long been known to chemists as the postulate of the predominance of electrostatic or covalent interaction in individual acid–base reactions (including donor–acceptor reactions[13]). This fact, which follows from classical polarisation concepts of coordination chemistry, has been pointed out in monographs[36-38] and original papers[13,39]. Here it is interesting to note that in his paper published in 1962, Hudson[40] states directly that polarisable ions tend to react at polarising centres, while non-polarisable ions react at charged non-polarising centres".

Nevertheless, these postulates, which are familiar and comprehensible to chemists and which have been tested on numerous examples[1-25,30-38,41], have been frequently disregarded and have not yet been considered in the discussion of many general and specific problems of organic, inorganic, and coordination chemistry as well as in the chemistry of organometallic compounds.

In this connection the undoubted usefulness of the HSAB principle in individual correlations and the general correlation of a large number of experimental facts concerning primarily the stability and reactivity of inorganic, organic, and coordination compounds and organometallic compounds must be recognised. This is confirmed by the finding that the formulation of the HSAB principle[1,2] and its vigorous propagation[3-7] stimulated the consideration of problems of the stability of coordination[5-7,13] and organic[4,6,14-16] compounds and their reactivity[4,8,14,17,24], the problem of electronegativity[18,19], and also the consideration of the nature of the attacking agent in quantum-chemical estimations of reactivity[20].

In the present review an attempt is made to apply the HSAB principle in the discussion of the problem of the location of the coordinate bond in the chemistry of coordination compounds. The enormous amount of experimental data accumulated on this problem has already been the subject of some discussion[7,12,24,25,33,42], but this has been unduly narrow[12,42] or insufficiently objective[33].

Among the very large amount of data published on this question, we have considered mainly those of the last five years.

II. THE FUNDAMENTAL CONCEPTS OF THE PRINCIPLE OF HARD AND SOFT ACIDS AND BASES

Using the criteria of hardness and softness, Pearson compiled Tables classifying acids and bases[1-6]. Despite the wide range of acids and bases covered and the satisfactory treatment of the preferred paths for reactions, Pearson's classification is in many ways arbitrary and in many cases cannot be used to account for the reactivity of coordination and organic compounds as well as organic derivatives of the elements.

The stability series of complexes with electron-donating atoms found on the basis of the existing classifications[4,29,30]:

$$\text{hard}\begin{cases}N \gg P > As > Sb\\ O \gg S > Se > Te\\ F \gg Cl > Br > I\end{cases}\qquad \text{and soft}\begin{cases}N \ll P < As < Sb\\ O \ll S \sim Se \sim Te\\ F < Cl < Br < I\end{cases}$$

are valid only when one disregards electronic and steric factors in molecules[14], which may alter significantly the "softness" and "hardness" of both an acid and a base. This has been frequently pointed out[7,10,31,32] in the assessment of the stability series of complexes using the classification of Ahrland, Chatt, and Davies[30]; these remarks are undoubtedly valid also for Pearson's classification Tables. When estimating "hardness" and "softness" of acids and bases, it is particularly important to take into account electronic and symbiotic effects[4,7,43], which may result in the "transfer" of an acid or base, particularly those of intermediate types, from one category to another (SA–IA–HA or SB–IB–AB). Numerous data useful in understanding the arbitrary nature of this type of classification in organic chemistry are given in a paper by Nesmeyanov and Kabachnik[41], in the reviews of Gompper[44] and Shevelev[14], and in Sokolov's papers[24,45] or organic derivatives of the elements.

In estimations of "hardness" and "softness", an important role must be attributed to specific reaction conditions and the effect of the solvent[4,14,40]. We believe that in this respect the "hardness" of the proton and "softness" of the methyl cation (CH_3^+) are particularly instructive. The entire data quoted by Pearson[4] appear to be consistent with his conclusion that the methyl cation is "softer" than the proton. However, data on the affinities of the proton and the methyl cation for various bases in the gas phase suggest that they are equally "hard".[13]

Thus Pearson's classification as well as earlier classifications (Chatt, Schwarzenbach)[29,30] are very approximate and should be used with a certain amount of caution.

Classifications of acids and bases according to Yatsimirskii[13].

No.	Groups	Acids	Bases
1	Ionic	Cs^+, Rb^+, NH_4^+	BR_4^-
2	σ-Acceptor acids, σ-donor bases	H^+, CH_3^+, CR_3^+, BR_3	H^-, CH_3^-, NR_3, NH_3
3	Strong σ-acceptors and donors; weak π-acceptors and donors	Li^+, Be^{2+}, Mg^{2+}, Al^{3+} Sc^{3+}, Zr^{4+}, Hf^{4+}	OH^-, H_2O, OR^- $RCOO^-$, XO_n^{2-}, F^-
4	Strong σ, π-acceptors; strong σ, π-donors	Tl^+, Pb^{2+}, Sn^{2+}, Bi^{3+} Ga^{3+}, In^{3+}, Tl^{3+}	Cl^-, Br^-, S^{2-} RS^-, R_2S
5	π-Acceptors; π-donors	Fe^{n+}, Co^{n+}, Ni^{2+}, Cu^{n+} Ag^+, Cd^{2+}, Pt^{II}, Pd^{2+}	—
6	π-Donors; π-acceptors	—	CO, CN^-, $C_5H_5^-$ CNS^-, R_3P

In this connection Yatsimirskii's classification, based on the assignment of acids and bases to different categories on the basis of the types of bonds formed by them, appears to be more correct[13].

Not being in a position to characterise in detail each of the groups quoted in the Table, we shall point out that groups 2 and 3 are hard (group 1 belongs to the category of acid–base reactions with electrostatic interaction[13,26]) and groups 4–6 combine soft acids and bases.

We see the advantages of Yatsimirskii's classification not only because of a more rigorous approach to the nature of acid–base interaction in its derivation but also because of the more correct distribution of cations and anions among different classes which follows from it. These considerations concern primarily the H^+, CH_3^+, and CR_3^+ hard cations which belong to one group, and the separate assignment of Al^{3+} and Sc^{3+} to hard cations (group 3) and of Ga^{3+} and In^{3+} to soft cations (group 4). It is shown below that in most cases the classification of all the cations included in group 5 as soft is justified. At the same time the assignment of quadrivalent zirconium and hafnium to hard cations (group 3) is not always justified and in this case account must be taken of the symbiotic effects of anions[4,7,43].

A quantum-chemical basis has been obtained for the HSAB principle[5,46,47] using the mathematical apparatus of the simple perturbation theory[48]. This approach is unduly narrow and suffers from many disadvantages[20,49]. However, such discussion is outside the scope of the present review.

III. THE LOCATION OF THE COORDINATE BOND IN SYSTEMS WITH SEVERAL ELECTRON-DONATING CENTRES: COMPETITIVE COORDINATION

In the discussion of the problem of competitive coordination, one must distinguish non-conjugated and conjugated systems. The first type includes saturated compounds (or compounds with isolated multiple bonds) where the reaction centres are separated from one another by at least one atom with a saturated valence. In compounds of the second type, the electron-donating centres are linked in a single mesomeric system (ambident compounds[50])†. From the theoretical standpoint, such division is based on the important difference between localised and delocalised orbitals.

1. Experimental Methods for Solving the Problem of Competitive Coordination

X-Ray diffraction analysis constitutes a direct and reliable method for the determination of the site where the coordinate bond is located and the complete elucidation of the structure of complexes. It has been frequently used to unravel molecular structures with different potential electron-donating centres: complexes of pseudohalides (NCX; X = O, S or Se),[12,51,52] urea,[33,53] thiourea,[54–56] dimethyl sulphoxide[57], morpholine[58], thiocarbazide[59,60], thioacetamide[61], and many other complexes[10,33]. However, the scope of X-ray diffraction analysis is limited owing to the amount of labour involved.

