Ferrocenophanes are ferrocenes in which the two cyclopentadienyl rings are linked by a bridge consisting of several carbon atoms or atoms of other elements. However, the name ferrocenophane is also sometimes given to compounds in which the carbon atoms of the same cyclopentadienyl ring are linked by a bridge. The properties of such compounds differ little from those of disubstituted homoannular ferrocenes and are not dealt with in the present review.

Attempts to synthesise the ferrocenophane system were undertaken soon after the discovery of ferrocene since, it was evident that a bridge between the two rings should introduce interesting modifications into the properties of the molecule. The first ferrocenophane was synthesised in 1957 and since then studies in this field are continually attracting attention, since ferrocenophanes proved to be useful models for the investigation of the structural, stereochemical, and certain theoretical problems. The synthesis of ferrocenophanes with a single bridge has developed fairly widely so that the simplest of them are quite readily available and have been tested for practical purposes. On the other hand, the synthesis of ferrocenophanes with a number of bridges presents considerable difficulties.

The study of the properties of ferrocenophanes has shown that among them compounds with small bridges are particularly interesting. Such ferrocenes do not simply combine the characteristics of ferrocenes and cyclophanes, the properties of both being transformed in a specific manner. In contrast to ferrocenophanes, the analogous compounds with other transition metals (titanium, cobalt, nickel, and chromium) are so far represented only by isolated examples. They too are discussed in the present review.

The only previous review on ferrocenophanes[1] deals with the literature up to 1966, but since then many new ferrocenophanes have been synthesised and the range of interest shown in this field has greatly expanded; there is therefore no doubt about the need for a new review. We may note that isolated data on ferrocenophanes for the period 1964–1972 may be found in annual reviews of literature on ferrocene[2-10].

According to the proposed nomenclature[1,11], all ferrocenophanes can be divided into two groups. The first includes compounds where within the limits of one ferrocene nucleus the rings are linked by one or several bridges. Derivatives where two or more ferrocene nuclei are linked by chains of atoms, so that each ferrocene fragment constitutes as it were a bridge in relation to the other, may be assigned to the second group. For compounds of the first type, the length of the bridge is represented by a number in square brackets or by several numbers in square brackets if there are several bridges. The positions of the bridges are indicated by numbers in round brackets. The numbering begins with the longest bridge, proceeds along the bridge and completely around the ring, and then along the next bridge (in order of decreasing length of the bridges). The heteroatoms are designated by a number indicating their position in the bridge. For compounds of the second type, a set of numbers indicating the lengths of all the bridges joining the ferrocene nuclei is indicated within a single set of square brackets. A new nomenclature, common to all phanes (cyclophanes and metallocenophanes), was proposed recently[12].

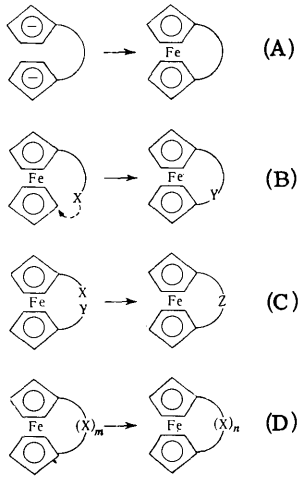
II. METHODS OF SYNTHESIS OF FERROCENOPHANE SYSTEMS†

There are several fundamental approaches to the synthesis of ferrocenophanes. The first makes it possible to obtain a ferrocenophane together with the synthesis of the

† A. A. Pogrebnyak, a Diploma student at Moscow State University, took part in writing this chapter.

ferrocene nucleus and may be called the direct method (see Scheme 1, A).

Scheme 1



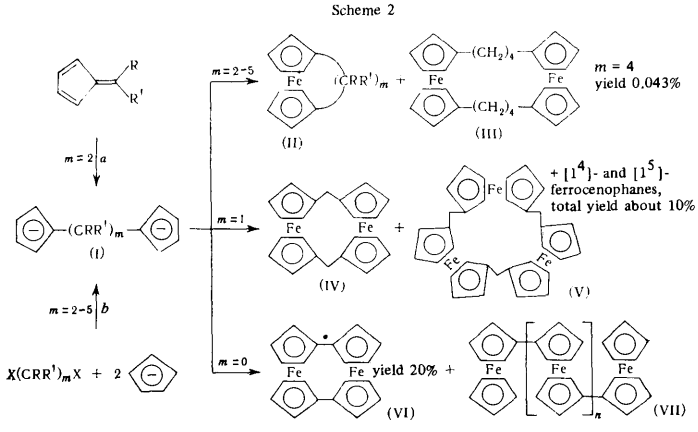
Another method consists of intramolecular substitution in the second cyclopentadienyl (CPD) ring; a group entering into the composition of a substituent in the first ring (B) is then involved in the substitution. In the third method the bridge may be formed by the closure of two heteroannular substituents (C). Finally there is a possibility of a transition from [*m*]- to [*n*]-ferrocenophanes ($m < n$ or $m > n$) by the expansion or contraction of the bridge (D). In addition other special methods used in specific instances are also known.

Naturally each of the fundamental approaches described has many different versions. In the present review all the methods are classified according to these four fundamental types.

A. DIRECT SYNTHESIS

Direct synthesis is understood as the formation of the ferrocenophane system from dicyclopentadienide dianions of type I (Scheme 2) where both cyclopentadienyl rings are linked by a bridge beforehand. In this case ferrocenophanes are obtained by the same method as the usual ferrocenes (the reaction is most often carried out in the presence of anhydrous $FeCl_2$).

Scheme 2



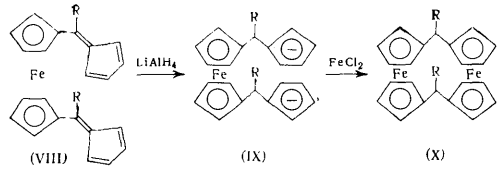
Type (I) dianions are usually obtained by the reaction of the cyclopentadienide anion with the corresponding dihalogeno-compounds (Scheme 2, method *b*). Thus the reaction of the cyclopentadienide anion with $\alpha\omega$-dihalogenoalkanes ($m = 2-5$) yields hydrocarbons in which the two cyclopentadiene rings are linked by a chain of methylene units and which are converted into the dianions (I) after appropriate treatment. The reaction of (I) with $FeCl_2$ makes it possible to synthesise bridged ferrocenes but the yields in this process are very low (with the exception of the case where $m = 2$) and therefore only the synthesis of [2] ferrocenophane is of preparative importance. Naturally the yields of [*m*] ferrocenophanes fall sharply with increase of chain length (Table 1), while the amount of polymeric products increases.

Table 1. Type (II) ferrocenophanes.

No.	*m*	R	R′	Method of synthesis	Yield, %	M.p. (b.p.), °C	Refs.
1	2	CH_3	CH_3	*a*	low	168—169	13,14,16
2	2	CH_3	$CH(CH_3)_2$	*a*		(150—160/1.2)	14
3	2	CH_3	$CH_2CH(CH_3)_2$	*a*		(170—180/2—4)	14
4	2	CH_3	$CH(C_2H_5)(CH_2)_3CH_3$	*a*		(113—123/5)	14
5	2	CH_3	C_6H_5	*a*		(138—165/3—5)	14
6	2	H	H	*b*	50	104—107	15,16
7	3	H	H	*b*	2.5	106—107	17
8	4	H	H	*b*	0.053	58—59	17
9	5	H	H	*b*	0.025	61—62	17

A convenient method for the preparation of dianions with $m = 2$ consists of the interaction of fulvenes with sodium (Scheme 2, method *a*). A whole series of [2] ferrocenophanes containing various substituents in the bridge (Table 1), particularly the widely investigated 1,1,2,2-tetramethyl[2]ferrocenophane, have been synthesised by this procedure.

For $m = 1$ [dianion (I) is obtained from methylene dihalide and the cyclopentadienide anion], the reaction does not lead to [1] ferrocenophane, since the unduly large strain and the mutual inclination of the rings must have an effect on the molecule of this compound; the product is a mixture of [1^n]ferrocenophanes, the lowest members of which are (IV) and (V) (Scheme 2)[18-20]. The molecular weights of all these compounds have been determined mass-spectrometrically. The dianion (IX), which can also be obtained from difulvene (VIII) on treatment with $LiAlH_4$, is formed as an intermediate in this reaction. The interaction of (IX) with $FeCl_2$ yields [1,1]ferrocenophane (X).[21]



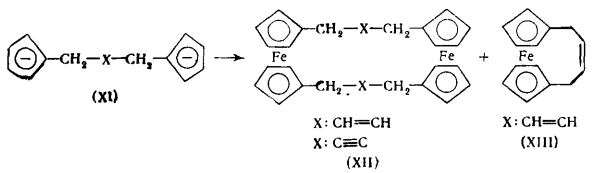
When $m = 0$, the reaction of the dicyclopentadienide dianion (I) with $FeCl_2$ in tetrahydrofuran (THF) gives [0,0]ferrocenophane (VI) together with the polymeric polyferrocenyl (VII).[22]

[4,4]Ferrocenophanes containing double and triple bonds in the bridges [compounds (XII)] have been obtained recently[19]. When *trans*-1,4-dichlorobut-2-ene is used as

the starting material, the monomeric derivative (XIII) is formed in addition to (XII). It is interesting that the ^{1}H NMR spectra indicate a *cis*-disposition of the methylene groups of the bridge relative to the double bond (the spin–spin splitting of the olefinic protons is 10.4 Hz).

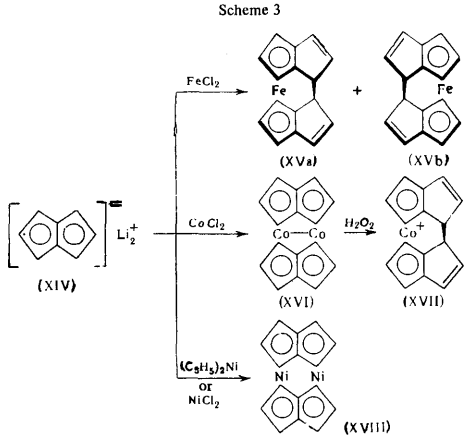
Ferrocenophanes containing silicon atoms in the bridge have been obtained from the corresponding dianions, for example from $[C_5H_5(CH_3)_2SiSi(CH_3)_2C_5H_5]^{2-}$.[23,24]

The direct method has also been used for the synthesis of titanocenophane. The reaction of the dianion (I) ($m = 1$, R = R′ = H) with $TiCl_4$ gave a 30% yield of 1,1′-methylenetitanocene dichloride[19]. The cyclopentadiene rings in this compound are inclined relative to one another, but the non-bridged initial titanocene dichloride has the same structure and therefore the introduction of the monomethylene bridge does not distort the geometry of the molecule, in contrast to [1]ferrocenophane (which has still not been synthesised). Bridged derivatives of titanocene with a silicon or germanium atom in the bridge have been recently synthesised by a similar procedure[25].



Several different bridged metallocene derivatives have been synthesised by Katz and coworkers[26,27] using the dianion (XIV) (Scheme 3).

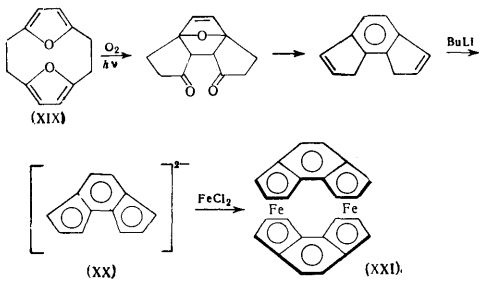
Scheme 3



The structures of compound (XV)[28] and (XVII) are similar to that of "bis-(π-azulene)iron"[29,30] (see below).

The two cyclopentadienide anions from which [*m*,*n*]-ferrocenophanes are obtained may be linked not by one but by two chains[31] and by condensed benzene [the dianion (XX)][32] or naphthalene[33] rings. The dianion (XX), obtained by the photochemical oxidation of furanocyclophane (XIX), gives rise to the interesting ferrocenophane (XXI) on treatment with $FeCl_2$.[32] The corresponding nickel compound was obtained similarly[34]. A dicobalt derivative analogous to the ferrocenophane (VI) has been synthesised recently[35].

A single instance of the synthesis of bisarenemetal π-complexes, in which two benzene rings are linked by a bridge, is known. The reaction of *trans*-stilbene with $CrCl_3$ in the presence of triethylaluminium results in the formation of 1,1′-tetramethylene-βγ-diphenylbisbenzenechromium, which has been isolated as the iodide salt. Its pyrolysis yields 1,2,3,4-tetraphenylbutane, which confirms the proposed structure[36].



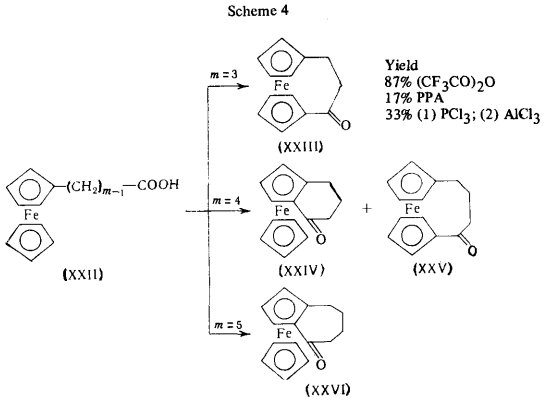
B. INTRAMOLECULAR SUBSTITUTION IN THE CYCLOPENTADIENE RING

This procedure has many different versions and leads both to ferrocenophanes containing a purely hydrocarbon bridge and to [*m*,*n*]ferrocenophanes. The intramolecular cyclisation of ferrocenylpropionic acids, whereby [3]ferrocenophanes can be obtained, has been developed in greatest detail[37–72].

1. Intramolecular Acylation

Rinehart and Curby obtained the first ferrocenophane (XXIII)[37] by the cyclisation of β-ferrocenylpropionic acid (XXII) in the presence of polyphosphoric acid (PPA). However, it was found that the method has a very limited applicability and is suitable only for the synthesis of [3]ferrocenophanes[39,40]. Thus, whereas the cyclisation of γ-ferrocenylbutyric acid still gives a small yield of the corresponding [4]ferrocenophan-1-one[41], acids with a longer methylene chain yield exclusively products of homoannular cyclisation or polymers (Scheme 4)[42–46].

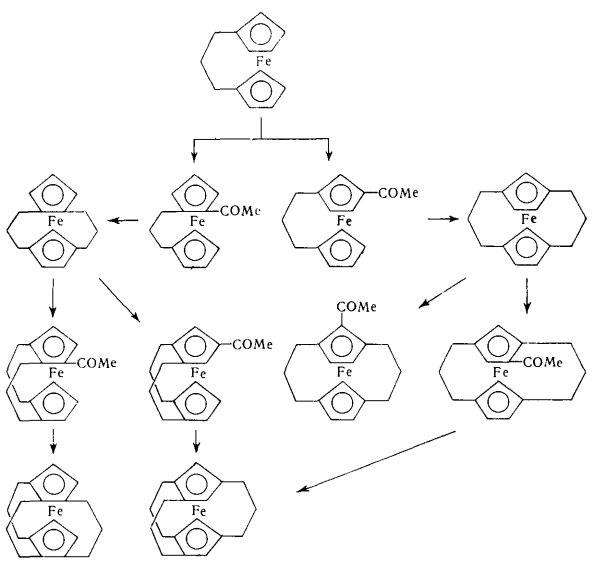
Scheme 4



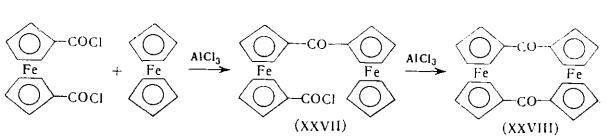
The reaction does not proceed via a heteroannular mechanism in all cases, even for $m = 3$. Thus, when there is a fairly bulky substituent in the cyclopentadiene ring or in the propionic acid chain, a considerable amount of the homoacylation product is formed[47–51]. Nevertheless [3]ferrocenophanes have been obtained mainly by this

method hitherto. The initial β-ferrocenylpropionic acid (XXII, $m = 3$) can be conveniently synthesised from acetylferrocene[39] or ferrocenealdehyde[47,52-54] according to the following schemes respectively: $FcCOCH_3 \rightarrow FcCOCH_2COOC_2H_5 \rightarrow FcCH_2CH_2COOH$ or $FcCHO \rightarrow FcCH=CHCOOH \rightarrow FcCH_2CH_2COOH$. The [3]ferrocenophan-1-one obtained by the cyclisation of β-ferrocenylpropionic acid is readily reduced to [3]ferrocenophane by a mixture of $LiAlH_4$ and $AlCl_3$.[55] By consecutive application of the above stages and of reduction, Rinehart et al.[47] obtained ferrocenophanes with two and three bridges. One of the possible syntheses is illustrated in Scheme 5. [3]Ferrocenophanes with a number of bridges were obtained similarly by Schlögl and coworkers[53,56-58]. Two-bridge ferrocenophanes containing three-, four-, and five-membered bridges in various combinations have been described[59-61]. It is noteworthy that the synthesis of multibridge ferrocenophanes consists of many stages and is very laborious. French chemists have made a detailed study of the cyclisation of substituted β-ferrocenylpropionic acid[45,46,48-51,62-72].

Scheme 5



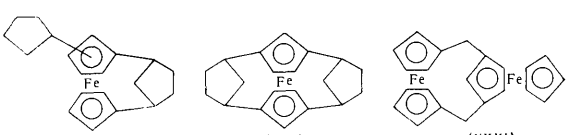
The synthesis of [1,1]ferrocenophanes (XXVIII) by the Friedel–Crafts reaction is closely related to the cyclisation of aliphatic ω-ferrocenyl acids discussed above[73,74]. This reaction proceeds via the formation of the intermediate (XXVII)[75], whose geometry promotes electrophilic attack on the second ring. Compound (XXVIII) has also been obtained from ferrocenecarboxylic acid chloride[76]. The cyclisation of *o*-carboxybenzeneferrocene [probably *o*-carboxybenzoylferrocene [Ed. of Translation)] does not lead to ferrocenophanes[43,44].



(XXVII) (XXVIII)

2. Other Examples of Substitution in the Cyclopentadiene Ring

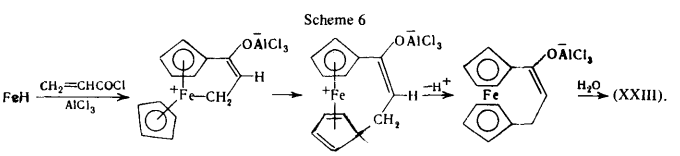
Bridged ferrocenes can be formed not only in intramolecular acylation but also in the heteroannular alkylation of ferrocene by olefins. The ferrocene molecule is cleaved by hydrogen fluoride[77] or phosphoric acid[78] with liberation of cyclopentadiene, which then alkylates other ferrocene molecules. In the simultaneous intramolecular alkylation of both rings the product is a ferrocenophane which can also be obtained by the reaction of ferrocene with anhydrous $AlCl_3$ in benzene[79] or in methylene dichloride[80], or by treating ferrocene with zinc chloride[81,82]. Apart from the ferrocene with a single bridge, the derivative (XXIX) and the ferrocene (XXX) with two bridges are also formed[83]. The structures of these compounds have been demonstrated by chemical methods and by ^1H NMR[83]. By alkylating ferrocene with methylene dichloride, Neuse and coworkers obtained the ferrocenophane (XXXI) together with polymeric products[80]. Apart from other products, the reaction of ferrocene with formaldehyde in the presence of acids gives the ferrocenophane (IV).[84]



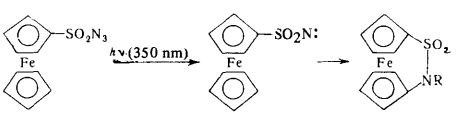
(XXIX) (XXX) (XXXI)

An interesting and synthetically important reaction was recently described by Turbitt and Watts[85]. When ferrocene reacts with acryloyl chloride, [3]ferrocenophan-1-one (XXIII) and propionylferrocene are formed, the ratio of the products depending on the reaction temperature. When the reaction is carried out at −78°C, compound (XXIII) is obtained in 40–60% yield. The sequence of stages leading to (XXIII) proposed by the authors is illustrated in Scheme 6.

Scheme 6



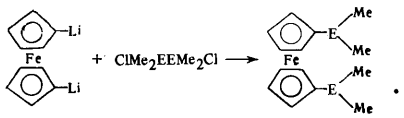
The nitrene (XXIII) formed when compound (XXXII) is irradiated in benzene attacks the second ring, giving the ferrocenophane (XXXIV) with two heteroatoms in the bridge[86]:



(XXXII) (XXXIII) (XXXIV)

Organometallic and halogeno-derivatives of ferrocene have been used to synthesise ferrocenophanes. Thus several bridged compounds containing silicon or germanium atoms in the bridge [for example (XXXVI) with E = Si or Ge] have been obtained by the reaction[23,87] of 1,1-dilithioferrocene (XXXV) with the corresponding dichlorides.

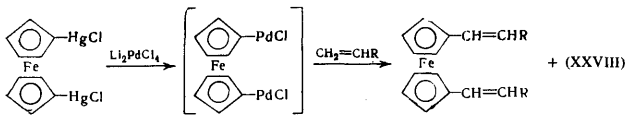
Some of these ferrocenophanes have also been obtained by the direct method (A).



(XXXV) (XXXVI)

The interesting 1,2,3-trithia[3]ferrocenophane is formed when compound (XXXV) reacts with sulphur[88]. Treatment of dibenzylferrocenylacetonitrile with butyllithium leads to the substitution of one of the hydrogen atoms of the free cyclopentadiene ring by lithium, and, after intramolecular attack on the CN group, 1-aza-3,3-dibenzyl[3]ferrocenophan-1-ene is formed[89]. [0,0]Ferrocenophane (VI) has been obtained by the reaction of (XXXV) with cobalt chloride, or of 1,1'-diodoferrocene with copper[90], or by heating a mercury derivative of ferrocene with silver[91]. A copper derivative of 1-bromo-1'-ethynylferrocene was also used to synthesise [2,2]ferrocenophane-1,13-diyne[92]. In a study of the addition of ferrocene to olefins in the presence of palladium salts, Kasahara et al. observed the formation of [0,0]ferrocenophane (VI).[93] When this reaction is carried out in the presence of carbon monoxide, [1,1]ferrocenophane-1,12-dione (XXVIII) is formed[94] (Scheme 7).

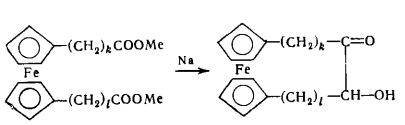
Scheme 7



C. CYCLISATION INVOLVING TWO HETEROANNULAR SUBSTITUENTS IN THE FERROCENE NUCLEUS

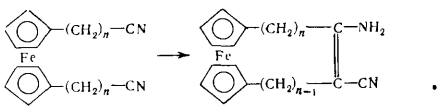
1. Cyclisation of 1,1'-Disubstituted Alkylferrocenes with ω-Functional Groups

The acyloin cyclisation developed by Schlögl and Seiler[95,96] is a universal method for the preparation of ferrocenophanes with a bridge of any length. In this procedure a 1,1'-di-(ω-methoxycarbonylalkyl)ferrocene (XXXVII) is condensed in the presence of finely divided sodium in boiling xylene. Acyloin [m]ferrocenophanes with m = 4, 6, 8, 9, or 10 have been obtained. Tnis method is less suitable for the synthesis of ferrocenophanes with an odd number of carbon atcms in the bridge, since in this case the required starting materials are the asymmetric diesters (XXXVII, $k \neq l$), which are difficult to obtain.



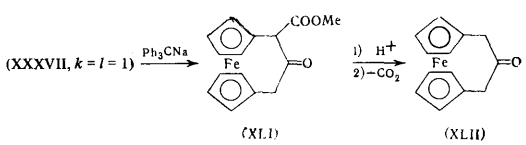
(XXXVII) (XXXVIII)

The cyclisation of the corresponding symmetrical dinitriles (XXXIX, n = 1, 2, 5, or 7)[97,98], which can be obtained by various methods[98-101], has been suggested for the synthesis of ferrocenophanes with an odd value of m. The sodio-derivative of N-methylaniline or (for n = 1) methylmagnesium iodide were used as catalysts. This method made it possible to synthesise macrocyclic [11]- and [15]-ferrocenophanes[98]:



(XXXIX) (XL)

The possibility of employing the Dieckmanncyclisation for synthesising ferrocenophanes has so far been demonstrated in only one instance[102]. Under the influence of triphenylmethylsodium, the diester (XXXVII, $k = l = 1$) is converted into the bridged ferrocene (XLI), which decarboxylates to the ketone (XLII) after hydrolysis:

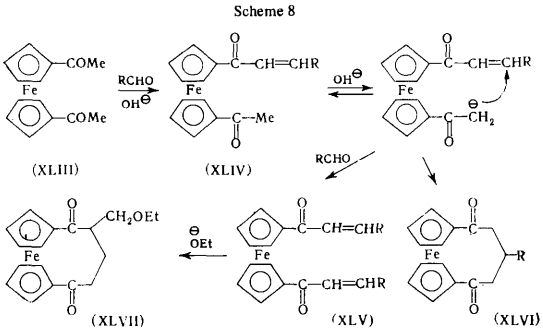


(XLI) (XLII)

2. Cyclisation with the Intermediate Formation of a Carbanion and Its Attack on a Double Bond

In 1960 Hauser and coworkers isolated two products after the reaction of 1,1'-diacetylferrocene (XLIII) with benzaldehyde in the presence of alkali: the red 1,1'-dicinnamoylferrocene (XLV, R = C_6H_5) and a yellow product to which the structure of a bridged diketone (XLVI, R = C_6H_5) was attributed (Scheme 8).[103] The ratio of the products depends on the amount of benzaldehyde introduced into the reaction. Thus, when 1 mole of benzaldehyde per mole of (XLIII) is used, the yield of (XLV) is 6–13% and the yield of the ferrocenophane (XLVI) is fairly high (66–68%).

Scheme 8



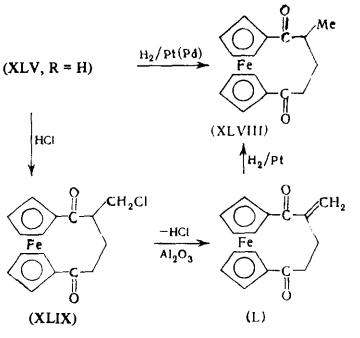
With increase of the amount of aldehyde to 6 moles, the yield of (XLVI) falls to 5% and the amount of (XLV) increases to 75%. Furdik et al. soon showed that not only benzaldehyde but also other aromatic[104-106] and aliphatic aldehydes[107] can be used in this reaction. It was found that, for aliphatic aldehydes and m-nitrobenzaldehyde, the yields of ferrocenophanes are significantly lower (about 10%) and that only the dicinnamoyl derivatives (XLV) are formed in the reactions with o- and p-nitrobenzaldehydes. The condensation also occurs under the influence of acid catalysts[108].

The formation of ferrocenophanes from various 1,1-diacylferrocenes was investigated in later studies[109-111].

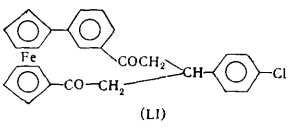
The ferrocenophane (XLVI, R = H) has also been obtained from 1-acetyl-1′-acryloylferrocene (XLIV, R = H)[112,113] or from 1-acetyl-1′-β-chloropropionylferrocene[114], which confirms the scheme proposed for the formation of the ferrocenophane. It was also found[115] that 1,1′-dicinnamoylferrocene (XLV, R = C_6H_5) undergoes retroaldol condensation under the influence of a base with formation of compound (XLIV, R = C_6H_5), which then condenses to (XLVI, R = C_6H_5) in 92% yield. Barr and Watts showed[113] that the reaction of 1,1′-diacetylferrocene with formaldehyde in aqueous ethanol solution of sodium hydroxide yields as the main product the ferrocenophane (XLVII), formed by the condensation of 1,1′-diacryloylferrocene (XLV, R = H).

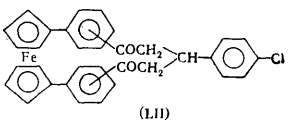
It is interesting that the catalytic hydrogenation of 1,1-diacryloylferrocene (XLV, R = H) over platinum or palladium leads to the formation of a new C–C bond and of the ferrocenophane (XLVIII). The same product was synthesised by the cyclisation of (XLV, R = H) under the influence of HCl with subsequent dehydrochlorination of the product (XLIX) to (L) and catalytic hydrogenation of the latter (Scheme 9).[116]

Scheme 9



An instance of the formation of 4,methyl[4]ferrocenophan-1-one by the intramolecular attack of the carbonion on the double bond of 1-acetyl-1′-isopropenylferrocene[117,118] is also known. Treatment of difulvene (VIII, R = CH_3) with sodamide leads to the formation of a ferrocenophane with a three-membered bridge[74,119]. Toma and Salisova recently employed the method involving addition to an activated double bond in order to synthesise ferrocenophanes with different bridge lengths[120,121]. 3-Phenylacyl[3]ferrocenophan-1-one, 2-(*p*-chlorophenyl)-1-cyano[4]ferrocenophan-1-one, and 3-(*p*-chlorophenyl)[7]ferrocenophane-1,5-dione were obtained in this way[120]. The method proved to be convenient for the synthesis of compounds (LI) and (LII).[121]



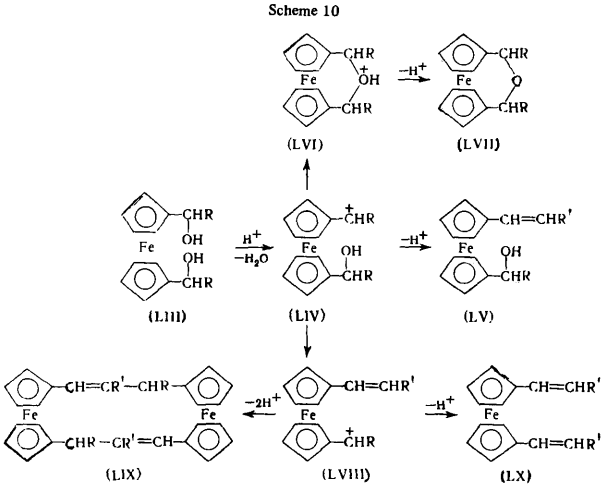


Finally one should note that the polymerisation of 1,1′-divinylferrocene[122] and 1,1′-di-isopropenylferrocene[123] yields high-molecular-weight products containing ferrocenophane rings.

3. Cyclisation with the Intermediate Formation of a Carbonium Ion

Cyclisation with the intermediate formation of a carbonium ion with the charge in the α-position relative to the ferrocene nucleus is widely used to synthesise [3]ferrocenophanes. The ease of formation of these carbonium ions is well known. Carbonium ions such as (LIV) (Scheme 10) are formed following the elimination of the hydroxy-group from α-ferrocenylmethanols (LIII) under the influence of acids. The reaction can proceed further in several ways. When R is not a powerful electron acceptor (R = alkyl, aryl, or hydrogen), the next stage involves attack by the hydroxyl of the α-carbonium centre with subsequent elimination of a proton from (LVI), which results in the formation of 2-oxa[3]ferrocenophane (LVII, R = Alkyl, aryl, or H)[13,124-135]. When R′ in the β-position relative to the ferrocene ring is a powerful electron acceptor, for example CN or $COOC_2H_5$ (then R = CH_2CN or $CH_2COOC_2H_5$), the carbonium ion (LIV) eliminates a proton from the β-position particularly easily and is converted into the olefin (LV), which then gives rise to the diolefin (LX) via the same mechanism[98,101]. Species of the type of (LVIII) can dimerise following intermolecular attack by the carbonium ion on the double bond with formation of the ferrocenophane (LIX, R = CH_3, R′ = H).[133] We may note that intramolecular attack on the double bond, leading to [3]ferrocenophane, is also possible.

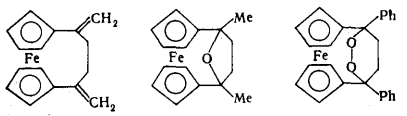
Scheme 10



The α-carbonium ion can also be formed by the hydrolysis of the quaternary salt $N^+Me_3I^-$, which has in fact been used in the synthesis of 2-oxa[3]ferrocenophane[129,133,135].

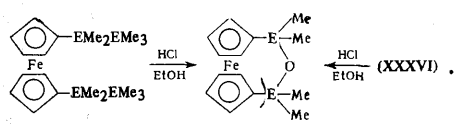
Hisatome and Yamakawa[136] found recently that, on treatment with HCl in benzene, 1,1′-di-(α-hydroxyisopropyl)ferrocene undergoes an unusual condensation leading to the [4]ferrocenophanes (LXI) and (LXII) apart from the uncylised ferrocenes. The analogous reaction of 1,1′-di-(α-hydroxy-α-phenylethyl)ferrocene yielded[137] a series of [4]ferrocenophanes, including the peroxide (LVIII) whose structure was confirmed mass-spectrometrically. The acid-catalysed dimerisation of 2-ferrocenylpropene

results in the formation of a [3]ferrocenophane containing the ferrocenyl group in the 1-position[138].



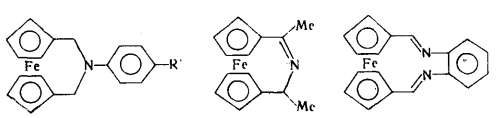
(LXI) (LXII) (LXIII)

Hydrolysis or alcoholysis of various 1,1′-disubstituted ferrocenes whose substituents consist of silicon or germanium atoms has been used to synthesise the corresponding ferrocenophanes with an oxygen atom in the bridge[24,139-142]. Thus Kumada et al.[141] obtained the bridged ethers (LXV) from both uncylised ferrocene (LXIV) and from the ferrocenophane (XXXVI, E = Si or Ge):



(LXIV) (LXV) (XXXVI).

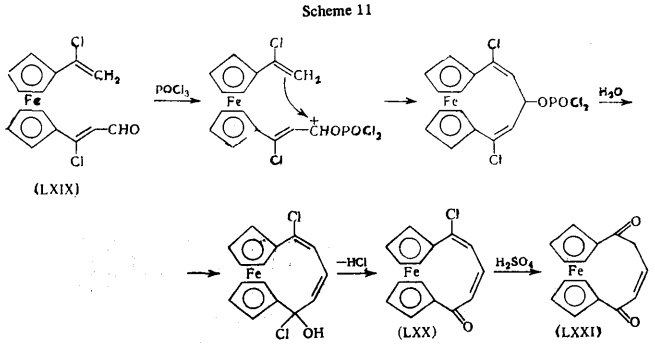
The dicarbinol (LIII, R = H) was used[143,144] to obtain 2-aryl-2-aza[3]ferrocenophanes (LXVI), which are formed when (LIII) is treated with aryl isocyanates (R′ = H, OCH_3, or NO_2). It is noteworthy that another three-membered ferrocenophane (LXVII) with a nitrogen atom in the bridge was synthesised by the reduction of 1,1′-diacetylferrocene monoxime[145]. Condensation of ferrocene-1,1′-dialdehyde with *o*-phenylenediamine[146] resulted in a product to which the authors attributed the structure (LXVIII). The condensation of ferrocene-1,1′-dicarboxylic acid dichloride with hydrazine leads to a polymer in which [3]ferrocenophane rings were detected[147].



(LXVI) (LXVII) (LXVIII)

The reaction of the $\alpha\beta$-unsaturated aldehyde (LXIX) with $POCl_3$ in dimethylformamide leads[148] to the bridged dienone (LXX), which can be converted into compound (LXXI) by treatment with sulphuric acid[113]. A mechanism has been proposed for the formation of the ferrocenophane (LXX) (Scheme 11)[116]:

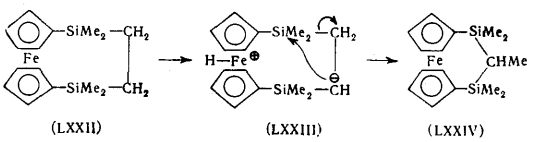
Scheme 11



(LXIX) (LXX) (LXXI)

D. EXPANSION AND CONTRACTION OF THE BRIDGE

Ferrocenophanes can be obtained from other ferrocenophanes with longer or shorter bridges. Thus the reaction of [3]ferrocenophan-1-one (XXIII) with diazomethane results[54] in the expansion of the bridge and the formation of two [4]ferrocenophanes containing carbonyl groups in the 1- and 2-positions. Both ketones can be reduced to [4]ferrocenophane by a mixture of $LiAlH_4$ and $AlCl_3$ or by the Wolff–Kishner method. 1-Aza[4]ferrocenophane has been obtained by the Beckmann rearrangement from [3]-ferrocenophan-1-one[149]. An instance of bridge contraction and conversion from [4]- to [3]-ferrocenophanes is known. On prolonged heating up to 380°C, compound (LXXII) is converted into (LXXIV).[150] The authors suggest that a proton is initially transferred from one of the methylene groups of the bridge to the iron atom with formation of the carbanion (LXXIII), which then rearranges to (LXXIV):

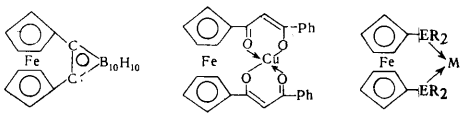


(LXXII) (LXXIII) (LXXIV).

E. OTHER METHODS OF SYNTHESIS

An unusual rearrangement with formation of the interesting [2]ferrocenophane (LXXV) containing a carborane ring in the bridge was described by Zakharkin et al.[151]

Certain 1,1′-disubstituted ferrocenes proved to be convenient bidentate ligands for the formation of complexes with various metals, for example (LXXVI)[152] and (LXXVII) with E = P or As, R = CH_3 or C_6H_5, and M = $Cr(CO)_4$, $Mo(CO)_4$, $W(CO)_4$, $Ni(CO)_2$, $Ni(CO)I_2$, PtX_2, or PdX_2 (X = halogen)[75,153,154].



(LXXV) (LXXVI) (LXXVII)

It is suggested that diacetylferrocene forms complexes with $AlCl_3$[155] and $SnCl_4$[156] in which the metal atom is coordinated to both carbonyl groups simultaneously. The hypothesis has been put forward that the blue compound formed when ferrocene and $AlCl_3$ are dissolved in carbon tetrachloride is a kind of ferrocenophane in which the two ferrocene rings are linked by two aluminium atoms[157]. The interaction of 1,1′-di(acetoacetyl)ferrocene with a nickel(II) salt resulted in the formation of a polynuclear ferrocenophane[158]. Finally the anhydride of ferrocene-1,1′-dicarboxylic acid is apparently a bridged dimer[159].

III. CHEMICAL PROPERTIES

A bridge of any length in ferrocenophanes gives rise to a definite steric hindrance to the approach of the attacking agent towards the cyclopentadiene rings and short bridges ($m = 2$) also distort the ferrocene structure, resulting in an inclination of the rings, to such an extent that the behaviour of ferrocenophanes of this kind differs qualitatively from that of non-bridged 1,1′-disubstituted ferrocenes. This can be illustrated by the following examples.

Whereas the reductive cleavage of ferrocene and its alkyl derivatives by lithium in propylamine results in the formation of the corresponding cyclopentadienes (yield from 45 to 77%), [3]ferrocenophane decomposes only partly under these conditions and [3][3](1,3)ferrocenophane is completely resistant to the reaction of lithium[160].

Table 2. The β/α ratio in the acetylation products[161].

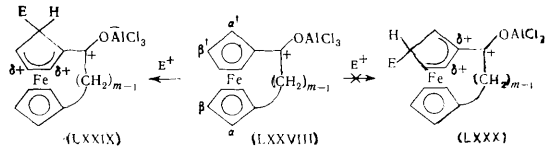
[3]Ferrocenophane	1.57
[4]Ferrocenophane	1.65
[5]Ferrocenophane	2.19
3-Phenyl[5]ferrocenophane	2.62
1,1'-Dimethylferrocene	1.95
1,1'-Diethylferrocene	2.88

Ferrocenophanes (with $m \geq 3$) behave similarly to 1,1'-dialkylferrocenes in reactions with electrophilic agents. Rinehart et al.,[47] Rosenblum et al.,[54] and Watts and coworkers[161-163], who made a detailed study of the acetylation of [m]ferrocenophanes, found that the ratio of the acetyl[m]ferrocenophane isomers $\beta/\alpha > 1$ and increases with the length of the bridge[161], i.e. a behaviour similar to that of 1,1'-dialkylferrocenes is observed (Table 2). However, molecular orbital calculations[164] lead to the expectation that the α-isomer should predominate. For this reason, the preferential formation of the β-isomer in the acetylation of [m]ferrocenophanes and 1,1'-dialkylferrocenes is explained by the dominant influence of steric factors. With $m = 4$ and particularly with $m = 5$, the bridge methylene groups hinder markedly the α-positions in the cyclopentadiene rings.

Table 3. The ratio of the products of the acetylation of [m]ferrocenophan-1-ones[163] [for the significance of the symbols see the structure (LXXVIII)].

m	β/α	α'/α	$(\alpha+\beta)/\alpha'$
3	4.2	0.6	9.5
4	1.2	0.5	4.5
5	0.8	0.01	170

The acetylation of acetylferrocene results in the formation of a small amount of the 1,2-diacetyl derivative (the 1,3-isomer was not found) in addition to the main product 1,1'-diacetylferrocene. Derivatives containing the acetyl group in the β'-position of the ring bound to the carbonyl group were also not found among the products of the acetylation of [m]ferrocenophan-1-ones[163] (Table 3). On the other hand, the amount of the α-substituted products (particularly with $m = 3$ or 4) is fairly appreciable. This finding was accounted for in the following way. The aluminium chloride used in the acetylation reaction forms a complex with the carbonyl group of [m]ferrocenophanone, which results in the formation of the strongly polarised structure (LXXVIII). If the rate-determining stage is the formation of the σ-complex (LXXIX) or (LXXX), the addition of the acetylium ion to the α'-position should predominate despite the steric hindrance, since in this case [structure (LXXIX)] the sites with a reduced electron density are more remote from the carbonium centre formed from the carbonyl group than in the β'-addition [structure (LXXX)]:

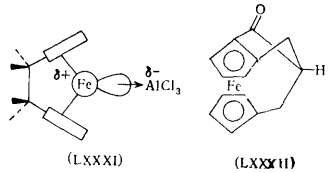


(LXXIX) (LXXVIII) (LXXX)

Thus the result is consistent with molecular orbital calculations and electronic factors presumably predominate in this case over steric factors. The sharp increase of the ratio β/α for $m = 3$ (cf. Table 2 and 3) was explained[163] on the basis of the *trans*-effect—the concept, which was adduced for the first time to account for the electronic effects in metallocenes. The diacetylation of [3]ferrocenophane has been described[61].

It is very remarkable that [2]ferrocenophane cannot be acetylated[14,16,161], whereas it is protonated at the iron atom significantly more readily than all other ferrocene derivatives[15,16]. This is shown by the disappearance of the 472 nm band ($\epsilon = 450$) from the [2]ferrocenophane spectrum after the addition of 0.1% sulphuric acid to the alcoholic solution[15,16]. The marked mutual inclination of the rings in this compound probably causes an electronic rearrangement in the molecule and withdrawal of electron density (of three filled non-bonding orbitals) from the side opposite to that of the bridge. This leads to a sharp increase of the basicity of the compound. The coordination of one of the electron pairs with $AlCl_3$ induces a flow of electron density from the rings to the iron atom, as a result of which the compound loses the capacity for electrophilic substitution [structure (LXXXI)][161].

A somewhat lower rate of solvolysis of 1-acetoxy[3]ferrocenophane compared with the corresponding non-bridged ferrocene derivatives has been observed, which has been attributed to some destabilisation of the α-carbonium centre in the ferrocenophane molecule, since in this case the cationic centre and the cyclopentadiene ring are non-coplanar[165].



(LXXXI) (LXXXII)

Several studies have been made on reactions involving the bridge, see for example Refs. 113, 116, 166, and 167. Some of these reactions were mentioned in the description of the methods of synthesis of ferrocenophanes. [3]Ferrocenophanes with a carbonyl group in the 1-position[168] or 2-position[169] were converted into tosylhydrazones from which the corresponding carbenes were generated. It was shown that the carbenes exist in the triplet state[169]. When the two tosylhydrazones were heated with sodium hydride, [3]ferrocenophan-1-ene was obtained. It is interesting that the reduction of ferrocenophane (LXXXII) gives rise only to the corresponding carbinol and the hydrocarbon could not be obtained[9,170].

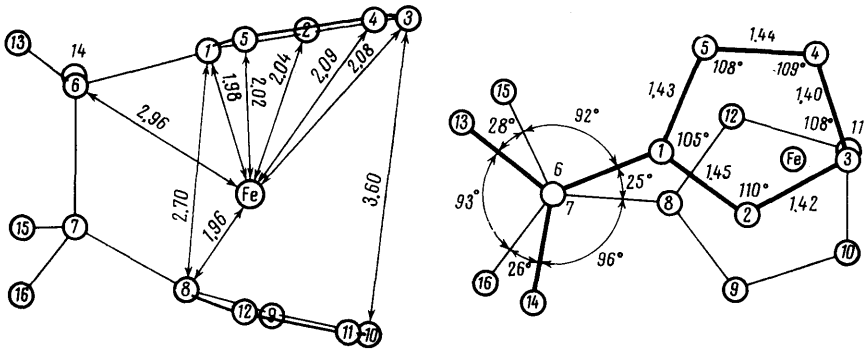


Figure 1.

IV. STUDIES BY PHYSICAL METHODS

A. Structural Studies

The structures and conformations of bridged ferrocenes were discussed theoretically in early investigations[171,172]. The determination of the crystal and molecular structures of 1,1,2,2-tetramethyl[2]ferrocenophane[173] showed that the two cyclopentadiene rings in this compound are inclined relative to one another at an angle of 23° and, in contrast to ferrocene, are staggered to the extent of only 9°. The strain in this system is shown by the fact that the dihedral angle in the bridge is only 26°. The bond lengths slightly exceed the normal values. The structure of this compound is illustrated in Fig. 1. We may note that, according to a calculation[174], the distortions in the structure accompanied by inclination of the rings by up to 45° should not be reflected in the metal–ring bond energy.

The mutual inclination of the cyclopentadiene rings in [3]ferrocenophan-1-one is naturally smaller than in the more strained [2]ferrocenophane, amounting to 8.8°.[175] Some of the experimental angles and bond lengths (Å) are indicated in Fig. 2. The second bridge in [3][3](1,3)ferrocenophane does not increase appreciably the mutual inclination of the rings (the angle is 9°).[176] The two cyclopentadiene rings in this molecule are in the eclipsed prismatic conformation. A virtually eclipsed conformation was also found in 1,2,3-trithia[3]ferrocenophane (the angle of ring inclination is 2.85°).[177] The crystal and molecular structures of [1,1,1]ferrocenophane[178] and the molecular structure of [1,1]ferrocenophane[179,180] have also been determined and the crystal lattice constants of the compounds (XLVI, R = thienyl)[181] and (LXXVII, E = As, R = CH_3, and M = NiI_2CO)[182] have been published.

X-Ray diffraction analysis of "bis-(π-azulene) iron" showed that this compound is a ferrocenophane in which the two seven-membered rings are non-planar and are linked via the *ortho*- and *para*-positions with formation of a two-membered bridge[29,30]. A similar structure was recently found for bis(pentalenyl)iron[28]. This compound exists in the form of two enantiomers (XVa and XVb).

B. The Study of Conformational Mobility

The cyclopentadiene rings in the ferrocene molecule are parallel and the barrier to their mutual rotation about the axis passing through the iron atom and the centre of the ring is very small (0.9 kcal mole^{-1} compared with 3.0 kcal mole^{-1} for rotation about the C–C axis in ethane)[183]. The introduction of a bridge into the ferrocene molecule precludes such rotation, but the mutual rotational oscillations of the rings persist and their amplitude should diminish with decrease of the length of the bridge. X-Ray diffraction analysis (see above) established that the cyclopentadiene rings are mutually inclined in [*m*]ferrocenophane molecules with fairly short bridges (*m* = 2 or 3).

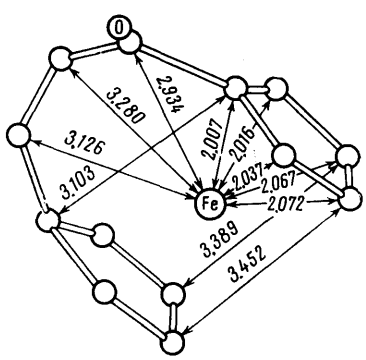

Figure 2.

Models have shown that with longer bridges the rings are parallel. The decrease of conformational mobility following the introduction of a bridge and particularly the mutual inclination of the rings are reflected in the spectroscopic characteristics of ferrocenophanes. Thus the sharp deformation of the [2]ferrocenophane molecule is reflected by the marked bathochromic shift of the "440 nm" band, associated‡ with the $A_{2g}(e_{2g} \rightarrow e_{2g}^*)$ transition[184], to 472 nm (Table 4). Its intensity increases at the same time. On the other hand, the displacement from conjugation of the carbonyl groups in the α-positions of the bridge

‡ Other assignments have also been made (see the paper of Barr and Watts[185] and the reference quoted therein).

leads to a hypsochromic shift of the above band. This effect has been observed in electronic spectra on passing from 1-acetyl-1′-methylferrocene to its bridged analogues—[3]- and [4]-ferrocenophan-1-ones[54]. The absorption maximum in the spectrum of the bridged [5]ferrocenophane-1,5-dione occurs at a lower wavelength (452 nm) than in the spectrum of the uncyclised and unstrained 1,1′-diacetylferrocene (460 nm).[186] Comparison of the electronic spectra of [3]ferrocenophane and [3]ferrocenophan-1-ene shows that there is virtually no conjugation of the double bond with the ferrocenyl fragment[168].

Table 4. Electronic spectroscopic data[15,185] [λmax (nm) and ϵ].

Compound	λ, nm	ϵ
Ferrocene	440	90
1,1′-Dimethylferrocene	437	100
1,1′-Di-(t-butyl)ferrocene	442	105
[2]Ferrocenophane	472	450
[3]Ferrocenophane	442	185
[4]Ferrocenophane	433	100
[5]Ferrocenophane	448	110
1,1′-Di(methoxymethyl)ferrocene	434	110
2-Oxa[3]ferrocenophane	443	220

Table 5 shows that an increase of the strain in the molecule and the displacement of the carbonyl group from conjugation with the cyclopentadiene ring as the length of the bridge is reduced are reflected in the infrared spectra [a shift of ν(C=O) towards higher frequencies].

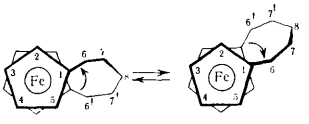
Table 5. The stretching vibration wave-numbers of the carbonyl group[54,113].

Compound	ν, cm^{-1}
[5]Ferrocenophan-1-one	1642
[5]Ferrocenophane-1,5-dione	1658
[4]Ferrocenophan-1-one	1647
[4]Ferrocenophan-2-one	1681
[3]Ferrocenophan-1-one	

The protons of the cyclopentadiene rings are shown in the ^{1}H NMR spectra of [m]ferrocenophanes[54,183,186] by multiplets, characteristic of an AA′BB′ system, resembling the corresponding signals in the spectra of 1,1′-disubstituted ferrocenes with electron-donating substituents[101]. Whereas in the spectrum of [4]ferrocenophane whose cyclopentadiene rings are parallel the signal of the above protons constitutes a fairly narrow singlet (40 MHz in C_6D_6), in the spectra of [3]- and particularly [2]-ferrocenophane, whose cyclopentadiene rings are inclined, the above signal splits into two triplets corresponding to the α- and β-protons. In the spectrum of the latter the spacing between the triplets reaches 0.54 p.p.m. The anomalous spectra of [2]- and [3]-ferrocenophanes were explained by the fact[183] that, owing to the mutual inclination of the rings, the orbitals of the lone electron pairs of the metal are rehybridised. The resulting asymmetric distribution of electron density in the space between the cyclopentadiene rings leads to different degrees of shielding of the α- and β-protons [structure (LXXXI)].

Detailed studies of the temperature variation of the ^{1}H NMR spectra of ferrocenophanes to investigate the conformational mobility of the molecules have not been made. It is only known that the methylene singlet in the spectrum of the [3]ferrocenophane is slightly broadened at −55°C[183] and the multiplet due to the cyclopentadiene protons of [5]ferrocenophane loses its fine structure at −110°C and at the same time shifts towards a high field[186]. The changes in the spectra of 1,2,3-trithia[3]ferrocenophane with increase of temperature indicate the mobility of this molecule[88].

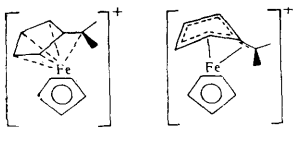
The ^{13}C NMR spectrum of [5]ferrocenophane was investigated recently[186]. The carbon atoms of the cyclopentadiene rings give rise to three signals with δ = 68.4 and 66.9 p.p.m. ($C_{2,5}$ and $C_{3,4}$) and 89.2 p.p.m. (C_1) relative to tetramethylsilane (in CH_2Cl_2 at +15°C). The bridge methylene groups give rise to three signals in the range δ = 22–26 p.p.m. Whereas one of these signals, probably associated with $C'_{6,6}$, does not change its position when the temperature is altered (in the range between −70° and +70°C), the other two signals shift appreciably to a lower field with increase of temperature. This change in the spectrum may be caused by the conformational transitions (LXXXIIIa) ⇌ (LXXXIIIb) due to the mutual rotation of the cyclopentadiene rings and the inversion of the bridge. The change in the contributions of the conformational populations as the temperature is altered leads to a significant change in the average anisotropic screening of the C_7 and C_8 nuclei in the inhomogeneous magnetic field[187] due to the ferrocene rings. The ^{13}C NMR spectrum of [5]ferrocenophane-1,5-dione may indicate a lower conformational mobility of the molecule[186].



(LXXXIIIa) (LXXXIIIb)

C. Application of Ferrocenophanes in the Study of α-Ferrocenylcarbonium and Ferricenium Ions

The problem of the structure of α-ferrocenylcarbonium ions has been solved with the aid of ferrocenophanes. To account for the unusual stability of α-ferrocenylcarbonium ions, two fundamental alternative structures, (LXXXIV) and (LXXXV), were proposed. In the first the cyclopentadiene ring with the α-carbonium centre assumes a fulvenoid configuration and is displaced relative to the iron atom, while in the second the cyclopentadiene ring is deformed and the carbonium centre approaches the iron atom.

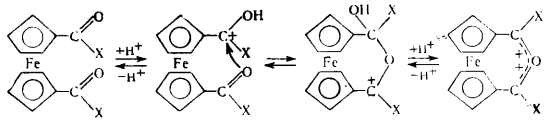


(LXXXIV) (LXXXV)

If structure (LXXXIV) is correct, the introduction of a bridge in the α- or β-position with respect to the carbonium ion centre should prevent the displacement of the

cyclopentadiene ligand, whereas a bridge of this kind cannot interfere with the deformation of the ring. [3]- and [4]-Ferrocenophanes with the $-\overset{+}{C}H_2$, $-CH\overset{+}{C}H_3$, or $-\overset{+}{C}(CH_3)_2$ cationic centre in the α- or β-positions with respect to the bridge have been obtained[188-192]. It was found that these compounds are no less stable than the cations without a bridge and that the ^{1}H NMR spectra of ferrocenophanes with a carbonium ion centre resemble those of the corresponding 1,1′-dialkylferrocenes with a cationic centre in the α- or β-position with respect to the alkyl substituent. On this basis, preference was given to structure (LXXXV). Japanese workers investigated the ^{1}H NMR spectra[3] of [3]- and [4]-ferrocenophane carbonium ions[191] in which the positive charge arises at the α- or β-carbon atom of the bridge. The authors believe that the spectra reflect the molecular deformations arising in consequence of the interaction of the positive charge both with the π electrons of the cyclopentadiene rings and with the iron atom.

In a study of ^{1}H NMR spectra the formation of the bridged dications (LXXXVII) in solutions of 1,1′-diacylferrocenes (LXXXVI) in strong acids was postulated[193]. When [5]ferrocenophane-1,5-dione is dissolved in concentrated sulphuric acid, a carbonium ion is formed, which is reflected[194] in the ^{13}C NMR spectrum. Comparison of the ^{13}C NMR spectra of mono- and 1,1′-di-acylferrocenes in protic acids[194] also indicates the possible formation of the bridged ion (LXXXVII).



(LXXXVI) (LXXXVII)

Bitterwolf and Ling[195] showed that in a strongly acid medium ($BF_3.H_2O$) biferrocenyl, diferrocenylmethane, and 1,2-diferrocenylethane are readily protonated as both iron atoms, which is reflected in the ^{1}H NMR spectra. However, in contrast to ferrocene, the solute is then oxidised, the rate of oxidation increasing with decrease in the length of the chain joining the two ferrocene fragments. The oxidation of [1,1]ferrocenophane is very rapid and is accompanied by the liberation of one mole of hydrogen. The hydrogen atoms in the specific conformation of the diprotonated [1,1]ferrocenophane (Fig. 3) probably approach one another and a chemical bond is formed between them, which leads to the elimination of hydrogen. The iron atoms are then oxidised.

[0,0]Ferrocenophane can be oxidised at one of the iron atoms with formation of ferricenium picrate or fluoroborate. An intense absorption, consisting of a double band at 1550 nm (ϵ = 2100) and 1140 nm, was observed in the electronic spectrum of this compound[22,196]. The position of this band and its molar extinction coefficient are independent of the solvent and concentration, which enabled the authors to assign this absorption to an intramolecular electron transfer between the two iron atoms. [1,1]Ferrocenophane gives rise to a picrate which absorbs at 780 nm[22]. In both cases the band undergoes a sharp hypsochromic shift relative to its position in the spectrum of ferrocenylferricenium picrate (1900 nm, ϵ = 551).[197]

D. Other Studies

It has been established that the two bands in the region of 1000 and 1100 cm^{-1}, characteristic of the vibrations of the unsubstituted cyclopentadiene rings, are absent from the infrared spectra of ferrocenophanes, but almost always occur in the spectra of mono- or homopoly-substituted ferrocenes. This feature can be used to establish whether the intramolecular cyclisation reaction is homoannular or heteroannular (see Scheme 4).

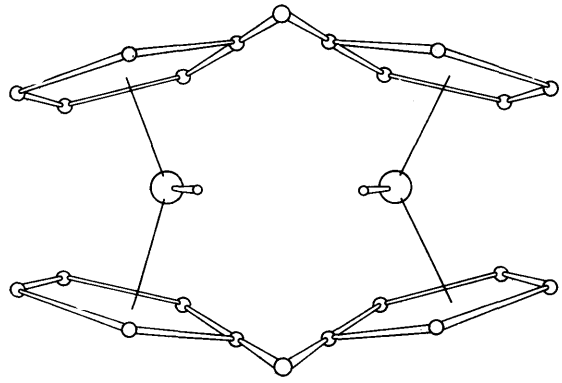


Figure 3.

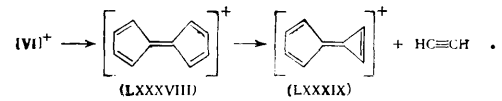
The dipole moments of [m]ferrocenophanes have been measured[198] and have been found to decrease in the following sequence: Me_4[2]§ > [3] > [4] > [5] (1.00, 0.85, 0.81, and 0.76 D respectively), owing to the increase of the mobility of the molecule with increase in the length of the bridge. It is interesting that the dipole moments of β-acetyl[m]ferrocenophanes (m = 3, 4, or 5) are equal to the sums of the dipole moments of acetylferrocene and the corresponding [m]ferrocenophane. This finding was explained by the hyperconjugation between the methylene and carbonyl groups in the $CH_3CO-C_5H_3-CH_2-$system. The polarographic behaviour of various ferrocenophanes has been studied[199,200] and their magnetic susceptibilities have been measured[200]. It was found that [m]ferrocenophanes are oxidised electrochemically more readily than ferrocene and are comparable in this respect to 1,1′-dialkylferrocenes[199]. Under these conditions, [2]ferrocenophane decomposes, since the ferricenium cation formed is unstable. The magnetic anisotropy of the carbonyl group in 2-acetyl[3]ferrocenophane has been discussed[201].

Unfortunately systematic and detailed mass-spectrometric studies on ferrocenophanes have not been made[202,203]. The spectra of [5]ferrocenophanes, like those of the majority of the ferrocene derivatives, are characterised by an intense molecular ion peak. The fragmentation of this ion for the simplest [5]ferrocenophane is accompanied by the loss of CH_3, C_2H_5, C_3H_5, and C_4H_7. When the bridge contains an α-carbonyl group, CO is the first to be eliminated[113]. Very intense M^+ and M^{2+} peaks were observed in the spectrum of [3][3](1,3)ferrocenophane. The fragmentation of the molecular ion involves the loss of methyl, acetylene, ethylene, and propene with subsequent decomposition of the ions formed[204]. The mass spectra of [1,1]-ferrocenophanes have been described[21,202,205]. Apart from the most intense M^+, M^{2+}, and Fe^+ peaks,

§ 1,1,2,2-Tetramethyl[2]ferrocenophane.

the [0,0]ferrocenophane spectrum shows small peaks with m/e 128 and 102, which may be due to the (LXXXVIII) and (LXXXIX) ions respectively[90]. The spectra of [2,2]ferrocenophane-1,13-diyne[92] and 1-hydroxy[3]ferrocenophane[206] have been published. The formation of an ion corresponding to the ferrocenophane (LXX) was noted in the fragmentation of the dicarbinols (LIII)[206]:

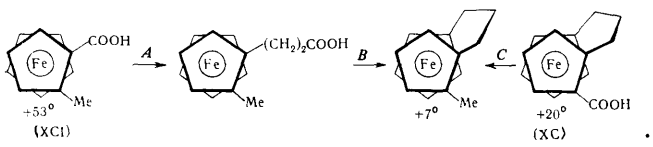


V. THE STEREOCHEMISTRY OF FERROCENOPHANES

The configurational and conformational studies on metallocenes, particularly on [3]ferrocenophanes, have been reviewed by Schlögl[207,208].

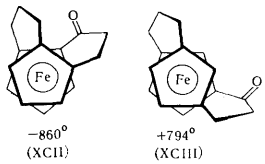
Monosubstituted [m]ferrocenophanes, as well as homoannular disubstituted ferrocenes, should exist in the form of two optical isomers. Detailed stereochemical studies have so far been made only on [3]ferrocenophanes. The key compound for the determination of the absolute configurations of these derivatives is [3]ferrocenophane-α'-carboxylic acid (XC), the absolute configuration of which was established by a correlation with methylferrocene-α-carboxylic acid (XCI), as shown in Scheme 12. The transformations were carried out as follows: Stage A involves the transformations COOH → CHO → CH = CHCOOH → CH_2CH_2COOH, stage B involves cyclisation with the aid of $(CF_3CO)_2O$ and reduction by a mixture of $LiAlH_4$ and $AlCl_3$, and stage C involves reduction by the same mixture. The absolute configuration of the acid (XCI) had been established previously[209]. Similar studies have been made also for ferrocenophanes containing substituents in the β-position[210]. Apart from chemical correlations, the Horeau method of kinetic resolution was used to establish the configuration of [3]ferrocenocarboxylic acids by the interaction of their anhydrides with (-)-α-phenylethylamine[210].

Scheme 12



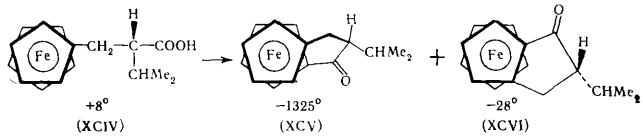
The doubly bridged ketone (XCII) was synthesised by a series of consecutive transformations from the acid (XC) obtained by the resolution of the racemate with (-)-α-phenylethylamine. The β-derivative (CXIII) was obtained similarly[210].

The intramolecular cyclisation of 1-(β-carboxypropyl)-1′-methylferrocene yielded the corresponding α- and β-methyl[3]ferrocenophanones with the oxo-group in the bridge. Each ketone was resolved into its optical isomers by the formation of methylhydrazones[210].

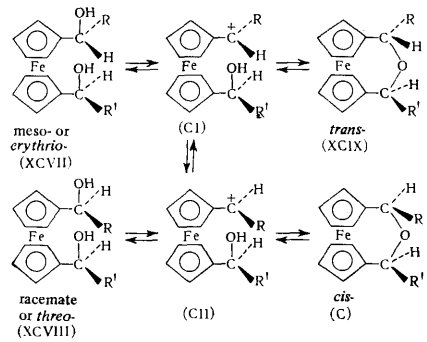


The study of the circular dichroism (CD) of optically active homo-disubstituted ferrocenes and [3]ferrocenophane substituted in the α-position of the ring led to conclusions concerning the preferred conformations of the substituents or the bridge[208,211]. The study of the dipole moments and the temperature variation of the circular dichroism of α- and β-substituted (in the cyclopentadiene ring relative to the bridge) [3]ferrocenophanes showed that the activation energy for the inversion of the bridge is significantly higher for the α-derivative, as was to be expected, and this results in the existence of a preferred bridge conformation[211]. Moreover, on passing from [3]ferrocenophanes α-substituted in the cyclopentadiene ring to the β-substituted derivatives, a decrease of the amplitude of the Cotton effect may be noted and in certain cases the sign of the curves is reversed[212].

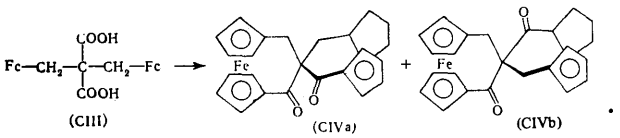
The chirality of the ferrocenophane molecule may be caused by the introduction of a substituent not only in one of the rings, as in the above discussion, but can arise also when an asymmetric centre is introduced into the bridge. The cyclisation of the optically active acids $FcCH_2CHRCOOH$, leading to ketones with hetero- and homo-bridges, which also exhibit optical activity [for example compounds (XCV) and (XCVI)], has been described[48,49].



A careful study of the stereochemistry of the 1,1′-diol⇌2-oxa[3]ferrocenophane interconversions was made by Yamakawa and Hisatome[213]. 1,1′-Di-(α-hydroxyalkyl)ferrocenes can exist in the *meso*-form (*erythro*- if R ≠ R′) (XCVII) and as the racemate of two optical isomers (*threo*- when R ≠ R′) (XCVIII). The resolution into the *meso*-form and the racemate was achieved by 7–8 recrystallisation of the product obtained by the reduction of the corresponding diacylferrocene. On treatment with dilute HCl, the mixture of compounds (XCVII) and (XCVIII) is converted into a mixture of the *cis*- and *trans*-isomers of the ferrocenophane, (C) and (XCIX) respectively, which can be separated chromatographically. The ferrocenophanes (XCIX) and (C) are converted reversibly into the diols (XCVII) and (XCVIII) on treatment with acid alumina. It is significant that the interconversions are stereospecific. The relative amounts of the products in the (XCVII) ⇌ (XCIX) and (XCVIII) ⇌ (C) interconversions have been determined but small amounts of another isomer are also obtained in these processes owing to the equilibrium (CI) ⇌ (CII) between the two forms of the intermediate carbonium ion.

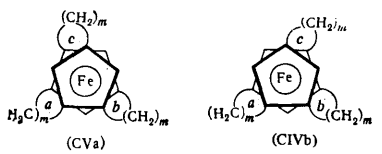


When the acid (CIII) was treated with $(CF_3CO)_2O$, a mixture of stereoisomeric spiranes (CIV) was obtained[214] and was resolved by chromatography on partly acetylated cellulose[215].



(CIII) (CIVa) (CIVb)

Optical isomerism of a new type may be expected for the ferrocenophanes (CV, $m = 4$ or 5) with three bridges, which have not yet been synthesised. Models show that such ferrocenophanes with fairly long bridges can exist in the antiprismatic configuration. The introduction of two bridges (a and b) restricts the mutual rotational oscillations of the rings, while the third bridge (c), which has rotated to the left or to the right, should result in the formation of two enantiomers—(CVa) and (CVb) respectively.



(CVa) (CIVb)

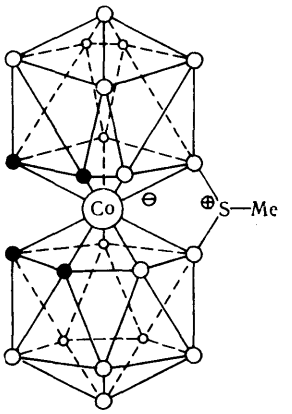
VI. APPLICATIONS

The use of ferrocenophane models for the solution of certain theoretical problems and the synthesis of polymers containing ferrocenophane fragments was mentioned above.

It has been suggested that [2]ferrocenophanes (Table 1, Nos. 1–5) be used as additives to epoxy-resins and silicones[14]. It was found recently that [3]ferrocenophanes with silicon and oxygen atoms in the bridge are effective inhibitors of the oxidation of polyorganosiloxanes[216,217]. Bridged cyclic ethers[218–221] and thioethers[218] exhibit biological activity and can be used in the treatment of diseases associated with iron deficiency in the organism. Derivatives of [3]ferrocenophan-1-one[167,222] and also 1-aza[4]ferrocenophane[149] exhibit a similar activity. These compounds have proved useful also as additives to fuel. It has been suggested that 2-aza[3]ferrocenophane be used in macromolecular chemistry. The dicarbinol formed on reduction of 3-phenyl[5]ferrocenophane-1,5-dione was converted into a bridged ether and thioether, which can be used as pesticides, dyes, fuel additives, and medicinal preparations for the treatment of iron-deficiency diseases[223]. Like titanocene dichloride, 1,1′-methylenetitanocene dichloride can be used for the fixation of molecular nitrogen and also as a cocatalyst in the polymerisation of olefins[19].

ADDENDUM

Japanese workers described recently the synthesis of bridged bicyclic ferrocenes with two nitrogen atoms in the bridge by the reaction of the 1,1′-diacetylferrocene–$AlCl_3$ complex with o-phenylenediamine[224]. French chemists continued the study of the stereochemistry of substituted [3]ferrocenophanes[225]. Plešek et al.[226] synthesised the interesting bridged carborane derivative (CVI).



(CVI)

Turbitt and Watts made special use of ferrocenophane models in a detailed study of α-ferrocenylcarbonium ions[227]. Continuing the investigation of ferrocenophanes by ^{13}C NMR, Nesmeyanov et al.[228] obtained the spectra of certain [3]ferrocenophanes and the carbonium ion formed when [3]ferrocenophan-1-one is dissolved in CF_3COOH. The introduction of the phenyl substituent in the 3-position of the bridge of [5]ferrocenophane results in the non-equivalence of all five carbon atoms of the cyclopentadiene ring owing to the diastereotopy (and the anisochronic properties) of the nuclei within each of the two pair $C_{(2)} - C_{(5)}$ and $C_{(3)} - C_{(4)}$ arising following the introduction of the substituent[228]. This effect was observed previously for non-bridged mono-substituted ferrocenes containing a chiral centre in the substituent[229–231].

Organophosphorus Complexones†

M.I.Kabachnik, T.Ya.Medved', N.M.Dyatlova, and M.V.Rudomino

Organophosphorus complexones are a new group of highly effective complex-forming compounds capable of binding metal ions in aqueous media. The principal trends in the development of studies on the synthesis and properties of organophosphorus complexones are discussed and methods for the modification of their structures and their most interesting applications are indicated.
The bibliography includes 130 references.

I. INTRODUCTION

Progress in many branches of science and engineering is to a large extent associated with the development of the chemistry of coordination compounds with polydentate ligands, among which complexones occupy one of the leading places. The chemistry of complexones opens up virtually unlimited possibilities for the modification of the properties of cations, which creates vast prospects for their extensive application. However, the inadequate assortment of these compounds has limited the range of their applications. Until recently, these ligands were used mainly only in analytical chemistry as titrating and masking agents. Virtually the only available and widely used complexone was ethylenediaminetetra-acetic acid, the possible applications of which are extremely limited[1,2].

The development of modern engineering and of the national economy places new tasks before science. A number of important problems of this kind, such as the cleaning of thermal power engineering equipment, the separation of elements with similar properties, the treatment of plant chlorosis, the elimination of incorporated metals from the organism, the metallation of dielectric materials, and the stabilisation and catalysis of complex systems can be solved successfully by employing complexones. However, the complexone-type ligands used in the solution of these problems must possess in each individual case a set of properties ensuring their optimal applicability. For this reason, it was necessary to create a large assortment of complexones with a wide range of complex-forming properties and in the first place complex-forming agents capable of giving rise to complexes with maximum stability over a wide pH range, from strongly acid to strongly alkaline media, and also selectively acting compounds with a specific set of properties. The first of these problems is solved by combining in the structure of the complexone the highly basic nitrogen atoms with polydentate salt-forming groups. The solution of the second problem involves much greater difficulties, since it is necessary to chelate selectively metal ions with similar physical and chemical properties, dimensions, steric configurations, and, what is most important, similar tendencies towards complex formation. The difficulties are aggravated also by the fact that, by virtue of their polydentate nature and in most cases the flexibility of their steric configuration which permits a multiplicity of conformations with deformation of the bond angles and lengths within certain limits, complexones become very readily adapted to the geometrical requirements of the cations.

A higher selectivity in chelate formation, particularly for polydentate compounds, can be achieved only by synthesising a special reagent taking into account the complete set of properties of the internal ligand contour and the cation and also the postulated structure of the chelate to be formed. The change in the electronic states at the sites responsible for coordination and the rigidity of the system is also important.

The ligand molecule with the specified properties should be synthesised on the basis of the known correlation between the structure of the ligand and its properties, the theory of the action of complexones (by varying the number of their binding sites), the nature of the electron-donating atoms and their immediate environment, the stereochemistry of the molecule as a whole, the number of rings formed and their dimensions, the rigidity of the system, and the distribution of electron density among the sites responsible for coordination.

One of the fundamentally new and promising ways of the specific synthesis of a complexone molecule involves the incorporation in the latter of aminoalkylphosphonic acid groups[2-4]. The specificity of the chelating agent containing a phosphonic acid group is determined primarily by its stereochemistry, which differs from that of the carboxy-group. The phosphonate ion is almost tetrahedral (distorted tetrahedron) with a threefold symmetry axis. The carboxylate ion is planar with a planar symmetry. The valence angles and bond lengths are also different.

π-Bonding between the oxygen and phosphorus atoms is much weaker than between oxygen and carbon atoms in the carboxy-group. The polarisability of the P–O bonds in

† Partly reported at the Second Symposium on the Inorganic Chemistry of Phosphorus, Prague, 1974.

the phosphoryl group is greater than that of the C–O bond in the carboxy-group. For this reason, on the one hand the inductive effect plays a major role in phosphonic acid compounds and on the other the phosphonic acid group is highly nucleophilic. In the presence of the two hydroxy-groups of the phosphonic acid which are potentially capable of coordination, the stereochemistry of such complexones allowed an *a priori* assumption that the higher stability of their chelates is a result of the possible formation of additional rings and led to the expectation that they will be selective with respect to cations with an enhanced coordination capacity and high electrostatic characteristics.

Although the properties of aminoalkylenephosphonic acids were first reported by Schwarzenbach and coworkers as early as 1949,[5] the interesting and extremely specific properties of organophosphorus complexones were not discovered either in that investigation or in later studies by Martell and coworkers[6-9] dealing with the phosphorus analogues of the familiar complexone ethylenediamine-tetra-acetic acid (EDTA). Only comprehensive investigations using potentiometric, polarographic, infrared spectroscopic, NMR, and ESR methods, carried out mainly by Soviet investigators, led to the discovery of the specificity of the interaction of phosphorus-containing complexones with the cations of elements in various Groups of Mendeleev's Table[2-4,10-16].

The present review does not claim to cover completely the literature on organophosphorus complexones, since its aim is to characterise the principal trends of the developments in this field. At the start of studies on

organophosphorus complexones, polyaminopolyphosphonic acids were difficult to obtain. For this reason, a special series of studies were made to develop convenient methods for the synthesis of compounds of this type.

They were based on the principle of the synthesis of α-aminoalkylphosphonic acids discovered by Kabachnik and Medved' at the beginning of the 1950s, which consists of the simultaneous or consecutive treatment of an amine and an oxo-compound by phosphorus(III) derivatives capable of existing in the form of two tautomers [3,17-22].

In the synthesis of alkylenediaminediphosphonic and alkylenediaminepolyphosphonic acids the amine is the corresponding diamine (usually ethylenediamine) and the oxo-compounds are aldehydes or ketones or the Schiff bases prepared beforehand from the diamine and the oxo-compound.

The phosphorus-containing component can be any derivative of phosphorous, phosphonous, or hypophosphorous acid. Esters, for example dialkyl phosphites or phosphonites, are used in the two-stage synthesis; the ester group is subsequently hydrolysed. In the single-stage synthesis (a modification of the method of Moedritzer and Irani[21]) phosphorous acid is employed. In the synthesis of ethylenediaminedi(alkylenephosphonous) acid we employed hypophosphorous acid as the phosphorus-containing component.

There is now a possibility of obtaining the following principal types of organophosphorus complexones by the above methods which have a wide range of applicability.

(1) Alkylenepolyaminebis[dialkyl(arylalkyl)methylenephosphonic] acids:

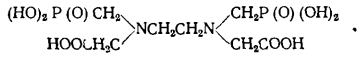
$$(HO)_2P(O)C(R'R'')NH[CH_2-X-CH_2]_nCH_2NHC(R'R'')P(O)(OH)_2$$

R', R''=H, Alk, Ar; $n = 0,1$; X=O, NH, S, CH_2 .

(2) Alkylenepolyaminepoly(alkylenephosphonic) acids, for example:

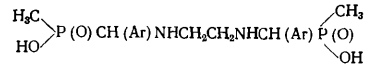
$$[(HO)_2P(O)CH_2]_2NCH_2CH_2N[CH_2P(O)(OH)_2]_2 .$$

(3) Alkylenediaminediaceticdi(alkylenephosphonic) acids:



(4) Alkylenediaminedi(arylmethylenephosphonous) acids:

(5) Alkylenediaminedi(arylmethylenephosphinic) acids:



As a result it became possible to synthesise and investigate a series of compounds the structure of which includes phosphonic, phosphonous, and phosphinic acid fragments, fully phosphorylated derivatives of polyamines, complexones with heteroatoms and aromatic groups, and complexones containing simultaneously carboxy- and phosphono-groups or phosphono- and hydroxy-groups.

Some of the complexones synthesised and the abbreviations used to designate them are listed in Table 1, which also includes references to their syntheses. The last three acids in Table 1, the widely familiar carboxyl-containing complexones, are included for comparison.

II. DISSOCIATION OF AMINOPHOSPHONIC ACIDS

A betaine-like zwitter-ionic structure is characteristic of both aminocarboxylic acids and their phosphorus analogues but the basicity of the amino-group in aminophosphonic acids is higher than in aminocarboxylic acids (Table 2).

Table 2. Negative logarithms of the dissociation constants of phosphorus-containing complexones.

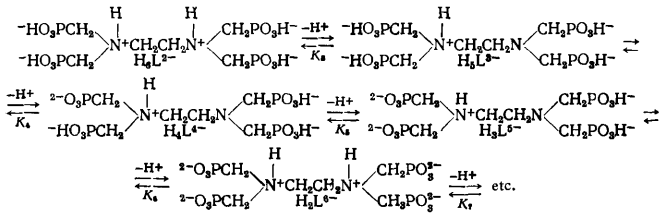
*Hexamethylphosphoramide (Ed. of Translation).

The study of the deprotonation of polyaminopolyphosphonic acids showed[2-4,23,24] that the PO_3H_2 group dissociates at low pH. With increase of pH, the PO_3H^- groups dissociate and finally in the alkaline region the protons dissociate from the betaine nitrogen atoms. When the complexone molecule contains hydroxyphenyl groups, the phenolic hydroxyls are the last to dissociate at still higher pH than the betaine protons. In such cases stable hydrogen bonds may be formed.

In the course of more far-reaching studies on the mechanism of the acid dissociation of aminopolyphosphonic acids by infrared spectroscopy it was shown[25] that the dissociation of the third, fourth, and fifth protons from ethylenediaminetetra(methylenephosphonic) acid results in the formation of anionic forms in which protonated phosphono-groups are linked to one protonated and one non-protonated nitrogen atom, as shown below:



The presence of a deprotonated nitrogen atom in the anions H_5L^{3-}, H_4L^{4-}, and H_3L^{5-} suggests that metal–nitrogen bonds are more likely to be formed in acid complexes of EDTMPO.

It has been shown, also by infrared spectroscopy, that in the dissociation of ethylenediaminediaceticdi(methylenephosphonic) acid the species with protonated and deprotonated nitrogen atoms may exist in equilibrium. A similar view concerning the order of the dissociation of

protons in ethylenediaminemono(methylenephosphonic) and ethylenediaminedi(methylenephosphonic) acids was expressed by Uhlig and Achilles[28].

Comparison of the dissociation constants of aminophosphonic acids in the group under consideration with those of the analogous aminocarboxylic acids shows that the unusually high and close values of the last two dissociation constants, corresponding to the dissociation of the betaine protons, constitute a significant difference. In diphosphonic acid this is shown particularly clearly with increase of the length of the methylene chain joining the aminoalkylphosphonic acid groups; the difference between the last dissociation constants decreases to a factor of ten and less, which can be accounted for by the decrease of the inductive effect exerted by one amino-group on another.

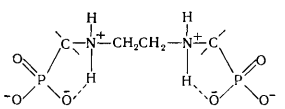
In tri-, tetra-, and penta-phosphonic acids the decrease of the mutual influence of the two positively charged nitrogen atoms is probably associated partly with the high charge of the anion and partly with the electrostatic binding (hydrogen bonding) of the betaine protons.

Table 2 shows that an increase of the number of iminomethylphosphonic acid groups initially increases the last two dissociation constants on passing from ethylenediaminedi(methylenephosphonic) acid to ethylenediaminetetra(methylenephosphonic) acid, but, on passing from the latter acid to diethylenetriaminepenta(methylenephosphonic) acid, the last two constants hardly change. This can be accounted for by an increase of the basicity of the nitrogen atom with the increasing negative charge in the molecule. Then, when the charge becomes large, the introduction of a new group alters it relatively little. A similar phenomenon has been observed in phosphates.

The combination of highly basic betaine nitrogen atoms and polydentate salt-forming groups in alkylenepolyaminepoly(alkylenephosphonic) acids leads to their deprotonation over a wide pH range, which extends the pH range in which complexes exist.

III. COMPLEXES WITH ALKALI METALS

All phosphorus-containing complexones form complexes on interaction with alkali metal cations. Thus ethylenediaminebis(dimethylmethylenephosphonic) acid forms the equimolar complexes



in the region corresponding to the dissociation of the betaine protons, i.e. at pH > 8 (K_{st} = 3.06 for LiX, 2.30 for NaX, < 1 for KX, and 3.37 for CsX). Their stability exceeds that of the corresponding EDTA complexes. We attribute this to the specific features of the effect of the phosphono-group and in particular to the involvement in complex formation of both oxygen atoms in the hydroxy-groups at the phosphorus atom. The participation of phosphono-groups of ethylenediaminebis(dimethylmethylenephosphonic) acid in coordination to alkali metals only at fairly high pH values can probably be explained by the necessity for the dissociation of the hydrogen bonds in the structure (see above) to liberate all the oxygen atoms of the phosphono-groups and also by the necessity to increase the overall negative charge of the molecule.

IV. COMPLEXES WITH ALKALINE EARTH METALS AND BERYLLIUM

Polyalkylenepolyaminepolyphosphonic acid containing not more than two phosphono-groups forms hardly any complexes with alkaline earth metals including calcium. An increase of the number of phosphono-groups and also their combination with carboxy-groups leads to the formation of stable complexes with alkaline earth metals, the logarithms of whose stability constants reach 8–9 (Table 3). Depending on the pH of the medium, complexes protonated to different extents are formed[2-4,12-14,27].

Table 3. Logarithms of the stability constants of the complexes MX.