Most studies in this field have used spectroscopic methods, among which vibration spectroscopy has the greatest importance[62–74]. Its scope in coordination chemistry has been quite fully discussed in well known monographs[9,38,42,68,69] and therefore does not require special consideration. We shall only mention that, when infrared spectroscopy is employed, one must use considerable caution in those cases where the displacements of

†In their review, Norbury and Sinha[33] did not always consider the necessity for the conjugation of reaction centres in the definition of ambident ligands. Therefore, among the ambident compounds they consider, there are also non-conjugated systems, for example 1,4-oxathiane.

many ligand vibration frequencies during coordination interaction are used to draw conclusions as to the location of the bonds. The most accurate of such information has been obtained from calculations of molecular infrared spectroscopic data [69,70]. We believe that low-frequency infrared spectroscopy [71-74], whereby it is possible to determine directly the type of M–X bonds (X is an electron-donating atom), is promising in the study of the type of coordination [73].

Among other methods, mention should be made of electronic spectroscopy. Comparison of the theoretically predicted behaviour of a ligand in coordination to different electron-donating atoms with the experimental spectrum yields reliable evidence on the location of the bond. An instructive series of such studies have been carried out [75-79]. Other methods for using electronic spectroscopic data in the solution of the problem of competitive coordination are also known [33,78].

On further development of NMR spectroscopy, this method too will find wide application in this field of coordination chemistry. However, so far its use is limited (see for example, Refs. 17, 62, 63, 71).

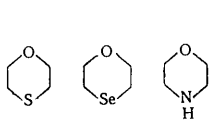
Modern quantum-chemical methods yield definite quantitative values for the electron distribution in molecules and therefore may be used to predict the direction of attack in systems with several electron-donating centres. Although so far few studies involving quantum-chemical calculations have been made in this field [12,52,80-84], they suggest that the coordinate bond is usually located at the electron-donating atom with the highest negative π-electron density.

In conclusion we may note that best results may be obtained by employing a combination of methods‡, including synthetic methods [75,80].

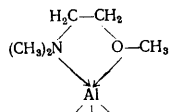
2. Non-conjugated Systems

The available literature data show that the location of the coordinate bond in non-conjugated systems in general obeys the requirements of the HSAB principle when account is taken of the hybrid state of the electron-donating atoms and of steric factors.

1,4-Oxathiane (I) and its selenium analogue (II) are perhaps the most successful models for the consideration of competitive coordination from the standpoint of the HSAB principle:



(I) (II) (III)



(IV)

Compounds (I) and (II) contain atoms, isolated from one another, belonging to the same group of the Periodic System, so that, according to the HSAB principle, in their interaction with hard acids, the coordinate bond should be preferentially located at the oxygen atom (hard centre) and in the interaction with soft acids, at the sulphur [compound (I)] or selenium [compound (II)] atom (soft electron-donating atoms). Experiments have confirmed these considerations.

‡The application of Mössbauer spectroscopy in this field is also promising [64,85].

The possibility of different sites of location of the coordinate bond (at oxygen or sulphur atoms) involving oxathiane was first formulated by Hendra and Powell [86], who established that in complexes with $CuCl_2$, $HgCl_2$, and $PtCl_2$, 1,4-oxathiane behaves as a monodentate ligand (only one of the electron-donating atoms is involved in coordination interaction). Subsequently it was shown in a series of studies [17,87-93] that the hard acids AlX_3 (X = Cl or Br)§ and BF_3 combine with the hard nucleophilic centre (oxygen) while the softer transition metal halides in the highest state of oxidation¶ combine with the soft sulphur and selenium atoms.

Platinum, palladium, rhodium [93], and mercury [92,94] salts also combine with the sulphur atom of compound (I). The above studies were carried out mainly by infrared and NMR spectroscopic methods [62,87-93] and the reliability of the conclusions may be open to certain objections because the vibration frequencies of the C–X–C linkages (X = O, S, or Se), on whose behaviour in coordination interactions the principle conclusions are based, are relatively non-characteristic. The work of McEwen and Sinn [94], where the coordination of mercury and sulphur atoms was demonstrated by an X-ray diffraction study of the $HgCl_2.I_2$ complex, is superior in this respect.

Morpholine (III) contains identically hybridised oxygen and nitrogen atoms, the first of which, being more electronegative [95], is therefore harder than amino-nitrogen. In this case too the location of the coordinate bond agrees with conclusions based on the HSAB theory: soft (AgI) [58] and intermediate (salts of many bivalent [96,97] and tervalent [98] metals) acids combine with the nitrogen atom. Only in the case of $Al(CH_3)_3$ is it possible to obtain a complex with the composition $2Al(CH_3)_3$.(III) where both centres are involved in the coordination interaction [99]. Probably the coordinate bond involves the oxygen atom also in the platinum complexes of morpholine [100]. Identically hybridised oxygen and nitrogen atoms are present also in α-dimethylamino-β-methoxyethane which forms a cyclic structure (IV) with $Al(CH_3)_3$. [101] However, in this case it is difficult to assess the competitive interaction of oxygen and nitrogen atoms owing to both the limited selection of acceptors and to the energy gain usually observed on formation of cyclic structures of type (IV). The latter factor must be always considered in the study of the competitive coordination of ligands the electron donating centres of which may be involved in the formation of metal-containing rings.

This approach appears to be particularly useful in studies of the possibility of the coordination of acids and their esters. These compounds are convenient models for a comparison of the coordination capacities of the sp^3-hybridised nitrogen atom (amino-group) and the oxygen atom (amino-group) and the oxygen atom in the sp^2-hybrid state (the carbonyl group). On the basis of the foregoing considerations, amino-nitrogen may be regarded as a softer electron-donating centre than the carbonyl oxygen.

§In the review of Norbury and Sinha [33], the halides AlX_3 are erroneously included in the group of acids combining with the sulphur atom of oxathiane.

¶The softness of cations of this kind is associated not only with the highest degree of oxidation of the metal but also with the symbiotic effect of the X anion. In particular $TiCl_4$ forms more stable complexes with dialkyl sulphides than with ethers [88], i.e. is a soft acid according to the HSAB classification.

This idea is confirmed by the finding that in complexes of α- and γ-amino-acids (AH) of the type $[(AH)_2Pt(NH_3)_2]Cl_2$ as well as in the glycine complexes $(GlH)-Pt(GlH)_2Cl_2$, the soft acid $PtCl_2$ is linked to the amino-nitrogen [102,103]. Similarly α-aminoacid esters may react with salts of comparatively soft bivalent metals as monodentate ligands with preferential formation of an M–N bond (only with methyl-L-tryptophan is coordination involving the C=O group observed) [104]. However, in most cases [105–107] amino-acids behave as bidentate ligands and form cyclic chelate compounds.

Similar cyclic structures arise in the coordination interaction of thio- and seleno-semicarbazides [108,109] with metal salts, although there is evidence that comparatively soft acids combine preferentially with the softer sulphur and selenium atoms [110,111]†.

Aminonitriles with the general formula $R_2N(CH_2)_nCN$ have two electron-donating centres: sp^3- and sp-hybridised nitrogen atoms. If one bears in mind that the electronegativity, which in many ways determines the hardness of nucleophilic agents [4], increases with the amount of s-character in the hybrid orbitals of the nitrogen atoms [95,112], one must assume that the nitrogen atom of the nitrile group is a harder donor than the amino-nitrogen. Therefore, in agreement with the HSAB principle, only may assume that hard acids will combine preferentially with the hard nitrile nitrogen and soft acids with the amino-nitrogen. Experimental data agree with these considerations. In the case of hard BCl_3, an increase of the vibration frequencies of the nitrile group in the aminonitrile with $R = C_2H_5$ and $n = 1$ is observed [113], showing that the coordinate bond involves the nitrile nitrogen [114–116]. The comparatively soft MX_4 (M = Sn, Ti, or Zr; X = Cl or Br) form complexes without involving the nitrile group [113]. However, with $n = 2$ or 3, the MX_4 also form cyclic structures and both electron-donating nitrogen atoms of the aminonitrile are involved in the coordination interaction [112].