Cation	EDBDMPO	EDDADMPO	EDTMPO	DETPMPO
Mg^{2+}	<2	8.54	8.63	6.40
Ca^{2+}	<2	9.02	9.33	7.11

The consecutive protonation of the normal complexes as the pH is reduced can be demonstrated for magnesium complexes of nitrilotrimethylphosphonic acid[12,13].

Table 4. Parameters of the infrared and NMR spectra of magnesium complexes of nitrilotri(methylphosphonic) acid.

Complex anion	ν(CH), cm^{-1} as	ν(CH), cm^{-1} s	ν(PO_3), cm^{-1}		δ_H, p.p.m.	$\delta_{^{31}P}$, p.p.m.
MgL^{4-}	2946					
	2877	2841	1099,1068	971	3.20	16.63
$MgHL^{3-}$	3000	2937	1106	973	2,83	7,65
MgH_2L^{2-}	2998	2946	1164,1103	971	2,76	7.20
MgH_3L^{-}	—	—	1167,1084	966	—	—
	2939					
L^{6-}	2845	2790	1083	969	3.45	17.67

The infrared spectrum of the solution of the normal complex $[MgL]^{4-}$ shows an increase in the symmetrical stretching vibration wavenumber ν(C–H) approximately by 50 cm^{-1} compared with the fully deprotonated free ligand. This is associated with the formation of a stable covalent Mg ← N bond. The formation of this bond is also confirmed by the chemical shifts to a high field of the proton doublet in the ^1H NMR spectra and the phosphorus triplet in the ^{31}P NMR spectra relative to the free ligand.

The bond between magnesium and oxygen atoms of the phosphono-groups is largely ionic, which is also indicated by the slight increase of the PO_3^- vibration frequency in the complex compared with the ligand.

When the first proton adds to the complex, the N–H bond is formed, this being accompanied by a characteristic increase of the C–H stretching vibration wavenumbers by 100 cm^{-1}. The second proton adds to an oxygen atom of one of the phosphono-groups, which is reflected by the appearance in the spectrum of the PO_3H^- band with a characteristic wavenumber of 1164 cm^{-1}. The third

proton adds to the second phosphono-group (the intensity of the 1164 cm^{-1} band then increases). All these conclusions are confirmed also by the ^{1}H and ^{31}P NMR spectra.

Table 5. Logarithms of the stability constants of polynuclear ethylenediaminebis(dimethylmethylenephosphonic) acid.

M^{2+}	$BeMH_2L$	$AlMH_2L$	$LaMH_2L$	$CdMH_2L$	M^{2+}	$BeMH_2L$	$AlMH_2L$	$LaMH_2L$	$CdMH_2L$
Mn	8.7	9.8	6.2	6.9	Ni	8.9	10.3	6.3	7.0
Fe	8.8	10.0	6.3	7.0	Cu	13.5	14.8	11.4	11.8
Co	8.9	10.1	6.3	7.0	Zn	10.1	11.3	7.2	7.8

The ability of these compounds to form stable mononuclear and dinuclear complexes with beryllium is particularly noteworthy[28-30]. The study of the mechanism of the complex formation process showed that it involves the interaction of beryllium with the phosphono-groups only; the nitrogen atoms of the iminoalkylphosphonic acid groups are not involved in complex formation. The free coordination sites in the complexes can be occupied by other cations with formation of polynuclear complexes having two coordination centres consisting of two different cations[28-31] (Table 5).

V. COMPLEXES WITH TRANSITION METALS

In the interaction with transition metals the specific features of phosphorus-containing complexones are shown primarily by the formation of stable hydrogen-bonded complexes, which is not characteristic of the carboxyl-containing prototypes. Among the normal complexes, those of copper are particularly stable (Table 6).

Thus the stability constant of the copper complex of ethylenediaminebis(dimethylmethylenephosphonic) acid (EDBDMPO, phosphicine) exceeds that of the corresponding EDTA complex by two powers of ten. The difference between the stabilities of the copper and other transition metal complexes is exceptionally large. Thus the stability of the phosphicine-copper complex exceeds those of the nickel and zinc complexes approximately by nine powers of ten (the stabilities of the corresponding EDTA complexes are similar). It has been established by ESR and electronic spectroscopy[11] that in the ground state of the copper(II) complex of ethylenediaminebis(dimethylmethylenephosphonic) acid the unpaired electron is in the $d_{x^2-y^2}$ orbital (the x and y axes are directed towards the electron-donating ligand atoms) and therefore the complex has the structure of an extended octahedron. The copper atom is linked to the two nitrogen atoms, which are located in the plane containing the unpaired electron and the other coordination sites are occupied by the oxygen atoms of the phosphono-groups. The bonds in the plane of the complex have an amount of covalent character typical for copper complexes.

Stable complexes with phosphorylated derivatives of polyamines are formed by readily hydrolysed elements: iron, aluminium, indium, gallium, titanium, and chromium. The high stability of their protonated complexes, in many cases exceeding the stability of the normal complexes of the corresponding aminopolycarboxylic acids, is remarkable.

The nature of these interactions can be illustrated using as an example the formation of aluminium nitrilotri(methylphosphonate). Aluminium forms two types of complexes with nitrilo(trimethylphosphonic) acid: sparingly soluble polynuclear compounds and soluble monoprotonated and normal compounds. In the region corresponding to the dissociation of the first three protons an insoluble compound is formed and is isolated as the hydrate $Al_3H_3L_2 \cdot 9H_2O$.

Table 6. Logarithms of the stability constants of transition metal complexes.

Complexone	Cu^{2+}	Ni^{2+}	Co^{2+}	Zn^{2+}	Mn^{2+}	Cd^{2+}
NTP	17.75	11.96	14.37	>16.37	10.20	11.55

	20.35	11.23	11.19	13.38	8.00	
EDTMPO	11.14	9.12	8.51	9.90	6.99	8.81
	18.95	15.30	15.49	17.05	12.70	13.88
EDDADMPO	9.4	9.49			7.0	
	18.5	15.23	16.03	16.85	13.63	

Note. The numerals in the upper row refer to the $\lg K_{st}$ for the protonated complexes MH_2L and those in the lower row refer to the $\lg K_{st}$ for the normal complexes ML.

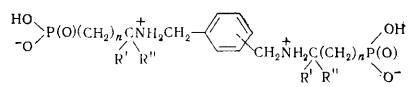
Infrared spectra show that in polynuclear compounds of this kind the bond between aluminium and nitrogen is weakened; evidently in this case the entire coordination capacity of aluminium is saturated by the oxygen atoms of the phosphono-groups. With increase of pH, the polynuclear complex gradually dissolves with formation of the soluble mononuclear complex AlH_2L^{2-} and its subsequent deprotonation and the formation of the stable normal mononuclear complex AlL^{3-}. In the presence of an excess of aluminium in the pH range 5–6 the sparingly soluble dinuclear complex Al_2L is formed and is isolated from solution as the hexahydrate. The study of the ^{1}H NMR spectra of the normal mononuclear complex showed the presence of the Al–N bond. The change of the chemical shifts relative to the fully deprotonated ligand reaches 0.28 p.p.m. The addition of an excess equivalent of alkali (pH 6.86–9.08) does not cause precipitation and no changes take place in the NMR spectra. A further increase of pH (9.1–10.7) leads to the appearance in the spectrum of two pairs of signals; one of these is intense and corresponds to the aluminium complex and the second, weak signal corresponds to the monoprotonated form of the ligand (HL). A further increase of pH leads to an increase of the intensities of the second pair of bands with their subsequent equalisation and is accompanied by the precipitation of aluminium hydroxide from solution.

In all probability the complex AlL^{3-} is present in solution in equilibrium with the monohydroxo-complex $[(AlOH)HL]^{3-}$, which is due to the great tendency of aluminium to form a bond with the water hydroxyl. This hypothesis is confirmed by the presence in the infrared spectrum of the solution of bands indicating the formation of a bond between nitrogen and a proton (N–H). The existence in the complexes of, as it were, a "disproportionated" water molecule is probably generally characteristic of compounds formed by readily hydrolysed cations.

The interaction of phosphorus-containing complexones with iron is unusual. Interpretation of the infrared, NMR, and ESR spectra and also of potentiometric data for iron complexes of carboxyl- and phosphorus-containing analogues leads to the conclusion that at low pH the interaction of the cation with the two groups of ligands proceeds via different mechanisms. Whereas carboxylated amines form very stable water-soluble normal 1 : 1 complexes with Fe^{3+}, phosphorylated amines give rise to protonated polynuclear water-insoluble complexes. Their inner sphere consists entirely of the oxygen atoms of the phosphono-groups. On passing to alkaline media, the stability of the nitrilotriacetic, EDTA, and other complexes with Fe^{3+} falls owing to the weakening of the bonds between the oxygen atoms of the carboxy-groups and the central ion caused by hydrolytic processes. Under these conditions, polynuclear complexes of phosphorylated amines are converted into normal soluble mononuclear and dinuclear complexes with formation of a thermodynamically favourable ring comprising M–N bonds [32].

Analysis of the ESR spectra of iron complexonates established the symmetry of the immediate environment of the central atom in these compounds. The compounds have a spectrum characteristic of Fe^{3+} in the high-spin state $^6A_1$—it consists of a single broad symmetrical line, which indicates hexagonal symmetry of the local environment of the iron ion; the splitting caused by the tetragonal or trigonal components of the crystal field is absent. These results are fully consistent with the determinations of the magnetic susceptibilities of these complexes (μ_{eff} = 5.86 Bohr magnetons, i.e. $s = 5/2$).

Table 7. Logarithms of the stability constants of the protonated complexes of xylylenediaminedialkylenephosphonic acids.



Position in ring	n	lg K_{st} for MH_2L complexes						
		R′	R″	Ni^{2+}	Cu^{2+}	Fe^{3+}	Dy^{3+}	UO_2^{2+}
m-	0	CH_3	CH_3	—	3.92	—	6.48	8.40
p-	0	CH_3	CH_3	—	<3	—	4.78	8.32
p-	1	H	H	—	4.08	—	6.17	9.4(ppt)
		EDBDMPO		3.84	8.33	>10	6.20	8.52

The introduction of a hydroxyl into the structure of the chelating agent increases the stability of the resulting compounds. *N*-(2-Hydroxyethyl)ethylenediaminetri(methylenephosphonic) acid prevents the hydrolysis of iron even when the complexes are boiled at pH > 12. [33]

Extremely stable highly coloured iron(III) and titanium(IV) complexes are formed by ethylenediaminedi-(*o*-hydroxyphenylmethylenephosphonic) and the corresponding phosphonous acids. However, the mechanisms of complex formation are different in the two cases: complexes with simultaneous participation in the coordination of all the electron-donating atoms may be formed with the phosphonous acid, while in the case of the phosphonic acid, where there is a greater number of binding sites, there is apparently competition between the oxygen atoms of the phosphono-group and the phenoxide ion [34,35].

The potential ability of aminoalkylphosphonic acids to increase the number of their binding sites by the inclusion of the oxygen atoms of the phosphono-groups favours the formation of complexes with the lanthanides, which have high coordination numbers and a high affinity for oxygen. Thus the stability of the protonated complexes of ethylenediaminebis(dimethylmethylenephosphonic) acid with the lanthanides is close to that of the corresponding normal ethylenediaminediacetic acid (EDDA) complexes and the stability of the protonated complexes of ethylenediaminediaceticdi(methylenephosphonic) acid exceeds that of the normal EDDA complexes by 6–7 powers of ten. A definite selectivity in the formation of complexes with individual lanthanides is observed.

The formation of complexes with the uranyl ion is interesting: the stability of its protonated complexes with phosphorylated polyamines is very high. The enhanced selectivity in relation to the lanthanides and the uranyl ion is promoted by the increased rigidity of the polymethylene chain joining the nitriloalkylphosphonic acid groups [36]. Thus xylylenediaminebis(dimethylmethylenephosphonic) acids, where the presence of the aromatic ring in the chain between the nitrogen atoms prevents the free rotation of the individual units and fixes the positions of the electron-donating atoms in space, proved to be effective only in relation to the large lanthanide and uranyl cations and to behave as weak complex-forming agents in relation to transition metals, including iron(III) (Table 7).

The difference between the pH ranges where polynuclear insoluble complexes of the above triply charged elements exist permitted the employment of organophosphorus complexones, particularly nitrilotri(methylenephosphonic) acid, as new selective reagents for gravimetric analysis [37].

Aluminium is deposited in the form of the polynuclear complex $Al_3H_3L_2.9H_2O$ from 0.1 *N* hydrochloric acid solutions. In this medium magnesium and alkaline earth metals altogether fail to form complexes. Certain transition metals, such as chromium, copper, and zinc, form less stable soluble complexes, so that their undesirable effect as well as the coprecipitation of transition metals can be eliminated by adding diethylenetriaminepenta-acetic acid as a masking agent (Table 8).

Table 8. Schemes for the possible determinations of metal cations in the presence of a number of elements.

Element determined	Conditions of determination	Elements not interfering with determination	Masking substance
Al	0,1 *M* HCl	Ni, Co, Cu, Zn, Cd, Mn, Cr, Fe, Ca, Mg, Sr, Ba	DTPA
Fe	2 *M* HCl	Ca, Mg, Sr, Ba, Be, Al, Ni, Co, Cu, Zn, Cd, Mn	—

The iron complexonate is stable even in 2 *N* hydrochloric acid, i.e. iron can be determined in the presence of the same elements as in the determination of aluminium. The possibility of determining iron in the presence of aluminium, whose complex decomposes in this medium, is most interesting. The difficulty of separating these metals and also of determining one metal in the presence of the other is generally known.

Our quantitative analytical methods can be successfully used in the analysis of polymetallic systems, in particular

in the analysis of various alloys and steels. Studies on these lines are being continued and the first successful results have already been obtained.

---o0o---

The specific features of the activities shown by phosphorylated polyamine derivatives, distinguishing them from their carboxy-containing analogues, can be accounted for by the unusual structure of the internal ligand contour, caused by the increase of the number of electron-donating atoms by the inclusion of the oxygen atoms of the phosphono-groups, their high nucleophilicity, and their stereochemistry, which determines the geometry of the complex.

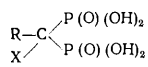
On this basis and experimental results, we postulated three most probable mechanisms for complex formation involving the phosphono-group[4,30,37]. The first mechanism presupposes the formation of a four-membered ring in which the metal ion is coordinated to the two oxygen atoms of the phosphono-group. Under these conditions, the metal can be coordinated in two ways. In the first way the metal ion is coordinated at the midpoint between the two oxygen atoms of each phosphono-group so that the ligand field has an approximately octahedral or tetrahedral coordination, but the oxygen atoms are not located at the vertices of the corresponding polyhedron, forming a new distorted polyhedron in which the coordination number of the metal is higher than usual. This hypothesis does not rule out the possibility of the formation by certain metal ions of complexes whose structure includes four-membered rings where the oxygen atoms of the phosphono-groups lie at the vertices of the polyhedra. Our approximate calculations showed that the strain in the rings with sp^2-hybridised oxygen atoms is insignificant.

The second mechanism presupposes the formation of an eight-membered ring where at least two metal ions are coordinated in turn to the four oxygen atoms of the two phosphono-groups. The complex can then be stabilised by internal hydrogen bonds formed by the coordinated water and the oxygen atoms of the phosphono-groups.

Finally the third type of coordination involves the formation of a network polymer in which the phosphono-group behaves as the tridentate moiety of the ligand. This type of coordination is characteristic, for example, of the insoluble polynuclear beryllium complex of nitrilotri(methylenephosphonic) acid. Three atoms of tetracoordinate beryllium close the ring within one complexone molecule. The remaining oxygen atoms are joined via the metal atoms to other similar molecules.

VI. HYDROXY- AND AMINO-ALKYLIDENEDIPHOSPHONIC ACIDS

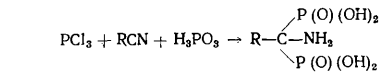
Our conclusion concerning the ability of phosphorylated complexones to form stable protonated complexes, based on the employment in the interaction with cations of only the electron-donating functions of the oxygen atoms in the phosphono-groups, constituted the basis for a detailed study of structurally simpler ligands containing a compact complex-forming group—half-substituted alkylidenediphosphonic acids with a hydroxy- or an amino-group at the carbon atom joined to two phosphono-groups. 1-Hydroxyalkylidenediphosphonic and 1-aminoalkylidenediphosphonic acids are compounds of this kind.



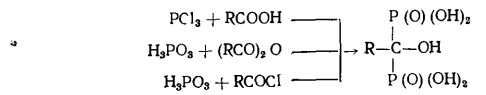
[X = OH or NH_2 and R = alkyl(C_1–C_{11}) or aryl].

Examples of this group of substances have been known for a long time. Thus hydroxyethylidenediphosphonic acid $CH_3C(OH)(PO_3H_2)_2$ has been known since the end of the previous century. During the last decade, many patents dealing with the methods of synthesis of substances of this type were published and various practical applications were suggested for them (see below), but quantitative studies on their complex-forming properties were carried out recently mainly by the present authors.

Aminoalkylidenediphosphonic acids were synthesised by the interaction of phosphorus trihalides with carboxylic acid nitriles in the presence of phosphorous acid[37,38]:

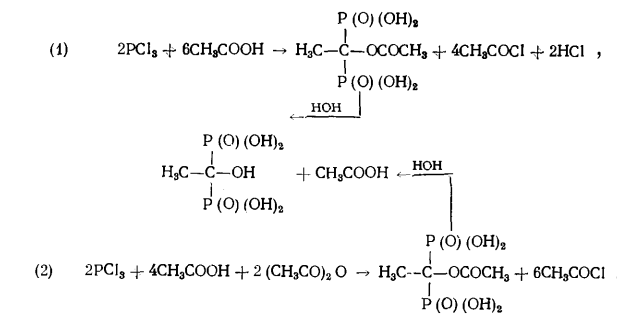


Hydroxyalkylidenediphosphonic acids were obtained by the acylation of phosphorous acid or phosphorus trichloride by carboxylic acids, their anhydrides, or halides[39–43]:



Among the compounds investigated, 1-hydroxyethylidenediphosphonic acid (HEDP) is at present of greatest practical interest. This is due to the ready availability of the starting material and the comparative simplicity of the synthesis, which have made industrial manufacture of this product a realistic proposition.

The reaction of phosphorus trichloride with acetic acid has been used to synthesise HEDP [reaction (1)]:



Together with acetoxyethylidenediphosphonic acid, which is readily hydrolysed to HEDP, acetyl chloride and hydrogen chloride are also produced in this reaction[42,43]. This permitted the joint industrial synthesis of HEDP and acetyl chloride. By the additional introduction of acetic anhydride into the reaction [reaction (2)], the maximum utilisation of the starting material is achieved and corrosive hydrogen chloride is virtually eliminated.

The complex-forming properties of α-substituted alkylidenediphosphonic acids are due to their structures[38,44]. The combination in one molecule of two highly acidic phosphono-groups and also of hydroxy- or amino-groups, which play the role of the basic centre in the molecule, enable these ligands to form stable complexes, not only normal but also protonated, with alkaline earth, transition, and lanthanide elements (Table 9), extending thereby the pH range corresponding to the existence of the complexes from acid to alkaline solutions. A unique property of HEDP is its ability to interact with cations in a strongly acid medium, up to 6 *N* nitric acid.

The steric configuration of their molecules enables α-substituted alkylidenediphosphonic acids to behave as tridentate ligands in coordination with a single cation despite

the presence of five electron-donating atoms and promotes the formation of very stable dinuclear complexes with both alkaline earth and transition metals. HEDP is known to form not only dinuclear but also polynuclear chain complexes with certain cations, in particular with calcium.

With aluminium, iron(III), thorium, and zirconium ions, the relatively low effective number of binding sites in HEDP, which cannot "saturate" the coordination capacity of the complex-forming ion, gives rise to the possibility of the formation of 1 : 2 metal : ligand complexes in the presence of an excess of HEDP, while in the presence of another ligand in the system mixed complexes may be formed. The frequent employment of HEDP in a mixture with other complex-forming agents is due to its ability to form such mixed complexes.

Table 9. Logarithms of the stability constants of alkylidenediphosphonic acid complexes.

	MDP			HEDP				ABDP			
	ML	M_2L	ML_2	ML	MHL	M_2L	ML_2	ML	MHL	M_2L	ML_2
Be^{2+}	—	19.1		16.5	13.4	25.7		16.2	10,4	23,4	
Al^{3+}	14.1		23.0	21.4	15.3	27.2	25.9	18.8	22,5		26.3
Fe^{3+}	19,9		26.6	21.6	16.2	29,1	25.2				
Ln^{3+}	12—13		20—22	18—20	15—16			16—17	11—12		22—24

Comparison of alkylidenediphosphonic acids with organophosphorus ligands containing a nitrogen atom in the alkylene chain linking the two phosphono-groups showed that the complex-forming capacity of alkylidenediphosphonic acids is not inferior, at any rate in the acid region, and in many instances actually superior to that of alkylenepolyamine-di(alkylenephosphonic) acids in which nitrogen is involved in coordination with the metals only after the betaine protons have been titrated.

Together with common properties determined by the presence of phosphono-groups, namely the preferential formation of complexes with cations having small (beryllium and iron) or large (alkaline earth metals) radii, the capacity to form stable complexes at acid pH, the tendency to form dinuclear complexes, etc., alkylidenediphosphonic acids have a number of characteristic features.

Thus alkylidenediphosphonic acids form fairly stable complexes with alkaline earth metals and very stable complexes with beryllium. Comparison of the stabilities of the complexes MHL of hydroxy- and amino-alkylidenediphosphonic acids with methylenediphosphonic acid (MDP) complexes ML, which have the same structure and are formed only via the coordination of the cation to the oxygen atoms of the phosphono-groups, shows that the stability constants of the complexes of substituted alkylidenediphosphonic acids with alkaline earth and certain transition metals differ little from the corresponding constants of the MDP complexes.

The stability constants of the protonated HEDP complexes of multicharged readily hydrolysed cations are higher than the constants of the corresponding normal MDP complexes, which is evidence for additional coordination of the hydroxy-group to these cations (Table 9).

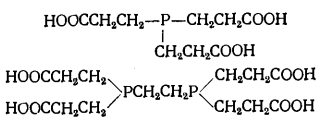
The higher stability of the normal complexes of these cations apparently indicates the involvement of the deprotonated hydroxy-group in complex formation. It is noteworthy that the stability constants of such HEDP complexes are higher than the constants of the corresponding aminobenzylidenediphosphonic acid (ABDP).

The stability of the normal HEDP complexes with iron(III), thorium, and uranium cations is particularly high. Apart from the high coordination capacity, the tendency to form coordinate bonds with oxygen is in this instance of primary importance.

The high capacity of these compounds to combine with metals and the selectivity of their action in relation to beryllium, aluminium, titanium, and thorium combined with their ready availability make them extremely promising ligands.

VII. COMPLEXONES WITH TERVALENT PHOSPHORUS

The specific features of the formation of complexes by organophosphorus complexones make possible the solution of many interesting problems. However, the problem relating to the formation of complexes in an aqueous medium of elements such as silver, mercury, vanadium, and molybdenum could not be solved with the aid of polyamine derivatives. We suggest that complexones in which tervalent phosphorus atoms instead of nitrogen atoms behave as electron-donating species are of interest in this respect[27,45].



The tendency of the above metals to stabilise the bonds with tervalent phosphorus atoms by the formation of an additional d_π bond (apart from the phosphorus–metal coordinate σ-bond), as a result of the transfer of an electron pair from the 4*d* orbitals of the above metals to the unfilled *d* orbitals of phosphorus which have similar energies, leads to the formation of stable complexes with these elements.

We have now investigated complexone analogues derived from phosphines, in which electron-donating phosphorus(III) atoms and acidic phosphono-groups are combined in the same molecule. These constitute a new type of promising ligands.

VIII. APPLICATIONS OF PHOSPHORUS-CONTAINING COMPLEXONES

The knowledge of the main physicochemical characteristics and of the specific features of the behaviour of phosphorus-containing complex-forming ligands suggests many potential applications of these substances in various branches of science and engineering.

Systematic study of the biological properties of alkylenebisnitrilodialkylphosphonic acids has led to the possibility of the employment of substances of this kind for the elimination from the organism of incorporated toxic metals and also has led to the discovery of their influence on the elimination of certain biologically important elements and on the state of metal complexes in the organism.

A biological investigation of organophosphorus complexones carried out at the Institute of Labour Hygiene and Professional Diseases of the Academy of Medical Sciences of the USSR revealed a unique property of this group of substances, namely virtual absence of toxicity.

The ability of alkylenebisnitrilodialkylphosphonic acids to form very stable complexes with copper leads to the elimination of copper from the organism and to the possibility of their use in the treatment of haepatocerebral dystrophy. The formation of stable water-soluble complexes with beryllium suggested that ethylenediaminebis-(dimethylmethylenephosphonic) acid ("phosphicine") can be used as an agent for accelerating the elimination of beryllium from the organism without affecting the calcium metabolism [3,46-48]. Experimental studies demonstrated the usefulness of phosphicine for the acceleration of the elimination of lead from the organism [3]. The efficiency of diethylenetriaminepenta(methylenephosphonic) acids in eliminating uranium has been discovered [49].

HEDP salts, particularly the sodium salt, are able to regulate the calcium content, which suggests their employment in the treatment of the imbalance of the calcium metabolism in the organism and to prevent or reduce the formation of stone, including dental calculus [50-57]. It has been shown that HEDP salts have an inhibiting effect on the deposition of calcium phosphate *in vitro* and *in vivo* in the aorta and in the kidneys of rats [58-60]; they retard osteoporosis [61].

HEDP salts increase the bactericidal activity of phenolic compounds, which suggests their employment in disinfectants, shampoos, mouth washes, tooth pastes, and many other similar products [62-64]. Ditin salts of HEDP have been suggested for the prophylaxis of dental caries [65].

In view of their high capacity for combination with metals, phosphorus-containing complexones may be recommended as effective agents for the dissolution of corrosive deposits and also for the etching of aluminium.

HEDP and its bivalent metal, cobalt, chromium, lead, nickel, and particularly zinc complexes inhibit the corrosion of aluminium, iron, copper, and alloys [66-73]. Metal diphosphonates are not hydrolysed, in contrast to the familiar corrosion inhibitors (polyphosphates) and are stable in the temperature range 20-300°C [71].

The HEDP complex of zinc (sodium or ammonium salt) has been proposed as an inhibitor of the corrosion of a copper surface and as an inhibitor of the corrosion of iron and its alloys [66,70]. It has been noted that the zinc complex is non-toxic [67,73], which makes it superior to the familiar inhibitors, for example chromates.

The employment of HEDP in the composition of alkaline etching solutions for aluminium and its alloys makes it possible to prevent completely the formation of hydrated alumina on the surfaces of the components in etching baths [74,75] and improves the quality of the varnishing of the aluminium surface; it is used as a reagent for the electrochemical deposition of metals [77-79].

The applications of complexones in electroplating led to the development of a highly effective process for the metallation of dielectric materials (which is extremely important for radioelectronics and space engineering) and of a fundamentally new technology for the deposition of metals on the surface of steels without the employment of toxic electrolytes. By varying the process conditions, a wide range of colours of various metallic and non-metallic materials was obtained [75].

Studies dealing with the employment of phosphorus-containing complexones in synthetic detergent and wetting agent compositions have developed particularly extensively in the last decade [80-92]. Hitherto sodium triphosphate has been used as the activating additive to synthetic wetting agents. Its disadvantages include a tendency to hydrolyse with conversion into insoluble orthophosphates, which are deposited on the surfaces of the reservoirs or the articles being treated. On the other hand, wetting agents containing organophosphorus ligands prevent the formation of insoluble deposits [93] and maintain the cleaning capacity of the solutions for a longer time than polyphosphates [94], improve the properties of anionic, non-ionic, and amholytic detergents [85], and in combination with surface-active agents synergise the wetting capacity of detergents [95-97].

Detergents containing HEDP are suitable for washing even in cold water [87].

Complexone salts are used as components of soap [97,98], including toilet soap. The addition of a mixture of HEDP and a polyaminopolycarboxylic acid, for example EDTA, to superfat soaps stabilises them [99] and permits the manufacture of soaps which are effective in hard water [100].

Hydroxyethylidenediphosphonic and nitrilotri(methylphosphonic) acids have been suggested as stabilisers for peroxide compounds; the efficiency of the additive is not lost even in the presence of considerable amounts of polyvalent cations [82,101-104]. The applications of HEDP in cosmetics are described in a number of publications [105,106].

To improve the contrast and colour purity in the treatment of monochrome and colour photographic reversal materials in acid and alkaline solutions, the employment of a tin complex of HEDP has been recommended [107].

The specific features of the action of the new complexones have opened up great possibilities also in the traditional field of the application of complexones, namely in analytical chemistry for effective and in certain instances also selective analytical determinations, which were impossible or difficult when EDTA was used. Alkylenepolyaminedi(alkylmethylenephosphonic) and polyalkylphosphonic acids can be used for the fractional determination of cations in combinations which are difficult to separate (copper-nickel, beryllium-alkaline earth metals, individual pairs of lanthanides, etc.). It has been suggested that ethylenediaminebis(dimethylmethylenephosphonic) acid be used as a highly sensitive titrant in the amperometric determination of beryllium in its alloys with magnesium and aluminium [108]. The quantitative deposition of zirconium by means of this acid in highly acid media can be used to determine zirconium and to separate it from associated elements. Ethylenediaminedi-(*o*-hydroxyphenylmethylenephosphonous) and ethylenediaminedi-(*o*-hydroxyphenylmethylenephosphinic) acids are highly sensitive selective reagents for titanium and tervalent iron [34,35,109]. HEDP has been suggested as a titrant in the complexometric determination of thorium [110].

Nitrilotri(methylphosphonic) acid is used in the determination of beryllium in the presence of alkaline earth and other elements [111].

The application of organophosphorus complexones as masking agents is noteworthy. Thus ethylenediamine-*NN'*-diacetic-*NN'*-di(methylenephosphonic) acid masks beryllium in the hydroxide precipitation reaction, this being the first instance of the masking of beryllium [112]; HEDP can be used as a masking and complex-forming agent for calcium [113-115], aluminium, and titanium [116], and polyvalent and heavy metals [117,118].

The differentiation of the stabilities and solubilities of protonated lanthanide complexes as a function of pH permits the chromatographic separation of yttrium, cerium, and other lanthanides with similar properties using eluent solutions of ethylenediaminebis(dimethylmethylenephosphonic), ethylenediaminetetra(methylenephosphonic), and hydroxyethylidenediphosphonic acids [119,120]. The use of HEDP for the re-extraction of protactinium [121] and also for the elimination of neptunium from plutonium

and the radiometric determination of neptunium in its preparations[122] have been described.

The ability of polyaminopolyphosphonic acids with a large number of binding sites and also of NTP and HEDP to bind alkaline earth metals in complexes permitted the application of these compounds as water softeners[123,124], to prevent the precipitation of calcium carbonate, sulphate, hydroxide, and phosphate in industrial equipment[125,126], and to remove scale formed previously[127].

In view of its ability to bind metal ions, HEDP can be used in the textile industry[128] to eliminate calcium and magnesium ions, which can give rise to undesirable tints on dying and can distort the colour of the fabric.

Phosphorus-containing complexones can be used in the chemical industry to remove admixtures of metal ions from the starting material.

Compounds of this kind can be used effectively in the petroleum and gas extraction industry. Thus it has been recommended that HEDP[129] be added to solutions of inorganic acid used to acidify boreholes and to impart greater fluidity to the liquid being extracted, which makes it possible to maintain in solution calcium, magnesium, and iron salts.

Phosphorus-containing complexones also found applications in agriculture[130]. Apart from the most important elements such as potassium and phosphorus, which are introduced into the soil, in many instances it is necessary to introduce also microelements—manganese, molybdenum, copper, and cobalt. However, when these elements are added to soil in the form of liquid phosphate fertilisers they are precipitated as insoluble complexes. The addition of a complex-forming agent such as HEDP eliminates this defect[55,115]. HEDP esters are used as pesticides in the fight against pests damaging agricultural crops[117]. Thus comprehensive studies of the properties of phosphorus-containing complexones and their salts have led to an unusually wide range of their possible applications, some of which have already been successfully realised in practice.

Advances in the Synthesis and Manufacture of α-Aminoacids

E.N.Safonova and V.M.Belikov

The review deals with the existing industrial chemical methods for the manufacture of aminoacids as well as new methods and new versions of the existing methods for their synthesis. Much attention has been devoted to methods of asymmetric synthesis of aminoacids, including homogeneous asymmetric hydrogenation. Enzymatic methods for the synthesis of certain aminoacids from chemical raw materials are examined. The literature of the last 7-8 years is mainly considered. The bibliography includes 385 references.

I. INTRODUCTION

Together with the continuous search for new methods of synthesising aminoacids, during the last 7–8 years the existing methods have been investigated further and those which are most convenient for practical application have been selected and developed. This approach has been dictated by the colossal and rapidly growing need for aminoacids in various branches of the world's economy.

Major advances have been made in the field of asymmetric synthesis avoiding the need for the optical resolution of racemic aminoacids, which has been and still remains one of the greatest disadvantages of the chemical methods for the synthesis of aminoacids.

In terms of their biological value, aminoacids can be divided into two groups—non-essential aminoacids which the animal and human organism can synthesise at a sufficient rate to build up its own proteins and essential aminoacids which it cannot synthesise. The organism can obtain essential aminoacids only from outside in the form of food. If an essential aminoacid is missing from food or its amount is insufficient, the protein cannot be synthesised; this entails emaciation and death of the organism. For this reason, there is a need to balance the diet, i.e. to add the missing aminoacids to the less valuable [second class] proteins, which increases their nutrient value. Animal feed has been successfully balanced in animal husbandry by the addition of the missing methionine and lysine[1,2]. In the food industry grain products have not so far been balanced on a large scale by the addition of pure aminoacids, although this procedure does improve the nutrient properties of plant protein and hence increases the amount of first class protein suitable for use in food. The latter is particularly important, since a real possibility has arisen of meeting the rapidly growing requirements for food protein without altering the nature of the diet and organoleptic properties of the products[3,4]. Nevertheless at the present time the main consumption of aminoacids in the food industry comes from the employment of sodium glutamate as a powerful taste-improving agent. In many countries it is added to all products which are to be preserved, frozen, or stored for a long time; it is used in communal and domestic catering as a mixture with table salt[5,6]. Compositions imitating the taste and smell of food products are also made up of a mixture of aminoacids[3,7].

Aminoacids are also successfully employed in medicine. After severe operations, burns, and in other stress states, the human organism is unable to assimilate proteins in an amount necessary for regenerative processes, which impairs the state of the patient. In such cases aminoacid feeding is resorted to either in the usual way or by the introduction of a solution of aminoacids directly into the bloodstream. The excellent therapeutic effect achieved in such cases has given rise to a considerable requirement for aminoacid mixtures. Children suffering from phenylpyruvate oligophrenia are fed a mixture of aminoacids free from phenylalanine.

Table 1 (Belikov[1]).

Aminoacid	Amount manufactured, tonnes per year	Method of preparation
L-Glutamic acid	180000	Microbiol., chemical
DL-Methionine	32000	Chemical
L-Lysine	8000	Microbiol.
Glycine	2000	Chemical
L-Tryptophan	20	Chemical
L-Threonine	20	Microbiol., chemical

Certain individual aminoacids, both present in and absent from natural proteins, are employed in medicine. Thus methionine is used in the cirrhosis and fat infiltration of the liver, in dystrophy, and in atherosclerosis. Glutamic acid is mainly used in the treatment of diseases of the central nervous system: schizophrenia, epilepsy, psychoses, shock, etc. γ-Aminobutyric acid and its derivatives are widely used for these purposes. Until recently the only treatment for Parkinson's disease was surgical intervention in the region of the brain. An effective therapeutic agent—3,4-dihydroxyphenylalanine (DOPA) (plus its derivatives)—has now been found. The requirement for this aminoacid is very great.

Aminoacids are used as the starting materials for the synthesis of polypeptides, many of which are very active

physiologically, and also for the synthesis of other medicinal preparations.

Finally aminoacids have also found technical applications. When they are introduced into a polycondensation process, the resulting oligomers, while lacking the biological activity of proteins, nevertheless resemble them in structure and imitate some of their important physical properties. Artificial wool, silk, and leather are widely manufactured in this way, and are not inferior in their properties to the natural materials. The total world manufacture of aminoacids in 1972 is characterised approximately by the figures quoted in Table 1.

The relative contributions of aminoacids to various branches of the economy can be demonstrated using Japan as an example, where the manufacture of aminoacids has developed to the greatest extent:

The structure of the applications of aminoacids in Japan

Food industry	65%
Animal husbandry	18%
Medicine	15%
Others	2%

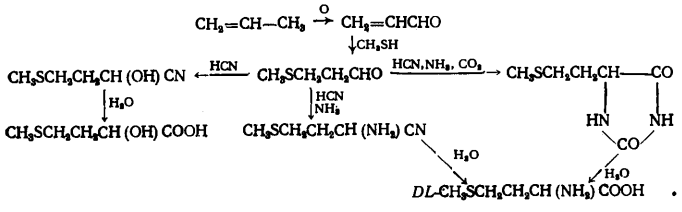
The world requirement for aminoacids increases by 10% annually[1].

II. INDUSTRIAL CHEMICAL SYNTHESES

1. Methionine

The chemical synthesis of methionine, an aminoacid mainly consumed in poultry farming, has been most thoroughly developed[1,2,8]. Methionine is unique in its biological properties. Its L- and D-isomers are assimilated to equal extents by the organism. Moreover, the replacement of the amino-group by the hydroxy-group does not affect its nutrient properties. The hydroxy-analogue of methionine is manufactured in the USA. The manufacture of DL-methionine has begun in the USSR. It is also manufactured in the German Federal Republic, France, and Japan. The scale of the manufacture of methionine is greater than that of any other essential aminoacid[9].

The starting material for the synthesis is propene—a petroleum cracking product. Propene is oxidised to a acrolein, which is converted by a series of reactions into racemic methionine:

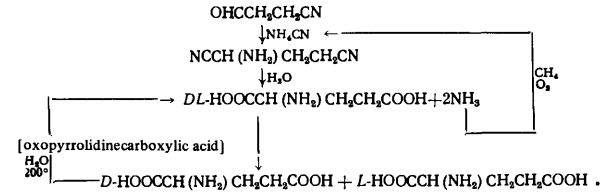


The sequence of reactions can be altered: cyanoallyl alcohol is initially obtained from acrolein and is then converted into highly pure DL-methionine in 80% yield[10]:

A number of other modifications and improvements of the basic process have been proposed[11-23].

2. Glutamic Acid

The raw material for the industrial manufacture of L-glutamic acid is acrylonitrile, obtained by the oxidative ammonolysis of propene. The reaction of acrylonitrile with carbon monoxide and hydrogen is carried out at an elevated temperature and pressure in the presence of $Co_2(CO)_8$ with formation of β-cyanopropionaldehyde, which also serves as the raw material in the synthesis of tryptophan. The subsequent reactions can be represented by the following scheme:

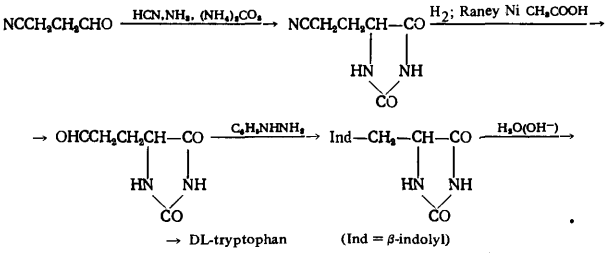


The racemic glutamic acid is resolved into its optical isomers by continuous selective crystallisation. This operation is based on the fact that the solubility of DL-glutamic acid in solutions of its salts (for example, its hydrochloride or its ammonium salt) is almost twice the solubility of the optical isomers. As a result, saturated solutions of DL-glutamic acid are supersaturated with respect to the optical isomers. The introduction of a seed of the L-isomer induces its crystallisation. The optical purity of the resulting L-glutamic acid is 95%.

After neutralisation, the monosodium salt of L-glutamic acid is obtained with an optical purity of 99.8%; it is used as an anabolic agent (to increase weight). The D-isomer of glutamic acid racemises at 200°C and is recycled[5,6]. The synthesis[24-40], cleavage[5,6,41,42], and racemisation[5,6,43] processes have been developed with careful allowance for possible complications, side reactions, and the possibility of the utilisation and reutilisation of the components and waste products of the synthesis. About 1200 tonnes of L-glutamic acid were obtained in Japan in 1972.[1]

3. Tryptophan

The industrial synthesis of tryptophan from β-cyanopropionaldehyde was achieved in Japan by the Ajinomoto Company[8,44-46]:



The overall yield of DL-tryptophan amounts to about 60%.[46] It is resolved into optical isomers also by the selective crystallisation of the ammonium[47] or zinc[48] salt of *N*-acetyl-DL-tryptophan, a procedure which is also used to purify DL-tryptophan[49-51].

4. Threonine

The synthesis of DL-threonine by the condensation of copper glycinate with acetaldehyde, which was proposed

in 1957,[52] proved to be the most convenient for the industrial manufacture from the standpoint of the raw material, yield, and economy. It is at present used in Japan[8]:

Copper glycinate + $CH_3CHO \xrightarrow{(OH^-)}$ "copper threoninate" →

→ DL-threonine complex (precipitate) + DL-allothreonine complex (solution)

↓

L-threonine + D-threonine.

The complex "copper threoninate" formed consists mainly of the DL-threonine complex. The DL-allothreonine complex obtained simultaneously is much more soluble in water, which makes it possible to separate the diastereoisomers by filtration[53-56]. Several versions of the synthesis have been developed on the basis of this scheme[57-60].

Selective crystallisation is used for the resolution of DL-threonine into optical isomers, as for glutamic acid[8]. The DL-allothreonine and D-threonine formed in the synthesis and after resolution into optical isomers are converted into L-threonine by a number of procedures. Thus L-threonine can be obtained from D-threonine by stereospecific reactions in which the formation of oxazoline derivatives plays an important role[61]. The same derivatives can be used to convert DL-allothreonine into DL-threonine[62,63]. Furthermore, the isomerisation of the copper complex of allothreonine in an alkaline medium in the presence of acetaldehyde leads to an equilibrium mixture of the allothreonine and threonine complexes, with the latter predominating[57,64]. Under these conditions, D-threonine may racemise into a mixture of DL-threonine and DL-allothreonine with inversion at both asymmetric atoms[8].

5. Glycine

In connection with the development of industrial methods for the synthesis of aminoacids by incorporating completed α-aminoacid fragments using glycine and its acyl derivatives, the requirement for these has increased. This is indicated by the large number of patents dealing with the development of new methods for the synthesis of glycine and its derivatives from available raw materials and also with the improvement of the existing methods.

The existing process for the manufacture of glycine from monochloroacetic acid and ammonia in the presence of hexamethylenetetramine and ammonium ions can be carried out continuously with a rational utilisation of the waste and a yield of 96.5%.[65-69] The interaction of monochloroacetic acid with the ammine complexes $[Cu(NH_3)_4]SO_4.H_2O$, $[Co(NH_3)_6](NO_3)_3$, $[Ni(NH_3)_6](NO_3)_2$, and $[Zn(NH_3)_4]SO_4.3H_2O$ yields the corresponding metal glycinates, which can be used in the synthesis of aminoacids[70].

Another process has been developed in which glycine is synthesised from formaldehyde, hydrogen cyanide, and ammonia (by the Strecker or Bucherer–Bergs methods)[71,72]. The resulting aminoacetonitrile can be converted into pure glycine via an oxazole derivative by the reaction with acetone[73]. Glycine can be obtained in 77% yield by the hydrolysis of hydantoin[74,75]. An 80–96% yield of glycine is obtained by the oxidation of acrylonitrile in the presence of tungstic acid or tungsten heteropolyacids[76]. Glycine synthesised by the oxidation of monoethanolamine in the presence of CuO and KOH is used in the synthesis of threonine[58]. *N*-Acylglycines can be obtained by treating hydroxymethyl and alkoxymethyl derivatives of various amides with carbon monoxide in 100% sulphuric acid:

$$\left.\begin{matrix}RCON(R')CH_2OH\\ RCON(R')CH_2OCH_3\end{matrix}\right\} \xrightarrow{H_2SO_4} [RCON(R')CH_2^{\oplus} \leftrightarrow RC\overset{\oplus}{O}N(R')=CH_2] \rightarrow$$

$$\xrightarrow{1)\ CO;\ 2)\ H_2O} RCON(R')CH_2COOH\ .$$

Usually R′ = H and the yields are between 20 and 88%.[77-79] Apart from their ready conversion into the free aminoacid, *N*-acylglycines can be used for the synthesis of peptides[80] and also as one of the components of the azlactone synthesis[81].

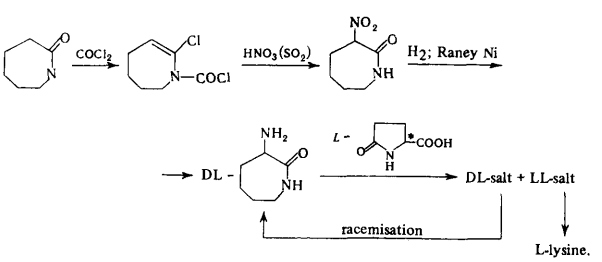
6. Aspartic Acid

DL-Aspartic acid is manufactured from ammonium fumarate or maleate, maleic anhydride being used as the starting material for the synthesis of the latter. A solution of ammonium maleate (or fumarate) in aqueous NH_4Cl with added ammonia (pH ~ 7.5) is heated for 75 min at 180°C. DL-Aspartic acid is isolated at the isoelectric point in 79% yield. The mother liquors and imino-$\alpha\alpha'$-disuccinic acid formed as a by-product are returned to the process[82]. Different versions of this synthesis have been described[83-89].

The method of asymmetric synthesis of L-aspartic acid from ammonium fumarate in a continuous process with the aid of microbial aspartase fixed in a polyacrylamide gel has been recommended for its industrial manufacture[90]. A 1 M solution of ammonium fumarate at pH 8.5 in the presence of $MnCl_2$ is passed through a 5 × 100 cm column filled with the carrier and the fixed enzyme at a rate of 160 ml h^{-1} at 37°C. After the usual treatment, pure crystalline L-aspartic acid is obtained in 95% yield. The enzyme retains its full activity for 7–8 days, but in the subsequent 22–23 days its activity falls to 25%.

7. Lysine

The chemical synthesis of lysine from ϵ-caprolactam has been achieved on an industrial scale in Holland[2,8]:



The resolution into isomers was carried out at the DL-α-aminocaprolactam stage by the crystallisation of the diastereoisomeric salt with L-pyroglutamic acid[2].

A number of patents deal with problems associated with the manufacture of lysine from ϵ-caprolactam. Methods have been described for the formation of α-halogeno-derivatives of ϵ-caprolactam[91,92], including those employing phosgene[93-96], and for their subsequent conversion into DL-lysine[97-100]. Procedures have been developed for the preparation and purification of α-amino-ϵ-caprolactam[101,102], for the resolution of the racemate[103-107], for the racemisation of optically active forms[108,109], and for hydrolysis with formation of lysine[110-117].

8. 3-(3,4-Dihydroxyphenyl)Alanine (DOPA)

Interest in 3,4-dihydroxyphenylalanine arose comparatively recently in connection with the observation of its therepeutic activity against one of the commonest severe nervous disorders in the elderly—Parkinson's disease[118]. Only the L-form has a therapeutic effect. The present requirement for this aminoacid is very great. L-DOPA is obtained by extraction with methanol from broad beans (*Vicia faba*): 1 kg of beans yields 18.7 g of L-DOPA.[119]

The development of a method for homogeneous asymmetric hydrogenation (see above) served as a basis for the experimental manufacture of L-DOPA. It is synthesised by the hydrogenation of 4-hydroxy-3-methoxyacetamidocinnamic acid, obtained by the azlactone synthesis from vanilline. The optical yield reaches 90%. Rhodium complexes with asymmetric *o*-anisylmethylcyclohexylphosphine are used as the catalyst[120-122]. This process is the first asymmetric chemical synthesis of an aminoacid on an industrial scale.

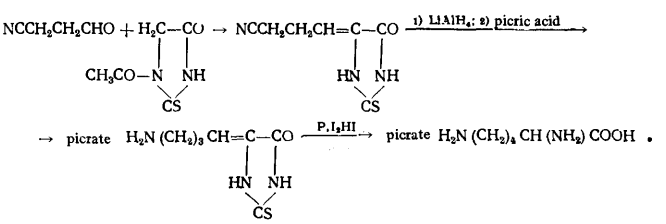
9. β-Alanine

The industrial synthesis of this important natural β-aminoacid[123] involves the addition of an excess of ammonia to acrylonitrile[124,125]. The process is carried out continuously, the yield of β-alanine exceeding 95%.[126] Acrylic acid[127,128] or acrolein[129] can be used instead of acrylonitrile. β-Alanine is used in the synthesis of pharmacological preparations, in particular of panthothenic acid[127] and also in the synthesis of polyamides[130].

III. METHODS FOR THE PREPARATION OF AMINOACIDS

1. From Unsaturated Compounds

Unsaturated compounds—acrylonitrile, acrolein, methyl acrylate, vinyl acetate, butadiene, ethylene, etc.—are widely used for the synthesis of aminoacids. The hydroformylation reaction constitutes a promising method for their conversion into aminoacids and has already been achieved on an industrial scale. The aldehydes or their derivatives obtained in this reaction are subsequently converted into aminoacids by the cyanohydrin or hydantoin syntheses. The industrial syntheses of L-glutamic acid and L-tryptophan from β-cyanopropionaldehyde, obtained by the hydroformylation of acrylonitrile[8], have already been discussed. An attempt has been made to employ this aldehyde also in the synthesis of lysine. It could not be condensed with hydantoin, hippuric acid, or rhodanine, but 1-acetyl-2-thiohydantoin proved to be suitable for this purpose. After the reduction of the condensation product with $LiAlH_4$ and hydrolysis, DL-lysine picrate was obtained in 18% yield with respect to β-cyanopropionaldehyde[131]:



The synthesis of *N*-acylaminoacids from aldehydes (or directly from olefins) and amides has been achieved with the aid of the hydroformylation reaction[132]:

$$RCHO + CH_3CONH_2 + CO \rightarrow RCH(NHCOCH_3)COOH.$$

Since the reaction of an aldehyde, amide, and carbon monoxide catalysed by $Co_2(CO)_8$ proceeds under conditions similar to those in the hydroformylation of olefins, a single-stage conversion of an olefin into an *N*-acylaminoacid is possible:

$$RCH=CH_2 + CH_3CONH_2 + 2CO + H_2 \rightarrow RCH_2CH_2CH(NHCOCH_3)COOH.$$

The reaction is carried out at 110–150°C, 150 atm of CO, and 50 atm of H_2 in 10–80 min. The solvents are dioxane, ethyl acetate, and acetic acid. *N*-Acetyl derivatives of the following aminoacids have been obtained in this way (the percentage yields are indicated in brackets): glycine (26), alanine (68), α-aminobutyric acid (46), valine (70), phenylalanine (56), α-amino-γ-cyanobutyric acid (58), the γ-monomethyl ester of glutamic acid (70), and methionine (64). Benzamide and the amide of lauric acid have been used in place of acetamide. The application of this method in the synthesis of acylglycines was discussed above[77-79]. Carbonylation of Schiff bases yields polypeptides and aminoacids:

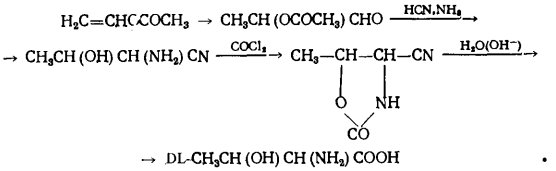
$$R'N=CHR + CO \rightarrow [R'NCH(R)CO-]_n \xrightarrow{H_2O} R'NHCH(R)COOH.$$

Alanine has been obtained in this way with R = CH_3 and R′ = H.[80]

DL-Glutamic acid can be synthesised in 88% yield from the dimethylacetal obtained by the hydroformylation of methyl acrylate in the presence of methanol[133]:

$$CH_2=CHCOOCH_3 \rightarrow (CH_3O)_2CHCH_2CH_2COOCH_3 \xrightarrow{HCN,\ H_2O} \rightarrow NCCH(OH)CH_2CH_2COOCH_3 \xrightarrow[2)\ H_2O(H^+)]{1)\ NH_4OH} DL\text{-}HOOCCH(NH_2)CH_2CH_2COOH.$$

An interesting synthesis of threonine from α-acetoxypropionaldehyde, obtained by oxo synthesis from vinyl acetate, has been described:



A mixture of 91% of DL-threonine and 9% of DL-allothreonine is obtained in 30% yield[134].

The diacetate derived from α-acetoxyacetaldehyde can be used in the synthesis of DL-serine:

$$H_2C=CHOCOCH_3 \xrightarrow{Br_2} CH_2BrCHBrOCOCH_3 \xrightarrow{(CH_3CO)_2O} CH_3OCOCH_2CH(OCOCH_3)_2 \xrightarrow{NaCN,NH_3} CH_3OCOCH_2CH(NH_2)CN \xrightarrow{H_2O(H^+)} CH_2(OH)CH(NH_2)COOH.$$

The yield of DL-serine is 78%.[135] DL-Serine can be obtained via hydantoin by treating the triacetate with NaCN and $(NH_4)_2CO_3$.[136] A mixture of DL-threonine and DL-allothreonine has been obtained in the same way from propenyl acetate in 64% yield[135].

DL-Glutamic acid is obtained by cyanohydrin synthesis from acrolein:

$$H_2C=CHCHO \xrightarrow{HCN,\ NH_3} [NCCH_2CH_2CH(NH_2)CN] \xrightarrow{H_2O(OH^-)} \rightarrow HOOCCH(NH_2)CH_2CH_2COOH.$$

Acrolein homologues can be used in the synthesis of glutamic acid homologues[137-139]. Various α-amino-β-hydroxyacids are obtained from αβ-unsaturated acids

via epoxy-compounds[140-146]. Thus *E*-crotonic acid yields DL-threonine[140]:

$$E\text{-}CH_3CH{=}CHCOOH \xrightarrow{H_2O_2;\ Na_2WO_4} trans\text{-}CH_3CH(O)CHCOOH \xrightarrow{HCl} \rightarrow erythro\text{-}CH_3CH(OH)CH(Cl)COOH \xrightarrow{NH_3} CH_3CH(OH)CH(NH_2)COOH .$$

The bromohydrin of crotonic acid can be converted into DL-threonine by reaction with urotropine[147] or by photochemical ammoniolysis[148]. These studies constitute a development of Carter's method[149,150].

DL-Methionine can also be obtained from crotonic acid. On treatment with C_2H_5OH and $(C_2H_5)_3N$, the acid chloride is converted into the ester with simultaneous migration of the double bond to the $\beta\gamma$-position; this is followed by the addition of CH_3SH, bromination with $P_2Br_2Cl_4$, amination, and hydrolysis. The yield of DL-methionine relative to crotonic acid is 32.5%.[151]

A number of intermediates formed in the synthesis of DL-serine from methyl acrylate or acrylonitrile have been described[152-155]. DL-Glutamic acid is obtained in 30% yield by the cyanoethylation of *N*-acylaminoacetonitriles[156] and also in 40% yields by the cyanoethylation of 2-phenyl-5-oxazolone (azlactone)[157]. Considerable amounts of β-alanine and DL-aspartic acid are obtained from the waste products in the manufacture of acrylonitrile by the oxidative ammonolysis of propene after a simple treatment[158]. The addition of dichloroacetic acid esters to butadiene yields $\alpha\epsilon$-dichlorohexenoic acid esters, which are converted by ammoniolysis, hydrogenation, and hydrolysis into DL-lysine[159,160]. Butadiene has been used to synthesise lysine via the nitro-derivative[161-164]. Various aminoacids can be obtained from the polychloroalkane formed in the telomerisation of ethylene with carbon tetrachloride[165] or trichloroacetic acid[166].

2. From Ketones

Monoaminomonocarboxylic acids can be obtained from methyl alkyl (or aryl alkyl) ketones in several ways via α-hydroxyiminoketones:

$$RCH_2COCH_3 \xrightarrow{R'ONO} RC(=NOH)COCH_3 \xrightarrow{NaBrO} RC(=NOH)COOH \xrightarrow[(A)]{H_2;\ Raney\ Ni;} RCH(NH_2)COOH$$

$$RC(=NOH)COCH_3 \xrightarrow{Zn/CH_3COOH} RCH(NHCOCH_3)COCH_3 \xrightarrow{O_2(HCl)} (C)$$

$$RC(=NOH)COCH_3 \xrightarrow{(C_2H_5O)_2SO_2} RC(=NOC_2H_5)COCH_3 \xrightarrow{NaClO} RC(=NOC_2H_5)COOH$$

$$(C) \xrightarrow{H_2;\ Pd/C} (B)$$

The following products were obtained [the method of preparation, R, and the percentage yield relative to the ketone (in brackets) are indicated]: *A*, $C_6H_5CH_2$ (53);[167] *B*, $C_6H_5CH_2$ (40);[168,169] *C*, $C_6H_5CH_2$ (-);[170] *A*, p-$CH_3OC_6H_4CH_2$ (46); *A*, 3,4-$CH_2O_2C_6H_3CH_2$ (45); *A*, C_6H_5 (44);[171] *B*, CH_3 (15);[168,169,172] *C*, CH_3 (80, with respect to the oxime)[170,173]; *B*, i-C_3H_7 (31—34.4);[168,169,172] *C*, i-C_3H_7 (-);[170] *B*, $CH_3(CH_2)_3$ (51—63);[172] *C*, s-C_4H_9 (-).[170,173]

In addition, the methylene group in methyl ketones can be halogenated, the halogen replaced by an amino-group, and the product oxidised by atmospheric oxygen. DL-Valine and DL-alanine have been obtained in this way[174]:

$$CH_3COCH_2R \xrightarrow{Br_2} CH_3COCHBrR \xrightarrow{NH_3;\ CH_3OH} [CH_3COCH(NH_2)R] \xrightarrow{O_2;\ HCl} \rightarrow DL\text{-}RCH(NH_2)COOH .$$

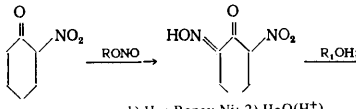
(R=CH_3; i-C_3H_7)

Acetylacetamide, obtained from diketen, is used as the starting material for the synthesis of a wide variety of aminoacids[175,176]:

$$CH_3COCH_2CONH_2 \xrightarrow{RBr} CH_3COCH(R)CONH_2 \xrightarrow{KOBr} CH_3COCH(R)NH_2 \xrightarrow{O_2} \rightarrow RCH(NH_2)COOH .$$

R- S-C_4H_9; i-C_4H_9; $C_6H_5CH_2$; $CH_3SCH_2CH_2$; $HOOCCH_2CH_2$.

The nitrosation of cyclic ketones is used in the synthesis of DL-lysine from cyclohexanone[177-179] and nitrocyclohexanone[180-184]:



$$\xrightarrow{R_1OH;\ NaOH} O_2N(CH_2)_4C(=NOH)COOR_1 \xrightarrow{1)\ H_2;\ Raney\ Ni;\ 2)\ H_2O(H^+)} H_2N(CH_2)_4CH(NH_2)COOH .$$

3. Carboxylation of Amines

Several studies have been made on the introduction of the carboxy-group into the amine molecule:

$$RCH_2NH_2 + 2H_2O_2 \xrightarrow{Na_2WO_4} RCH{=}NOH \xrightarrow{2NaHSO_3} RCH(NH_2)SO_3Na \xrightarrow{NaCN} RCH(NH_2)CN \xrightarrow{H_3O(H^+)} RCH(NH_2)COOH .$$

On treatment with bisulphite, $RCH(NHOH)SO_3Na$ is probably formed as an intermediate and is then reduced to the amine by the excess bisulphite. Alanine, serine, and phenylalanine have been obtained in yields of 71, 68, and 75% respectively[185]. It is desirable to employ readily available amines in the synthesis of aminoacids by this procedure. The interaction of the sodium salt of a sulphonic acid with KCN for the introduction of the carboxy-group has also been used in the synthesis of α-methyl-DOPA.[186]

Isonitriles obtained in a preliminary step from amines have been carboxylated:

$$RCH_2NH_2 \rightarrow RCH_2NC \xrightarrow[NaH]{OC(OC_2H_5)_2} RCH(NC)COOC_2H_5 \xrightarrow{1)\ H_3O(H^+);\ 2)\ H_2OOH^-} \rightarrow RCH(NH_2)COOH .$$

$$RCH_2NH_2 \rightarrow RCH_2NHCHO \rightarrow RCH(NC)COOC_2H_5$$

Diethyl carbonate in dimethylformamide (DMF) in the presence of NaH was used as the carboxylating agent. The following percentage yields with respect to the isonitrile (in brackets) were obtained for different R: C_6H_5 (57); 4-$CH_3OC_6H_4$ (54); 4-$CH_3C_6H_4$ (51); 4-Cl—C_6H_4 (56); 3.4-$(CH_2O_2)C_6H_3$ (60); 2-furyl (55); H (32). Dimethyl carbonate and also ethyl chloroformate or CO_2 in the presence of butyl-lithium can be used as carboxylating agents. Conditions for the reaction with aliphatic amines, with the exception of methylamine, have not been found[187,188]. DL-Valine was obtained in 46% yield by treating a solution of isobutylamine in a mixture of dioxane and 35% HCl with 30% hydrogen peroxide, the reaction system being simultaneously bubbled with CO_2 at 30°C for 1.5 h. DL-Alanine was obtained similarly from ethylamine[189]. The direct carboxylation of amines, in particular methylamine, by formic acid, formates, or carbon dioxide is carried out under the influence of γ- or ultraviolet radiation. The yields are low[190].

4. From Nitroacetic Acid Esters

Nitroacetic acid esters O_2NCH_2COOR (R = CH_3 or C_2H_5), obtained from nitromethane, provide an almost

universal starting material for the synthesis of α-amino-acids. The method is based on the exceptional reactivity of the methylene group of the nitroacetic acid ester due to the presence of adjoining nitro- and ester groups. The nitroacetic acid ester contains a potential α-aminoacid grouping: different substituents are introduced into its molecule and the nitro-group is then reduced to the amino-group[191].

A general scheme for the synthesis of aminoacids from nitroacetic acid esters was published in 1969.[3] The most extensive studies in recent years dealt with the synthesis of tryptophan and phenylalanine. Attention was concentrated on reduction of β-substituted α-nitropropionates and α-nitroacrylates which are formed as intermediates.

The reduction of β-indolyl-α-nitropropionic acid esters does not present much difficulty and proceeds smoothly in both catalytic[192] and electrochemical[193] processes. The β-indolyl-α-nitropropionate, obtained by heating the gramine salt of the nitroacetic acid ester, yields DL-tryptophan after reduction of the nitro-group and hydrolysis[194]:

$$\mathrm{IndCH_2N(CH_3)_2 + O_2NCH_2COOC_2H_5 \rightarrow [gramine\ salt\ of\ NAE] \xrightarrow{110^\circ}}$$
$$\rightarrow \mathrm{IndCH_2CH(NO_2)COOC_2H_5 \xrightarrow{H_2;\,Raney\ Ni} IndCH_2CH(NH_2)COOC_2H_5 \rightarrow}$$
$$\xrightarrow{\mathrm{H_2O/C_2H_5OH(OH^-)}} \text{DL-tryptophan}$$

(Ind = β-indolyl; NAE = nitroacetic acid ester).

The reduction of aromatic derivatives of α-nitroacrylic acid is more difficult[192,195,196].

β-Indolyl-α-nitroacrylates have been obtained in two ways: by the condensation of indole with β-alkoxy-α-nitro-acrylates (without condensing agents)[195,197] and also by the condensation of indole-3-aldehyde with nitroacetic acid esters in the presence of acid catalysts[196,198,199]:

$$\left.\begin{array}{l}\mathrm{IndH + C_2H_5OCH{=}C(NO_2)COOCH_3}\\ \mathrm{IndCHO + O_2NCH_2COOC_2H_5}\end{array}\right\} \xrightarrow[\text{Ind = β-indolyl)}]{\text{HCl, SOCl}_2\text{, AlCl}_3} \mathrm{IndCH{=}CH(NO_2)COOR}\ .$$

The use of alkaline catalysts leads mainly to isoxazoline *N*-oxides[200]. The reduction of β-indolyl-α-nitroacrylates in the presence of Raney nickel in alcohol proceeds with considerable charring[196]. The best results were obtained using two successive hydrogenation stages: initially in the presence of palladium black and then in the presence of Raney nickel[195]. In the first stage β-indolyl-α-nitro-acrylate is partially converted (52%) into β-indolyl-α-nitropropionate ester, which is then readily hydrogen-ated to the tryptophan ester. Together with the catalytic procedure, a method was developed for the electrochem-ical reduction of β-indolyl-α-nitroacrylacrylate in aqueous alcoholic and aqueous dioxane mixtures at pH 1–3 in the presence of metals with a high hydrogen overvoltage. The yield of DL-tryptophan reaches 60%.[201,202] The characteristics of the electrochemical reduction were elucidated by polarography and electrolysis at a controlled potential. It was found that both electrochemical and catalytic reduction proceed in steps, but the saturated nitro-ester is not formed; the principal intermediate in the reduction reaction is the oxime[203,204]. The inadequate yield of the desired product can be accounted for by the instability of the oxime and also of the initial β-indolyl-α-nitroacrylate and other intermediates in the acid medium[193].

Electrochemical reduction of α-nitrocinnamic acid ester gives a 65% yield of DL-phenylalanine. Higher yields could not be achieved owing to the instability of the initial ester and the intermediates under the experimental conditions[193,205,206].

The catalytic reduction of phenyl nitroacrylates was carried out in alcoholic solutions[207], but the process may be complicated by the addition of the alcohol to the double bond and other side reactions[208–211]. On the other hand, β-isopropyl-ββ-dimethyl-, and β-ethyl-β-methyl-α-nitro-acrylates are hydrogenated in the presence of Raney nickel in methanol, yielding respectively DL-leucine, DL-valine, and DL-isoleucine[212,213]. Steric factors probably play a role in these reactions and the rate of hydrogenation exceeds the rate of addition of methanol[212].

Nitroacetic acid ester has been used to synthesise DL-lysine from butadiene:

$$\mathrm{H_2C{=}CH{-}CH{=}CH_2 \xrightarrow{N_2O_4,\,I_2} O_2NCH_2CH{=}CHCH_2I \xrightarrow{O_2NCH_2COOC_2H_5}}$$
$$\rightarrow \mathrm{[O_2NCH_2CH{=}CHCH_2CH(NO_2)COOC_2H_5} \xrightarrow{\text{1) H}_2\text{; Pd/C; 2) H}_2\text{O(H}^+\text{)}} \text{DL-lysine}\ .$$

The yields were about 20% and about 70% in the condensation and reduction stages respectively[161–164].

A number of aminoacids have been obtained by the *C*-alkylation of methyl nitroacetate by alkyl halides in aprotic dipolar solvents via the mechanism:

$$\mathrm{RX + O_2NCH_2COOCH_3 \xrightarrow{CH_3ONa} RCH(NO_2)COOCH_3 \xrightarrow{\text{1) H}_2\text{; Raney Ni; 2) H}_2\text{O(H}^+\text{)}}}$$
$$\rightarrow \mathrm{RCH(NH_2)COOH}\ .$$

The resulting nitro-esters are isolated in the form of crystalline ammonium salts, are hydrogenated for 1 h at 20°C and 3–3.5 atm, and the product is hydrolysed with 6 *N* HCl.[214,215]. The following products were obtained in this way (the yields are given with respect to nitro-acetic acid ester): DL-aspartic acid, 55% (90%[215]); DL-glutamic acid, 73.5% (83%[215]); DL-alanine, 63%; DL-valine, 13.5%; DL-phenylalanine, 40%; DL-αα-di-aminobutyric acid, 3.8%; DL-ornithine, 18.5%; DL-lysine, 12%.

Methods for the synthesis of γ-aminoacids, some of which have a sedative effect on the nervous system, have been developed on the basis of nitroacetic acid ester[216].

5. From Aliphatic, Aromatic, and Heterocyclic Compounds and Other Aminoacids

A new method for the preparation of α-aminoacids from carboxylic acids in a single stage consists of the amination of α-lithio-lithium salts of *O*-alkylhydroxylamines in hexametapol at −15°C:

$$\mathrm{RCH_2COOH \xrightarrow{LiN(n\text{-}C_3H_7)_2} RCHLiCOOLi \xrightarrow{NH_2OR'} R\ CH(NH_2)CCOH}\ .$$

The yields of phenylglycine and valine reached 55.5 and 33.9% for a 32.8% conversion of the initial acid. Best results are obtained with *O*-methylhydroxylamine[217].

DL-DOPA is obtained by the hydrolysis of 5-(3,4-iso-propylenedioxybenzyl)hydantoin, which is synthesised in five stages from 4-methylcatechol[218]. Lysine has been obtained from cyanobutyraldehyde by hydantoin synthesis with subsequent hydrogenation and hydrolysis[219,220]. A number of papers deal with the details of the hydrolysis of the hydantoins derived from various aminoacids. The hydrolysis is carried out as a rule under alkaline conditions in an autoclave with periodic release of the excess pressure[74,75,221–223]. A number of other improvements have been proposed to the cyanohydrin synthesis[224,225].

The hydroxylation of the aromatic ring is used for the synthesis of aminohydroxyacids. Thus L-DOPA is

obtained in about 50% overall yield from the methyl ester of *N*-acetyl-L-tyrosine[226]:

$$L\text{-}4\text{-}HOC_6H_4CH_2\overset{*}{C}H(NH_2)COOCH_3 \xrightarrow{(CH_3CO)_2O} \rightarrow L\text{-}4CH_3OCOC_6H_4CH_2\overset{*}{C}H(NHCOCH_3)COOCH_3 \xrightarrow{AlCl_3} \xrightarrow{AlCl_3} \rightarrow L\text{-}3,4\text{-}(CH_3CO)(OH)C_6H_3CH_2\overset{*}{C}H(NHCOCH_3)COOCH_3 \xrightarrow{1)\ H_2O_2,\ NaOH;\ 2)\ HBr} \rightarrow L\text{-}3,4\text{-}(OH)_2C_6H_3CH_2\overset{*}{C}H(NH_2)COOH.$$

Hydroxylation of the methyl ester of *N*-acyl-L-tyrosine by benzoyl peroxide gave L-DOPA in about 35% overall yield[227,226].

The hydroxy-group was introduced into the *N*-acyl-L-tyrosine molecule by reaction with atmospheric oxygen in the presence of Fe^{2+} and enediol compounds (ascorbic acid)[229]. Proline reacts with atmospheric oxygen in aqueous solutions on irradiation with ultraviolet or visible light in the presence of semiconducting metal oxides and sulphides. Proline is then converted into hydroxyproline in 1.5 h in 52% yield[230].

Methods have been proposed for the chlorination[231,232] of ω-benzoylaminocaproic acid, the ammoniolysis of the resulting chloro-derivatives[233], and subsequent hydrolysis[234,235], the overall process leading to DL-lysine. These reactions have been examined in detail in the present author's earlier review[191]. Diaminopimelic acid derivatives can serve as lysine precursors. Thus α-cyanopimelic acid diamide was converted into DL-lysine by the Hofmann rearrangement with subsequent hydrolysis[236].

A series of fairly complicated reactions permit the conversion of furfural into DL-glutamic acid[237,238]. Glutamic acid can serve as the starting material for the synthesis of other aminoacids. Thus L-proline and *N*-methyl-L-proline can be obtained from L-glutamic acid[239].

Optically active ornithine (D or L) can be obtained from optically active glutamic acid (D or L) in seven stages with an overall yield of 40%.[240] In its turn, each of the optically active forms of ornithine can serve as the starting material for the synthesis of L- and D-proline[241,242] and L-arginine can be obtained from L-ornithine in virtually one stage[243,244]. DL-Serine and its derivatives are used for the synthesis of DL-cystine[245-248]. L-Tyrosine can be converted into L-phenylalanine by the reduction of the *O*-tosylate[249,250].

6. From Simple Gases

In connection with the problem of the chemical evolution and the origin of life on earth, experiments were begun in 1953 on the non-biological synthesis of aminoacids under conditions simulating "earth's primary atmosphere". It was shown that aminoacids are formed comparatively readily from gaseous methane–water–ammonia mixtures in the presence or absence of hydrogen under the influence of various physical factors. These may be electrical discharges, irradiation, with visible and ultraviolet light as well as with hard ionising radiation, heating, and exposure to ultrasonic waves. Numerous experiments resulted in the formation of twelve of the natural aminoacids and various mechanisms for their formation from gaseous mixtures and certain other simple compounds, which had been synthesised beforehand under the same conditions, have been proposed[251-256]. In all experiments of this kind the yields of aminoacids are extremely low[251]. However, a method was recently patented where a mixture of methane, ethane, ammonia, and water in argon is subjected to the action of a shockwave and cooling by rapid expansion. A mixture of glycine, alanine, valine, and leucine is then obtained with 36% conversion with respect to ammonia[257].

7. From Glycine Derivatives

a. On the basis of isocyanoacetic acid esters. A familiar method for the alkylation of α-*N*-acylaminomalonic esters has been used to synthesise tryptophan[258,259], lysine[260], and glutamic acid[261]. Isocyanoacetic acid ester can be converted into higher homologues by alkylation in a similar manner. The isocyano-group is then converted into the formylamino-group and the aminoacid is obtained after hydrolysis. DL-Tryptophan was obtained in this way in 49% overall yield[262]:

$$IndCH_2N(CH_3)_3I + C{=}NCH_2COOCH_3 \xrightarrow{NaH} IndCH_2CH(N{=}C)COOCH_3 \rightarrow \xrightarrow{CH_3COOH,\ CH_3OH} IndCH_2CH(NHCHO)COOH \xrightarrow[(OH^-)]{H_2O/CH_3OH} \text{DL-tryptophan}.$$

(Ind = β-indolyl)

The reaction of isocyanoacetic acid ester with alkyl halides or tosylates cannot be stopped at the monoalkylation stage[263]. α-Amino-β-hydroxyacids can be obtained by the reaction of isocyanoacetates with aldehydes[264]:

$$C{=}NCH_2COOCH_3 + C_6H_5CHO \xrightarrow{(C_2H_5)_3N} C_6H_5CH(OH)CH(N{=}C)COOCH_3 \rightarrow \xrightarrow{1)\ CH_3OH(HCl);\ 2)\ H_2O(OH^-)} C_6H_5CH(OH)CH(NH_2)COOH.$$

The methyl ester of DL-DOPA was obtained by the same procedure in 83% yield from methyl isocyanoacetate and the dibenzyl ether of 3,4-dihydroxybenzaldehyde:

$$C{=}NCH_2COOCH_3 + 3,4\text{-}(C_6H_5CH_2O)_2C_6H_3CHO \xrightarrow{t\text{-}C_4H_9OK} \rightarrow 3,4\text{-}(C_6H_5CH_2O)_2C_6H_3\underset{\displaystyle O^-K^+}{\underset{|}{C}}HCH(N{=}C)COOCH_3 \xrightarrow{CH_3OH/H_2O(HCl)} \rightarrow 3,4\text{-}(C_6H_5CH_2O)_2C_6H_3CH{=}\underset{\displaystyle NH_2\cdot HCl}{\underset{|}{C}}{-}COOCH_3 \xrightarrow{H_2;\ Pd/C} 3,4\text{-}(OH)_2C_6H_3CH_2\underset{\displaystyle NH_2\cdot HCl}{\underset{|}{C}}HCOOCH_3.$$

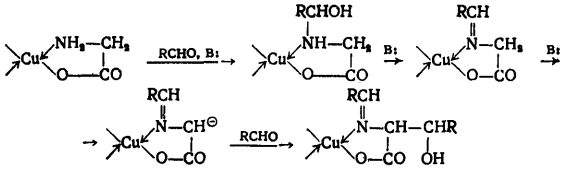
3,4-Methylenedioxy- and 3,4-dimethoxy-benzaldehydes can be used in the reaction. In this case the methylene or methyl groups are removed with BBr_3 after treatment of the isocyano-group and hydrogenation[265]. The report of the above investigation contains a reference to the possibility of obtaining a wide variety of aminoacids by this procedure. A partial asymmetric synthesis of α-methyl-DOPA, which is used as a hypotensive agent, involving the *C*-alkylation of α-isocyanopropionic acid esters by optically active alcohols, has been proposed[266].

The synthesis of silicon- and tin-containing aminoacids from ethyl *NN*-bis(trimethylsilyl)glycinate and the corresponding alkyl halides has been achieved; the reaction with carbonyl compounds yields α-amino-β-hydroxyacids[267].

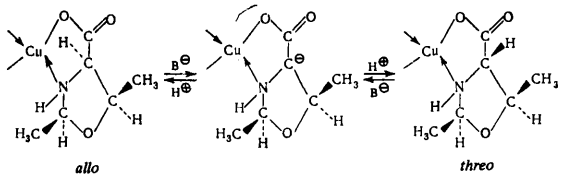
The sodio-derivative of this ester was used to synthesise 2-amino-6-nitrocaproic acid, which is used in peptide synthesis as a protected lysine derivative[268].

b. On the basis of glycine bound in a complex. Alkylation of glycine complexes by aldehydes and certain ketones permits the synthesis of a number of α-amino-β-hydroxyacids[269-277]. The akabori reaction, giving in a single stage threonine with an excess of the *threo*-form, is typical[52]. The study of the reaction mechanism showed that the intermediate reactive species is probably a copper complex of the Schiff base of the aminoacid and the aldehyde, which has a sufficiently acid C–H group for the formation of a carbanion in an alkaline medium and for its further reactions[278-280].

The reaction of copper glycinate with aldehydes proceeds as follows:



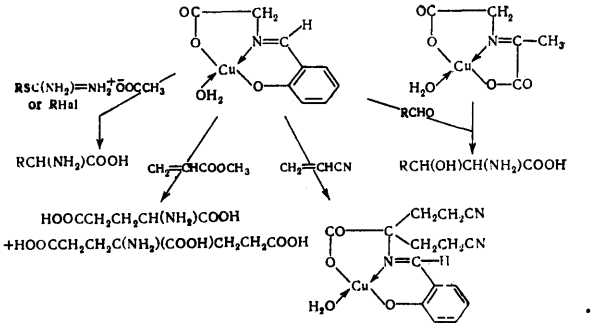
An X-ray diffraction study of crystalline copper threoninate ($C_{12}H_{20}O_6N_2Cu.2H_2O$) showed that the complex has a tetracyclic structure in which two five-membered rings are formed by the bonds between the aminoacids and copper and a further two oxazoline rings are formed by the intramolecular nucleophilic addition of the alkoxide ion to the C=N double bond[281,282]. The less hindered configuration of the substituents in the complex corresponds to the *threo*-form, which is the reason for the stereospecificity of the Akabori reaction and also for the conversion of the *allo*-form of the complex into the *threo*-form in an alkaline medium[57,58,278]:



allo *threo*

Thus, apart from being involved in the synthesis, the aldehydes plays the same role in the Akabori reaction that the pyridoxal molecule plays in alkylation processes catalysed by pyridoxal-dependent enzymes[283,284].

Further development of these studies led to the discovery of chemical systems which not only simulated certain aspects of enzymatic reactions but also gave rise to processes, which do not occur in the living organism. Such systems are the complexes of the Schiff bases of salicylaldehydes and aminoacids with transition metal ions. Salicylaldehyde plays the role of pyridoxal, preventing alkylation at the nitrogen atom[285] and increasing the reactivity of the C—H bond of the aminoacid, while the metal atom imparts in addition a rigidity to the system, which is ensured in nature by the enzyme protein. This permitted asymmetric synthesis with the aid of these systems[286]. The use of salicylaldehyde[283,284,287-289] and pyruvic acid[279,288,289,291] permitted the synthesis under mild conditions of threonine and other α-amino-β-hydroxyacids. In addition, the methylene group of glycine was alkylated by the reaction of alkyl halides[288] and acrylonitrile[285] with copper salicylidene- and 1-carboxy-ethylidene-glycinates and by the reaction of the latter with aldehydes. The alkylation of glycine bound in the complex can be represented by the following scheme:



The reaction with aldehydes has been most thoroughly investigated. Copper salicylideneglycinate was alkylated by aldehydes in water at about 25°C at pH 7.0—8.0. The following aminoacids were obtained by this procedure (the percentage yield and the ratio of the *threo*- and *erythro*-forms are indicated in brackets): threonine [89, (31—34)/(66—69)]; phenylserine [45, (79—84)/(21—26)]; hydroxyaspartic acid (51, 64/36), and serine (2.6, -).[283] The reaction of copper 1-carboxyethylideneglycinate with aldehydes was carried out in an atmosphere of nitrogen, in water or in methanol, at 25—30°C in a moderately alkaline medium. More than ten aliphatic, aromatic, and heterocyclic α-amino-β-hydroxyacids were obtained in this way, including serine, threonine, β-hydroxyleucine, and β-hydroxy-β-phenylalanine in yields of 28, 82, 75, and 67% respectively[179,280].

Copper salicylideneglycinate is alkylated by alkyl halides in dimethylformamide (DMF) at 65°C in the presence of KOH with formation of low yields of alanine, valine, leucine, isoleucine (traces), phenylalanine, and aspartic acid[288]. The alkylation of copper(II) or cobalt(II) salicylideneglycinate by thiuronium salts having the general formula $RSC(NH_2)=NH_2^+ CH_3COO^-$ in acetic acid in the presence of sodium acetate gives particularly good results. The yields of phenylalanine, aspartic acid, and glutamic acid obtained by this method are 50—60%.[292]

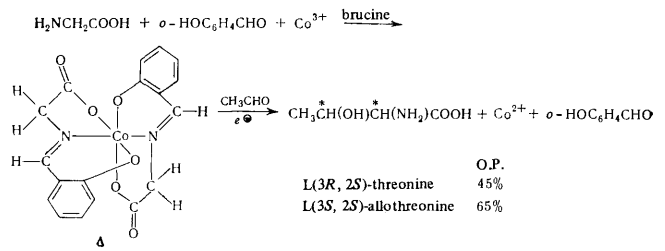
The interaction of copper salicylideneglycinate with methyl acrylate in water at 35°C and pH 11.4 in the course of 15 min results in the formation of 46% glutamic acid and 17% of 4-amino-4-carboxypimelic acid with a residue of 35% of unreacted glycine. When 1-carboxyethylideneglycinate is employed, similar results are obtained, but the contribution of side processes (deamination, decarboxylation) increases[284,289]. The above results show that, by employing glycine complexes, it is not only possible to simulate natural process but also to achieve processes which do not occur in nature, and this leads to new ways of synthesising aminoacids.

Inert octahedral cobalt(III) complexes such as sodium bis-(*N*-salicylideneglycinato)cobaltate, which have a fairly acid C—H group, can also be used for the *C*-alkylation of glycine by acrylonitrile, acetaldehyde, and methacrylate. The resulting inert complexes of the reaction products can be readily reduced electrochemically to labile cobalt(II) complexes, which dissociate into the aminoacid, salicylaldehyde, and Co^{2+}. The mixture is separated with the aid of ion-exchange resins. A significant advantage of the cobalt(III) complexes is the absence of side processes (bisalkylation, alkylation at the nitrogen atom) in the reaction with methyl acrylate. This results in the formation of glutamic acid in a single stage and in a high yield[293,294].

Cobalt(III) complexes are also interesting because they exhibit dissymmetry due to the rigid fixation of the ligands in the octahedron and also the asymmetry of the ligands themselves. The possibility, in principle, of employing dissymmetric mixed cobalt(III) complexes for the asymmetric synthesis of aminoacids was demonstrated in the synthesis of threonine (asymmetric yield 8%)[295] and alanine (asymmetric yield 14%)[296]. These syntheses are examined in detail in Morrison and Mosher's book[297]. The stereoselectivity of the reactions of cobalt(III) complexes with glycine Schiff bases permitted their employment for the asymmetric synthesis of aminoacids, i.e. essentially for the simulation of the stereospecificity of natural enzymes. For this purpose, potassium bis-(*N*-salicylideneaminoalkylcarboxylato)cobaltate was resolved into optical isomers, the absolute configurations of which were estab-

lished on the basis of circular dichroism spectra, ^1H NMR, and reactivity[298].