Not only individual atoms but also the π bonds of unsaturated hydrocarbons can behave as soft electron-donating centres. Electron-donating systems of this kind include allylamines [117–120] and aminoallene and aminoacetylene hydrocarbons [121].

Depending on the reaction conditions, allylamine can behave as a monodentate or a bidentate ligand. As expected, in the first case $PtCl_2$ combines with the π bond of the ethylene group [119], which is a softer centre, and in the second case it combines with both electron-donating centres, forming dimeric bridge structures [117,118] or monomeric cyclic structures [119,120]. The latter are characteristic also of complexes of bivalent nickel, cobalt, manganese, copper, iron, zinc, and cadmium and tervalent iron, chromium, cerium, and praseodymium with aminoallene, aminoethylene, and aminoacetylene ligands [121].

3. Systems with Conjugated Bonds (Ambident Ligands)

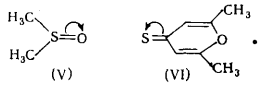
Examination of competitive coordination in compounds with conjugated electron-donating centres is very important not only because of the great range (mentioned above) of the reactivities of ambident systems but also because it deals with the salt [122] or structural [123] isomerism, which is extremely important for coordination symmetry‡.

From the standpoint of the HSAB principle, the problem of the location of the coordinate bond in conjugated systems with several electron-donating centres is of special interest, since nucleophilic atoms in ambident compounds become harder or softer, mainly under the influence of electronic effects, than in the isolated ligands or in the non-conjugated systems discussed above.

a. Ambident Ligands with Electron-donating Atoms of Elements in the Same Periodic Group

Oxygen and sulphur (selenium) atoms. In conjugated systems containing the hard oxygen atoms and the soft sulphur and selenium atoms, the position of the coordinate bond is generally consistent with the requirements of the HSAB concept: typical [1,25] soft acids (Pt, Pd, Rh, Hg) form a bond with the sulphur and selenium atoms, while harder acids (Al, Th) combine with the oxygen atom [10,33]. However, with intermediate acids (salts of bivalent metals, metal carbonyls), the oxygen atom is preferentially involved in the formation of the coordinate bond [33], although a bond with the sulphur atom is also observed. Thus not only iridium [126,127], palladium [128], platinum [129], and rhodium [130], but also cobalt [28,131] forms bonds with the sulphur atom of the sulphite anion. A bond with the sulphur atom is formed by the majority of metals [33,132,133] and their carbonyls [134] in complexes with sulphur dioxide and also sulphones and sulphonyl chlorides [33]. On the other hand, the hard $AlCl_3$ forms with the ligands of the last type complexes involving Al–O bonds [135].

There is a particularly large amount of data concerning the location of the coordinate bond in sulphoxide complexes. Intermediate and hard cations [10,28,136–143], organometallic derivatives [144–147], and even metal carbonyls [148] combine with the oxygen atom of dimethyl sulphoxide (DMSO) (V). However, in accordance with the HSAB principle, soft acids are coordinated via the sulphur atom [33,149–156]. The conclusions reached concerning the mode of coordination of DMSO give rise to no doubts not only owing to the reliability of the assignment of the S=O frequencies [68] but also because the conclusions were in many cases based on X-ray diffraction data [144,157–159]. Complexes with M–O bonds only have been described for dimethyl selenoxide [10,33]:



(V) (VI)

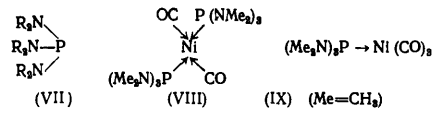
The different coordination behaviour of sulphoxides (compared with oxathiane and oxaselenane discussed in the preceding section) can probably be accounted for by a mesomeric effect which increases the "softness" of the oxygen atom. A similar effect may be observed for the sulphur atom in 2,6-dimethyl-4-thiopyrone (VI), for which M–S bonds have been described [160].

Nitrogen and phosphorus atoms. Tri-(*NN*-dialkylamino)phosphines (VII)—ambident systems containing tervalent electron-donating nitrogen and phosphorus

†It was stated in this study that the mode of coordination of thiosemicarbazide depends on the assignment of the metals to the Chatt classes a and b.

‡Recently this type of isomerism has been referred to as linkage isomerism in non-Soviet literature [5,124]; in Soviet coordination chemistry this concept is given a different significance [125].

atoms—are extremely sensitive to the "hardness" and "softness" of acids:



(VII) (VIII) (IX) (Me=CH_3)

The soft HgI_2, CdI_2,[161] and BH_3 [162,163] form adducts with aminophosphines which involve an M–P bond, while the harder BR_3, BCl_3, BF_3,[163] and PCl_3 [164] attack the nitrogen atom and dissociate the P–N bond:

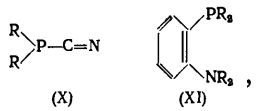
$$(NMe_2)_3P \rightarrow BH_3 \xleftarrow{(BH_3)_2} P(NMe_2)_3 \xrightarrow{BX_3(X=F,Cl)} Me_2NBX_2 + PX_3 .$$

Molecular complexes involving the "soft" phosphorus atom are also formed[161] when aminophosphines react with $Ni(CO_4)$ (VIII, IX). The soft diborane also adds to the phosphorus atom in *N*-diphenylphosphinotriphenylphosphazenes[165]:

$$(C_6H_5)_3P{=}N{-}P(C_6H_5)_2 + (BH_3)_2 \rightarrow (C_6H_5)_3P{=}N{-}\overset{\overset{C_6H_5}{|}}{P}{:}BH_3 + BH_3 .$$
$$\underset{C_6H_5}{|}$$

The coordination interaction of AlX_3 (X = H, Cl, or Br) with phosphorus(III) cyanides (X) probably involves the phosphorus atom[166].

Dialkyl-(*o*-dialkylphosphinophenyl)amines (XI) are interesting ambident systems[167]:



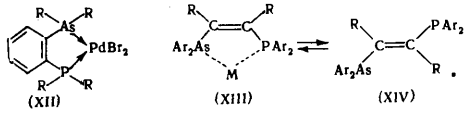
(X) (XI)

where R = alkyl or aryl. However, the formation of complexes by ligands of this type has not so far been investigated.

Here we may mention the exceptionally high electron-donating activity shown by tervalent phosphorus in ambident systems containing phosphorus and nitrogen atoms when interacting with halogens[165,168] oxygen, sulphur, selenium, tellurium[165], and other substances[165,170,171].

Quinquevalent phosphorus has almost no electron-donating properties and its derivatives are fairly active electron-acceptors[169,172]. Thus PF_5 is a stronger Lewis acid than BF_3—one of the hardest acids[173]. In agreement with this finding, ambident systems containing quinquevalent phosphorus and nitrogen behave as monodentate ligands, which form on coordination interaction complexes with exclusively M–N bonds. The complexes of phosphazenes are similar coordination compounds[174].

Phosphorus and arsenic atoms. Dialkyl-(*o*-dialkylphosphinophenyl)arsines are ambident systems containing electron-donating phosphorus and arsenic atoms, which form cyclic structures (XII) with the soft $PdBr_2$:[175]



(XII) (XIII) (XIV)

Probably metal-containing rings of this kind should be characteristic also of the *cis*-isomers of ethylene derivatives (XIII),[176] but, when the electron-donating centres in the ambident system (XIV) are in the *trans*-positions and for the *meta*- and *para*-substituted derivatives of compound (XII), it is very likely that the reaction will take place separately at the phosphorus and arsenic atoms[177]. Preferential coordination should be even more characteristic of analogous derivatives with nitrogen and phosphorus atoms and particularly of those with nitrogen and arsenic atoms[177].

b. Conjugated Systems with Electron-donating Atoms (of Group V and VI Elements)

Nitrogen and oxygen (sulphur, selenium) atoms. The simplest ambident systems containing nitrogen and oxygen systems are NO and NO_2 groups.