The reaction of Δ-isomers (−530) or Λ-isomers (+530) of potassium bis-(*N*-salicylideneglycinato)cobaltate with acetaldehyde (water, pH 11.2, acetaldehyde : complex = 100 : 1, temperature 12°C, time 6 h) is stereospecific with formation of L(*S*)- or D(*R*)-threonine respectively:

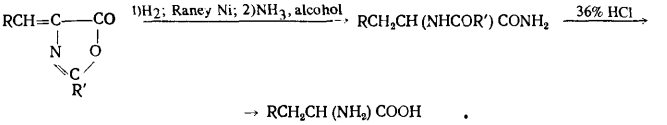


The overall yield is 86% and the ratio *threo* : *allo* = 1.25.[286]

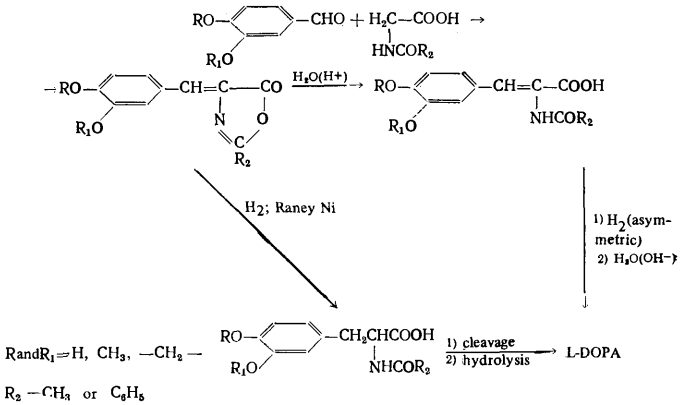
The replacement of one of the ligands in the complex with the absolute Δ-configuration of the glycine residue by the (*S*)-valine residue results in the formation of (*S*)-threonine with an asymmetric yield reaching 82%.[298] When account is taken of the synthetic possibilities of these complexes[293,294] and of a series of studies on their properties[298-300], the above approach to the problem of asymmetric synthesis of aminoacids can prove extremely fruitful.

c. On the basis of *N*-acylglycines.

N-Acylglycines are employed as compounds containing the α-aminoacid fragment in the synthesis of aminoacids by the azlactone method. In the classical version azlactones are obtained by the reaction of acylglycine with aromatic aldehydes in the presence of acetic anhydride. Hydrolysis or alcoholysis of the azlactone yields α-acylaminoacrylic acid or its ester, whose subsequent reduction and hydrolysis lead to the aminoacid[81]. Later it was shown that the reaction can also be carried out with aliphatic aldehydes and ketones[301]. It proved possible to achieve the catalytic reduction of azlactones in an alkaline medium, omitting the conversion stage into α-acylaminoacrylic acids. The resulting α-acylaminoacid amides are hydrolysed smoothly to the α-aminoacids:



The following aminoacids were obtained in this way (the percentage yield with respect to the azlactone is indicated in brackets): phenylalanine (84); tyrosine (78); 3,4-dimethoxyphenylalanine (64); 4-hydroxy-3-methoxyphenylalanine (46.5); valine (75); isoleucine (62); leucine (54); and certain other aminoacids[302]. The reduction of azlactones by hydrogen obtained as a result of the catalytic decomposition of HCOOH gave rise to the formation of *N*-acylaminoacids (derivatives of phenylalanine, tryptophan, and valine) in 85—93% yield[303]. The application of the method to the synthesis of cystine[304] and histidine[305] also gives good results. 4-Hydroxy-3-methoxy-,[306-309] 3,4-dihydroxy-,[310] 3,4-dimethoxy-,[311,312] and 3,4-methylenedioxy-benzaldehydes[313] have been used to synthesise L-DOPA by the azlactone method. The corresponding azlactones can be converted into L-DOPA in two ways. The first consists of the catalytic[306,310] or electrochemical[309] reduction of the azlactone with subsequent enzymatic separation[309] of the optical isomers of the β-aryl derivatives of *N*-acylalanines (DOPA precursors) via diastereoisomeric salts with acid[314] or alkaline[306-308,311-313,315] agents and also by selective crystallisation[316-318]. The hydrolysis of the corresponding L-isomers leads to L-DOPA.



The second procedure involves the hydrolysis of the azlactones with subsequent asymmetric catalytic hydrogenation of the resulting *N*-acylaminoacrylates in the presence of homogeneous dissymmetric phosphine—rhodium catalysts. This new method of asymmetric synthesis can probably be used for the industrial manufacture of optically active aminoacids from unsaturated precursors[120,319].

IV. ASYMMETRIC SYNTHESIS

1. Homogeneous Asymmetric Hydrogenation

The catalytic hydrogenation of unsaturated aminoacid precursors with the aid of dissymmetric catalysts has evident advantages over syntheses employing chiral agents to induce a new asymmetric centre—by the saving achieved as a result of the elimination of the expensive optically active starting material, the simplicity of the operations, and the minimal number of side reactions. Until recently, studies in this field concerned the modification of heterogeneous metallic catalysts with various chiral agents in order to make them stereospecific. The degree of asymmetric synthesis in hydrogenation using such catalysts is as a rule low or sometimes poorly reproducible results are obtained[297,320-323].

A new fruitful approach to this problem became possible as a result of two advances in the last decade: the discovery of homogeneous catalytic hydrogenation of olefins with the aid of rhodium(I) complexes with phosphine ligands[324] and the development of procedures for the synthesis of chiral phosphines[325,326]. The application of rhodium complexes with chiral phosphines as homogeneous catalysts for the hydrogenation of *N*-acylaminoacrylic acids permitted the asymmetric synthesis of α-aminoacids with a high degree of stereospecificity[120,319,327,328] and in high yields. The effect of the structure and the optical purity of the chiral phosphine and also of the hydrogenation conditions on the stereospecificity of the catalyst was investigated by Knowles et al.[120,327]. The results are in Table 2.

Table 2 shows that the employment of *o*-anisylmethylcyclohexylphosphine with 95% optical purity leads to a

product with 85–90% optical purity, i.e. almost complete stereoselectivity is achieved. The optically pure enantiomer can be obtained by a single recrystallisation.

Table 2 (Knowles et al.[327]). Substrates: 3-(CH_3O)-4-(OH)C_6H_3CH=C($NHCOC_6H_5$)COOH (I) and 3-(CH_3O)-4-(CH_3OCO)C_6H_3CH=C($NHCOCH_3$)COOH (II).

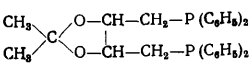
Acyl derivatives of α-aminoacids of the (*S*)-series (l-series) are obtained when (+)-phosphine–rhodium catalysts are used. The employment of catalysts with (-)-phosphine promotes the formation of aminoacids of the unnatural (*R*)-series (D-series)[120,319]. Kagan and Dang studied the hydrogenation of a series of *N*-acylaminoacrylic acids in the presence of a catalyst based on the bisphosphine derivative of natural (+)-tartaric acid[319,328].



"Kagan's diphosphine".

The data for the asymmetric hydrogenation of *N*-acylaminoacrylic acid derivatives using homogeneous rhodium catalysts based on (+)-*o*-anisylmethylcyclohexylphosphine (A) and Kagan's (-)-diphosphine (B) are summarised in Table 3.

Table 3 shows that the hydrogenation of aromatic systems with chiral phosphine–rhodium catalysts leads to *N*-acylamino-derivatives of L-phenylalanine, L-3,4-dihydroxyphenylalanine, and L-tryptophan in a high optical yield. The above investigations led to the development of a method for the synthesis of L-DOPA from 4-hydroxy-3-methoxybenzaldehyde (vanillin) and its industrial manufacture on its basis has begun[120–122]. The results obtained with aliphatic aminoacid derivatives are more modest, but the limited number of systems investigated precludes definite conclusions at present. Under the conditions adopted, 4-benzylidene-2-methyloxazolone and 5-benzylidenehydantoin are not hydrogenated, although the catalyst retains its activity[319]. This is somewhat unexpected, since azlactones (see end of previous section) are capable of being reduced in the presence of heterogeneous catalysts to *N*-acylaminoacid amides[302].

Comparative characteristics of the catalysts show that both systems have high stereoselectivities, although catalyst B gives higher optical yields with *N*-acetyl derivatives, while in the presence of A the replacement of the acetyl group by the benzoyl group does not affect the stereoselectivity[120,319].

[a] The amount of metal is expressed as a percentage.

Catalysts for asymmetric homogeneous hydrogenation can be obtained by mixing $[Rh(hexa\text{-}1,5\text{-}diene)Cl]_2$ or $RhCl_3.3H_2O$ with two molecules of a chiral ligand and brief preliminary hydrogenation[120]. The most convenient initial form of the catalyst consists of solid derivatives of the type $[Rh(diene)L_2]^+BF_4^-$, which are stable in air and which readily adsorb hydrogen to form the active catalysts. The latter apparently has an octahedral structure with two stable phosphine linkages. Hydrogen, the substrate, the solvent, and the reaction product are present in dynamic equilibrium in the remaining four coordination sites.

In a complex of this type there is a stereospecific (*cis*-addition) intramolecular transfer of hydrogen to the olefinic double bond with formation of a saturated compound. If the ratio phosphine : rhodium > 2, the complex loses its catalytic activity. The bonds between rhodium and a large number of phosphine molecules probably prevent simultaneous coordination with the olefin[319]. The structural correspondence between the substrate and the ligand is of first importance for high stereospecificity in hydrogenation. The hydrogenation stereoselectivity of the catalyst based on *o*-anisylmethylcyclohexylphosphine is promoted by the methoxy-group, which forms a hydrogen bond with the acylamino-group, thereby determining the relative positions of the substrate and the ligand in the reaction complex. In addition, the methoxy-group, which is a planar ligand, does not form a stable bond with the metal and does not affect its coordination with the other reacting molecules[120]. The high stereospecificity of the catalyst based on Kagan's diphosphine is due to the coordination rigidity of the diphosphine–rhodium chelate, which is increased as a result of the *trans*-configuration of the acetamide ring[319].

The rhodium(I)—neomenthyldiphenylphosphine system [based on natural (-)-menthol] has been used to hydrogenate *E*-β-methylcinnamic acid. This resulted in the formation of (+)-methylhydrocinnamic acid with an optical purity of 61% and in 80% chemical yield[329]. The employment of this catalyst for the hydrogenation of acylaminoacrylic acid would be interesting, since the enamide group in the substrate has been found to have a favourable effect on the steric course of the reaction[319].

2. Method of Asymmetric Induction†

The most extensive studies on the asymmetric synthesis of aminoacids by the reductive transamination of ketoacids with subsequent hydrogenolysis have been carried out by Hiskey and Northrop[330,331] and by Harada and coworkers[332-337]:

$$RCOCOOR' + R^*NH_2 \rightarrow RC(=NR^*)COOR' \xrightarrow{H_2;\ Pd/C} R\overset{*}{C}H(NHR^*)COOR' \rightarrow$$
$$\xrightarrow{1)\ H_2;\ Pd(OH)_2/C;\ 2)\ H_2O\ (H^+)} R\overset{*}{C}H(NH_2)COOH + R^*H + R'H\ .$$

[R* = ArĊH(NH₂) AlK; R' = H, Na, C_2H_5, or (-)-menthyl.]

The following aminoacids were obtained in this way (R and the percentage optical purity are indicated): CH_3, 40—80; C_2H_5, 32—42; i-C_3H_7, 28; $C_6H_5CH_2$, 5—14; C_6H_5, 24—30; $HOOCCH_2$, 45—58; $HOOCCH_2CH_2$, 6—56. The configuration of the newly formed asymmetric centre corresponds to the configuration of the chiral amine employed. The two groups of investigators used different methods for the treatment and isolation of the products and for this reason their results, while in general comparable, differ somewhat. The results of the investigations have been discussed in detail in reviews[297,320]. Attempts have been made in recent studies to elucidate the influence of temperature[338-340] and of the solvent[341,342] on the degree of asymmetric synthesis in these reactions.

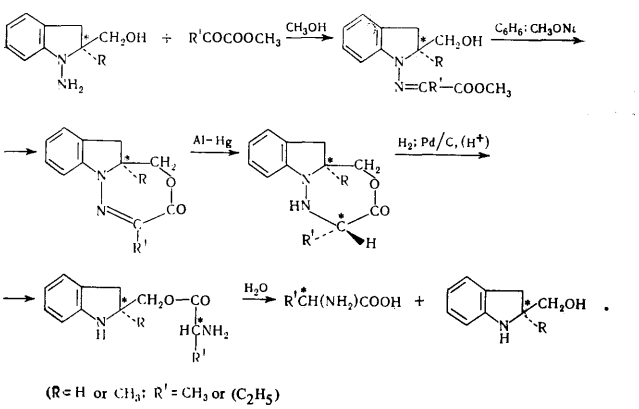
The same method was used to synthesise optically active dipeptides from the esters of the azomethine derivatives of *N*-(α-oxoacyl)-α-aminoacids:

$$CH_3C(=NCH_2C_6H_5)CONHCH(R)COO(i\text{-}C_4H_9) \xrightarrow{H_2;\ Pd/C}$$
$$\rightarrow CH_3\overset{*}{C}H(NH_2)CONH\overset{*}{C}H(R)COO(i\text{-}C_4H_9).$$

Here the aminoacid residue plays the role of the chiral agent and the L(S)-aminoacid induces a new asymmetric centre with L(S)-configuration when the group R is larger than CH_3. The groups R and the optical purities expressed as percentages were as follows: CH_3, 64; C_2H_5, 42; i-C_3H_7, 32; i-C_4H_9, 39; $C_6H_5CH_2$, 25; $CH_3COOC_4H_9$-i, 25; C_6H_5, 0.[343]

The catalytic hydrogenation of various prochiral substrates with C=O, C=C, or C=N bonds in the presence of optically active bases in various solvents leads to very low optical yields[344]. The reduction of the C=N double bond in the Schiff bases of ketoacids with the aid of $NaBH_4$ and subsequent hydrogenolysis give better results in terms of both chemical and asymmetric yield than catalytic reduction[345]. In almost all the known cases the optical purity of the aminoacids (without additional purification) is low. The inadequate stereospecificity of the non-enzymatic reductive transamination reaction in these examples is apparently due to the inadequate rigidity of the intermediates undergoing hydrogenation. Their conformation is such that the alternative approach of hydrogen to the prochiral centre is not fully excluded and this leads to partial formation of the aminoacid with the opposite configuration. Moreover, the irreversible loss of the chiral agent lowers the practical value of this method.

An asymmetric synthesis of α-aminoacids with high chemical yields and high optical purities was achieved by Corey and coworkers[346-348]. *N*-Amino-2-hydroxymethyl- and *N*-amino-2-(α-hydroxyethyl)-indolines were used as chiral aminating agents. The 2-hydroxymethylindoline formed in the reaction was reconverted by nitrosation and reduction into the initial *N*-amino-derivative with only slight losses. All the *N*-aminoindoline derivatives had the (*S*)(-)-configuration and induced the formation of the D(*R*)-configuration at the new asymmetric centre. The explanation is that the rigid conformation of the seven-membered ring in the intermediate hydrazonolactone ensures the approach of hydrogen, with formation of a new asymmetric centre, in the *cis*-position relative to the substituent (hydrogen or the methyl group) in the α-position with respect to the indoline nitrogen. The results are in Table 4.



(R = H or CH_3; R' = CH_3 or (C_2H_5))

When recrystallised hydrazinolactone is used, the optical purity of the resulting aminoacid is 99 ± 1% for alanine and 98 ± 2% for α-aminobutyric acid[347].

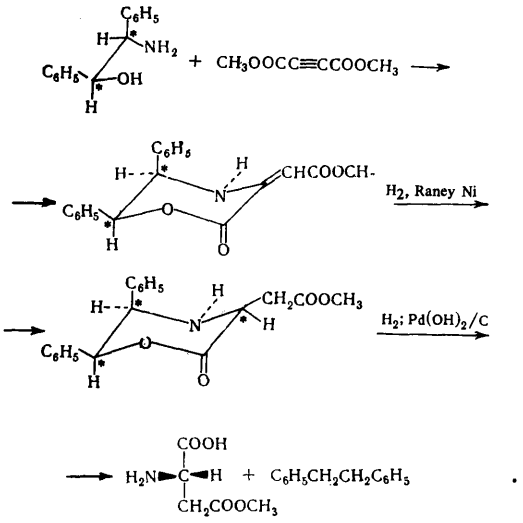
Table 4 (Corey et al.[347,348]).

D(*R*)-Aminoacid obtained	Chiral aminating (*S*)(-)-agent							
								
	yield, %		yield, %		yield, %		yield, %	
	total	optical	total	optical	total	optical	total	optical
Alanine	67	78—82	50	75	52	96	41	92
α-Aminobutyric acid	47	85—90	—	—	55	97	41	96
Valine	—	—	—	—	15	97	—	—
Leucine	—	—	—	—	54	99	—	—

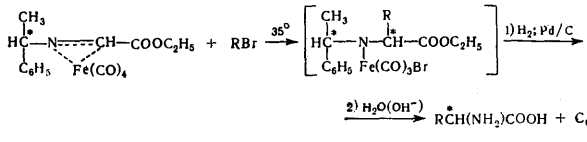
D-Alanine was obtained with an optical purity of 40% and a chemical yield of 10% by the transamination of ethyl pyruvate with chiral *N*-aminoanabasine, which can be regenerated[349,350].

† A new type of asymmetric induction—the synthesis of chiral α-aminoacids with the aid of dissymmetric cobalt(III) complexes—is examined in the section dealing with syntheses based on glycine bound in complexes.

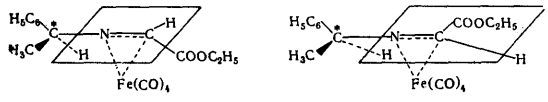
Almost complete stereoselectivity was achieved in the hydrogenation of the cyclic compound obtained by the condensation of *erythro*(+)-1,2-diphenylethanolamine and dimethyl acetylenedicarboxylate:



The stereospecificity of the hydrogenation of the exocyclic double bond is determined by the nature of the intermediate ring in which there is a difference between the degrees of steric hindrance of its two surfaces, namely the axial phenyl group prevents the approach of hydrogen from the axial side. In the hydrogenolysis of the reduced product, methyl L(S)-aspartate was obtained with an optical purity of 98% and in almost quantitative chemical yield[352,353]. High stereospecificity, owing to the rigid fixation of the reaction centre, is achieved in the alkylation by alkyl halides of the π-complexes of the α-methylbenzylimino-derivative of ethyl glyoxylate in the presence of iron nonacarbonyl:



The groups R used, the chemical yields, and the optical purities obtained (expressed as percentages) were as follows: $C_6H_5CH_2$, 53, 77; o-$CH_3OC_6H_4CH_2$, 28, 95; $C_2H_5OOCCH_2$, 24, 78. Alanine is not obtained when the complexes are alkylated with methyl iodide. The optical yield decreases with increase of temperature; the racemate of phenylalanine was obtained at 80°C with a chemical yield of 100%. A pair of diastereoisomeric complexes in proportions of 1:9 is obtained for each of the enantiomeric imines:

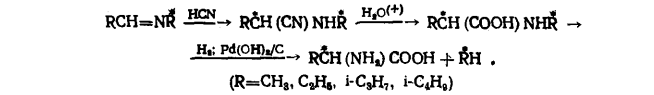


complexes obtained from the D-imine

When the diastereoisomer formed in excess is employed in the reaction, the L-amino-acid is obtained from the D-imine and conversely[354].

Chiral alkylarylamines have been used as aminating agents in yet another series of reactions but the optical purities of the resulting aminoacids are as a rule low.

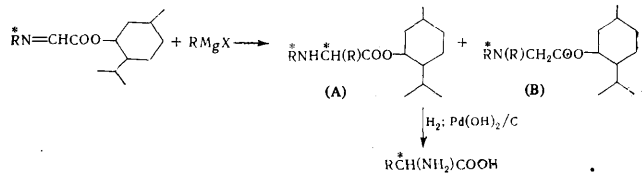
Thus optically active aminoacids have been obtained by the addition of hydrogen cyanide[355] or benzyl cyanide[356] to the azomethines obtained from aldehydes and chiral amines:



(R=CH_3, C_2H_5, i-C_3H_7, i-C_4H_9)

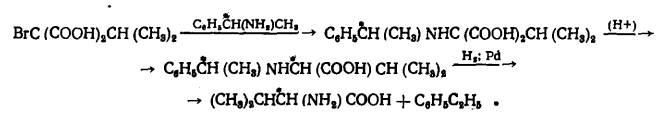
The chemical yields of the aminoacids are 9–58% [355] and 15–57% [356] and the optical purities are 22–58% [355] and 17–37%.[356] However, according to other data, a number of aminoacids with chemical yields of 40–60% and optical purities of 98–99% have been obtained by the addition of hydrogen cyanide to Schiff bases. The configuration of the resulting centre corresponds to that of the chiral amine[357].

The chiral imines of (-)-methyl glyoxylate combine with organomagnesium compounds by the following mechanism:

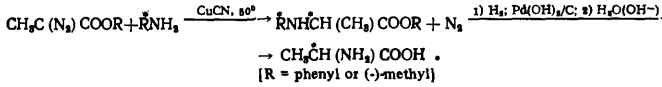


The overall chemical yield of A + B is 45–55%.[358,359] The mode of reaction depends on the structure of the group R in the organomagnesium compound. When R = CH_3, CH_2 = $CHCH_2$, or t-C_4H_9, A is the main addition product, which leads to an aminoacid. When R = C_2H_5, n-C_3H_7, s-C_4H_9, or $C_6H_5CH_2$, the main product is B, which yields *N*-alkylglycines. Optically active alanine was obtained in this way in a chemical yield of 41–45%. The configuration of the resulting aminoacid is determined by (-)-menthol and the optical purity depends on the configuration of the chiral amine: both (*S*)- and (*R*)-amines lead to L(*S*)-alanine with optical purities of 47.5 and 65%.[358] Organocadmium adds selectively to imines with formation of A exclusively. Alanine, norvaline, valine, and phenylalanine have been obtained with their aid in chemical yields of 55–70% and with optical purities of 38–46%.[359]

Valine has been obtained at 20°C in almost quantitative yield with an optical purity of 23% by the selective decarboxylation of (benzylmethylamino)isopropylmalonic acid and its configuration was the opposite of that of the amine employed[360]:



Optically active alanine was obtained by the insertion of the carbene formed in the decomposition of α-diazopropionic acid ester in the N–H bonds of a chiral amine:



[R = phenyl or (-)-menthyl]

The optical purity of the alanine was 12–26% and the configuration was the opposite of that of the inducing amine; the chirality of the ester group [(-)-menthyl] plays a secondary role[361].

Aspartic acid with an optical purity between 21 and 67% has been obtained from chloroacetonitrile and monochloroacetic acid anhydride by a series of reactions involving chiral amines:

$$\overset{*}{R}NH_2 + ClCH_2CN \rightarrow \overset{*}{R}NHCH_2CN \xrightarrow{(ClCH_2CO)_2O} \overset{*}{R}N(COCH_2Cl)CH_2CN \xrightarrow{B:}$$
$$\rightarrow \overset{*}{R}N{-}\overset{*}{C}HCN \xrightarrow{H_2O(H^+)} HOOC\overset{*}{C}HN(\overset{*}{R})CH_2COOH \xrightarrow{H_2;\ Pd(OH)_2/C}$$
(with $\overset{*}{R}N{-}\overset{*}{C}HCN$: $OC{-}CH_2$)
$$\rightarrow HOOCCH_2\overset{*}{C}H(NH_2)COOH .$$

The configuration of the resulting aminoacid is the opposite of that of the inducing amine. The optical purity depends on its structure: α-methylbenzylamine, α-ethylbenzylamine, and α-methylnaphthylamine give 41–49, 19–29, and 54–67% respectively[362]. The same dependence of the configuration of the resulting aminoacid on that of the inducing amine is observed in the synthesis of alanine from α-bromopropionamide. The optical yield of D(R)-alanine is between 11 and 36%.[363] The Baumgarten reaction[364] has been used for the asymmetric synthesis of aminoacids. Thus L(S)-phenylalanine, L(S)-alanine, L(S)-phenylglycine, and L(S)-leucine with optical purities of 62, 33, 27, and 75% respectively have been obtained by the rearrangement of (-)-menthyl N-chloroimidates. When (-)-2-methyl-1-butanol is used instead of (-)-menthol, better results are obtained[365].

The possibility of employing chiral alkylboranes[366] and aminoboranes[367] for the asymmetric synthesis of aminoacids has been demonstrated.

The following aminoacids have been obtained by the cyanohydrin synthesis using chiral amines [the aminoacids, their chemical yields (%) (in brackets), and optical purities (%) are listed]: alanine (42–47), 41–50; α-aminobutyric acid (27–32), 36–51; valine (17–26), 31–45; leucine (28–32), 22–39. The configuration of the resulting aminoacid is the same as that of the initial chiral amine. After additional purification, alanine can be obtained with an optical purity of 90%.[297,368] Aromatic S(L)-α-methylaminoacids (α-methyl-DOPA, tyrosine, and phenylalanine) have been synthesised from the corresponding methyl ketones by the cyanohydrin method. Virtually complete stereospecificity has been achieved with the aid of (4S, 5S)-(+)-5-amino-2,2-dimethyl-4-phenyl-1,3-dioxane as the chiral amine[369].

V. ENZYMATIC METHODS FOR THE SYNTHESIS OF AMINOACIDS

The employment of enzymes makes it possible to achieve under extremely mild conditions transformations which normally require cumbersome multistage synthesis. Moreover, enzymatic reactions are stereospecific and lead to the formation of only one enantiomer (usually the natural enantiomer). The culture liquids of various strains of micro-organisms and purified and immobilised enzymes are used for such reactions.

The widely employed selective enzymatic hydrolysis of acyl derivatives of L-aminoacids with the aid of acylases of various origins[370,371] is more correctly regarded as resolution of racemates and will not be considered here.

Enzymatic syntheses proper include, for example, the formation of L-tryptophan from indole, pyruvic acid and ammonia, which is carried out in a single stage in the presence of pyridoxal phosphate under the influence of the tryptophanase present in the culture liquid of *Escherichia coli*. For an initial concentration of 6.5%, 72% of tryptophan is obtained after 48 h (34°C and pH 8.8).[372] This synthesis was based on a study of the mechanism of the cleavage of tryptophan by the above enzyme. The reaction was reversed by increasing the concentration of the decomposition products. A complex of the enzyme with α-aminoacrylic acid served as an intermediate in this synthesis[373]. The exchange of the p-hydroxyphenyl group for the 3,4-dihydroxyphenyl group in the formation of L-DOPA by the interaction of L-tyrosine and catechol in the presence of crystalline β-tyrosinase and pyridoxal proceeds via the same complex. The replacement of catechol by other substrates leads to the possibility, in principle, of the formation of numerous aminoacids[374].

The synthesis of tryptophan from indole, pyruvic acid, and ammonia is catalysed by tryptophanase immobilised on Sepharose bound covalently to pyridoxal 5'-phosphate[375].

L-DOPA can be obtained by the enzymatic hydroxylation of L-tyrosine derivatives under the influence of enzymes from different strains of fungi[376–378]. The reaction occurs when L-tyrosine protected by acylation is incubated with the culture of the fungus in an appropriate nutrient medium. The protection of the amino-group prevents deamination and racemisation. The fermentation gives a mixture of 57% L-tyrosine and 25–30% of L-DOPA. Microorganisms can also convert D-tyrosine into D-DOPA. The authors of the method believe it to be one of the most economical[376]. Polyphenol oxidase with tyrosinase activity, bound covalently to DEAE-cellulose subjected to preliminary treatment with 6-amino-2,6-dichloro-s-thiazine, was used to synthesise L-DOPA by this method. A disadvantage is 75% loss of activity of the immobilised enzyme in 24 h.[379] A recently developed method for the continuous conversion of ammonium fumarate into L-aspartic acid has already been considered (see Section II, 6).

Data for the enzymatic synthesis of certain aminoacids are summarised in Table 5.

Table 5.

Enzymic transformation	Yield, %	References
L-Aspartic acid formed from fumaric acid and NH_3	90	90, 380
L-Alanine formed from L-aspartic acid	90	380
L-Tyrosine formed from phenol, pyruvic acid, and NH_3	90	380
L-DOPA formed from catechol, pyruvic acid, and NH_3	70	380
L-DOPA formed from L-tyrosine	65–70	377
L-Tryptophan formed from indole, pyruvic acid, and NH_3	72	372

The *meso*-form of diaminopimelic acid is known to be converted into L-lysine under the influence of decarboxylase in the presence of pyridoxal phosphate. It was obtained from synthetic diaminopimelic acid with the aid of partially purified microbial decarboxylase[381]. The racemic diaminopimelic acid remaining after the decarboxylation of the *meso*-form can be converted into the *meso*-form by epimerisation[382–384].

The esters of racemic acylaminoacids undergo selective hydrolysis under the influence of chymotrypsin or subtilisin, which results in a high yield of the L-acylaminoacid. The D-form remains as the non-hydrolysed ester. In particular, benzoyloxycarbonyl-L-phenylalanine was obtained by this procedure[385].

Enantioselective Effects in Coordination Compounds

V.A.Davankov, A.A.Kurganov, and S.V.Rogozhin

The present Review represents the first attempt to unify and systematise the numerous data on the development of enantioselective effects in the formation and chemical reactions of coordination compounds, as well as in their catalytic and adsorption properties. Enantioselectivity (thermodynamic or kinetic), while being a consequence of the chiral structure of the inner coordination sphere of the complex, may develop even in processes involving only the ligands of the outer coordination sphere. The present state of the chemistry of coordination compounds not only permits but even requires that enantioselective effects should be considered separately from all types of stereospecific effects. A list of 307 references is included.

I. INTRODUCTION

During recent decades the stereochemistry of coordination compounds has been a field of intense research by chemists of the most diverse schools and specialisation. On it converge the interests of biochemists attempting to understand the role of metal ions in the steric peculiarities of the action of metal enzymes, inorganic chemists investigating the electronic structure of coordination compounds and the nature of the metal–ligand bond, investigators of macromolecular compounds studying the part played by catalysts in stereoselective and stereospecific polymerisation, and finally organic chemists using asymmetric induction in complexes to effect asymmetric syntheses.

II. REFINEMENT OF STEREOCHEMICAL TERMINOLOGY

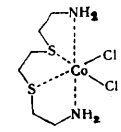
The variety of approaches to the stereochemistry of coordination compounds has led to ambiguity in the interpretation by different scientists of the same stereochemical terms. In many cases careless terminology makes an inadequate understanding of the stereochemical peculiarities of the processes investigated; moreover, it causes a substantial delay in the transition from a descriptive, qualitative study of these features to their accurate quantitative measurement.

The Reviewers consider that it is first necessary to delimit perfectly clearly the regions of application of the terms "selectivity" and "specificity": the former should be used for the characteristics of selection, of the choice of potential reactants present in the system; and the latter term to represent the specific direction of the reaction.

Processes should be termed *stereoselective* when a reactant species is able to select for reaction one of several stereoisomers of a second component. For example, we have a particular case of stereoselectivity—enantioselectivity—if the choice is made between two enantiomers. Such selection can be made, of course, only by a chiral reactant species. Thus we imply by *enantioselectivity* a difference between two molecules (or structures), which are optical enantiomers, in their interaction with a third chiral molecule (or structure).

The term *stereospecific* should be applied to processes leading to the preferential formation of one or more possible stereoisomers of the reaction product. For example, we have a particular case of stereospecificity—enantiospecificity—when a new asymmetric centre predominantly of one of two possible configurations appears in the reaction product. Asymmetry can be induced, of course, only when the initial compounds contain at least one chiral centre. Thus we shall understand by the *enantiospecificity* of a process the ability of chiral centres present in a system to dictate a certain configuration to newly formed chiral centres.

Among stereoselective processes, in the broad meaning of this term, we must include e.g. the selective reaction of boric acid (or acetone) only with those vicinal glycols whose hydroxy-groups are in the *cis*-position. An example of a stereospecific process is the exclusive formation of the symmetrical (±)-*cis*-complex of 3,6-dithiaoctane-1,8-diamine with cobalt(III)



although other stereoisomers of this complex are theoretically possible.

The stereochemical characteristics of reactions may be governed both by kinetic and by thermodynamic factors. Kinetic enantioselectivity, for example, is apparent in a difference in the rates of interaction of a chiral structure with enantiomers of a second reactant. Thermodynamic enantioselective effects are shown by differences in the stability or other properties of two labile diastereomeric adducts formed. Typical examples of kinetically and

thermodynamically enantioselective processes are respectively the difference in the rates of enzymic hydrolysis of the L- and D-isomers of amides of α-amino-acids and the difference in the adsorbability of these isomers on the surface of optically active quartz. The selective oxidation of D-isomers of amino-acids by D-amino-acid oxidase isolated from pigs' kidneys is an example of a kinetically enantioselective process leading to a decrease in the number of asymmetric centres in a system.

Enantiospecificity can by definition occur only in processes in which the number of chiral centres increases. For example, (+)-propylenediamine-*NNN'N'*-tetra-acetic acid interacts enantiospecifically with Co^{2+} ions to form the complex $(-)_{5461}$-[Co(+)-PDTA]$^{2-}$, in which the configuration of the asymmetric cobalt is unambiguous. Asymmetric syntheses are also the result of enantiospecific processes.

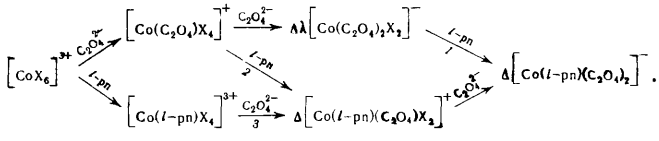
The delimitation of the concepts "selectivity" and "specificity" permits quantitative characterisation both of the selective ability of reactant species and of the directional nature of a process by use of the "degree of stereoselectivity α_{sel}" and the "degree of stereospecificity α_{sp}" respectively. The necessity of such discrimination is dictated by the fact that many processes exhibit both stereoselective and stereospecific effects, usually with different values of α_{sel} and α_{sp}.

Thus processes involving racemates and leading to an increase in the number of asymmetric centres in the system may be characterised by both enantioselectivity and enantiospecificity. In the reaction between racemic propylenediamine (*dl*-pn) and Co^{3+} ions in the presence of activated carbon, for example, Dwyer and his coworkers observed the formation of only four structures:

$$Co^{III} + dl\text{-pn} \begin{cases} \nearrow \Lambda(+)\,[Co(d\text{-pn})_3]^{3+} + \Delta(-)\,[Co(d\text{-pn})_3]^{3+} \\ \searrow \Delta(-)\,[Co(l\text{-pn})_3]^{3+} + \Lambda(+)\,[Co(l\text{-pn})_3]^{3+} \end{cases}$$
$$85\% \qquad\qquad 15\%$$

These data show that the degree of enantiospecificity of the process $\alpha_{sp} = (85 - 15)/(85 + 15) = 70\%$ is lower than the degree of enantioselectivity $\alpha_{sel} = 100\%$, since *d*-isomers of propylenediamine react only with those isomers of the complexes which already contain ligands of the same *d*-configuration, but form final tris-complexes of both Λ- and Δ-configurations.

It must be emphasised that knowledge of the reactants and the final reaction products alone may be insufficient for analysis of the steric aspects of the process. Thus the reaction of cobalt(III) with *l*-propylenediamine and oxalate ions leads to preferential formation of Δ-[$Co(C_2O_4)_2$*l*-pn]$^-$, which can be represented formally by the scheme



Only a knowledge of the reaction mechanism can indicate whether the final result is a consequence of enantioselective effects at stage *1* or of enantiospecific effects at stage *2* or *3*.

Previous reviewers of aspects of the stereochemistry of coordination compounds [1-7] have used the motley terminology of the original sources, and have not attempted to systematise the experimental results in conformity with the nature of stereochemical phenomena. The present Review is confined to a survey of enantioselective effects in coordination compounds. Enantiospecific aspects will be touched on only to the extent to which they appear in stereoselective processes.

III. ENANTIOSELECTIVITY IN COMPLEXES OF α-AMINO-ACIDS AND THEIR DERIVATIVES

Stereoselective and stereospecific effects in the equilibrium systems formed by kinetically labile complexes of copper, nickel, zinc, manganese, cobalt(II), aluminium, and iron with ions of alkali and alkaline-earth metals should be thermodynamic in nature. In non-equilibrium (reacting) systems of these complexes, however, the observed stereoselective and stereospecific effects would probably result from a combination of thermodynamic and kinetic contributions, as in the formation of kinetically inert complexes of cobalt(III), chromium(III), platinum-group metals, and several others.

1. Thermodynamic Effects

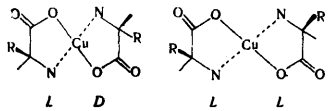
In contrast to tetrahedral and octahedral structures, the metal atom in square planar bis-complexes of copper with α-amino-acids (Aa) is not an independent centre of asymmetry. These complexes can therefore exhibit only enantioselective effects connected with the difference between the D- and L-isomers of the amino-acid in their interaction with an asymmetric structure such as the complex of the copper ion with one asymmetric amino-acid ligand. Enantioselectivity may thus occur at the stage of formation of the bis-complex. It should be apparent in a difference in thermodynamic stability between the optically active structure [$Cu(L\text{-}Aa)_2$] and the *meso*-structure [Cu(D-Aa)(L-Aa)] or in a difference in some properties of their solutions. Since the complexes are not stable diastereomers in solution, even a difference in their electronic spectra† must be ascribed to enantioselectivity, for a change in position of the energy levels of the *d*-orbitals of the copper ion indicates a difference in interaction between ligands within these two structures. Spectral differences may in principle be connected also with displacement of the *cis-trans* isomeric equilibrium, but bis-complexes of copper with bidentate α-amino-acids are assumed to have a *trans*-structure in dilute solutions [9-11].

It must be emphasised that the difference in properties between the crystalline complexes [$Cu(L\text{-}Aa)_2$] and [Cu(D-Aa)(L-Aa)]—including their solubilities—cannot be identified with the stereoselectivity of their formation. The properties of the solid phase are determined by the totality of other interactions, which, although characterised by exceptionally high stereoselectivity, are only indirectly related to the processes involved in formation of the complexes.

A conformational examination of complexes of α-amino-acids led Corey and Bailar [12] to the conclusion that five-membered chelate rings formed by the ligand with the central metal ion have an almost planar structure. There is then hardly any interaction between two chelate rings

†The molar extinction of a racemate would in general differ from that of the optically active enantiomers in the region in which the latter exhibit circular dichroism [8]. In most cases, however, this difference is vanishingly small.

in a complex. Substituents R attached to α-carbon atoms of ligands in square planar bis-complexes are separated by considerable distances



L D *L L*

and are also unable to produce stereoselective effects. Later calculations of the conformation of five-membered amino-acid chelate rings have shown[13] considerable flexibility, absence of any one preferred puckered conformation, and insignificant interactions between two chelate rings. In fact, most of the experimental results obtained until recently supported this theoretical conclusion that stereoselectivity was absent in amino-acid complexes of copper.

The slight difference (2–3%) in molar extinction observed originally[14] between solutions of copper complexes of optically active and of racemic alanine (Ala) and phenylalanine (Phe) was disproved by the later investigations of Gillard and his coworkers, who showed[15,16] that the spectral characteristics of the D-alanine and L-alanine complexes were unaffected when their solutions were mixed in equal proportions, and that the pH dependence of the spectra of the L-alanine and DL-alanine complexes was the same, which suggests that the homogeneous and mixed complexes—[Cu(L-Ala)$_2$] and [Cu(D-Ala)(L-Ala)]—have the same stability (degree of formation).

The absence of enantioselective effects leads to a purely random distribution of ligands, in which the equilibrium concentrations of the bis-complex structures [M(D-Aa)$_2$], [M(D-Aa)(L-Aa)], and [M(L-Aa)$_2$] are in the proportions[17] 1 : 2 : 1, and those of the tris-complex structures [M(D-Aa)$_3$] [M(D-Aa)$_2$(L-Aa)], [M(D-Aa)(L-Aa)$_2$], and [M(L-Aa)$_3$] are[18] 1 : 3 : 3 : 1. In both cases the potentiometric titration curves of L- and DL-amino-acids in the presence of metal ions M coincide exactly.

Table 1. Formation constants for mono- and bis-complexes (lgβ_1 and lgβ) of metals with alanine (pK_1 = 2.54 ± 0.04 and pK_2 = 9.93 ± 0.06) and with phenylalanine (pK_1 = 2.41 ± 0.04 and pK_2 = 9.35 ± 0.06) in 0.37 M $NaNO_3$ at 20 ± 0.1 °C.

	D	4.62	~9	4.43	~8.5
	DL	4.65	~9	4.41	~8.5

Simeon and Weber tried to detect enantioselectivity in the formation of the bis-complexes of alanine and phenylalanine with several metals[19], making a careful potentiometric titration of these systems with the use of D-, L-, and DL-amino-acids. The formation constant of the bis-complex (lgβ in Table 1) was independent of the steric configuration of the ligands, within the limits of experimental error (±0.05 for copper and nickel, and ±0.10 for the remaining ions). This applies not only to the square planar complexes of copper but also to the more complicated structures formed by metal ions of coordination number exceeding 4.

Potentiometric titration did not reveal enantioselectivity in complexes of copper with alanine, valine (Val)[16,20], proline (Pro)[16], or leucine (Leu), nor in bis-complexes of nickel with alanine, valine, and leucine[20]. Study of the optical rotatory dispersion of bis-complexes of copper with several L-amino-acids and their mixed complexes with optically inactive ligands led to the conclusion[21] that steric interactions between the two ligands in the [Cu(L-Aa)$_2$] system are so small that the Cotton effect is almost unaffected. While reaching this conclusion, the authors do not comment on their earlier report[22,23] of some difference in the pH dependence of the electronic spectra of complexes with optically active and with racemic alanine, valine, and especially proline, indicating that the homogeneous structures are less stable than the *meso*-complex [Cu(D-Aa)(L-Aa)].

The long standing view[1-4] that enantioselectivity is absent from copper complexes with bidentate amino-acids was not inconsistent with the difference (within the limits of experimental error) between the stability constants of mixed copper complexes of L-proline with L- and D-valine (lgβ = 16.89 ± 0.09 and 17.00 ± 0.20 respectively) calculated from the optical rotatory dispersion of the system[24]. Nor was this view disproved by some difference[25,26] in the electron spin resonance spectra of vitrified aqueous–methanolic solutions of copper complexes of L- and DL-alanine, -valine, -proline, and -serine (Ser), since there was no certainty that microcrystals of these complexes differing markedly in the e.s.r. properties were not formed when the solutions were cooled.

The first measurements of the stability of copper complexes of the terfunctional α-amino-acid–asparagine (Asp-NH_2)—potentiometric titration showed that the homogeneous structures—[Cu(D-As-NH_2)$_2$] and [Cu(L-Asp-NH_2)$_2$]—were more stable than the mixed complex [Cu(D-Asp-NH_2)(L-Asp-NH_2)], and that the quantities of the former in the equilibrium solution exceeded the concentration of the mixed complex fourfold[27]. However, more careful potentiometric measurements of the stability constants have shown that enantioselectivity is absent from the bis-complexes of copper with such terfunctional amino-acids as asparagine[28-30], aspartic acid (Asp), glutamine (Glu-NH_2), glutamic acid (Glu)[29,30], 2,3-diaminopropionic acid, and histidine (His)[20,31], as well as from mixed complexes[32] of histidine with threonine (Thr).

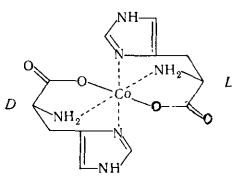
The presence of thermodynamic enantioselectivity in octahedral bis-complexes of cobalt(II) with terdentate histidine was first demonstrated in 1963 by McDonald and Phillips[33]. These workers observed, in the proton magnetic resonance spectra of solutions of the complex with DL-histidine, signals that were absent from solutions of the optically active complex, and they attributed the signals of the *meso*-complex [Co(D-His)(L-His)]. Study of the dependence of their intensity on the concentration ratio of D- and L-isomers of the ligand led to the calculated constant $K = 11.5$ for the equilibrium

$$[Co(L\text{-}Aa)_2] + [Co(D\text{-}Aa)_2] \rightleftharpoons 2[Co(L\text{-}Aa)(D\text{-}Aa)]$$

(in the absence of enantioselectivity $K = 4$[17]). Thus the mixed complex is formed preferentially in this system, its stability exceeding that of the homogeneous complex by 0.32 kcal mole^{-1}.[34] These results have been confirmed

by potentiometric titration[20,31,34]. Selectivity is still greater in complexes of histidine with nickel(II): the difference $\delta\Delta G^\circ$ in the Gibbs free energies of the individual structures reaches 0.49 kcal mole^{-1}.[34] The contents of the mixed structure in the complexes of DL-histidine with bivalent cobalt, nickel, zinc, cadmium, and copper are respectively 62%, 72%, 63%, 53%, and 50%,[31] corresponding to degrees of enantioselectivity of 24%, 44%, 26%, 6%, and 0. The high enantioselectivity observed with the nickel complexes is apparent also in their spectral properties: the absorption bands of the complex with L-histidine at 356 and 556 nm are rather wider and below the bands of the racemic complex, which moreover are somewhat displaced to longer wavelengths[31].

Enantioselectivity in octahedral histidine complexes is attributed[30,31,34] to the tendency of the bulky imidazole and similarly charged carboxylate donors to occupy *trans*-positions, which is possible only if the two histidine molecules have opposite configurations:



The degree of enantioselectivity then depends on the regularity of the octahedron and on the diameter of the central metal ion[30,31]. It is interesting that the rates of formation of [MHis$_2$] complexes in which M = Ni, CoII, Zn are independent of the configuration of the ligands. The poorer stability of the structures [M(D-His)$_2$] and [M(L-His)$_2$] than of [M(D-His)(L-His)] is evident in higher rate constants of the reverse reaction (dissociation) for the homogeneous structures[35,36]. It is noteworthy that, in contrast to the situation existing in solution, the crystalline complexes of nickel and zinc with DL-histidine are constructed from the homogeneous structures [M(D-His)$_2$] + [M(L-His)$_2$].

No stereoselectivity has been found in octahedral bis-complexes of terdentate 2,3-diaminopropionic acid with nickel[31], aspartic and glutamic acids with nickel and cobalt[29,30], and cysteine (CySH) with nickel and zinc[30,37]. On the other hand, Ritsma[30] has observed considerable intensification of enantioselective effects in histidine complexes on the introduction of alkyl substituents into the α-amino-group (Table 2). Benzyl- and dimethyl-histidine exhibit appreciable enantioselectivity even on coordination with copper, but the resulting complexes undoubtedly differ in structure from the square complexes of α-amino-acid type. Furthermore, Ritsma[30] finds that the optically active protonated complexes of copper with histidine are rather more stable, whereas at pH > 6 the *meso*-structure is apparently slightly more stable[32].

Barnes and Pettit studied the thermal effects accompanying the formation of copper complexes of alanine, valine, proline[38], and aspartic acid, copper and nickel complexes of glutamic acid and histidine, and also the zinc complex of histidine[38,39]. Enantioselective effects were observed only with histidine: differences between calculated enthalpies of formation of the individual *meso*-complex and the optically active complexes $\delta\Delta H^\circ$ were +0.67 ± 0.17, +0.57 ± 0.05, and −0.67 ± 0.17 kcal mole^{-1} with nickel, zinc, and copper respectively. Thus the enhanced stability of the symmetrical *meso*-complexes of nickel and zinc is mainly an enthalpy effect, as is suggested by the closeness of the values of $\delta\Delta H^\circ$ and $\delta\Delta G^\circ$

Table 2. Difference in Gibbs free energies $\delta\Delta G^\circ$ (in kcal mole^{-1}) of mixed and homogeneous structures—[M(D-Aa)(L-Aa)] and [M(L-Aa)$_2$]—from results of potentiometric titration with μ = 0.1 M at 25°C. Negative values indicate that the mixed structure is the less stable[30].

Amino-acid	Co^{II}	Ni^{II}	Cu^{II}	Zn^{II}
Histidine	+0.32	+0.49	0.0	+0.28
N-Methylhistidine	+0.69	+1.03	0.0	+0.49
N-Benzylhistidine	+0.28	+0.74	−0.25	<0.0
NN-Dimethylhistidine	+1.06	+1.62	+0.56	+1.20

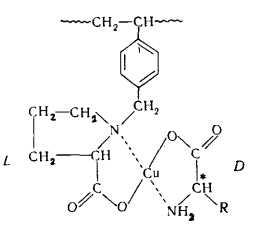
Cysteine		0.0		~0.0
Penicillamine		−0.55		>0.0

(Table 2). With copper, on the other hand, complexes with ligands of the same configuration should be preferred. (This unexpected result was ascribed to the tendency of copper to form tetragonal *cis*-structures in which histidine is coordinated through the imidazole ring and the amino-group.) However, the considerable enthalpy effect is probably balanced by entropy factors.

Complexes of cobalt(II) with L- and with DL-histidine differ not only in thermodynamic stability but also in the rate constants of their reversible oxidation[40] by molecular oxygen to the structure [CoHis$_2$]$_2$O$_2$.

The presence of enantioselectivity in complexes of bifunctional amino-acids was first shown unambiguously by Davankov and Rogozhin[41,42], by using a new method—ligand-exchange chromatography[43]—for studying kinetically labile mixed complexes. If one ligand (stationary) is bound covalently to an insoluble polymeric support, chromatography of a mixture of mobile ligands on such a sorbent in the presence of complexing metal ions permits determination of the relative thermodynamic stabilities of all the mixed complexes whose formation involves the stationary ligand. The stability of these mixed complexes increases in the same sequence as the affinity of the mobile ligands for the sorbent. Racemic amino-acids were subjected to chromatography, in the presence of copper, nickel, or zinc ions, on sorbents having chiral amino-acid groups. These ions become centres for the formation of mixed sorption complexes of the stationary chiral ligands of the sorbent and the mobile ligands, i.e. molecules of the separable racemate. Thermodynamic enantioselective effects in the formation of these sorption complexes are responsible for the separation of the isomers of the racemate, which is transported by the mobile phase in a column of such sorbent.

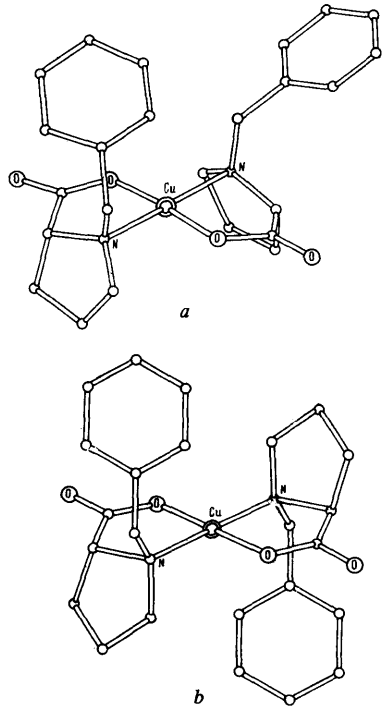
In the presence of copper ions, for example, a sorbent obtained by reaction between L-proline (or L-hydroxyproline) and a chloromethylated macrocellular styrene copolymer forms considerably more stable mixed complexes with D-than with L-amino-acids[44]:



If the mobile ligands are D- and L-proline, the difference in their free energies of sorption reaches $\delta\Delta G^\circ$ = 0.45 kcal

mole^{-1} (determined under static conditions)[45,46]. The simplicity and great sensitivity of ligand-exchange chromatography enabled thermodynamic enantioselectivity to be detected in many labile complexes of bi- and ter-dentate amino-acids, hydroxy-acids, amino-alcohols, and other compounds[47,48].

The presence of enantioselectivity in solutions of complexes of several bifunctional amino-acids with copper was then demonstrated also by classical methods. Davankov et al. first studied complexes of *N*-benzylproline as a model of the unit in the dissymetric sorbent used. Potentiometric titration indicated[49,50] that an equilibrium is established with *N*-benzyl-DL-proline in aqueous solution, in which the concentration of the *meso*-complex [Cu(*N*-$C_6H_5CH_2$-D-Pro)(*N*-$C_6H_5CH_2$-L-Pro)] exceeds that of each of the two homogeneous complexes by factors of 14 ± 4. This corresponds to a degree of enantioselectivity of complex formation α_{sel} = 75%, or $\delta\Delta G^\circ$ = 1.15 kcal mole^{-1}. The poorer stability of the homogeneous structure [Cu(*N*-$C_6H_5CH_2$-L-Pro)$_2$] is conclusively supported by spectrophotometric investigations and by polarimetric titration, the latter of which can also be used[50] to calculate α_{sel}. X-Ray examination of the complexes[51-54] suggests that the benzyl radicals tend to occupy apical positions in the coordination sphere of copper, which is possible (see diagram) for both ligands only if they differ in configuration[54].



Structures of the complexes: *a*) [(*N*-$C_6H_5CH_2$-L-Pro)$_2$Cu]; *b*) [(*N*-$C_6H_5CH_2$-D-Pro)(*N*-$C_6H_5CH_2$-L-Pro)Cu].

The enantioselectivity of formation of copper complexes of amino-acids is a consequence of unequal interaction between the two ligands in the structures [Cu(D-Aa)(L-Aa)] and [Cu(L-Aa)$_2$]. Such interaction can occur by direct contact between individual fragments of the ligands (as in the *N*-benzylproline complexes), through solvent molecules coordinated in axial positions, or finally through the solvent sheath (outer coordination sphere). Interligand interactions may lead to distortion of the chelate unit of the complex, which is clearly apparent in a difference between the electronic spectra of [Cu(L-Aa)$_2$] and [Cu(D-Aa)(L-Aa)], or distortion of the conformation of the ligands and purchasing of the five-membered chelate rings. If such distortions occur in the optically active complex [Cu(L-Aa)$_2$], they can easily be detected by comparing its optical rotatory dispersion or circular dichroism spectra with those of the mixed complex with glycine [Cu(L-Aa)Gly]. The intensity ratio of these spectra is exactly 0.5 (without displacement of the maxima) only in the absence of distortion in the [Cu(L-Aa)$_2$] structure. This method has been used to investigate complexes of alanine, valine, proline, and hydroxyproline (Hypro) containing various combinations of methyl and benzyl substituents in the amino-group[55]. Maximum interligand interactions (and hence stereoselective effects) are observed in complexes of amino-acids containing two substituents in the amino-group, e.g. in complexes of *N*-benzylproline, *N*-benzyl-*N*-methylalanine, and hydroxy-*N*-methylproline.

Transmission of interligand interactions through axially coordinated water molecules must be adduced e.g. to explain why the complex [Cu(*N*-$C_6H_5CH_2$-L-Pro)(L-Pro)] is less stable than [Cu(*N*-$C_6H_5CH_2$-L-Pro)(D-Pro)]. The value $\delta\Delta G^\circ$ = 0.9 ± 0.2 kcal mole^{-1} calculated for this system from the circular dichroism spectra[56,57] agrees satisfactorily with ligand-exchange sorption data[45].

Solvation of the complexes also has a very considerable influence on interligand interactions, until the sign of the enantioselective effect is reversed on passing from one solvent to another[58]. The first example of the successful study of the influence exerted on enantioselective effects by the structure of the outer coordination sphere may well be an investigation[59] of the e.s.r. spectra of the [Cu(*N*-$C_6H_5CH_2$Pro)$_2$] complexes in methanol and in a chloroform–toluene mixture.

The work of Davankov, Rogozhin, and Kurganov has shown that enantioselectivity is extremely widespread in the copper complexes of α-amino-acids, but only after thorough investigation by potentiometric and polarimetric titration, spectrophotometry, circular dichroism, etc. can the presence or absence of enantioselectivity in a particular system be stated with certainty. The most sensitive method, however, is ligand-exchange chromatography.

Bernauer et al.[60] used this method to show that the chiral complex of iron(III) with 2′-hydroxyethyl-D-propylenediaminetriacetic acid L-[Fe(D-HEPDTA)]$^-$ forms mixed complexes more readily with the D-isomers of acetyl and benzoyl derivatives of leucine, alanine, phenylalanine, and methionine (Met) than with their enantiomers ($\delta\Delta G^\circ$ falls in this sequence from 0.10 to 0.02 kcal mole^{-1}). In the reaction of the (–)- and (+)-isomers of α-methylbenzylamine with the copper, nickel, and zinc complexes of D(–)-propylenediaminetetraacetic acid $\delta\Delta G^\circ$ reaches 0.3 kcal mole^{-1} [61] (investigation of the same system by partition between water and heptane gives $\delta\Delta G^\circ \simeq 0.14$ kcal mole^{-1}). Thus enantioselectivity is revealed even with unidentate ligands, which probably replace one of the acetate groups in the complexes of the above multidentate ligands.

Angelici and his coworkers have made a series of studies on the enantioselectivity of complex formation by α-amino-acids whose amino-group contains substituents

tending to coordinate with a metal, e.g. the carboxymethyl (Cm) and pyrid-2-ylmethyl (Pc) groups. Potentiometric titration showed[62] that *N*-carboxymethyl-L-valine forms somewhat more stable mixed copper complexes with L-leucine, L-phenylalanine, L-alanine, L-serine, D-valine, and L-leucine ethyl ester than with their enantiomers. *N*-Carboxymethyl derivatives of L-isoleucine (Ileu), L-serine, *N*-benzyl-L-alanine, and *N*-benzyl-L-leucine also form mixed copper complexes preferentially[63] with the L-isomers of valine, leucine, and threonine. *N*-Carboxymethyl-L-aspartic and *N*-carboxymethyl-L-glutamic acids, on the other hand, show greater affinity for the D-isomers of amino-acids. The authors attempted to explain the observed effects by the *cis*-structure of the bisamino-acid complex of copper, in which the *N*-carboxymethyl group occupies an axial position[63]. However, X-ray examination has shown[64] that the carboxymethyl group in the complex $[Cu(N\text{-Cm-L-Val})(H_2O)_2]$ is situated in the main plane of coordination. It is equally difficult to explain the fact that *N*-pyrid-2′-ylmethyl-L-aspartic acid and its *N*-6′-methylpyrid-2′-ylmethyl analogue form more stable mixed copper (and nickel) complexes with the L-enantiomers of alanine, phenylalanine, tryptophan (Try), threonine, leucine, and valine[65]. The situation is somewhat clearer with the bis-complexes of nickel and cobalt(II) with the *N*-*o*-hydroxybenzylalanine, where the homogeneous structures are more stable (Table 2). All three donor atoms of this ligand are clearly located in the same plane [sic], but nevertheless Ritsma[30] is rightly cautious in interpreting interligand interactions in its complexes.

Enantioselective effects obviously result from the action of many factors, whose contributions are at present still difficult to assess. Only detailed and comprehensive investigation will enable enantioselectivity to be explained even in the simplest systems, e.g. the fact that with *N*-benzylvaline the homogeneous complex $[Cu(N\text{-}C_6H_5CH_2\text{-L-Val})_2]$ is the most stable[58], where as with *N*-benzyl-D-proline, in contrast, the *meso*-structure $[Cu(N\text{-}C_6H_5CH_2\text{-D-Pro}).(N\text{-}C_6H_5CH_2\text{-L-Pro})]$ is the more stable.

2. Kinetic Effects

In an interesting case of kinetic enantioselectivity reported by Hix and Jones[66] catalysis of the alkaline hydrolysis of a histidine ester by histidinatonickel(II) is preceded by formation of the mixed complex $[NiHisHisOCH_3]^+$. The overall rate of hydrolysis is 40% lower when histidine and its ester have the same configuration than when the ligands have opposite configurations. The bidentate ligand $HisOCH_3$ can add to the complex $[NiHis]^+$ in six different ways, but only in one case—with the ligands having opposite configurations—can the preferred *trans*-structure be formed with the ester group in a position favourable for coordination. Since thermodynamic enantioselectivity is not observed in a mixed complex, the differences in rates of hydrolysis result from coordination of the ester carbonyl. It is significant that enantioselectivity is absent if complexes of histidine with copper are used for catalysis[67,68]: the coordination number 4 of copper ions leaves no vacant positions for the coordination of ester groups.

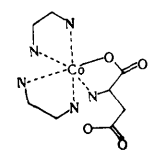
Blackburn and Jones[69-71] extended study of catalysis of the hydrolysis of amino-acid esters by complexes of nickel with amino-acids to another seventeen different systems, but only in one system $[NiTryHisOCH_3]^+$ was appreciable enantioselectivity found. Nevertheless, Angelici[62] observed that the complex $[Cu(N\text{-Cm-L-Val})]$ catalyses hydrolysis of the methyl esters of D-leucine and D-phenylalanine rather more strongly than that of the L-isomers. Similar though smaller effects were observed in catalysis by the copper complex of *N*-carboxymethyl-D-phenylglycine.

A difference (2–4-fold) has been observed in the rates of hydrolysis of the methyl esters of D- and L-phenylalanine in the presence of a copper complex of poly-L-lysine. The catalytic effect becomes stronger with increase in the molecular weight of the polymer. It is supposed[72,73] that at pH 7 hydrolysis is catalysed in a mixed complex, which is more easily formed with D-phenylalanine. Finally, there are indications[74] that the ethyl ester of L-phenylalanine is hydrolysed more rapidly in the presence of *trans*-$[CoCl_2(l\text{-pn})_2]Cl$ than in the presence of its enantiomer *trans*-$[CoCl_2(d\text{-pn})_2]Cl$. The mechanism of this process is quite complicated, and the stage at which stereoselective effects develop is difficult to assess.

In 1929 Shibata and Tsuchida[75] discovered that the laevorotatory complex $[CoClNH_3en_2]^{2+}$ accelerates selectively the oxidation of L-3′,4′-dihydroxyphenylalanine (dopa). Although a subsequent check[76] on this report has not shown the presence of enantioselectivity, but has merely established a general catalytic effect by the complex independent of its configuration, the enantiomers of dopa are in fact oxidised at different rates in the presence of a mixed copper complex of protoporphyrin with L-histidine or with its cyclic dimer[77] and also in the presence of a copper complex of poly-L-lysine[78-80].

A special group of kinetically enantioselective processes are involved in the formation of inert complexes of cobalt(III) from compounds of which one is a racemate, while the other is optically active. Enantiospecificity is usually also observed in these processes. Unfortunately, most authors omit both a detailed analysis of the stereochemical features of these reactions and also the important experimental data (e.g. conversion and yield of product) required for much analysis.

The fact that the Λ-isomers of the complexes are the first to react when L-glutamic acid interacts with racemic $\Delta\Lambda$-$[CoCO_3en_2]ClO_4$[81] and with racemic $\Delta\Lambda$-$[Co(H_2O)_2en_2].(ClO_4)_3$[82] must be regarded as a case of kinetic enantioselectivity. The preferentially formed Λ-$[Co(L\text{-Glu})en_2].ClO_4$, furthermore, is sparingly soluble, and separates in optically pure form. Analogous enantioselectivity is observed when *d*-tartaric acid is used[81,82] instead of L-glutamic acid, but is absent when bidentate amino-acids[81,83] and lactic acid[81] are employed. Gillard and his coworkers[81,82,84] attributed this to three-point interaction of L-glutamic acid with the complex by formation of a hydrogen bond between the γ-carboxyl and an amino-group of ethylenediamine, which is possible only when the complex itself has the Λ-configuration:



However, X-ray examination has shown[83] that such a hydrogen bond is not formed, at least in the crystalline state.

Even the fact of kinetic enantioselectivity in the systems studied by Gillard has since been subjected to criticism[85,86]. The proportions of Λ- and Δ-complexes in the final equilibrium mixtures from the reactions of $\Delta\Lambda$-$[CoCO_3en_2]^+$ with L-glutamic and L-aspartic acids in the presence of

activated carbon were found to be 70 : 30 for $[Co(L\text{-}Glu)en_2]^+$ and 60 : 40 for $[Co(L\text{-}Asp)en_2]^+$. The observed effects are regarded [85] as thermodynamic in character. From a check on these results and study of the alkaline epimerisation of L-glutamic acid in the final complex it has been concluded [86] that no selective or specific effects occur in this system at all.

The absence of kinetic enantioselectivity in the interaction of racemic *cis*-bisethylenediaminecobalt(III) with optically active alanine [81-83], leucine, and phenylalanine [83] is fully consistent with the absence of enantiospecificity observed earlier [87] in the formation of a chiral configuration of cobalt on the reaction of symmetrical *trans*-$[CoCl_2en_2]Cl$ with the L-isomers of these amino-acids.

Among the 24 possible structures each containing 2 amino-acid residues which may result from the reaction of a hexanitrocobaltate(III) with DL-alanine, only the 4 complexes

$(+)_{589}[Co(L\text{-}Ala)_2(NO_2)_2]^-$ $(+)_{589}[Co(D\text{-}Ala)_2(NO_2)_2]^-$
$(-)_{589}[Co(L\text{-}Ala)_2(NO_2)_2]^-$ $(-)_{589}[Co(D\text{-}Ala)_2(NO_2)_2]^-$

are formed stereospecifically [88]. In the main coordination plane they contain two carboxylate anions and two nitro-groups in *cis*-positions [89]. Enantioselectivity is apparent in this system in the identical configuration of the two amino-acid residues in each structure. The enantiospecificity of complex formation is less marked: the two L-alanine molecules produce only slight predominance of the $(-)_{589}$-complex over the $(+)_{589}$-structure.

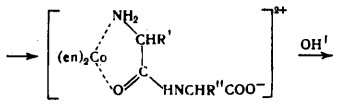
A very complicated mixture of complexes $[CoAla_{3-n}(L\text{-}Asp)_n]^{n-}$ (n = 0–3) is formed by the reaction of $[Co(CO_3)_3]^{3-}$ with L-aspartic acid and DL-alanine in the presence of activated carbon [90]. Here selective and specific effects should be examined separately for each group of structures. The mer-Λ-structures of the complexes $[CoAla(L\text{-}Asp)_2]^{2-}$ contain mainly L-alanine, but the fac-Δ-structures contain D-alanine. The analysis for a system containing L-proline and D- or L-aspartic acid is just as complicated [91].

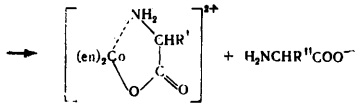
Contrary to expectation, enantioselectivity has not been found in the kinetically controlled reaction of L-proline with racemic β-$[CoOH(H_2O)trien]^{2+}$ or with its dichloro-analogue [92-94]: in both cases roughly equal quantities of Δ- and Λ-isomers of β_2-$[Co(L\text{-}Pro)trien]^{2+}$ are formed. X-Ray examination has shown [93,95] that steric interactions between ligands are in considerable measure eliminated by distortion of the angles of the coordination octahedron.

Nor have departures from a random distribution of complexes been observed in the reaction of *trans*-*NN'*-ethylenebisacetylacetoniminatodiaquocobalt(II) with DL-alanine, DL-valine, and DL-α-methylbenzylamine respectively [96]. In the final complexes two unidentate amino-acid ligands coordinated through the amino-groups occupy *trans*-positions in the coordination octahedron, and are unable to influence each other.

Nor is kinetic enantioselectivity observed in the reaction of the dipeptide L-leucylglycine with racemic $[CoOH(H_2O)en_2]^{2+}$. [97] If, on the other hand, an L-amino acid is a *C*-terminal group, as e.g. in glycyl-L-phenylalanine and glycyl-L-tyrosine, such a dipeptide reacts with the Δ-isomer of the complex twice as rapidly as with the Λ-enantiomer:

$$[Co(en)_2(H_2O)(OH)]^{2+} + H_2NCHR'CO{-}HNCHR''COO^- \longrightarrow$$





However, the dipeptide L-leucyl-L-tyrosine, which contains two L-amino-acids, reacts almost exclusively with the Λ-complex [97]. (It may be mentioned here that thermodynamic enantioselectivity has not been observed in the copper complex of glycylphenylalanine [98].)

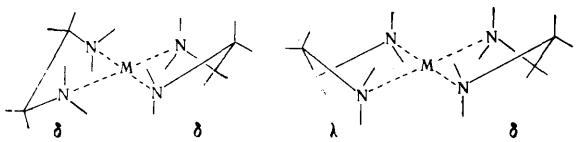
IV. COMPLEXES OF DIAMINES AND THEIR DERIVATIVES

Enantioselective effects were discovered considerably earlier in diamine complexes than in amino-acid complexes. In 1920 Smirnoff [99] detected only the two complexes Δ-$[Pt(l\text{-}pn)_3]^{3+}$ and Λ-$[Pt(d\text{-}pn)_3]^{3+}$ in the products of the reaction of platinum(IV) salts with *dl*-propylenediamine: i.e. the reaction occurred with complete enantioselectivity and enantiospecificity. Analogous situations were found in the formation of complexes of cobalt(III) with propylenediamine [100] and of cobalt(III) and rhodium(III) with cyclopentane-*trans*-1,2-diamine (cpn) [101]. The instability of complexes containing ligands differing in configuration is confirmed by their ease of disproportionation into homogeneous structures. For example, only Λ-$[Co(d\text{-}cpn)_3]^{3+}$ and Δ-$[Co(l\text{-}cpn)_3]^{3+}$ are formed by the action of *l*-cyclopentanediamine on Λ-$[CoCl_2(d\text{-}cpn)_2]^+$. [101,102] High selectivity is already observed at the stage of formation of the bis-complexes. Thus the oxidation of cobalt(II) in the presence of *dl*-cyclopentanediamine leads to the formation of *trans*- or *cis*-$[CoCl_2(d\text{-}cpn)_2]^+$ and $[CoCl_2(l\text{-}cpn)_2]^+$, but not that of $[CoCl_2(d\text{-}cpn)(l\text{-}cpn)]^+$. [101,103] The results of these investigations led Jaeger [104] to the conclusion that complexes of mixed structure are not in general stable, while the optical configuration of the metal atom is determined unambiguously by the configuration of the ligand.

However, the formation of diamine complexes does not always follow this rule strictly. Thus Werner [105] was able to obtain all eight theoretically possible isomers of $[Co(NO_2)_2enpn]^+$. Both possible isomers Δ- and Λ-$[Co(l\text{-}cpn)en_2]Cl_3$ are also formed by the action of *l*-cyclopentanediamine on ΔΛ-*cis*-$[CoCl_2en_2]Cl$, although only two of the four possible structures—Δ-$[Co(l\text{-}cpn)en_2]^{3+}$ and Λ-$[Co(d\text{-}cpn)en_2]^{3+}$—are formed enantioselectively by racemic *dl*-cyclopentanediamine [101,106]. Thus kinetic enantioselectivity, which undoubtedly occurs in the formation of octahedral tris-complexes with diamines, may remain unnoticed, as occurs in the first case, where the reaction conditions constrain *l*-cyclopentanediamine to react not only with Δ-$[CoCl_2en_2]^+$ but also with its Λ-enantiomer. Reaction of *d*-tartaric acid with both enantiomers of $[CoCO_3en_2]^+$ can be achieved in just the same way [107,108], although the Δ-isomer is the first to react [108], forming Δ-$[Co(d\text{-}tart)en_2]^+$. Both isomers of *dl*-tartaric acid can be made to react with Δ-$[CoCO_3(l\text{-}pn)_2]^+$, [109] whereas, when excess of tartaric acid is used, the complex reacts selectively with *d*-tartaric acid to form stable Δ-$[Co(d\text{-}tart)(l\text{-}pn)_2]^+$. [110] Its less stable diastereomer Δ-$[Co(l\text{-}tart)(l\text{-}pn)_2]^+$, being in contact with excess of the *dl*-acid, exchanges its acid ligand selectively for *d*-tartrate, so that the uncomplexed tartaric acid is considerably enriched with the *l*-enantiomer [110,111]. Similarly Δ-$[CoCO_3(l\text{-}pn)_2]^+$ prefers to exchange its carbonate ligand for the (−)-enantiomer of α-chloro- or α-bromo-propionic acid and for the (−)-lactate ion [110], which can be used for the partial resolution of racemates of these acids. On the

other hand, optically active lactic acid resolves the racemate of $[CoCO_3en_2]^+$, undergoing ligand exchange only with one isomer [112]. Nevertheless, appreciable enantioselectivity was not observed [106] in the exchange of Δ-$[CoCO_3(l\text{-pn})_2]^+$ with DL-alanine.

Corey and Bailar in their classic paper [12] made a conformational analysis of the complexes of diamines in order to elucidate the causes of the enantioselective and enantiospecific effects. Since the angle in a complex is only 86–88°, the theory of these workers indicates that the five-membered chelate ring should be puckered considerably more strongly than the cyclopentane ring, and there should be a clear difference between equatorial and axial positions for substituents. Interaction between the two chelate rings occurs through the hydrogen atoms of the chelated amino-groups. In square planar structures this interaction is about 1 kcal mole^{-1} smaller with the same conformation of the two rings, e.g. $\delta\delta$, than in a *meso*-structure, e.g. $\delta\lambda$



The difference in energy in tetrahedral structures is rather smaller. In octahedral tris-complexes interaction between the three rings is minimal when they have the same configuration: $\delta\delta\delta$- and $\lambda\lambda\lambda$-conformations of the rings are preferred respectively for the Λ- and Δ-configurations of chiral tris-complexes. The energy of the isomeric complexes increases by 1.8 kcal mole^{-1} in the sequence

$$\Lambda[\delta\delta\delta] < \Lambda[\delta\delta\lambda] < \Lambda[\delta\lambda\lambda] < \Lambda[\lambda\lambda\lambda] .$$

Interaction between chelate rings and a tendency for substituents to occupy an equatorial position may lead to the appearance of enantioselective effects in complexes of substituted 1,2-diamines. In tetrahedral and in octahedral *cis*-biscomplexes, as well as in octahedral tris-structures, moreover, enantiospecific formation of the configuration of the metal atom itself must be expected.

Satisfactory agreement with theory has since been found [95,113] in experimental verification of the views developed by Corey and Bailar. Dwyer, Sargeson, et al. made a detailed study of complex formation by cobalt(III) [114–119] and platinum(IV) [120,121] with propylenediamine. In contrast to earlier investigations, they discovered the existence of complexes containing ligands differing in configuration [117, 118,121] and even the formation of diastereomeric pairs of tris-*l*-propylenediamine [117,114,120,121]. On the hypothesis that thermodynamic equilibrium is established among all structures in the reaction mixture with cobalt(III) complexes in the presence of activated carbon, the authors calculated the differences in their free energies, which reached 1.6 kcal mole^{-1}, close to the values calculated by Corey and Bailar (Table 3).

Closely similar values have been obtained [122] by cobalt-59 nuclear magnetic resonance spectroscopy, which enables the composition of a mixture of trispropylenediaminecobalt(III) complexes to be analysed. The same method shows that, in the presence of activated carbon, equilibrium is displaced towards statistically more probable though energetically less favourable structures. However, it remains unproven whether carbon enables true equilibrium to be established. Diastereomers may well possess different sorbabilities of carbon, but hence also different rates of conversion. In any case it is clear that in this system kinetic enantioselective and enantiospecific effects differ from thermodynamic effects.

A more detailed study has begun of the composition of complexes of cobalt(III) and chromium(III) with cyclopentane-*trans*-1,2-diamine [123] and of cobalt(III) with cyclohexane-*trans*-1,2-diamine (chn) [95].

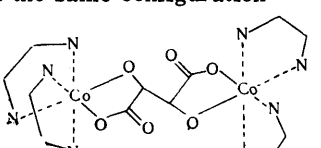
Table 3. Differences in Gibbs free energies $\delta\Delta G^\circ$ (kcal mole^{-1}) of diastereomers of complexes of cobalt(III) with propylenediamine.

Complex	Diastereomers		$\delta\Delta G^\circ$	Ref.
$[Co(l\text{-pn})(C_2O_4)_2]^-$	Λl	Δl	0.27	116
$[Co(l\text{-pn})_2(C_2O_4)]^+$	Λll	Δll	0.20	116
$[Co(en)_2(pn)]^{3+}$	Λl	Δl	0.45	117
$[Co(en)(pn)_2]^{3+}$	Λll	Δll	1.2	117
$[Co(pn)_3]^{3+}$	Λlll	Δlll	1.6	117
	Λddl	Λddd	0	118
	Δddl	Λddl	0.52	118
	Λlll	Λdll	0.53	118

The conformational ideas of Corey and Bailar have since been re-examined by Gollogly and Hawkins [124,125], who conclude that the chelate ring of a 1,2-diamine can assume many energetically similar conformations and that the $\Lambda(\delta\delta\delta)$ structure for $[M\,en_3]$ is more favourable than $\Lambda(\lambda\lambda\lambda)$ by at most 0.85 kcal mole^{-1}, while there is hardly any difference in energy between the $(\lambda\delta)$- and $(\delta\delta)$-structures for the *trans*-biscomplex. This last conclusion is consistent with the absence of thermodynamic enantioselectivity in complexes of propylenediamine, cyclohexane-*trans*-1,2-diamine, butane-2,3-diamine, and stilbenediamine with copper and nickel [126,127]. This unexpected result was obtained by calorimetric, potentiometric, and spectrophotometric methods.

Good examples of kinetic enantioselectivity are the reactions of $\Lambda(+)_{5461}$-$[CoEDTA]^-$ [128] and $\Lambda(-)_{5461}$-$[Co(+)\text{-PDTA}]^-$ [129] with racemic *dl*-propylenediamine, resulting in the formation of $\Lambda(+)$-$[Co(d\text{-pn})_3]^{3+}$, while the optically pure *l*-diamine remains in solution, since it does not undergo ligand exchange. When racemic $[CoEDTA]^-$ is treated with optically active *l*-propylenediamine, on the other hand, only the Δ-complex undergoes exchange [128].

A molecule of *d*-tartaric acid, on reacting in acid medium with racemic $\Delta\Lambda$-$[CoCO_3en_2]^+$, at once replaces carbonate ions in two complexes, always selecting a pair of complexes of the same configuration [108,130], e.g.



Enantioselectivity was unexpectedly high in electron transfer from $[Cr\,phen]^{2+}$ to $[Co\,phen_3]^{3+}$, where "phen" denotes 1,10-phenanthroline. When Λ-$[Co\,phen_3]^{3+}$ was used as oxidant, the racemic chromium complex yielded Δ-$[Cr\,phen_3]^{3+}$ of optical purity 92%. [131] A possible explanation is that only Δ-$[Cr\,phen_3]^{2+}$ undergoes oxidation, while the Λ-enantiomer is rapidly racemised. Very slight (1–2%) enantioselective effects have been observed [132] on the exposure of $[CrC_2O_4phen_2]^+$, $[Cr(C_2O_4)_2phen]^-$, and $[Cr\,bipy_3]^{3+}$ to the circularly polarised beam of an argon laser. The rates of isomerisation of enantiomers are

obviously different under these conditions. Ordinary light has a similar effect on the complex $[Cr\,phen_3]^{3+}$ if antimony *d*-tartrate is present in solution[133].

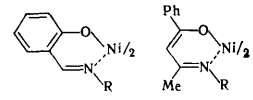
The Pfeiffer effect, first discovered in complexes of zinc with phenanthroline and with bipyridyl[135], is closely connected with enantioselective phenomena[134]. Three principal aspects—asymmetric induction, asymmetric transformation, and asymmetric synthesis—are distinguished at the present time[136], among which the first process has no connection with stereoselectivity. Asymmetric transformation involves a displacement, under the influence of an optically active compound, of the equilibrium between two labile enantiomers[137]. With the racemate of *cis*-$[CoCl_2en_2]^+$ in (−)-butane-2,3-diol, for example, the proportions of (+)- and (−)-isomers become 4 : 1.[138] The *trans*-$[CoCl_2en_2]^+$ complex can exist as three conformers (δδ, δλ, λλ), one of which is a *meso*-structure, while the other two are enantiomers distinguished by opposite puckering of the chelate rings. One of these chiral forms is stabilised in the optically active solvent, and the complex exhibits the Cotton effect[136]. A similar explanation applies to the appearance of Cotton effects with *cis*-$[CrCl_2en_2]^+$ and *cis*-$[CoCl_2trien]^+$ in (−)-butane-2,3-diol[136], with trisphenanthroline complexes of nickel, zinc, and cadmium in the presence of *l*-lactic acid[139,140] and of mercury in that of dibenzoyl-*d*-tartaric acid[139], and with $[Ni\,bipy_3]^{2+}$ in the presence of *l*-lactic acid[140]: the asymmetrising action of the optically active component is attributed to the difference in energy of its interaction (solvation or association) with the enantiomers of the complex. In the case of the diastereomeric ion-pairs of $[Ni\,phen_3]^{3+}$ with *d*-α-bromocamphorsulphonic acid this difference is $\Delta\delta G^\circ = 0.07$ kcal mole^{-1}.[141] Such considerable enantioselective effects with complexes are explained by the inclusion of the optically active component in the outer coordination sphere. In individual cases a chiral solvent may probably play a direct part in ligand exchange, as in the dissolution of *cis*-$[CoCl_2en_2]^+$ in *l*-propane-1,2-diol, which replaces chloride ions predominantly in the Λ-complex[142].

In the case of the Pfeiffer effect asymmetric synthesis implies the conversion of a non-chiral compound into an optically active structure. For example, the complex *trans*-$[CoOHCl\,en_2]^+$, which dissolves in (−)-butane-2,3-diol when heated to 70 °C, exhibits absorption and circular dichroism spectra identical with those of the optically active *cis*-$[CoOHCl\,en_2]^+$ in aqueous–methanolic solution. The degree of enantiospecificity of this isomerisation is evidently quite high[136].

A difference in the interaction of two enantiomeric complexes with an optically active solvent may also be evident in a difference in solubility[138]. The presence of an optically active con ponent in solution may change significantly the diffusion constants of the enantiomers[143–145]. Enantioselectivity in the association processes underlying such phenomena was demonstrated on the systems formed by *d*-tartaric acid with the enantiomers of $[Co\,en_3]^{3+}$[146] and by the enantiomeric tartaric acids with Λ-$[Co(d\text{-}pn)_3]^{3+}$.[147]

V. COMPLEXES OF SCHIFF BASES

Less detailed study has been made of enantioselective phenomena in complexes of Schiff bases. Fundamental investigations were made by Holm and his coworkers, who showed[148–151] that an equilibrium is established between tetrahedral and square planar forms of bis-complexes of Schiff bases with nickel(II) in non-coordinating solvents. The position of equilibrium depends mainly on the size and type of radical R attached to the nitrogen atom. Since the square planar form is diamagnetic, while the tetrahedral form is paramagnetic, signals from the two forms are easily distinguishable in the nuclear magnetic resonance spectrum. In the latter case the signals from *meso*-structures and optically active molecules, formed when a racemic Schiff base is used, can also be distinguished. Three pairs of diastereomers

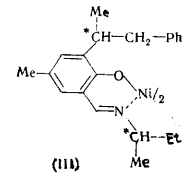


(I) (II)

are then formed, but complexes with optically active ligands give only one series of signals owing to rapid inversion[151,152] of the tetrahedral configuration $\Delta \rightleftharpoons \Lambda$.

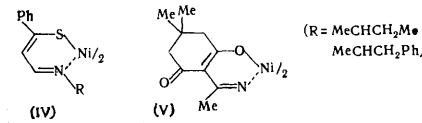
$$\Delta(ll),\ \Delta(dd),\ \Delta(ld) \equiv \Lambda(dd),\ \Lambda(ll),\ \Lambda(dl).$$

With *NN'*-disubstituted disalicylideniminatonickel(II) complexes (I: R = $CH_3CH_2CH(CH_3)$ or $C_6H_5CH_2CH(CH_3)$) the total concentration of *meso*(*dl*)-complexes (in square planar and tetrahedral forms) is roughly double the total concentration of each of the optically active structures[149,151]. With the *meso*-structure, however, the equilibrium is shifted further towards the tetrahedral form than with the optically active structures[148–152]. This difference is especially marked with nickel and zinc complexes of types (I) and (II) having a bulky substituent attached to nitrogen (R = $C_6H_5CH(CH_3)$): in this case the tetrahedral *meso*-complexes are more stable than the tetrahedral optically active structure by 0.08 kcal mole^{-1}.[152]



(III)

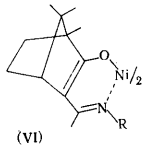
Six pairs of diastereoisomers may be formed by tetrahedral complexes of the Schiff base (III), which contains two asymmetric atoms[153]. Signals characteristic of each pair have been observed in the nuclear magnetic resonance spectrum, and the free energy of interconversion of planar square into tetrahedron has been determined from the temperature dependence of the signals. As in the preceding cases, the *meso*-structures of the complexes show a greater preference for the tetrahedral form than do the optically active complexes, the difference in the free energies of transition amounting to 0.3–0.4 kcal mole^{-1}. The considerable difference in the equilibrium positions is apparent in enhanced extinction and enhanced magnetic susceptibility of a solution of the complexes obtained from the racemic ligand in comparison with a solution of the optically active complex[153].



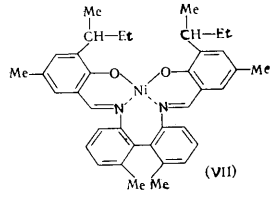
(IV) (V) (R = MeCHCH$_2$Me, MeCHCH$_2$Ph)

This difference is still larger in nickel complexes of γ-imino-thiols (IV).[154,155] When R = $C_6H_5CH_2CH(CH_3)$, the magnetic moments determined for complexes of the racemic and optically active ligands are respectively 2.40 and 2.08 β, whence the magnetic moment of the pure *meso*-form was calculated as 2.68 ± 0.12 β. The difference in

the free energies of interconversion of planar square into tetrahedron for *meso*-structure and optically active complex is 0.7 kcal mole^{-1}, so that the equilibrium proportions of the corresponding tetrahedral form are respectively 77% and 54%.[155] Considerably smaller effects are observed in *N*-substituted 2-acetiminodimedonato-complexes (V), where square planar forms predominate with both *meso*-structures and optically active bis-complexes[156]. The opposite situation is found in nickel complexes of *N*-alkylated aminomethylenecamphors (VI), where the equilibrium for the optically active complexes—but not for the *meso*-structures—is displaced further towards the tetrahedral form[157,158]. Thus, in a large number of bis-complexes of Schiff bases with nickel ions, enantioselectivity is apparent in a difference in stability ratios of square planar and tetrahedral forms between *meso*-complexes and the two optically active complexes.



(VI)



(VII)

An interesting case of the enantioselective solvation of complexes of quadridentate Schiff bases (VII) has been described by Ernst et al. In such complexes the Δ or Λ configuration at the metal atom is determined unambiguously by the configuration of the atropoisomeric ligand, and equilibrium between planar and tetrahedral structures is established without racemisation of the complex[159]. In non-chiral solvents the n.m.r. spectrum contains signals from three pairs of diastereomers, but signals from all the enantiomers—Δ(*ll*) and Λ(*dd*), Δ(*dd*) and Λ(*ll*)—can also be distinguished in chiral solvents. If, however, the solvent used is not 100% optically pure, the splitting of the signals observed initially from these diastereomeric pairs gradually disappears (with pinene of optical purity 90% in about 1 h). This unusual pattern was explained[160] by selective solvation of the Δ(or Λ)-isomers of the complex by *d*(or *l*)-pinene, with the formation now of the enantiomeric, n.m.r.-equivalent pairs Δ*d* and Λ*l*. Initially both Δ- and Λ-isomers are more strongly solvated by the solvent enantiomer present in excess, but the spectrum contains signals of the two pairs of enantiomers. With the establishment of equilibrium Δ- and Λ-enantiomers undergo enantioselective solvation, and the splitting of their signals disappears.

Complexes of Schiff bases obtained from pyridoxal and α-amino-acids have aroused considerable research interest in connection with their important role in biological transaminations. Complexes of zinc and aluminium with alanine derivatives[161] and of aluminium with derivatives of serine[162,163], alanine, leucine, threonine, α-aminobutyric acid, and norvaline[163] have been studied by n.m.r. spectroscopy. Octahedral complexes containing two planar terdentate ligands exist as three diastereomeric pairs. The homogeneous diastereomers of the optically active L-serine derivative differ by about 0.9 kcal mole^{-1} in energy; the *meso*-complex occupies an intermediate position with respect to stability[162]. Appreciable enantioselectivity has not been observed in complexes of the Schiff base of alanine: the quantities of the *meso*-structure and of optically active complexes in the equilibrium solution are roughly the same[161].

Nevertheless, Holm[152] reported the presence of enantioselectivity in the zinc and nickel complexes of the Schiff bases obtained from esters of alanine and phenylalanine with salicylaldehyde. Different properties have also been found[164] in copper complexes of *N*-salicylidene derivatives of aspartic acid. The greater stability of the homogeneous structure than of the *meso*-structure was shown by polarimetric titration for the copper complexes of Schiff bases of salicylaldehyde and α-methylbenzylamine[165].

When a chiral ketone (*S*-2-hydroxy-6,6′-dimethyl-2′-nitro-5-nitrosodiphenyl) is used to catalyse the racemisation of D- and L-alanine in the presence of copper ions, some difference (3–5%) is observed in the rates of racemisation of the enantiomers. Racemisation probably takes place in a complex of the resulting Schiff base[166].

VI. COMPLEXES WITH OTHER LIGANDS

The first communication on enantioselectivity in complexes probably appeared as early as 1900, when copper complexes of *dl*-tartaric acid were found[167] to be more stable than those of the optically active acid. It has been observed also that the solution obtained by mixing equal quantities of complexes of *l*- and *d*-tartaric acids absorbs light 19% more strongly than does either of the initial solutions[168–171]. In acid medium only monotartratocopper was detected, its formation constant being the same for *l*- and *dl*-tartaric acids[172,173]. More detailed investigations of this system showed that differences arise in alkaline solution, where polynuclear complexes are formed[171], whose composition is different with *l*- and with *dl*-tartaric acids. Electron spin resonance data[174] and X-ray diffraction[175] also indicate that the complexes are dinuclear.

The vanadyl ion also forms more stable complexes with *dl*-tartaric acid than with the optically active acid[171,176]. Both e.s.r. data[176] and X-ray examination[177] show that the complex is dinuclear and that steric interactions are smaller if the ligands differ in configuration[177]. The absorption spectra of complexes of VO^{2+} with *dl*- and *l*-tartaric acids also differ sharply[176], the former being red–brown in colour, and the latter violet. A difference is apparent also in resistance to oxidation[178], although the oxidation products are the same with the two complexes. A detailed survey has been made of the stereochemistry of dinuclear complexes of tartaric acid[179]. Stereoselectivity of formation of tartaric-acid complexes has been observed also with nickel[180] and antimony(III),[181] structures containing two ligands of the same configuration being the more stable here.

In the case of eight-coordinated zirconium(IV) and hafnium(IV) complexes, *dl*-hydroxy-acids (mandelic, lactic) ensure better formation of hydrogen bonds than do optically active ligands, whose complexes are less stable[182].

Different equilibrium positions and different activation energies of the transition between planar square and tetrahedron have been found for bis-complexes of nickel and cobalt(II) with racemic and optically active phosphines[183]. Considerable enantioselectivity develops in bis-complexes of nickel with penicillamine (ββ-dimethylcysteine), where the optically active structures are more stable than the *meso*-structure by 0.55 kcal mole^{-1}. These diamagnetic complexes probably have a square planar structure with a paired *cis*-arrangement of β-thiol and α-amine donors[30,37].

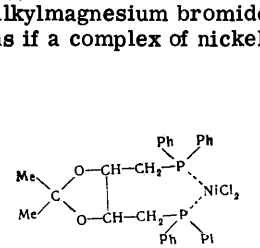
Selective photochemical decomposition by circularly polarised light of cobalt(III) and chromium(III) trioxalates[184–187] and of chromium(III) trisacetylacetonate[188]

leads merely to a slight enrichment of the mixture with one of the enantiomers. Measurement of the relative viscosity of solutions of optically active and racemic [$CrAcac_3$] in the presence of di-isopentyl *d*-tartrate has been used to study enantioselective effects of solvation of the complex[189]. Considerable Pfeiffer effects have been observed in complexes of tin(IV) and titanium(IV) with acetylacetone and dibenzoylmethane[190], as well as on aluminium tris-acetylacetonate, cobalt(III) and chromium(III) trioxalates, and zinc bisbenzoylacetonate[134].

The occurrence of kinetic enantioselective effects in labile complexes enables stereoselective polymerisation to be accomplished by means of coordination catalysts, which ensure selection, and addition to the growing polymer chain, of monomers of only one steric configuration. As a result, optically active polymer chains are formed from a racemic monomer mixture. For example, the complex of diethylzinc with methanol effects stereoselective polymerisation of racemic methyloxiran, which is proved by the possibility of separating the final polymer into two fractions of opposite optical activity[191-193]. Enantioselectivity with respect to monomers is due to the presence in the complex of a chiral terminal unit of the growing chain. The configuration of the whole chain is obviously determined by the chance configuration of the first monomer unit which entered the coordination sphere of the complex. If, however, the initial catalytic complex contains a chiral ligand, it already exerts control at the stage of reaction with the first monomer molecule. The whole of the polymer formed is then optically active, while the unchanged monomer is enriched with the second enantiomer. Such stereoselective polymerisation of *dl*-methyloxiran is catalysed by complexes of diethylzinc with optically alcohols (e.g. borneol)[194-198], amines[199], glutamic ester[200], amino-acids[201], complexes of iron(III) chloride with bornyl ethyl ether[202] and of triethylaluminium with the *N*-carboxy-anhydride of L-alanine[203], and also by magnesium *d*-tartrate[204,205].

Analogous processes of stereoselective and stereo-elective polymerisation by means of coordination catalysts have been reported for racemic alk-1-enes[206-210], α-amino-acid *N*-carboxyanhydrides[211,212], and also mixtures of methyloxiran and such anhydrides[213,214]. The possibility exists for using this process for the partial resolution of racemic compounds[215], e.g. methylthi-iran, where the effects of kinetic enantioselectivity are especially considerable.

The ability of an asymmetric complex catalyst to effect the selection of substrate enantiomers explains such reactions as the enantioselective oxidation of catechol in the presence of (+)-[$CoClNH_3en_2$]Br_2[76,213] and the reduction of racemic methylmethoxynaphth-1-ylphenylsilane by means of lithium tetrahydroaluminate in the presence of (+)-quinidine to optically active methylnaphth-1-ylphenyl-silane[217]. Similarly, the reaction of halogenated alkenes with a racemic s-alkylmagnesium bromide yields optically active hydrocarbons if a complex of nickel with an optically active diphosphine



is used as catalyst[218].

VII. USE OF ENANTIOSELECTIVE EFFECTS IN COMPLEXES FOR THE RESOLUTION OF RACEMATES

All methods for the resolution of racemates (in contrast to the separation of diastereomers) are inevitably based in some way on enantioselective processes. Resolution of a racemate entails either selective chemical modification of one of the enantiomers or its transfer to a separate phase. Kinetic enantioselective effects correspond to the first condition. The use of thermodynamic enantioselectivity in labile complexes for the practical separation of enantiomers is possible only in two-phase systems.

The first attempts to use enantioselective effects in complex formation for the resolution of racemates were undertaken by Bailar[106] as early as 1939. Only considerably later was partial resolution of tartaric acid accomplished by reaction with [$CoCO_3(l\text{-pn})_2$]$^+$.[110,111] The optical purity of *l*-tartaric acid, which showed less tendency to replace the carbonate ligand in the complex, reached 80%. A similar effect was observed with lactic and α-chloropropionic acids, where 30% resolution was achieved[110]. Considerable enrichment of the solution with *l*-propylenediamine occurs in the reaction of the *dl*-diamine with Λ(+)-[CoEDTA]$^-$.[128] Complete resolution of the diamine is possible when Λ(−)-[CoPDTA]$^-$ is used[129]. Similarly, *dl*-cyclohexanediamine can be successfully resolved by means of [$CoCO_3(l\text{-pn})_3$]$^+$,[219] and the resolution of (±)-[CoEDTA]$^-$ effected by means of *l*-propylenediamine[129].

The propylenediamine which distils from a solution containing the copper or nickel complex of *d*-tartaric acid and excess of the *dl*-diamine exhibits weak negative rotation[220] (optical purity 2–3%). On the other hand, distilling the diamine over [Cu_2(L-Glu)$_2H_2O$] gives 4% enrichment with *d*-propylenediamine. If excess of DL-alanine is added to a solution containing the copper complex of *d*-tartaric acid or L-glutamic acid, [$CuAla_2$] precipitates out enriched 3.8% with D-alanine or 3.3% with L-alanine[220]. Harada has reported[221-223] the resolution of DL-aspartic acid on its addition to a solution of the copper complex of L-glutamic acid, L-proline, or L-alanine. In all cases the complex [Cu(D-Asp)$_2$] is precipitated, in the last case in 40% yield of optical purity 95%. Detailed study of this process showed[224] that the presence of L-alanine in solution considerably accelerates crystallisation of the copper complex of D-aspartic acid in comparison with that of the L-aspartic-acid complex only in the pH range 2.7–5.3, while the proportions of copper and aspartic acid in the precipitate vary in the range 1 : 1.2–1.3. After deposition of the D-aspartic-acid complex, its enantiomer begins to crystallise with equally high optical purity. Similarly, D-lysine tungstophosphate crystallises preferentially[225] on the addition of dodecatungstophosphoric acid to a solution containing DL-lysine hydrochloride and $\Delta(-)_{5461}$-[CoEDTA] (or the complex cobalt(III) cyclohexanediamine-tetra-acetate). The true nature of the enantioselective processes leading to acceleration of the crystallisation of one enantiomer of a racemate from a solution containing an optically active component or a solid[226] is still not clear.

The enrichment with D-alanine (by 13.8%) of the complex [$CoAla_3$], formed when [Co(L-Asp)$_2$]$^-$ is treated with excess of DL-alanine at pH 9.5–10 in the presence of activated carbon, is probably due to kinetically controlled enantioselective exchange of ligands. The additional presence of powdered cellulose raises the optical purity

of D-alanine in the precipitated complex to 30–35%.[227] A still greater effect is produced by chitosan and its derivatives[228]. Accompanying this process by the action of DL-alanine and L-aspartic acid on $\Delta\Lambda$-$[Co(CO_3)_3]^{3-}$ showed[229] that ligand exchange involved the intermediate formation of (–)-$[CoCO_3(L\text{-}Asp)_2]^{3-}$, after which (–)-$[Co(D\text{-}Ala)_2L\text{-}Ala]$ was precipitated.

The possibility of using stereoelective polymerisation tion[215] or enantioselective hydrogenation[217] to resolve racemates has been mentioned in preceding Sections. Gillard[230] indicates that micro-organisms may be used to resolve $[CoGly_3]$.

A very large number of publications have appeared on the separation of enantiomers of stable complexes by chromatographic methods using dissymmetric stationary phases. The peculiarities of the chromatographic method in practice enable even very slight enantioselective effects of ligand exchange in the outer coordination sphere of these complexes to be exploited. Thus the different degrees of association of the enantiomers of $[M\,en_3]^{3+}$ (M = Co^{II}, Cr^{III}, Rh^{III}) with *d*-tartaric acid[231] or with aluminium(III) *d*-tartrate[232,233] permit complete separation of these enantiomers by thin-layer chromatography or electrophoresis. Trisacetylacetonates of these metals are partly resolved during extraction with di-isopentyl-*d*-tartrate[234] or with a solution of (+)-$[Co\,en_3]^{3+}$.[235]

Selective sorption on optically active quartz was proposed[236,237] for the separation of enantiomers of $[CoClNH_3en_2]^{2+}$ and $[CoClNH_3DMG]^{+}$ (where DMG = dimethylglyoximato). This method proved acceptable also for separating enantiomers of $[CoCO_3(NH_3)_2en]^{+}$,[238] $[CoDMG_3]$,[239] disalicylidenetriethylenetetraminecobalt(III),[240] and several others[241]. Chromatography on columns of optically active quartz has effected the resolution of several cobalt and chromium complexes[241–244] (some of these results have not been confirmed[245,246]), $[CoEDTA]^{-}$,[247] bisbenzoylacetonatoberyllium(II),[248] tetrahedral nickel complexes of formazans[249,250], oxalate[244] and acetylacetonate[251] complexes of cobalt(III) and chromium(III), and the complex of platinum(II) with *N*-ethyl-*N*-methylglycine[252]) which contains an asymmetric nitrogen atom). The enantiomers of trishexafluoroacetylacetonatochromium(III) have been separated by gas chromatography[253,254]. Sodium perchlorate crystals have been reported[255,256] as possessing a similar ability to resolve racemates of complex compounds.

The largest effects in the separation of enantiomers are usually observed in chromatography on carbohydrates (Table 4). The hydroxy-groups of these sorbents obviously play an active part in forming the outer coordination sphere of the complexes. In some cases the efficiency of the chromatographic process can be considerably enhanced (up to complete separation of the enantiomers) if an optically active eluant, e.g. sodium *d*-tartrate solution, is used[284,285].

Significantly more modest successes have been achieved in the separation of enantiomeric complexes by means of synthetic dissymmetric ion-exchange resins containing optically active groups—quinine[286], tartrate or antimonyltartrate anions, and also Λ-$[Co\,en_3]^{3+}$ anions[287].

Rogozhin and Davankov's proposed[288–292] ligand-exchange chromatography[43] of racemates—a new principle for the separation of enantiomers capable of complex formation—is based on enantioselective effects of inner-sphere ligand exchange. Chromatography is conducted on a sorbent having chiral complexing groups, in the presence of metal ions (copper, nickel, zinc, etc.) giving kinetically labile complexes. Thermodynamic enantioselective effects develop in the formation of a mixed sorption complex incorporating in the chiral stationary ligand, the metal ion, and the mobile ligand (the racemate molecule). These workers synthesised a wide range of dissymmetric sorbents based on a cross-linked macro-network polystyrene framework with bidentate[293–295] and terdentate[296–300] stationary ligands like α-amino-carboxylic and α-amino-phosphonic[301] acids. Racemates of many compounds capable of complex formation—amino-acids, amino-alcohols, diamines, heterocycles, etc.—have been resolved on these sorbents[44,47,48]. The high enantioselectivity of complex formation in these systems ($\delta\Delta G^{\circ}$ may exceed 1 kcal $mole^{-1}$ [50,56–58]) ensures exceptionally high selectivity of sorption of enantiomers, which can be exploited for their separation not only on an analytical but also on a preparative scale. Better separations are observed when the total denticity of stationary and separable ligands coincides with the coordination number of the metal atom[44]. The efficiency of separation is influenced by the degree of saturation of the sorbent with metal ions[45,46], temperature, eluant concentration, and several other factors[302].

Table 4. Resolution of racemates of coordination compounds by chromatography on carbohydrates.

Sorbent	Resolvable complex	Ref.
D-Lactose	Cr^{III} trisacetylacetonate	189,257,260
	Co^{III} trisacetylacetonate	257-262
	Rh^{III} trisacetylacetonate	259-261
	Ru^{III} trisacetylacetonate	259
	Y^{III}, Gd^{III} trisacetylacetonates	263
	Co^{III} trisbenzoylacetonate	259
	Cr^{III} trisbenzoylacetonate	264
	Ni^{II}, Cu^{II} bis-β-keto-imines	265
	bisacetylacetonatopropylenediaminevanadyl	266
	tris-5-methylhexane-2,4-dionatocobalt(III)	267
Starch	trisethylenediamine-cobalt(III), -chromium(III)	268,269
	trisglycinatocobalt(III)	268-271
	Co^{III} trisdithiocarbamate	268,269
	Co^{III} trisdithiocarbaminate	269
	Co^{III}, Cr^{III} trioxalates	269
	bisglycylglycinatocobalt(III)	271
	bisethylenediaminecobalt(III)	272
	tris-L-α-aminoisobutyratocobalt(III)	273
	hexamethyl-1,4,8,11-tetra-azacyclotetradeca-1,7-dienatonickel(II)	274
Cellulose	Co^{III} trioxalate	272,275
	tris-α-amino-carboxylatocobalt(III)	275
	trisalkylene-1,2-diaminecobalt(III)	276,277
	tribenzo[*b*, *f*, *j*]-1,5,9-triazacyclododecenato-nickel(II)	278
Carboxymethylcellulose	hexakis-2-aminoethylthiolatotricobalt(III)	279
	Co^{III} bisiminodiacetate	280
	Co^{III} trimethylenediaminetetra-acetate	280
	dichlorobisphenanthrolinerhodium(III)	281
Diethylaminoethylcellulose	Co^{III} ethylenediaminetetra-acetate	282
Phosphorylated cellulose	trisethylenediaminecobalt(III)	282
	Co^{III} bisiminodiacetate	282
	bisdiethylenetriaminecobalt(III)	282
SE-Sephadex	bisdiethylenetriaminecobalt(III)	283

Similarly, a sorbent based on a styrene—divinylbenzene copolymer with *N*-carboxymethyl-L-valine—a stationary terdentate ligand—has been synthesised by Angelici et al.[303,304]. In the presence of copper ions racemates of isoleucine—and rather less effectively those of valine and alanine—are partly resolved on this sorbent.

Bernauer [60,61,305,306] proposed a somewhat modified method of ligand-exchange chromatography: a stationary chiral complex of iron(III) with 2'-hydroxyethyl-D-propylenediaminetriacetic acid L-[Fe(D-HEPTA)]$^-$ was bound by an ionic bond—not a covalent bond—to a polymeric carrier (Dowex 1 × 2 anion-exchange resin). Only acid racemates, which preserve the overall negative charge of the complex when one of its acetate ligand groups is replaced, can be resolved on such a solvent. This condition is satisfied by acetyl and benzoyl derivatives of leucine, alanine, phenylalanine, and methionine, which were in fact partly resolved by ligand chromatography. In all cases the more stable mixed complexes formed derivatives of D-amino-acids, the ratio of sorbed D- and L-ligands falling in the above sequence of amino-acids from 1.08 to 1.03 ($\delta\Delta G^\circ$ = 0.10–0.02 kcal mole^{-1}). Bernauer [61] has used a chiral stationary complex of copper, nickel, or zinc with D(−)-propylenediaminetetra-acetic acid of total charge 2- to strengthen the bonding of the complex to the anion-exchange resin carrier. On such a sorbent 60% separation of α-methylbenzylamine isomers is observed ($\delta\Delta G^\circ$ = 0.3 kcal mole^{-1}).

It is interesting that Bruschtein [307], in an earlier study of the interaction of polymers of *N*-acryloyl and *N*-methylacryloyl derivatives of L-amino-acids (glutamic and aspartic acids, glycine, asparagine) with copper complexes of propylenediamine and of tyrosinamide, detected no enantioselective effects.

---o0o---

Thus a fairly large number of processes, in which thermodynamic or kinetic enantioselective effects develop in one form or another, are already known in the chemistry of coordination compounds. These effects are observed both in the coordination of chiral ligands and in processes involving only the outer coordination sphere of the complex. The literature on enantiospecific effects is equally vast, but could not be considered within the scope of the present Review.

Quantitative Effect of the Pentafluorophenyl Ring on the Reactivity of Substituents

V.M.Vlasov and G.G.Yakobson

The quantitative effect of the pentafluorophenyl ring on the reactivity of substituents (hydrogen, alkyl, aryl, carboxyl, amino, hydroxyl, and halogens) is surveyed. The efficiency with which fluorine atoms at different positions in the benzene ring influence a reaction centre is discussed. An analysis of the σ-constants of the pentafluorophenyl group is also given. A list of 106 references is included.

I. INTRODUCTION

The chemistry of polyfluorinated aromatic compounds has developed rapidly during recent years[1-7]. One of the main lines of research in this field has been the study of reactions that involve nuclear substituents while leaving nuclear fluorine atoms unchanged.

The introduction of fluorine atoms instead of hydrogen atoms into an aromatic ring has a significant effect on the properties of substituents attached to the ring, which sometimes leads to reactions uncharacteristic of the corresponding hydrocarbon derivatives. No generalisations have been published on the quantitative effect of a polyfluorinated aromatic ring, in particular pentafluorophenyl, on the reactivity of atoms and groups, so that it is of interest to discuss the published information. Since the great majority both of synthetic papers and especially of papers on quantitative aspects of the effect of a polyfluorinated aromatic ring are concerned with pentafluoro-derivatives of benzene, the present Review will deal with the effect of the pentafluorophenyl ring on the reactivity of substituents attached to it. In several cases the effect of the pentafluorophenyl group is compared with those of other groups, e.g. mono-, di-, and poly-fluorophenyl, pentachlorophenyl, nitrophenyl, and trifluoromethyl†.

Since the effect of a pentafluorophenyl ring on a substituent varies with the nature of the latter (or its reactive centre)[9], a detailed study of this effect on key groups—such as alkyl, carbonyl, amino, nitro, etc.—may give information on the specific properties of polyfluorinated aromatic compounds. Here, therefore, we shall first discuss the effect for each specific group, and at the end of the Review attempt to generalise the data on the effect of the pentafluorophenyl ring.

† The effect of the trifluoromethyl group on the reactivity of functional groups has been reviewed[8].

II. HYDROGEN ATOMS

The electron-accepting properties of the fluorine atoms in fluorinated benzenes confer an acidic character on the carbon—hydrogen bonds, which is apparent e.g. in increased rates of isotopic exchange compared with benzene[10-12].

Table 1. Relative rates of exchange of deuterium and tritium at various positions in fluorobenzene and benzylidyne trifluoride with lithium cyclohexylamide in cyclohexylamine at 25°C.[11]

Compound	Rate relative to benzene	
	D	T
o-Deutero(tritio)fluorobenzene	6.3×10^5	3.4×10^5
m-Deutero(tritio)fluorobenzene	107	86
p-Deutero(tritio)fluorobenzene	11.2	9.1
m-Deutero(tritio)benzylidyne trifluoride	580	390

The data in Table 1 suggest that the acidity of the carbon—hydrogen bond will increase strongly as fluorine atoms accumulate in the benzene ring. The kinetic parameters of the base-catalysed exchange of tritium in polyfluorobenzenes (Table 2) show that *ortho*-fluorine atoms make the most significant contribution to the kinetic acidity of polyfluorobenzenes, and are followed by *meta*-fluorine atoms and finally the *para*-fluorine atom (by factors respectively of 260 000, 247, and only 23). The enhanced reactivity of pentafluorobenzene in comparison with *m*-difluorobenzene and 1,2,3,4-tetrafluorobenzene is due primarily to the difference in activation energy[13].

Results on the thermodynamic acidity of polyfluorobenzenes have been obtained by Streitwieser et al.[14] in a study of equilibria of the type

$$ArH + R^-Cs^+ \overset{K}{\rightleftarrows} Ar^-Cs^+ + RH$$

in cyclohexylamine, where ArH is a polyfluorobenzene, and RH an indicator hydrocarbon (Table 3).

Table 2. Rate constants and activation parameters of the exchange of tritium in polyfluorobenzenes in methanolic sodium methoxide at 40°C.[13]

Compound	Rate constant $10^4 k_2$, $M^{-1}\,s^{-1}$	Activation	
		energy ΔH^*, kcal mole^{-1}	entropy ΔS^*, e.u.
C_6HF_5	1360	18	—5.6
1,2,4,5-$C_6H_2F_4$	58	—	
1,2,3,5-$C_6H_2F_4$	5.6	—	
1,3-$C_6H_4F_2$	0.0061	27.9	1.9
1,2,3,4-$C_6H_2F_4$	0.0053	27.3	—0.3

It is interesting to compare results obtained on the kinetic and thermodynamic acidities of polyfluorobenzenes. Streitwieser et al.[14] evaluated the partial reaction rate factors for the exchange of deuterium in methanolic sodium methoxide (Table 2) or tritium in cyclohexylamine (CHA) (Table 1), as well as the equilibrium factors (Table 3) for fluorobenzenes, these being the difference between the thermodynamic acidities of benzene and of the fluorobenzene (Table 4). Good agreement between factors calculated from kinetic and from thermodynamic data is evident from Table 4.

Table 3. Thermodynamic acidity of polyfluorobenzenes and benzene in cyclohexylamine relative to 9-phenylfluorene (pK_a = 18.49).[14]

Compound	pK_a (at 34°C)	Indicator hydrocarbon (pK_a)
C_6HF_5	25.85	9-t-butylfluorene (24.23)
1,2,3,4-$C_6H_2F_4$	31.52	di-*p*-biphenylylmethane (30.83) triphenylmethane (31.45)
1,2-$C_6H_4F_2$	34.98	tri-*p*-tolylmethane (34.98)
C_6H_6	43	

The difference in thermodynamic acidity between benzene and pentafluorobenzene is easily calculated by means of these factors. Replacement of five hydrogen atoms in the benzene molecule by fluorine increases the equilibrium acidity (pK_a) of the carbon—hydrogen bond by 15.8—17.1. Approximately the same result was obtained from polarographic data for symmetrical organomercury compounds: values of pK_a for benzene, pentafluorobenzene, and pentachlorobenzene were respectively 37, 23, and 30.5.[15,16]

The considerably more acidic character of the carbon—hydrogen bond in pentafluorobenzene than in pentachlorobenzene is obviously due primarily to the strong inductive effect of fluorine atoms, which is the predominant factor in stabilising aryl anions whose lone electron pair is located in a σ-orbital. The acidic character of this bond in pentafluorobenzene is shown in its ability to react even with alkyl-containing Grignard reagents[17], which usually react only with compounds having $pK_a \leq 21$.[18]

The introduction of fluorine into an aromatic ring lowers the reactivity of the latter towards electrophilic reagents. Thus the rate of nitration of fluorobenzene in sulphuric acid at 25°C is lower than that of benzene by a factor of 8.5.[19] The electrophilic reactivity diminishes considerably with increase in the degree of fluorination of the aromatic ring (Table 5).[20-22]

Table 4. Partial rate and equilibrium factors for fluorobenzenes.

Position of fluorine	Partial rate factors		Equilibrium factors (Ref.14)
	MeONa—MeOH[a]	LiCHA—CHA (Refs.11,14)	
ortho-	5.25	5.43	5.7
meta-	2.07	1.95	2.3
para-	1.13	1.03	1.1

Quantum-chemical calculation of the electron density (allowing for π-and σ-charges) on the carbon atoms in the isomeric tetrafluorobenzenes and in pentafluorobenzene predicts the sequence

$$1,2,4,5\text{-}C_6H_2F_4 < 1,2,3,4\text{-}C_6H_2F_4 < C_6HF_5 < 1,2,3,5\text{-}C_6H_2F_4$$

of increasing reactivity towards electrophilic reagents[23].

Table 5. Rate constants of the sulphonation of polyfluorobenzenes in oleum (100.12% H_2SO_4) at 25°C.[22]

Compound	k, s^{-1}	Compound	k, s^{-1}
1,4-$C_6F_2H_4$	16.1	C_6F_5H	0.000512*
1,2,3,4-$C_6F_4H_2$	0.0079		

* Concentration of oleum 101.17%.

This sequence diverges somewhat from results for the sulphonation (Table 5) and nitration of polyfluorobenzenes[24]. The experimental reactivity sequence for electrophilic substitution in polyfluorobenzenes is

$$1,2,4,5\text{-}C_6H_2F_4 < C_6HF_5 < 1,2,3,4\text{-}C_6H_2F_4 \sim 1,2,3,5\text{-}C_6H_2F_4.$$

Thus deactivation of the aromatic ring towards electrophilic reagents depends on the positions and the number of fluorine atoms present. This is supported also by a study of the protiodesilylation and protiodestannylation of fluoroaryltrimethyl-silanes and -stannanes respectively (Table 6).[25] Additivity of the effects of the fluorine atoms is not observed in these processes (partly owing to steric acceleration of the reactions).

Polychlorobenzenes show a similar pattern: pentachlorobenzene is nitrated more rapidly than 1,2,4,5-tetrachlorobenzene by factors of ~4,[19] whereas the nitration of

Table 6. Relative rate of the protiodestannylation of fluoroaryltrimethylstannanes $ArSn(CH_3)_3$.[25]

Ar	k_{rel}	Ar	k_{rel}
Ph	1.0	*m*-FC_6H_4	0.22
p-FC_6H_4	0.93	C_6F_5	0.43
o-FC_6H_4	0.41		

chlorobenzene takes place correspondingly more slowly than that of benzene[19]. The variety of effects of the halogens in a polyhalogenated system obviously cannot be explained by the principle of additivity. Furthermore, pentafluorobenzene is inert towards nitric acid in 90% sulphuric acid, whereas pentachlorobenzene is nitrated under these conditions[19].

III. ALKYL AND ARYL GROUPS

The kinetic acidity of an α-C—H bond in toluene is enhanced by fluorine atoms in *ortho*- and *meta*-positions, but is diminished by a *para*-fluorine atom (Table 7).[26]

Table 7. Relative rates of exchange of substituted α-deuterotoluenes and α-tritiotoluenes $RC_6H_4CH_2D(T)$ with lithium cyclohexylamide in cyclohexylamine at 50°C.[26]

R	relative rate		
	ortho	*meta*	*para*
H	1	1	1
F	12	22	0.73
CF_3	—	60	180

The rate of deuterium exchange for α-deutero-2,5-difluorotoluene in cyclohexylamine at 25°C exceeds the corresponding rate for α-deuterotoluene by a factor of 350.[11] The strong acidifying effect of a *meta*-fluorine atom is obviously due to its inductive, electron-accepting effect, whereas a mesomeric, electron-donating effect is also exerted by *ortho*- and *para*-fluorine atoms. The superposition of these effects explains why a *p*-fluorine atom becomes a weak donor and destabilises the benzyl anion, whereas *o*-fluorine exerts a weaker acceptor effect than does *m*-fluorine[27]. The electron-donor character of a *p*-fluorine atom has been observed also in a study of the effect of substituents on the rate of alkaline cleavage of *para*- and *meta*-substituted benzyltrimethylstannanes[28].

The effect of *ortho*- and *para*-fluorine atoms on the acidity of an α-C—H bond in fluorotoluenes is similar to the effect of fluorine atoms on an α-carbanion centre in aliphatic systems, the "Hine effect".[29-33] If the carbanion is planar, *p*—*p* interaction between the lone electron pair of the fluorine atom and the lone pair of the negatively charged carbon atom leads to its destabilisation[29-33]. If, on the other hand, the carbanion is pyramidal, it is stabilised by the electron-accepting inductive effect of the α-fluorine atom[33,34]. Thus, in contrast to the *p*-fluorobenzyl anion, which is probably planar, the carbanion generated from 2-*p*-fluorophenyl-2-hydrohexafluoropropane is more stable than its analogue unsubstituted in the ring; in the absence of steric hindrance, this indicates the pyramidal geometry of such carbanions[35].

Thus it follows from the above data that the stability of fluoroarylated carbanions is determined primarily by the relation between the oppositely directed inductive and mesomeric effects of the fluorine atoms. Not only the type of hybridisation of the carbon atom with the lone electron pair but also steric factors preventing coplanarity of the benzene ring and the neighbouring carbanion centre are important for stabilisation of the carbanion. Thus the thermodynamic acidity of 2—6-pentafluorotoluene considerably exceeds that of toluene ($\Delta pK_a = 10$).[36] This can probably be explained by the existence of the pentafluorobenzyl anion in a conformation such that the adjacent carbanion centre, probably of sp^2 type, does not lie in the plane of the benzene ring (values of pK_a for $C_6H_5CH_3$, $C_6F_5CH_3$, *p*-$NO_2C_6H_4CH_3$, and *p*-$CF_3C_6H_4CH_3$ are respectively 35,[15] 25,[36] 26,[37] and 28 [36]). The stability of the pentafluorobenzyl anion is close to that of the *p*-nitrobenzyl anion, and exceeds that of the *p*-trifluoromethylbenzyl anion.

Table 8 compares the stabilities of polyfluorinated di- and tri-arylmethyl anions with those of their non-fluorinated analogues. Successive replacement of phenyl by pentafluorophenyl in a series of di- and tri-arylmethanes leads to an increase in the thermodynamic acidity (pK_a) of the α-C—H bond by 5—6. Roughly the same increase is produced by replacing phenyl by *p*-nitrophenyl. Trifluoromethyl has a greater acidifying effect than has phenyl, as can be seen from the values of pK_a for tris-trifluoromethylmethane and trispentafluorophenylmethane.

The triphenylmethyl anion, in which the α-carbon atom possesses hybridisation approximating to the sp^2 type[44], is a convenient model for revealing the inductive effects of substituents, since the benzene rings assume a propeller conformation (mean angle of deflection of ring 31.7°,[44] close to the 35° calculated theoretically[45]), which diminishes substantially their resonance interaction with the carbanion centre. This factor is most important for polyfluorinated triphenylmethyl anions‡, and is reflected

‡ It may be supposed that the mean angle of deflection of the pentafluorophenyl rings in the trispentafluorophenylmethyl anion will also be at least 31.7°.

in their enhanced thermodynamic stability in comparison with non-fluorinated analogues. However, transmission of the effect of a substituent by a conjugation mechanism is not completely excluded in polyfluorinated triarylmethyl anions: thus the introduction of an electron-donating substituent (methyl, methoxy) at a *para*-position in trispentafluorophenylmethane weakens the thermodynamic acidity of the corresponding methine acid. The contribution of each pentafluorophenyl group ($\Delta pK_a \simeq 5.2$) to the thermodynamic stability of the trispentafluorophenylmethyl anion, which is due predominantly to the inductive effect of the fluorine atoms, can be confirmed by calculation based on a different model, the 9-pentafluorophenylfluorenyl anion. Here the carbon atom with a lone pair of electrons is in the sp^2-hybrid state, but the pentafluorophenyl group should occur mainly in a conformation§ preventing resonance interaction of the fluorine atoms with the carbanion centre owing to steric repulsion of the hydrogen atoms at positions 1 and 8 in fluorene and the *ortho*-fluorine atoms of the pentafluorophenyl group. The differences ΔpK_a between the thermodynamic acidities of phenyl- and pentafluorophenyl-fluorenes have been calculated by means of the correlation[48] $pK_a = -4.557\sigma^* + 21.85$, representing the dependence of the thermodynamic acidity of 9-substituted fluorenes on the Taft induction constant σ^* of the 9-substituent. Substitution of the constant $\sigma^* \simeq 1.9$ for the pentafluorophenyl group[49] with the use of $pK_a = 18.6$ for 9-phenylfluorene[48] yields the difference $\Delta pK_a = 5.4$, which coincides with the contribution of the pentafluorophenyl group to the thermodynamic acidity of trispentafluorophenylmethane.

The possibility of varying the ratio of resonance and inductive effects of the pentafluorophenyl group has been shown for mesomeric carbanions of the type $[C_6F_5C^-RR']Na^+$, where R = R′ = $COOC_2H_5$, CN, COC_6H_5, etc.[50–53] It is significant that the carbon atom with the lone pair in these carbanions is usually in an sp^2-hybrid state, which favours resonance interaction of the fluorine atoms when the pentafluorophenyl group is coplanar with the carbanion centre. Depending on the relative parts played by the electron-accepting groups R and R′ in delocalisation of the negative charge and also on their spatial requirements, however, the conformation of the pentafluorophenyl group may change substantially, and hence also the relative contributions of resonance and inductive effects of this group. The influence of the fluorine atoms of the pentafluorophenyl group on the stability of mesomeric carbanions can be traced in the differences in acidity $\Delta pK_a = 0.5$, 0.4, 0.1, and 0 for the series of *para*-substituted methine acids—$XC_6F_4CH(COOC_2H_5)_2$, $XC_6F_4CH(CN)COOC_2H_5$, $XC_6F_4CH(CN)C_6F_5$, and $XC_6F_4CH(CN)C_6H_5$—where X = H, F respectively. Whereas the *para*-fluorine atom acts as an acceptor in derivatives of polyfluorinated phenylmalonic acids, in polyfluorinated diarylacetonitriles replacing a *para*-hydrogen by fluorine either does not affect or diminishes pK_a, so that the *para*-fluorine atom is now a donor rather than an acceptor[53].

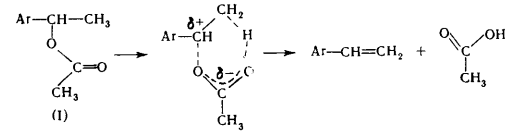
The thermodynamic acidities of various polyfluorinated carbonyl compounds and their non-fluorinated analogues show (Table 9) that the effect of the pentafluorophenyl group on the stability of mesomeric carbanions depends on the type of carbanion. Thus steric interaction between the two pentafluorophenyl groups in the carbanion from bispentafluorophenylmethyl phenyl ketone $(C_6F_5)_2CHCOC_6H_5$ deflects them from coplanarity, and the mesomeric carbanion is largely destabilised by the inductive effects of these groups. Whereas introduction of a phenyl group into deoxybenzoin $C_6H_5CH_2COC_6H_5$ leads to weakened thermodynamic acidity in diphenylmethyl phenyl ketone[54], bispentafluorophenylmethyl phenyl ketone is more acidic than is pentafluorodeoxybenzoin ($\Delta pK_a = 3.8$).

Table 9. Thermodynamic acidity of polyfluorinated carbonyl compounds and their non-fluorinated analogues with respect to 2,4-dinitrodiphenylamine in 1,2-dimethoxyethane.

Compound	pK_a	ΔpK_a per C_6F_5	Ref.
$PhCH(COOEt)_2$	14.2	1.4	50
$C_6F_5CH(COOEt)_2$	12.8		
p-$NO_2C_6H_4CH(COOEt)_2$	12.6	—	50
$PhCH_2COPh$	16.1	0.8	54
$C_6F_5CH_2COPh$	15.3		51
$C_6F_5CH_2COC_6F_5$	11.7		51
$Ph_2CHCOPh$	16.6	2.5	54
$(C_6F_5)_2CHCOPh$	11.5		52

The relation $\Delta pK_a = -0.077\delta_p + 14.508$ has been established[53] for polyfluoroarylated mesomeric carbanions $[C_6F_5C^-RR']Na^+$, where ΔpK_a is the difference between the thermodynamic acidities of non-fluorinated and fluorinated methine acids—C_6H_5CHRR' and C_6F_5CHRR'—and δ_p is the chemical shift (from trichlorofluoromethane as internal standard) of the *para*-fluorine atom in the pentafluorophenyl group of the fluorinated carbanion (in 1,2-dimethoxyethane as solvent). Since the chemical shift δ_p in pentafluorobenzene derivatives represents primarily the resonance effect of the substituent[23,55], the fractional destabilising effect of *ortho*- and *para*-fluorine atoms, expressed as the chemical shift δ_p in the fluorinated mesomeric carbanions, correlates with the difference in relative stability between non-fluorinated and fluorinated carbanions ΔpK_a. It follows from this correlation that, the greater the degree of conjugation of the pentafluorophenyl group with the carbanion centre (the greater the chemical shift δ_p), the smaller the difference in stability between the mesomeric carbanions of benzyl type containing phenyl or pentafluorophenyl groups.

Data have been obtained also on the effect of the pentafluorophenyl group on the positively charged benzyl carbon atom. In a kinetic study of the pyrolysis of α-methylfluorobenzyl acetates



(I)

(in the transition state the positive charge is concentrated mainly on the benzyl carbon atom) Taylor[56] found that the effects of fluorine atoms in the benzene ring were not additive. The acetate (I) with Ar = C_6F_5 is less reactive than that with Ar = C_6H_5 by a factor of 4.6, whereas a calculation based on additivity would indicate a factor of 7.75. The fact that the five fluorine atoms together are less strongly electron-accepting than if they had acted

§ The phenyl group in the 9-phenylfluorenyl anion is not coplanar with the carbanion centre, the angle of deflection being 30–39°.[46,47]

separately further confirms the peculiarity of the polyhalogenated system noted above in discussing the reactivity of incompletely fluorinated aromatic compounds.

Interesting results have been obtained by Taylor[57] in a study of the protiodetritiation of mon- and penta-fluorobiphenyls containing tritium in the *ortho*-, *meta*-, and *para*-positions of the non-fluorinated benzene ring (Table 10). In this typical electrophilic aromatic substitution the pentafluorophenyl group is primarily *para—ortho* orienting, although in comparison with the electronic effect of the phenyl group, of course, it quite strongly deactivates the aromatic ring towards electrophilic agents. Comparison of the observed partial rate factor of 0.0158 for the *para*-position in pentafluorobiphenyl with the calculated additive value of 0.044 also indicates a relative weakening of the electron-accepting power of the fluorinated phenyl group as fluorine atoms accumulate.

Table 10. Partial rate factors of the protiodetritiation of fluorinated biphenyls ArC_6H_4T.[57]

Ar	Position of tritium		
	ortho	*meta*	*para*
Ph	45	0.81	48
p-FC_6H_4—	—	—	26.3
o-FC_6H_4—	5.13	—	6.42
m-FC_6H_4—	4.25	—	4.65
C_6F_5—	0.0095	0.0053	0.0158

It is interesting to compare the above kinetic results on electrophilic reactions with data on the effect of the pentafluorophenyl group on the thermodynamic stability of carbonium ions of the triarylmethyl type. Successive replacement of phenyl by pentafluorophenyl in a triarylmethanol results in a decrease in stability (pK_{R^+}) of the corresponding polyfluorinated triarylmethyl cation by 3.2—4.0 (Table 11)[58-60]. About the same decrease in stability of the triphenylmethyl cation occurs on introduction of a *p*-nitro-group.

Table 11. Values of pK_{R^+} of substituted triarylmethanols.

The calculated additive value of pK_{R^+} for trispentafluorophenylmethanol, allowing for the values in Table 11, is −18.1, which agrees quite well with the experimental value. A possible explanation of the additivity of the effects of fluorine atoms in this equilibrium process, in contrast to the kinetics of the pyrolysis of aryl acetates and the kinetics of protiodetritiation, is that the requirement of the reaction centre for resonance stabilisation cannot be satisfied in polyfluorinated triarylmethyl cations of propeller structure¶. Nevertheless, in the transition state of the protiodetritiation of pentafluorobiphenyl, for example, the pentafluorophenyl group may approach coplanarity with the non-fluorinated benzene ring, which will increase the electron density at the *ortho*- and *para*-positions[57].

These considerations are supported by a comparison of the effects of *para*-fluorine atoms on the thermodynamic stability of trismono(and per)fluoroarylmethyl cations (Table 12). Whereas the introduction of *para*-fluorine atoms into the triphenylmethyl cation increases the stability of the carbonium ion $(p\text{-}FC_6H_4)_3C^+$ ($\Delta pK_{R^+} = 0.58$), the corresponding replacement of hydrogen by fluorine in the cation $(p\text{-}HC_6F_4)_3C^+$ leads to a diminution of stability in the cation $(C_6F_5)_3C^+$ (−0.6). Since values of ΔpK_{R^+} for all the substituents studied are lower with the polyfluorinated carbinols than with their non-fluorinated analogues, while the contribution of the three 2, 3, 5, 6-tetrafluorophenyl groups to destabilisation of the cations remains about the same ($\Delta pK_{R^+} = 10.5—12.1$), good correlation is not observed between the pK_{R^+} for the polyfluorinated carbinols $(p\text{-}XC_6F_4)_3COH$ and the σ^+-constants of the substituents[60]. Filler et al. also suggested[60] the correlation

$$pK_a = 0.534\,pK_{R+} + 25.35$$

linking the pK_{R^+} of polyfluorotriarylmethanols and the pK_a of the corresponding triarylmethanes.

IV. CARBOXYL GROUP

The dissociation constants of fluorinated benzoic acids show (Table 13) that the effect of a fluorine atom on acidity depends on its position. Thus the acidity diminishes on passing from *ortho*- to *para*-derivatives. The electron-accepting influence of chlorine atoms is so much stronger than that of fluorine atoms that pentachlorobenzoic acid approaches 2, 4, 6-trinitrobenzoic acid in strength, whereas pentafluorobenzoic acid is only about as strong as 2, 5-dinitrobenzoic acid. Additive calculation of pK_a for several polyfluorinated benzoic acids gives good agreement with experimental values. It must be noted that additivity of the effects of substituents in the benzene ring is not peculiar to fluorine atoms, but is exhibited by other substituents—both acceptor (chloro, bromo, nitro) and donor (methyl, hydroxy)[65].

¶ The calculated[45] angle of deflection of the benzene rings in the triphenylmethyl cation is 44°. The corresponding angle in the trispentafluorophenylmethyl cation may be assumed to be at least as large.

In connection with the additivity of the effects of fluorine atoms on the acidity of benzoic acids, Table 14 shows that the influence of a *para*-substituent R on acidity is about the same in the tetrafluorobenzene as in the benzene ring ($\Delta pK'_a \simeq \Delta pK''_a$), the contribution of the four fluorine atoms being almost identical for all the *para*-derivatives studied ($\Delta pK'''_a = 2.25-2.39$). The form of the correlation dependence of pK_a on the σ_p-constants of the substituent is therefore the same for *para*-substituted benzoic acids as for their fluorinated analogues[63].

The influence of the pentafluorophenyl group on the acidity of the carboxy-group, accomplished through a system of double bonds, can be followed in *p*- and *m*-pentafluorophenylbenzoic acids (Table 15). The effects of a *para*-substituent R are about the same in benzoic and tetrafluorobenzoic acids ($\Delta pK'_a \simeq \Delta pK''_a$), except when R = C_6F_5. Whereas the effect of a *p*-pentafluorophenyl group on acidity is quite large on the fluorinated acid ($\Delta pK_a = 0.42$), the effect is very small on benzoic acid (+0.06). Such anomalous behaviour of *p*- and *m*-pentafluorophenylbenzoic acids may be attributed to the specific influence of the medium (75% methanol + 25% water), in which unexpected results have been obtained for other polyfluorinated substituents, e.g. perfluoroisopropyl[66].

Sheppard[66] suggested the alternative explanation that the decrease in acidity of *p*- and *m*-pentafluorophenylbenzoic acids is due to $p-\pi$ donation of unshared electrons of the *ortho*-fluorine atoms to the π-system of the adjacent non-fluorinated ring. However, the existence of such an effect of fluorine atoms in the biphenyl system is doubtful, for *o*-fluorotritiobenzene and 2-fluoro-4′-tritiobiphenyl undergo protiodetritiation at almost the same rate, although the latter reaction would have been the more rapid in the presence of $p-\pi$ donation[57].

The acidity of carboxylic acids falls, of course, when the substituent and the carboxyl are separated by one or especially several methylene groups. The substituent, in particular a pentafluorophenyl group, will then have only an inductive effect on the reaction centre. Table 16

shows that the effects of fluorine atoms at different positions in the benzene ring, exerted through methylene bridges on the acidity of carboxylic acids, fit well into an additive scheme of calculation of pK_a for the pentafluorophenyl group, whose total electron-accepting power is comparable with that of the ethoxycarbonyl group.

V. AMINO-GROUP

The pK_a values of the fluorinated conjugate acids of anilines show (Table 17) that the acidity of the conjugate acid of pentafluoroaniline can be calculated additively from the pK_a values for the conjugate acids of monofluoroanilines. The predominant contribution to the acidity is made by the *ortho*-fluorine atoms, while the *meta*-fluorine atoms have rather less effect. In polyfluoroanilines greater acceptor effects are exerted by a *p*-bromine atom and by 2,4-chlorine atoms than by fluorine atoms at these positions. The total electron-accepting effect of the five fluorine atoms on the acidity of the conjugate acids of anilines can be compared with that of an *o*-nitro-group; trifluoromethyl has a considerably smaller effect.

The conductance through a system of conjugated bonds of the effect of the pentafluorophenyl group on the ionisation of the conjugate acids of amines has been estimated only for *m*- and *p*-pentafluorophenyl-*NN*-dimethylanilines, since it is difficult to estimate the basicity of the anilines because of their sparing solubility in aqueous systems[66]. Table 18 shows that the electron-accepting effect of both *m*- and *p*-pentafluorophenyl groups on the ionisation of the conjugate acids of *NN*-dimethylaniline is considerably smaller than that for perfluorinated alkyl groups, which parallels the effects observed in the ionisation of substituted benzoic acids (Table 15). The greater electron-accepting effect of the *para*- than of the *meta*-group can be attributed to non-coplanarity of the benzene rings and a consequent diminution in the effect of conjugation of the pentafluorophenyl group[57].

* Calculated by an additive scheme[9].

The inductive effect of the pentafluorophenyl group on the ionisation of conjugate acids of amines can conveniently be traced in systems in which the group is separated from the reaction centre by a methylene bridge (Table 19). Such systems are characterised by additivity of the effects of fluorine atoms at different positions in the ring, as noted above for carboxylic acids of the type $Ar[CH_2]_nCOOH$ (Table 16). The pentafluorophenyl group is comparable in its inductive effect with such groups as alkoxycarbonyl and difluoromethyl, but weaker than trifluoromethyl.

VI. HYDROXY-GROUP

Fluorinated phenols and aromatic alcohols may be expected to be more acid than their non-fluorinated analogues, in view of the electron-accepting inductive effect of the pentafluorophenyl group. Table 20 gives data on the effect of aromatically bound fluorine atoms on the acidity of phenols, with for comparison the effects of a nitro-group and chlorine atoms. Additivity of the effects of fluorine atoms at different positions in the benzene ring is evident for phenols, as for benzoic acids and anilines, the main contribution to the acidity of pentafluorophenol being made by the *ortho*-fluorine atoms, and a rather smaller contribution by the *meta*-atoms, while a *para*-fluorine atom has almost no effect on the acidity of phenol.

Table 20. Acidities of substituted phenols ArOH (in water at 25°C).

* Calculated by additivity from data in Refs. 62 and 74.

The electron-accepting power of the pentachlorophenyl group is considerably stronger than that of the pentafluorophenyl group, because fluorine atoms at *ortho*- and *para*-positions are more efficient than are chlorine atoms

in supplying electron density by a mechanism of conjugation to the reaction centre. The effect of the pentafluorophenyl group on the acidity of the hydroxyl exceeds that of *p*-nitrophenyl and approaches that of 2,4-dinitrophenyl.

	12.8	80					

* Calculated value.

As a consequence of the electron-accepting inductive effect of fluorine atoms, fluorinated aromatic alcohols are more acidic than their non-fluorinated analogues (Table 21). The trifluoromethyl group has a stronger acidifying action on alcohols than has the pentafluorophenyl group. It is noteworthy that the latter group makes different contributions to the acidities of primary and of tertiary alcohols: whereas the difference between the pK_a values of benzyl and pentafluorobenzyl alcohols is 1.5, the corresponding difference between the tertiary alcohols $C_6H_5C(CF_3)_2OH$ and $C_6F_5C(CF_3)_2OH$ is only 0.9. If one trifluoromethyl group in perfluoro-t-butyl alcohol is replaced by pentafluorophenyl, the acidity (pK_a) of the alcohol falls by 2.5. When two trifluoromethyl groups are replaced, the acidity of the alcohol falls by only 1.9 (per pentafluorophenyl group). Further substitution produces almost no change in the contribution of a pentafluorophenyl group to the acidity of the alcohols, since the difference in pK_a between trispentafluorophenylmethanol and perfluoro-t-butyl alcohol is ~5.6, which gives ~1.9 per pentafluorophenyl group.

VII. HALOGENS

Whereas the introduction of fluorine atoms into an aromatic ring lowers its reactivity towards electrophilic reagents (Section II), the reactivity of the polyfluorinated aromatic ring towards nucleophilic reagents is sharply increased[4,7]. Results for the reaction of mono-, di-, and poly-fluorobenzenes with methanolic sodium methoxide show (Table 22) that the rate of nucleophilic substitution increases significantly with the accumulation of fluorine atoms. The position of these atoms relative to the reaction centre is extremely important: thus the rate of nucleophilic substitution is least in 1,2,4,5-tetrafluorobenzene among its isomers, owing to $I-\pi$ repulsion of the *para*-fluorine atom in the transition state (an intermediate structure of the Wheland type is the least stable)[88,89]. As with aromatic electrophilic substitution (Section II) the effects of the fluorine atoms in polyfluorobenzenes on nucleophilic substitution are not additive: the calculated rates are higher than the experimental values. Thus the accumulation of fluorine atoms in the benzene molecule leads to a relative slowing down of nucleophilic aromatic substitutions on the one hand, and to a relative increase in the rate of electrophilic aromatic substitutions on the other. Quantum-mechanical calculation of the electron density (allowing for π- and σ-charges) on the carbon atoms bearing fluorine in polyfluorobenzenes predicts the reactivity sequence

$$C_6H_2F_4 > 1,2,3,4\text{-}C_6H_2F_4 > 1,2,4,5\text{-}C_6H_2F_4;\ C_6HF_5 > C_6F_6$$

towards nucleophilic reagents[23]. This corresponds satisfactorily to experimental results allowing for the statistical factor for hexafluorobenzene.

* Relative rate allowing for statistical factor.

Table 23 gives the relative rates and kinetic parameters of the reactions of halogenated benzenes with sodium methoxide. The relative lability of a fluorine atom in hexafluorobenzene is closely similar to that of the *para*-fluorine atom in pentafluorobenzene, owing to the approximately equal difference in stabilities of both ground and

transition states for these compounds[89]. The lower mobility of a fluorine atom in hexafluorobenzene than in pentachlorofluorobenzene shows that the five fluorine atoms are less strongly accepting than are the five chlorine atoms, since $I-\pi$ repulsion is greater for a fluorine atom than for a chlorine atom[89]. Effective participation of *p*-electrons of lone pairs on fluorine atoms in destabilising the carbanion type of transition state obviously reverses the sequence of the halogens observed in the stability of polyhalogenated aryl anions (Section II). Table 23 shows that the total electron-accepting effect of five fluorine atoms and five chlorine atoms is close to that of a nitro-group *ortho* or *para* to a halogen.

Table 24. Rates of nucleophilic substitution of *para*-fluorine atom in compounds *p*-RC_6H_4F (k_2') and C_6F_5R (k_2'') with methanolic sodium methoxide at 50°C.

* Rates calculated by proposed[84] Hammett correlation equation.

Since additivity is lacking in the effect of fluorine atoms on the rate of nucleophilic substitution, it is of interest to examine comparative data on the effect of a substituent on the rate of substitution of a *para*-fluorine atom in fluorinated and in non-fluorinated benzene derivatives. Table 24 shows that the transmissibility of the effect of the substituent R from the *para*-position to the reaction centre is different for compounds of types *p*-RC_6H_4F and C_6F_5R, since the ratios $k_2'(R)/k_2'(H)$ and $k_2''(R)/k_2''(H)$ are unequal. On the other hand, the contribution of the four fluorine atoms at positions 2, 3, 5, and 6 vary for different substituents R, which is responsible for differences in the ratio k_2''/k_2'. It follows from this analysis of the rates of nucleophilic substitution of the *para*-fluorine atom in compounds *p*-RC_6H_4F and C_6F_5R that the electron-accepting effects of substituents such as nitro, cyano, and trifluoromethyl are weaker in polyfluorinated compounds than in their non-fluorinated analogues, whereas the effects of weakly accepting substituents (chloro and especially fluoro) are quite close with the two types of compounds. Therefore no correlation is observed between the rates ($\lg k$) of the reactions of sodium methoxide with substituted pentafluorobenzenes and the σ_p-constants of the substituents[86]. A satisfactory correlation is obtained if σ_p^--constants are used for strongly accepting substituents, and σ_p-constants for weakly accepting substituents[84,92,93].

Table 25 shows that the relative rates of nucleophilic substitution of the *para*-fluorine in pentafluorobenzene derivatives C_6F_5R are considerably dependent on the reagent and the solvent[92-98]. The rates with charged nucleophiles (methoxide and phenoxide ions) exceed the rates with uncharged nucleophiles (piperidine). The influence of the solvent helps to explain the differing reactivities of polyfluorinated benzenes. Table 26 shows that methanol has a slight effect on the rate of reaction of the substituted pentafluorobenzenes with piperidine, especially when R = C_6F_5.[93] The probable reason is solvation by methanol of the substrates in initial and transition states, that of the fluorine atoms tending to lower the accepting power of the pentafluorophenyl group (Table 29). Weakening of the acceptor character of this group in 75% methanol has been noted earlier in connection with the acidity of benzoic acids (Table 15).

* Parentheses enclose relative rates of substitution of the *para*-fluorine at 100°C.[93]

An interesting solvent effect has been detected in the reaction of hexafluorobenzene[93] or methyl pentafluorobenzoate[94] with sodium methoxide in methanol or in a binary methanol–benzene mixture (Table 26). Addition of benzene to methanol diminishes the reaction velocity, probably owing to weakening of electrostatic interaction of the reagent and the fluorine atoms *ortho* to the reaction centre (breakdown of the so called "built-in solvation") and the steric retarding effect of the methanol-solvated fluorine atoms located *ortho* to the reaction centre[93]. The solvation of these atoms increases their bulk and

intensifies their steric interaction with the substituent. Probably for this reason the Hammett correlations for the reactions of substituted pentafluorobenzenes with piperidine are satisfied with poorer indices in methanol than in aprotic solvents (Table 27).[92,93]

The effects of the fluorine atoms in the polarographic reduction of pentafluorohalogenobenzenes are satisfactorily additive[99]. Whereas their contributions to the half-wave reduction potentials of pentafluorophenyl bromide and iodide decrease in the sequence $o > m > p$, in the case of the chloride and hexafluorobenzene the contributions are independent of the positions of the fluorine atoms in the benzene ring. These results suggest that the mechanism of the electrochemical detachment of fluorine and chlorine is different from that for bromine and iodine in pentafluorohalogenobenzene derivatives[100].

Several quantitative data have been published on the reactions of polyfluorinated aromatic compounds with radical agents. Thus the ratio of the rate constants for the phenylation of hexafluorobenzene and benzene by phenyl radicals generated by the decomposition of benzoyl peroxide is 0.44. The rate-determining stage of the process is probably addition of the phenyl radical to the aromatic substrate with formation of a radical σ-complex[101].

VIII. EFFECTIVENESS OF FLUORINE ATOMS

The effectiveness of fluorine atoms at different positions of the pentafluorophenyl group in influencing the reaction centre can be assessed both from thermodynamic data (ratio of ΔpK_a values for pentafluorophenyl- and *m*-fluorophenyl-benzene derivatives) and from kinetic data (ratio of reaction rate constants for these derivatives) (Table 28).

[a] Present work. [b] Ratio of differences in half-wave potentials $-E_{\frac{1}{2}}$. [c] Ratio of values of ΔpK_{R^+}.

These ratios show that the effects of *o*-, *m*-, and *p*-fluorine atoms depend on the nature of the reaction centre[9]. The efficiencies of the fluorine atoms in the pentafluorophenyl group are about the same—*o* > *m* > *p*—for reactions 16—18, 20, and 22 (Table 28), since they are governed solely by the inductive effect of the pentafluorophenyl group. The same sequence applies to reactions 1—3, 6, 7, 15, 19, and 21, in which the electron-accepting inductive character of the fluorine atoms also prevails. With all these reactions the effects of the

a Calculated from data of Ref. 63.

b Calculated by means of the equation[78,63]

$$pK_a\ (RCOOH) = -1.795\ \sigma^*(R) + 5.275\ ,$$

$$pK_a\ (C_6F_5COOH) = 1.67\ .$$

c Calculated by means of the equation[80]

$$pK_a = -1.44\ \Sigma\sigma^* + 16.67\ ,$$

with pK_a = 8.80 for $C_6H_5C(CF_3)_2OH$ [81] and σ* = 2.6 for the trifluoromethyl group[80].

d Calculated from data of Refs. 92 and 93.

e Calculated by means of the equation

$$\sigma_R^0 = (-2.44 + 0.0521\ \nu + 0.132\ pK_a)\ ,$$

from data of Ref. 106 with pK_a = 3.48 for $C_6F_5CH_2COOH$ [9] and ν = 35.76 MHz for $C_6F_5CH_2Cl$.[49]

fluorine atoms of the pentafluorophenyl group exhibit satisfactory additivity. Such additivity may thus be expected in nucleophilic reactions such as 1, 2, 3, 6, and 7 and in the dissociation of various acidic groups, e.g. reactions 15—22, involving a transition state or intermediate product without a significant contribution by *p*-electrons of lone pairs on the fluorine atoms, when the predominant stabilising effect will be the electron-accepting inductive effect in the sequence $o > m > p$.

The distribution of negative charge in the intermediate σ-complex in nucleophilic substitutions (reaction 4 in Table 28) depends to a considerable extent on the position of the fluorine atoms in the ring, since the participation of *p*-electrons of the fluorine atoms in this process is very substantial. Here, therefore, the stabilising effects of the fluorine atoms vary in the sequence $m > o > p$, and are non-additive.

Reaction 8 (Table 28) probably involves formation of a hydrogen bond between the reagent and an *ortho*-fluorine atom of the substrate, which accelerates the reaction[102]. In this case, of course, additivity of the effects of the fluorine atoms cannot be expected.

Electrophilic reactions such as 9—14 (Table 28), involving transition states or intermediate compounds with a significant contribution by *p*-electrons of lone pairs on fluorine atoms, exhibit the sequence $p > o > m$, corresponding to the predominant contribution by the positive conjugation effect of *ortho*- and *para*-fluorine atoms in the benzene ring. As with aromatic nucleophilic substitution, the effects of the fluorine atoms in the pentafluorophenyl group are not additive. An exception is reaction 14, for reasons discussed above (Section III).

Directly opposite requirements must obviously be met for resonance stabilisation of the σ-complexes in nucleophilic and in electrophilic aromatic substitution. Hence the former reactions become relatively slower (Section VII), and electrophilic substitutions relatively faster (Section II), than the additive rates to be expected with increasing degree of fluorination of the benzene ring.

IX. ANALYSIS OF σ-CONSTANTS OF PENTAFLUOROPHENYL GROUP

Quantitative data on the electronic effects of the pentafluorophenyl group can be derived as various σ-constants from thermodynamic measurements of pK_a or reaction velocities, as well as from the fluorine-19 n.m.r. chemical shifts of the corresponding pentafluorobiphenyl derivatives. Table 29 gives various σ-constants of the pentafluorophenyl group obtained for various reaction series. These data show that, with respect to its inductive effect (σ_m, σ^*, and σ_I constants), this group is a strong electron-accepting substituent in comparison with phenyl, but is weaker than trifluoromethyl. Its electron-accepting inductive effect is closely similar to those of ethoxycarbonyl and pentachlorophenyl. It is significant that the σ_I^*-constants of the pentafluorophenyl and phenyl groups, obtained from the ionisation constants of tertiary alcohols[81], are only about one-third of the analogous σ^*-constants deduced from the ionisation constants of carboxylic acids, and that the σ^*-constant in a tertiary alcohol containing two pentafluorophenyl groups is larger than that in the corresponding alcohol containing only one such group[81]. This effect (Section VI) may be attributed to $p-\pi$ interaction of trifluoromethyl groups and the benzene ring, which weakens the acceptor properties of phenyl and pentafluorophenyl groups[71]. Introduction of a second pentafluorophenyl group into the tertiary alcohol weakens the $p-\pi$ interaction owing to the increased *I*-effect of the field due to this group. It is significant that chlorine-35 nuclear quadrupole resonance has revealed an increase in the electron-accepting *I*-effect of pentafluorophenyl also in compounds of the type C_6F_5CHClR (R = Cl, CH_3, $COOC_2H_5$, C_6F_5).[49] The change in ^{35}Cl n.q.r. frequency in the compound $C_6F_5CHClCF_3$ might give information on the $p-\pi$ interaction of trifluoromethyl and pentafluorophenyl groups. The value of the σ_I-constant for the latter (and other groups) deduced from the fluorine-19 n.m.r. shifts of the pentafluorophenyl ring are usually 0.1 below the corresponding values obtained by Taft's method[66]. Nevertheless, Taft's method for estimating the σ-constants of a substituent, involving the ^{19}F n.m.r. chemical shifts of monofluorobenzene derivatives[104], will give values close to the σ-constants determined from other reaction series.

The σ_m-constants are smaller than the σ_p-constants for various reaction series, although it would appear that the opposite relation should apply, since the resonance effect of pentafluorophenyl expressed as the σ_R^0-constant is very slight. However, this last constant disregards direct polar conjugation of the substituent with the reaction centre, which is very important for the pentafluorophenyl group, as the preceding discussion has shown, for instance, in electrophilic and nucleophilic aromatic substitutions. It is highly probable that a constant effect of a *p*-pentafluorophenyl group cannot be expected, expressed as a narrow range of values of the σ_p-constant: rather a considerable range may be expected depending on the conditions of stabilisation of the transition state or the intermediate compound in various reactions. Whereas the values σ_m and σ_m^+ lie in the range 0.22—0.34, the corresponding range for σ_p, σ_p^+, and σ_p^- is 0.255—0.66. The relation $\sigma_m^+ > \sigma_p^+$ reflects the effective resonance participation of the pentafluorophenyl group in the distribution of positive charge in electrophilic reactions[57].

The very low values of the σ_m- and σ_p-constants derived from the ionisation of benzoic acids in 75% aqueous methanol, and also the decrease in the σ_p^--constant obtained from the correlation with the rate constants of nucleophilic aromatic substitution in methanol[92,93], are due (Section VII) to solvation by the alcohol of the fluorine atoms in the pentafluorophenyl group, which becomes less strongly accepting.

---o0o---

Thus the survey of the effect of the pentafluorophenyl ring on the reactivity of various functional groups has revealed an interesting combination of acceptor and donor properties of the fluorine atoms, which interact specifically with various functional groups. The effects of the pentafluorophenyl group connected predominantly with $p-p$ interaction of the fluorine atoms and the reaction centre are especially interesting.

The Chemistry of Unsubstituted Mono- and Di-amidrazones

A.L.Rusanov

The literature data on the methods of preparation and the reactions of unsubstituted mono- and di-amidrazones are discussed. Particular attention has been devoted to the employment of di-amidrazones in the synthesis of heterochain polymers. The bibliography includes 111 references.

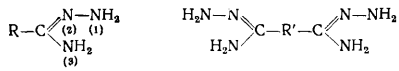
IV. Unsubstituted diamidrazones in the synthesis of heterochain polymers 799

I. INTRODUCTION

Unsubstituted mono- and di-amidrazones, which can be represented by the general formulae



are finding increasing applications in the synthesis of monomeric and high-molecular-weight organic compounds. However, there are virtually no systematic literature data on the synthesis, properties, and applications of these compounds, since the reviews published previously were devoted mainly to the chemistry of substituted amidrazones[1,2] in which at least one of the hydrogen atoms at the nitrogen atoms was substituted by some group and also to the chemistry of compounds (for example, aminoguanidine) containing, together with amidrazone groups, other functional groups[3-5]. Moreover, the advances in the field of high-molecular compounds obtained on the basis of unsubstituted diamidrazones were not considered in any of the earlier reviews.

The present survey deals mainly with problems associated with the methods of synthesis, principal reactions, and applications of unsubstituted mono- and di-amidrazones, the employment of diamidrazones in the chemistry of high-molecular-weight compounds being analysed in greatest detail.

II. METHODS OF SYNTHESIS

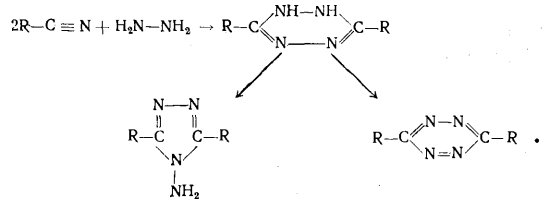
1. Interaction of Nitriles with Hydrazine

The simplest method for the preparation of amidrazones involves the interaction of nitriles with hydrazine or hydrazine hydrate[6]:

This reaction involves in its first stage nucleophilic attack by hydrazine on the carbon atoms of tne nitrile group and therefore its feasibility is to a large extent determined by the positive charge on the carbon atom of the nitrile group. The reaction of nitriles with hydrazine under mild conditions has been used successfully to synthesise unsubstituted amidrazones with one heterocyclic substituent: 2-thiazolylamidrazone, unsubstituted amidrazone[7], 4-alkyl- and phenyl-2-pyridylamidrazones[8,9], 2-quinolylamidrazone[8], 2-pyrimidinylamidrazone[8], 2-(1,10-phenanthrolinyl)-amidrazone[8], 3-isoquinolylamidrazone[10], and pteridinylamidrazones[11,12]. A number of perfluoroalkylamidrazones have been obtained in high yields by this method[13-15].

Certain unsubstituted diamidrazones have been synthesised by the reaction of hydrazine with dinitriles. Oxalodiamidrazone has been obtained from dicyanogen and hydrazine at room temperature[16-19]. Diamidrazones have been obtained under analogous conditions from the corresponding dinitriles of perfluoro-derivatives of dicarboxylic acids[13] and 2,6-dicyanopyridine[20].

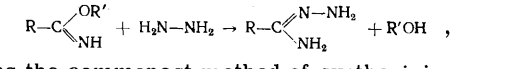
In some cases the reaction requires an increase of temperature, frequently to 100°C and above. Under these conditions, side products may be formed, including derivatives of 4-amino-1,2,4-triazole, dihydrotetrazine, and *s*-tetrazine[21]:



In order to synthesise amidrazones under the mildest possible conditions to avoid the occurrence of side reactions, one of the reaction components is frequently activated. Thus the "activated" state of nitriles is achieved by converting them into imidoesters, amidines, and thioamides.

2. Interaction of Imidoesters, Amidines, and Thioamides with Hydrazine

The reaction of imidoesters or their salts with hydrazine, which takes place according to the Scheme

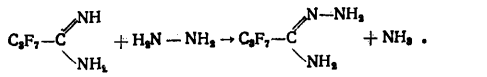


constitutes the commonest method of synthesising unsubstituted amidrazones. In a series of classical studies by

Pinner[22-27] amidrazones were synthesised from carbocyclic and heterocyclic aromatic acid imidoesters. In most cases amidrazones were not obtained in the form of free bases, but as their more stable salts. Subsequent investigations[28-31] demonstrated the applicability of this reaction to derivatives of a number of aromatic and aliphatic-aromatic acids, although the amidrazones were not isolated but were used *in situ* for further reactions. Subsequent studies of this reaction showed that it can be applied successfully to derivatives of aliphatic acids[32,33]. The extension of this method to the synthesis of unsubstituted diamidrazones made it possible to obtain the corresponding derivatives of isophthalic[34], terephthalic[35], pyridine-2,6-dicarboxylic[36], and oxalic[37] acids.

The method of synthesis of unsubstituted amidrazones based on the interaction of acid thioamides with hydrazine, has been widely used:

This reaction can be successfully employed to prepare various pyridylamidrazones[38,39] and benzamidrazone[38]. Oxalodiamidrazone has been synthesised in high yield by the reaction of dithioxamide with hydrazine[18,40]. The employment of the corresponding amidines as the "activated nitriles" for the synthesis of unsubstituted amidrazones is much less common. Nevertheless, Brown and coworkers[13] succeeded in synthesising perfluorobutyramidrazone by the reaction of perfluorobutyramidine with anhydrous hydrazine according to the following Scheme:



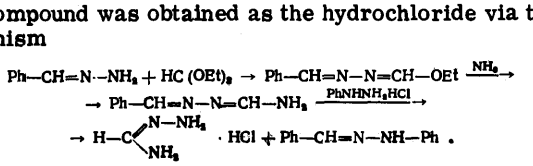
Together with the substitution of the cyano-group by more reactive functional groups, attempts were made to activate hydrazine. The employment of sodium hydrazide in place of hydrazine proved to be the most effective.

3. Interaction of Nitriles with Sodium Hydrazide

The synthesis of unsubstituted amidrazones from nitriles and sodium hydrazide via the mechanism

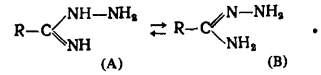
is a reaction common to many nitriles and takes place under mild conditions with high yields. It can be used successfully to synthesise unsubstituted monoamidrazones[41,42]—acetamidrazone, caprinamidrazone, myristamidrazone, heptadecanecarboxamidrazone, stearamidrazone, benzamidrazone, salicylamidrazone, α-naphthamidrazone and β-naphthamidrazone—and also for the synthesis of a number of unsubstituted diamidrazones of aliphatic dicarboxylic acids[43]—dodecanedicarboxylic, sebacic, suberic, pimelic, adipic, and glutaric.

A specific method of synthesis, differing from the processes described previously, has been proposed for the preparation of the first member of the homologous series of unsubstituted monoamidrazones—formamidrazone[44]. This compound was obtained as the hydrochloride via the mechanism



Other synthetic pathways, frequently used to prepare substituted amidrazones and discussed by Neilson et al.,[2] have not found extensive applications in the synthesis of unsubstituted amidrazones.

When the methods of their synthesis were considered, the structure proposed by Pinner[25] was attributed to all amidrazones. Nevertheless, many investigators[2,45] acknowledge the possibility of the tautomerism



There are at present no data confirming unambiguously the validity of any particular view, but study of the structures of certain substituted and unsubstituted amidrazones by infrared spectroscopy and NMR showed that structure (B) is preferable[46,47]. On the other hand, the infrared spectra of perfluoroalkylamidrazones contain three absorption bands in the range 3100–3500 cm^{-1} due to the stretching vibrations of the NH and NH_2 groups[13]; two other intense absorption maxima are associated with the vibrations of the C=N bond (1600–1700 cm^{-1}) and the deformation vibrations of the NH_2 groups (1655 cm^{-1}). Weak absorption maxima in the region of 1590 cm^{-1}, which are characteristic of NH deformation vibrations, have also been noted in the spectra of the products.

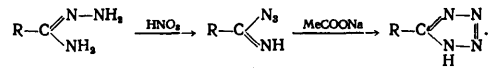
III. REACTIONS

1. Homocondensation of Amidrazones

Typical reactions of amidrazones, which greatly hinder their synthesis, are homocondensation processes, proceeding, according to Pinner's data[23,26] via the formation of dihydrotetrazines subsequently converted into compounds similar to those described above.

2. Interaction of Amidrazones with Nitrous Acid and Its Esters

When amidrazones are treated with nitrous acid or its esters, tetrazoles are formed[48,49]. This reaction proceeds via the formation of an azide imide, which subsequently rearranges to the tetrazole:

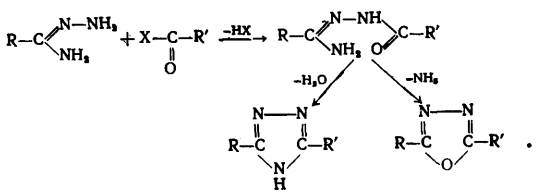


This reaction has been used successfully to synthesise tetrazoles containing alkyl[42], aryl[23,25,26], heterocyclic[24,38], and other substituents[50] in the 5-position and also to synthesise a number of bistetrazoles[43]. In all cases the tetrazoles were synthesised smoothly and the final products were obtained in nearly quantitative yields. An exception is acetamidrazone, which decomposes under the usual diazotisation conditions in an acid medium with formation of acetic acid, ammonium chloride, and hydrazoic acid; 5-methyltetrazole was synthesised successfully by the reaction of acetamidrazone with ethyl nitrite in ethanol[32,33].

3. Interaction of Amidrazones with Carboxylic Acids and Their Derivatives

The reaction of unsubstituted amidrazones with carboxylic acids and their derivatives (esters, anhydrides, and chlorides) leads to the formation of acylamidrazones,

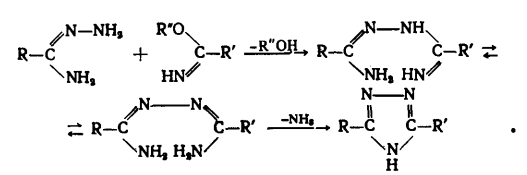
which are then converted into either 1,2,4-triazoles or 1,3,4-oxadiazoles, depending on the conditions in their subsequent treatment:



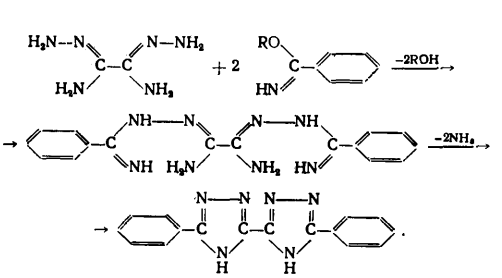
1,2,4-Triazoles are synthesised[51,52] by the above method via the thermal cyclodehydration of acylamidrazones in the absence of solvent or in *m*-cresol, *N*-methyl-2-pyrrolidinone, and hexamethylphosphoramide[53]. This reaction has been used successfully to synthesise 1,2,4-triazoles from aromatic acid amidrazones[26,53-55]. Mono- and arylbis-[3-(*o*-nitrophenyl)-1,2,4-triazoles], which are intermediates in the synthesis of triazoloquinazoline systems, have been obtained under analogous conditions[56-62].

1,2,4-Triazoles have been synthesised under the same conditions from the amidrazones of aliphatic monocarboxylic acids[42] and oxalodiamidrazone[63,64]. However, the cyclisation of acylamidrazones in the presence of strong acids (dichloroacetic[53,63-65], trifluoroacetic, phosphoric, and sulphuric[53]) is accompanied by the liberation of ammonia and the conversion of the acylamidrazone moieties into 1,3,4-oxadiazole moieties.

The possibility of the alternative formation of 1,2,4-triazole and 1,3,4-oxadiazole rings disappears when imidoesters are used as the carboxylic acid derivatives, since the "dihydrazidines" formed in the first stage of the reaction are converted only into the corresponding 3,5-disubstituted 1,2,4-triazoles[22-27]:



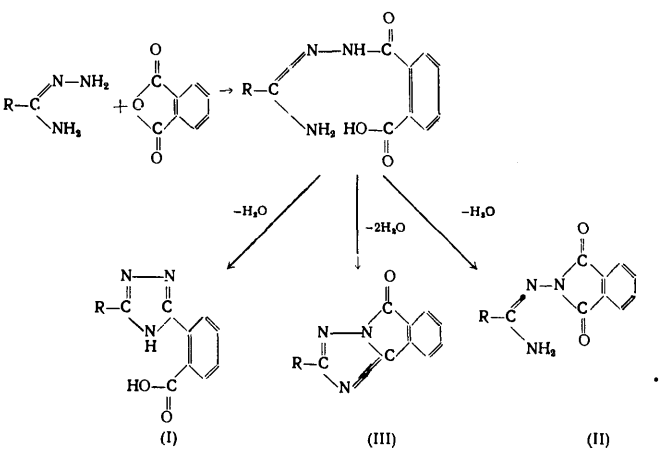
The above reaction, like the homocondensation of amidrazones discussed previously, greatly hinders their synthesis from imidoesters. This synthetic method has been used to prepare bi-5-phenyl-1,2,4-triazol-3-yl by the reaction of oxalodiamidrazone with ethyl benzimidate or its hydrochloride[66,67]:



4. Interaction of Amidrazones with Cyclic Anhydrides of Aromatic Di- and Tetra-carboxylic Acids

In contrast to the reactions of amidrazones with carboxylic acid derivatives, their interaction with aromatic *ortho*- and peri-dicarboxylic acids and their derivatives (particularly anhydrides) was investigated comparatively recently in connection with research in the field of thermostable heterocyclic polymers[34,67-78].