Nitrosyl complexes involve exclusively bonds with the nitrogen atom[33,38]. This conclusion was initially based mainly on infrared spectroscopic data and was recently confirmed for a series of complexes by X-ray diffraction studies[33,178].

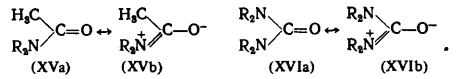
For the nitrite ion, in the study of the complexes of which salt isomerism[33,36,180] was discovered[179], two types of complexes are known: nitro-complexes in which the metal is linked to the nitrogen atom and nitrito-complexes in which a bond with the oxygen atom is formed (in the latter case cyclic structures are also possible)[33]. The majority of hard and soft metals form nitro-complexes and only a few very unusual compounds $[Ni(NO_2)_2L_X]_2$, $K_3Cu(NO_2)_5$, $K_4Ni(NO_2)_6$, etc. involve the formation of nitrito-complexes[28]. For both ions considered, the site of the coordinate bond is independent of the "hardness" or "softness" of the cations, being determined to a large extent by the ligand environment. Thus compounds of the type $ML_X(NO_2)_2$ (L = ammonia, ethylenediamine, pyridine, and its 2-amino-derivatives) are typical nitro-complexes, while 1,2-diphenylene-ethylenediamine is known to form also nitrito-complexes[33].

A similar situation arises also for cyanato-complexes[33,52]. It has been shown[52] that all the known cyanate complexes may be divided into four groups in terms of the mode of coordination of the NCO^- anion: in the first group NCO^- is coordinated via the nitrogen atom (isocyanates), in the second group via the oxygen atom (cyanates), the third group includes compounds with isocyanate bridges of the type $M\diagdown\!\!\diagup NCO$, and the fourth group includes compounds in which the NCO groups play the role of outer-sphere ions. The M–NCO structure has been observed for manganese(II), iron(II), cobalt(II), nickel(II), copper(II), zinc(II), cadmium(II), silver(I), lead(II), and indium(III) in compounds of the type $M(NCO)_n mL$ (L = pyridine, 2-aminopyridine, 2,2′- or 4,4′-dipyridyl, 1,10-phenanthroline, or urotropine). The same structure is characteristic of the typical soft platinum(II) and palladium(II) cations. The NCO group interacts via the nitrogen atom also with the "soft" mercury, silver, cadmium, and copper, but in this case bridge structures are formed (the third group).

The second group of compounds, involving the M–O bond includes only a few complexes with mercury(II), molybdenum(III), rhenium(IV), and rhenium(V). Preferential coordination via the nitrogen atom, which has been frequently demonstrated by systematic infrared spectroscopic[52,69,74] and X-ray diffraction[52] studies, agrees with the high π-electronic charge at the nitrogen atom of the cyanate anion[181–183].

A different picture is observed for the amides of monocarboxylic acids (XV), which behave mainly as

monodentate ligands with the coordinate bond located at the oxygen atom[33]:

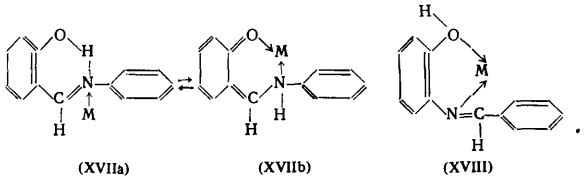


(XVa) (XVb) (XVIa) (XVIb)

Such coordination, which can be explained[184] by the enhanced electron density at the oxygen atom associated with the mesomeric effect of conjugation in (XVb), is characteristic of salts of Group I[185,186] and III–V[9,33,184,187-193] metals, the UO_2 cation[194-197], certain bivalent metals[198-203], and the soft platinum(II) and palladium(II)[33]. This type of coordination has been fairly convincingly demonstrated on the basis of infrared spectra (decrease of the stretching vibration frequencies of the amide bands[204]) and follows also from X-ray diffraction data[12,52] and NMR spectra[184]. The coordination interaction of MX_n with aminoacetophenone[205] and *NN*-dimethylamino-derivatives of unsaturated aromatic ketones[206] takes place similarly. At the same time in a few studies it has been suggested that complexes may be formed via the nitrogen atom[207], the N–M–O bridge linkage[33], and even via the hydrogen atom attached to the carbonyl carbon atom of dimethylformamide[208,209]. The above hypotheses and particularly the last one appear to be unlikely.

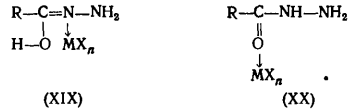
The possibility that the nitrogen and oxygen atoms of urea and its *N*-derivatives are involved in coordination interaction has been more rigorously demonstrated. It has become generally accepted[38,42,68] that, on coordination via the nitrogen atom, urea has the structure (XVIa) and the coordination via the oxygen atom is due to the mesomeric conjugation effect in (XVIb). It ought to be possible to apply successfully the HSAB principle to this compound in order to account for the location of the coordinate bond at the nitrogen atom in the complexes with the "soft" palladium and platinum[33] and at the oxygen atom in the complexes of "hard" acids[33,38,42,203,210-223]. However, the finding[224] that the "hard" BF_3 is coordinated at the nitrogen atom of *N*-alkyl(aryl)-substituted urea shows that in this case the HSAB concept should be employed with much caution§.

Among other ligands containing nitrogen and oxygen atoms, mention should be made of *p*-hydroxyazomethines (XVII, XVIII):



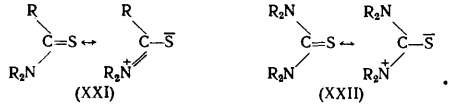
(XVIIa) (XVIIb) (XVIII)

For the complexes (XVIIa–XVIII) with MX_X (M = M^I, M^{II}, M^{III}, M^{IV}, or M^V; X = Cl, Br, or I), the formation of the quinonoid configuration (XVIIb), where the metal is linked to the oxygen and nitrogen atoms[235,236], is quite likely to occur, as well as structures in which the metal is bound to the nitrogen atom (XVIIa, XVIII).[225-234] The data obtained in the study of the structures of the complexes of transition metal, cadmium, and zinc halides with acetyl and benzoyl hydrazides are also consistent with the above considerations[237]. However, the "imidol" structure (XIX), rather than the hydrazide structure (XX), attributed in this case to the complexes requires additional proof:



(XIX) (XX)

In contrast to nitrogen- and oxygen-containing ligands, ambident systems with nitrogen and oxygen atoms enter into coordination interactions mainly in accordance with the HSAB principle. The behaviour of the thiocyanate anion is particularly instructive in this respect. The interaction of soft metals (platinum, palladium, silver, gold, and mercury) with this anion always results in the formation of a bond via the sulphur atom[5,12,33,52,68], while hard metals are linked to the hard nucleophilic centre—the nitrogen[12,33,52,238-242]. Such preferential coordination¶ via the nitrogen or sulphur atom in the thiocyanate ion has been rigorously demonstrated by infrared spectroscopic[12,28,69,243-245] and X-ray diffraction studies[12,33,52] and has been frequently discussed as a classical example of competitive coordination[12,33]. At the same time it is regarded as proven that, regardless of their "hardness" or "softness", metals react with thioamides[33,246,247] and thiourea[248-270] to form preferentially complexes with an M–S bond. Probably, as for amides and urea, the formation of structures with strongly polarised C=S bonds (XXI–XXII) leads to a reduced electrondensity at the nitrogen atom and makes it relatively inaccessible to coordination interaction:



(XXI) (XXII)

However, it has been suggested that "soft" acids [platinum(II) and palladium(II)] are linked to the nitrogen atom in *N*-methylthiourea[271] and intermediate acids ($TiCl_4$) are linked to the nitrogen atom in thiourea itself[272]. The possible involvement of the sulphur atom in thiourea in coordination interaction with the soft Ag^+ cation follows also from a potentiostatic study of complexes of the type $Ag^+[(NH_2)_2CS]_n$.[273] One cannot rule out the possibility that thiourea forms with soft metals (palladium, mercury) bridge structures in which nitrogen and sulphur atoms are simultaneously involved in coordination[274,275].

The site of the coordinate bond containing nitrogen and selenium atoms is also consistent with the HSAB principles: metals of class a (hard cations) prefer the hard nitrogen atom and those of class b (soft cations) prefer the soft electron-donating centre—the selenium atom[12,33,51,52,276].

As a result of many years of systematic study by Soviet chemists[12,51,52,276], the most complete data on the competitive coordination of nitrogen and selenium atoms have been obtained for the selenocyanate ion $NCSe^-$. The results yielded by infrared spectroscopic[52,69,276] and X-ray diffraction[12,52] methods make it possible to divide[276] selenocyanate complexes into three groups: ionic selenocyanates and complexes in which the metal is linked to the nitrogen or selenium atom. Ionic selenocyanates are formed by alkali metals, strontium, barium, and thallium:

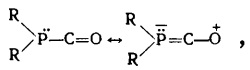
§The authors themselves[224] believe that the coordination of BF_3 at the nitrogen atom can be justified from the standpoint of the HSAB principle by its greater rigidity compared with the oxygen atom. However, this explanation conflicts with the coordination of the "soft" platinum(II) and palladium(II) via the nitrogen atom in urea[33].

¶One cannot exclude also the possibility of forming bridge structures in which the thiocyanate ion is linked to transition metal atoms via both electron-donating atoms[12,33].

complexes involving the selenium atom are characteristic of the soft cations of silver, gold, mercury, and the platinum metals [33,276]. The remaining metals form complexes via the nitrogen atom [12,33,276-283]. Cadmium, lead, and tervalent cobalt, which are capable of forming complexes both via the nitrogen and selenium atoms, may be regarded as an intermediate group of metals [74,276,281]. There is also a group of two-metal complexes in which the $NCSe^-$ anion behaves as a bridge [274,276]. The structure of these compounds also fits into the framework of the HSAB principle. Soft metals form a bond with selenium and hard and intermediate metals with the nitrogen atom. Thus in the complex $CoHg(SeCN)_4$ cobalt is linked to the nitrogen atom and mercury to selenium: the analogous lead derivative evidently has the same structure [276].

As was in fact to be expected, in complexes of selenourea and its *NN*-derivatives with soft metals, a linkage between the metal and selenium atom is formed [10,284,285]. This structure occurs also in mixed complexes of tervalent cobalt of the type $[Co(DM)_2Seu_2]X$ and $[Co(DM)_2(Seu)ThiO]X$, where DM = dimethylglyoxime, Seu = selenourea, ThiO = thiourea, and X = acid residue [221,286].

Phosphorus and oxygen (sulphur, selenium) atoms. As in the systems containing phosphorus and oxygen atoms, tervalent phosphorus exhibits a more pronounced electron-donating capacity than does the oxygen atom [170,171,287]. Thus the study of the infrared spectra of complexes of metal halides with the phosphides of monocarboxylic acids (XXIII) shows that, regardless of the "hardness" or "softness" of the acids, the coordinate bond involves the phosphorus atom (the stretching vibration frequencies of the C=O group increase) [287]:



(XXIII)

where R = alkyl, aryl, or arylalkyl.

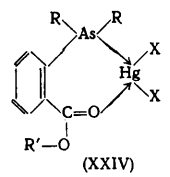
This result, which conflicts with the HSAB principle† might be explained by the conjugation of the carbonyl group with the *d* orbitals of phosphorus, which leads to the appearance of a negative charge at the phosphorus atom and a positive charge at the oxygen atom together with a decrease in the order of the C=O bond [288,289]. However, there are serious objections to such an explanation associated with the absence or an insignificant degree of p,π conjugation in systems with tervalent phosphorus [171].

In contrast to tervalent phosphorus, quinquevalent phosphorus has almost no electron-donating properties and in systems with $\rangle P{=}X$ (X = O, S, or Se) groups, the donor–acceptor interaction involves exclusively the X atoms. There are numerous literature data concerning the coordination interactions of metals with $POCl_3$, $PSCl_3$, and $R_3P = O$ which are quoted by Webster [172] and by Bridgland and McGregor [290] and for similar interactions involving $R_3P = Se$ by Nicpon and Meck [291].

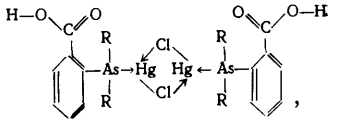
†Preferential coordination via the oxygen atom and not the phosphorus atom would be expected [1,4,16].

Arsenic and oxygen (sulphur) atoms. There are comparatively few data available for the discussion of the site of the coordinate bond in ambident systems containing tervalent arsenic and Group VI elements as electron-donating centres.

It has been shown that, in complexes of HgX_2 (X = Cl, Br, or I) with dialkyl(aryl)-2-carboxyphenylarsine and its derivatives, mercury is linked to the arsenic atom and the carbonyl oxygen [compound (XXIV)]: [292]



(XXIV)



(XXV)

where R = CH_3, C_6H_5, or C_7H_7 and R′ = H or CH_3 in compound (XXIV) and R = C_6H_5 in compound (XXV).

It has been suggested that 2-carboxyphenyldiphenylarsine forms a dimeric bridge structure in which the soft $HgCl_2$ is linked only to the soft electron-donating centre—the arsenic atom is (XXV). [292]

Like quinquevalent phosphorus, quinquevalent arsenic has no electron-donating properties and therefore in ligands of the type $R_3As = X$ (R = alkyl or aryl; X = O or S), the coordination interaction involves exclusively the X electron-donating atom [290,293-295]. This conclusion has been confirmed by studies on the complexes $R_3As{=}X \rightarrow MYn$ in the far infrared (the vibrations of the M–X bonds have been detected in the range 270 to 450 cm^{-1}). [296,297]

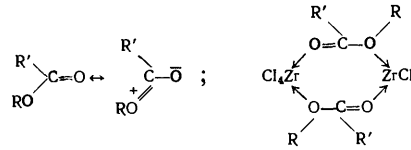
c. Ambident Systems with Identical Electron-donating Atoms

Analysis of the literature data shows that even for electron-donating atoms which are identical but subjected to different electronic and steric influences in the molecule, one may formulate the problem of competitive coordination. For such nucleophilic centres, the concepts of "hardness" and "softness" can probably retain their significance in the sense of a greater or smaller accessibility to coordination attack by electrophilic agents.

The postulate of an increased electron-donating capacity by nucleophilic atoms with increasing *p* character of the hybrid orbitals [298-300], which follows from Paulings' theory, would appear to predict an increase of preferential coordination in the following sequence of electron-donating atoms with different types of hybridisation: $sp < sp^2 < sp^3$. However, this postulate is probably valid only for isolated or non-conjugated systems. On the other hand, in ambident compounds the direction of coordination attack depends significantly on the distribution of electron density (the π-electronic densities at the nucleophilic centres), the degree of localisation of electrons at the electron-donating atoms, and steric factors.