According to the results of the majority of investigators[34,67-73], the first stage of the reaction of unsubstituted amidrazones with phthalic anhydride involves the formation of *o*-carboxybenzamidrazones, the subsequent cyclodehydration of which gives rise to compounds having the structures, according to the data of various workers, of *o*-carboxyphenyl-1,2,4-triazoles (I)[67], *N*-phthalimidoamidines (II)[72], and isoindolo[1,2-]-*s*-triazol-5-ones (III)[34,68-71]:

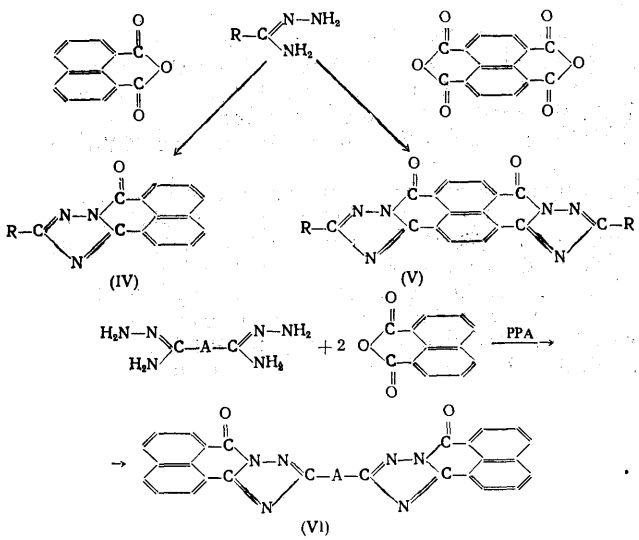


(I) (III) (II)

Subsequent studies on these reactions[73-75] established unambiguously that the final products have isoindolo[1,2]-*s*-triazol-5-one structures of type (III), while *o*-carboxyphenyl-1,2,4-triazoles and *N*-phthalimidoamidines are intermediates. The process takes place via the interaction of the initial amidrazones with phthalic anhydride in polar aprotic solvents and subsequent heating of the resulting *o*-carboxybenzamidrazones. It could not be carried out in polyphosphoric acid (PPA)[79], probably because of the possible interaction of the final heterocycle with the amidrazone (which has not yet reacted) via the O=C–N< linkage[71,75].

In contrast to the reaction of amidrazones with phthalic anhydride, their reaction with naphthalic anhydride takes place most successfully in PPA[71,74-78]. Condensation of monoamidrazones with the anhydrides of naphthalic and naphthalene-1,4,5,8-tetracarboxylic acids and also of diamidrazones with naphthalic acid anhydride in PPA gave nearly quantitative yields of substituted benzo-*s*-triazoloisoquinolinones (IV), bis(benzo-*s*-triazoloquinazolinones)

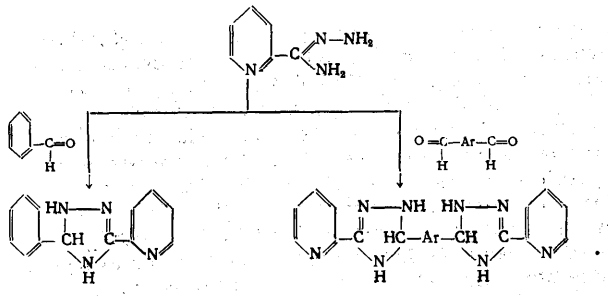
(V), and also benzobis-1,2,4-triazolophenanthrolinediones (VI):



5. Interaction of Amidrazones with Aldehydes and Ketones

This reaction was first investigated by Pinner[23,24], who showed that, when unsubstituted amidrazones interact with benzaldehyde in an acid medium, Schiff bases are formed:

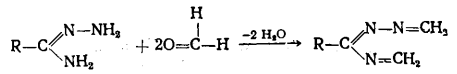
By extending this reaction to fluorinated monoamidrazones[15], it was possible to obtain *N*-benzylideneheptafluorobutyramidrazone whose subsequent treatment with I_2 and then $NaHSO_3$ led to the formation of 2-(heptafluoropropyl)-5-phenyl-1,2,4-triazole. According to Hergenrother and Carlson[80], who investigated the reaction of 2-pyridylamidrazone with aromatic mono- and di-aldehydes, the cyclic products of this reaction are disubstituted mono- and bis-triazolines:



These are not converted into the corresponding 1,2,4-triazoles on treatment with sulphur, chloranil, dimethyl sulphoxide (DMSO), and $FeCl_3$ under different conditions.

These workers carried out the reaction of 2-pyridylamidrazone with a number of mono- and di-ketones: acetophenone, *pp'*-diacetylbiphenyl, *p*-diacetylbenzene and 2,6-diacetylpyridine; the corresponding 3-methyl-substituted mono- and bis-triazolines were obtained[80].

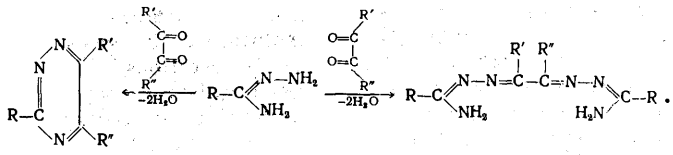
The condensation of amidrazones with an excess of highly reactive carbonyl compounds, for example with formaldehyde, involves both $N_{(1)}$ and $N_{(3)}$ atoms of the amidrazone group[27]:



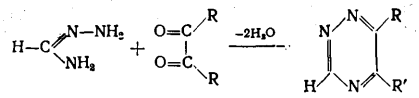
The possibility, in principle, of the interaction of both reaction centres with the carbonyl compounds led to a successful reaction between unsubstituted amidrazones and α-dicarbonyl compounds.

6. Interaction of Unsubstituted Amidrazones with α-Dicarbonyl and Polycarbonyl Compounds

This reaction results in the formation of 1,2,4-triazines[26] or acyclic products[81]:

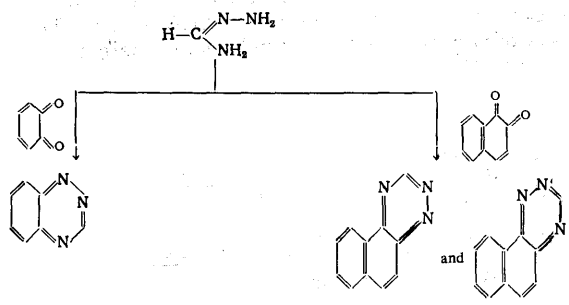


It has been widely used to synthesise a number of 1,2,4-triazines by the interaction of monoamidrazones with α-dicarbonyl and bis-α-dicarbonyl compounds and also of diamidrazones with α-dicarbonyl compounds. Thus the reaction of formamidrazone with various α-dicarbonyl compounds yielded mono- and di-substituted 1,2,4-triazines[82]:



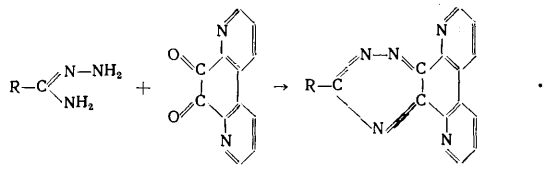
A series of 1,2,4-triazines with aromatic carbocyclic and heterocyclic substituents were synthesised from unsubstituted mono- and di-amidrazones by Case[8,9], Culbertson[83,84], and Hergenrother[85-87].

The syntheses of condensed systems incorporating 1,2,4-triazine rings, based on the interaction of unsubstituted amidrazones with *o*-quinones and related systems, are widely used[8,9,82]. Thus the reaction of formamidrazone with *o*-benzoquinone and 1,2-naphthoquinone gave rise to 1,2,4-benzotriazine and two isomeric naphthotriazines[82]:

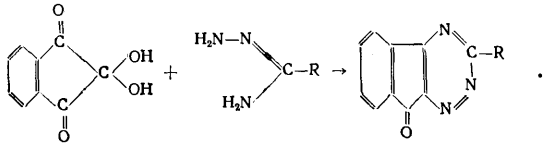


Even more condensed systems—substituted 1,2,4-triazino[5,6-*f*]-4,7-phenanthrolines—were obtained by Case

by the reaction of a number of amidrazones with 4,7-phenanthroline-5,6-dione[8,9]:



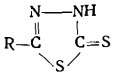
Together with α-dicarbonyl compounds, polycarbonyl compounds can also be made to react with amidrazones; thus triketones or their hydrates condense with amidrazones to form condensed heterocycles, incorporating 1,2,4-triazine moieties[35]:



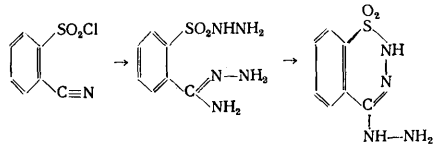
Ketoacids and ketoesters having the general formula RO–CO–CO–CO–CO–OR can also be employed as polycarbonyl compounds in condensation reactions with amidrazones[88,89]. The products of their condensation with amidrazones are 1,2,4-triazinepolycarboxylic acids or their esters.

7. Other Reactions of Amidrazones

Together with the syntheses of heterocyclic compounds from amidrazones which were discussed above, other reactions of these compounds were investigated. Thus, when amidrazones derived from aromatic carbocyclic and heterocyclic acids were treated with CS_2, 1,3,4-thiadiazole-5-thiones were obtained in high yields (73–95%):

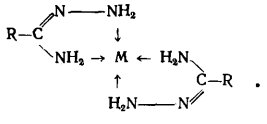


(R = phenyl, naphthyl, 2-, 3-, and 4-pyridyl, 2-quinolyl, etc.). Aromatic acid amidrazones containing a sulphonyl hydrazide group in the *o*-position, undergo intramolecular cyclisation; thus benzamidrazone-*o*-sulphonyl hydrazide—the product of the interaction of *o*-cyanobenzenesulphonyl chloride with hydrazine—readily cyclises to 4-hydrazino-1,2,3-thiadiazine 1,1-dioxide[91]:



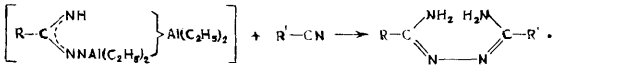
8. The Formation of Metal Complexes

Amidrazones form complexes with transition metal ions which are highly coloured with distinct melting points.



Complex formation proceeds so readily that it can serve as a basis of analytical methods for the determination of microamounts of both amidrazones and transition metal ions. In particular, it has been observed that oxalodiamidrazone can be used to detect microamounts of nickel[18].

The reaction of two equivalents of triethylaluminium with amidrazones in benzene results in the formation of tetrameric bis(diethylalumino)amidrazones[92]:



These compounds are soluble in benzene and on reaction with nitriles are converted into 1,4-disubstituted diazabuta-1,3-diene-1,4-diamines.

IV. UNSUBSTITUTED DIAMIDRAZONES IN THE SYNTHESIS OF HETEROCHAIN POLYMERS

Whereas unsubstituted monoamidrazones have found only limited applications (among derivatives of the pyridine series, several substances with pharmacological and antimicrobial activities were found[31,39,93–95]), unsubstituted diamidrazones of dicarboxylic acids have been assuming increasing importance as monomers for the synthesis of a number of heterochain and in particular heterocyclic polymers.

Examination of the reactions involving the formation of heterocycles from amidrazones which were discussed above shows that, like *o*-phenylenediamine, unsubstituted amidrazones readily react with (1) carboxylic acids and their derivatives forming on subsequent cyclisation 1,3,4-oxadiazole or 1,2,4-triazole rings (2-substituted benzimidazoles are formed from *o*-phenylenediamine), (2) with the cyclic anhydrides of aromatic *ortho*- or peri-dicarboxylic acids and subsequent formation of heterocycles which can be combined under the common name aroylene-*s*-triazoles (under analogous conditions, *o*-phenylenediamine gives rise to aroylenebenzimidazoles), and (3) with α-dicarbonyl compounds to form 1,2,4-triazines (under analogous conditions, *o*-phenylenediamine leads to the quinoxaline ring). Since bis-(*o*-phenylenediamines) have been widely used in recent years in the synthesis of thermostable heterocyclic polymers[96], their "analogues" (diamidrazones) have naturally also attracted attention as potential polyfunctional monomers.

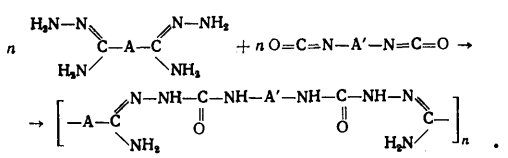
Since the nucleophilic reactivity of the hydrazine moieties of amidrazones is comparable to that of the imido-groups in *o*-phenylenediamine or is actually superior[80], polymers based on diamidrazones can be synthesised under the same conditions as the polymers based on bis-(*o*-phenylenediamines).

However, one should note that diamidrazones have one significant advantage over bis-(*o*-phenylenediamines). Thermostable heterocyclic polymers are usually synthesised[97] by a two-stage process involving polyfunctional monomers; linear prepolymers are synthesised in the first stage under mild conditions, which means that each monomer used in the process must have two functional groups. The linear polymers formed in the first stage have free functional groups distributed in such a way that in the second stage heterocycles can be formed under the influence of heat or chemical agents. The synthesis of linear polymers in the first stage entails the necessity for a selective polycondensation process, usually selective polyamidation. When the polyamidation is carried out by

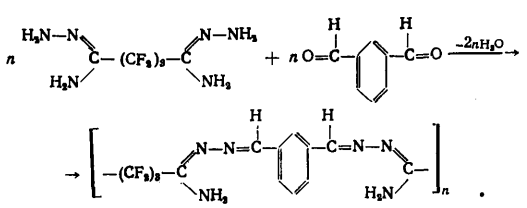
the interaction of polyfunctional nucleophilic compounds with polycarboxylic acid derivatives, process selectivity is achieved more readily the greater the difference between the nucleophilic reactivities of the reaction centres in the *o*- or α-positions relative to one another[98,99]. An alternative condition for selective polyamidation is rapid deactivation of the reaction centre after the group in the *o*- or α-position relative to it has entered into the amidation reaction. Since the amino-groups of bis-(*o*-phenylenediamines) exhibit comparatively similar nucleophilic reactivities, their reactions with highly reactive carboxylic acid derivatives frequently involve the breakdown of the selectivity of the processes, leading to gel formation and the prepolymers cannot therefore be converted into the desired products. In contrast to bis-(*o*-phenylenediamines), in diamidrazones the nucleophilic reactivities of the hydrazine and amidine centres differ sharply, which makes it possible to carry out polycondensation processes involving them with a high degree of selectivity. In combination with the relative availability of many diamidrazones and their resistance to oxidation, this factor makes these compounds extremely promising monomers.

All that has been said above applies not only to the reactions of diamidrazones with polycarboxylic acid derivatives but also to their reactions with dicarbonyl compounds and di-isocyanates.

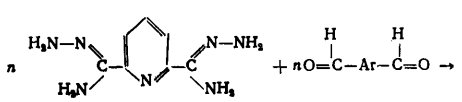
High-molecular-weight film- and fibre-forming poly-(carbamoylamidrazones) were obtained by the reaction of diamidrazones with di-isocyanates in aprotic dipolar solvents containing lithium chloride at 20–50°C:[100]

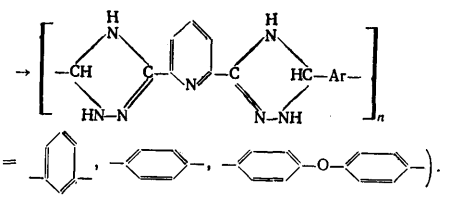


Polymers incorporating fragments of the Schiff base type (polyarylidene-amidrazones) have been obtained by the reaction of hexafluoroglutarodiamidrazone with isophthalaldehyde[101]:



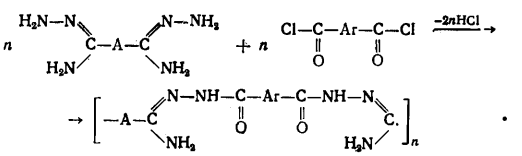
In both instances[100,101] there is a possibility of the conversion of the resulting polymers into heterocyclic systems, but there are no unambiguous data showing that this possibility is in fact realised. In contrast to these studies, Hergenrother and Carlson[80] showed unambiguously that the reaction of the diamidrazone of pyridine-2,6-dicarboxylic acid with aromatic dialdehydes leads to the formation of polytriazolines:





Polytriazolines are soluble to a limited extent in *m*-cresol, dimethylacetamide, dimethyl sulphoxide, and formic and trifluoroacetic acids. The intrinsic viscosities of solutions of these polymers are 0.51–0.61 dl g^{-1}, which makes it possible to obtain strong elastic films from their solutions in acids. According to the results of thermogravimetric analysis, the degradation of these polymers begins in the temperature range 280–400°C; attempts to convert them into the corresponding poly-1,2,4-triazoles were unsuccessful.

A number of studies were made on the interaction of diamidrazones with dicarboxylic acid dichlorides with consequent conversion of the resulting poly(acylamidrazones)[53-54,63,64,101-108]. Poly(acylamidrazones) were synthesised by the reaction of oxalic[63,64,103-108], isophthalic[102], terephthalic[102], and pyridine-2,6-dicarboxylic acid[53,54] diamidrazones with aromatic dicarboxylic acid dichlorides under the conditions of interfacial polycondensation[53,54,63,64,103-108] and low-temperature polycondensation in aprotic amide solvents[53,54,63,64,102,104]:

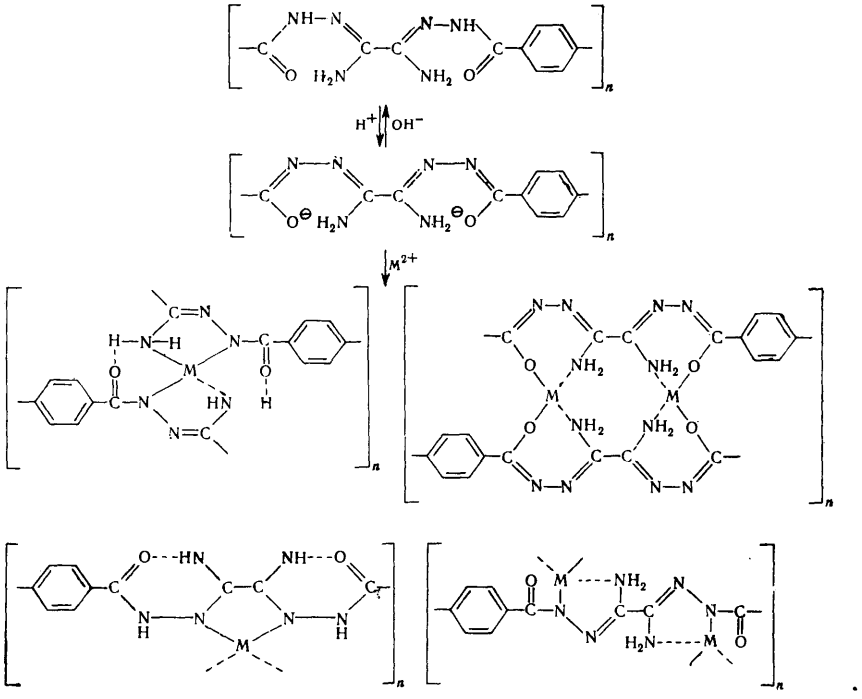


The poly(acylamidrazones) with the highest molecular weights among those obtained exhibit film- and fibre-forming properties[53,54,103,105,107-110].

The poly(acylamidrazones) were converted into the corresponding poly-1,2,4-triazoles by heating in high-boiling solvents, for example *m*-cresol[53,54], or by heat treatment in the solid phase at a temperature exceeding 250°C.[53,54,63,64,102,105,108] The polymers obtained by the solid-phase heat treatment of poly(acylamidrazones) contain 1.4–4% of oxadiazole rings according to the analysis of the products formed[53,54]. The cyclisation of poly(acylamidrazones) in strong acids (dichloroacetic[63,64], trifluoroacetic[53,54], PPA[53,54], and sulphuric[53,54]) was accompanied by the formation of poly-1,3,4-oxadiazoles.

The poly-1,2,4-triazoles and poly-1,3,4-oxadiazoles obtained in this way are soluble in concentrated sulphuric acid and, according to the results of dynamic thermogravimetric analysis, begin to undergo degradation in air at about 420°C.

Chelate polymers, produced by the interaction of poly-(acylamidrazones) with various metal cations (Ca^{2+}, Ba^{2+}, Sn^{2+}, Zr^{2+}, Zn^{2+}, Cd^{2+}, Bi^{2+}, Pb^{2+}, Cu^{2+}, Fe^{2+}, Au^{+}, etc.), are of exceptional interest in connection with the urgent problem of the synthesis of fire-resistant polymers[103,109]. Chelate polymers have been most widely synthesised from poly(acylamidrazones) based on oxalodiamidrazones and terephthaloyl chloride and the following structure has been proposed for them[103]:



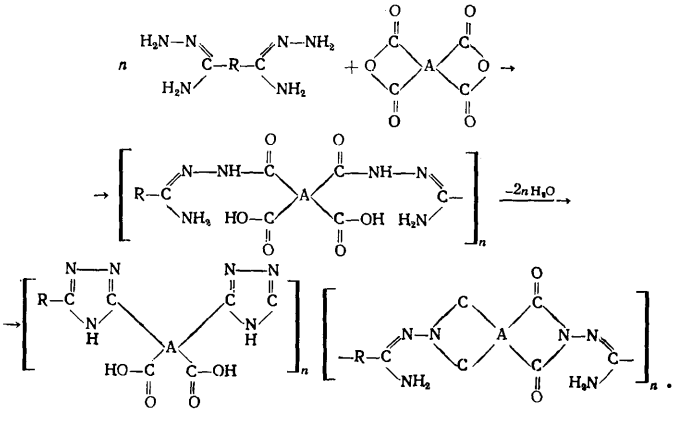
These polymers are highly fire-resistant and are used as the fire-resistant fibre Enkatherm[103]. The Table presents the comparative oxygen indices of various fibres, demonstrating the appreciable advantage of Enkatherm over other fibres.

Characteristics of the fire resistance of a number of fibres.

Polymer fibre	Temp. of spontaneous inflammation, °C	Oxygen index	Polymer fibre	Temp. of spontaneous inflammation, °C	Oxygen index
Cotton	400	0.18	Polyacrylonitrile	560	0.18
Polypropylene	440	0.18	Wool	590	0.25
Acetate	480	0.18	Nomex	—	0.28
Polyester	510	0.20	Polybenzimidazole	—	0.41
Nylon	530	0.22	Enkatherm	—	0.52

Among the series of other attempts at the synthesis of polymers based on diamidrazones and dicarboxylic acid derivatives, special mention should be made of the work of Ried and Giesse[67], who achieved the reaction of oxalo- and terephthalo-diamidrazones with the ethyl bisimidoesters of the same acids in lower alcohols with subsequent heat treatment. According to the authors[67], the reaction products are low-molecular-weight poly-1,2,4-triazoles.

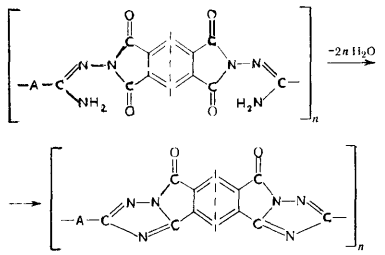
The synthesis of partly "ladder-types" polymers based on the diamidrazones of dicarboxylic acids has been attracting increasing attention recently. The interaction of diamidrazones with dianhydrides was achieved for the first time by Ried and Giesse[67] in the specific instance of the reaction of oxalodiamidrazones and pyromellitic and cyclopentanetetracarboxylic acid dianhydrides in pyridine. The structure of polytriazoles containing carboxylic acid side chains was attributed to the products. Another structure (polyamidinoimide) was proposed for the products of the reaction of diamidrazones with pyromellitic acid dianhydride[72]:



The first stage of the process—the synthesis of poly-(*o*-carboxy)acylamidrazones—was carried out in dimethyl sulphoxide. The resulting high-molecular-weight polymers were converted into films and subjected to polycyclodehydration.

In the course of subsequent investigations[34,68-71] it was shown that poly(amidinoimides) are merely intermediates formed under comparatively mild cyclisation conditions;

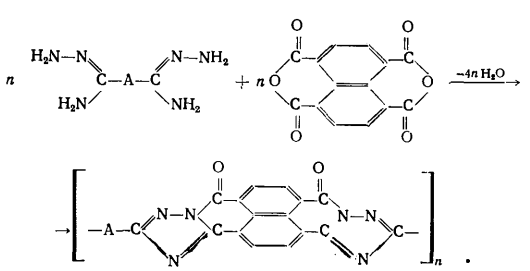
at higher temperatures they are converted into polytriazoloisoindolones:



In the spectroscopic study of the structures of the polymers obtained the authors[67,72] probably failed to take into account the fact that polytriazoloisoindolones, like many other heterocyclic polymers, are incompletely cyclised polymeric structures and contain a considerable number of defective units, which are responsible for the appearance of additional absorption bands in the infrared spectra of the polymers.

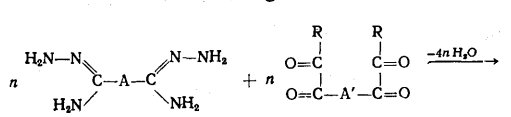
The presence of defective units in the polymeric structures under consideration and also the tendency of the isoindolotriazolone rings themselves to undergo degradation at the $\rangle C-CO-$ and $-OC-N\langle$ bonds and to hydrolyse are responsible for the comparatively poor thermal characteristic of these polymers—the majority of polytriazoloisoindolones begin to undergo degradation at temperatures not exceeding 400°C.[69-71]

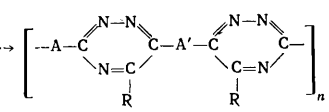
Polybenzobistriazolophenanthrolines (polynaphthoylenetriazoles), produced by the reaction of dicarboxylic acid diamidrazones with naphthalene-1,4,5,8-tetracarboxylic acid or its dianhydride, have a much higher thermal stability[71,73,76-78]. They are synthesised by single-stage polycyclocondensation in PPA or by two-stage polycyclocondensation with the first stage carried out in hexamethylphosphoramide in accordance with the following scheme:



The single-stage process in PPA, whereby film-forming polymers with a logarithmic viscosity of the solutions of about 2.5 dl g^{-1} may be obtained, is more effective in relation to the above polymers. Polybenzobistriazolophenanthrolines, which are soluble in sulphuric and methanesulphonic acids, begin to lose weight appreciably in air at 500°C under the conditions of dynamic thermogravimetric analysis and at a temperature in excess of 400°C under the conditions of isothermal thermogravimetric analysis.

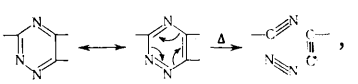
A number of high-molecular-weight poly-1,2,4-triazines have been obtained by the reaction of dicarboxylic acid diamidrazones with bis-(α-dicarbonyl) compounds[85-87,111] in accordance with the following scheme:





The reaction of dicarboxylic acid diamidrazones with diglyoxals was achieved by Hergenrother[85,87] and Culbertson[111] in polar organic solvents (*m*-cresol[85,87], hexamethylphosphoramide[111], etc.) between 0°C and the boiling point of the solvent with subsequent heat treatment of the polymers or without it. The initial diamidrazones were derived from pyridine-2,6-dicarboxylic[85,111], oxalic[87,111], and also malonic, succinic, glutaric, adipic, sebacic, isophthalic and terephthalic acids[111]. The diglyoxals employed were *pp'*-oxybis(phenyleneglyoxal) hydrate[85,87,111], 1,4-diglyoxaloylbenzene, *pp'*-thiobis(phenyleneglyoxal)[87,111], 1,2-diglyoxaloylnaphthalene, 2-chloro-1,3-dioxalylbenzene, etc.[111]

The fully aromatic poly-1,2,4-triazines exhibit limited or partial solubility in polar solvents of the type of *m*-cresol, dimethyl sulphoxide, dimethyl acetamide, and hexamethylphosphoramide. According to the results of dynamic thermogravimetric and differential thermal analyses, they begin to undergo intense degradation at about 400°C in air and at 450°C in an inert medium. The comparatively low thermo-oxidative and thermal stability of these polymers can be accounted for by the ease of liberation of nitrogen,



and the oxidation of the $\rangle C-H$ fragment of the triazine ring[85].

Poly-1,2,4-triazines, which are much more soluble in polar solvents and have a much higher thermo-oxidative stability compared with the polymers discussed above, were obtained by the reaction of dicarboxylic acid diamidrazones with dibenzils. The dicarboxylic acid diamidrazones employed were derived from pyridine-2,6-dicarboxylic[85,86] and oxalic[87] acids and the dibenzils were *pp'*-oxydibenzil[85-87] 1,3- and 1,4-bis(phenylglyoxaloyl)benzenes, *pp'*-thiodibenzil[86,87], as well as *pp'*-methylenedibenzil, and *pp'*-carbonyldibenzil[86]. The resulting polymers soften at 270–330°C, in contrast to unsubstituted poly-1,2,4-triazines, and exhibit a high resistance to isothermal heat-induced ageing in air at 260°C in the course of 1000 h[87]; at 290°C these polymers lose 20–25% of the initial weight in the course of 45 h. The polymers can be used as thermostable adhesive films and binders for fibreglass[86].

Mutual Influence of Ligands in Complexes

Yu.N.Kukushkin

The review deals with the theoretical concepts and experimental data on the mutual influence of ligands in complexes. Studies published after 1952 are covered.
The bibliography includes 166 references.

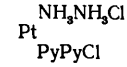
I. INTRODUCTION

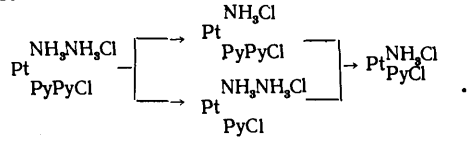
The problems of the mutual influences of atoms was raised by Chernyaev in relation to inorganic chemistry. In 1925 he formulated the *trans*-influence rule [1], which, after Werner's coordination theory had been devised, became the most important generalisation in the chemistry of complexes. In recent years certain non-Soviet scientists have tended to attribute the discovery of the trans-*influence* to Werner. This tendency began with the review of Quagliano and Schubert [2], who, referring to Werner's paper [3], claimed that Werner introduced the concept of the elimination of groups in the *trans*-position.

This situation apparently arose because Jørgensen, who supported Blomstrand's views on the structure of complexes, assumed that Peyrone's chloride has the structure

When it reacts with pyridine, the product is a mixed tetrabase complex to which the following structure was attributed



Its cleavage by hydrochloric acid proceeds via the following stages:



Werner laid the foundations of coordination theory [3]. In his communication he explained the isomerism of dichlorodibaseplatinum(II) complexes from the standpoint of the hypothesis, which he put forward for the first time, that platinum(II) complexes have a planar structure. He developed his planar structure hypothesis on the basis of

Jørgensen's experimental data[4]. He introduced the concept of the planar configuration of platinum(II) complexes and concluded that, when $[Pt(NH_3)_4]^{2+}$ reacts with hydrochloric acid, the complex $[Pt(NH_3)_2Cl_2]$ with the *trans*-configuration is obtained. However, the *trans*-cleavage rule (Jørgensen's rule) can in no way be regarded as the *trans*-influence rule. Chernyaev's *trans*-influence rule includes not only Jørgensen's rule but also Peyrone's and Kurnakov's rules. Thus there are no grounds for attributing to Werner the discovery of the *trans*-influence rule.

In March 1952 a conference was held on the *trans*-influence rule[5], where 25 years of the study and refinement of Chernyaev generalisation were assessed. This review presents the main achievements in this field during the last two decades.

In 1952 the *trans*-influence rule was based on complexes of bivalent and quadrivalent platinum and partly bivalent palladium[6,7]. Lebedinskii's preparative studies demonstrated *trans*-influence in compounds of tervalent rhodium and iridium (Ref. 5, p. 95). On the other hand, Ablov merely posed the question of *trans*-influence in tervalent cobalt complexes and Volshtein did the same in relation to tervalent chromium complexes. In summarising the conference proceedings, Chernyaev expressed his confidence that the *trans*-influence rule would be extended to many other elements in Mendeleev's Periodic System.

One may say that at present the vast majority of studies on *trans*-influence are carried out with platinum compounds. However, investigations of *trans*-influence in cobalt complexes have developed on a large scale and this problem is dealt with in a special review[8] published in 1969. Many studies have been made on *trans*-influence in rhodium(III) complexes and others on tervalent gold and ruthenium have been published. Isolated investigations have been made on *trans*-influence in gallium, tin, chromium, rhenium, and iron compounds.

A characteristic feature of the studies after 1952 is the change from a qualitative approach to quantitative investigation of the phenomenon. The first attempt at a quantitative characterisation of *trans*-influence was made by Gel'man and Karandasheva[9]. The development of these investigations enabled Zvyagintsev and Karandasheva to devise a quantitative *trans*-influence scale for individual ligands[10,11]. Kinetic studies on substitution reactions involving platinum(II) complexes enabled Grinberg and Kukushkin to discover in 1957 the *cis*-influence of ligands in complexes[12].

II. THEORY OF *TRANS*- AND *CIS*-INFLUENCE

The theories of *trans*-influence have been described in detail in a number of books and reviews[13-17]. Therefore they need not be considered in detail and only those which constituted important stages in the development of the *trans*-influence rule need be enumerated.

The Grinberg–Nekrasov polarisation theory[18,19] must be regarded as the first theory of this kind. Grinberg's interpretation of *trans*-influence on the basis of the oxidation-reduction interaction of the ligand with the central atom[20] extended the applicability of the polarisation theory. This theory has a considerable predictive power and is still used to account for the σ-*trans*-influence of ligands.

The next stage was Syrkin's explanation of *trans*-influence[21] on the assumption of ds-hybridisation in complexes. In recent years these views have again attracted the attention of theoreticians in relation to the phenomenon of "rehybridisation" of the hybrid dsp^2 orbitals of the central atom[22-24].

An important stage in the development of the theory of *trans*-influence was the high trans-influence of unsaturated ligands such as ethylene and carbon monoxide established by Gel'man[25]. The polarisation theory proved incapable of accounting for these facts. However, they served as the foundation for the development of the theory which was proposed almost simultaneously by Chatt and coworkers[26,27] and by Orgel[28]. The Chatt–Orgel theory refers to ligands with pronounced π-acceptor properties, such as ethylene, phosphines, or carbon monoxide. Owing to the π-acceptor properties of these ligands, the formation of metal–ligand double bonds becomes possible. A σ-bond is formed via the donor–acceptor mechanism and a π-bond is formed as a result of the overlapping of the filled d orbital of platinum having appropriate symmetry with the vacant orbital of the π acceptor (Fig. 1).

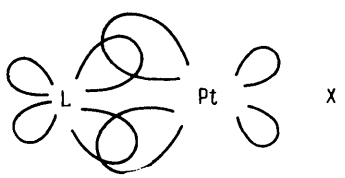


Figure 1. Schematic illustration of the formation of a metal–ligand π-bond.

In this case the ligand L can be phosphine or a sulphur-containing species. This scheme (Fig. 1) explains the enhanced rate of substitution of the ligand X. When a π-bond is formed, the attack on the Pt–X bond is facilitated and the transition state, which is an intermediate having a trigonal bipyramidal configuration, is stabilised (Fig. 2).

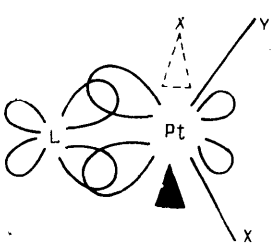

Figure 2. Schematic illustration of the stabilisation by the ligand of the intermediate with a trigonal bipyramidal configuration.

Bersuker pointed out a very significant feature of the Chatt–Orgel theory, namely he stressed the inter-relation between the σ-donor and π-acceptor properties of ligands[29]. In the donor–acceptor interaction the ligand gives up its σ electrons to the central atom and thereby reduces the

energies of its own π orbitals. As a result it becomes a stronger π-acceptor. It is thus found that the more marked the σ-donor properties the greater the possibilities of the reverse charge transfer from the central atom to the π orbitals of this ligand (Fig. 3).

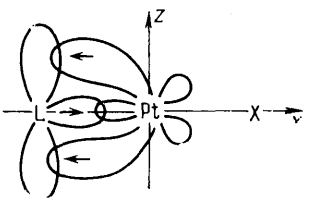

Figure 3. Schematic illustration of the σ- and π-type interactions of the orbitals of the ligand and the central atom.

Baranovskii and Sizova, who refined Bersuker's views, note[30] that the enhancement of the electron-donating capacity of the ligand in the *trans*-position with respect to L stimulates the transfer of electron density to the π^* orbital of the ligand L and at the same time hinders the shift of electrons from L to the central atom via the σ-bond. Thus, in considering the relative contributions of the donor–acceptor and dative components of the metal–ligand bond, one must also take into account the electron-donating properties of the ligand in the *trans*-position with respect to L.

On the basis of σ- and π-electronic effects, Langford and Gray[31] suggested that *trans*-influence be subdivided into σ- and π-trans-influences. Accordingly two series of ligand were obtained:

Ligand series based on the σ-effect

$$\underset{0.5169}{H^-} > \underset{0.3770}{PR_3} > \underset{0.360}{DMSO} \sim \underset{0.3574}{SCN^-} > \underset{0.3494}{CH_3^-, CO, CN^-} > \underset{0.3357}{Br^-} > \underset{0.3332}{Cl^-} > \underset{0.3139}{NH_3} > \underset{0.2877}{OH^-} > \underset{0.189}{C_2H_4}$$

Ligand series based on the π-effect

$$\underset{0.136}{DMSO} > \underset{0.096\ 0.124}{C_2H_4} > \underset{0.093}{CO} > \underset{0.088}{CN^-} > \underset{0.066}{NO_2^-} > \underset{0.052}{SCN^-}$$

The relative positions of the ligands in these series were established on the basis of the corresponding overlap integrals. The ligands in the σ-*trans*-influence series were arranged in sequence on the basis of the overlap integrals between the $6p$ orbital of platinum and the corresponding $p\sigma$ valence orbital of the ligand $[\int(6p\sigma/np\sigma)]$. The relative positions of the ligands in the π-*trans*-influence series were estimated from the overlap integrals between the $5d\pi$ orbital of platinum and the free π^* molecular orbital of the ligand. Mathematical radical functions for platinum were taken from Basch and Gray[32] and those for the ligand atoms from Clementi[33].

It has been shown[34–37] that the *trans*-influence of dimethyl sulphoxide (DMSO) in platinum(II) complexes is very close to that of ethylene. The properties of the complex ion $[Pt(DMSO)Cl_3]^-$ resemble those of the ion $[Pt(C_2H_4)Cl_3]^-$.[35,38] Baranovskii et al. calculated the corresponding overlap integrals and established the positions of DMSO and ethylene in the ligand σ- and π-*trans*-influence series[39]. The molecular orbitals of DMSO and ethylene were calculated by the LCAO-MO SCF method in terms of the CNDO approximation[40,41].

These values are indicated in the corresponding series. The overlap integral $\int(5d\pi/\pi^*C_2H_4)$ is close to the value obtained by Langford and Gray[31]. The difference between them can be explained by the different choice of the radial component of the p-function of carbon and the fact that Langford and Gray estimated the bond lengths on the basis of covalent radii, while Baranovskii et al.[39] used neutron diffraction data for the complex $K[Pt(C_2H_4)Cl_3].H_2O$.[42]

The calculations of the overlap integrals led to the conclusion that DMSO has a much greater σ-*trans*-influence than ethylene. It was concluded on the basis of the overlap integrals $\int(5d^{Pt}_{\pi}/\pi^*)$ for DMSO and ethylene that their π-*trans*-influences are similar and it is difficult to determine unambiguously their relative positions in the *trans*-influence series.

Bersuker's scheme[29,43] explains the *cis*-influence of ligands which was observed for platinum(II) compounds. Indeed, the shift of σ-electrons from the ligand L to the central atom should depend on the σ-donor properties of the ligands in the *cis*-position with respect to the given ligand (Fig. 3), If the σ-donor properties of the *cis*-neighbours are pronounced, the result should be a smaller shift of σ electrons from L to the central atom and this in turn should lead to a decrease of the π-acceptor interaction of the ligand with the central atom and hence to a decrease of the *trans*-influence of L. This mechanism of *cis*-influence explains satisfactorily the experimental observation that the *cis*- and *trans*-influence series are opposed. The view that the ligand which labilises the substituent on the opposite side stabilises the adjacent substituent and conversely was put forward in an earlier investigation[12]. Indeed, ammonia and pyridine have small *trans*-influences compared with chlorine, but they exhibit a marked *cis*-influence[44,45]. The studies of Grinberg and Kuz'mina on the exchange of chlorine in the complex ion $[Pt(C_2H_4)Cl_3]^-$ occupy a special place among these investigations. They showed that ethylene, which has a large *trans*-influence, fixes the *cis*-disposition of the chlorine atoms in the complex[46,47]. The opposed *trans*- and *cis*-influence series of the ligands C_2H_4, Cl^-, NH_3, and Py follows clearly from data for the rates of chlorine isotope exchange compared in Table 1.

Table 1. Rate constants for the exchange of chlorine in platinum(II) complexes.

Complex ion	Cl–Pt–Cl	L–Pt–Cl	Refs.	Complex ion	Cl–Pt–Cl	L–Pt–Cl	Refs.
$Cl\ Cl^{2-}$ Pt $Cl\ Cl$	$1.04\cdot10^{-5}$	$1.04\cdot10^{-5}$	44	$C_2H_4\ Cl^-$ Pt $Cl\ Cl$	$4.92\cdot10^{-6}$	Very rapid	46
$NH_3\ Cl^-$ Pt $Cl\ Cl$	$2.91\cdot10^{-5}$	$4.16\cdot10^{-6}$	45	$DMSO\ Cl^-$ Pt $Cl\ Cl$	$4.96\cdot10^{-4}$	Very rapid	33
$Py\ Cl^-$ Pt $Cl\ Cl$	$3.82\cdot10^{-5}$	$2.87\cdot10^{-6}$	45	$DMSO\ Cl^-$ Pt $Cl\ Cl$	$1.55\cdot10^{-4}$	Very rapid	48

Together with Kuz'mina and other coworkers, the author investigated the *cis*-influence of dialkyl sulphoxides on the rate of exchange of chlorine[35,48,49]. These studies

established that the chloride ion located in the opposite position relative to a dialkyl sulphoxide exchanges almost instantaneously, i.e. at the "zero exchange" rate. This behaviour of complex ions of the type $[Pt(R_2SO)Cl_3]^-$ in relation to the exchange of the chloride ion in the *trans*-position is analogous to the behaviour of $[Pt(C_2H_4)Cl_3]^-$.[46] This is also evidence for the closeness of the *trans*-influences of DMSO and ethylene.

The rate of exchange of the *cis*-chloride ions in the complexes $[Pt(R_2SO)Cl_3]^-$ proved to be unexpectedly high. Despite their large *trans*-influence, dialkyl sulphoxides do not fix the chloride ions in the *cis*-positions, but actually labilise them. The chloride ions on the Cl–Pt–Cl axis in the diethyl sulphoxide complex are extremely mobile, but are nevertheless approximately three times less mobile than in the dimethyl sulphoxide compound. This is probably related to the increase of the size of the alkyl groups, which should lead to the "screening" of the chloride ions.

It follows from the calculation on the electronic structure of the DMSO molecule by the LCAO-MO SCF method in terms of the CNDO approximation[49] that the oxygen $p\pi$ orbitals have a marked electron-donating capacity. The *cis*-influence of DMSO in complex ions of the type $[Pt(DMSO)Cl_3]^-$ can be accounted for by the interaction of the p_y orbitals of oxygen and the central atom, which labilises the bond between platinum and the chlorine in the *cis*-position (Fig. 4).

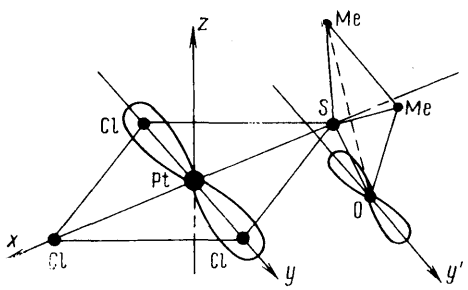

Figure 4. Schematic illustration of the interaction of the p_y orbitals of the central atom and the oxygen atom of the coordinated sulphoxide.

The majority of theories have been devised to account for the kinetic aspect of *trans*-influence. However, numerous data have now accumulated, which permits the consideration of *trans*-influence in the ground and not the transition state of the complex. Thus techniques such as X-ray diffraction, vibrational spectroscopy, NMR, etc. permit the detection of the *trans*-influence in the static state of the complex. A clear tendency to distinguish the trans-influences in the static and dynamic states has arisen in the world literature. To distinguish them, the first is referred to as the *trans*-influence and the second as the *trans*-effect. In addition one should add that two cases are also investigated in the dynamic state: on the one hand the rate of reaction and on the other the position of the reaction equilibrium. Thus in the dynamic state two aspects of the *trans*-effect are considered: the kinetic and thermodynamic aspects.

The investigation of Zumdahl and Drago[24] occupies a special place among studies on the theory of *trans*-influence. Using Hoffmann's modification of the extended Hückel methods, these workers calculated the electronic structures of a number of complexes of the type *trans*-$[PtL(NH_3)Cl_2]$. The complexes are arranged in Table 2 in order of increasing *trans*-influence of the ligand L which had been determined earlier. Some of the ligands in this series are hypothetical, for example, H_2S or PH_3. The hydrocarbon groups in these ligands have been replaced by the hydrogen atom to simplify the calculations and economise computer time. The authors[24] assume that all the ligands considered behave as σ-donors only; their π-acceptor properties are neglected.

Table 2. Overlap populations for the complexes *trans*-$[PtL(NH_3)Cl_2]$.

L	Pt–L bond length, Å	Overlap populations						
		Pt–N	Pt–Cl	Pt–L	$Pt(6p_y)$–L	$Pt(6p_y)$–N	Pt(6s)–N	$Pt(5d_{x^2-y^2})$–N
H_2O	2.00	0.3370	0.3909	0.2406	0.1114	0.1235	0.1205	0.1275
NH_3	2.00	0.3221	0.3832	0.3221	0.1313	0.1313	0.1139	0.1145
Cl^-	2.33	0.3240	0.3843	0.3322	0.1759	0.1212	0.1181	0.1225
H_2S	2.30	0.3244	0.3745	0.4235	0.2070	0.1320	0.1158	0.1154
CH_3^-	2.15	0.3009	0.3724	0.4637	0.1945	0.1431	0.1036	0.0349
PH_3	2.25	0.3032	0.3569	0.5585	0.2435	0.1490	0.1054	0.0366
H^-	1.06	0.3074	0.3641	0.6069	0.2603	0.1415	0.1046	0.1009

One of the first tasks formulated by the authors[24] was to determine the relative bond strengths. They obtained this information by analysing the Mulliken orbital populations. Analysis of the populations yields two criteria for measuring the relative bond strengths in molecules: (1) overlap populations; 2) overlap energies. We may recall that the overlap population is a measure of electron density in the region between two atomic orbitals. It follows from a consideration of the populations (Table 2) that the more marked the *trans*-influence of the ligand L the weaker the opposite Pt–N bond. This is consistent with the *trans*-influence for σ-ligands. It is interesting that the decrease of the population of the Pt–N bond is not due to the decrease of the involvement of the platinum 6*s* and $5d_{x^2-y^2}$ orbitals. Calculation shows that the involvement of this orbital in the platinum–nitrogen bond also increases when the *trans*-influence of the ligands is enhanced. On the other hand, the decrease of the population of the platinum–nitrogen bond is due to the reduced involvement of the platinum 6*s* and $5d_{x^2-y^2}$ orbitals. A similar conclusion concerning the decrease of the involvement of the 6*s* and $5d_{x^2-y^2}$ orbitals with enhancement of the *trans*-influence of the opposite substituent was reached[22] on the basis of the ^{195}Pt–^{31}P interaction constant. We may appropriately recall that the important role of the 6*s* and $5d_{x^2-y^2}$ orbitals in the transmission of *trans*-influence was first pointed out by Syrkin[21].

Another interesting conclusion is that the Pt–Cl bonds in the *cis*-position are also weakened with enhancement of the *trans*-influence of L. Both conclusions refer to molecules in the static state.

Table 2 shows that, on passing from a ligand with a weak *trans*-influence (H_2O) to one with a strong *trans*-influence (H^-), the bond is weakened only to the extent of 10%. This finding suggests that the weakening of the bond is not the fundamental cause of *trans*-influence in the kinetics of substitution reactions at least for σ-linked ligands. Therefore, like Langford and Gray[31], Zumdahl and Drago[24] conclude that the reasons for the difference between the rates of substitution over a wide range is different degrees of stabilisation of the transition state.

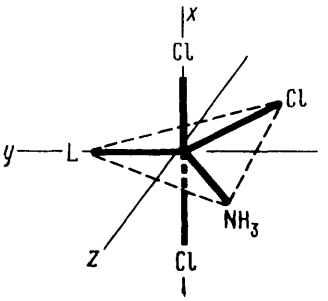

Figure 5. The directions of the Cartesian coordinate axes in the trigonal bipyramidal intermediate.

Zumdahl and Drago explained the *trans*-influence of σ-linked ligands in the following way. In the ground state the ligand L and the leaving group (NH_3) share the same platinum orbital ($6p_y$). We shall assume that Cl^- enters into the complex and that the intermediate has the trigonal bipyramidal structure illustrated in Fig. 5. In this structure the entering and leaving groups (Cl^- and NH_3) lie on either side of the Pt($6p_y$) orbital and employ both p_y and p_z orbitals for the formation of bonds. Thus L occupies more than half of the $6p_y$ orbital. This implies that, when L is a powerful σ-donor and can effectively occupy part of the vacant p_y orbital, the transition complex will be stabilised. Thus the difference between the energies of the ground and transition states will be relatively small for ligands which can effectively interact with the p_y orbital. Powerful σ-donors should behave as ligands of this kind. The calculated Pt($6p_y$)–L overlap populations (Table 2) show that there is an almost exact agreement between the capacity of the ligand to interact with the $6p_y$ orbital of platinum and its position in the experimental *trans*-influence series. The calculated overlap populations are listed in Table 3, which shows that, on passing from H_2O to H^-, the Pt–L bond is indeed strengthened, while the other bonds are weakened. The most interesting result are presented in Table 4, which includes the differences between the overlap populations of the individual bonds and orbitals in a tetracoordinate planar complex and a pentacoordinate bipyramidal complex. The difference shows that, on passing from H_2O to H^-, all the bonds are weakened to approximately the same extent. The Pt–Cl bond within the plane is missing in the ground state. Therefore, Table 4 in fact gives for it not the difference but the actual overlap population in this transition state. It is seen from Table 4 that, when L = H^-, the weakening of the Pt–L bond is much smaller than for L = H_2O. The difference refers almost completely to the Pt(6s)–L and Pt($d_{x^2-y^2}$)–L interactions. The sums of these reductions in strength are almost the same in the two cases.

Zumdahl and Drago[24] also calculated the difference between the activation energies for the transition from planar to pyramidal complexes for L = H^- and L = H_2O:

$$E_a = E_{H^-} - E_{H_2O} \ .$$

They found that the difference between the activation energies should be about 8 kcal mole^{-1}. Thus, for a ligand with a high *trans*-influence such as H^-, about 8 kcal mole^{-1} less is needed to pass from the planar to the trigonal bipyramidal configuration than for a ligand with a weak *trans*-influence (H_2O).

Table 3. Overlap populations in trigonal bipyramidal complexes.

Complex	Pt($6p_y$)–L	Pt–L
$PtH_2O(NH_3)Cl_3^-$	0.1602	0.1895
$PtH(NH_3)Cl_3^{2-}$	0.3356	0.5868
Pt–Cl (on *x* axis)	Pt–Cl (in the plane)	Pt–N
0.3441	0.3117	0.2920
0.3198	0.2859	0.2674

Table 4. Differences between overlap populations.

L	Pt($6p_y$)–L	Pt(6s)–L	Pt($5d_{x^2-y^2}$)–L
H_2O	0.0488	–0.0071	–0.0447
H^-	0.0753	–0.0142	–0.0382
Pt–L	Pt–Cl (on *x* axis)	Pt–Cl (in the plane)	Pt–N
–0,0511	–0.0468	0.3117	–0.0450
–0,0213	–0.0443	0.2859	–0.0400

Yatsimirskii recently examined the possible types of ligand interactions in complexes[50]. The analysis of the σ-type and π-type interactions of metal and ligand orbitals for the molecular fragment LMX in the *xy* plane is interesting. Tables 5 and 6 list the squares of the coefficients of the linear combinations of the corresponding atomic orbitals.

Table 5 shows that, for the *trans*-disposition of the ligands L and X, there is almost 100% orbital overlapping. On the other hand, for the *cis*-disposition, the orbital overlap is only to the extent of 50%. The same situation obtains also when π-bonds are formed.

Thus, when the dissociation of M–X bonds is considered, it follows from Tables 5 and 6 that the ligands with pronounced σ- and π-donor properties should have a labilising effect directed mainly to the *trans*-partner. With reference to the work of Zumdahl and Drago[24], one may mention that, for unequal overlap populations of the atomic orbitals, this conclusion is no longer so evident.

For ligands with electron-accepting properties, the M–X bonds should be strengthened. The ligand in the *trans*-position has greater influence than the ligand in the *cis*-position. The conclusions which follow from Chatt's Orgel's and Bersuker's ideas remain valid for the associative mechanism.

Table 5. Characteristics of the σ-type interaction of the metal orbitals with the orbitals of ligands in the *xy* plane.

Metal orbitals	*trans*-L	X	*cis*-L
$d_{x^2-y^2}$	1/4	1/4	1/4
S	1/6	1/6	1/6
P_x	1/2	1/2	0
P_y	0	0	1/2
d_{z^2}	1/12	1/12	1/12
P_z	0	0	0
Common orbitals with X	100%	—	50%

Table 6. Characteristics of the π-type interaction of the metal orbitals with the orbitals of ligands in the *xy* plane.

Metal orbitals	*trans*-L	X	*cis*-L
d_{xy}	1/4	1/4	1/4
d_{xz}	1/4	1/4	0
d_{yz}	0	0	1/4
Common orbitals with X	100%	—	50%

An important result of Yatsimirskii's study [50] is the conclusion that the *trans*- and *cis*-influence series may be reversed, depending on the reaction mechanism (dissociative or associative).

Yatsimirskii's remark [50] that, apart from the formation of common orbitals, Coulombic interactions between the ligands and the central atom are important is also significant. Naturally the Coulombic interaction is more marked the more effective the charges on the central atom in the ligand. This interaction leads to non-directional effects. The decrease of the effective charge on the central atom of the complex should facilitate dissociation and weaken association and conversely.

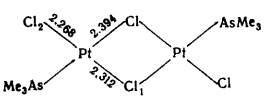
III. CRYSTAL-CHEMICAL MANIFESTATION OF *TRANS*-INFLUENCE

The number of studies undertaken to establish a relation between the *trans*-influence of individual ligands and the corresponding bond lengths increased considerably in recent years. The earlier investigations in this field were carried out exclusively on platinum complexes. The studies carried out up to 1962 have been analysed in Kukina's review [51]. Later studies are described in other reviews [52,53]. Bokii and Kukin's study [54] is one of the first where it was shown convincingly that interatomic distances depend on the nature of the ligand in the *trans*-position. In the complex $K[Pt(C_2H_4)Br_3].H_2O$ the bromine atom in the *trans*-position relative to ethylene is approximately 0.1 Å further away from the platinum atom than the bromine atom located opposite another bromine atom. A difference between the Pt–Br distances was observed also in the salt *cis*-$[Pt(C_2H_4)(NH_3)Br_2]$. Here too the platinum–bromine bond length on the C_2H_4–Pt–Br axis is greater by approximately 0.1 Å than that on the NH_3–Pt–Br axis [55,56].

A change in interatomic distances probably occurs only for a large difference between the *trans*-influences of the inner-sphere ligands. Thus the Pt–Cl interatomic distances in the complex $K[Pt(NH_3)Cl_3]$ cannot be inferred. The differences are within the limits of experimental error [57,58]. It has been shown [59] that the Pt–Cl and Pt–N bond lengths in *cis*- and *trans*-$[Pt(NH_3)_2Cl_2]$ are almost the same.

The Pt–Cl and Pt–Br bond lengths in complexes usually vary within fairly narrow limits. It has been found that in the hydride compounds *trans*-$[Pt(PEt_3)_2BrH]$ [60] and *trans*-$[Pt(PPh_2Et)_2ClH]$ [61] the above bond lengths are unusually large. The authors explained this by the strong *trans*-influence of the ligand H^-. An increase in the lengths of the Pt–X bonds located opposite trialkylphosphine has been observed in the trialkylphosphine complexes *trans*- and *cis*-$[Pt(PR_3)_2X_2]$ where X is a halide ion. The Pt–Cl bond length in the *trans*-isomer is 2.30 Å, while in the *cis*-isomer it increases to 2.37 Å. [62,63] From this it follows that the phosphine groups have a fairly marked *trans*-influence.

The interatomic distances and valence angles in the bridged compound $Pt_2Cl_4[As(CH_3)_3]_2$ have been determined [64,65]. It has been established that the Pt–Cl distance in the *trans*-position relative to arsenic is greater than the normal distance approximately by 0.1 Å.



These data are regarded as evidence for a marked *trans*-influence of trimethylarsine. A similar situation is observed in the dimeric tripropylphosphine complex *trans*-$PtCl_4(PPr_3)_2$. [66] We may mention that the Pt–Br distances involving the bridge and terminal bromine in $[N(C_2H_5)_4]_2[Pt_2Br_6]$ differ by 0.04 Å. [67] The difference is of the same order of magnitude as that between the Pt–Cl_1 and Pt–Cl_2 distances in $Pt_2Cl_4[AsMe_3]_2$.

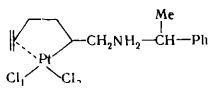
The Pt–Cl bond lengths in certain platinum(II) complexes have been compiled in the review of McWeeny et al. [68] It is interesting to quote this Table in a somewhat extended form (Table 7).

It is clear from Table 7 that the atoms can be arranged in the following sequence in terms of the *trans*-influence in platinum(II) complexes:

$$Si > C \sim H^- > P > C = C,\ Cl > O\ .$$

The much greater *trans*-influence of the σ-linked carbon atom compared with that of the olefinic π-bond merits attention. Apart from the data in Table 7, this is also indicated by the results of other investigations [72,73]. Bombieri et al. [73] studied the cyclic platinum complex [PtLPyCl], where L is methoxycyclo-octa-1,5-diene. This ligand undergoes ring closure via the σ-linked carbon atom on one side and the olefinic π-bond on the other. It was established that the Pt–N bond located opposite the Pt–C bond is unusually long (2.02 Å). This can be regarded as evidence in support of the strong *trans*-influence of the carbon atom.

It has been shown [74] that the Pt–Cl_1 bond located opposite the σ-linked carbon atom in the complex



is longer by 0.09 Å than the Pt–Cl_2 bond in the *trans*-position relative to the olefinic π-bond. A similar situation has been observed in dimeric μ-acetate complexes of palladium [75]. The Pd–O bonds located opposite the σ-linked carbon atom are longer than the Pd–O bonds located opposite the olefinic π-bond. The difference between the *trans*-influences of the olefinic π-bond and the σ-linked carbon atom has also been discussed in other reports [76,77]. Two studies in recent years established a marked *trans*-influence of the hydrocarbon groups in rhodium complexes. Thus the length of the rhodium–nitrogen bonds located opposite the ethyl group in the complex ion $[Rh(C_2H_5)(NH_3)_5]^{2+}$ is 2.256 Å, while the length of the remaining rhodium–nitrogen bonds are 2.072 Å. [78]

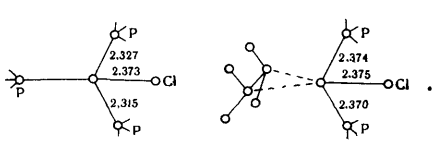
Table 7. Pt–Cl distances in the certain platinum(II) complexes.

Complex	*trans*-Ligand	Bond length, Å	Refs.
$[Pt(acac^*)_3Cl]^-$	O	2.28±0.01	69
trans- $[Pt(PEt_3)_2Cl_2]$	Cl	2.30±0.01	62
$[(C_{15}H_{17})_2Pt_2Cl_3]$	C=C	2.31±0.01	70
cis- $[Pt(PEt_3)_2Cl_2]$	P	2.37±0.01	63
trans- $[Pt(PMe_2Ph)_2Cl(CH_2SiMe)]$	C	2.415±0.005	71
trans- $[Pt(PPh_2Et)_2ClH]$	H	2.42±0.01	61
trans- $[Pt(PPhMe_2)_2(SiPh_2Me)Cl]$	Si	2.45±0.01	68

*acac = acetylacetonate ion.

A study of the structure of $\{RhPy_2Cl_2[P(o\text{-}C_6H_4CH_3)_2.(o\text{-}C_6H_4ClH_2)]\}$ showed that the Rh–Cl bond length is 2.399 Å on the Py–Rh–Cl axis and 2.531 Å on the C–Rh–Cl axis [79]. Thus, like the ethyl group, the benzyl group has a powerful *trans*-influence.

X-Ray diffraction studies on $[Rh(PPh_3)_3Cl]$ and $[Rh(PPh_3)_2(CF_2{=}CF_2)Cl]$ showed that, when triphenylphosphine is replaced by tetrafluoroethylene, there is no significant change in the Rh–Cl bond in the *trans*-position but the Rh–P bond in the *cis*-position relative to tetrafluoroethylene increases appreciably [80].



It has been shown [81] that in the octahedral complexes ML_3Cl_3 of the meridian type, where L = dimethylphenylphosphine and M = Re^{III}, Os^{III}, or Ir^{III}, the M–Cl and M–P bonds located opposite the phosphine groups are longer than those located opposite the chlorine atoms. The difference is approximately 0.1 Å (Table 8).

Very accurate measurements have shown [82] that the Ru–Cl bond in the *trans*-position relative to the water molecule in the complex $Cs[RuCl_5(H_2O)]$ is shorter than the other bonds. Presumably this is a consequence of the weak *trans*-influence of the water molecule.

Table 8. Bond lengths in compounds of the type ML_3Cl_3.

Bond	Re^{III}	Os^{III}	Ir^{III}
M–Cl (*trans* w.r.t. Cl)	2.353 (6)	2.347 (6)	2.361 (6)
M–Cl (*trans*-w.r.t. P)	2.454 (6)	2.439 (6)	2.429 (6)
M–P (*trans* w.r.t.Cl)	2.401 (6)	2.350 (6)	2.277 (6)
M–P (*trans* w.r.t.P)	2.458 (6)	2.408 (6)	2.363 (6)

It has been established [83] that the dimeric complex $[Ir_2(CO)_4Me_2Cl_4]$ is formed via a double chloride bridge. It is noteworthy that the Ir–Cl bridging bonds are marked non-equivalent. The length of the Ir–Cl bond in the *trans*-position relative to Me is 2.52 Å and the length of the bond in the *trans*-position relative to CO is 2.38 Å. These results can be regarded as supporting the much greater *trans*-influence of the alkyl group compared with that of the CO molecule.

In his review [53] Porai-Koshits quotes interesting data on the influence of the Rh–Rh bond in dimeric formate and acetate complexes resulting in an increase in the length of the Rh–H_2O, Rh–Cl, and Rh–Br bonds in the *trans*-positions. In addition he notes that the *trans*-ligands in their turn also affect the Rh–Rh bond length. In halide complexes this bond is much longer than in hydride complexes (2.45–2.47 and 2.35–2.38 Å respectively).

Porai-Koshits [53] notes that the structural manifestation of the *trans*-influence of ligands are extremely delicate and depend on many factors. It is still not always possible to take into account all these factors. Thus there are very conflicting manifestations of the *trans*-influence of a multiple bond. In molybdenum compounds the Mo=O double bond causes an appreciable lengthening of the *trans*-bond with any ligand. In rhenium and ruthenium complexes the increase in the length of the bond in the *trans*-position relative to M=O occurs only for neutral ligands but not for acido-ligands. The Os=N triple bond constitutes a special case. In the complex $K_2[OsNCl_5]$ the length of the Os–Cl bond on the N≡Os–Cl axis is increased to 2.60 Å compared with the other bonds, whose length is 2.32–2.37 Å. The problem of the dependence of the strength of the metal–ligand bond located opposite a multiply-linked ligand in hexacoordinate compounds has been examined theoretically [84]. The influence of the yl oxygen on the inner-sphere fluoride ions in Group V and VI transition metal complexes has been investigated by NMR. [85,86]

The structure of the octahedral terpyridyl complex of gallium $GaCl_3.2,2',2''$-terpyridyl has been investigated [87] and it has been established that the length of the Ga–Cl bond located opposite nitrogen is much smaller than that of the other two bonds on the Cl–Ga–Cl axis. The authors [87] attribute this finding to *trans*-influence.

IV. *TRANS*-INFLUENCE IN VIBRATIONAL SPECTROSCOPY

Force constants can serve as a measure of the strength of a chemical bond. When complexes of the same type are compared, the stretching vibration frequencies of chemical bonds are frequently used instead of force constants as a measure of the strengthening or weakening of the bonds.

We shall not consider here studies in which the relative strength of a metal–ligand bond was inferred from indirect data. They have been analysed in a monograph[16] (p. 315). Although the sensitivity of the metal ligand bond stretching vibrations to the type of ligand in the *trans*-position was established initially for Pt–H [88] and Pt–C bonds [89], it is nevertheless useful to begin the consideration of these data with studies where Pt–Cl vibrations were investigated.

Much information based on extensive experimental data concerning the influence of inner-sphere ligands on the Pt–Cl bonds was obtained by Chatt and coworkers[90]. Like Bersuker[29], the authors of this investigation concluded that there are at least two causes of *trans*-influence: the σ-electron shift from the ligand to the central atom and the π-electron shift from the central atom to the ligand. The σ-electron shift is probably the main cause of the strong *trans*-influence of hydrides and alkyl and aryl carbonions and the π-electron shift is characteristic of olefins. The σ-electronic mechanism of the transmission of *trans*-influence should weaken the bond in the *trans*-position for the molecule in the static state. On the other hand, the π-electronic mechanism should strengthen the bond in the opposite position.

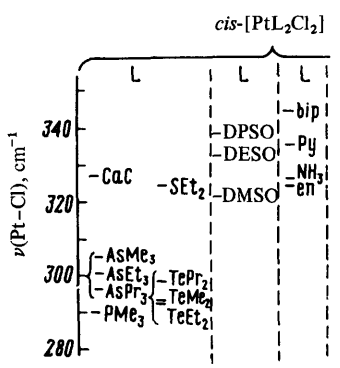


Figure 6. The spectroscopic *trans*-influence scale for ligands based on complexes of the type *cis*-$[PtL_2Cl_2]$.

A *trans*-influence scale has been set up for ligands on the basis of the Pt–Cl and Pt–Br stretching vibration frequencies[90]. The scale, supplemented by other data [91–93], is presented in Fig. 6. Compared with ammonia and pyridine (ligands with a weak *trans*-influence) phosphines and arsines lower the strength of the bonds in the opposite positions. It is claimed[23] that the *trans*-influence of phosphines is caused mainly by the σ-component, the π-component of phosphines being insignificant. Diethyl sulphide, diethyl selenide, and particularly cacodyl, which exhibit a powerful dynamic *trans*-effect (unlike phosphines), do not weaken but actually stabilise the bond in the opposite position. Basolo and Pearson[16] regard this finding as inconsistent with other experimental data (Basolo and Pearson[16], p. 316). However, bearing in mind that this scale refers to the *trans*-influence in the static state of the molecule, there is no inconsistency. Owing to the π-acceptor properties of sulphides and particularly of olefins, the effective charge on the platinum atom should increase and this should intensify the Coulombic interaction between the central atom and the ligand.

It has been shown by calculations and experimentally [36–38, 94, 95] that dialkyl sulphoxides have fairly pronounced π-acceptor properties. It was therefore interesting to establish their position in Chatt's *trans*-influence scale. Table 9 lists the vibration wave-numbers of the Pt–Cl bond in complexes of the type *cis*- and *trans*-$[Pt(R_2SO)_2Cl_2]$.

A similar Table has been compiled on the basis of studies [92, 93] on *cis*- and *trans*-$[Pt(DMSO)Cl_2L]$, where L represents amines or olefins (Table 10).

Table 9. The vibrational wavenumbers (cm^{-1}) of the Pt–Cl bond in the *cis*- and *trans*-complexes $[Pt(R_2SO)_2Cl_2]$.

Type of vibration	R_2SO				
	DMSO	DESO	DPSO		DiPSO
	cis	*cis*	*cis*	*trans*	*trans*
Pt–Cl	333 s. 309 s.	342 s. 322 s.	350 s. 326 s.	355 s.	353 s.

Table 10. The vibrational wavenumbers (cm^{-1}) of the Pt–Cl bonds in the *cis*- and *trans*-complexes $[PtL(DMSO)Cl_2]$.

Type of vibration	L							
	NH_3		NH_2CH_3		NH_2Et		C_2H_4	C_2H_6
	cis	*trans*	*cis*	*trans*	*cis*	*trans*	*cis*	*cis*
Pt–Cl	346 s. 312 s.	344 s.	334 s. 313 s.	348 s.	338 312	349	338 s. 311 s.	334 306

Chatt's *trans*-influence scale (Fig. 6) was established on the basis of data for complexes with a *cis*-configuration. The value of ν(Pt–Cl) on this scale is the average of the values for two Pt–Cl bands. The scale for compounds with a *trans*-configuration might characterise the *cis*-influence, but in fact it essentially reflects the non-directional influence of the effective charge of the central atom on the ligands having the opposite charge. The *trans*-influence scale leads to the following conclusions.

1. In terms of the overall influence of the σ-donor and π-acceptor properties, sulphoxides are close to olefins, particularly to cyclo-octadiene. The similarity of the properties of olefin and sulphoxide complexes has been frequently pointed out [32, 33, 36, 37, 47, 48].

2. Comparison of the positions of diethyl sulphide and diethyl sulphoxide shows that sulphoxides tend to fix chlorine in the *trans*-position to a greater extent. The presence of oxygen at the sulphur atom should enhance the effective charge of the sulphoxide sulphur atom compared with the sulphide sulphur atom. It has indeed been shown by X-ray emission spectroscopy [96, 97] that the effective positive

charge on the sulphur atom in a sulphoxide is higher than in a sulphide. The same conclusion was reached[95] on the basis of the acid properties of analogous sulphide and sulphoxide compounds. The higher effective positive charge may be the reason for the somewhat more marked π-acceptor properties of sulphoxides compared with the corresponding sulphides.

3. In mixed dimethyl sulphoxide–amine and dimethyl sulphoxide–olefin compounds with the *cis*-configuration the arithmetical mean of the Pt–Cl bond stretching vibration frequencies is approximately the same as for the disulphoxide compounds. When two strong π-acceptors are present in the complex, the involvement of each in the interaction with the *d* orbitals of platinum probably decreases to such an extent that the effective charge of the central atom remains approximately the same.

It is interesting to note that, despite the appreciable difference between the type of ligands, the Pt–Cl bond stretching vibration wavenumbers in the spectra of compounds having the *trans*-configuration remain virtually constant and are in the range 339 ± 3 cm^{-1}.[90,91,98,99] Since *trans*-diolefine compounds are unknown, they cannot be represented on this scale. It would be interesting to supplement the series of compounds by complexes of the type *trans*-$[PtA(C_2H_4)Cl_2]$.

In the series of compounds with the *trans*-configuration, disulphoxide complexes occupy an anomalously high position. Mixed sulphoxide–amine compounds have somewhat lower Pt–Cl bond vibration frequencies. One should note that in all the compounds investigated, the Pt–Cl stretching vibration frequencies are higher for compounds with the trans-configuration than for the corresponding *cis*-compounds. This may be related to the higher symmetry of charge distribution. The ligands L in the complexes *trans*-$[Pt(PMe_2Ph)_2LCl]$ have been arranged in the following series in terms of *trans*-influence on the basis of the Pt–Cl bond vibrations: Cl^-, Me^-, Me_2SiCH_2, Ph_2MeSi.[71] On passing from Cl^- to Ph_2MeSi, the vibration wavenumber of the bond in the *trans*-position falls from 370 to 242 cm^{-1}. This series is satisfactorily consistent with data for the *trans*-influence of the given ligands obtained by ^1H NMR and X-ray diffraction. The following *trans*-influence series has been established[100] on the basis of the Pt–Cl stretching vibration frequencies in the complexes $[Pt(AsEt_3)_2LCl]ClO_4$: $CO > RNC > ArNC > P(OPh)_3 \simeq \simeq P(PMe)_3 > AsEt_3 \simeq PEt_3$.

The Pt–H bond vibration wave-numbers in the spectra of the complexes *trans*-$[PtA_2LH]$, where A = PEt_3 or $AsET_3$, which have been determined by Chatt and Shaw[101], made it possible to arrange ligands in the following series in terms of the strength of the *trans*-influence:

$$NO_3^- < Cl^- < Br^- < I^- < NO_2^- < SCN^- < SnCl_3^- < CN^- \ .$$

It is interesting that it coincides almost completely with the series of ligands based on the Pt–C bond stretching vibration frequencies in the compounds *trans*-$[Pt(PR_3)_2(CH_3)L]$.[102] The series is $NO_3^- < SCN^- < Cl^- < Br^- < I^- < NO_2^-$. They are both analogous to the *trans*-influence series established at an early stage by the discoverer of *trans*-influence–Chernyaev. Only the thiocyanate ion deviates from the second series. The authors[102] suggested that in this case it may be coordinated via the nitrogen atom and not via the sulphur atom.

The *trans*-influence in iridium(III) compounds has been detected[103] by infrared spectroscopy. The study of the spectra of the meridional compounds $[Ir(PMe_3Ph)_3LCl_2]$ showed that in the series L = Cl^-, PR_3, or AsR_3, H^- there is a steady decrease of the Ir–Cl frequency, which can indicate a relative decrease of the strength of this bond. This is consistent with the variation of the *trans*-influence of the ligands:

$$H^- > PR_3 \simeq AsR_3 > Cl^- \ .$$

It was established in the same study that in the series of ligands L = Cl^-, H^-, Br^-, I^-, SCN^-, CN^- there is virtually no change in the vibration frequencies of the Ir–Cl bonds in the *cis*-positions.

A study of octahedral complexes of tervalent rhodium and iridium[104] established that the stretching vibration frequencies of the Rh–Cl and Ir–Cl bonds depend mainly on the nature of the ligands in the *trans*-positions. The ν(M–Cl) frequencies increase in the following sequence of ligands:

$$Cl^- < Br^- < I^- \sim CO < Me^- \simeq PR_3 \simeq AsR_3 < H^- \ .$$

A study of the Au–C bond vibration frequencies and the deformation frequencies of the methyl group in the ion $[Me_2AuX_2]^-$ showed[105] that the *trans*-influence series for gold(III) complexes is the same as for platinum(II):

$$Me_2S > Br^- > Cl^- > en > OH^- > H_2O \ .$$

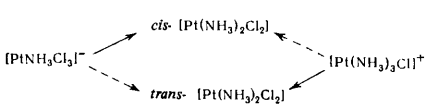
The substitution of two halide ions in the square planar ion AuX_4^- (X = Cl or Br) by two Me^- carbanions leads to the formation of complexes with the *cis*-configuration only and reduces the force constant of the bond Au–X by more than 30%.[105] Thus these data also indicate a much more marked *trans*-influence of the Me^- group compared with Cl^- or Br^-.

The infrared and Raman spectra of the complexes $Me_2SnX_4^{2-}$, where X = F, Cl or Br, have been investigated[106]. It was established that these compounds have the *trans*-configuration. After the substitution of two fluoride ions in SnF_6^{4-} by Me^-, there is some decrease of the force constant of the Sn–F bond. This happens to a smaller extent when a chloride ion is substituted and is altogether negligible in bromide compounds. The authors attribute this variation to the enhancement of the covalence of the tin–halogen bonds. They note that in transition metal compounds the bonds in the *trans*-position relative to the alkyl group are weakened, while in tin compounds the weakening is observed in the *cis*-position.

In contrast to other investigators, Ivannikova et al.[107] concluded that there is no correlation between ν(Pt–Cl) and the ligand *trans*-influence series for complexes of the type $[Pt(NH_3)_2LCl]X$. In most of the studies where such correlation has been established non-electolytic complexes were investigated. Possibly the results of Ivannikova et al.[107] can be accounted for by the fact that they employed compounds containing outer-sphere anions.

V. *TRANS*-INFLUENCE IN THE KINETICS OF SUBSTITUTION REACTIONS

The kinetic aspect of *trans*-influence follows clearly from the classical reactions of ammonia with chloroplatinate(II) to form *cis*-$[Pt(NH_3)_2Cl_2]$ and the cleavage of the tetrammine $[Pt(NH_3)_4]Cl_2$ by hydrochloric acid with formation of *trans*-$[Pt(NH_3)_2Cl_2]$. After excluding reaction stages without fundamental importance, these transformations can be represented schematically as follows:



It is difficult to imagine that the isomeric complexes *cis*-$[Pt(NH_3)_2Cl_2]$ and *trans*-$[Pt(NH_3)_2Cl_2]$ have the same free energy. Indeed, according to the literature[108] the difference between the total energies of these isomers is 3 kcal mole^{-1}, that of the *trans*-isomer being lower. It was established even earlier[109] that the *trans*-isomer is more stable from the energy standpoint, since dry solid *cis*-$[Pt(NH_3)_2Cl_2]$ is converted at 230°C into the corresponding *trans*-isomer as well as being decomposed. Thus the cleavage of the triammine by hydrochloric acid is consistent with thermodynamics and the interaction of the monoammine and ammonia with formation of *cis*-$[Pt(NH_3)_2Cl_2]$ follows the thermodynamically less favourable pathway. Consequently, kinetic factors play the main role in determining the direction of the reaction $[Pt(NH_3)Cl_3]^- + NH_3 = cis\text{-}[Pt(NH_3)_2Cl_2] + Cl^-$.[110,111] Subsequently others reached a similar conclusion[112]. It has been established[111] that a very small amount of *trans*-$[Pt(NH_3)_2Cl_2]$ is formed in the reaction between ammonia and chloroplatinate(II) in addition to *cis*-$[Pt(NH_3)_2Cl_2]$, and after the cleavage of the tetrammine the *trans*-isomer contains a small amount of *cis*-$[Pt(NH_3)_2Cl_2]$.

Subsequently it was shown[113,114] that the compounds *cis*-$[PtA_2X_2]$, where A = amine and X = Br or I, have a higher free energy than the corresponding *trans*-isomers, since on heating in the dry state the *cis* → *trans* isomerisation takes place with energy evolution. Depending on the nature of the amine, the isomerisation energies of the iodide and bromide complexes are 4–6 and 2–3 kcal mole^{-1} respectively.

The occurrence of the reaction via the thermodynamically less favourable pathway but in conformity with the *trans*-influence is probably a common phenomenon. It has been established in a number of studies[32,34,115–117] that the sulphoxide compounds *trans*-$[Pt(R_2SO)ACl_2]$ isomerise in the dry state to the more stable *cis*-isomers with energy liberation. However, the reaction of the ion $[Pt(R_2SO)Cl_3]^-$ with amines does not proceed via the thermodynamically more favourable pathway with formation of *cis*-$[Pt(R_2SO)ACl_2]$, but follows the kinetically more favourable pathway with formation of *trans*-$[Pt(R_2SO)ACl_2]$:

$$[Pt(R_2SO)Cl_3]^- \xrightarrow{+A} \begin{matrix} trans\text{-}[Pt(R_2SO)ACl_2] \\ \downarrow \\ cis\text{-}[Pt(R_2SO)ACl_2] \end{matrix}.$$

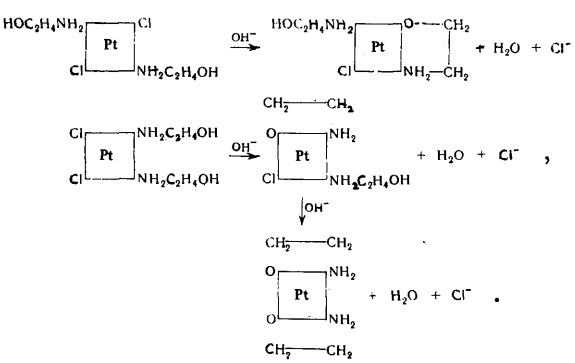
The kinetic manifestation of the *trans*-influence has been satisfactorily described in a number of books and reviews[13–16,30]. In recent years most kinetic studies of the *trans*-influence were made, as before, on platinum complexes. The exchange of labelled [^{14}C] diethylamine in complexes of the type *trans*-$\{PtL[^{14}C](NHEt_2)Cl_2\}$ in methanol and other non-aqueous solvents has been investigated[118]. The authors reached a number of interesting conclusions. Thus they established that triethylphosphine, arsine, and stibine can be arranged in the following sequence in terms of their *trans*-influence: $R_3Sb > R_3P > > R_3As$. The *trans*-influence of the alkyl derivatives of phosphorus, arsenic, and antimony in the reactions investigated is always greater than that of the aryl derivatives. The series $C_2H_4 \simeq$ i-PrCH=CHMe $\simeq Me_2C(OH)C{\equiv}CC(OH)Me_2 \gg Et_3Sb > Ph_3Sb > Me_3P > Et_3P >$ n-$Pr_3P > > Ph_3P > Et_3As \gg$ n-Pr_2S shows that the *trans*-influence of dipropyl sulphide is much smaller than that of phosphines, arsines, and stibines.

A major and interesting study[119] dealt with the kinetics of substitution in complexes of the type *trans*-$[PtL_2Cl_2]$ as a function of the nature of the inner-sphere ligand L and the entering ligand. It might have been expected that the results would make it possible to establish the ligand series in terms of the strength of the *cis*-influence. Unfortunately the rate constants are sometimes so close that the adjacent ligands in the series change places depending on the compounds investigated. For this reason, it was impossible to establish a rigorous *cis*-influence series. Nevertheless, an investigation[119] demonstrated unambiguously a greater *cis*-influence of triethylarsine compared with triethylphosphine, i.e. the opposite variation of the *trans*- and *cis*-influences of ligands was again confirmed. One should note that, among the ligands investigated, organic dialkyl sulphides exhibit both a weak *trans*-influence and a weak *cis*-influence.

Ammonia and aliphatic amines have a much weaker *trans*-influence than phosphines. It has been shown[120] that the *cis*-influence of ammonia and diethylbenzylamine greatly exceeds that of triethylphosphine. This applies both to the solvation of the complexes *trans*-$[Pt(PEt_3)_2Cl_2]$, *trans*-$[Pt(PEt_3)(NH_3)Cl_2]$, and *trans*-$[Pt(PEt_3).(NEt_2CH_2Ph)Cl_2]$ in methanol and to the chlorine isotope exchange reactions in these complexes.

Clear-cut findings indicating the manifestation of *trans*-influence were obtained in a study of the exchange of diethyl sulphoxide in the complex ions $[Pt(DESO)Cl_3]^-$ and $[Pten(DESO)Cl]^+$.[121,122] While the DESO exchange in the first complex is relatively rapid ($k = 7.6 \times 10^{-2}$ litre mole^{-1} s^{-1}), in the ion $[Pten(DESO)Cl]^+$ there is virtually no exchange. This can be undoubtedly attributed to a much weaker *trans*-influence of the amino-groups of ethylenediamine compared with the *trans*-influence of the chloride ion.

Stephen and Basolo established[123] that in the interaction of *trans*-$[Pt(NH_2C_2H_4OH)_2Cl_2]$ with alkali one of the ethanolamine molecules undergoes ring closure faster than the other. Studies have been made[124,125] on the rate of closure of ethanolamine rings in the isomeric *cis*- and *trans*-complexes $[Pt(NH_2C_2H_4OH)_2Cl_2]$. As a result, data were obtained showing that the closure of the first ring in the *trans*-complex is much faster than in the *cis*-complex. On the other hand, the second ring is formed much faster in the *cis*-complex than in the isomeric compound. This fact indicates the manifestation of *trans*-influence, which clearly follows from the following schemes.



Owing to the comparatively powerful *trans*-influence of chlorine, substitution on the Cl–Pt–Cl axis is much easier than on the Cl–Pt–NH_2R axis. Therefore, the closure of the first ring in *trans*-$[Pt(NH_2C_2H_4OH)_2Cl_2]$ is much faster. For the closure of the second ring in the *trans*- and *cis*-isomers of $[Pt(NH_2C_2H_4OH)(NH_2C_2H_4O)Cl]$, substitution on the Cl–Pt–OR and Cl–Pt–NH_2R axes respectively is necessary. The much higher rate of substitution of the second ring in the *cis*-complex is probably a consequence

of the greater *trans*-influence of the amino-group compared with the OR^- group. One may mention that in platinum(II) complexes the *trans*-influence of the amino-group of alanine bound in a cyclic form is somewhat greater than the *trans*-influence of the carboxy-group[126].

In thioethers forming metal complexes the sulphur atom is at the apex of a trigonal pyramid. Consequently there should be three conformers of platinum and palladium complexes of the type $[Pt(RSC_2H_4SR)X_2]$. An ^1H NMR study[127] has been made of the interconversion of these conformers, involving the inversion of the molecular structures relative to the sulphur atom. It was established that the rate of inversion in the complexes $[Pt(RSC_2H_4SR)X_2]$ and $[Pd(RSC_2H_4SR)X_2]$ depends on the *trans*-influence of the ligands X. The ligands X can be arranged in the following series in terms of their facilitating influence on the inversion process: $Cl^- < Br^- < I^- \ll Ph^-$. It has been shown that the inversion in the palladium complexes is much easier than in the corresponding platinum compounds.

The first kinetic study of the substitution reactions in rhodium(III) complexes was made by Zvyagintsev and Shubochkina[128]. Unfortunately, this study was not developed further subsequently. Systematic investigations, which clearly revealed *trans*-influence in complexes, were also made by Poë and coworkers[129–134]. They investigated extensively the kinetics of substitution reactions of the type

$$trans\text{-}[Rhen_2LY] + Z \rightarrow trans\text{-}[Rhen_2LZ] + Y \quad .$$

According to the results of these studies, the *trans*-influence series for rhodium(III) is as follows: $H_2O < OH^- \simeq \simeq NH_3 \leqslant Cl^- < Br^- < I^-$. In many respects it agrees with the corresponding *trans*-influence series for platinum(II).

It has been established[135] that the rate constants for the substitution of ammonia by water in the complexes $[RhEt(NH_3)_5]^{2+}$ and $[Rh(C_2F_2H)(NH_3)_5]^{2+}$ are smaller by several powers of ten than the rate constant for the substitution of ammonia in the ion $[RhH(NH_3)_5]^{2+}$. However, the analogous substitution in the ion $[RhCl(NH_3)_5]^{2+}$ is slower still. Thus the ligands investigated can be arranged in the following series in terms of their *trans*-influence in rhodium(III) complexes: $H^- \gg Et^- > C_2F_4H^- \gg Cl^-$.

It has been shown[131] that the relative *trans*-influence of ligands depends on the nature of the ligand eliminated from the complex.

The rates of substitution reactions in the iridium complexes *trans*-$[Iren_2X_2]^+$ (X = Cl, Br, or I) and *trans*-$[Iren_2LCl]^+$ (L = NO_2, Br, or I) with various nucleophiles were investigated spectrophotometrically[136]. It was established that these reactions are complicated neither by catalysis nor by stereochemical rearrangements. Their rates are independent of the nature and concentration of the entering ligand. This suggests that the reaction proceeds via a rate-determining stage:

$$trans\text{-}[Iren_2LX]^+ + H_2O \underset{\text{fast}}{\overset{\text{slow}}{\rightleftharpoons}} trans\text{-}[Iren_2LH_2O]^{2+} + X^- \quad ,$$
$$trans\text{-}[Iren_2LH_2O]^{2+} + Y^- \longrightarrow trans\text{-}[Iren_2LY]^+ + H_2O \quad .$$

It follows from the results[136] that the *trans*-influence increases in the series $NCS^- < Cl^- < Br^- < NO_2^- < I^-$. The position of the thiocyanate ion is different from that in the corresponding series for platinum(II). This is because in the iridium(III) complexes the thiocyanate ion is bound to the central atom via nitrogen[137].

The strong *trans*-influence of the hydride ion compared with the chloride ion can be inferred from the finding[138] that, when the complex $[PtH_2Cl(PEt_2Ph)_3]$ reacts with sodium iodide, the chloride ion is readily substituted by iodide. However, it has been established that the substitution for iodide of the chloride ion located opposite another chloride ion requires high temperatures and a long reaction time. The strong *trans*-influence of tertiary phosphines is indicated by the very rapid substitution of the chloride ion located opposite the phosphine in the meridional complex $[Ir(PEt_3)_3Cl_3]$. In hot acetone the substitution takes place in 3 min. On the other hand, the substitution of the two other chloride ions requires boiling for 3.5 h.

The hydrolysis of *cis*-$[Ruen_2X_2]^+$, *cis*-$[Ruen_2(OH)Cl]^+$, and $[Ru(NH_3)_5X]^{2+}$ has been investigated[139]. It was established that the hydrolysis does not entail stereochemical changes in the complexes. The authors put forward a mechanism involving a conjugate base in which *trans*-influence plays a significant role. They assumed that the rapid substitution of the halogen is associated with the *trans*-influence of the amido-group as a result of its interaction of the $p\pi$–$d\pi$ type.

A study[140] where the aquation of the ion $[Cr(H_2O)_5I]^{2+}$ in the presence of Cl^- ions was investigated is of interest. It was established that the main reaction products are $[Cr(H_2O)_6]^{3+}$, while $[Cr(H_2O)_5Cl]^{2+}$ is obtained in a yield of only 10–20%. In another study[141] this reaction was investigated using labelled [^{18}O] water. It was possible to show that the elimination of the ion from the complex is preceded by an appreciable exchange of water in the ion $[Cr(H_2O)_5I]^{2+}$. These findings together with the observation that the exchange of water in the ion $[Cr(H_2O)_5Cl]^{2+}$ is very slow led to the conclusion that the inner-sphere iodide ion has a labilising influence on the water molecule in the opposite position. This conclusion is quite likely and, if it is true, then the above observation can be regarded as the first reliable evidence in support of the occurrence of *trans*-influence in chromium(III) complexes.

trans-Influence in the iron(II)-phthalocyanine complex has been suggested by Jones and Twigg[142], who investigated the rate of substitution of DMSO by imidazole in the axial position in the complex $FePc(DMSO)_2$. The reaction was carried out in DMSO. It was found that the rate-determining stage is the substitution of the first DMSO molecule:

$$FePc(DMSO)_2 + Imid \rightleftharpoons FePc(DMSO)(Imid) + DMSO,$$
$$FePc(DMSO)(Imid) + Imid \rightleftharpoons FePc(Imid)_2 + DMSO.$$

The second molecule is substituted at a higher rate owing to the greater *trans*-influence of imidazole compared with DMSO.

One should note that, when there is only one possibility of substitution, (in the *trans*- or *cis*-position), it is dangerous to reach conclusions concerning directional intramolecular interaction.

Cobalt complexes undoubtedly occupy the first place as regards the number of kinetic studies on substitution reactions. Nevertheless, the problem of the applicability of the *trans*-influence rule to cobalt complexes has not been completely resolved. It is interesting that Basolo and Pearson, who contributed much to the study of the kinetics of substitution reactions in cobalt complexes, did not devote even a single chapter or paragraph to this problem in their book[16]. Although the review of Pratt and Thorp[8] is devoted to the *cis*- and *trans*-effects in cobalt complexes, it fails to elucidate this problem completely. They quote the following ligand series based on the *trans*-influence:

$$\text{alkyls, } SO_3^{2-} \gg \begin{matrix} CN^-,\ N_3^-,\ NO_2^-,\ NH_3 \\ HO^-,\ Cl^-,\ Br^-,\ I^- \end{matrix} > H_2O > NSC^- \quad .$$

Unfortunately, the *trans*-influence series for cobalt complexes depends on the type of complex used as a basis for the substitution reaction series. Any rule must have predictive power. However, for cobalt complexes the above series has so far had a comparatively low predictive power.

VI. THE MUTUAL INFLUENCE OF LIGANDS AND ACID PROPERTIES OF COMPLEXES

A great contribution to the study of the problem of the influence of inner-sphere ligands on the acid properties of complexes was made by Grinberg, who describes them in a monograph[13] (p. 388). As early as 1935, Grinberg and Ryabchikov showed[143] that in platinum(II) complexes ligands with a strong *trans*-influence reduce the acid dissociation of proton-containing groups located in the opposite positions. They studied the acid properties of the isomeric *cis*- and *trans*- complexes $[Pt(NH_3)_2(H_2O)_2]^{2+}$ and established that the first acid dissociation constant of the *trans*-isomer is higher than that of the *cis*-isomer. The second acid dissociation constants are close, but K_2 for the *cis*-isomer is somewhat higher. These findings were explained from the standpoint of the enhancement of the *trans*-influence of the ligands in the series $OH^- > NH_3 > H_2O$. According to the polarisation model of *trans*-influence, with increase of the σ-donor properties of the ligand the *trans*-ligand is depolarised with a consequent weakening of its acid properties. Since the *trans*-influence of water is weaker than that of ammonia, the first acid dissociation constant of the ion $\begin{bmatrix} NH_3 & & H_2O \\ & Pt & \\ H_2O & & NH_3 \end{bmatrix}^{2+}$ should indeed be higher than that of the ion $\begin{bmatrix} NH_3 & & H_2O \\ & Pt & \\ NH_3 & & H_2O \end{bmatrix}^{2+}$. The second dissociation constants are those of the ions $\begin{bmatrix} NH_3 & & OH \\ & Pt & \\ H_2O & & NH_3 \end{bmatrix}^{+}$ and $\begin{bmatrix} NH_3 & & OH \\ & Pt & \\ NH_3 & & H_2O \end{bmatrix}^{+}$. Since the *trans*-influence of the hydroxy-group is somewhat greater than that of ammonia, K_2 for the *cis*-isomer proved to be somewhat higher than for the *trans*-isomer.

This variation of the acid properties was confirmed[144,145] for other pairs of isomeric diaquo-complexes. A similar behaviour was discovered also for octahedral cobalt(III) and chromium(III) complexes[146]. Apart from the influence of the *trans*-ligands on the properties of inner-sphere proton-containing molecules, Grinberg and coworkers discovered the influence of the ligands in the *cis*-position with respect to the dissociating molecule[144]. In particular, they established that an inner-sphere pyridine molecule enhances the acid properties of H_2O molecules in platinum(II) complexes[144,147] and NH_3 molecules in platinum(IV) complexes[148-150]. Stetsenko systematically arranged the available information about the *trans*- and *cis*-influence of ligands on the acid properties of platinum complexes and demonstrated convincingly[151] that, following the replacement of NH_3 by another ligand, the acid properties of the *cis*- and *trans*-complexes $[PtA_2B_2]^{2+}$ change in the same direction (become stronger or weaker). However, the change in the acid properties of the *cis*-isomer is as a rule greater.

The hypothesis of the weakening of the acid properties of inner-sphere proton-containing molecules in both *trans*- and *cis*-positions with increase of the *trans*-influence of ligands is valid only for σ-donors. In 1955 Leden and Chatt[152] estimated the acid dissociation constant of the complex $[Pt(C_2H_4)(H_2O)Cl_2]$ and found it to be approximately 10^{-5}. Thus, despite the very strong *trans*-influence of ethylene, it does not weaken but actually enhances the acid properties of the inner-sphere water molecule. Grinberg postulated that *trans*-active ligands with pronounced π-acceptor properties can intensify the acid dissociation of inner-sphere ligands by increasing the effective positive charge on bivalent platinum[13] (p. 391). Numerous findings confirming this view have now been obtained[94,95,153-158]. The comparatively weak influence on the acid properties of the aquo-complexes of platinum(II) following the substitution of the ammonia molecule in the ion $[Pt(NH_3)_3(H_2O)]^{2+}$ by triphenylphosphine or triphenylstibine was somewhat unexpected[158].

The overall experimental data show that the mutual influence of ligands, shown by a change in acid properties, is relatively non-directional. If the proton-donating molecule is a σ-donor alone, then in principle the influence of the ligands on its acid properties may be reduced to the following cases (Fig. 7): I. by direct transmission of the influence of one ligand to another in the *cis*-position; II. by the transmission of the influence of σ-donors to the trans-position via the p_y orbital; III. by the transmission of the electron density of σ-donors in the *cis*-position via the $d_{x^2-y^2}$ orbital. Thus the increase of *trans*- or *cis*-influence, leading to an increase of electron density in the Pt–Rh bond, should weaken the acid properties of the coordinated molecule RH.

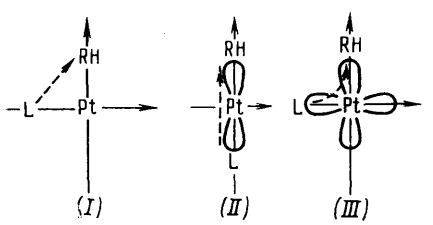


Figure 7. Schematic illustration of the transmission of the influence of a ligand with σ-donor properties.

A different situation should arise for ligands with π-acceptor properties (Fig. 8). If it is assumed that RH exhibits neither π-acceptor nor π-donor properties, then the influence of π-ligands on its acid properties can only be electrostatic. The effective charge of the central atom consists of the nuclear charge and the charges of the electrons in its orbitals. Since a limited number of orbitals are involved in interactions of the π-type, it is useful to infer the change of the effective charge from the shift of electron density in the corresponding orbitals. If the ligand L with π-acceptor properties is fixed on the *X* axis and the location of the ligand RH relative to it is varied, then mainly the d_{xy} and d_{xz} orbitals of the central atom will be involved in the interaction with L. When the ligands are in the *trans*-positions, the centres of gravity of the electron densities of the d_{xy} and d_{xz} orbitals will shift by a distance *l* to the π-acceptor and will be located on the *X* axis (IV*a*, IV*b*).

It is evident from Schemes V*a* and V*b* that for ligands in the *cis*-positions the centres of gravity of the d_{xy} and d_{xz} orbitals are also remote from RH but less so than for the *trans*-positions. Thus, in consequence of the π-acceptor properties of the ligand L, the acid properties of the RH molecule should be enhanced in both the *cis*- and *trans*-positions. However, the influence should be somewhat more marked for ligands in the *trans*-positions.

If the ligand L exhibits π-donor properties, then it should weaken the acid properties of RH in both the *trans*- and *cis*-positions and to a somewhat greater extent in the former case.

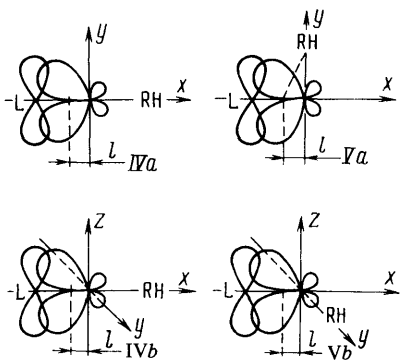

Figure 8. Schematic illustration of the transmission of the influence of a ligand with π-acceptor properties.

The mutual influence of ligands in relation to the acid properties of octahedral complexes, in particular platinum(II) complexes, is less definite. Grinberg and Gil'dengershel' established that the acid dissociation constant of the bromo-complex $[Pt(NH_3)_5Br]^{3+}$ is 5.6×10^{-9} and that of the chloro-analogue $[Pt(NH_3)_5Cl]^{3+}$ is 7.9×10^{-9}.[160] This is consistent with the polarisation model of *trans*-influence. The bromide ion, which has a stronger *trans*-influence than the chloride ion, causes a greater counter-polarisation of the ammonia molecule in the opposite position. As a result the acid properties of the bromo-complex are weaker than those of the chloro-complex. However, from this point of view the acid properties of *cis*-$[Pt(NH_3)_4Cl_2]^{2+}$ should be weaker than the acid properties of *trans*-$[Pt(NH_3)_4Cl_2]^{2+}$, since in the first case two of the four ammonia molecules are in the *trans*-positions with respect to the chloride ions. On the other hand, experimental data indicate more marked acid properties of the *cis*-isomer[161]. From this, it follows that the difference between the *trans*-influences of chlorine and ammonia in platinum(IV) complexes is less important than the repulsion of the protons of the molecules in the *cis*-positions or the polarity of the complex ion.

Spitsyn et al. established that the ligands can be arranged in a definite series in terms of their influence on the acid properties of certain platinum(IV) aquo-complexes. On this basis, they proposed a *trans*-influence scale for ligands[162].

---o0o---

In conclusion, one must say that so far there is no theory which explains all the experimental facts and which embraces all the aspects of the mutual influence of ligands in complexes. One of the problems which still awaits solution is the manifestation (or absence) of the mutual influence of ligands in equilibrium systems involving ligand substitution. Systematic studies on this problem are being made by Peshchevitskii[112,163-166].

The Reactions of Hydrocarbons on Membrane Catalysts

V.M.Gryaznov and V.S.Smirnov

The reactions of different classes of hydrocarbons on catalysts selectively permeable with respect to hydrogen are considered. The possibilities of membrane catalysts to increase the rate and selectivity of reactions, to obtain incomplete hydrogenation products, and to decrease the competition between the adsorption of the substance hydrogenated and hydrogen are demonstrated. The coupling of reactions on membrane catalysts whereby it is possible to achieve a reaction, which does not occur spontaneously, as a result of the decrease of the free energy of the coupled reaction when the substance common to the two reactions passes through the membrane catalyst is discussed.
The bibliography includes 135 references.

1. INTRODUCTION

Membrane catalysts differ from other heterogeneous catalysts in that they exhibit selective permeability with respect to only one reactant. The principal metals investigated as membrane catalysts are those which are to some extent permeable to hydrogen. Such metals have been used as cathodes on one surface of which hydrogen was obtained electrochemically and on the other a reaction with the hydrogen diffusing through the metal was carried out. Studies have also been made on the hydrogenation of olefins and of other reactions on a palladium membrane with gaseous hydrogen on its other side.

Even before the appearance of membrane catalysts, catalytic hydrogen redistribution processes between the molecules of the same or different substances were discovered (see Section 8). It was established that the best catalyst for such reactions is palladium, but the reason for this and also the mechanism of the redistribution of hydrogen remained obscure.

Studies on the redistribution of hydrogen in unsaturated cyclic hydrocarbons on palladium and platinum films showed (see Gryaznov's review[1]) that the process consists of a set of dehydrogenation and hydrogenation reactions. The ratios of the rates of these reactions depend on the ability of the catalyst to absorb hydrogen removed from the dehydrogenated molecules, to maintain it in an active state for hydrogenation, and to supply it to the molecules undergoing hydrogenation. This idea explains the advantages of palladium over other metals as hydrogen redistribution catalysts as well as many other experimental results.

Subsequently the reactions of hydrocarbons involving the elimination and addition of hydrogen were studied on membrane catalysts permeable with respect to hydrogen alone. This made it possible to achieve coupled reactions[2-6], occurring on different sides of the membrane catalyst, as a result of the transport through the catalyst of a substance, for example hydrogen, which is formed on one surface of the catalyst and is consumed on the other. Two reactions coupled in this way accelerate one another without mixing all the reactants involved in them, which was inevitable in coupled reactions known previously, occurring in a single reaction volume in the absence of a catalyst or on the same catalyst surface. Similar results were obtained independently[7] in the USA. In recent years new membrane catalysts and methods for the preparation on them of olefinic dienes, cyclo-olefins, and aromatic hydrocarbons were developed in the USSR[8-15].

This review surveys the journal and patent literature dealing with the reactions of hydrocarbons on membrane catalysts and with the coupling of reactions on such catalysts.

2. EFFECT OF THE HYDROGEN SORBED BY THE CATALYST ON REDUCTION REACTIONS

The catalytic activation of hydrogen dissolved in palladium was noted in a report[16] on the diffusion of hydrogen through palladium. In contact with hydrogen-saturated palladium, iron(III) salts were converted into iron(II) salts and hydrogen halides were obtained from the halogens. Certain organic compounds were reduced on palladium[17]. Granular zinc coated with palladium black and treated with hydrochloric acid to saturate the palladium with hydrogen was used for this purpose[18]. Subsequently the total hydrogenation of benzene, toluene, xylenes, and ethylbenzene was achieved on palladium black[19]. It was noted[20] that benzobicyclononene is hydrogenated to dicyclohexylmethane on palladised activated charcoal both in the presence and absence of free hydrogen.

It was shown in 1934[21] that below room temperature the hydrogen sorbed by a palladium film hydrogenates olefins faster than the hydrogen entering from the gas phase. The rate of hydrogenation of ethylene or butene under the experimental conditions[22] was not limited by the rate of hydrogen

transfer from the bulk of the palladium layer onto its surface. In the course of hydrogenation hydrogen is extracted from palladium faster than on evacuation with a high-vacuum pump. At higher temperatures the rate of hydrogenation of benzene is independent of the partial pressures of the reactants. On this basis, it was postulated that the hydrogen dissolved in palladium participates in the reaction with adsorbed benzene[23]. The constancy of the rate of hydrogenation of benzene (on raising the temperature from 120° to 220°C in the presence of a palladium catalyst deposited on silica gel[24] and from 168° to 220°C on palladium black[25]) was interpreted[25] as a consequence of phase transitions in the palladium–hydrogen system. When the palladium catalyst is saturated by hydrogen at room temperature in the course of several tens of hours, its activity with respect to the hydrogenation of benzene falls sharply. On treatment with benzene vapour, the activity of the catalyst is gradually restored, which was interpreted[26] as proof that the hydrogen-rich β-phase of the palladium–hydrogen system is catalytically inactive. The increase of the activation energy for the hydrogenation of benzene with decrease of temperature leads to the same conclusion[27]. On the basis of all these data for the hydrogenation of benzene, it was concluded[28] that pure palladium and the α-phase of the palladium–hydrogen system are catalytically active and that on formation of considerable amounts of the β-phase the activity falls sharply.

Nickel, platinum, copper, and tungsten films obtained by the condensation of their vapours in a high vacuum are inactive with respect to the hydrogenation of ethylene, but films of these metals prepared in the presence of specific amounts of hydrogen, oxygen, or nitrogen are catalytically active[29]. The promotion of Raney nickel catalysts by hydrogen was discovered[30–32] in the hydrogenation of various substances by the hydrogen retained in the catalysts. The hydrogen adsorbed by the catalyst was removed reversibly and without an appreciable decrease of the activity of the catalyst. The removal of the hydrogen dissolved in the metal was irreversible with deactivation of the catalyst, since the consumption of structural hydrogen in hydrogenation alters the composition of the active surface. The activity was restored[33] by heating Raney nickel at 300°C in hydrogen.

In contrast to Raney nickel, palladium black retains its catalytic activity and the capacity to sorb hydrogen at room temperature after the removal on hydrogenation of the hydrogen retained by it[34].

As a result of several extractions of hydrogen from Raney nickel by the substance hydrogenated, the active structure of the catalyst is completely disrupted[35]. After this, the time required to saturate the catalyst surface by hydrogen until the attainment of the reversible hydrogen potential increases sharply and the hydrogen deposited on the surface is not involved in hydrogenation. The ability of palladium to give up comparatively readily the adsorbed and dissolved hydrogen makes it one of the best catalysts for low-temperature hydrogenation. The rate of reaction increases with increase of pressure to 3 atm, despite the fact that the catalyst surface is covered by hydrogen at a pressure as low as 1.5–2 atm. At low temperatures an increase of hydrogen pressure increases the degree of involvement in the reaction of the hydrogen dissolved in palladium. To elucidate the state of the hydrogen sorbed by Raney nickel, a potentiometric method was used[36]. In the course of the hydrogenation of acetylene a constant potential of the nickel catalyst was rapidly reached and the removal of hydrogen from the catalyst continued at a high rate, which the authors[37] regarded as proof that the hydrogen dissolved in the catalyst is also involved in the reaction.

With increase of the palladium content on the surface of the carrier, there is initially a slow and then a rapid increase of the rate of hydrogenation of unsaturated compounds in solution, which was explained by the appearance[38] of palladium crystals in which hydrogen is dissolved. This is consistent with the finding that in the region of low surface coverages of the carrier by palladium the rate of hydrogenation of triple bonds is lower than that of double bonds. When the coverage of the carrier corresponds to a sharp increase of the rates of both these processes, triple bonds are hydrogenated more readily than double bonds, as on massive palladium. In the latter case the author[38] assumes that triple bonds are hydrogenated mainly by the dissolved hydrogen, while in the presence of a catalyst with a low percentage of palladium it involves adsorbed hydrogen. A similar explanation of the increase of the specific activity of palladium with respect to hydrogenation for high surface coverages of the carrier by palladium was given in an earlier study[39], where it was suggested that the formation of the palladium crystal lattice and the dissolution of hydrogen in it lead to a type of activation of hydrogen different from that on catalysts with a low percentage of palladium. Such increase of the specific catalytic activity with increase of the degree of coverage has not been observed in catalytic oxidation[40].

In view of the foregoing findings, data on the catalytic activities of palladium hydride phases are interesting, but few such results are available. When the α- and β-phases of the palladium–hydrogen system coexist, the rate of hydrogenation of ethylene and propene on palladium hydride increases according to Wicke's data[41] by a factor of two with increase of the hydrogen: palladium atomic ratio from 0.1 to 0.4. Under these conditions, the surface concentration of hydrogen is not determined by its partial pressure but by its volume concentration in palladium. The rate of hydrogenation is not limited by the diffusion of hydrogen from the bulk phase to the catalyst surface and the rate of sorption of hydrogen at -78°C by palladium powder falls by a factor of 100 on passing from pure hydrogen to an equimolar ethylene–hydrogen mixture. Data for the hydrogenation kinetics and even the results of experiments with palladium deuteride show that atomic hydrogen adds to adsorbed olefin molecules on the palladium surface in the rate-limiting stage[42].

As already mentioned, it has been concluded[28] that the formation of considerable amounts of the β-phase of the palladium–hydrogen system reduces sharply the catalytic activity for the hydrogenation of benzene. The rate of hydrogenation of propene on the palladium catalyst decreases[43] after the catalyst has been treated with hydrogen. A similar effect has been observed[44] in the hydrogenation of ethylene on nickel. On the other hand, the catalytic activity of a nickel–copper alloy increases after treatment with hydrogen. The catalytic activity of nickel–palladium alloys containing between 9.5 and 25 wt.% of palladium changes little[45] after treatment with hydrogen, while the activity of nickel films for the ethylene hydrogenation reaction decreases after treatment with hydrogen. Evidence has been obtained[46,47] for the decrease of the catalytic activity of nickel and nickel–copper films on formation of hydride phases.

Thus the activity of many metallic hydrogenation catalysts increases following the sorption by the catalyst of specific amounts of hydrogen, while the formation of hydrogen-rich phases can reduce the catalytic activity.

3. HYDROGENATION BY HYDROGEN SUPPLIED THROUGH THE MEMBRANE CATALYST

In a number of studies hydrogenation reactions were investigated on a catalyst cathode through which hydrogen, obtained electrolytically on the other surface of the same cathode, passed to the reaction zone. The hydrogenation was then achieved either electrocatalytically or by the usual catalytic procedure.

A study[48] of the electrodiffusion of hydrogen through a palladium cathode showed that the rate of permeation by hydrogen increases after the addition of substances such as pyridine, sodium arsenite, and hydrogen sulphide to the electrolyte from which hydrogen passed to the cathode. On the other hand, the addition of the same substances to the electrolyte in contact with the outlet surface of the membrane electrode decreased the rate of diffusion of hydrogen. Electrochemical reduction of pyridine to piperidine on a nickel catalyst was accelerated by the addition of mercury(II) chloride, in contrast to the usual catalysis. This was explained[48,49] by the fact that the adsorption of the poison molecules on the surface of the cathode reduces sharply its adsorption potential and facilitates the transfer of the hydrogen atoms adsorbed on the cathode to the molecules undergoing hydrogenation.

The reduction of various substances on membrane steel, palladium, and platinum foil catalysts has been studied[50] with the aid of a nickel test tube part of the lateral surface of which had been replaced by the foil. Within the tube, there was an axial platinum anode and the electrolyte. The tube was immersed in a hot solution of the substance to be hydrogenated. The tube broke up fairly rapidly in the course of the experiment and the principal results were obtained for membranes welded to the edges of a slot in a copper disc to which two glass cylinders with reflux condensers were clamped via polyethylene washers. One cylinder, fitted with a platinum anode, contained the electrolyte and the other a solution of the substance hydrogenated. One surface of the membrane was the cathode and the hydrogen evolved on it passed to the other surface, where catalytic reduction took place. However, such steel and palladium membranes too worked for only a short time owing to recrystallisation and chemical effects leading to the formation of a leak. A platinum membrane could be used much longer. Partial hydrogenation of oleic acid to stearic acid and the reduction of nitrobenzene to aniline were carried out on a platinum membrane at a rate of hydrogen transfer of 6×10^{-6} g-atom cm^{-2} min^{-1}.

Subsequently a study was made[51] of the interaction of oxygen with electrolytic hydrogen diffusing through a steel membrane. It was found that at low current densities the oxygen adsorbed on the outlet surface of the membrane reduces the rate of permeation of hydrogen and at higher current densities it increases the rate of permeation compared with experiments in which the recombining hydrogen was desorbed into a vacuum. The formation of water in the interaction between adsorbed oxygen and hydrogen diffusing through the membrane was observed only in certain experiments at the maximum experimental temperature of 180°C. When a mixture of gaseous hydrogen and oxygen was supplied to the hydrogen-saturated surface of the membrane, water was not formed. At temperatures up to 190°C molecular nitrogen did not react with the hydrogen diffusing through a steel membrane and did not affect the rate of permeation of hydrogen through it.

Cyclohexene was hydrogenated within a palladium–silver alloy tube on the outer surface of which hydrogen was obtained electrochemically[53]. The hydrogenation of ethylene in a palladium tube through the walls of which diffused hydrogen obtained by the electrolysis of a solution of alkali on the outer surface of the tube proceeds much faster at 50°C than in the absence of the supply of hydrogen through the catalyst[53,54]. The hydrogenation of acetylene is accelerated even more as a result of the diffusion of hydrogen through the walls of a palladium tube[55]. However, an increase of the rate of reaction was not observed in the hydrogenation of maleic acid[56] where hydrogen diffused through both a smooth palladium membrane and one coated with palladium black. The authors[56] noted that these results confirmed the conclusion[57] that an electron is initially supplied to the molecule being reduced and then a proton, which can migrate from solution in cathodic reduction and from palladium in the usual catalytic hydrogenation.

It was shown[58] that hydrogen atoms from the palladium membrane are not involved in chain reactions of hydrogen with chlorine and with oxygen. Subsequently[59] a palladium membrane in contact with hydrogen on one side and with an ethylene–hydrogen mixture on the other was used to investigate the steady-states of the catalyst in heterogeneous reactions. A decrease of the concentration of hydrogen in the palladium foil was observed in the hydrogenation of ethylene compared with the concentration in equilibrium with the partial pressure of hydrogen in a mixture of ethylene. These results led to the conclusion that hydrogen atoms are involved in the reaction, but ethylene is hydrogenated simultaneously also by molecular hydrogen adsorbed on palladium. The exchange of hydrogen and deuterium, the interaction of hydrogen and oxygen, and the hydrogenation of ethylene on a palladium membrane were investigated by a similar method[60,61]. These reactions have radical mechanisms. If the amount of oxygen in the mixture with hydrogen is much greater than required by stoichiometry, the steady-state concentration of atomic hydrogen on the surface of the membrane catalyst is found to be smaller by a power of ten than the equilibrium concentration. No deviations from the steady-state concentration of atomic hydrogen from the equilibrium value were observed in the course of the hydrogenation of ethylene at temperatures from 200° to 300°C. This result, which differs sharply from that obtained at much lower temperatures[22], shows that at 200°C the rate of dissociation of hydrogen molecules and of recombination of hydrogen atoms on the palladium surface is greater by a power of ten than the rate of hydrogenation, while below room temperature the rates are comparable. A method has been developed[62,63] for the investigation of the mechanism of heterogeneous catalytic reactions with the supply and removal of hydrogen through a palladium capillary. In particular, the hydrogenation of ethylene in a gradient-free system was studied on the surface of this capillary. The kinetic data obtained at 200°C are consistent with the hypothesis of the consecutive addition of hydrogen atoms to the ethylene molecule. At higher temperatures the reaction mechanism changes.

A membrane consisting of a porous partition on which the catalytically active substance is deposited has been suggested for the liquid-phase hydrogenation of organic substances[64]. Hydrogen is supplied on one side of this partition, for example a glass sinter with a layer of nickel, and on the other side the substance to be hydrogenated, for example cottonseed oil, is present. The catalyst is not mixed with the hydrogenation products and the process can be made continuous and not cyclic. Later it was noted[65] that porous membrane catalysts can be used in principle also for the dehydrogenation and oxidation of organic compounds in the liquid phase. However, porous membrane catalysts are unsuitable for gas-phase processes, since

not only hydrogen but also the substance hydrogenated or oxidised can diffuse through the pores to the second reactor zone. Moreover, one loses an important advantage of non-porous membrane catalysts, namely that the hydrogen (or oxygen) transferred through them enters the reaction zone in the active, atomic state.

A study[66] of the diffusion of oxygen through a palladium membrane showed that the oxygen supplied via the membrane increases the catalytic and electrochemical activity of the membrane, in contrast to adsorbed oxygen, which inhibits electrochemical oxidation (for example of formic acid). The diffusion through the same membrane of part of the hydrogen formed in the dehydrogenation of formic acid decreases the oxidation current. It has been established[67,68] that, in the oxidation of hydrazine on a palladium membrane, the hydrogen formed as an intermediate in the electrochemical process is sorbed. Sorption of hydrogen can occur in the dissociation of the intermediates in the oxidation of hydrazine.

To transfer atomic hydrogen through palladium and palladium alloy partitions to the substance hydrogenated, a reactor with a spiral palladium tube was employed[69]. Hydrogen was supplied within the spiral and ethylene or styrene was hydrogenated on its outer surface by the hydrogen diffusing through palladium. A tube made of palladium alloy containing 23% silver, coated on the outside by a layer of gold 0.025 mm thick, served as the catalyst for the hydrogenation of cyclohexene[70]. The gold layer prevents the diffusion of hydrogen through the membrane from the side in contact with cyclohexene vapour, while hydrogen within the tube can diffuse through the walls. It was found that the rate of hydrogenation is proportional to the olefin pressure and the square of the degree of surface coverage of the catalyst by atomic hydrogen. The isomerisation of but-1-ene and *trans*-but-2-ene was not observed at 300°C on a palladium–silver tube which had no gold coating and was permeable to hydrogen from both sides[71], while the introduction of hydrogen into the tube caused rapid isomerisation of both hydrocarbons on the outer surface of the tube. With increase of the amount of hydrogen which has diffused, the hydrogenation of the butenes to butane became the dominant process. The removal of hydrogen via the membrane catalyst led to the dehydrogenation of butane, but the catalyst lost its activity after the complete removal of hydrogen. The supply of hydrogen through the membrane catalyst restored its activity, while gaseous hydrogen did not have this effect. The authors[71] explained this by the stable adsorption of olefins on the catalyst, which prevents the adsorption of hydrogen from the gas phase. According to their data[71], the first stage in the isomerisation of olefins is the addition of a hydrogen atom to the olefin molecule, after which hydrogen is split off. The diffusion of hydrogen formed in the dissociative adsorption of olefins on a palladium–silver alloy into the bulk of the alloy reduces the surface concentration of atomic hydrogen and the catalytic activity of the alloy with respect to isomerisation. The alloy consisting of 40% of palladium and 60% of gold, which dissolves much less hydrogen, exhibits a steady activity with respect to isomerisation.

The hydrogenation of but-1-ene and cyclohexene on the gold-plated surface of a palladium–silver tube with hydrogen supplied via its walls is slower by a factor of 60–200 than the diffusion of hydrogen through the same palladium alloy (with 23% of silver) alone. The rate of hydrogenation increases with increase of the rate of diffusion of hydrogen, which was explained[72] by a change in the distribution of hydrogen concentrations in the membrane.

Experiments with a thin-walled tube made of a palladium alloy containing 25% of silver, where the vapour of the substance to be hydrogenated was supplied inside the tube and hydrogen at a pressure of 3.5 atm was on the outside, showed[73] that, despite the low surface area of the membrane catalyst (9.8 cm^2), but-1-ene is hydrogenated to the extent of 82% at a temperature as low as 50°C. At this temperature the rate of diffusion of hydrogen through the catalyst (2.5 ml min^{-1}) does not reach the rate of supply of butene (3 ml min^{-1}). It is suggested[73] that in the presence of the olefin at the outlet surface of the membrane the permeability with respect to hydrogen may be enhanced by its rapid removal from the surface by the molecules being hydrogenated. After passing butene for 10 h, no decrease of catalytic activity was observed. At 250°C olefinic and acetylenic compounds, including even di-t-butylethylene which is sterically hindered, were hydrogenated quantitatively.

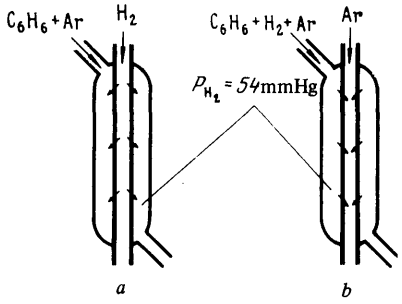

Figure 1. Schematic illustration of the supply (*a*) and removal (*b*) of hydrogen through a membrane catalyst in the course of the hydrogenation of benzene at a constant hydrogen partial pressure in the reaction zone.

The hydrogenation of benzene on the palladium alloy with 5% of nickel and the effect of the adsorption of benzene and cyclohexane vapours on the permeability of this membrane catalyst with respect to hydrogen and on its activity have been investigated[74,75]. It was established that the adsorption of cyclohexane vapour has little effect on the diffusion of hydrogen through the palladium–nickel alloy, while the adsorption of benzene vapour reduces the permeability. At a constant temperature and constant benzene and hydrogen partial pressures in the reaction zone the rates of hydrogenation are not the same for the supply and removal of hydrogen through the membrane catalyst (see the schematic arrangement in Fig. 1). This indicates the absence of equilibrium between the adsorbed hydrogen and the gas phase. The supply of hydrogen through the membrane catalyst increases the rate of hydrogenation of benzene only for a low ratio of the partial pressures of hydrogen and benzene in the reaction zone. If, on the other hand, the ratio is sufficiently high to ensure the required concentration of adsorbed hydrogen, then the supply of hydrogen via the membrane catalyst decreases the rate of hydrogenation, probably as a result of the displacement of some of the benzene molecules from the catalyst surface. The hydrogenation of benzene on the membrane catalyst leads not only to cyclohexane but also to cyclohexene, which is thermodynamically unstable under these conditions.

The high selectivity of hydrogenation on a membrane catalyst is due to the fact that the concentration of hydrogen adsorbed on its surface can be regulated by altering the hydrogen pressure on the opposite side. For this reason, membrane catalysts make it possible to obtain incomplete hydrogenation products and lead to new possibilities for reducing the competition between the adsorption of the substance hydrogenated and hydrogen, for estimating their surface concentrations, and for investigating the mechanism of reactions involving the addition of hydrogen.

4. HYDRODEALKYLATION OF BENZENE AND NAPHTHALENE HOMOLOGUES ON PALLADIUM ALLOYS

The hydrodealkylation reaction of benzene and naphthalene homologues is important not only in connection with the growing production of benzene from toluene and naphthalene derived from petroleum but also for the partial elimination of alkyl groups, for example in order to convert dimethylnaphthalenes into methylnaphthalenes. It was particularly important to elucidate the possibility of hydrodealkylation on palladium alloys suitable for use as membrane catalysts, because this is one of the few reactions involving the addition of hydrogen which is thermodynamically feasible at the temperatures of the dehydrogenation of alkanes and alkenes considered in the subsequent sections.

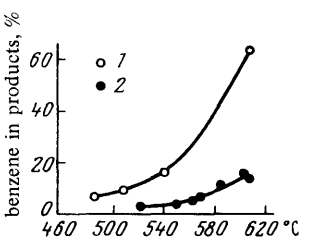

Figure 2. Variation of the benzene content in toluene hydrodealkylation products on the quenched (1) and unquenched (2) palladium–10% rhodium alloy.

It was found[76] that the rate of hydrodemethylation of toluene on the palladium alloy with 10% of rhodium increases by a factor of 6 with increase of temperature from 500° to 590°C. The activity of the catalyst can be increased by special heat treatment before the experiments, as was observed previously[77–79] for platinum films. Fig. 2 shows that after "quenching", the exposure of the palladium–rhodium alloy to a stream of hydrogen at 700°C for 20 min, and rapid cooling to the temperatures of the catalytic experiments, the rate of hydrodemethylation of toluene increases by a factor of 4 compared with the value before the heat treatment. The activity of the palladium alloy with 5.5% of nickel in relation to the hydrodemethylation of toluene proved to be lower than that of the alloy with 10% of rhodium, but after the above heat treatment of the catalyst the yield of benzene from toluene reaches 65% at 605°C.

The palladium alloy with 5% of rhenium catalyses the hydrodemethylation of toluene at a temperature as low as 320°C, but the yields are low and increase little with increase of temperature[80]. Toluene is converted into benzene to the extent of 21% at 547°C on the palladium alloy with 2% of molybdenum[81].

In a study of the effect of the substituent position in methyl- and dimethyl- naphthalenes on the rate of their hydrodemethylation binary alloys of palladium with molybdenum, rhenium, and nickel, consisting of solid solutions, were employed[82,83]. In the presence of alloys with 2.5 and 15% of molybdenum, 5% of rhenium, and 5% of nickel, the methyl groups of alkylnaphthalenes are eliminated more readily from the β-positions than from the α-positions. For example, at 527°C on the palladium–nickel alloy α-methylnaphthalene is converted into naphthalene to the extent of 29%, while the conversion of β-methylnaphthalene is 36%. Under the same conditions, the 1,6-dimethylnaphthalene conversion products were found to contain 1.5 times more α-methylnaphthalene than β-methylnaphthalene. These results are not complicated by isomerisation. In particular, the hydrodemethylation of 1,4- and 1,5-dimethylnaphthalene does not lead to the formation of β-methylnaphthalene.

The higher rate of elimination of groups in the β-positions and the absence of the isomerisation of α-methylnapthalene to β-methylnaphthalene were explained by postulating that alkylnaphthalene molecules are adsorbed via the plane of the ring on the flat sections of the catalyst surface. The carbon atoms of the methyl groups in the α-positions which deviate according to Coulson[84] from the plane of the naphthalene ring owing to the overlapping of the van der Waal's spheres of the methyl group and the hydrogen atom in the peri-position, are more remote under these conditions from the catalyst surface than the carbon atoms of the β-methyl groups in the plane of the naphthalene ring (Fig. 3).

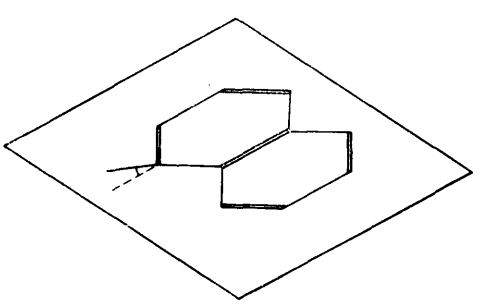

Figure 3. Schematic illustration of the adsorption of an α-methylnaphthalene molecule on a planar section of the catalyst surface.

This model suggests that the dimethylnaphthalenes in which the deviations of the methyl groups from the plane of the ring are particularly marked would be most difficult to demethylate. The available data[85] show that these deviations are maximum in 1,8-dimethylnaphthalene, the deviations of the two adjacent α- and β-methyl groups in 1,2-dimethylnaphthalene are somewhat smaller, and the deviations of the two adjacent β- and β′-methyl groups in 2,3-dimethylnaphthalene are smaller still. It has been stated[83] that the rate of hydrodemethylation should increase

in the following sequences of dimethylnaphthalenes: 1,8 < 1,2- < 2,3- < 1,4-, 1,5- < 1,3-, and 1,6- < 2,6- and 2,7-. The experimental data for the palladium alloy with 5% of nickel at 525°C are consistent with the above sequences (Table 1).

Table 1.

Dimethylnaphthalene	2,3-	1,4-	1,5-	1,6-	1,3-	2,6-
Yield of hydrodemethylation products, %	27,8	35,5	36,3	36,8	37,0	42,4

Experiments with dimethylnaphthalenes on the palladium–2% molybdenum alloy at 477°C also confirmed[81] the above reactivity series (Table 2).

Table 2.

Dimethylnaphthalene	1,8-	1,2-	2,3-	1,6-	2,6-
Yield of hydrodemethylation products, %	8	10	13	24	31

5. DEHYDROGENATION OF ALKANES AND ALKENES WITH ELIMINATION OF THE HYDROGEN FORMED THROUGH MEMBRANES

Many investigators attempted to increase the degree of dehydrogenation reactions by removing the hydrogen formed through membranes. Thin-walled platinum or palladium tubes, heated to 800°C, which were not used as dehydrogenation catalysts but merely as membranes permeable to hydrogen, were suggested for this purpose[86].

Porous partitions[87] obtained by subliming zinc from the walls of a brass tube were used as the catalytic membranes (cf. Warrick and Mack[88]). Palladium was also tested as the refractory component of the alloy; zinc was sublimed from a palladium–copper–zinc alloy. Such porous membranes were naturally not permeable to hydrogen alone and in addition they lost their permeability on contact with the vapours of hydrocarbons and other organic compounds. Porous tubes in which iron(III) and chromium oxides were deposited on the walls of the pores as well as perforated tubes where iron(III), molybdenum, aluminium, and chromium oxides were pressed into the apertures suffered from the same disadvantages[89].

Oxygen-permeable membranes have been proposed[90] to increase the degree of dehydrogenation of hydrocarbons. The reactor is divided into two zones by thin-walled silver tubes. The initial hydrocarbon is supplied to one zone filled with an alumina–chromium oxide catalyst or another dehydrogenation catalyst. The hydrogen formed on dehydrogenation is partly oxidised by the oxygen diffusing through the walls of the silver tubes from the other zone of the reactor where air is admitted. The decrease of the partial pressure of hydrogen achieved in this way in the dehydrogenation zone ensures a 20% conversion of butene into butadiene with a selectivity of 0.94 at 538°C and a pressure of 1.2 atm, whereas under the same conditions but in the absence of silver membranes dehydrogenation does not take place at all. It is noteworthy that the authors[90] failed to say anything about the diffusion of hydrogen from the dehydrogenation zone via the walls of the silver tubes, although the permeability of silver to hydrogen is greater by a factor of 3 than the permeability to oxygen. For this reason, the above effect might have been caused by the diffusion of hydrogen through the silver membranes and not of oxygen. The high selectivity, which is usually not observed in oxidative dehydrogenation, can also be explained from this point of view.

The method of preparation of hydrogen from hydrogen-containing substances[91], for example by the conversion of methane in a mixture with water vapour on a nickel catalyst at 450°C, provides for the removal of the hydrogen formed via the walls of tubes made of the palladium–25% silver alloy. The tubes are threaded through the catalyst bed in such a way that no point on the surface of the granular catalyst is further than 6 mm from the surface of the tubes. It is emphasised[91] that the tubes serve only as membranes permeable to hydrogen but do not exhibit a catalytic effect, since they cannot compete with the granular catalyst, which has a much greater surface area.

In contrast to the methods for the removal of hydrogen from the dehydrogenation zone[86–91], other workers[92,93] used foils made of binary alloys of palladium with nickel, ruthenium, rhodium, rhenium, silver, and platinum as membrane catalysts permeable to hydrogen alone. It was found[92] that, in the presence of the palladium alloy with 5.5 wt.% of nickel, isopentane is converted into isoprene and isopentenes. With increase of temperature to 558°C, the content of isoprene in the product reaches 18.6% and that of isopentenes 10.5%. On the palladium alloy with 10% of rhodium, 23.9% of isoprene and 6% of isopentenes were obtained from isopentane at 588°C. The dehydrogenation of 2-methylbut-1-ene on the palladium alloy with 5.5% of nickel at 287°C led to 81% of isoprene without side products[8]. A similar high activity and selectivity in the dehydrogenation of 2-methylbut-1-ene was shown by the palladium alloy with 10% of rhodium in the presence of which 78.7% of isoprene was obtained at 271°C.

The kinetics of the dehydrogenation of chromatographically pure 2-methylbut-1-ene, 2-methylbut-2-ene, and 3-methylbut-1-ene were investigated[93] on the palladium–5.89% nickel alloy. With increase of temperature from 340° to 400°C, the yield of isoprene from 3-methylbut-1-ene was found to be higher than for other isopentenes and to increase for a virtually constant content of the remaining isopentenes in the products. Consequently under these conditions isoprene is obtained from 3-methylbut-1-ene and not from its isomerisation products. At higher temperatures isoprene is formed mainly from 2-methylbut-2-ene produced by the isomerisation of 3-methylbut-1-ene. The dehydrogenation of pure 2-methylbut-2-ene to isoprene is complicated to a relatively small extent by isomerisation, since the change in the content of the 2-methylbut-2-ene isomerisation products is small compared with the increase in the content of isoprene when the temperature is increased. On the other hand, the isomerisation of 2-methylbut-1-ene to 2-methylbut-2-ene is much faster than dehydrogenation: the contents of 2-methylbut-2-ene and isoprene in the reaction products of 2-methylbut-1-ene and 2-methylbut-2-ene are almost the same.

A mixture of 95% of 2-methylbut-2-ene and 5% of 2-methylbut-1-ene was dehydrogenated at the Sterlitamak experimental SKI-3 synthetic rubber factory in enlarged reactors with membrane catalysts made of the same alloy[93]. At 430°C, a rate of supply of the mixture of the vapours of isopentenes and argon of 2.4 litre h^{-1}, and a partial pressure of isopentenes of 3 mmHg the yield of isoprene in the initial period of the experiment was 38.8%. The hydrogen evolved diffused through the membrane catalyst and was removed by the carrier gas. After 6 h of operation of the system, the yield of isoprene fell to 16.6%. Regeneration of the catalyst with air not only restored but also enhanced its activity. After operating for 20 h and four regenerations of the palladium–nickel foil catalyst, the maximum yield of isoprene at 430°C and a partial pressure of isopentenes of 3 mmHg was 54%.

The foregoing findings show that palladium alloy membrane catalysts exhibit a high activity and selectivity in the formation of isoprene and other dienes by dehydrogenation.

6. DEHYDROGENATION OF CYCLOHEXANE ON PALLADIUM AND PALLADIUM ALLOYS

The dehydrogenation of cyclohexane was investigated on palladium–ruthenium[94], palladium–silver[95,96], palladium–nickel and palladium–platinum[96], and palladium–tungsten and palladium–ruthenium[97] alloys, which are permeable to hydrogen alone, as well as on palladium foil[98]. Experiments[95] with a tube made of the palladium–23% silver alloy around which the required hydrogen pressure or a vacuum was established while the external surface served as the catalyst showed that the dehydrogenation of cyclohexane results in the formation of cyclohexene, the content of which increases at low hydrogen pressures in the reaction zone and at high rates of elimination of hydrogen from this zone. It is interesting that in the complete absence of hydrogen the catalyst did not show any activity in relation to the dehydrogenation of cyclohexane. The results led to the following mechanism for the dehydrogenation involving adsorbed hydrogen atoms and hydrogen atoms dissolved in the catalyst:

$$C_6H_{12} + H_{ads.} \xrightarrow{k_1} C_6H_{11}^{\cdot} + H_{ads.} + H_{soln.},$$

$$C_6H_{11}^{\cdot} + H_{ads.} \xrightarrow{k_2} C_6H_{12},$$

$$C_6H_{11}^{\cdot} \underset{k_4}{\overset{k_3}{\rightleftarrows}} C_6H_{10} + H_{ads.}.$$

Having assumed that cyclohexane molecules, the cyclohexyl radicals formed them, and cyclohexene molecules are adsorbed on the catalyst, it was found that in the steady state the concentration ratio $[C_6H_{10}]/[C_6H_{12}] = k_1k_3/k_2k_4[H_{ads}]$, i.e. is inversely proportional to the concentration of adsorbed hydrogen atoms. This is consistent with experimental data. After prolonged contact of the reaction mixture with the membrane catalyst, benzene was found in the products.

A study of the dehydrogenation of cyclohexane to benzene on palladium foil in a flow-circulation system showed[98] that the rate of reaction is described satisfactorily by the equation $w = kp^m_{C_6H_{12}}p^n_{H_2}$, where $m = 0.5$ and $n = 0.2$ at 250°C and $m = 0.6$ and $n = 0.5$ at 322°C. The fact that the p_{H_2} exponent is positive and does not exceed 0.5 under the conditions indicated suggests, in agreement with Gryaznov et al.[96], that hydrogen atoms adsorbed on the catalyst are involved in the dehydrogenation of cyclohexane. Together with hydrogen molecules, cyclohexane molecules, whose adsorption with the dissociation of one C–H bond can lead to the formation of cyclohexyl radicals, can serve as a source of hydrogen atoms. Further removal of hydrogen atoms led to the formation of species still more depleted in hydrogen until the formation of benzene molecules. Only benzene was found in the desorbed cyclohexane dehydrogenation products at temperatures below 350°C. If the rate-limiting stage is the conversion of the complex formed by a cyclohexane molecule from the gas phase and an adsorbed hydrogen atom into a hydrogen molecule and an adsorbed cyclohexyl radical and the subsequent conversion of the latter into benzene virtually corresponds to equilibrium (like the adsorption of cyclohexane molecules on hydrogen atoms), then the rate of dehydrogenation should be proportional to the degree of surface coverage of the catalyst by the complex $C_6H_{12}.H_{ads}$. Using the Langmuir equation, it is possible to obtain the following expression for the reaction rate:

$$w = \frac{k\,a\,a_{H_2}p_{C_6H_{12}}\sqrt{p_{H_2}}}{1 + a\,p_{C_6H_{12}} + a_{H_2}\sqrt{p_{H_2}}},$$

where k is the rate constant and a and a_{H_2} are the adsorption coefficients of cyclohexane and hydrogen respectively. The term including the partial pressure of benzene does not enter into the equation owing to the low degrees of dehydrogenation of cyclohexane. The linear relations between $p_{C_6H_{12}}/w$ and $p_{C_6H_{12}}$ and between $\sqrt{p_{H_2}}/w$ and $\sqrt{p_{H_2}}$ correspond to this equation. The experimental data, some of which are presented in Fig. 4, are indeed described by linear plots in terms of the above variables (Figs. 5 and 6). The kinetic equations derived on the assumption that the rate-limiting stage is the interaction of an adsorbed hydrogen atom and a cyclohexane molecule with formation of an adsorbed C_6H_{11} radical and an H_2 molecule are also consistent with the experimental data. On the other hand, if the rate-limiting stage is assumed to be, following Kiperman[99], the adsorption of cyclohexane molecule with elimination of a hydrogen atom or the interaction of an adsorbed hydrogen atom and one of the intermediates in the dehydrogenation of cyclohexane, then it follows from the resulting kinetic equations that the reaction should be inhibited by hydrogen. This has not been observed experimentally[98].

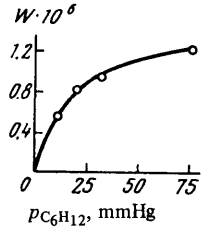

Figure 4. Variation of the rate of dehydrogenation of cyclohexane (C_6H_{12}) on palladium foil with its vapour pressure (250°C, hydrogen pressure 350 mmHg).

The catalytic activity of binary palladium alloys in relation to the dehydrogenation of cyclohexane depends in a complex manner on the nature and amount of the second alloy component[96]. Palladium alloys containing 20, 40, and 50% of silver are less active than pure palladium. The formation of the Kurnakov compounds Pd_3Ag_2 and PdAg does not

lead to an enhancement of catalytic activity. The introduction of between 0.1 and 1.5% of platinum into the palladium alloy results in an improvement of the catalytic activity of palladium at temperatures below 400°C and the palladium alloy with 5% of nickel is more active over the entire experimental temperature range than pure palladium. On the other hand, the alloy with 10% of nickel is inferior to pure palladium as regards activity. Consequently the catalytic activity of palladium–nickel alloys in the dehydrogenation of cyclohexane passes through a maximum as the nickel content in the solid solution is increased. A similar relation has been found[94] for palladium–ruthenium alloys: the most active alloy in the dehydrogenation of cyclohexane contains 8.36% of ruthenium, while those with 7.0 and 9.2% of ruthenium are somewhat less active.

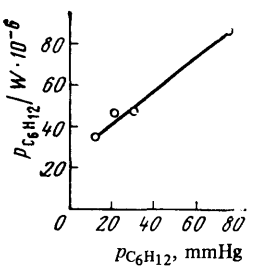

Figure 5. Variation of $p_{C_6H_{12}}/w$ with cyclohexane vapour pressure (250°C, hydrogen pressure 90 mmHg).

It has been noted that, with increase of the ruthenium content from 1 to 9%, the permeability of the palladium–ruthenium alloys to hydrogen, measured by the method of Mishchenko and Gryaznov[100], passes through a maximum for a ruthenium content of about 6%. The long-term tensile strength of this alloy at 550°C amounted to 11 kgf mm^{-2} over a period of 1000 h, [94] which is higher by a factor of almost 5 than that of pure palladium. The short-term tensile strength of deformed palladium–ruthenium alloys extended *in vacuo* increases with increase of the ruthenium content to 9% at 500° and 900°C. The above data lead to the conclusion that palladium alloys containing between 6 and 9% of ruthenium are optimal as regards catalytic activity in the dehydrogenation of cyclohexane, permeability to hydrogen, and mechanical properties. One must emphasize that, together with a high activity, the membrane catalyst must exhibit an adequate permeability to hydrogen and mechanical strength, so that thin-walled designs can be employed.

7. DEHYDROCYCLISATION OF *n*-ALKANES ON PALLADIUM ALLOYS

The dehydrocyclisation of straight-chain hexane, heptane, octane[9], and decane[82] under non-chromatographic pulse conditions was investigated on a foil made of the palladium alloy with 5.5% of nickel. At 618°C 9% of benzene was formed from hexane in a stream of hydrogen and cleavage to methane, which occurred at higher temperatures, was not observed. Heptane in a stream of argon at 587°C gave rise to 65% of aromatic hydrocarbons, including 50% toluene and 15% of benzene. The main octane dehydrocyclisation product on the same alloy proved to be *o*-xylene. *n*-Decane was converted into naphthalene to the extent of 3% at 553°C, while at higher and lower temperatures the yields of naphthalene were smaller.

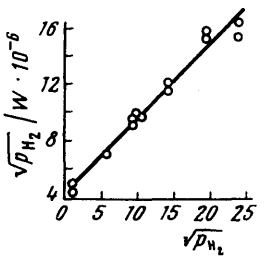

Figure 6. Variation of $\sqrt{p_{H_2}}/w$ with $\sqrt{p_{H_2}}$ at 250°C and a cyclohexane vapour pressure of 60 mmHg.

The palladium alloy with 10% of rhodium[76] showed a higher activity with respect to the dehydrocyclisation of *n*-heptane than the palladium alloy with 5.5% of nickel: 46% of toluene and 24% of benzene were obtained at 550°C on the palladium–rhodium, while on the palladium–nickel alloy under the same conditions the yields were 37% of toluene and 8% of benzene.

Palladium–rhenium alloys were tried as catalysts for the dehydrocyclisation of *n*-alkanes[101,102]. The product obtained from heptane at 625°C on the alloy containing 5% of rhenium consisted of 14% of toluene and 34% of benzene. The dehydrocyclisation of octane on the same catalyst is accompanied to an even greater extent by the hydrodealkylation of the aromatic hydrocarbon products to benzene.

The palladium alloy with 5% of ruthenium proved to be one of the most active catalysts of the dehydrocyclisation of *n*-alkanes[103]. Hexane, which, as shown by the experiments described previously, is dehydrocyclised with greater difficulty than *n*-alkanes with a higher molecular weight, gave rise to 58% of benzene at 575°C on a foil made of this alloy. In the presence of the palladium alloy containing 5% of tungsten and 1% of ruthenium, 54.7% of benzene and 2.6% of toluene were obtained from *n*-heptane at 590°C.

The high activity of palladium alloys used as hydrogen-permeable membrane dehydrocyclisation catalysts is particularly important, since alkanes widely occurring in different types of petroleum are converted by this reaction into more valuable aromatic hydrocarbons and the formation of one mole of such hydrocarbons is accompanied by the generation of four moles of hydrogen, which can be used on the other side of the same membrane catalyst for hydrodealkylation and other reactions.

8. THE COUPLING OF CATALYTIC HYDROGEN ELIMINATION AND ADDITION REACTIONS

By definition[104] coupled reactions consist of a system of two reactions occurring in the same medium the course of one of which depends on the other. A study of coupled oxidation reactions in solution showed[104] that coupling is possible only for complex processes with formation of an

intermediate which constitutes a link between the primary and secondary reactions. The conclusion reached in a monograph[104] that in coupled reactions chemical energy is transferred as such from one process to another must be regarded as even more general. We shall return to this conclusion after a brief survey of the results of studies of coupled reactions on the same surface of a heterogeneous catalyst.

The coupling of catalytic hydrogen elimination and addition reactions has been observed[105] in the hydrogenation of methyl tetrahydroterephthalate. It was found that at room temperature in the presence of palladium foil the hydrogenation process is accompanied by the dehydrogenation of part of the starting material to the terephthalate ester. The authors[105] noted that palladium black having lost its hydrogen in the hydrogenation reaction is again saturated with hydrogen from the tetrahydroterephthalate ester and not the hydrogen present in a free state. In the presence of a large amount of palladium black at room temperature the dehydrogenation of dihydronaphthalene predominates[106] over the thermodynamically unavoidable hydrogenation, since the absorption of hydrogen by palladium displaces the equilibrium. Cyclohexadiene has been converted into benzene and cyclohexene and the latter to benzene and cyclohexane on the palladised asbestos at temperatures below 130°C in a stream of carbon dioxide[107]. In these "irreversible catalytic" reactions (as defined by Zelinskii) hydrogen is not evolved, since the hydrogenation of one molecule of cyclohexene causes the hydrogenation of two other such molecules and the dehydrogenation of one cyclohexadiene molecule causes the hydrogenation of another such molecule. Similar reactions of hydrocarbons of different classes with double bonds in the rings and in side chains, with a triple bond in the side chain, and in bicyclic hydrocarbons with and without bridging groups have been investigated[108–124]. The conversion of ethylene into ethane and acetylene and of propene into propane and propyne has been observed[125] on palladium films and to a lesser extent on platinum films.

Various substances can serve as hydrogen donors and acceptors. In particular it has been stated[126] that between 240° and 260°C methylcyclohexane behaves as a donor and benzene as an acceptor of hydrogen. This pair of coupled reactions was subsequently investigated[127] on palladised silica gel. Petroleum naphthenes, which can be converted into valuable aromatic hydrocarbons, have been noted as particularly interesting hydrogen donors[126] and liquid vegetable oils have been noted as interesting hydrogen acceptors. However, this system has not been investigated and the possibility of the hydrogenation of unsaturated acids by the hydrogen obtained in the dehydrogenation of ethanol was confirmed by experiments using a nickel catalyst.

On the hypothesis that the energy required for the endothermic dehydrogenation of the hydrogen donor is provided by the exothermic hydrogenation of the hydrogen acceptor. Vesterberg and Braun[128] explained certain experimental data and calculated the ΔG°_{298} for pairs of coupled reactions: dehydrogenation of cyclohexane or methylcyclohexane–hydrogenation of maleic or fumaric acid, dehydrogenation of bibenzyl–hydrogenation of trimethylethylene. It was noted that the predominance of the maximum useful work obtained in the hydrogenation of the hydrogen acceptor over the corresponding quantity obtained in the dehydrogenation of the donor is a necessary but naturally not a sufficient condition for coupling. Another problem is to ensure a sufficient rate of the coupled reactions in the presence of the given catalyst.

The hydrodecyclisation (ring hydrogenolysis) of ethylcyclopentane coupled with the dehydrogenation of cyclohexane has been achieved[129,130] on platinised charcoal. The same hydrogen donor has been used[131] for the coupled hydrogenation of propenylbenzene to propylbenzene, of *trans*-stilbene to bibenzyl, of 1,1-diphenylethylene to 1,1-diphenylethane, etc. The use of ethylene as the acceptor of the hydrogen evolved in the dehydrogenation of n-butane on an alumina–chromium oxide catalyst increased[132] the yield of butadiene from 9.3 to 16.4%.

In all the studies described in this section the coupling of the reactions made it possible to increase their rate or selectivity. However, all the components of coupled reactions were present in the same volume and the separation of the resulting multicomponent mixtures frequently proved to be difficult and reduced the advantages of coupling.

9. THE COUPLING OF REACTIONS ON MEMBRANE CATALYSTS

It was suggested in 1964[2,3,5,11] that, in order to increase the efficiency of catalytic processes, two reactions be carried out on different sides of a partition made of a catalytically active substance or one coated by catalyst layers. Three types of coupling of catalytic reactions are then possible.

1. In the absence of the transfer of reactants through the catalyst the heat evolved in any exothermic reaction occurring on one catalyst surface can be used to carry out any endothermic reaction on the other catalyst surface. Any catalyst with adequate thermal conductivity can be used for such energy coupling of catalytic processes. Catalysts with low thermal conductivity can be deposited in the form of thin layers on the surface of a heat conducting partition.

2. When the substance formed as a result of the reaction on one catalyst surface and consumed in the reaction on the other surface is transferred through the catalyst, the thermodynamic equilibria in both reactions will be displaced and the degrees of conversion will increase. A catalyst permeable to the chosen substance alone is necessary for such thermodynamic coupling.

3. If the substance formed on one side of the catalyst and consumed on the other is transferred through the catalyst in an active, for example atomic, state, a specific (kinetic) coupling of the reactions is possible. To remove the substance from the catalyst surface where it is formed, the recombination and desorption stages are no longer required and its reaction on the other catalyst surface does not need activation.

The above types of coupling of catalytic processes can occur both separately and in combination with one another. The degree of coupling of two reactions is chosen in such a way that the steady-state process is stable. A distinctive feature of the coupling of reactions on a membrane catalyst is that the transfer of chemical energy from one process to the other[104] with minimal dissipation of energy is possible. The non-spontaneous reaction ($\Delta G_1^\circ > 0$) can be achieved as the result of the free energy of the other reaction ($\Delta G_2 < 0$), provided that $|\Delta G_2^\circ| > |\Delta G_1^\circ|$.

The use of hydrogen formed in the reaction on one side of the partition of a palladium or palladium alloy tube to carry out on the other side of the partition a reaction involving the addition of hydrogen is an example of the coupling of catalytic reactions. Thermodynamic calculations have shown[5] which hydrogen addition reactions are possible at temperatures sufficiently high for industrially important dehydrogenation reactions. In particular at 427°C (700°K)

ΔG° for the hydrodemethylation of toluene is negative and its absolute value is higher than the positive ΔG° for the dehydrogenation of butene to butadiene. Therefore thermodynamic limitations are lifted from the latter reaction when it is coupled with the hydrodemethylation of toluene.

The removal of hydrogen from the dehydrogenation of dehydrocyclisation zone via the membrane catalyst increases the equilibrium degree of conversion. At 527°C (800°K) and an overall pressure of 1 atm the equilibrium yield of butadiene from but-2-ene is 15%. If 90% of the hydrogen formed is removed from the reaction zone, the yield of butadiene increases to 38% and after the elimination of 98% of the hydrogen the equilibrium yield rises to 73%.

A palladium foil dividing the reactor in half can be used as the simplest example of a membrane catalyst. If the upper half of the reactor contains butene, the latter will be dehydrogenated to butadiene on the upper surface of the palladium foil, as shown in Fig. 7. The hydrogen formed in the dehydrogenation process dissolves in the palladium and migrates in an atomic form across the foil, whose cross-section is illustrated in Fig. 7 by a shaded band. On the lower surface of the palladium foil, atomic hydrogen can be used, for example, for the hydrodemethylation of toluene or for other hydrogen addition reactions.

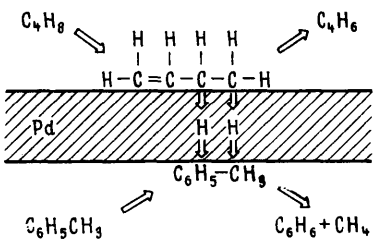

Figure 7. Schematic illustration of the coupling of butene dehydrogenation and toluene hydrodemethylation reactions on a palladium membrane catalyst.

In the general case any reaction involving the formation of hydrogen can take place on one surface of a membrane catalyst permeable to hydrogen alone:

$$A \rightarrow B + H_2 \quad , \qquad (1)$$

while on the other surface any hydrogen addition reaction can occur:

$$C + H_2 \rightarrow E \quad . \qquad (2)$$

It is of course necessary that reactions (1) and (2) should proceed at the same temperatures and pressures, since the thermal conductivity of a thin membrane is high and its strength is low. If reaction (1) is carried out separately from reaction (2), then a specific degree of surface coverage of the catalyst by hydrogen Θ_1^* is established under the specified conditions and, when reaction (2) takes place separately from reaction (1), the degree of surface coverage is Θ_2^*. The rates of these reactions can be expressed by the equation

$$w_i = k_i f_i(\mathbf{p}_j)\left[1 - \frac{\varphi_i(\mathbf{p}_j)}{K_{pi}}\right],$$

where i is the number of the reaction, j the reactant index, $\mathbf{p}_j$ the vector of the reaction mixture composition, $k_i f_i(\mathbf{p}_j)$ the rate of reaction disregarding its reversibility, $\varphi_i(\mathbf{p}_j)$ the expression of the law of mass action, and K_{pi} the equilibrium constant for the ith reaction.

If reactions (1) and (2) are carried out on a membrane catalyst, then under the same conditions the degree of surface converages of the two catalyst surfaces will be different (Θ_1 and Θ_2 respectively) owing to the transfer of hydrogen through the catalyst. The rate of transfer of hydrogen is determined by Θ_1 and Θ_2 and the coefficient β:

$$w_H = \beta(\theta_1 - \theta_2) \quad .$$

If the rate of transfer of hydrogen is higher than the rate of its formation by reaction (1), then the inequalities

$$\theta_1^* > \theta_1 > \theta_2 > \theta_2^*$$

constitute the main condition for the coupling of the reactions on a membrane catalyst permeable to hydrogen alone[133].

The three types of coupling discussed above involve (1) the maintenance of isothermal conditions owing to the transfer of heat from the exothermic hydrogen addition reaction zone to the endothermic hydrogen elimination reaction zone (energy effect), (2) an increase of the quantity $(1-\varphi_i(\mathbf{p}_j)/K_{pi})$ in consequence of changes in the equilibrium conditions (thermodynamic effect), and (3) an increase of the rate of reaction $k_i f_i(\mathbf{p}_j)$ when no account is taken of its reversibility (kinetic effect).

A mathematical model of the coupling of reactions on a membrane catalyst can be constructed taking into account three levels: (a) the molecular level including the stages of catalytic reactions; (b) the element of the membrane catalyst where catalytic reactions are combined with hydrogen and heat transfer through the catalyst; (c) the reactor with the membrane catalyst.

The first level is described by the kinetic equations for the corresponding reactions and the second level by a combination of these equations, the heat balance equation, and the equation for mass transfer through the catalyst. Analysis of these equations showed[133] that they have a steady-state solution characterising the stability of the coupling of the two reactions on the membrane catalyst.

The experimental evidence for the coupling of reactions, one of which involves the evolution and the other the addition of hydrogen, on different sides of a catalyst selectively permeable to hydrogen alone was obtained[4] in the dehydrogenation of cyclohexane within a palladium tube and in the hydrodealkylation of toluene or *o*-xylene on its outer surface by the diffusing hydrogen. Both reactions and hydrogen transfer are accelerated under the conditions of such coupling compared with the conditions where the reactions are carried out separately. The coupling of the dehydrogenation of *trans*-but-2-ene at 380°C and a pressure of 1.4 atm with the hydrogenation of benzene on the other surface of a palladium tube resulted in the formation of 6.1% of butadiene. This yield is three times higher than the equilibrium yield at the given temperature and a pressure of 1 atm without the removal of the hydrogen formed. The amount of butadiene collected from a unit geometrical surface area of the palladium membrane catalyst was 2000 times greater than for the K-16 industrial catalyst (according to Tyuryaev and Kolobikhin's data[134]).

The efficiency of the coupling of heterogeneous catalytic reactions is much higher than that of the simple removal of the hydrogen formed from the dehydrogenation zone. For example, the rate of formation of butadiene increases by a factor of five when a stream of argon onto the other side of

the membrane catalyst is replaced by a stream of a mixture of toluene vapour and argon, i.e. when the diffusing hydrogen is combined.

The use of membrane catalysts permeable to hydrogen in processes involving the evolution of hydrogen not only accelerates them but also suppresses side reactions. For example, in the dehydrogenation of isopentenes under flow conditions at 410°C on the surface of a thin-walled tube made of 94.5% palladium–5.5% nickel alloy with an inert gas flowing along its other surface, the yield of isoprene increases from 14 to 21%, without the formation of undesirable impurities (penta-1,3-diene and cyclopentadiene), as a result of the decrease of the partial pressure of hydrogen in the dehydrogenation zone from 15 to 5 mmHg.[133]

As shown in Sections 3–7, binary alloys of palladium with nickel, ruthenium, rhodium, rhenium, molybdenum, and other metals can be used as membrane catalysts permeable to hydrogen alone. These alloys exhibit a high permeability to hydrogen and are superior to pure palladium as regards catalytic activity with respect to dehydrogenation, dehydrocyclisation, hydrogenation, and hydrodealkylation of hydrocarbons.

For the continuous removal of the hydrogen formed in the dehydrogenation of alkanes, it has been suggested[7] that the hydrogen diffusing through a palladium or palladium alloy membrane be burnt. The heat of combustion of hydrogen makes it possible to reduce the supply of heat needed to carry out the endothermic dehydrogenation reaction. In the dehydrogenation of ethane under a pressure of 8.6 atm at 452°C up to 0.7 vol.% of ethylene was obtained on the inner walls of a palladium–25% – silver alloy tube when a mixture of nitrogen with 0.7 vol.% of oxygen was present outside the tube at a pressure of 7 atm. The combustion of the hydrogen removed from the dehydrogenation zone is not an optimal method for its combination, since the hydrogen which has migrated to the palladium alloy is extremely active in hydrogenation and other hydrogen addition reactions. Moreover the hydrogen obtained in the dehydrogenation of hydrocarbons on palladium membrane catalysts is sufficiently pure for the manufacture of semiconductor devices. Nowadays millions of cubic metres of hydrogen are purified daily for such purposes by diffusion through palladium without the synthesis of any other products.

In the industrial manufacture of vitamins and pharmaceutical preparations the hydrogenation or dehydrogenation processes are frequently carried out on porous (Raney) metals, blacks, and other catalysts whose fine particles contaminate the products. The greater mechanical strengths of membrane catalysts makes it possible to prevent the contamination of products by catalyst particles and to avoid the loss of catalysts, for example palladium.

It was discovered in recent years that catalysts for many industrial processes are best prepared by depositing the metals onto the surface of alumina or aluminium silicate blocks resembling honeycombs in shape. Such block catalyst offer a resistance to the flow of gas which is even lower than that of spherical catalysts, which were the best known previously. Block catalysts make it possible to reduce the volume of the reactor and the consumption of noble metals. A change from granulated catalysts in tubes or on reactor shelves to catalysts consisting of the constructional elements of the reactor has been suggested. It is easy to assess the prospects opened up by the next stage in this development— the creation of a reactor with a membrane catalyst for carrying out simultaneously two coupled processes.

Reactor designs with a membrane catalyst in the form of tubes have been proposed[135]. This system resembles a heat exchanger with a floating head, which eliminates the deformation of thin-walled palladium alloy tubes owing to differences between the thermal expansion coefficients of the alloy and the material of the reactor shell. Thin-walled tubes are welded to two collectors, one of which serves as the lid of the reactor shell and is fitted with a partition ensuring that the initial substance flows from above downwards in one half of the total number of tubes and from below upwards in the other half.

To increase the surface area of the membrane catalyst per unit volume of the reactor, reactors have been developed with a membrane catalyst in the form of flat or corrugated plates and also in the form of a double helix. To prevent the deformation of the membrane catalyst, specially corrugated sheets of a stronger material, inert with respect to hydrocarbons or coated by a thin layer of the catalytically active substance, can be inserted between the plates or the turns of the helix.

Membrane catalysts may consist of a combination of a selectively permeable but catalytically relatively inactive substance and the catalytically active component. When the active component (metal) is sufficiently dispersed and the reactant, for example hydrogen, is transferred from the metal to the carrier (membrane), the limitations due to the rate of diffusion of the given reactant through the massive metal are lifted. This can ensure the operation of membrane catalysts at low temperatures. Moreover, a membrane with different metal or alloy particles attached to its two sides makes it possible to extend the range of reactions capable of being coupled. Such a membrane can serve as a model for biological membrane-enzyme system.

Membrane catalysts make it possible to investigate heterogeneous catalysts in open systems. When the zones of two reactions coupled as a result of the transfer through the catalyst of the substance evolved in one reaction and consumed in the other is separated by a membrane catalyst, not only is the mixing of the reactants of the two reactions prevented but it is also possible to obtain more complete data for the elementary stages of these reactions, which is very important in view of the decisive role of the coupling of the stages in catalysis.

The Reactions of Certain Aromatic Cations

S.V.Krivun, O.F.Alfërova, and S.V.Sayapina

The review gives a systematic account of the most characteristic reactions of heteroaromatic cations and also tropylium and cyclopropenylium salts. The properties of these cations are compared and classified in accordance with three types: 1. reactions involving recyclisation; 2. reactions of substituents in aromatic cations; 3. reactions with retention of the ring. Attention has been concentrated on the recyclisation reactions and studies which have not been described in previous reviews. The bibliography includes 220 references.

CONTENTS

I. Introduction 835
II. Reactions of aromatic cations involving recyclisation 835
III. Reactions of the substituents in aromatic cations 841
IV. Reactions with retention of the ring 843

I. INTRODUCTION

There has been a considerable growth of interest recently in cyclic aromatic cations. Most attention has been devoted to pyrylium salts owing to their unique capacity to be converted into a wide variety of benzenoid, non-benzenoid aromatic, and heterocyclic compounds. Such reactions are not characteristic of thia- and selenapyrylium, flavylium, and xanthylium salts, their reactions proceeding mainly with retention of the initial ring. Tropylium and cyclopropenylium cations—the most typical representatives of charged non-benzenoid aromatic systems—have also attracted much attention. The purely theoretical interest in these compounds has been combined with a search for their direct practical applications, which has led to important results. Thus certain derivatives of pyrylium salts enter into valuable light-sensitive compositions for electronic engineering (see, for example, Refs. 1 and 2). Extensive experimental data on the reactions of aromatic cations have now accumulated. On the other hand, many of the available reviews are devoted mainly to the synthesis of these compounds (see, for example, Refs. 3–10) and no systematic account has been given of the reactions of the cations. Dimroth's review of the reactions of pyrylium salts and aromatic compounds[4] is an exception. Ring expansion reactions of cyclopropenylium cations, ring contraction reactions of tropylium cations, a number of new examples of the recyclisation of pyrylium salts, and also numerous reactions of heteroaromatic cations with retention of the ring were discovered in recent years. Therefore the present review is restricted to a brief consideration of the transformations of pyrylium salts into aromatic systems, attention being concentrated on studies of the reactions of aromatic cations which have not been described in the reviews published previously.

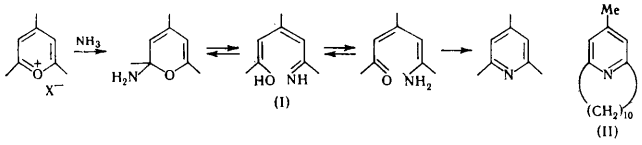
All the reactions of aromatic cations can be divided into three main types: 1. reactions of aromatic cations involving recyclisation; 2. reactions of substituents in aromatic cations; 3. reactions with retention of the ring.

II. REACTIONS OF AROMATIC CATIONS INVOLVING RECYCLISATION

When nucleophilic agents add to aromatic cyclic cations, their aromaticity is destroyed which frequently leads to ring opening. If there is a possibility of the formation of a new aromatic system, the open-chain form cyclises.

1. Pyridines and Pyridinium Salts. *N*-Oxides

The most typical example of the reactions of pyrylium salts is their interaction with ammonia and its derivatives leading to the formation of pyridine and other heterocyclic nitrogen-containing bases. In an early study Baeyer[11] established that pyrylium salts are readily converted into pyridine derivatives on heating with an aqueous ammonium carbonate solution. After Baeyer and Piccard[12], Dilthey[13], Gastaldi[14], and Balaban and Nenitzescu[15] synthesised a series of substituted pyridines from the corresponding pyrylium salts. The reaction almost always proceeds readily and with a quantitative yield. It is convenient to employ aqueous and alcoholic ammonia solutions[11,13] or ammonium acetate in acetic acid[16]. The reaction mechanism consists of nucleophilic attack by ammonia on the α-position of the pyrylium ring, the opening of this ring, and subsequent closure of the pyridine ring[17]:

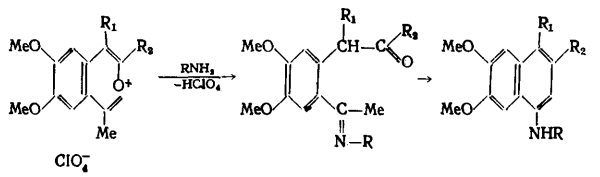


Balaban and Toma succeeded in isolating the intermediate iminoenols[17]. The conversion of the pyrylium salt into a pyridine derivative does not occur when the oxygen atom of the pyrylium salt heteroring is provided by the phenolic component, i.e. neither chromylium nor xanthylium salts can be converted into quinolines or acridines[18,19]. However, Dimroth[19] found that naphthopyrylium salts nevertheless react with ammonia to form benzoquinoline derivatives.

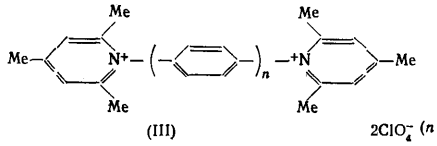
5,6,7,8-Tetrahydrochromylium[20–26] and 2-benzopyrylium[24–26] salts as well as a number of salts condensed with pyrrole, thiophen, indole, and selenophen rings[23,24,26–30] or steroid moieties[31,32] are also capable of being converted into the corresponding pyridine derivatives. Balaban et al. used this reaction to synthesise compound(II)—an analogue of natural muscopyridine[33].

Like ammonia, primary aliphatic and aromatic amines interact with 2,4,6-trisubstituted pyrylium salts, forming *N*-alkyl- and *N*-aryl-pyridinium salts[11,17,34]. A number of investigators[11,12,15,17,34] used this method to prepare pyridinium compounds which are otherwise difficult to obtain.

A non-trivial reaction of primary amines with 2-benzopyrylium salts, leading to naphthylamines, has been described[35]:

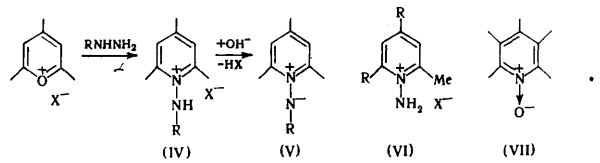


2,4,6-Trimethylpyrylium perchlorate reacts with aromatic diamines to form bispyridinium salts (III):[36]



(III) $2ClO_4^-$ ($n = 1, 2$)

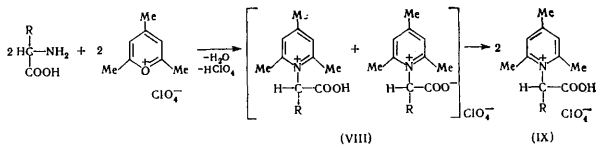
Phenylhydrazine, α-methylphenylhydrazine[4,37,38], and semicarbazide[15] behave similarly, the products being aminopyridinium salts of type (IV). In the presence of bases the salts (IV) are converted into coloured pyridine-betaines (V):[39,40]



(IV) (V) (VI) (VII)

Hydrazine hydrate leads to 1-aminopyridinium salts (VI).[41] A similar reaction has been described for *sym*-octahydroxanthylium[42]. Pyrylium salts react with hydroxylamine form the *N*-oxides of substituted pyridines (VII).[15,43] *p*-Hydroxyphenylpyridinium salts (obtained from pyrylium salts and aminophenols), which are converted by bases into pyridinia-*N*-phenol-betaines[44,45], are interesting.