Oxygen atoms. Numerous studies designed to establish the site of the coordinate bond in complexes of organic acids and esters with Lewis acids have shown that the oxygen of the carbonyl group is the electron-donating atom [9,16,38,42,68]. Regardless of the "hardness" or "softness" of the acids and the bulk and the electronic effect of the substituents (R and R′), the infrared spectra of the complexes (XXVI) always show a decrease of the stretching vibration frequency of the carbonyl group [301-309], which is

fairly convincing evidence [33,37] in favour of the reaction involving the carbonyl oxygen‡:

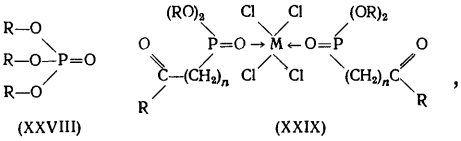


(XXVI)
R = alkyl or aryl;
R' = H, alkyl or aryl

(XXVII)
R=C_2H_5; R'=CH_3

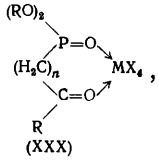
This direction of coordination attack (which contradicts Pauling's theory [311] can probably be accounted for by σ, π conjugation in compounds (XXVI), which leads to an increase in electron density at the carbonyl oxygen in esters compared with aldehydes or ketones and to a decreased capacity of the alkoxy-oxygen (the alcoholic oxygen) for participation in coordination interaction (compared with alcohols and ethers).

At the same time there is reason to suppose that not only carbonyl but also alkoxy-oxygen (alcoholic oxygen) of esters and organic acids may be involved in coordination interaction. In this case the non-planar dimers (XXVII) are formed in solution [312]. Evidently one cannot rule out the possibility of the formation in the condensed phase of coordination polymers involving the alkoxy- and carbonyl oxygen. Therefore, the conclusions concerning the site of the coordinate bond based solely on infrared spectroscopic data must be treated with caution. Dipole moments may prove very useful in solving this problem [313].



(XXVIII) (XXIX)

where M = Sn or Ti;



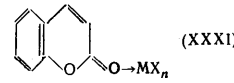
(XXX)

where M = Ti or Sn and X = Cl, Br, or I.

In alkyl phosphate complexes the coordinate bond is located solely at the oxygen of the phosphoryl group [compound (XXVIII)], [314-317] the electron-donating activity of which surpasses even that of the carbonyl group, since in complexes of α-ketophosphinic acids [318] and β-phosphonocarbonyl compounds [319] with the composition $MX_4.2L$ the coordination involves only the phosphoryl oxygen [compound (XXIX)]. On the other hand, in complexes with the composition $MX_4.L$, cyclic structures (XXX) are formed, the coordination interaction in which involves the carbonyl and phosphoryl but not the alkoxy-oxygen atoms, in agreement with the foregoing considerations [318,319].

‡In this connection one can hardly agree with the view of Pilipenko and Savranskii [301] that the carbonyl oxygen has a lower coordination capacity compared with the hydroxyl oxygen in the conjugated systems which they considered.

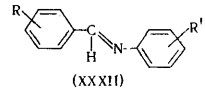
The formation of the complexes by the halides of Group III–V elements with the keto-derivatives (XXXI) involves the carbonyl oxygen [320]:



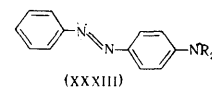
(XXXI)

where M = Ti, Sn, Zr, In, Ga, or Nb, X = Cl, Br, or I, and n = 3–5.

Nitrogen atoms. The azomethines (XXXII) and the azo-compounds (XXXIII) containing an amino- or a dimethylamino-group in the aromatic ring are suitable examples for discussing the problem of the site of the coordinate bond in ambident systems with sp^3- and sp^2-hybridised nitrogen atoms:



(XXXII)
a. R = p-$N(CH_3)_2$; R' = H
b. R = m-$N(CH_3)_2$; R' = H
c. R = H; R' = m-$N(CH_3)_2$
d. R = H; R' = p-$N(CH_3)_2$
e. R = R' = p-$N(CH_3)_2$

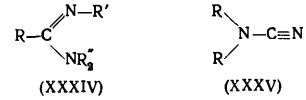


(XXXIII)
a. R = H
b. R = CH_3

It was established on the basis of infrared and ultraviolet spectra and quantum-chemical calculations that the formation of complexes by compound (XXXII) with the chlorides of Group IV and V elements involves the nitrogen atom of the azomethine group, which has the maximum π-electron density [80].

Only in compound (XXXIIc) is the electron-donating centre the amino-nitrogen [80], which forms also quaternary salts [75]. In view of the small difference between the ultraviolet spectra of the adducts of $CuCl_2$, $CoCl_2$, and $HgCl_2$ with 4-aminoazobenzene (XXXIII, R = H) and the spectrum of the initial azo-compound, one must assume that the coordinate bond in such compounds is located at the amino-nitrogen [67,76,77]. At the same time, BF_3, $SnCl_4$, and $SbCl_5$ form bonds preferentially with the nitrogen atom of the azo-group [77-79].

It has recently been shown that in the amidines (XXXIV) with sp^2- and sp^3-hybridised nitrogen atoms the coordinate bonds formed on interaction with $SnCl_4$ [321] and $B(n\text{-}C_3H_7)_3$ [322] is located at the nitrogen atom of the azomethine group:



(XXXIV) (XXXV)

where R = H, alkyl, or aryl and R' = R'' = aryl for compounds (XXXIV) and R = H or alkyl for compounds (XXXV).

Cyanamide and its *NN*-dialkylderivatives (XXXV) are the simplest ambident systems with sp^3- and sp-hybridised nitrogen atoms. On interaction with MX_4 (M = Sn, Ti, or Zn and X = Cl or Br), cyanamide itself behaves as a bidentate ligand, while its dialkyl derivatives are coordinated via the harder nitrogen atom of the nitrile group [323]. Probably in the case of sp^3- and sp-hybridised nitrogen atoms the direction of coordination attack is determined mainly by the negative π-electron densities§, although one

§The sp-hybridised nitrile nitrogen has a much higher negative π-electron charge density (−0.279) than that of the amino-nitrogen (−0.064). [324]

canot rule out the possibility that the bulky ethyl substituents prevent the location of the bond at the amino-nitrogen[325].

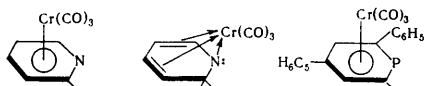
Thus the principal factor determining the mode of addition of electrophilic agents (acids) in ambident systems with several competing but identical electron-donating atoms is the magnitude of the negative π-electron charge density. This conclusion is directly related to the HSAB principal and the familiar postulate that the most nucleophilic centre in the molecule is the electron-donating atom with the highest negative potential.

d. Specific Ambident Systems

Heteroaromatic compounds. In five-membered heterocycles with a single heteroatom (furan, thiophen, selenophen, and pyrrole), which have two potential electron-donating centres (the heteroatom and the π-electron system), coordination interaction involves mainly¶ π electrons[9,327-334].

There is at present no doubt about the validity of this conclusion: (1) metal carbonyl π complexes of pyrrole[331,334], thiophen[335,336], and selenophen[336] have been synthesised; (2) azoferrocene has been obtained on the basis of the π-electron system of pyrrole[332,333]; (3) measurements of the dipole moments and studies on the infrared spectra of thiophen and furan complexes of $SnCl_4$ indicate the occurrence of π-electron coordination interaction[9,327-329].

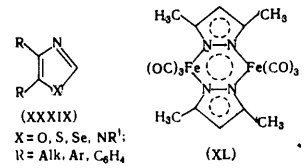
In contrast to five-membered heterocycles, six-membered heterocyclic nitrogen-containing systems (pyridine, quinoline, and many of their derivatives) react with metal salts exclusively via the nitrogen atom[337,338]. The reported synthesis of a chromium tricarbonyl π complex of pyridine (XXXVI)[339] was disproved by the same investigators[340]†, who showed that the π complex[339] is in fact a π,σ derivative of the hydrogenated pyridine ring[340] and the amino-olefinic system (XXXVII) is involved in coordination interaction. It is interesting to note that a similar π,σ bond has been attributed to the magnanese tricarbonyl derivative of pyrrole[342]. At the same time 2,4,6-triphenylphosphorine (phosphabenzene—L) forms both σ complexes with the compositions $L(CO)_5$ and $L(CO)_4$ and the π complex $L(CO)_3$ with the structure (XXXVIII):[343]



(XXXVI) (XXXVII) (XXXVIII)

The azoles (XXXIX)[334,345]—five-membered heterocycles with two heteroatoms one of which is nitrogen—and their aromatic analogues behave in coordination interaction like the six-membered heteroaromatic systems (pyridine) and not like the thiophen (furan, pyrrole) systems.

Azole-containing systems form mainly σ complexes via the nitrogen atom of the azole ring with Group II,[346-349] III,[350-353] IV,[354-359] and V[357-358] metal salts, Group III metal derivatives[359,360], and Group VI metal carbonyls[361-363]



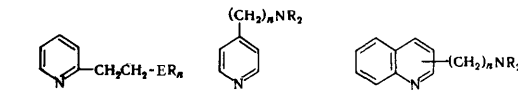
(XXXIX) X = O, S, Se, NR^1; R = Alk, Ar, C_6H_4 (XL)

However, objections have been made against the involvement in the coordination interaction of the π-electron system of the azole ring[364] and the electron pair of the X heteroatom[365] and therefore we believe that additional tests are required. The properties of the 3,5-dimethylpyrazole complex of iron carbonyl can be accounted for not only from the standpoint of π complex formation but also by the formation of the dimeric structure (XL), resembling that of the complexes of pyrazole with BF_3[366] and AlR_3.[359,360]

The hypothesis concerning the possible coordination via the X heteroatoms conflicts with the familiar postulate that sp^3-hybridised O, S, Se atoms and NR groups of azoles have no electron-donating properties[344,367]. Moreover, the negative π-electronic charge density is almost wholly localised at the nitrogen atom (the X atom is positively charged), which, was shown above to constitute the principal factor responsible for the location of the coordinate bond at the competing heteroatoms of the ambident system‡.

Thus, according to published data, heteroaromatic systems behave predominantly as monodentate ligands: five-membered systems (pyrrole, thiophen, furan, and selenophen) are π-electron donors and six-membered nitrogen containing systems and azoles are σ-electron donors.

Derivatives of heteroaromatic systems. The non-conjugated systems (XLI–XLIV) form several classes of complexes[368-374]:



(XLI-XLII) (XLI): E = P, As, N: R = Alk. Ar; $n = 2$ (XLII): E = O, S: R = H, Alk; $n = 1$ (XLIII) R = H, Alk, Ar. $n = 1, 2$ (XLIV) R = H, Alk; $n = 1, 2$

Nickel(II), cobalt(II), and zinc(II) salts form cyclic structures with 2-(β-diphenylphosphinoethyl)pyridine (XLI, E = P) involving the nitrogen and phosphorus atoms[368]. On the other hand, when there is a considerable difference in hardness, for example between the nitrogen and arsenic atoms, the above salts interact only with the nitrogen atom, while the soft copper(I) halides interact with the "soft" arsenic atom[369].

¶There is some evidence for the possibility of the quaternisation of the sulphur atom of thiophen[326]. The hydrogenated five-membered systems readily form σ-complexes via the heteroatom[9,327-330].

†Unfortunately this erroneous study was employed by Candlin et al. in their monograph[341] as an example of a π complex of a heterocyclic ring.

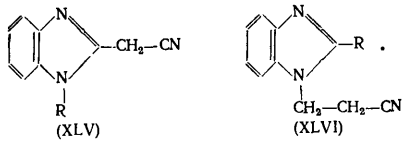
‡The high negative π-electron charge density at the oxygen atom of oxazole[367] suggests that the coordination interaction with "hard" cations (BF_3, AlX_3) may take place via this atom.

In a study of complex formation in a series of 2-[β-hydroxy(mercapto)ethyl]pyridines (XLII), it was noted[370] that the coordinate bond with relatively soft MX_2 is located at the nitrogen of the pyridine ring and not at the harder oxygen and sulphur atoms.

It is believed that α-substituted aminoethylpyridines (XLI, E = N) can form complexes of three types: (1) cyclic compounds with transition metals involving both electron-donating centres[371-374]; (2) complexes with NiI_2 involving only the amino-nitrogen[371]; (3) complexes of Group IV metal (tin and titanium; n = 2) tetrachlorides[375] and niobium oxide trichloride[376] involving the nitrogen atom of the pyridine ring.

γ-Derivatives of pyridine (quinoline) also form complexes of MX_4 and $NbOCl_3$ via the nitrogen atom of the pyridine (quinoline) ring[357,375,376]. These results in general agree with the greater hardness of MX_4 and $NbOCl_3$ compared with NiI_2 (in addition to the greater softness of the metal itself[13], the symbiotic effect[4,14] of the soft iodide anion probably operates in this case). However, it is noteworthy that Uhlig and Maeser[371] did not study the infrared spectroscopic behaviour of the pyridine ring and therefore their results should be treated with some caution.

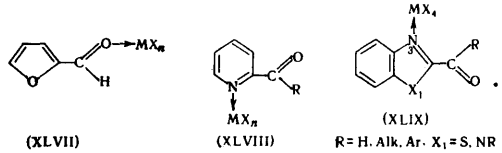
In complexes of $SnCl_4$ and $TiCl_4$ with cyano-derivatives of the benzazole series (XLV, XLVI), coordination interaction probably involves the softer nitrogen atom of the azole ring[377]:



(XLV) (XLVI)

MX_n forms complexes via the oxygen atom with carbonyl derivatives of five-membered heteroaromatic system having one heteroatom. Stable neutral complexes of furfural with MX_4 have been isolated[378,379], their infrared spectra showing a considerable decrease in the frequency of the carbonyl stretching vibrations indicating that the coordinate bond involves the carbonyl oxygen [compound (XLVII)].[37,68]

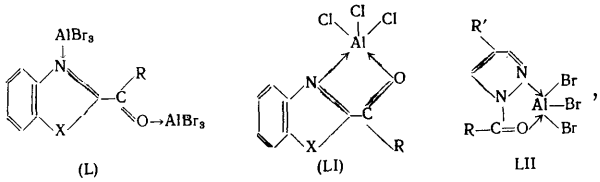
On the other hand, the formation of complexes via the nitrogen atom is characteristic of pyridyl ketones (XLVIII)[380] and carbonylazoles (XLIX)[353,377,381] containing electron-donating nitrogen and oxygen atoms:



(XLVII) (XLVIII) (XLIX)

R = H, Alk, Ar. X_1 = S, NR

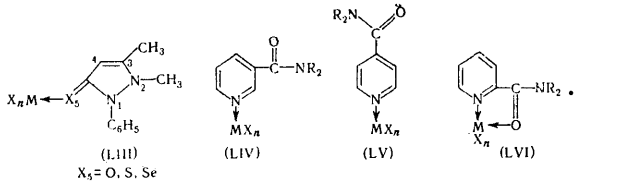
Only with AlX_3 (X = Cl or Br) and carbonylazoles can coordination interaction involve both electron-donating centres with the formation of complexes (L) having the composition $2AlBr_3$.(L) or, under favourable steric conditions, of cyclic compounds of types (LI) and (LII)[83,353,356,381]



(L) (LI) LII

where X = S or NCH_3 and R = H or CH_3.

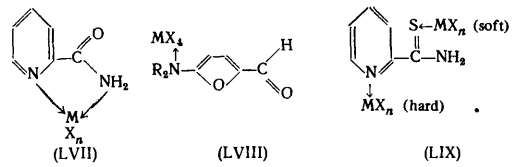
Antipyrine (LIII) and its derivatives should seemingly be included among nitrogen- and oxygen-containing ambident systems. However, the localisation of a high negative π-electron charge at the oxygen atom[81,382-384] renders antipyrine a monodentate ligand in which coordination interaction involves exclusively the exocyclic oxygen atom regardless of the type of MX_n.[81,384-391] Thio- and seleno-antipyrines behave similarly[81,389]:



(LIII) (LIV) (LV) (LVI)

X_5 = O, S, Se

The coordination interactions of MX_n with pyridine-carboxylic acid amides and thioamides is unusual. Nicotinamide (LIV) and isonicotinamide (LV) form complexes with the coordinate bond involving preferentially the nitrogen atom of the heterocyclic ring[380,392,393]. On the other hand, depending on the composition of the complexes and the properties of MX_n, picolinamide forms cyclic structures in which complex formation involves the pyridine nitrogen and the carbonyl oxygen [compound (LVI)][394] or the amino-nitrogen [compound (LVII)][395-397].