Certain aminoacids, aminoacid esters, and peptides react with pyrylium salts via the amino-group to form quaternary pyridinium derivatives of aminoacids, peptides, and pyrimidines[34,46-48]. It is suggested that the interaction of aminoacids and peptides with 2,4,6-trimethylpyrylium proceeds via the formation of the betaines (VIII), which are then converted into the pyridinium salts (IX):

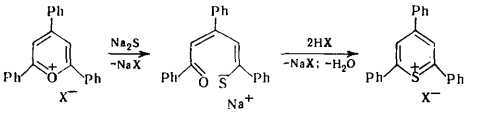


(VIII) (IX)

It has also been suggested that pyrylium salts can block the primary amino-groups in biological systems without involving other functional groups. This can occur in reactions with aminoacids and proteins but not with aminopurines, aminopyrimidines, nucleotides, and nucleic acids[47,48].

2. Thiapyrylium Cations

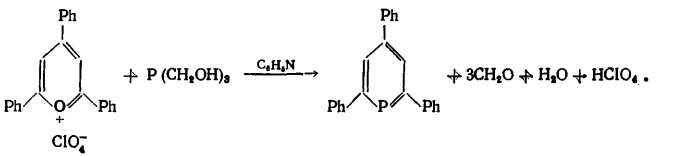
The addition of sodium sulphide to pyrylium salts leads to the opening of the pyran ring. After the addition of an inorganic acid, the resulting open-chain species undergoes ring closure at the sulphur atom. The reaction usually proceeds in acetone, the products being thiapyrylium salts[49]. Wizinger and Ulrich[49,50] proposed the following reaction mechanism:



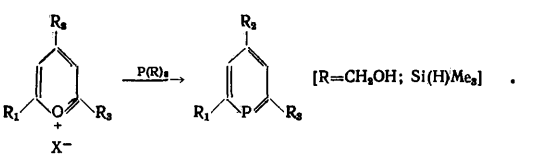
The reaction of chromylium and isochromylium salts with sodium sulphide in aqueous acetone solution does not result in the formation of the corresponding benzothiapyrylium salts[19].

3. Phosphabenzene Derivatives

The attempts to synthesise phosphorin—a representative of a new class of heterocyclic compounds—were undertaken a long time ago[51]. Success was achieved for the first time by Märkl[52], who obtained 2,4,6-triphenylphosphabenzene from 2,4,6-triphenylpyrylium perchlorate and tri(hydroxymethyl)phosphine by the reaction



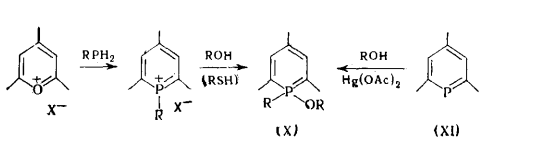
Subsequently Tolmachev and Kozlov extended this method to various pyrylium salts[53] and Zhungietu et al.[54] extended it to indolyl- and pyrrolyl-pyrylium salts[54]. Three main methods for the synthesis of phosphabenzene derivatives from pyrylium salts are now known: 1. from tri(hydroxymethyl)phosphine in pyridine[52]; 2. from tris-(trimethylsilyl)phosphine in acetonitrile[55]; 3. from phosphine in butyl alcohol under pressure[56]:



We may note that the third method is the most general and is suitable for the synthesis of any alkyl- or aryl-phosphabenzene.

Benzophosphorins cannot be obtained from chromylium salts. Nor is oxygen replaced by phosphorus in isochromylium salts[55,57]. The recyclisation (carried out by Dimroth[19]) of naphthopyrylium salts into naphthophosphorins is therefore particularly interesting.

The syntheses of the various *P*-substituted phosphorins (X) (1-aryl-, 1-alkyl-, 1-alkoxy-, or 1-mercapto-phosphabenzene) are possible[58,59] both directly from pyrylium salts and primary phosphines and via compounds (XI) by the reaction



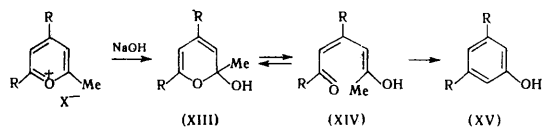
(X) (XI)

Dimroth described the conversion of 2,4,6-triphenylphosphabenzene into the corresponding anion[57], radical, radical-anion[57], and dianion, and also its oxidation to the

radical-cation[60]. Phosphabenzenes constitute a unique heterocyclic system the formation of which involves the *d*-orbitals of phosphorus. A number of studies have been made on the physical and chemical properties of phosphorins[55-62].

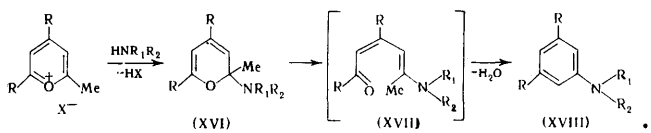
4. Aromatic Hydrocarbons and Their Functional Derivatives

Trisubstituted pyrylium salts containing an α-methyl group in the ring are converted into substituted phenols on refluxing with a 10% solution of alkali[11,14,15]. This reaction, which has been discovered by Baeyer and Piccard[12], proceeds via the intermediate formation of the pseudobase (XIII), which is converted into compound (XV) via the tautomeric ketone (XIV):



(XIII) (XIV) (XV)

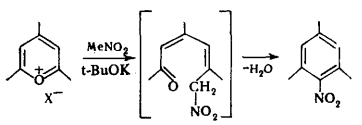
Deuterated alkylphenols have been obtained in this way[63]. Dulenko and coworkers used this reaction to synthesise thionaphthene and selenonaphthene systems[64]. The addition product (XVI) undergoes ring opening when acted upon by both secondary amines and alkali. The intermediate (XVII) subsequently condenses to *NN*-disubstituted amines (XVIII)[65]:



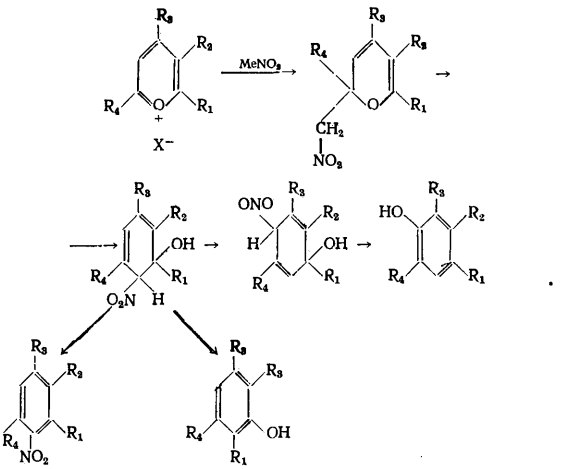
(XVI) (XVII) (XVIII)

The reaction is of interest for the synthesis of certain tertiary aromatic amines which are otherwise difficult to obtain, for example aminostilbenes[66]. *N*-Arylindolines have been obtained in this way from indoline[67].

Dimroth and coworkers[68-70] discovered a novel method for the preparation of alkyl- and aryl-substituted nitrobenzenes by the reaction of pyrylium salts with nitromethane in the presence of potassium t-butoxide. The reaction proceeds as follows:

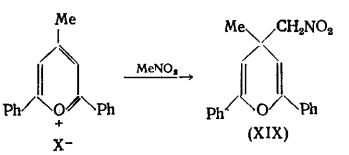


Phenylenebispyrylium salts yield the corresponding terphenyls[71]. When this reaction is carried out in the presence of one mole of base (potassium t-butoxide) in chlorobenzene, dichloroethane or ethyl alcohol, substituted phenols are obtained[72]:



Chromylium salts do not react with nitromethane and isochromylium salts are also not converted into 2-nitronaphthalene derivatives (according to Dimroth's data[70]). 2,4-Diphenyl-5,6,7,8-tetrahydrochromylium fluoroborate can be successfully converted into the corresponding 1-nitro-2,4-diphenyltetrahydronaphthalene[4].

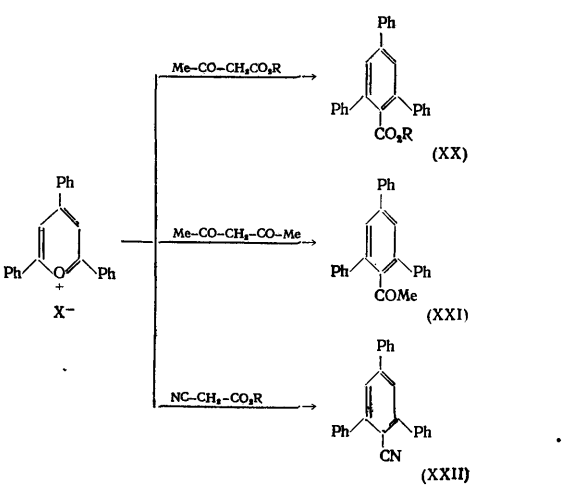
If the 4-position is free or contains the methyl group, the addition of CH_3NO_2 with formation of the stable pyran (XIX) is sterically more favourable[4]:



(XIX)

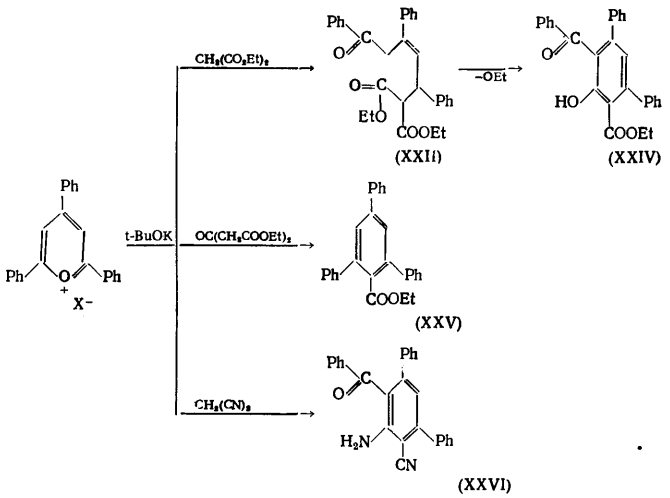
Trisubstituted pyrylium salts react with phenylnitromethane to form tetrasubstituted nitrobenzenes[73].

Compounds containing an active methylene group also react to form benzene derivatives. Their reaction with 2,4,6-triphenylpyrylium in the presence of two moles of potassium t-butoxide leads to the elimination of the acetyl or ethoxycarbonyl group with subsequent formation of the benzene derivatives (XX), (XXI), and (XXII)[74]:



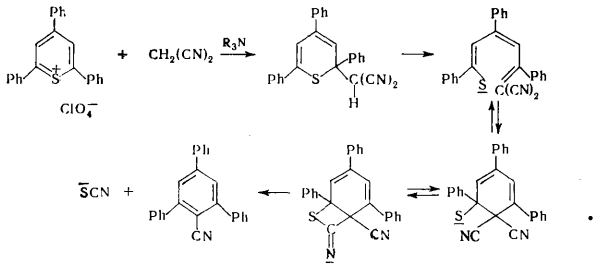
(XX) (XXI) (XXII)

The interaction of triarylpyrylium cations with malonic ester leads to the ring-opening product (XXIII), which recyclises without the elimination of the ethoxycarbonyl group to the benzene derivative (XXIV). The reaction with the diester of acetonedicarboxylic acid leads similarly to the formation of the benzoate ester (XXV) and the reaction with malonodinitrile results in the formation of the aminonitrile (XXVI) [75]:

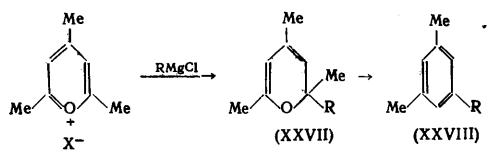


(XXII) (XXIV) (XXV) (XXVI)

In the series of heteroaromatic cations reactions involving recyclisation to benzene derivatives are characteristic only of pyrylium salts. The single instance of the conversion of 2,4,6-triarylthiapyrylium into a substituted benzonitrile has been described [76]. This reaction is believed to proceed via the mechanism:

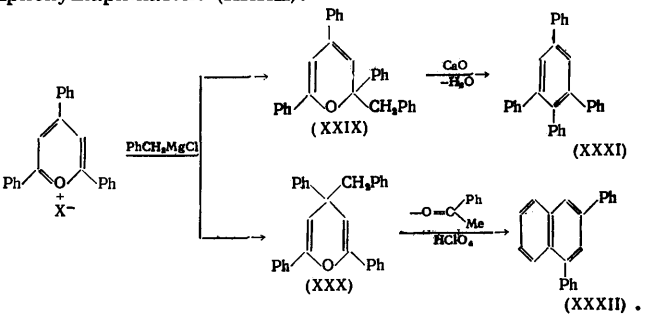


When 2,4,6-trisubstituted pyrylium salts are acted upon by a Grignard reagent, the nucleophilic addition of the organomagnesium compound takes place preferentially in the α-position of the pyran ring. If this position of the pyran (XXVII) contains a methyl or methylene group, recyclisation to the substituted benzene (XXVIII) takes place [71,73]:



(XXVII) (XXVIII)

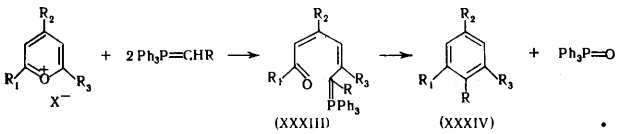
Benzyl-lithium or benzylmagnesium chloride acts similarly on 2,4,6-triphenylpyrylium. On heating with CaO, the product (XXIX) is converted into tetraphenylbenzene (XXXI), while the product (XXX) gives rise to diphenylnaphthalene (XXXII): [68,75,77]



(XXIX) (XXXI) (XXX) (XXXII)

Phenanthrene and benzothiophen derivatives were obtained in the same way [75,77].

Thus there are two methods for the recyclisation of pyrylium salts into benzene derivatives: (1) by using the α-methyl group of the pyrylium ring and (2) by the introduction into the ring of a carbon atom of the nucleophilic component. Preference must be given to the second method, since it is more universal and leads to a wide range of aromatic compounds. A novel instance of the conversion of triarylpyrylium salts into benzene derivatives by an intramolecular Wittig reaction has been described by Märkl [78]:

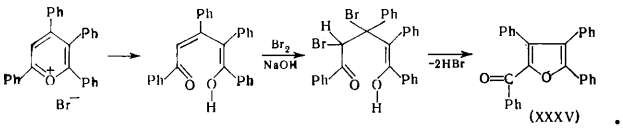


(XXXIII) (XXXIV)

The intermediate phosphoranes (XXXIII) can be isolated or converted immediately into hydrocarbons of type (XXXIV).

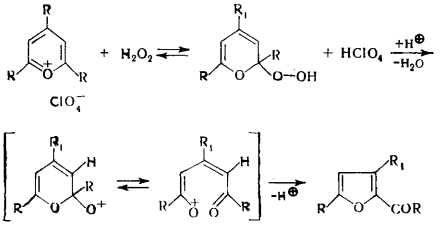
5. Ring Contraction Reactions

An important feature of certain aromatic cations is their ability to undergo ring contraction reactions under the influence of inorganic nucleophiles. This is most typical for pyrylium salts. Thus in an early investigation Dilthey [79,80] found that 2,3,4,6-tetraphenylpyrylium bromide is converted into the furan (XXXV) by the reaction

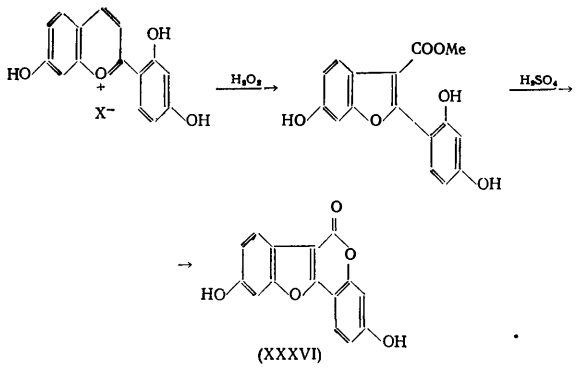


(XXXV)

Balaban and Nenitzescu [63,81] achieved the recyclisation of trialkylpyrylium salts into furans with the aid of hydrogen peroxide and proposed the following reaction mechanism:

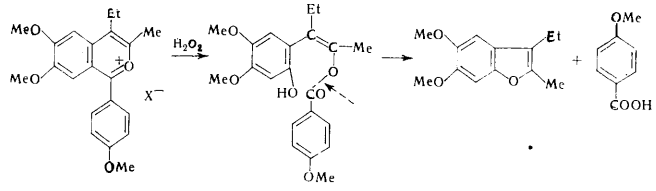


Benzopyrylium salts react with hydrogen peroxide to form benzofuran derivatives. Coumoestrol (XXXVI), an oestrogenic plant preparation, was synthesised in this way [82]:

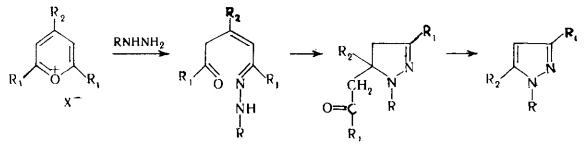


(XXXVI)

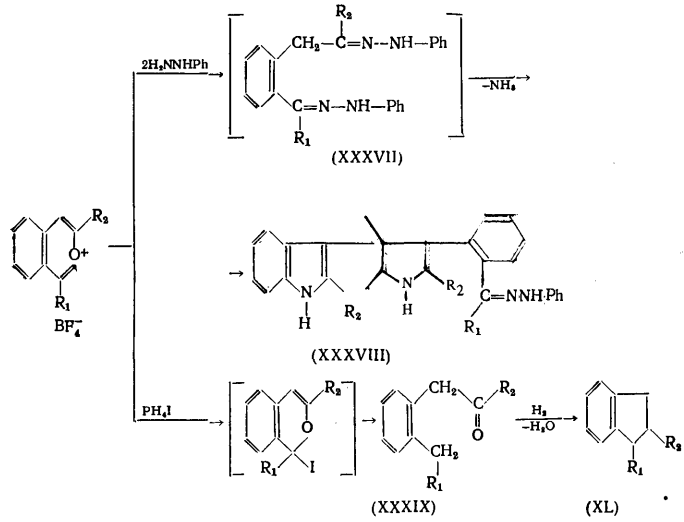
Benzofuran derivatives are also formed when 2-benzopyrylium salts are oxidised by hydrogen peroxide [83]:



When 2,4,6-trisubstituted pyrylium salts are acted upon by two-centre nucleophiles, the reaction probably involves the α- and γ-positions of the pyran ring, which ultimately leads to recyclisation with formation of a five-membered ring containing two heteroatoms. Thus, on reaction with a twofold excess of hydrazine or phenylhydrazine, pyrylium salts are converted into pyrazoles [42,46,84]:

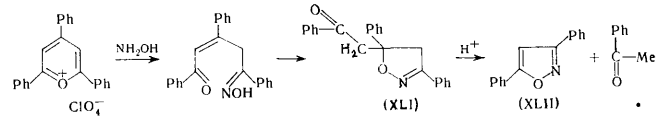


The reaction of chromylium salts with hydrazine and phenylhydrazine also proceeds with ring contraction [85]. When an isochromylium salt reacts with phenylhydrazine, the product is an indole (XXXVIII) formed via the bisphenylhydrazone (XXXVII). [19] The reaction of an isochromylium salt with phosphonium iodide (PH_4I) in glacial acetic acid results in the formation of an indan (XL) via the intermediate ketone (XXXIX) [19] in accordance with the following scheme:



(XXXVII) (XXXVIII) (XXXIX) (XL)

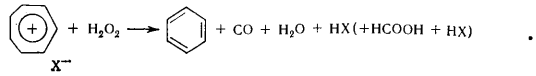
Like hydrazine and phenylhydrazine, hydroxylamine (another two-centre nucleophile) leads to isoxazolines (XLI), which can be readily converted further into isoxazoles (XLII): [84,86]



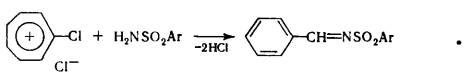
(XLI) (XLII)

Zhungietu and coworkers [87,88] applied this reaction to 4-indolylpyrylium salts and obtained indole derivatives containing isoxazole and isoxazolium rings.

The seven-membered ring of the tropylium cation has been found to contract to a six-membered ring on treatment with hydrogen peroxide. Vol'pin and coworkers [7] showed that, when the tropylium ion is treated with dilute hydrogen peroxide, the products are benzene, carbon monoxide, and formic acid:



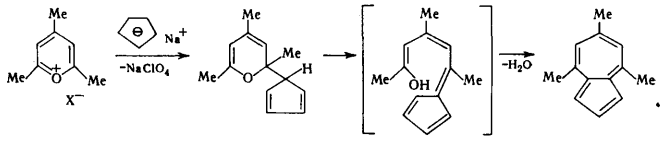
When a chlorine-substituted tropylium cation reacts with sulphonamides in the presence of dimethylamine, a rearrangement with ring contraction also takes place [89]:



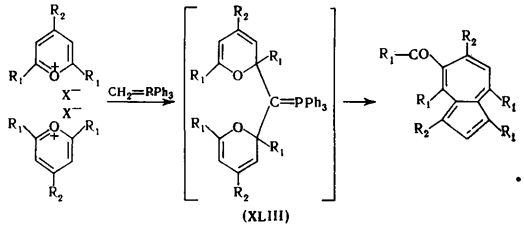
6. The Expansion of the Rings of Aromatic Cations

Formally the reaction of pyrylium salts involving the expansion of the six-membered ring to a seven-membered ring can be represented as the interaction of both α-positions of the pyran ring with a two-centre nucleophilic agent (organic or inorganic). Historically the first

instance of such a reaction was the synthesis of 4,6,8-trimethylazulene by the interaction of 2,4,6-trimethylpyrylium perchlorate with cyclopentadienylsodium in tetrahydrofuran (THF), developed by Hafner and Kaiser [90]:



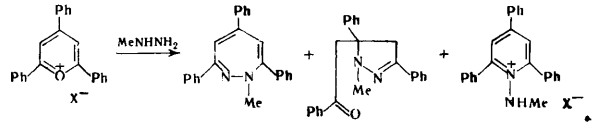
This type of synthesis was extended to other pyrylium salts [91]. When 1,3-dimethyl-5,6,7,8-tetrahydro-2-benzopyrylium perchlorate was allowed to react with cyclopentadienylsodium, 4,10-dimethyl-5,6,7,8-tetrahydrobenzazulene was obtained [92]. The synthesis of azulenes from pyrylium salts by the Wittig reaction proceeds in a somewhat different way [78,93]. Thus methylenetriphenylphosphorane reacts with two molecules of a pyrylium salt as follows:



(XLIII)

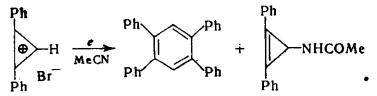
The reaction probably takes place via the intermediate (XLIII).

Pyrylium salts react with alkylhydrazines and hydrazines to form 1,2-diazepines, albeit in low yields [94], the main product being *N*-aminopyridinium salts:

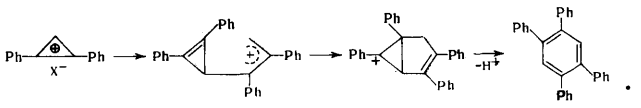


1-Aminopyridinium derivatives, formed from alkylpyrylium salts and hydrazine, can be converted subsequently into diazepines [95]. Zhungietu [88,96] obtained diazepines from indolylpyrylium salts. When 2,4,6-triphenylthiapyrylium tetrafluoroborate was treated with hydrazine, 3,5,7-triphenyl-4*H*-1,2-diazepine was isolated [94]; Balaban confirmed its structure [84,97].

The addition of nucleophilic agents to the cyclopropenylium cation frequently leads to ring opening and the formation of less strained four-, five-, or six-membered cyclic systems. Thus 1,2,4,5-tetraphenylbenzene was isolated on reduction of the 1,2-diphenylcyclopropenylium cation in acetonitrile [98,99]:

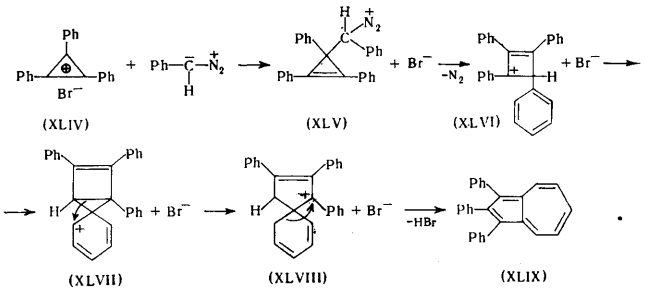


The following mechanism has been proposed on the basis of the structure of the final product for the reaction of the 1,2-diphenylcyclopropenylium cation with cyclopropene leading to tetraphenylbenzene [98]:



The analogous reaction of triphenylcyclopropenylium bromide with 1,2,3-triphenylcyclopropene leads to hexaphenylbenzene. Its yield is small, the main product being 2,3-diphenylindan.

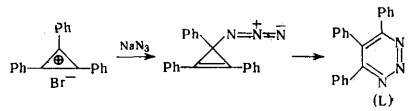
Yet another method for the synthesis, from cyclopropenylium salts, of azulenes which are otherwise difficult to obtain is based on the scheme



(XLIV) (XLV) (XLVI)

(XLVII) (XLVIII) (XLIX)

The addition of phenyldiazomethane to the cation (XLIV) results in the formation of the diazonium salt (XLV), which reacts further in a series of consecutive steps [(XLVI) → (XLVII) → (XLVIII) → (XLIX)]. [99] On reaction with sodium azide, compound (XLIV) is converted into 4,5,6-triphenyltriazine (L): [100,101]

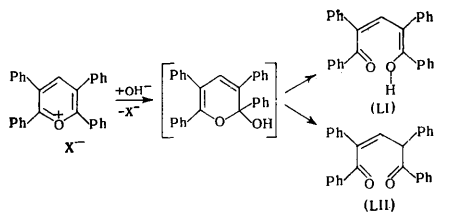


(L)

This reaction, involving the formation of a stable unstrained ring, is typical for many cyclopropene derivatives.

7. Ring Opening

The opening of the rings of cyclic cations whose recyclisation to a new aromatic system is impossible may be regarded as the simplest reaction of aromatic cations with nucleophilic agents. The products of the addition of hydroxide ions [102,103], cyanide ions [104], and phenylhydrazines [105] have been investigated in fair detail. The hydrolysis of 2,3,5,6-tetraphenylpyrylium salts yields two isomers—the enolketone (LI) and a *cis*-diketone (LII):

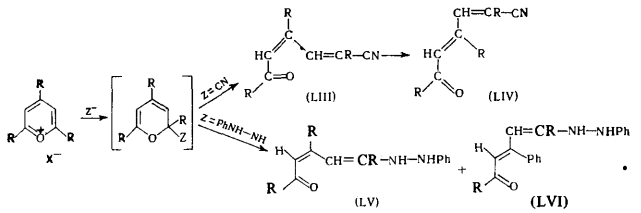


(LI)

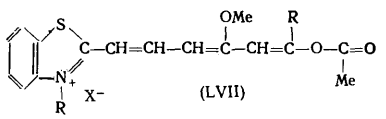
(LII)

Balaban and Nenitzescu [104] established that the cyanide ion reacts with a pyrylium salt to form a cyano-*cis*-alkadienone (LIII), which is converted in an acid medium

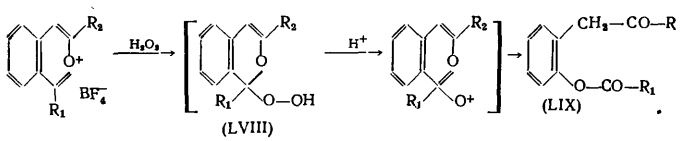
into the *trans*-isomer (LIV). The reaction of arylpyrylium salts with phenylhydrazine gives rise to two isomers and only α-phenylhydrazides (LV) are converted into pyridinium salts[37], while β-phenylhydrazides (LVI) remain in the open-chain form[105]:



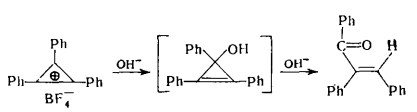
Tolmachev[106,107] studied the interaction of alkoxypyrylium and benzopyrylium salts with quaternary salts of nitrogen-containing heterocycles containing active methyl or methylene groups. The products are cyanines: in certain cases the pyrylium ring is opened and cyanine dyes of type (LVII) are formed:



When isochromylium salts are acted upon by hydrogen peroxide, the oxidation product (LVIII) is formed and then the phenyl ester (LIX). The phenyl ester was also obtained previously by Dilthey[108] from a chromylium salt on treatment with hydrogen peroxide:



Triphenylcyclopropenylium salts readily undergo ring opening merely on treatment with aqueous alkali[109,110]:



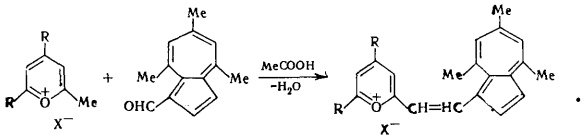
III. REACTIONS OF THE SUBSTITUENTS IN AROMATIC CATIONS

The substituents in aromatic cations alter significantly the course of certain reactions involving the retention of the pyrylium ring. Thus, when pyrylium salts containing methyl substituents are dissolved in heavy water or in deuterated acetic acid, the hydrogen atoms of the methyl groups are replaced by deuterium[63,111,112]. Deuterated or partly deuterated 2,4,6-trimethylpyrylium salts serve as the starting materials for the synthesis of aromatic or heterocyclic compounds with deuterated side chains[113].

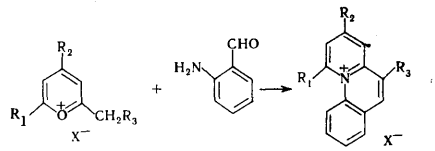
The nitration of 2,4,6-triphenylpyrylium perchlorate involves all three benzene rings, the α-phenyl groups being nitrated in the *meta*-position and the γ-phenyl group in the *para*-position[114-116]. Less active electrophilic agents (acyl and alkyl cations) do not react with phenylpyrylium salts.

1. Condensation via the α- or γ-Methyl Group

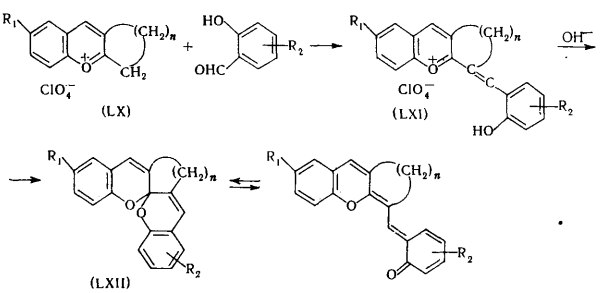
The condensation of α- or γ-methylpyrylium salts with aromatic aldehydes has been examined[117-126]. On reaction with azulenealdehydes, α-methylpyrylium salts give rise to pyrylium derivatives of azulene[127]:



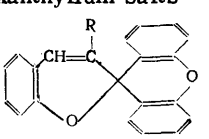
On the basis of the ability of methylpyrylium salts to react with aldehyde and amino-groups, Dimroth[128] proposed a simple method for the synthesis of benzo[*c*]-quinolizinium salts from 2,4,6-trisubstituted pyrylium salts with an α-CH_2R group and 2-aminobenzaldehyde:



The condensation of 3-formylflavene with the methyl groups of various pyrylium salts has been studied[129]. When 1-methyl-3-phenyl-5,6,7,8-tetrahydro-2-benzopyrylium perchlorate was condensed with aliphatic, aromatic, and heterocyclic aldehydes, 1-styryl derivatives were obtained[130,131]. Styryl derivatives of type (LXI), which on treatment with bases are converted into the spiropyrans (LXII), were synthesised from 2,3-cycloalkenobenzopyrylium salts (LX) and *o*-hydroxybenzaldehydes[132]:

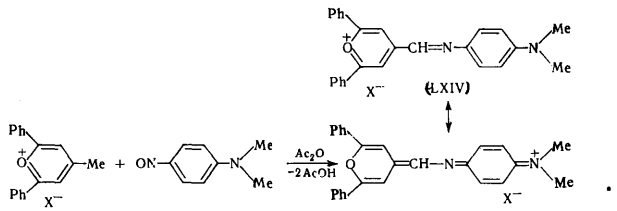


The conversion of styryl derivatives into spiropyrans is possible only for benzopyrylium salts. In the styryl derivatives obtained on the basis of pyrylium salts, the pyrylium ring is opened[132]. The alkyl group in the 9-position of xanthylium salts also condenses with the carbonyl group of aromatic aldehydes[133], forming intensely coloured styrylxanthylium salts[134]:

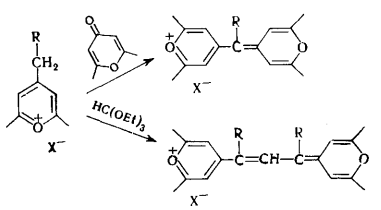


The products of the condensation of alkylxanthylium salts with *o*-hydroxybenzaldehydes are converted into spiropyrans of type (LXIII)[135]. Methyl-, ethyl-, and benzyltropylium salts react similarly with aromatic aldehydes[136], forming styryltropylium salts. Although *NN*-dimethyl-*p*-nitrosoaniline is much less reactive, nevertheless it condenses under severe conditions with α- and γ-methyl or methylene groups to form mesomeric *NN*-dimethylaminophenyliminomethylpyrylium perchlorates [Schiff

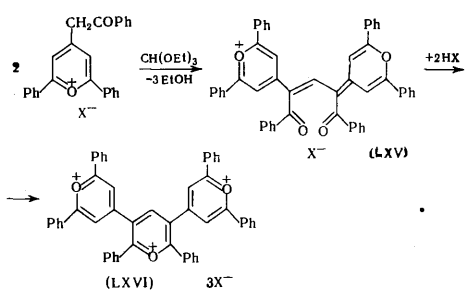
bases of type (XLIV)]. Acid hydrolysis of the resulting ketoimines leads to the corresponding ketones, while aldimines remain unchanged[137]. The following condensation mechanism has been proposed:



The condensation with pyrones takes place under analogous conditions. A number of investigations[138-141] led to the development of a method for the synthesis for pyrylocyanines which are important in practice. Pyrylocyanines are obtained also by the condensation of methyl or methylene derivatives of pyrylium salts with orthoformic ester[142]:

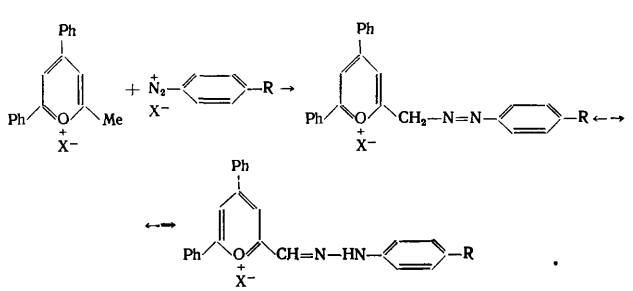


The pyrylocyanine (LXV), obtained from 2,6-diphenyl-4-phenylacylpyrylium and orthoformic ester, cyclises on protonation to the trispyrylium cation (LXVI):[143]



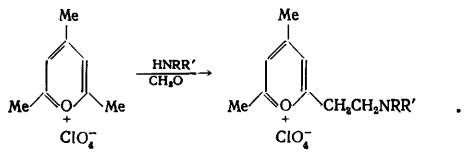
The interaction of pyrones of various pyrylium salts in acetic anhydride has been investigated[139-144]. The products are coloured symmetrical and asymmetric pyrylocyanines.

It was shown[145,146] that, in the presence of hydrogen chloride, 6-methyl-2,4-diphenylpyrylium chloride undergoes azo-coupling with diazonium salts in alcoholic solution:



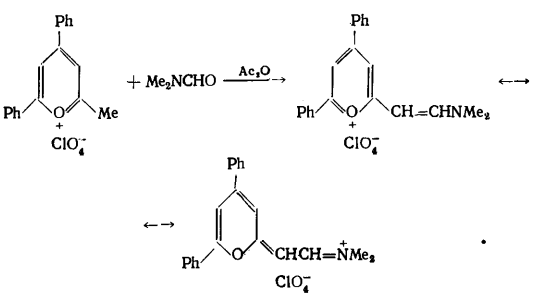
The methyl group in the 9-position of xanthylium also condenses with diazonium salts, forming azo-compounds[147].

Owing to the high reactivity of the hydrogen atoms of the α-methyl groups, it was possible to introduce pyrylium salts into the Mannich reaction with formaldehyde and various amines to form aminopyrylium salts[148]:

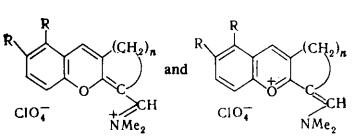


The Mannich reaction has been carried out also with certain natural amines[148].

The reaction of α-methylpyrylium salts with *NN*-dimethylformamide in acetic anhydride yields monoiminium salts, while the reaction with the Vilsmeier complex gives rise to di-iminium salts[149]:



Monoiminium salts can be obtained from alkylpyrylium salts and *NN*-dimethylthioacetamide in acetic anhydride or on the basis of other *NN*-dialkylamides in the presence of phosphoryl chloride. On hydrolysis, the iminium salts give rise to aldehydes or ketones[149]. 2,3-Cycloalkenobenzopyrylium has been formulated and vinylformylated[150]. The compounds obtained can be represented by two formulae:

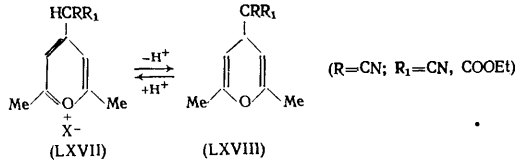


2. Nucleophilic Substitution of the Alkoxy-Groups of Cyclic Cations

The alkoxy-groups in the 4-position of pyrylium salts very readily undergo nucleophilic substitution even by weak nucleophilic agents. Thus, when 4-methoxy-2,6-dimethylpyrylium perchlorate is recrystallised from ethanol, the methoxy-group is substituted by the ethoxy-group, while recrystallisation of the ethoxypyrylium salt from methanol reconverts it into 4-methoxy-2,6-dimethylpyrylium[151]. In water alkoxy-groups are substituted by hydroxy-groups, alkoxypyrylium salts being hydrolysed to pyrones[11]. Thiols (such as phenylmethanethiol) and secondary amines (such as piperidine or morpholine) behave similarly[151,152].

On reaction with 4-alkoxypyrylium salts, sulphides (H_2S, NaHS, and Na_2S) replace alkoxy-groups by mercapto-groups[153]. Compounds containing active methylene groups

displace the methoxy-groups in the pyrylium salts with formation of compounds of type (LXVII), which can be converted into the methylenepyran derivatives (LXVIII)[154]:

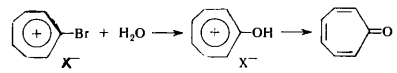


(LXVII) (LXVIII)

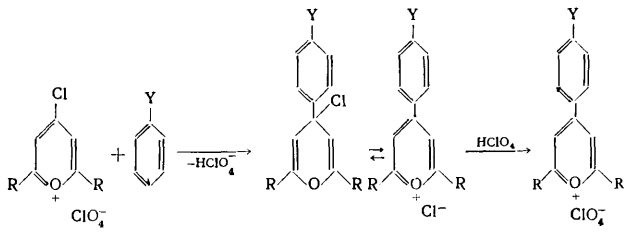
The reaction of methoxytropylium salts with secondary amines in acetonitrile give rise similarly to dialkylaminotropylium derivatives[155]. The reactions of alkoxytropylium and cyclopropenylium cations with various nucleophilic agents have been described[156].

3. Reactions of Halogenopyrylium and Halogenotropylium Salts

The reaction of bromotropylium salts with water results in the formation of tropones[157]:

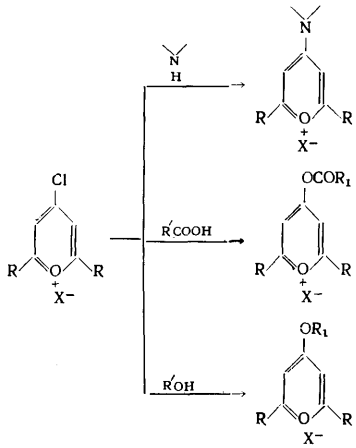


It was shown recently[158,159] that halogenopyrylium salts can react with organic nucleophilic agents to form pyrylium salts with substituents corresponding to the nucleophilic agent employed [salts of type LXIX]:



(LXIX)

The above reaction was also applied to thiapyrylium, benzopyrylium, and xanthylium salts[159]. 4-Halogenopyrylium salts react with secondary cyclic and acyclic amines[160] and also with hydroxy-compounds (alcohols, acids, and phenols)[161] to form amino-, alkoxy-, acyloxy-, and phenoxy-pyrylium salt derivatives respectively (the *N*- and *O*-pyrylation reactions):



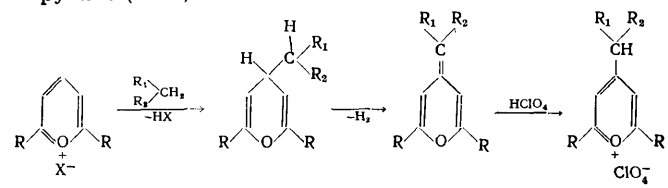
In the reaction of the chlorotropylium cation with alcohols, mercaptans, and alkylarylamines nucleophilic substitution analogous to *N*- and *O*-pyrylation takes place[89,162].

IV. REACTIONS WITH RETENTION OF THE RING

Numerous reactions of aromatic cations with nucleophilic agents take place preferentially with retention of the ring. Monocyclic 2,4,6-trisubstituted pyrylium salts constitute an exception. However, if the γ-position in the pyrylium ring is not substituted, there is a possibility of nucleophilic attack on this free position with formation of the relatively stable 4*H*-pyran.

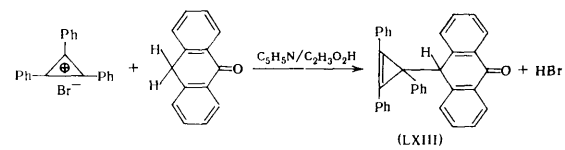
1. Interaction with Compounds Containing Active Methylene Groups and with Organometallic Compounds

2,6-Disubstituted pyrylium cations react with compounds containing active methylene groups in the presence of potassium t-butoxide to form the corresponding 4*H*-pyrans (LXX):[163,164]



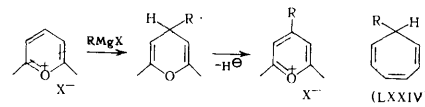
(LXX) (LXXI) (LXXII)

The pyrans (LXX) react with acids to reform the initial salts and only by mild oxidation to (LXXI) or by reaction with triphenylphenoxy-radicals and subsequent treatment with perchloric acid is it possible to convert the system into a new pyrylium salt (LXXII). Wizinger and coworkers condensed pyrylium and thiapyrylium salts with compounds containing active methylene groups in the presence of sodium acetate[165,166]. Similar reactions are also known in the flavylium series[164,167]. Tropylium salts form substituted tropilidenes in reactions of this kind[168,169]. The reactions of tropylium salts with aliphatic aldehydes[170,171], aliphatic and aliphatic-aromatic ketones[169], and compounds containing activated double bonds proceed similarly. In the series of cyclopropenylium cations these reactions have been little investigated. Triphenylcyclopropenylium bromide is known to react with anthrone in the presence of pyridine and acetic acid to form compound (LXXIII):[172]



(LXIII)

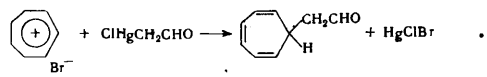
Aromatic cations readily react with organometallic compounds. In an ethereal solution of a Grignard reagent, pyrylium salts are converted into 4*H*-pyrans, which can split off a hydride ion with formation of 2,4,6-trisubstituted pyrylium salts[163]. Thus 2,6-diphenylpyrylium perchlorate can be converted into 4-alkyl-2,6-diphenyl- or 4-aryl-2,6-diphenyl-pyrylium salts[163]:



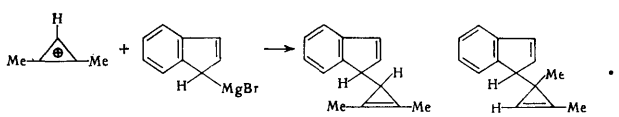
(LXXIV)

When acted upon by organometallic compounds, tropylium bromide is converted into tropylidenes (LXXIV)[156,173]. The reaction of the cyclopropenylium ion with organomagnesium and organolithium compounds proceeds

similarly [174,175]. The reaction of tropylium salts with certain organomercury compounds is interesting [170,171]:

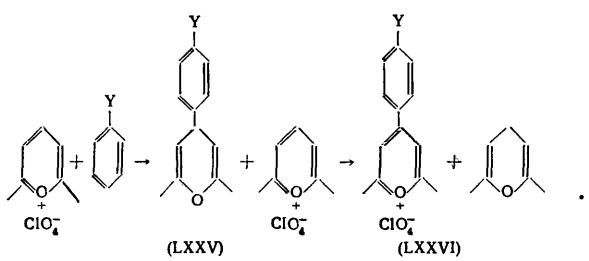


Tropylium cations react with cyclopentadienylsodium or cyclopentadienyllithium to form cyclopentadienylcycloheptatriene [156,171]. The dimethylcyclopropenylium cation reacts with indenylmagnesium bromide to form a mixture of two isomeric dimethylindenylcyclopropenes. The formation of the mixture shows that the charge of the cyclopropenylium cation is distributed among the three ring carbon atoms and is not fixed at any one of them [176]:



2. The Pyrylation Reaction

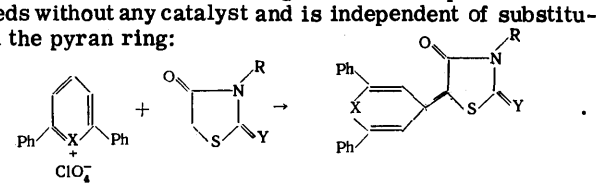
Pyrylium salts without substituents in at least one of the α- and γ-positions should presumably interact with reactive compounds to form new 2*H*- or 4*H*-pyrans [for example (LXXV)]. However, it was found [177-179] that the intermediate pyran (LXXV) splits off a hydride ion in the presence of 2,6-diphenylpyrylium perchlorate and is converted into the pyrylium cation (LXXVI) via the mechanism



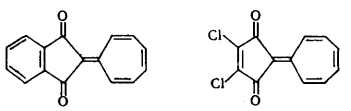
(LXXV) (LXXVI)

The elimination of a hydride ion by the pyrylium cation is possible only when there is a fairly high electron density in the γ-position of the pyran (LXXV) (higher than in the pyran whose γ-position is free). The pyrylation reaction has been extended to nucleophilic agents and heteroaromatic cations [179].

Earlier Wizinger and coworkers [165,166] carried out the condensation of thiapyrylium and flavylium salts with dimethylaniline in acetic acid in the presence of sodium acetate and Krönke and Dickore carried out the reaction in acetic anhydride [164], but these reactions have not become commonly used in the synthesis of pyrylium salts. The reaction of various 4-azolidinones with unsubstituted pyrylium salts has been investigated [180]. The process proceeds without any catalyst and is independent of substitution in the pyran ring:

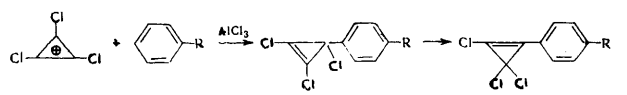


The substitution of a mobile hydrogen atom in the series of tropylium salts by the cycloheptatrienyl residue has been used extensively in the synthesis of cycloheptatriene derivatives [181]. Thus it proved possible to introduce the seven-membered ring into the molecules of various cyclic compounds [182,183]. Hafner et al. [184] and Anderson and Reploge [185] introduced the tropylium group into azulene and Kitahara et al. obtained the quinones (LXXVII) and (LXVIII) of the sesquifulvalene series with the aid of the tropylation reaction [186]:

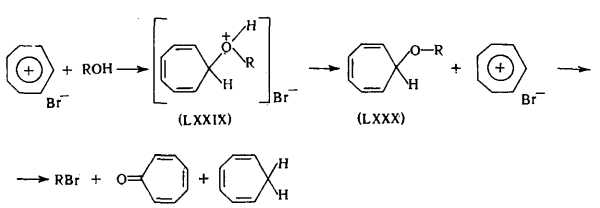


(LXXVII) (LXXVIII)

The trichlorocyclopropenylium cations enters into reactions involving electrophilic substitution of the aromatic ring (with benzene, toluene, chlorobenzene, and fluorobenzene) [187,188] of the Friedel–Crafts type:

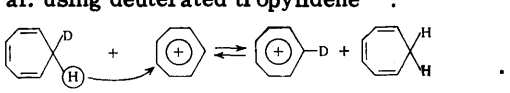


The reaction can be carried out with subsequent substitution of the three positions. Tropylium and cyclopenylium cations react with alcohols (primary, secondary, and tertiary) to form alkoxy-derivatives of tropylidene and cyclopropene [189,190]. It is believed that the first step in the reaction of the tropylium cation with alcohols is the formation of an oxonium compound (LXXIX), which readily loses a proton and is converted into an alkyl tropyl ether (LXXX). The latter interacts with a second molecule of the tropylium salt to form cycloheptatriene, tropene, and an alkyl halide [190]:

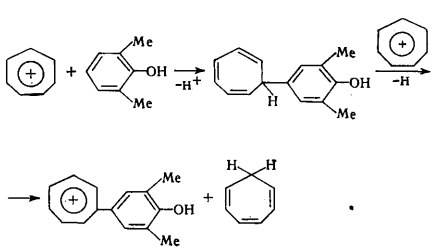


(LXXIX) (LXXX)

Kursanov et al. [191] studied the reaction of the tropylium ion with ethers. The hydride shifts in the tropylium–cycloheptatriene system have been examined in detail by Vol'pin et al. using deuterated tropylidene [192]:



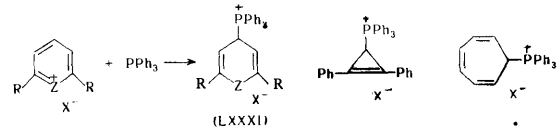
Repeated hydride shifts in this system lead to a redistribution of deuterium between tropylium and cycloheptatriene. Numerous reactions of the tropylium ion with reactive organic compounds take place with hydride ion transfer. Thus, according to van Helden et al. [193], the reaction with 2,6-dimethylphenol proceeds via the mechanism



Numerous hydride shift reactions involving the tropylium ion have been examined in detail in a monograph [194].

3. Organophosphorus Derivatives of Aromatic Cations

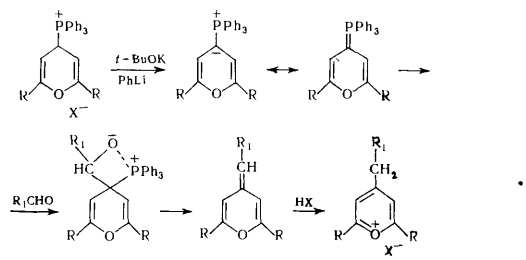
Heteroaromatic cations with a free α- or γ-position react readily and almost quantitatively with triphenylphosphine to form phosphonium salts (LXXXI).[195,196] It was found that this reaction is applicable also to tropylium and cyclopropenylium ions[197]:



(LXXXI)

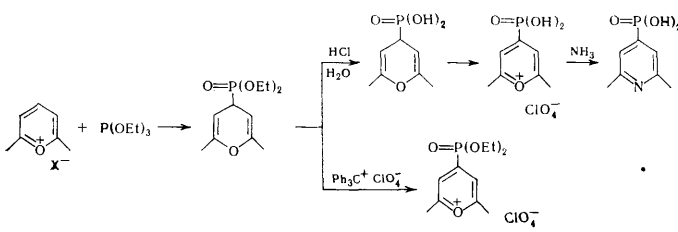
(X = ClO_4, BF_4, Br. Z = O, S, Se)

When bases are allowed to act on a suspension of these salts in ether, with cooling (to −30°C and below), phosphoranes are formed (for example, from phosphonium salts and phenyl-lithium or potassium t-butoxide); these normally react with carbonyl compounds[195]:



The synthesis of phosphonium salts and phosphoranes and the reactions of the latter with carbonyl compounds have been studied in very great detail[198]. The reaction is general and permits the variation of the carbonyl components within wide limits[199].

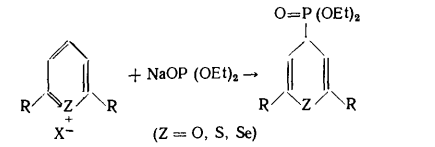
The reaction of the halides of the aromatic cations considered with triethyl phosphite, which is of the type of the Arbuzov rearrangement, has been investigated in detail[200–202]. The resulting phosphonates undergo various further reactions. For example, pyranylphosphonates (obtained from various pyrylium salts and triethyl phosphite) have been converted by acid hydrolysis into pyranylphosphonic acids and the latter have been converted by the elimination of a hydride ion into the corresponding pyrylium salts with a phosphonic acid residue. The recyclisation of these salts led to pyridylphosphonic acids:



On the other hand, pyranylphosphonate is readily converted into pyrylylphosphonate. The reaction is applicable to any charged aromatic systems but cyclopropenyl- and cycloheptatrienyl-phosphonic acids and their esters could not be converted into the corresponding salts.

The Arbuzov rearrangement in the series of aromatic cations is carried out under fairly severe conditions, which gives rise to side reactions. This rearrangement is applicable only to the corresponding chloride, bromide, and iodide salts. However, the latter are difficult to obtain, hygroscopic, and frequently unstable on storage.

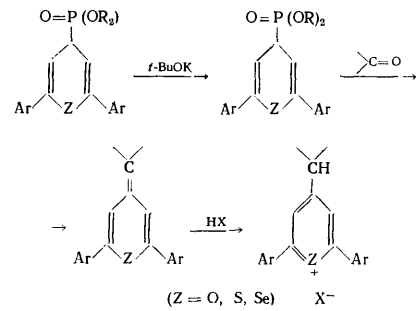
These advantages can be avoided by carrying out the Michaelis–Becker reaction of the above compounds with the sodium salt of diethyl phosphite[203]:



(Z = O, S, Se)

The resulting phosphonates are converted into phosphonic acids and into pyrylium salts with phosphorus containing substituents[204], as described above.

Phosphonates derived from various aromatic cations and obtained by the Michaelis–Becker reaction interact with potassium t-butoxide to form coloured reactive carbanions. The latter readily react *in situ* with various carbonyl compounds to form ultimately arylidene or alkylidene derivatives of pyrans and similar compounds[204,205]. The following reaction mechanism has been proposed:

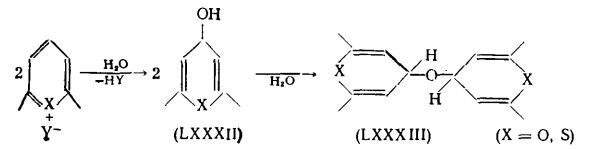


(Z = O, S, Se) X^-

This is probably the simplest and most convenient method for the introduction of an exocyclic double bond into pyran, thiapyran, selenapyran, and other cyclic systems based on pyrylium, flavylium, xanthylium, tropylium, cyclopropenylium, and other salts.

4. Interaction with Certain Inorganic Nucleophilic Agents

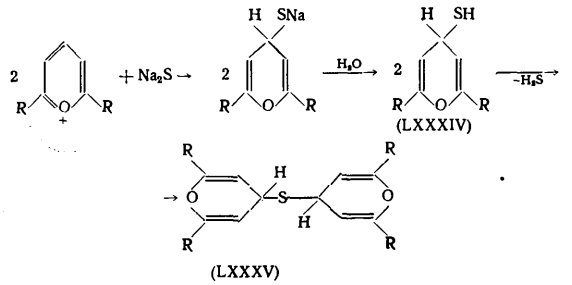
Pyrylium and thiapyrylium salts with a free γ-position are converted in the presence of organic bases (pyridine, hexamethylenetetramine) into di-($\alpha\alpha'$-diphenyl-γ-pyranyl) or di-($\alpha\alpha'$-diphenyl-γ-thiapyranyl) ether (LXXXIII).[206] The reaction most probably proceeds via the intermediate formation of 4-hydroxy-2,6-diphenylpyran (LXXXII):



(LXXXII) (LXXXIII) (X = O, S)

Organic bases can be replaced by aqueous sodium bicarbonate. This method for the conversion of pyrylium salts into dipyranyl ethers is similar to the formation of ditropyl[173], dicyclopropenyl[10], and dixanthyl[207] ethers from the corresponding salts. It is interesting that the reaction of 2,6-diphenylpyrylium perchlorate with sodium sulphide in an aqueous ethereal medium does not result in the formation of the corresponding dipyranyl sulphide analogous to diparanyl ether[206] and ditropyl sulphide[173].

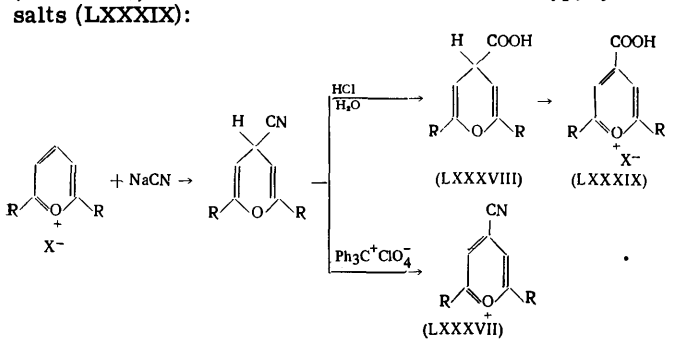
It was found that the mercaptopyran (LXXXIV) is formed under these conditions and only on heating in inert solvents does it split off hydrogen sulphide and is converted into dipyranyl sulphide (LXXXV):[208]



(LXXXIV)

(LXXXV)

The reaction of γ-unsubstituted pyrylium salts with potassium cyanide in an aqueous ethereal medium leads to the corresponding γ-cyanopyrans (LXXXVI). On being refluxed with triphenylmethyl perchlorate the latter split off a hydride ion and are converted into γ-cyanopyrylium salts (LXXXVII).[208] On the other hand, hydrolysis of pyrans by dilute hydrochloric acid yields carboxypyrans (LXXXVIII), which can be converted into carboxypyrylium salts (LXXXIX):

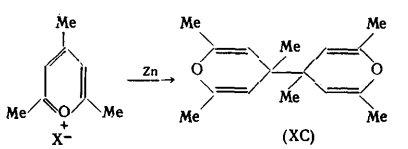


(LXXXVIII) (LXXXIX)

(LXXXVII)

The interaction of KCN with 2,4,6-trisubstituted pyrylium ions has been studied in a series of pyrylium salts[104], but the possibility of the conversion of the cyanopyrans formed initially into carboxypyrans or especially into cyano- and carboxy-pyrylium salts is ruled out in this case. The reaction of tropylium and diphenylcyclopropenylium salts with potassium cyanide leads to the formation of 7-cyanocycloheptatriene[7,156] and 3-cyano-1,2-diphenylcyclopropene respectively[8,175]. The reaction of tropylium salts with ammonia has been studied in detail. Depending on the component ratio and the reaction conditions, mono-, di-, and tri-tropylamines or their mixtures can be formed[156]. It was expected that γ-unsubstituted pyrylium salts would react similarly. However, pyridine was obtained unexpectedly[208]. Aminopyran could not be obtained either by reaction with sodamide or with potassium phthalimide. In the latter case a phthalimide derivative of pyran is readily obtained but Gabriel hydrolysis (and hydrazinolysis) leads to appreciable charring[208].

Balaban et al.[209] showed that, when metallic zinc is allowed to react with 2,4,6-trimethylpyrylium perchlorate, the salt undergoes one-electron reduction with formation of 2,2',4,4', 6,6'-hexamethyl-4,4'-bispyran (XC):

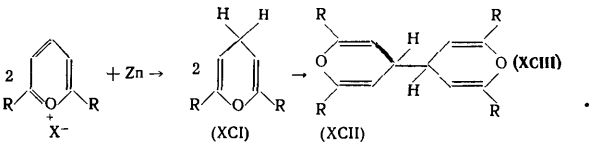


(XC)

The same product was obtained by the reaction of the disodium salt of the cyclooctatetraene dianion with trimethylpyrylium perchlorate[210].

On heating with metal powders (magnesium, copper, zinc, and aluminium) in organic solvents (alcohol and acetonitrile), triarylpyrylium salts are reduced with formation of intensely coloured species—stable free radicals[211].

When this reaction is carried out with γ-unsubstituted pyrylium salts in a polar solvent, the radicals (XCI) formed recombine and the bipyranyls (XCII) are obtained[212]:

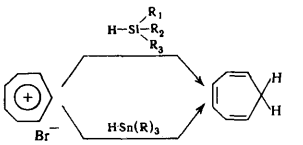


(XCI) (XCII) (XCIII)

The corresponding dimers have been synthesised from flavylium salts and their 3-alkyl- or 3-aryl-derivatives by the reaction with zinc dust in acetonitrile[213]. When xanthylium salts react with dispersed silver, stable radicals are also formed[214]. The synthesis of bitropyl (XCIII) using zinc dust and other metal powders has been described for the series of tropylium salts[173]. The tropylium ion can be reduced to bitropyl by transition metal complexes[171]. The analogy between pyrylium salts and non-benzenoid aromatic cations in the formation and recombination of radicals is completed by the cyclopropenylium ion[215].

The reduction of pyrylium salts by sodium tetrahydroborate leads to the formation of mixtures of substituted 4*H*-pyrans and pentadienones[216,217]. On reduction with sodium tetrahydroborate in alcohol, flavylium perchlorate is also converted into dimers[218].

When tropylium bromide is acted upon by lithium tetrahydroaluminate or sodium tetrahydroborate (as hydride ion donors), cycloheptatriene is formed. This property of tropylium as a hydride ion acceptor has been used to investigate hydride shifts[219]. It was found that Si-H and Sn-H bonds can also be broken heterolytically under the influence of tropylium bromide[220]:



The cyclopropenylium cation is reduced by lithium tetrahydroaluminate to cyclopropene[174].

Diene Synthesis with 2-Pyrones and 2-Pyridones

N.P.Shusherina

The principal aspects of Diels-Alder synthesis with six membered heterocyclic dienes (2-pyrones and 2-pyridones) as well as the latest data on the *endo-exo* selectivity of this reaction are considered.
The bibliography includes 121 references.

I. INTRODUCTION

The diene synthesis reaction discovered more than 40 years ago constitutes at present a universal method for the preparation of a wide variety of cyclic systems. The employment in the Diels–Alder reaction of heterocyclic compounds with a conjugated system of C=C double bonds, among which furan, oxazole, 2-pyrone, and 2-pyridone derivatives react via the normal (4+2)-cycloaddition mechanism (with yields of adducts on a preparative scale), is of particular interest.

The practical and theoretical problems of diene synthesis with furans and oxazoles have been discussed in a number of papers and monographs [1,2], while the behaviour of 2-pyrones and 2-pyridones in this reaction has been scarcely considered in the review literature [3].

The studies published in the last decade, in which the interaction of 2-pyrones and dienophiles was used to obtain barrelene, colchicine analogues, compounds of the cyclohexatriene series and various aromatic and bridged polycyclic compounds which are difficult to obtain otherwise, demonstrate the wide synthetic possibilities of the use of 2-pyrones in the Diels–Alder reaction.

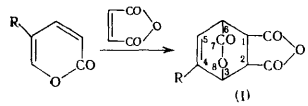
The reactions of 2-pyridones with dienophiles lead to the formation of bicyclic systems with an endazocarbonyl bridge. Extremely interesting theoretical data have been obtained in a study of the stereochemistry of diene synthesis with 2-pyrones and 2-pyridones.

The present review gives a systematic account of the literature on diene synthesis with the above six-membered heterocycles.

II. MONOADDUCTS OF 2-PYRONES {DERIVATIVES OF 8-OXABICYCLO[2,2,2]OCT-4-EN-7-ONE}

1. Synthesis

The ability of 2-pyrones to eneter into diene synthesis was first observed by Diels and Alder in the reactions of 2-pyrone and 5-methoxycarbonyl-2-pyrone (methyl coumalate) with maleic anhydride. The authors [4] showed that the monoadducts (I) {derivatives of 8-oxabicyclo-[2,2,2]oct-4-en-7-one} are formed on refluxing equimolar amounts of the initial reactant in toluene at 110°C:



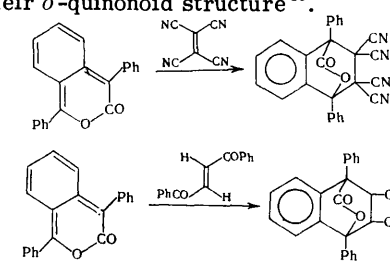
(R = H, COOMe) (I)

However, owing to their thermal instability the monoadducts of 2-pyrones are difficult to obtain. They can be synthesised only from 2-pyrones and dienophiles which enter into diene synthesis at temperatures below the decomposition temperatures of the monoadducts. It has been established that alkyl and particularly aryl groups in the 6-position of the initial 2-pyrone reduce the stability and hinder (frequently altogether preclude) the formation of the monoadducts [5,6] (cf. the part of subsection 2 dealing with thermolysis).

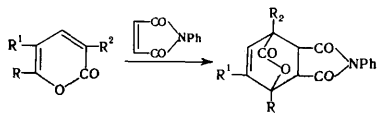
According to Alder's rule [1], electron-accepting substituents in the molecules of the initial pyrone reduce the yield of monoadducts (see Table).

An idea concerning the relative reactivities of dienophiles in reactions with 2-pyrones can be gained from a study [14] where it was shown that the yield of the monoadducts of the *o*-quinonoid 2-benzopyrone fell and the duration of the reaction increased in the series of the following dienophiles: *N*-phenylmaleimide (yield up to 85%, 25 min), dimethyl maleate (32%, 1.5 h), dimethyl fumarate (12%, 3 h).

The successive employment of tetracyanoethylene and benzoylethylene as dienophiles in reactions with 6-methyl- and 3,6-diphenyl-4,5-benzo-2-pyrones has been described. The unusual ease of this reaction is related to the enhanced diene reactivity of the above pyrones in consequence of their *o*-quinonoid structure [15].



Among the dienophiles enumerated above, only *N*-phenylmaleimide [16] has been studied in reactions with the usual 2-pyrones, monoadducts being formed at 110°C:



(R = R¹ = R² = H; R = R¹ = Me; R₂ = H; R¹ = R = H; R² = Br)

The ease of the reaction of 1,4-endoxy-1,4-dihydronaphthalene with 2-pyrone is due to the strain of the double bond in the dienophile [17]. The authors attributed the *exo*-configuration to the adduct without proof [17].

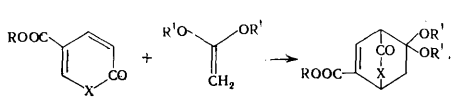
*An increase of the reaction temperature and of the duration of heating lead to a sharp lowering of the yields of the monoadducts owing to their conversion into bisanhydrides and bisimides (see Section III, 1). [5,6,11,12]

Keten diacetals, whose interaction with 5-alkoxycarbonyl-2-pyrones and their sulphur analogues gave monoadducts with yields on a preparative scale, proved to be extremely reactive dienophiles [18]:

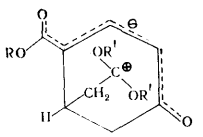


(X = O, S; R and R¹ = Me, Et)

This reaction involving 2-pyrones illustrates the possibilities of diene synthesis with "inverse electron demand", since here the electron donor is a dienophile (keten diacetal) whose double bond exhibits enhanced nucleophilic properties and the acceptor is the diene system of the 2-pyrone.

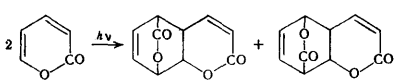
The present authors achieved the interaction with keten acetals via the inverse mechanism only for 2-pyrones with electron-accepting groups: the unsubstituted 2-pyrone does not enter into this reaction [18].

It might have been expected that two structural isomers would be obtained in the reaction of asymmetric diene synthesis addends—5-alkoxycarbonyl-2-pyrones and keten diacetals. However, in the instances investigated only the isomer with the *para*-disposition of the substituent was obtained, which the authors explain by the greater stabilisation of the transition state (A) of this isomer compared with the possible transition state for the *meta*-isomer [18].



(A)

On the other hand, the dimerisation of 2-pyrone (on ultraviolet irradiation) via a process of the diene synthesis type, in which the asymmetric 2-pyrone molecule behaves both as the diene and the dienophile, leads to a mixture of both possible structural isomers [19]:

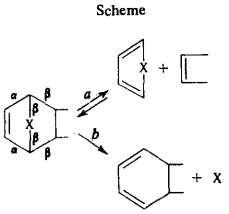


2. The Properties of Monoadducts

Thermolysis. A characteristic property of bridged 1,4-cycloadducts is their ability to dissociate on thermolysis the bond in the β-position relative to the double bond and to undergo retrodiene decomposition (reversible reaction *a*) and retrodiene elimination of the bridge (irreversible reaction *b*, see Scheme). Both modes of cleavage of the cycloadducts predicted by the Schmidt rule [20,21] are associated with a weakening of the above σ-bonds in ethylene compounds owing to the additional stabilisation of the intermediate species arising in the decomposition of these bonds, as happened, for example, with allyl cations.

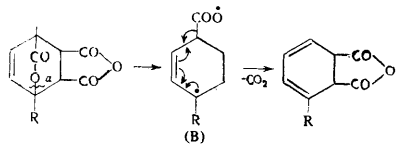
Among the known bicyclic adducts with various *endo*-bridges [X = CH_2, O, CO, $(CH)_2$], [1] the monoadducts of 2-pyrones (X = CO_2, see Scheme) are the least stable on heating, whereupon CO_2 is usually eliminated (retrodiene elimination of the bridge, reaction *b*). Certain adducts decompose at a temperature as low as 60°C and only in rare instances (in the absence of substituents at the head of the bridge) can they withstand heating above 130—140°C.

Scheme



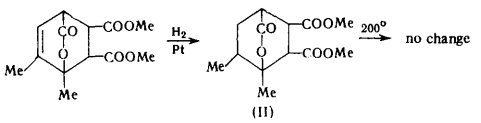
X = CH_2, $(CH_2)_2$, O, CO, CO_2

On the basis of the primary isotope effects of carbon and oxygen found for the monoadducts of 2-pyrone with maleic anhydride, Goldstein and Thayer [7] concluded that the elimination of CO_2 is a two-stage process, which begins with the dissociation of bond *a*. The resulting biradical (B) is converted further into the more stable cyclohexadiene system:

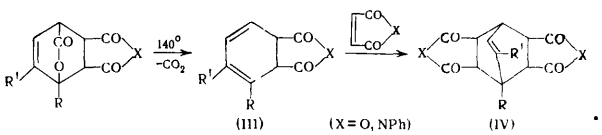


This hypothesis concerning the course of the thermolysis explains the instability of monoadducts with substituents at the bridgehead (R = alkyl or aryl) by the stabilisation of the biradical (B) owing to the $+I$ and $+M$ effects of the substituents. On the other hand, even weak electron-accepting groups in this position (for example CH_2Br and CH_2OCOMe, see Nos. 12–14 in Table) appreciably increase the stability of the monoadducts.

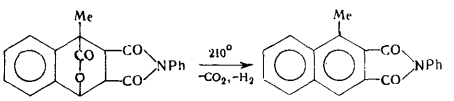
The lability of the bridge due to the influence of the double bond disappears in the hydrogenated adducts—8-oxabicyclo[2,2,2]octan-7-ones (II), which withstand heating above 200°C: [22]



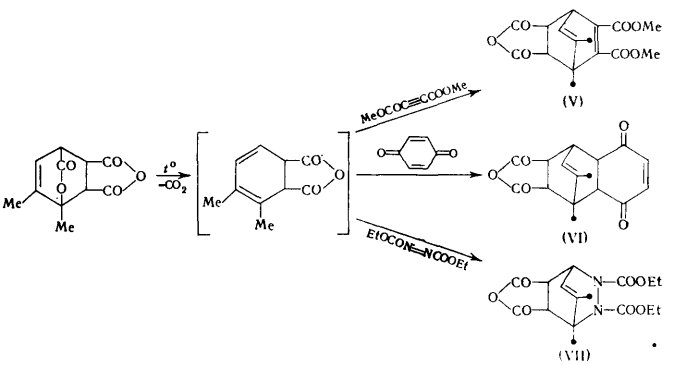
The products of the elimination of CO_2 from the adducts of 2-pyrones with maleic anhydride and *N*-phenylmaleimide, the corresponding derivatives of cyclohexadienecarboxylic acids (III), were characterised as bisanhydrides [5] and bisimides [6] (IV):



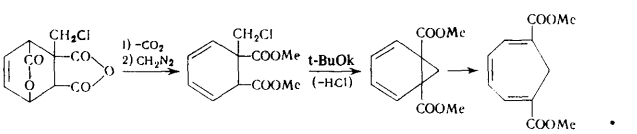
On heating above 200°C in nitrobenzene, the adducts are aromatised [14]:



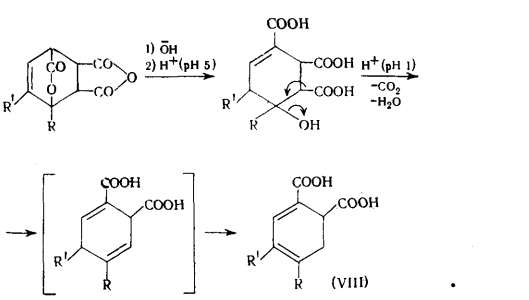
The thermolysis of the adducts with maleic anhydride in the presence of other dienophiles (acetylenedicarboxylic acid ester, benzoquinone, azodicarboxylic acid ester) made it possible to obtain mixed adducts with two dienophiles of different chemical types—compounds of the bicyclo[2,2,2]-octadiene (V) and bicyclo[2,2,2]octene (VI) series and a heterocyclic analogue (VII) of the latter with two nitrogen atoms in the ring [23]:



The cyclohexadiene systems formed on thermolysis of the monoadducts have been used also for other synthetic purposes, for example, for the formation of the cycloheptatriene ring [24,25]:

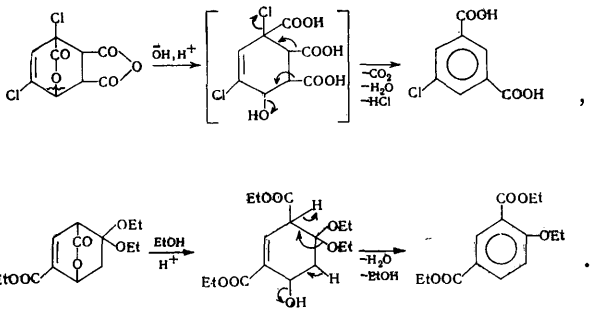


The opening of the lactone bridge under the influence of nucleophilic agents takes place with different degrees of difficulty depending on the substitution of the 6-position. Levina, Shusherina and coworkers, established that the hydrolysis of the bridge in the adducts of 5,6-disubstituted 2-pyrones with maleic anhydride (by treatment with aqueous solutions of alkali at 20–60°C) leads to the formation of the corresponding hydroxytricarboxylic acids which undergoes synchronous dehydration and decarboxylation at pH 1 (at 20°C), being converted into cyclohexadienedicarboxylic acids (VIII); the latter are readily aromatised on heating [13].

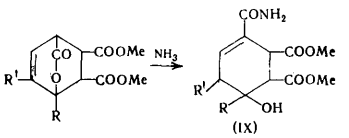


An example of the direct conversion of the adducts of 2-pyrones into aromatic compounds under the influence of nucleophilic agents is provided by the synthesis of 5-chloroisophthalic acid (in the alkaline hydrolysis of the adduct of 3,5-dichloro-2-pyrone with maleic anhydride [26])

and diethyl 4-ethoxyisophthalate (in the acid ethanolysis of the adduct of 5-ethoxycarbonyl-2-pyrone with the diethyl acetal of keten [18]):



In the ammonolysis of the esters obtained from the adducts of 2-pyrones with maleic anhydride it was possible to isolate the primary bridge-opening products—the amides of the corresponding hydroxyacids (IX): [27]

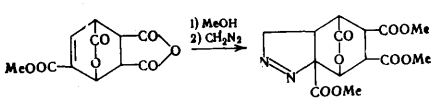


(IX)

It has been shown by ^{1}H NMR that the hydrolysis and ammonolysis of the monoadducts are accompanied by the migration of the double bond to the position conjugated with the carboxy- or carboxamido-groups arising in these processes [13,27].

Electrophilic addition to the double bond of the monoadducts of 2-pyrones (halogenation and oxidation) has been investigated to establish their configuration (see Section V).

1,3-Cycloaddition to the double bond of 8-oxabicyclo[2,2,2]oct-4-en-7-ones has been studied for adducts of alkyl coumalates with keten acetal [18], maleic anhydride, and *N*-phenylmaleimide [28]. The activated (by conjugation with the carboxy-group) double bonds of these compounds combine very readily with diazomethane, forming tricyclic Δ′-pyrazolines (X) with an endoxycarbonyl bridge:



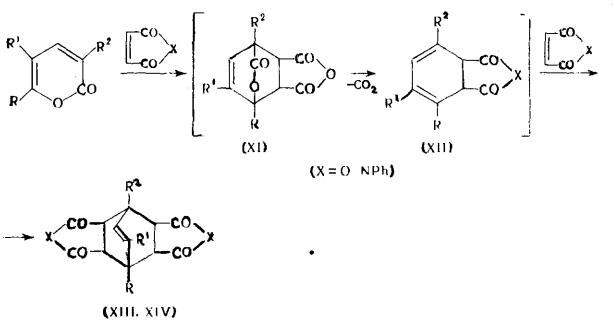
(X)

Similarly the adducts of alkyl coumalates with keten acetal combine with phenyl azide via the double bond [18]. However, the adducts of 2-pyrones with maleic anhydride without electron-accepting substituents at the double bond react neither with diazomethane nor with phenyl azide [28], which indicates an extremely weak strain of the double bond in 8-oxabicyclo[2,2,2]oct-4-en-7-ones whose geometry is close to that of the unstrained bicyclo[2,2,2]oct-4-enes [29].

III. DIENE SYNTHESIS WITH 2-PYRONES ACCOMPANIED BY THE ELIMINATION OR RUPTURE OF THE LACTONE IN THE MONOADDUCTS

1. Double Diene Synthesis (the Formation of Bridged Polycyclic Systems)

As a rule the interaction of 2-pyrones with dienophiles above 140°C is accompanied by the elimination of CO_2 from the monoadducts (XI) and the addition of a second dienophile molecule to the cyclohexadiene systems (XII) formed [3]†. Therefore, the reactions of 2-pyrones with maleic anhydride [4,11,12] and *N*-phenylmaleimide [16] under these conditions lead immediately to the bisanhydrides (XIII) and bisimides (XIV) respectively. The mechanism of the formation of (XIII) and (XIV) was confirmed by synthesis [the interaction of authentic *cis*-1,2-dihydrophthalic anhydride (XII, X = O) with maleic anhydride [4]] and also by the isolation of cyclohexadiene compounds (XII) in the thermolysis of the monoadducts (XI) (see above [16,17]):



(XI) (XII) (X = O, NPh)

(XIII, XIV)

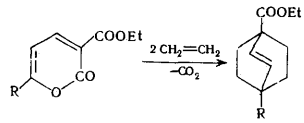
While the monoadducts can be obtained only from a few 2-pyrones substituted in specific positions (cf. the reaction described above), the products of double diene synthesis—bisanhydrides (XIII) and bisimides (XIV)—have been obtained from pyrones with different structures and a wide range of dienophiles. Thus bisanhydrides (XIII) are obtained in high yields from 6-aryl-2-pyrones [31], 5,6-dialkyl-2-pyrones [11,12], coumalic acid esters [32], tetrachloro-2-pyrones [26], 3-benzyl-2-pyrones [33], and other 2-pyrones [34-36] by the reaction with maleic anhydrides at 140°C.

High-melting crystalline bisanhydrides or the tetracarboxylic acid esters obtained from them are derivatives of 2-pyrones and are used to demonstrate the presence of the α-pyrone ring in the molecule [11,32-33,37].

Bisanhydrides are readily formed from 2-pyrones with weak electron-accepting groups (Br, CH_2Cl, CH_2OCOMe, NHCOMe) in the 3-position [38,39] (at 140°C) and also in the 3- and 5-positions [34,35]. However, 3-nitro- and 3-sulpho-2-pyrones [40,41] as well as 3,4,5-trichloro-6-phenyl-2-pyrone [26] do not react with maleic anhydride. A number of other dienophiles (benzoquinones and anthraquinones [32], acrylonitrile [42], phenyltriazoline-3-dione [43], and ethyl vinyl ether [18]) react with 2-pyrones only via the double diene synthesis mechanism (the elimination of CO_2 from

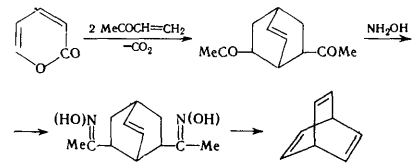
† Double diene synthesis occurs also with other cyclic dienes whose adducts readily eliminate the *endo*-bridge (for example with cyclone adducts [30]).

the monoadduct and the addition of a second dienophile molecule). 2-Pyrones react via this mechanism with ethylene, which is a weak dienophile (120–165°C, 1000 atm):[44]

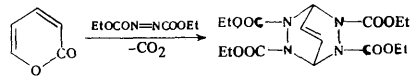


(R = Me, Et)

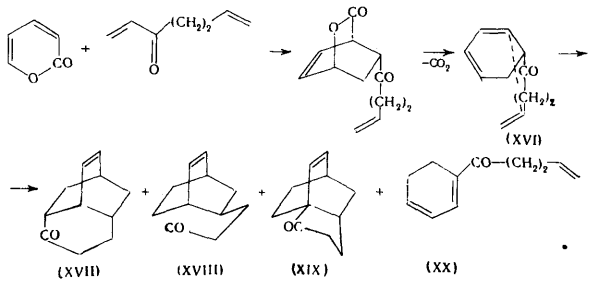
A classical example of the employment of double diene synthesis with pyrones is provided by the synthesis of barrelene {bicyclo[2,2,2]octa-1,4,7-triene} by the reaction of the unsubstituted 2-pyrone with methyl vinyl ketone[45,46] according to the following Scheme:



The employment of azodicarboxylic acid ester in diene synthesis with 2-pyrone made it possible to obtain a new heterocyclic system of the tetrazabicyclo[2,2,2]oct-2-ene series (XV):[47]

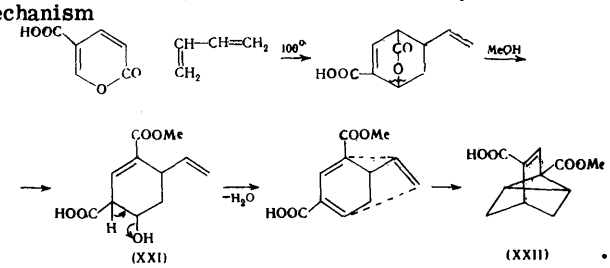


The recently investigated interaction of 2-pyrones with certain diene systems, which provide in succession both double bonds as dienophilic moieties, constitutes an unusual variant of double diene synthesis. Cyclohepta-1,6-diene-2-one reacts in this way with 2-pyrones. After the elimination of a CO_2 molecule from the monoadduct, the intramolecular interaction of the cyclohexadiene system of compound (XVI) with the double bond of the dienone fragment leads to the formation of a mixture of three isomeric tricyclic ketones (XVII), (XVIII), and (XIX) and the cyclohexadiene ketone (XX):[48]



(XVII) (XVIII) (XIX) (XX)

The double Diels–Alder reaction between coumalic acid and butadiene[49] served as a convenient method for the synthesis of tricyclene derivatives (XXII). When the process is carried out under pressure in methanol solution, the bridge in the monoadduct undergoes methanolysis, which is followed by intramolecular diene synthesis via the mechanism

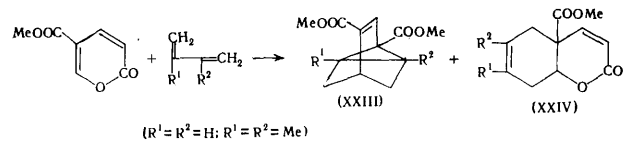


(XXI) (XXII)

Thus, in contrast to the examples described above, in this case the cyclohexadiene system does not arise in consequence of the elimination of the bridge but as a result of its rupture under the influence of methanol with subsequent dehydration of the hydroxyacid (XXI).