(LVII) (LVIII) (LIX)

The coordinate bond in the complexes of the tetrachlorides of Group IV elements with 5-(*N*-dialkylamino)-furfurals (LVIII) involves mainly the amino-nitrogen and not the carbonyl oxygen[399]. Whereas the direction of coordination attack in ambident systems containing nitrogen and oxygen atoms is difficult to predict§, in pyridine-carboxylic acid thioamides soft acids (Au, Ru, Os, Ag, and Rh) attack the "soft" sulphur atom and the harder transition metal salts attack the nitrogen atom [compound (LIX)], in agreement with the HSAB principle[400].

In the series of amino-,[82,348,353,401,402] azomethine[80,82], azo-,[348,403-405] and cyano-derivatives[406-407] of pyridine and azoles, the coordinate bond is preferentially¶ located at the electron-donating centre with the highest negative π-electronic charge[80,82], as for the aliphatic and aromatic ambident systems with nitrogen atoms hybridised in different ways.

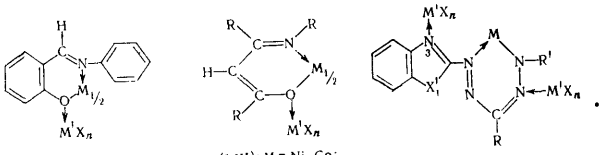
Metal chelate ambident systems. It has been shown[409-411] that metal chelates may be used as ligands in complex formation ("complexes as ligands",[411-412] "complexes of complexes"[413,414]). The problem of the location of the coordinate bond in such dinulcear complexes arose at once[409-419]. It is believed[409,411-415,417] that coordination interaction involves the oxygen atoms of

---

§In pyridine-2-acetamide, which has non-conjugated electron-donating centres, the coordinate bond is located in accordance with the HSAB principle: PdX_2 (X = Cl or Br) enters into coordination interaction with the soft nitrogen atom, while the harder MX_2 interact with the nitrogen and oxygen atoms[398].

¶It is believed that the formation of complexes with 2-amino-1,3,4-oxadiazole involves the amino-group[408].

the metal chelate unit of the inner-complex compounds of the Schiff bases (LX) and β-aminovinyl ketones (LXI). However, the investigators[410,416,418,419] concluded that the interaction of $SnCl_4$ and $TiCl_4$ with salicylideneanilinato-complexes leads to the rupture of the metal-containing ring and the location of the bond at the nitrogen atom of the azomethine group:



(LX): M = Ni, Cu; M' = Ni, Cu, Ti, Sn

(LXI): M = Ni, Co; M' = Sn, Ti

(LXII): M = Ni, Cu; M' = Sn, Ti; X = Cl, Br; X_1 = O, S, NR^1

In the metal chelates of the formazans of the benzazole series, the centres for the formation of a donor–acceptor bond with MCl_4 (M = Sn or Ti) are probably not only the nitrogen atom of the heterocyclic ring but also the nitrogen atoms of the formazan ring [compound (LXII)].[420]

The problem of competitive intramolecular coordination in metal chelates (the building up of square-planar and tetrahedral structures to octahedral structures) is probably directly related to these data. However, its discussion is outside the scope of the present review.

---o0o---

The HSAB principle is a simple and convenient formulation of a number of postulates relating to acid–base interaction and not a new law or theory. The main postulates of the HSAB principle are extremely useful for a systematic arrangement and explanation of experimental data accumulated on the problem of the location of the coordinate bond in systems with several electron-donating centres. A general description of data on competitive coordination in non-conjugated systems from the standpoint of the HSAB principle is particularly desirable (unfortunately fewest studies have been made precisely in this field).

For conjugated (ambident) systems, the concepts of the "hardness" and "softness" of the electron-donating atoms are extremely arbitrary: the nitrogen and oxygen atoms, which have been assigned by Pearson to the same class of hard bases, can function as soft nucleophilic centres, while the "soft" sulphur can become hard (thiourea, thioamides, thioantipyrine). Similarly in many cases the terminological concepts of "hardness" and "softness" lose their significance in the case of cations. Probably, in a consideration of the problem of competitive coordination in ambident systems, one cannot in general relate the concepts of the "hardness" and "softness" of nucleophilic atoms to the Schwarzenbach, Chatt, and Pearson classifications. In estimating the "softness" and "hardness" of electron-donating centres, it is more correct to take into account the properties characterising the "soft" and "hard" nucleophilic agents as defined by Pearson†. In the same connection, one should evidently assume that in any polyfunctional system it is possible to isolate centres for the preferential formation of a donor–acceptor bond. As shown above, the position of such a centre coincides in general with that of the electron-donating atom bearing the highest negative π-electron charge density.

†Regardless of its position in the Periodic System, any atom can evidently exhibit Pearson's "hard" or "soft" properties.

The experimental data discussed in the present review indicate the unusually pronounced interest in the problem of competitive coordination among both Soviet and foreign investigators. At the same time there have been still too few systematic and comprehensive discussions of the causes of a particular mode of coordination in polyfunctional ligands‡. In many cases the experimental data are insufficient for this purpose (a narrow selection of "acids" and "bases"), while in others (these include the majority of investigations) the aim of the study was to discover the location of the bond at a particular electron-donating atom.

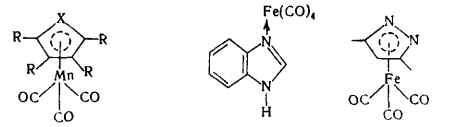
The tasks of the immediate future are probably specific synthesis of polydentate ligands with electron-donating centres of different types and specific selection of acids (both "hard" and "soft") for the solution and a comprehensive examination of the problem of competitive coordination. Such attempt designed to synthesise ligands are already being made[177,421] and they must be prosecuted in all possible ways. Naturally, the successful solution of the problem depends on the reliability of the experimental methods employed for this purpose.

A general description of data on competitive coordination in the chemistry of complex compounds may prove extremely useful in determinations of the mode of reactions in polyfunctional systems and for other branches of chemistry. We believe that the study of the problem of the location of the hydrogen bond and of the site of protonation of organic compounds with several electron-donating centres is particularly promising; the data which have accumulated[422–437] show that, in agreement with the HSAB principle, this process involves the hardest atom in non-conjugated and ambident systems. The question of the quaternisation of polyfunctional systems, primarily the amino-, azomethine, and azo-derivatives of nitrogen-containing heterocycles, is apparently closely related to this problem.

ADDENDUM

(to Section III, subsection 3d)

π-Complexes of manganese tricarbonyl with tetraphenylphosphole (LXIII) and tetraphenylarsenole (LXIV) have been synthesised[438]:



(LXIII): X = P; R = C_6H_5
(LXIV): R = C_6H_5; X = As

(LXV)

(LXVI): R = H, CH_3

Complexes (LXV) in which the ligand behaves as a monodentate base and is coordinated to the metal via the "pyridine" nitrogen atom have been described. Complexes (XL)[439,440] and (LXVI)[430] have been synthesised and the structure of a π-complex has been suggested for the latter[439].

Direct proof of the location of the coordinate bond at the "pyridine" nitrogen atom in benzazoles has been obtained in a study of ^{14}N NMR spectra of metal carbonyl complexes of azoles[441].

‡We believe that this problem has been most satisfactorily solved for pseudohalide ions[12,258,276].