The interaction of coumalic acid with isoprene and dimethylbutadiene takes place similarly[49]. The unusual behaviour of typical dienes functioning as dienophiles in the reaction with coumalic acid can be explained by the occurrence of diene synthesis with "inverse electron demand" (cf. Section II, 1).

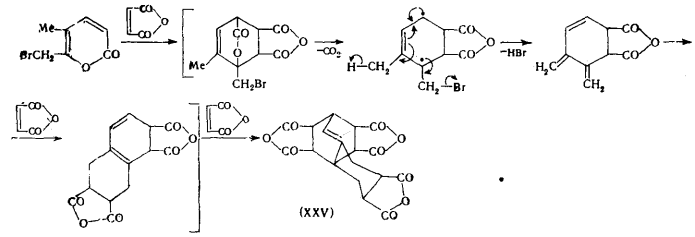
Methyl coumalate reacts with dienes in two ways—with formation of substituted tricyclo-octenes (XXIII) (as described above) and lactones (XXIV), which are obtained when methyl coumalate plays the role of the dienophile[50]:



(XXIII) (XXIV)

($R^1 = R^2 = H$; $R^1 = R^2 = Me$)

The only example of triple diene synthesis described in the literature is the synthesis of the tricyclic trisanhydride (XXV) by the reaction of 6-bromomethyl-5-methyl-2-pyrone‡ with an excess of maleic anhydride at 140°C according to the following Scheme[51]:

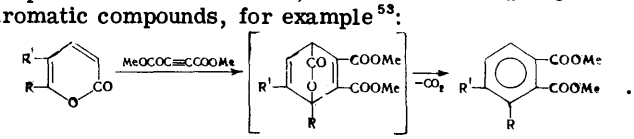


(XXV)

The above data illustrate the scope of diene synthesis with pyrones in the formation of polycyclic and "skeletal" systems.

2. Synthesis of Aromatic and Heterocyclic Compounds

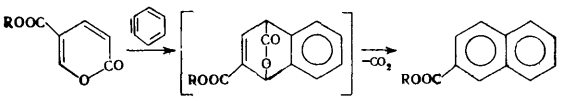
The formation of aromatic compounds by the reaction of 2-pyrones with acetylenic dienophiles was observed for the first time by Alder and Ricert[52]. The 1,4-cycloadducts produced initially in these reactions were not isolated, since they immediately split off the endoxycarbonyl bridge (because it is in the β-position with respect to two double bonds) and are converted into aromatic compounds, for example[53]:



The reaction of 2-pyrones with acetylenedicarboxylic acid ester resulted in the formation of satisfactory yields of hydroxy-,[52] dialkyl-,[53,54] and aryl-substituted[55] phthalic acids and hemimellitic acid[56] which are otherwise difficult to obtain. The reaction of diethylacetylene with 2-pyrone[57] to form *o*-diethylbenzene (yield 12%) proceeds with much more difficulty.

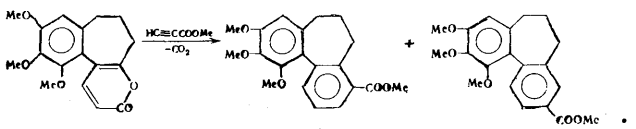
‡ The monoadduct was obtained from this pyrone at a temperature below 140°C.[5]

Derivatives of the naphthalene series have been obtained by the reaction of dehydrobenzene with alkyl coumalates [32]:

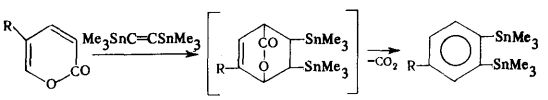


(R = Me, Et)

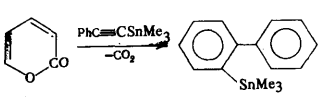
When asymmetric acetylenic dienophiles are used in reactions with 2-pyrones, the formation of a particular structural isomer is determined by polar and steric factors [58]. Thus the mode of addition of phenylacetylene to 2-pyrones is determined by the polar factor, since it proceeds in accordance with the charges of the initial reactants calculated by the Hückel method [58]. However, this rule breaks down when the dienophile employed is propiolic acid ester, which reacts with 2-pyrones to form both possible structural isomers [25,58], for example [25]:



New possibilities in the employment of diene synthesis with 2-pyrones have been discovered by Evnin and Seyferth [59]. To synthesis aromatic organotin compounds, they carried out the reaction of 2-pyrones with bis(trimethylstannyl)acetylene and trimethylphenylethynyltin:

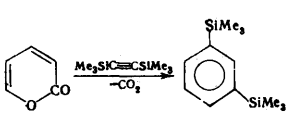


(R = H, Me, COOMe)



The study of the competing reactions of bis(trimethylstannyl)acetylene with 2-pyrone and 5-methoxycarbonyl-2-pyrone showed that only the less nucleophilic 5-methoxycarbonyl-2-pyrone reacts with the dienophile. This finding suggests that the interaction of 2-pyrones with bis(trimethylstannyl)acetylene proceeds via the inverse mechanism (cf. Section II, 1 and 2). [59]

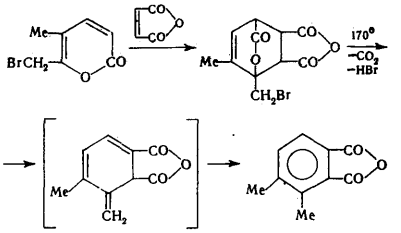
The use of bis(trimethylsilyl)acetylene in the reaction with 2-pyrone led unexpectedly to the formation of *m*-bis(trimethylsilyl)benzene as the main reaction product (53%) and only traces of the *o*- and *p*-isomers, which indicates the occurrence of a rearrangement [59]:



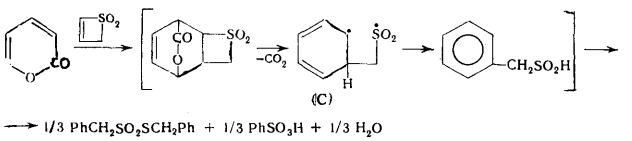
A special study [60] showed that the reason for the rearrangement is the acid-catalysed conversion of the *o*-isomer into the *m*-isomer. When acetylenic compounds of other Groups IV elements (tin and germanium) are used, such isomerisation does not take place, since the possible acid impurities are decomposed by these organometallic compounds as a result of the dissociation of the $M^{IV}-C$ bond, in agreement with the activity series of these metals (Sn ≥ Ge > Si) in protolytic reactions.

The authors admitted that the earlier explanation [59] of the above isomerisation as a result of the intermediate formation of non-Kekulé structures (prismane and benzvalene) is incorrect.

The formation of aromatic compounds in diene synthesis with 2-pyrones is possible for not only when acetylenic but also when ethylenic dienophiles are used, provided that together with the elimination of the bridge (CO_2) from the monoadduct, another simple molecule is also split off (hydrogen [32], hydrogen bromide [5], or an amine [18]), for example [5]:



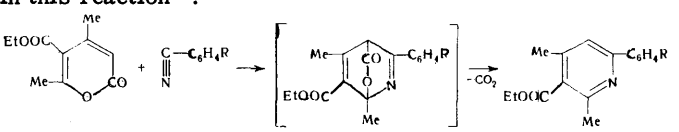
In the reaction of 2-pyrone with the sulphone derived from butadiene the resulting adduct also undergoes aromatisation in consequence of the elimination of CO_2 and the isomerisation of the biradical (C) to phenylmethanesulphinic acid, which disproportionates further according to the following mechanism [61]:



(C)

⟶ 1/3 $PhCH_2SO_2SCH_2Ph$ + 1/3 $PhSO_3H$ + 1/3 H_2O

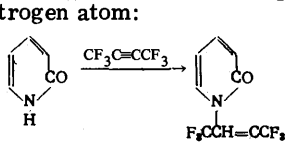
The interaction of 2-pyrones with nitriles via the mechanism of diene synthesis, accompanied by the elimination of CO_2 and the formation of substituted pyridines in a yield of about 20%, was described recently [62]. It is interesting that cyclones react similarly to nitriles, with the only difference that carbon monoxide is split off in this reaction [30]:



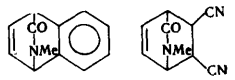
(R = H, Cl)

IV. DIENE SYNTHESIS WITH 2-PYRIDONES

The attempts to introduce 2-pyridones, nitrogen-containing analogues of 2-pyrones, into diene synthesis were unsuccessful for a long time. Pyridones unsubstituted at the nitrogen atom added to the double bonds of dienophiles (for example acrylonitrile [63], hexafluorobutyne [64], and acetylenedicarboxylic acid ester [65]) with formation of 2-pyridone derivatives alkylated or correspondingly vinylated at the nitrogen atom:



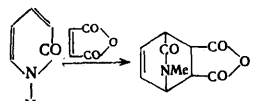
Among *N*-substituted 2-pyridones, only 1-methyl-2-pyridone could be made to undergo the diene synthesis reaction, giving rise to the adducts (XXVI) and (XXVII) respectively with dehydrobenzene [66,67] and fumarodinitrile [68] (yield 1–10%).



(XXVI) (XXVII)

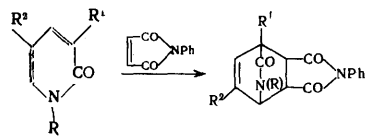
Owing to the low yields, the above reactions of 1-methyl-2-pyridone are of no preparative value. The 1,4-cycloadduct of this pyridone with tetracyanoethylene could not be obtained either [69].

In 1969 Japanese chemists obtained the adduct of 1-methyl-2-pyridone with maleic anhydride (XXVIII), in a yield of 42% (after heating for 72 h in toluene)§ [71,72], whose structure they demonstrated in detail both chemically and spectroscopically [72,73] (cf. the end of Section V).



(XXVIII)

Shusherina and coworkers succeeded in demonstrating that diene synthesis with 2-pyridones is a general reaction by employing *N*-phenylmaleimide and maleimide as dienophiles. It was found that not only do different *N*-substituted 2-pyridones form 1,4-cycloadducts (XXIX)—(XXXI) with these dienophiles in high yields [74,75], but also, and this is particularly interesting, even 2-pyridones unsubstituted at the nitrogen atom, whose interaction with other dienophiles gives rise to substitutional addition products only [63-65] (cf. the beginning of this Section) undergo this reaction to form Diels–Alder adducts (XXXII) and (XXXIII) in yields of about 50%: [76]



(XXIX–XXXIII)

(XXIX, R = Me, Pr, Bu, *i*-C_5H_{11}, H; R^1=R^2=H)
(XXX, R = Me, R^1 = H, R^2 = Me)
(XXXI, R = Me, R^1 = Me, R^2 = H)
(XXXII, XXXIII, R = R^1 = R^2 = H)

In contrast to the 2-pyrone adducts, the 1,4-cycloadducts of 2-pyridones {derivatives of 7-oxo-8-azabicyclo-[2,2,2]oct-4-ene-1,2-dicarboxylic acid} do not split off the bridge on thermolysis, but undergo retrodiene decomposition [75].

§ The cycloadduct could not be obtained by heating these reactants in benzene [70].

The results described indicate a lower diene reactivity of 2-pyridones compared with 2-pyrones. However, it is already evident that, by choosing a suitable dienophile, the Diels–Alder reaction can be widely employed in the series of 2-pyridones.

V. THE STEREOCHEMISTRY OF DIENE SYNTHESIS WITH 2-PYRONES AND 2-PYRIDONES

Like other cyclic dienes, 2-pyrones and 2-pyridones can give rise in reactions with dienophiles to monoadducts¶ with *endo*- and *exo*-configurations. The study of the *endo*–*exo* selectivity of diene synthesis, which was begun by Alder, has continued vigorously for more than 30 years. The interest in this subject is due to the employment of stereochemical data in the consideration of reaction mechanisms and transition state structures [1,77-80].

On the basis of experimental data obtained mainly in a study of diene synthesis with cyclopentadiene and its derivatives, Alder and Stein [81] concluded that the diene synthesis reactions are *endo*-stereoselective and formulated the so called Alder "*endo*-rule", which they accounted for by the possibility of the "maximum accumulation of unsaturation" only for the *endo*-orientation of the components. Further investigation of the stereochemistry of reactions between cyclic dienes and dienophiles with different structures revealed many exceptions to this rule. Thus doubt was cast on the *endo*-selectivity of diene synthesis discovered by Alder [82].

Different types of non-bonding (non-valence) or secondary-bonding interaction were considered as the main factors stabilising the *endo*- and *exo*-transition states [78-83]. The role of these forces in Diels–Alder reactions is much greater than in other processes owing to the "close packing" of the transition states, which promotes a greater proximity of the individual structural elements of the diene and dienophile [77].

Different versions of the concept, proposed at an early stage by Alder, of the overlapping of the π-orbitals of the multiple bonds of the diene and dienophile as the *endo*-orienting factor have been most widely discussed [78-81]. These ideas have now been confirmed theoretically by molecular orbital calculations and are used in the form of the Woodward–Hoffmann rule, correlating the secondary π-orbital interaction with orbital symmetry, to predict the steric course of cycloaddition reactions, including diene synthesis [84,85].

The important role of π-orbital interaction was demonstrated convincingly recently by the conversion of non-stereoselective Diels–Alder processes into *endo*-selective reactions by the introduction into the dienophile of a second and third double bond. Thus the reactions of 2,5-dimethyl-3,4-diphenylcyclopentadienone with non-conjugated mono-olefins (cyclopentene [86], *cis*-3,4-dichlorocyclobutene [87], and cycloheptene [88]), for which secondary π-orbital interaction is impossible, took place non-stereoselectively with formation of mixtures of *endo*- and *exo*-isomers, while the reactions with dienophiles having several multiple bonds (cyclopentadiene [86], tropone [86,89]

¶ The configurations of the bisanhydrides and bisimides, formed in diene synthesis, which were described above is not considered in this section since it is determined by the stereochemistry of the diene synthesis with cyclohexadiene systems and not by the nature of the 2-pyrones (see Section III, 1).

and cycloheptatriene [86]) gave only the *endo*-isomers. Thus the *endo*-rule received new experimental confirmation in these investigations†.

However, the secondary π-orbital interaction can influence stereochemistry only in kinetically controlled reactions. In those cases where *endo*–*exo* isomerisation of the adducts is possible and the stereochemical result is not determined by kinetics but by the thermodynamic stability of the stereoisomers, the more stable *exo*-isomers are frequently formed (particularly at relatively high temperatures), for example in the reactions of furan and its derivatives with maleic anhydride [21,92–94]. Furthermore, in order to be able to play a decisive role in the orientation of the components, π-orbital interaction must be sufficiently strong, as in the reactions of cyclic dienes with cyclic dienophiles containing several unsaturated groups (for example, with maleic acid derivatives and quinones) [1]. On the other hand, reactions with dienophiles whose double bond is activated by only one unsaturated group can occur non-stereoselectively (for example, the interaction of cyclopentadiene with acrylonitrile) [95].

One should also bear in mind that, when the diene molecule contains two unsaturation centres (for example, in fulvenes) the π-orbital interaction promotes both possible orientations of the reactants [1,78].

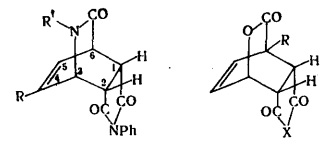
Together with π-orbital interaction, which occurs in the presence of additional unsaturated groups in the dienophiles, the stereochemistry of the reaction can be affected by saturated substituents of the diene and dienophile favouring the *endo*- or *exo*-approach of the reactants by the operation of electrostatic forces (attractive dispersion forces, repulsive van der Waals forces, and dipole–dipole interaction), which arise between the saturated diene and dienophiles substituents themselves and between the latter and the sp^2-carbon atoms of the diene [84,86]. The study of this factor, which can also be observed only under the conditions of kinetically controlled reactions, is made difficult by the fact that it may be determined by different types of interaction of the substituents some of which favour *endo*-selectivity and others favour *exo*-selectivity.

Studies on the effect of structural factors on the stereochemistry of diene synthesis have been made only recently [96–102]. For example, it has been established that the preferential formation of the *exo*-isomers in the reactions of cyclopentadiene with methacrylic acid and its derivatives is determined by the presence of the methyl group in the α-position of the dienophile [103–107]. It is at present difficult to decide [91] whether this is a consequence of the operation of repulsive forces between the hydrogen atoms of the methylene group of cyclopentadiene and the methyl group of the dienophile [101,107] or of attractive dispersion forces between the α-methyl group of the dienophile and the sp^2-carbon atoms of the diene [104,105].

The *endo*-selectivity of the reactions of cyclopentadiene with certain mono-olefins (cyclopropene, norbornene, allyl alcohol, and allyl bromide [108]) has been explained by the operation [86] of van der Waals forces.

It is evident from the data quoted that the problem of the *endo*–*exo*-selectivity of diene synthesis continues to remain controversial. More comprehensive investigation of various factors, particularly those determined by the structure of the dienophile, is necessary for its solution. In this sense the study of the stereochemistry of diene synthesis with 2-pyrones and 2-pyridones is of great interest.

The investigation by the present author (together with Levina, Stepanyants, and coworkers) of the configuration of the adducts of 2-pyrones with maleic anhydride and *N*-phenylmaleimide (by ^{1}H NMR‡ [6,16,109] and chemically [109,110], see below) and also of the adducts of *N*-alkylpyridones with *N*-phenylmaleimide by ^{1}H NMR‡ [74,75] showed that, in the absence of methyl groups at the ends of the conjugated system of multiple bonds of these heterocycles, the interaction with dienophiles proceeds *endo*-selectively with formation of the adducts (XXIX), (XXX), and (XXXIV)–(XXXVI).

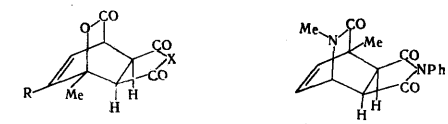


(XXIX, R = H, R' = Alk (Me, Pr, Bu, C_5H_{11})
(XXX, R = R' = Me)

(XXXIV, R = H, X = O)
(XXXV, R = Br, X = O)
(XXXVI, R = H, X = NPh

The interaction of the unsubstituted 2-pyrone with fulvene, discovered by Houk in 1973, also took place *endo*-stereoselectively [111].

On the other hand, 5,6-dimethyl-2-pyrone and 6-methyl-5-phenyl-2-pyrone form only *exo*-adducts with maleic anhydride and *N*-phenylmaleimide [(XXXVII)–(XXXIX)]. [6,16,109] A similar *exo*-influence of the methyl group in the 3α-position of the pyridone rings occurred in the interaction of 1,3-dimethyl-2-pyridone with *N*-phenylmaleimide, which led to the formation of the *exo*-adduct (XXXI) alone [75]:



(XXXVII, R = Me, X = O)
(XXXVIII, R = Ph, X = O)
(XXXIX, R = Me, X = NPh)

(XXXI)

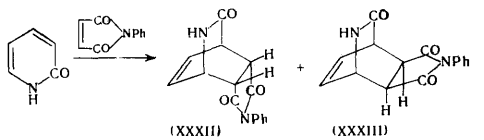
The observed breakdown of the Alder *endo*-rule for 5,6-disubstituted 2-pyrones and 1,3-dimethyl-2-pyridone cannot be due to thermal isomerisation, because the *exo*-adducts were obtained at the same (or lower) temperatures as the *endo*-adducts [16,109]. The effect of the secondary

† A fundamentally new explanation of the Alder *endo*-rule, based on the concept of the preferred geometry of the *endo*-overlapping of the π-orbitals of the carbon atoms of the diene and the dienophile directly involved in the formation of new bonds, was given by Herndon and Hall [90,91].

‡ The determination of the configuration of the adducts of 2-pyrones and 2-pyridones with maleic anhydride and *N*-methylmaleimide [(XXIX)–(XXXI) and (XXXIV)–(XXXIX)] by ^{1}H NMR [6,16,74–76,109] is based on the difference between the coupling constants of the protons at the bridgehead ($C_{(3)}H$ and $C_{(6)}H$) with the adjacent protons ($C_{(6)}H$ and $C_{(2)}H$) for the *endo*- and *exo*-isomers and also on the change in the chemical shifts of the $C_{(1)}H$, $C_{(2)}H$, and $C_{(6)}H$ protons for which the $C_{(1)}H$ and $C_{(2)}H$ signals of the *exo*-forms are in a higher field and those of the methine protons at the bridgehead ($C_{(6)}H$) are in a lower field compared with the signals of the corresponding protons in the spectra of the *endo*-forms.

π-orbital interaction, which determines the stereochemistry of the above Diels–Alder reactions with 2-pyrones [6,16,109] and *N*-alkyl-2-pyridones [74,75] unsubstituted at the ends of the conjugated system of multiple bonds, is probably suppressed in these heterocyclic dienes with 3- and 6-methyl [6,16,76,109] (or aryl [112,113]) groups, which favour the formation of *exo*-adducts.

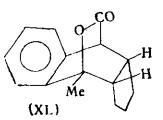
It is interesting that 2-pyridones unsubstituted at the nitrogen atom react with maleimide and *N*-phenylmaleimide via the Diels–Alder mechanism (cf. Section IV) non-stereoselectively with formation of a mixture of the *endo*-isomer (XXXII) and the *exo*-isomer (XXXIII).[76]



(XXXII) (XXXIII)

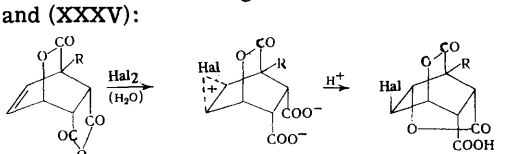
Thus the study of the stereochemistry of diene synthesis with 2-pyrones and 2-pyridones revealed for the first time the *exo*-orienting effect of the methyl and phenyl groups at the ends of the conjugated system of the heterocyclic diene in their interaction with maleic anhydride and *N*-phenylmaleimide.

However, in the reactions of 6-methyl-4,5-benzo-2-pyrone with nonconjugated dienophiles (cyclopentene, cycloheptene) the above influence of the methyl group was not observed: the reactions took place mainly with formation of the *endo*-adducts (XL), which the authors explained by the attraction of the methylene groups of the dienophile to the double bonds of the diene [114], as described above [104,105].



(XL)

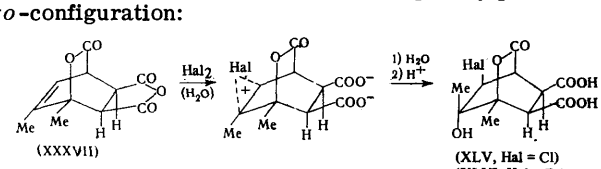
The use of chemical methods for the determination of the configuration of the adducts of 2-pyrones with maleic anhydride is based on the formation of different compounds from the *endo*- and *exo*-isomers on electrophilic addition to the double bond in the manner described for the adducts of other cyclic dienes with maleic anhydride [115–117]. Thus halogenation of the adducts (XXXIV) and (XXXV) in an aqueous medium yielded the halogenolactones (XLI)–(XLIV), formed as a result of the intramolecular stabilisation of the halogenonium ions produced initially [110,118], which confirms the *endo*-configuration of the adduct (XXXIV) and (XXXV):



(XXXIV, R = H)
(XXXV, R = Br)

(XLI, R = Br, Hal = Br)
(XLII, R = H, Hal = Cl)
(XLIII, R = H, Hal = Br)
(XLIV, R = H, Hal = I)

The formation of the halogenohydrins (XLV) and (XLVI) from the adduct (XXXVII) [110,118] demonstrates the impossibility of such stabilisation and consequently proves its *exo*-configuration:



(XXXVII)

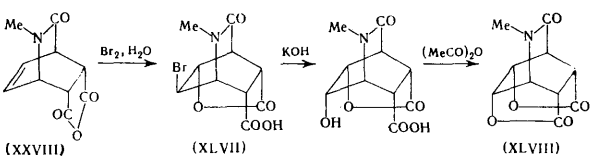
(XLV, Hal = Cl)
(XLVI, Hal = Br)

However, it is noteworthy that the halogenation of bridged bicyclic systems is accompanied by the Wagner–Meerwein rearrangement [92,119]. The formation of the isomeric halogenolactones from the *endo*- and *exo*-forms in such cases can lead to an incorrect interpretation of the stereochemistry of the reaction [92,120].

Since conclusions concerning the configuration of the adducts (XXXIV), (XXXV), and (XXXVII) based on the above reactions are consistent with ^{1}H NMR spectroscopic data (see above), one may conclude further that in the instances described the halogenation of the 2-pyrone adducts was not accompanied by a rearrangement.

The most reliable method for the determination of the configurations of bicyclic adducts—conversion into the iodolactone in which the possibility of the Wagner–Meerwein rearrangement is ruled out [121]—is unsuitable for the adducts of 2-pyrones with maleic anhydride, since the iodination of these systems takes place non-quantitatively and is accompanied by the rupture of the endoxycarbonyl bridge [118].

The *endo*-configuration of the adduct of 1-methyl-2-pyridone with maleic anhydride (XXVIII) (see Section IV) was established recently by the following series of transformations into the bromolactone (XLVII) and the bislactone (XLVIII): [71,72]



(XXVIII) (XLVII) (XLVIII)

The absence of the Wagner–Meerwein rearrangement in the bromination of the adduct (XXVIII) was demonstrated by the ^{1}H NMR spectra of the bromolactone (XLVII) and its deuteriated derivatives [73].

The data on the stereochemistry of diene synthesis with 2-pyrones and 2-pyridones described above show that the orientation of the components in these reactions is not determined solely by the secondary π-orbital interaction. Examples of the breakdown of the Alder rule when substituents are introduced in specific positions in the 2-pyrone [6,16,111] and 2-pyridone [75] rings and also the non-stereoselective course of the reactions with 2-pyridones unsubstituted at the nitrogen atom [76] are evidence for the important role of other factors, the nature of which will have to be elucidated in future investigations.

Photoconductance of Organic Polymers

V.S.Myl'nikov

Photoelectric phenomena in organic polymers are analysed, attention being paid mainly to experimental and theoretical information on the mechanism of photoconduction. Macroscopic photoelectric properties are shown to have common features in polymers, inorganic semiconductors, and organic semiconductors of low molecular weight. A list of 218 references is included.

I. INTRODUCTION

Isolated observations of an internal photoeffect in organic polymers at the beginning of the 1960s have now been replaced by regular and systematic investigations. Nevertheless, the short chapters in several monographs on organic semiconductors [1-10] and the single previous review [11] on the photoelectric properties of organic polymers have become out of date and do not give a full idea of the present-day state of this field of science. An attempt is now made to summarise information which has accumulated on the photoelectronics of organic polymers with the exception of organometallic and coordinated polymers, which have been considered in Ref. 12.

The investigation of photoelectric phenomena opens up great possibilities for studying the mechanism of the generation, drift, and recombination of current carriers, as well as for analysing the chemical and physical structure of organic polymers in the broadest sense. Use of a light beam ensures rapid transmission of information, uncoupling between individual channels of communication, high information capacity, and directional signals. In this connection organic polymers, with their specific physicochemical properties, are extremely promising materials for photosensitive cells with a wide range of uses in various technical devices. The Table sets out types of photosensitive organic polymers known at the present time.

II. POLYMERS WITH TRIPLE BONDS IN THE CONJUGATED CHAIN

Some of the first macromolecular compounds in which an internal photoeffect was detected [13] and studied systematically [11,13-28] were poly-ynes—compounds containing C≡C triple bonds in the conjugated chain—for which the main parameters determining the photoconductance and the photo-e.m.f. were examined. It was shown in particular that the dependence of the photocurrent i_{ph} on illuminance L is expressed by the formula $i_{ph} = \alpha L^n$, where $0.5 \leqslant n \leqslant 1$, [11,17-19] the photocurrent being proportional to the voltage raised to the power $1.2 < m < 1.7$. [17-19] In the large majority of poly-ynes the carriers of the photocurrent are positively charged [11,13,15-19], the kinetics of photoconduction is characterised by relaxation times from 10^{-5} s to a few minutes, and a hyperbolic law is obeyed [14].

Investigation and comparison of the photoconductance, photo-e.m.f., and absorption spectra [13,15-22] established that poly-ynes are intrinsic semiconductors, enabled the optical activation energies of photoconduction to be determined, and showed that the first stage in the generation of current carriers in polymers is the formation of excited molecular states or excitons. Preliminary exposure to ultraviolet radiation was found to activate the photoelectric sensitivity of poly-ynes [13,15]. Typical spectral curves of these compounds are shown in Fig. 1 for poly-*pp'*-diethylnylazobenzene

Optical activation energies of photoconduction determined from the photoconductance and photo-e.m.f. spectra agree with each other over the range 1.5–2.5 eV, and coincide with the edge of the fundamental absorption. This is evidence of the intrinsic character of conduction in poly-ynes. The optical activation energy of photoconduction is identical with the activation energy of electrical conduction [15], which indicates the common nature of these processes. The main photoconductivity maximum is situated, as in inorganic semiconductors, on the descending slope of the fundamental absorption, probably owing to the high rate of surface recombination.

With poly-ynes as example it was suggested that photoconduction in polymers should be regarded as a multistage process involving formation of an exciton and its subsequent dissociation on interaction with a defect or with another exciton [13,15-19]. Comparison of the absorption spectra of poly-ynes in solution and in the solid phase [16] indicates that intermolecular interaction is strengthened in the latter. The change in the photosensitivity of polymers produced by preliminary ultraviolet irradiation was explained by ionisation of the molecules followed by photopolymerisation [11,13,15] producing charged local centres, which is supported by the presence of a photoinduced electron spin resonance signal [17-20].

It is noteworthy in this connection that Wegner has obtained photoconducting polymers by exposing monomers containing conjugated triple bonds to ultraviolet radiation or high-energy electrons [28]. The photochemical modification of monomers with triple bonds and of polyacetylenes [29-31] is of interest for several recording systems. In all the cases examined the initial act of the photochemical reactions can be assumed to be the formation of free

electrons. This makes the investigation of photoelectric properties most promising for an understanding of the elementary acts in photochemical reactions. The discovery of photoconduction has enabled poly-ynes to be used for the preparation of electrophotographic layers [21,22]. Investigation of poly-ynes under electrophotographic conditions [24,25] has confirmed several effects and regularities observed under conditions of photoconduction and photo-e.m.f. (sign of carrier, spectral characteristics, activation of photosensitivity by ultraviolet radiation, etc.) and has enabled fresh information to be obtained on the properties of electrophotographic layers based on photosensitive polymers having triple bonds in the conjugated chain. It is noteworthy also that the photosensitivity of poly-ynes can be extended by dyes to longer wavelengths [18,19,34].

III. PRODUCTS OF THE THERMAL AND RADIATION-THERMAL TREATMENT OF POLYMERS

In the early stages thermal and radiation-thermal treatments were among the main methods of obtaining semiconducting organic polymer systems. Probably the first publications on the photoelectronics of these systems were brief communications by Mrosowski et al. on the possibility of using polyacrylonitrile and regenerated cellulose films pyrolysed at 800 °C as infrared detectors with sensitivity extending to 5 μm. [32,33] Pyropolymers based on poly(vinyl fluoride) and on a phenol–formaldehyde resin have since been proposed for infrared detectors [34,35]. Photoconduction has been observed in conjugated polymers based on acenequinone radical systems, polyacenes, Aniline Black, etc. by Pohl and his coworkers [36-39], who found that the *n*- and *p*-type conductivities of these compounds may vary from 10^3 to 10^{-13} ohm^{-1} cm^{-1}, and the mobilities of the current carriers from 10^{-6} to 100 cm^2 V^{-1} s^{-1}.

The photoconductance of the pyrolysis products of polyacrylonitrile was investigated in detail by Rozenshtein and his coworkers [40,41] who showed that, in the initial stage of thermolysis at 200–300 °C, conjugated segments of statistically unchanged lengths are formed in the polymer by cyclisation at nitrile groups. The kinetics of the growth of photoconductance during heat-treatment is

identical with that of the increase in the number of conjugated segments. Thus at this stage the increase in photoconductance is due solely to increase in the number of absorbing centres, not to a change in the mobility of the carriers. With rise in the treatment temperature the photoconductance spectra broaden and move to longer wavelengths with simultaneous increase in the absolute magnitude of the photoconductance and decrease in its relaxation time. Estimates of the upper limit of mobility based on the band model have shown that it increases from 0.01 to 40 $cm^2 V^{-1} s^{-1}$ with rise in the temperature of thermolysis from 200° to 500°C. The main result of work on the photoconductance of polyacrylonitrile must be regarded as the establishment that conjugated bonds are sufficient for the appearance of electronic conduction. Photoconduction may be observed in polyacrylonitrile also on complex formation with solvents, donor and acceptor molecules, as well as during its exposure to infrared radiation[42,43].

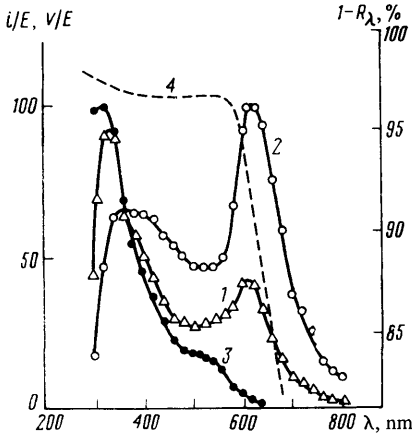

Figure 1. Spectra of poly-*pp'*-diethynylazobenzene[15,20]: 1) photoconductance; 2) as (1) after preliminary ultraviolet exposure (10 min); 3) photo-e.m.f. after preliminary ultraviolet exposure (10 min); 4) reflectance spectrum of unexposed polymer.

Exposure of a copolymer of vinylidene and vinyl chlorides to ultraviolet radiation results in the appearance of photosensitivity in the product[44-46]. The nature of the photoconductivity depends on the free radicals formed during irradiation, since conditions which induce and destroy the e.s.r. signal have similar effects on the photoconductance. Exposure to shorter wavelengths, e.g. X-rays, also produces an e.m.f. and induced conductance in polymeric materials[47-51].

Products of the radiation-thermal modification of polyethylene were investigated by Vannikov et al.[52,53]. Photocurrents of $\sim 10^{-12}$–10^{-14} amp were observed in the range 300–900 nm with light fluxes of 6 mW cm^{-2} and a multiplicity factor (ratio of photocurrent to dark current) exceeding 10. The activation energy of photoconduction ΔEph proved to be considerably smaller than the activation energy of electrical conductivity ΔEth, and decreased with increase in the photon energy on passing to more severely treated specimens. This decrease is probably due to the convergence of the conduction level of the polymer towards local levels determining the temperature dependence of the photoconductance. The photosensitivity under the same conditions of products based on poly(vinyl acetate) exceeds that of modified polyethylene some hundredfold[53].

Preliminary irradiation of high-pressure polyethylene with high-energy electrons led to a sharp increase in the photocurrent, whose principal region of sensitivity was situated in the near infrared[54,55]. Such irradiation had produced donor and acceptor traps, the formation of double bonds in the chains, and the cross-linking of separate macromolecules. A correlation probably exists between these double bonds and the traps of donor type. An energy diagram was given for the irradiated polyethylene with traps at levels 0.5, 1.1, and 1.7 eV below the conduction band. The activation energies for photoconduction and electrical conductivity are identical. The volt–ampere characteristics of the photocurrent indicate that space charges play an important part in establishing a photoresponse.

With polyimidazopyrrolones[56] at energies of ~ 15 mW cm^{-2} (polychromatic light) the observed current exceeded the dark current by a factor of 300. Maximum photosensitivity was reached after vulcanisation at 300°C for 24 h, when sensitivity was observed in the ultraviolet, visible, and near infrared regions with maxima at 610 and 550 nm. The photoconductance spectrum is displaced by about 35 nm to longer wavelengths compared with the optical absorption spectrum. Attempts to sensitise polymers by means of dyes were unsuccessful. The photocurrent obeys Ohm's law at field strengths of 10^2 to 10^5 V cm^{-1}. The observed thermal activation of the photocurrent suggests that generation of the carriers involves a complicated mechanism[56].

IV. POLYMERS WITH DOUBLE BONDS, HETEROATOMS, AND HETEROCYCLES IN THE CONJUGATED CHAIN

In this class of polymers photoconduction was first observed with certain polymeric Schiff bases and polyazines[57-59]. The lux–ampère dependence of the photocurrent was found to be below linear for all the specimens. The photocurrents increase exponentially with temperature and have activation energies of ~ 0.1–0.2 eV. The considerable polarisation phenomena made interpretation of the results difficult.

As the conjugated system in polyazopolyarenes[60] and their carbon analogues[61] becomes shorter, the photocurrent in the region of maximum absorption becomes smaller, the thermal activation energy of electrical conduction decreases, and the optical spectra undergo a hypsochromic shift. It is interesting that the activation energy of photoconduction increases with decrease in the photon energy. This has been linked with the molecular-weight distribution in the polymer, but requires detailed verification. In this case there may exist definite prospects for controlling and determining molecular-weight distributions in polymers by photoconduction methods. Variation of the activation energy of photoconduction with wavelength has been observed also in polydiphenyldiacetylenes[62], and is due to differences in the depth of the trapping levels involved in photoconduction. It has been shown for poly-ω-iodophenylacetylenes that the absorption in the range 400–1100 nm by various fractions is independent of the molecular weight of the polymer, the conjugated segments being shorter than the macromolecule[63]. The

photoconductance spectrum coincided with the form of the optical absorption spectrum. Photoelectric sensitivity was observed in a group of ladderlike polymers by Polak et al.[64] Photoconduction was suppressed by oxygen.

Photoconduction was established and studied in poly-*p*-phenylenes and several polyvinylenes by Beck[65,66]. The resistivity of specimens was $10-10^{15}$ ohm cm depending on the conditions of polymerisation and the oxygen content, and the activation energy of photoconduction varied from 0.025 to 0.96 eV. A tunnel mechanism of the passage of carriers through potential barriers was suggested for these polymers, and the mobility of the carriers was estimated as 0.6 $cm^2\ V^{-1}\ s^{-1}$.

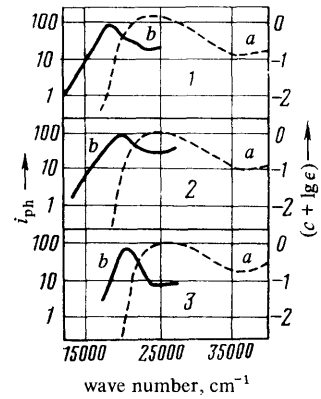
Grenishin, Cherkasov, and their coworkers[67-70] have been concerned with aspects of the relation between the structure and the photoelectric properties of polyenes (polyphenylacetylene, polydiphenylacetylene), acene structures (polydiphenylbutadiyne), structures with heteroatoms in the conjugated chain, and polymeric Schiff bases. Various methods have confirmed that the macromolecule is considerably larger than the average conjugated segment. The photosensitivity of polymeric Schiff bases[68] is independent of molecular weight over the range 200–1000, but increases tenfold on passing from amorphous to crystalline structures. Under electrophotographic conditions polymers containing carbon–nitrogen bonds exhibit photoconduction in the ultraviolet with quantum efficiencies of $(5-100)\times 10^{-6}$ el quantum^{-1},[69] which increase with the degree of delocalisation of electrons along the conjugated chain and with increased regularity of the structure. The photosensitivity of crystalline structures usually exceeds that of amorphous structures. It is generally concluded that segments of π-conjugation in polymers are no longer than those in low-molecular organic semiconductors, and hence that their electronic nature is the same. This evidently holds only for the stage of generation of photocarriers, which is regarded[70] as involving the formation and destruction of excitons as in poly-ynes.

The dependence of photoconductance on the chemical structure of the macromolecule has been studied on polystyrylpyrimidines[71]. With certain polymers and undispersed light the variation was about 10 000-fold. The photocurrent in a vacuum exceeds that in air almost hundredfold, a steady photoconductance is established within 1–2 min, and the range of photosensitivity is 400 to 900 nm. Maxima in the photoconductance spectra coincide with minima in the absorption spectra. No specific mechanism of photoconduction is suggested[71]. The variation in the absorption spectra of these compounds was ignored in the study of the effect of chemical structure on photoconductance, so that the results obtained by these workers must be approached with caution.

Photoconductance in the visible region has been observed with a multiplicity of several thousand in films obtained by the polymerisation in the glow discharge of monomers containing nitrogen, sulphur, selenium, and certain metal atoms[72,73]. A significant increase in photoconductance was observed on the addition of traces of iodine during polymerisation. The activation energy of photoconduction was 0.25 eV over the range 25–175°C, and 0.05 eV at lower temperatures. The first step in the generation of photocurrent carriers was regarded as the formation of excitons. Unfortunately, no information was given on the structure of the polymer films obtained in the discharge. They may contain several monomeric compounds which determine their properties. Photoemission data[74] indicate that films obtained in a discharge behave as large unsaturated molecules—not as polymers.

The action of dehydrogenating agents on poly(vinyl alcohol) yields a polymer having photosensitivity in the near infrared, electronic conductance with a concentration of charge carriers of 10^{16} cm^{-3}, and mobility 10^{-3} $cm^2\ V^{-1}\ s^{-1}$, both determined from the Hall constant[75]. Photosensitivity extending to 8 μm is observed in polyacetylene obtained by means of a Natta–Ziegler catalyst[76]. This polymer exhibited an identical thermal activation energy (0.27 eV) for electrical conduction and for photoconduction, which was regarded[76] as that needed for the transition of electrons from impurity levels to the conduction band. Prolonged exposure led to a decrease in photoconductance.

Indirect estimates have recently been supplemented by direct measurements of the mobilities of carriers in polymers. Thus values of $10^{-3}-10^{-5}$ $cm^2\ V^{-1}\ s^{-1}$ have been determined[77] for polydiphenylbutadiynes and poly(halogenophenylacetylenes). The results show the presence of many capture levels in these polymers.



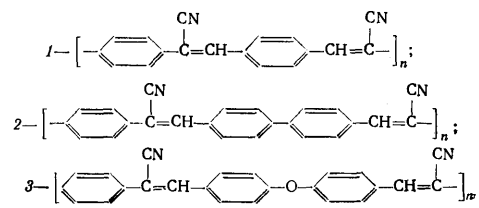


Figure 2. (*a*) Diffuse reflectance and (*b*) photoconductance spectra[79] of the polyxylidenes:

Extremely interesting work on the photoconduction of polyxylidenes[78,79] has established that the principal maxima are situated on the descending slope of the fundamental absorption, but an inverse correlation exists in the region of strong absorption (typical results are illustrated in Fig. 2). A correlation is shown between the optical activation energy of photoconduction, the activation energy of electrical conduction, and the theoretically calculated energies of $\pi-\pi^*$ transitions in isolated polymer molecules. Beyond four monomer units the optical absorption, fluorescence, and photocurrent spectra differ very little. This indicates that electron transitions in small conjugated segments are responsible for photophysical processes in polymers. Photoconduction was attributed to purely electron transitions, although a thermal activation energy of

of photoconduction was observed. Preliminary exposure to ultraviolet radiation leads to the appearance of a new maximum at longer wavelengths, which recalls the analogous phenomenon found with poly-ynes [10,13,20]. It is interesting that oxygen had opposite effects on the photoconductance at low and at high temperatures. The thermal activation energy of photoconduction lies between 0.03 and 0.2 eV depending on the surrounding atmosphere. In this work photoconduction was observed as far as the near infrared in polyarylenazomethines and polyarylenethiodiimides. All these polymers possess high resistances and may find application in electrophotography.

Photoelectric properties have been discovered and studied [80] in oligoanilines. The majority carriers in most compounds are positive holes. The optical activation energy of photoconduction is determined by shallow traps. The photoconductance spectra reproduce the absorption in the visible and the near infrared.

Finally, organic polymers containing conjugated bonds show a sharp increase in photosensitivity on reaction with electron-accepting compounds of low molecular weight [81-83]. This phenomenon is probably connected with the spectral sensitisation of low-molecular organic semiconductors by organic polymers with conjugated bonds [84].

V. POLYMERS WITH SATURATED MAIN CHAINS

Interest in photoelectric processes occurring in polymers with saturated main chains—in which conjugated bonds are either completely absent or are present in aromatic or heterocyclic side-chains—has recently increased sharply.

It has already been noted that certain types of polyethylene, after thermal treatment, develop photoelectric properties owing to the formation of segments with conjugated bonds [47,52,54,55]. Wintle et al. observed and investigated photoconduction in the untreated low-pressure polyethylene [85-88]. This work led to the most interesting conclusion, based on an examination of the absorption spectra of the polymer in solution and in the film, that the solid structure of the polymer was responsible for some absorption. The lack of correlation between photoconductance and absorption spectra indicated the impurity nature of the photoconduction. The mechanism of the production of free carriers in polyethylene was regarded as the distribution of charges in a series of irregularly connected barrier structures. It is noteworthy that van Roggen [94] detected barriers between single crystals of polyethylene that had been formed separately but were in contact. On application of an external field such structures function as current generators. Thermoluminescence data confirm the electronic–not ionic–nature of the conduction [95]. An exponential energy distribution of traps was shown [88] by the application of elementary band theory with the presence of short-range order to the charges trapped in the polymer chain. The conduction bands were very narrow, and mobility had a thermal activation energy of 0.1 eV. The photoconductance spectrum of polyethylene in the range 180–360 nm was determined by the corresponding structure in the optical absorption spectrum and the injection of electrons from the metal electrodes at their characteristic wavelength [90,91]. Photoelectric phenomena, governed mainly by contact-polarisation processes, were observed with polyethylene in the visible and in the near infrared from 0.6 to 1.7 μm. [89,91] Problems connected with the nature of photoelectric processes occurring in polyethylene and the role of the contacts have been discussed also in other papers [91-93,96,98,99]. The larger photocurrent observed with positive polarities on the leading electrode must be due to the photoinjection of holes, whose migration is determined by the Schottky type of emission [96]. The mobility of current carriers in polyethylene has been estimated as 10^{-5} cm^2 V^{-1} s^{-1} with activation energy ~0.25 eV, which is due to the thermal activation of charges out of traps or to a hopping mechanism of conduction [99]. Another study of the temperature dependence of photoconduction in polyethylene has appeared [97]. Papers on photoelectric processes in polyethylene are sometimes contradictory, especially with regard to the sign of the charge carriers, their mobility, and the interpretation of contact-polarisation phenomena.

Kryszewski et al. [100] observed photoconduction in the ultraviolet in polyethylene and several vinyl polymers; the multiplicity of the current reached hundredfold. It is significant that a larger photocurrent is observed in polymers having a higher degree of crystallinity; no clear relation was established between the photocurrent and chemical structure. The range of "saturated" polymers (i.e. containing no large conjugated fragments), in which photoelectric processes are observed has been extended considerably [101,102]. Photoelectrons emitted from the electrodes are assumed to govern conduction via traps. The current multiplicity reached 10^4 in individual commercial polymers (polyethylene, polypropylene, polystyrene, poly(ethylene terephthalate), polyvinylpyrrolidone, etc.). With several polymers (poly(vinyl fluoride), nylon-66, Viton, etc.) the density of the photocurrent attained 10^{-5} amp cm^{-2}, which is of interest for technical purposes. No special measures were undertaken to purify the commercial polymers, and most of the photoelectric processes in them are probably due to the presence of impurities and to contact phenomena.

Extremely interesting work has been done on the photoconductance of saturated organic polymers in the vacuum ultraviolet. Polystyrene shows an increase in photocurrent from 1400 to 500 Å. [103] Since the ionisation threshold of benzene molecules is 1330 Å, it may be assumed that the total ionisation energy is required to liberate an electron into the conduction band. The divergence between absorption and photoconductance spectra is interpreted here as the absence of an exciton stage in the generation of photocarriers. However, this disregards the effect of the thickness of specimens on the photoconductance spectrum. It is interesting that photocurrent and fluorescence increase simultaneously at wavelengths below 1400 Å. Detailed analyses have been made [104,105] of memory effects and of volt–ampère and lux–ampère relations in polystyrene. The volt–ampère characteristics are saturated at certain voltages, which depend on the light intensity. Oscillations of the photocurrent are observed in the same range. The mobility in amorphous polystyrene is 5×10^{-5} cm^2 V^{-1} s^{-1}; [106] the temperature dependence of charge transfer is small for jumps between molecular chains and strong for jumps between traps.

Aspects of the photoelectric properties of saturated polymers of type $[CH_2.CHR]_n$ have been dealt with in a series of papers by Grenishin, Cherkasov, et al. [107-113], who were the first to suggest using such systems to record images (electrography, photothermoplastic recording) in the spectral range 110–400 nm. Maximum photosensitivity under electrophotographic conditions was exhibited by layers of polyacrylonitrile, and minimum sensitivity by poly(vinyl chloride). In vinyl polymers the displacement (the product of the lifetime of the carriers and their

mobility) was 10^{-10} cm^2 V^{-1}, so that the carriers had a life of 10^{-7}–10^{-6} s, as mobilities in polymers of this type are 10^{-3}–10^{-4} cm^2 V^{-1} s^{-1}.[114] The quantum efficiency of the photoconductance of polystyrene in the range 110–160 nm is 2%. The optical absorption, reflectance, and photoconductance spectra indicated that the energy absorbed as exciton excitation is transmitted from "saturated" segments to aromatic side-chains, where dissociation with the formation of free carriers take place[108–112]. Analysis of the spectra of polystyrene showed that, the range up to 8 eV, absorption is determined by the properties of the monomer unit, but at higher energies by the electrons of the main chain. The absolute quantum efficiency of the photoeffect in the region of 6 eV was 10^{-4} el quantum^{-1}, which increased with the energy of the quantum to 0.4 el quantum^{-1} at 21 eV. Such high quantum efficiency may indicate the presence of a broad conduction band at a high level in the polymer. A partial criticism of the measurements on the photoconductance spectra of polystyrene suggests[115,116] that the application of a strong electric field in electrophotography may lead to distortion of the electron levels in the polymer and thereby to difficulties in distinguishing electrons involved in external and in internal photoeffects. These workers give a "band" model for polystyrene with an electron affinity of ~1.2 eV.

Vilesov et al.[117] have measured the photoelectric work functions of polyvinylcarbazole, poly(methyl methacrylate), polyvinylbutyral, and polystyrene as respectively 5.8, 5.9, 6.7, and 7.0 eV. Researches on the photoelectronics of "saturated" polymeric compounds include also investigations of pulsed photoconductance and of oscillating photocurrents in poly(vinyl chloride)[118], as well as the thermally stimulated conductance of poly(vinyl fluoride)[119].

Great interest is aroused by photosensitive systems comprising organic polymers into which have been introduced various photosensitive semiconductors such as zinc sulphide, cadmium sulphide, and zinc chloride, metal ions, dyes, and various doping agents[120–130].

Extremely promising investigations have been made during recent years on the photoelectric properties of charge-transfer complexes formed by two or more molecules. Such systems are distinguished by the appearance of a low-energy optical absorption band, by photosensitivity resulting from the transfer of charge, and by a sharp increase in conductance and photoconductance on complex formation. Papers have appeared on the photoelectronics of charge-transfer complexes of polystyrene[123,131–133]. One of the first and as yet one of the most actively investigated photosensitive polymer systems is polyvinylcarbazole[134–143] and its complexes[144–151,162–164], whose possible technical application in silverfree processes for recording images—electrophotography, photothermoplastic recording, etc.—is the primary reason for their interest[134–143]. References to the early patent literature on polyvinylcarbazole were given by Hoegl[135], together with data on the photoconductance of several polymers with heterocyclic and aromatic groups in the chain and of their complexes. The most photosensitive are probably complexes of polyvinylcarbazole with trinitrofluorene[138,145–149], electrophotographic layers of which are comparable in most of their characteristics with layers based on selenium[138]. The quantum efficiency in such layers reaches 0.15. Use of a laser source showed that, despite the extremely low mobility (5×10^{-8} cm^2 V^{-1} s^{-1}), the recombination rate constant is comparable with those for inorganic semiconductors. The nature, generation, and migration of current carriers in such systems have been discussed[148,149]. Photoconductance and a photoinduced electron spin resonance signal have been observed in complexes of polyvinylcarbazole with dinitrobenzene[150,151]. Hermann and Rembaum found that the Hall and Dember effects gave different signs for the carriers in iodine complexes of polyvinylcarbazole[162–164]. The photosensitivity spectra of such complexes cover the visible region with maxima in the ranges 400–500 and 700–800 nm. Pure polyvinylcarbazole possesses photoelectric sensitivity in the ultraviolet (Fig. 3). Sensitisation to the visible spectrum is therefore very important for technical purposes. A considerable number of papers have appeared on aspects of the spectral sensitisation of polyvinylcarbazole by dyes[129,134–139,142–145,151–159], and may form the basis of a separate review. The spectral sensitivity of polyvinylcarbazole can be extended by introducing other compounds, e.g. organocopper acetylides and poly-ynes[21,24,160,161].

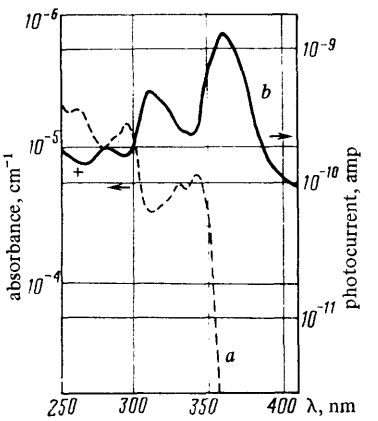

Figure 3. Spectra of polyvinylcarbazole[179]: *a*) absorption; *b*) photoconductance (with the illuminated electrode having positive polarity).

The mobility of holes in pure polyvinylcarbazole at room temperature is 0.001 cm^2 V^{-1} s^{-1} with a thermal activation energy of 0.12 eV.[165,166] The quantum efficiency of photogeneration is high (~0.1) and strongly dependent on the electric field[166,167]. The quenching of the photoluminescence of this polymer by an electric field is interesting in this connection[168]. The nature of the electrical conductivity of polyvinylcarbazole and the structure of the trapshave been examined[169,170].

Photoelectric phenomena have been studied at the contact between polyvinylcarbazole and metals[171–173]. The threshold photoemissions in the polymer were 1.28, 1.48, and 1.53 eV for gold, copper, and aluminium respectively. The ceiling of the valency band in polyvinylcarbazole is 6.1 ± 0.4 eV below the vacuum level. The development of a fine structure in the quantum efficiency spectrum is due to splitting of the electronic energy levels in the polymer by molecular vibrations. The width of the upper valency band in polyvinylcarbazole was estimated as < 0.11 eV. The generation of carriers is assumed[173] to involve intermediate formation of an exciton. Very interesting papers have appeared on the photoelectronics of polyvinylcarbazole at its interface with amorphous selenium[174–176]

and with cadmium sulphide and selenide[177]. Such heterogeneous systems may be expected to find application in several photosemiconducting devices.

A promising method for investigating the nature of photoelectric processes is the parallel study of the photoconductance and the luminescence of polymers. Examination of the latter has shown in particular that the energy absorbed by polyvinylaryls is not localised on side-chains, but is readily transmitted to neighbouring groups at distances of more than 1000 mean free paths[178,179].

Among other saturated polymers in which photoconduction has been observed and investigated are poly-1,3-diphenyl-5-*p*-vinylphenyl-2-pyrazoline[180], polyacenaphthylenes and their nitrile derivatives[181,182], poly-9-vinylanthracene[183], poly(vinyl chloride)[184,185], poly(pyrenylmethyl vinyl ether)[186], polytetrafluoroethylene exposed to X-rays[187], and an acenaphthene—formaldehyde resin[188]. All these polymers are high-resistance compounds of interest for electrophotography.

Finally, several papers have been published on the photoelectronics of biopolymers[189-024], the study of whose semiconducting properties is extremely promising for obtaining the energy parameters of these compounds and elucidating at a molecular level certain biophysical processes in living matter. The direct determination of the mobilities of charge carriers in proteins and nucleic acids gives values of 0.5–2 $cm^2 V^{-1} s^{-1}$.[197]

VI. MECHANISM OF PHOTOCONDUCTION IN ORGANIC POLYMERS

The experimental results surveyed in the preceding Sections show that the number of known photosemiconducting organic polymers is already quite large and is continuing to increase. They are of such varied types with respect to molecular (Table) and supermolecular structure that it is difficult to expect a single mechanism for the photoprocesses in all the compounds. Nevertheless, several quite general considerations will be discussed here.

The absolute photoelectric sensitivity (photoconductance, photo-e.m.f., etc.) of a polymeric compound should obviously be determined by two stages—(i) generation and recombination of free carriers and (ii) migration of the carriers through the polymer structure—a correct assessment of which would explain the following experimental principles, which have been established for most of the photoconducting polymers studied.

1. Photoelectric sensitivity is observed in polymers having conjugated bonds in the main chain in the macromolecule or in side groups.

2. The dependence of the photocurrent on the light intensity is below linear, and approaches linearity in isolated examples.

3. Ohm's law is satisfied for the photocurrent only up to field strengths of 100 V cm^{-1}.

4. Photoconduction is characterised by a wide range of relaxation times—from 10^{-5} s to several minutes.

5. The photoconductance and the electrical conductivity of polymers increase exponentially with rise in temperature, their activation energies being respectively 0.05–0.5 and 0.5–2.5 eV.

6. Mobilities of current carriers do not usually exceed 1 $cm^2 V^{-1} s^{-1}$.

7. Photoelectric effects are very sensitive to various external factors (preliminary exposure, effect of environment, illumination, etc.).

8. Photoelectric sensitivity is observed in the fundamental absorption band of the polymer, the main photoconductance maximum being located on the descending slope of the absorption spectrum.

A. Generation and Recombination of Carriers

One of the first papers on the photoconductance of organic polymers put forward the hypothesis, based on an analysis of the spectral dependence of photosensitivity in poly-ynes and on several experimental facts then known for low-molecular organic semiconductors, that the first step in the generation of current carriers in polymers is formation of an exciton, which migrates along the chain and between macromolecules[13]. The close similarity of the absorption spectra of polymers in solution and in the solid state[16,61,85] indicates that intermolecular interaction in solid polymers is quite small compared with orthodox inorganic photosemiconductors, and that the energy of the electromagnetic radiation is absorbed by individual molecules with formation of neutral excited states (excitons). The multistage generation of electron–hole pairs involving an exciton stage in the internal photoeffect in organic polymers has since received much additional confirmation[14-20,56,63,67-70,72,108-112,178,179] from data on photoconductance, luminescence, the effects of vapours and gases on photoconductance, etc. This view is now the most generally accepted. The exciton formed by the absorption of light migrates through the polymer matrix until it meets a defect or other excitons. Possible defects are disruptions in the chemical structure of the molecule, disruptions of crystallinity, cross-links between macromolecules, surfaces, etc. The number of defects in present-day polymers is so large that, in the majority of cases, these states govern the macroscopic properties. Nevertheless, direct measurement by luminescence methods of the diffusion constants of singlet and triplet excitons in polymers give extremely high values, of the order of 10^{-2}–10^{-6} $cm^2 s^{-1}$. Thus excitons are able during their existence to traverse 10–100 monomer units of the polymer. The capture of excitons by a defect or interaction with another exciton leads to its annihilation with formation of an electron–hole pair: carriers of one type remain attached to the defect, while those of the other type take part in conduction under the influence of the applied electric field, and the stage of charge transfer through the polymer structure is thus initiated.

It must be remembered that polymers have a considerable scatter of molecular weights, so that the excitons formed would also cover a certain range of energies. Such varied excitons, as well as factors influencing the drift of the carriers (barriers), may make a contribution to the usually small thermal activation energy of photoconduction (0.05–0.5 eV). This could explain in particular the wavelength dependence of this activation energy. However, there are data indicating that photoconductance is only weakly dependent on or completely independent of the molecular weight of the polymer[68,212]. However, the absence of significant bathochromic shifts in the fluorescence, absorption, and photoconductance spectra of polymers when the chain of conjugation exceeds a certain critical length[63,68,78,79,178,179] shows that the continuous chain of conjugation in organic polymers does not extend throughout the length of the macromolecule, but covers only a small number of monomer units (usually 2–7). This is supported by the observation of a hyperfine structure in the electron spin resonance spectra of certain

polyconjugated polymers[205]. It thus becomes clear why the introduction of various bridging groups which interrupt (or weaken) conjugation (those containing methylene, oxygen, nitrogen, or sulphur) does not lead to the disappearance of semiconducting properties.

Thus the optimum length of the system of conjugated bonds in polymers, that will lead to the specific photosemiconducting properties of these compounds, does not exceed a few units (usually < 10). This corresponds to the conjugated segments usually present in low-molecular compounds. Thus the first step in polymers, as in low-molecular organic semiconductors, is the formation of an exciton of a short segment of conjugated bonds. In this sense organic semiconductors of low and high molecular weights have the same electronic nature, as was to be expected. It now becomes clear why polymers with saturated main chains and aromatic side-chains can in principle be photosemiconductors, as is actually observed. The specific feature of polymeric compounds at this stage of generation of charge carriers is probably that the resulting exciton may possess a long lifetime owing to the rigidity of the polymer matrix, which ensures that excitons can migrate to great distances. The situation is analogous to the freezing of isolated molecules in solid solutions with the aim of lengthening the life of the excited state. The anisotropy of electrical properties would evidently be significant for polymers.

The concept of a "local activation effect", connecting the complex of physical (especially magnetic) and physicochemical properties of these compounds with their structural characteristics[206], may prove useful for discussing the photoconductance of polyconjugated polymeric systems obtained by thermal, radiation, etc. methods. Since photoconduction in "saturated" polymers has usually been studied on commercial specimens, it can reasonably be assumed that organic impurities having conjugated bonds were involved in the generation of current carriers. Direct ionisation of saturated bonds leading to the appearance of free carriers—and when irreversible to photodegradation of the polymer—is probably most feasible in the far and vacuum ultraviolet.

Recombination processes play a significant part in photosensitivity. They explain in particular the fact that maximum photoconductance in polymers is usually located on the descending slope of the fundamental absorption curve. Thus here, too, polymeric organic photosemiconductors behave similarly to the traditional inorganic semiconductors.

Preliminary exposure to ultraviolet radiation produces a change in photoelectric sensitivity both in organic polymeric[13–18,24,25,28,74,75] and in inorganic photosemiconductors (e.g. the formation of F-centres in crystals of alkali-metal halides, etc.[207,208]).

B. Migration of Carriers through the Polymer Matrix

Most organic polymers consist of alternating highly conducting regions (conjugated or condensed segments) and dielectric regions (disordered or amorphous structures). To effect photoconduction the electron–hole pair formed by breakdown of an exciton should drift in the applied electric field. The coincidence of the activation energy of electrical conductivity with the energy of the edge of the long-wavelength absorption and the red boundary of the photoeffect shows that the free carriers generated by the absorption of light are identical (even in the mechanism of drift) with those generated thermally.

A periodic chain of carbon atoms with the same number of hydrogen atoms attached would obviously have an electronic spectrum consisting of allowed and forbidden energy bands. Side groups replacing hydrogen atoms may act as impurities. Electropositive and electronegative substituents will correspond to acceptor and donor impurities. In contrast to covalent crystals, where impurity atoms may accept or donate one or more electrons, in the present case part of the electronic charge may be either fixed or released. Transfer of the complete charge may require several bonds acting in parallel. The numerous defects of various types present in the polymers at present available may also act as acceptor or donor impurities.

The mathematics of the band theory, which has been successfully used in studying the electronic properties of traditional inorganic semiconductors, is most fully developed at the present time. Most authors use this approach for the qualitative description of charge-transfer processes in organic polymers. When applied to macromolecular compounds, the band model supposes that current carriers move along generalised energy bands of π-electrons of the whole polymer. With decrease in the overlap of the π-electron wave functions the width of these bands diminishes, and in the limit they reduce to conduction energy levels, or to large effective masses of current carriers expressed in terms of the band model. This model implies strict periodicity in the structure of crystals and takes into account the potential for a real crystal in the effective mass of the current carriers. As already mentioned, however, most semiconducting polymers are heterogeneous or amorphous substances to a significant extent, and the application of a band model to polymers encounters certain difficulties. A possible way out may be to apply to such systems the theory of liquid and amorphous semiconductors, in which electronic properties are determined not by long-range but by short-range order[209,210]. These papers show that long-range order is sufficient but not necessary for the appearance of a band structure. Unfortunately, the main difficulties in discussing semiconducting processes in organic polymers in terms of a band model consist in the inability of this model to explain *quantitatively* several fundamental parameters observed experimentally. This applies primarily to the drift mobilities, which do not exceed a few units for most polymers, and in several cases are 10^{-6}–10^{-8} $cm^2\ V^{-1}\ s^{-1}$. The paradoxical situation arises in which the free path of the carriers becomes considerably shorter than the individual units in the molecule.

It is therefore most reasonable to adopt a hopping model of photoconduction for the majority of polymers. The free carriers formed by breakdown of an exciton probably remain localised in individual molecular segments or defects. Photoconduction is a consequence of a series of successive activated hops in the electric field. The activation energy of conductance then determines the probability of such hops[165,166]; the effective mobility or the effective concentration of current carriers should increase with rise in temperature. On theoretical grounds a hopping mechanism excludes the possibility that the Hall effect can be observed in systems where it operates. It is perhaps for this reason that attempts to observe the Hall effect on polymers have generally been unsuccessful.

The effect of light can in principle be regarded as lowering the potential barriers between separate macromolecules or regions of polyconjugation, which will increase the effective mobility of the carriers. Such a mechanism may perhaps be accepted for polymers in

which the concentrations of current carriers remain unchanged with rise in temperature. The appearance of non-equilibrium carriers exerting a polarising action may also lead to a lowering of barriers. The two processes (increase in carrier concentration and change in barrier height) may then occur simultaneously. Detailed analysis of the mechanism of conduction in semiconducting polymers is prevented by the insolubility or sparing solubility of most of the substances studied. As a consequence, comparative data are almost completely lacking on the absorption spectra of individual macromolecules (in solution) and on the absorption spectra and the photoeffect of polymers of uniform molecular weight in the condensed phase, so that no definite conclusions can be reached on collective interactions in polymeric semiconductors. It is therefore an urgent task to develop methods for synthesising soluble semiconducting polymers, which are necessary for assessing the role of intercrystalline and other defect interlayers in conduction processes, studied at present mainly on compressed pellets or powdered polymers.

A fruitful approach is to combine the concepts of hopping and band mechanisms for heterogeneous polymer structures. A band model can be applied to the motion of carriers within a conjugated segment, but transitions between such segments can be regarded as the activated surmounting of barriers. In fact, high-frequency measurements have shown that the activation energy within conjugated regions is almost zero[211]. With a large number of carriers present and sufficiently transparent barriers non-activated "percolation" of the former from one conjugated segment to another becomes possible.

---o0o---

The information on the photoelectric properties of polymers which has accumulated in a comparatively short time (10–15 years) is evidence of the rapid development of this field. However, future progress in scientific research and the widespread introduction of these materials into technology will encounter several obstacles. On a scientific level this is primarily the absence of clear ideas on the structure of many of the polymers investigated, which applies especially to products of the thermal, radiation, etc. treatment of polymers. Authors generally mention that the products obtained have a heterogeneous structure with regions of polyconjugation separated by certain barriers. Ideas on the size of the conjugated segments, crystallinity, packing, etc. are extremely vague. At the same time deductions are made on the relation between the chemical structure of a single macromolecule and the electrophysical properties of the whole polymer, which in such a situation is undoubtedly little justified. Analogous attempts to link semiconducting properties with specific chemical structures in the molecules of low-molecular organic semiconductors (dyes) have encountered substantial difficulties. It has not been shown that the decisive factor in establishing specific photosemiconducting properties in low-molecular organic compounds is the supermolecular structure, whereas the structure of the molecule (the presence of π-electrons) is responsible only for the fundamental possibility of such properties. This fully applies, in the opinion of the Reviewer, to polymeric compounds.

The situation is rather better with respect to polymers obtained by direct synthesis, for in most cases the chemical structure of the macromolecules is known exactly. Here too, however, the inadequacy of information on the significance of the physical structure of the products for their semiconducting properties is clearly felt. Little is known on the influence of defects and foreign impurities on the semiconducting properties of organic polymers. Yet it became possible to obtain inorganic semiconductors with specified properties only after they had begun to be thoroughly purified and then alloyed with definite impurities. For the solution of individual problems in semiconductor electronics the total content of impurities in inorganic semiconductors should not exceed 10^{-9}–10^{-10}%. For organic polymers in the best cases this ratio should be lower by factors of 10^{8}–10^{9}.

Thus it is not only important to seek powerful new semiconducting organic polymers but also urgently necessary to make a more detailed study of their specific physical structure as solids with simultaneous development of methods for their purification and for controlling impurities. Extremely promising work involves finding methods for and investigating mechanisms of the chemical and spectral sensitisation of photosensitivity in organic polymers by introducing molecules of sensitisers and of donor or acceptor agents.

The experimental and theoretical results surveyed in this Review show that organic polymers, hitherto regarded as exclusively insulating materials, possess several interesting photoelectric properties. The macroscopic development of these properties is analogous to those of inorganic and low-molecular organic photosemiconductors, which yet again emphasises the unitary nature of electronic processes in solids.

The voluminous literature on semiconducting organic polymers that has appeared during the past decade suggests that a new branch of the physics of solids—the physics of polymers having semiconducting properties—has recently been established. As with inorganic semiconductors, the study of photoelectric phenomena should become an independent section.

---o0o---

A group of Japanese workers have quite recently published a series of papers on the photoelectric properties of polyvinylcarbazole, its charge-transfer complexes, and its copolymers[213–217]. A book has appeared[218] on aspects of the application of organic polymers to electrophotography.

Theoretical Generalisation of the Coking of Various Fuels

D.D.Ruschev

The most important ideas on the coking of various types of solid and liquid fuel are examined. Theoretical results are given summarising the thermal degradation of model organic compounds and polymers. Processes involved in the coking of various petroleum products, coal tar, and their mixtures with weakly caking, low-grade coals are analysed. Data are presented on the plastic state and the caking of coals of different degrees of metamorphism. Consideration is given to the caking of lignites and to the effect of the type and origin of brown coal on the physicomechanical parameters of the coke. Formulae are set out for calculating the yield of chemical products in the coking of coals and for predicting the properties of the coke. A list of 94 references is included.

6. Caking of lignites and coking of mixtures of coal and brown coal with oily additives 882
7. Yields of chemical products from coal—properties and structure of coke 884

1. INTRODUCTION

The theoretical problems associated with coking processes are usually considered in connection with either the manufacture of metallurgical coke or the production of coke from heavy petroleum fractions and resinous products of the processing of coal. The former and older scientific approach was concerned mainly with physical and colloidal processes, whereas the latter was directed solely at the chemistry of the processes.

Muck[1] considered that coking took place in several stages. Coal softens when heated and acquires plasticity, which produces various states from slight stickiness to complete fusion. He related the swelling to the extent of melting and the rate of hardening: the gases evolved distended the softened mass and, provided that the pore walls permeating it were sufficiently strong, the latter remained unbroken until solidification occurred. Weding and Rao[2] denied that coal could melt, and explained coking by thermal decomposition of hydrocarbon and resinous components of coal, with the separation of free carbon and high-melting complex carbon-rich compounds, which settle on the carbon particles and consolidate them into monolithic lumps of coke. Simmersbach[3] supported the melting hypothesis, but assumed without justification that coal contained two modifications—"caking" and "lean" coals—which under certain conditions may pass one into the other.

Very unsuccessful attempts were made to relate the coking power of coals with their elementary composition. Interesting considerations were put forward by Simmersbach[4], who regarded the hydrogen and oxygen contents as more important than the carbon content: coal does not coke if it is either very rich (brown coal) or very poor (anthracite) in these elements. It postulated the existence of upper and lower limits to the hydrogen and oxygen contents, beyond which coking was impossible.

Many papers were published during the interwar period[5-10] linking caking and coking with the presence of bitumens in the coal. Berl and Körben[11] concluded that bitumens which distilled off at higher temperatures during coking were responsible for the formation of uncaked coke. If bitumens decompose below their boiling points, they may be converted into substances which cement the remainder of the coal and form strong coke. Several investigators[12-14] were doubtful about the role and significance of bitumens and their components for elucidating coking processes. The polemics on this aspect can be explained by the varied conditions under which bitumens were extracted and the absence of a reliable and unified method for measuring the strength and structural properties of coke.

The use of modern methods yielding fresh experimental information has led during recent decades to other interpretations of caking and coking processes. Illingworth[15] and Mott[16] directed attention to the adsorption and wetting of infusible humic substances by molten bitumens and put forward the "cementation" hypothesis, which was developed by Sapozhnikov[17] as the "adhesion" hypothesis. Yakovlev[18], Onusaitis[19], Aronov[20], and Permitina[21] also discuss caking and coking in physical and physicochemical terms, linking these processes with fusion, disolution, dispersion, wetting, etc. Interesting attempts have been made by Shapiro[22], Kustov[23], and other Soviet authors to explain the formation of coke in terms of colloid chemistry.

All the above hypotheses have the common defect of underrating the role and importance of chemical processes in coking. Audibert[24] regarded the formation of coke as a complicated chemical process yielding several new high-melting compounds. As the temperature is gradually raised, coal is converted into a continuously varying system of liquid, solid, and gaseous phases, and finally passes completely into the solid state. Panchenko and Klopotov[25] consider that chemical processes are responsible for the evolution of water and carbon dioxide, with the formation of new plastic products. In the opinions of Aronov and of Nesterenko[26] caking and coking depend on the relative proportions of hydrocarbon and oxygen compounds in the plastic products and on polycondensation processes. Angelova and Lazarov[27] have established that the plastic state is characterised by an increased content of functional oxygen groups resulting from the thermal destruction of ether and other bonds.

During recent years a broad debate has been conducted in the Soviet Union on the problems of caking and coking processes[28-32]. This has clearly shown that the words of Simmersbach[33]—"The cause of the caking of coal is a problem which, in spite of all the efforts made to solve it, still awaits its final solution"—are valid even today.

2. INVESTIGATION OF COKING ON MODEL ORGANIC COMPOUNDS AND POLYMERS

In a study of the coking of individual organic compounds Tilicheev[34] found that the rate increases with the molecular mass of the aromatic ring system of unsaturated cyclic hydrocarbons. Unsubstituted aromatic hydrocarbons are most rapidly carbonised. In order to study the mechanism of coking, differential thermal and thermogravimetric investigations have been made[35] on model organic compounds, most of which are products of the processing of coal and have been isolated from coal tar (Table 1). The highest coking value was obtained in the pyrolysis of truxene and bifluorenyl, which have the highest molecular mass, melt at a high temperature, and boil above 500°C. Coke is formed comparatively rapidly from chrysene, pyrene, and brazan, whose molecules consist of fused aromatic rings (Table 1). The pyrolysis of n-docosane, naphthalene, 2,6-dimethylnaphthalene, *o*-hydroxybiphenyl, and 2-hydroxy-4-methylquinoline occurs quite differently: their coking values are exceptionally small, and the time required to form 1% of coke varies from 963 min (with naphthalene) to infinity (*o*-hydroxybiphenyl).

Table 1. Physical constants and coking power of model organic compounds.

Compound	Mol. mass	M.p., °C	B.p., °C	Coking value, %	Time for 1% coke, min.
n-Docosane	310.6	44.9	380	0.092	1177
Naphthalene	128.2	80	218	0.110	963
2,6-Dimethylnaphthalene	156.0	111	262	0.031	3419
Fluorene	166.0	116	299	0.192	552
Bifluorenyl	330.4	249	500	17.485	6
Pyrene	202.2	150	394	3.903	27.2
Chrysene	228	255	441	4.025	26.3
Truxene	342	369	550	71.063	1.5
Brazan	218.2	205	395	2.064	51.5
o-Hydroxybiphenyl	170.2	59	286	trace	∞
2-Hydroxy-3-methylquinoline	159.2	240	390	0.038	2790
Carbazole	167.2	245	353	0.985	108

An interesting conclusion can be reached from a comparison of the differential thermal and thermogravimetric curves for n-docosane and naphthalene (*a* and *b* in Fig. 1). The former curves begin with endothermic effects representing their transitions from solid to liquid state. Very characteristic of docosane is the subsequent exothermic effect with its maximum at 245°C, whereas loss in weight due to vaporisation and thermal degradation begins above 280° and is accompanied by an endothermic effect at 309°C. The sublimation of naphthalene, which begins at 150°, is especially intense between 190° and 210°C, and is responsible for an endothermic effect: the weight of a specimen decreases by approximately 90% from 195° to 210°C.

The differential thermal curve for truxene (Fig. 2*c*) exhibits an immense exothermic effect with its maximum at 188°C, whereas changes in weight begin only above 435°C, which confirms the importance in coking of exothermic polymerisation and polycondensation processes occurring between 200° and 430°C. Brazan gives two exothermic effects in the same temperature range (Fig. 2*d*).

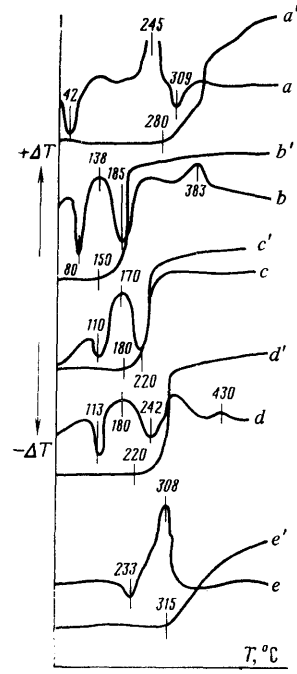

Figure 1. Differential thermal and thermogravimetric curves of: *a*,*a'*) n-docosane; *b*,*b'*) naphthalene; *c*,*c'*) 2,6-dimethylnaphthalene; *d*,*d'*) fluorene; *e*,*e'*) bifluorenyl.

It is very important to investigate the behaviour of cellulose, waxes, resins, and other coal-forming components of vegetable origin, which in more or less changed form play a considerable part in the formation of coke, in order to elucidate the processes involved in caking and coking. The heat-treatment of these coal-forming and other simply constructed natural or synthetic model substances of high molecular weight may yield very interesting information on the course of thermal degradation processes in the caking of coal and its conversion into coke. Krasyukov[36] has established that polyethylene does not form a coke residue, but polypropylene gives 16.2% of coke, which is identical with petroleum coke in texture and mechanical and electrical properties.

In investigations of the mechanism of coking, analogous experiments have been made with coumarone–indene resins, carnauba wax, technical paraffin wax, coal tar, cellulose, rosin, etc.[37,38] The results show (Fig. 3) that the characteristic endothermic effects of coumarone–indene resin and rosin (at 358° and 288°C) arise from thermal degradation associated with the evolution of volatile products. Pyrolytic processes begin in carnauba wax (*c* and *c'*) only above 370°, so that the endothermic effect is observed at 402°C.

Formation of a solid coke residue from technical paraffin wax (Fig. 3*d'*) is largely complete by 495°C. The coking value (6.516%) far exceeds that of n-docosane (0.092%). This means that the pyrolysis of a mixture of paraffin hydrocarbons creates more favourable conditions for accelerating coke formation. Coal tar gives an especially interesting differential thermal curve (*f*), characterised by an immense exothermic effect between 248° and 300°C. Heat-treatment of this mixture of many strongly aromatised compounds, of high molecular weight and high boiling point (above 400°C), leads to appreciable changes in weight only above 325°C, which is connected with the absorption of heat. Truxene and coal tar give closely similar differential thermal and thermogravimetric curves. The presence of a plateau on the differential thermal curve of the tar can be explained by the superposition of several exothermic effects similar to those of truxene with a maximum between 248° and 300°C, as can be seen from the proposed hypothetical scheme (Fig. 4).

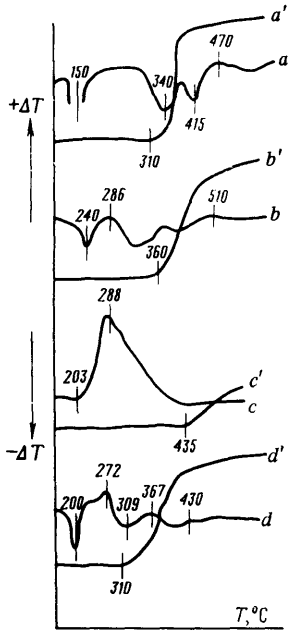

Figure 2. Differential thermal and thermogravimetric curves of: *a*,*a'*) pyrene; *b*,*b'*) chrysene; *c*,*c'*) truxene; *d*,*d'*) brazan.

Paraffin hydrocarbons, like aromatic hydrocarbons which sublime below the degradation temperature, yield a very small quantity of a coke residue consisting of highly fused aromatic compounds. Aromatic heterocyclic compounds containing oxygen and nitrogen usually undergo polymerisation—condensation processes with the formation of solid, non-volatile, strongly aromatised carbon-rich products constituting coke. Even before the start of degradation and vaporisation, the aromatic compounds of high molecular weight, which melt and boil at high temperatures, undergo intense polymerisation and polycondensation processes characterised by exothermic effects with a maximum in the range 250–310°C. They give a large quantity of a solid, non-volatile condensed residue, which forms the main mass of the coke.

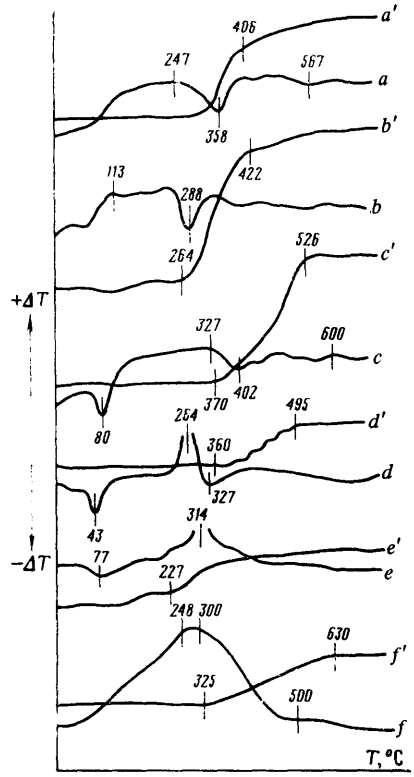

Figure 3. Differential thermal and thermogravimetric curves of: *a*,*a'*) coumarone–indene resin; *b*,*b'*) rosin; *c*,*c'*) carnauba wax; *d*,*d'*) paraffin wax; *e*,*e'*) cellulose; *f*,*f'*) coal tar.

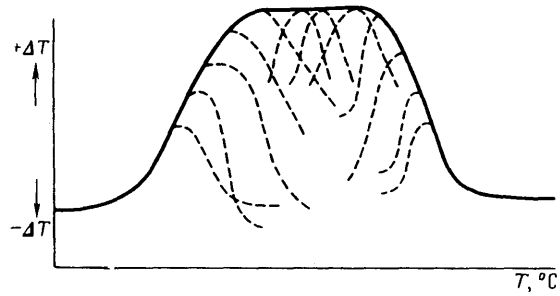

Figure 4. Aggregate differential thermal curve for a mixture of compounds.

3. MECHANISM OF THE FORMATION OF TAR COKE

Investigations of the coking of various tars, resins, and heavy hydrocarbon products and study of the properties of the resulting coke will yield additional information on

coking processes and their mechanism[39-46]. Paper chromatography indicates that silica-gel resins and asphaltenes predominate in vacuum and acid asphalt, kerogens and carbenes in mazut, and asphaltenes in coke-oven tar. Fig. 5 shows diagrammatically the yields of coke, liquid distillate, and gases obtained when these products are coked under laboratory conditions, and Table 2 lists the most important characteristics of the coke residue. Differences in hardness, porosity, and density among the cokes result from the different chemical compositions of the starting materials. Gas-works tar and stearin pitch, which are rich in paraffin hydrocarbons, yield the coke of lowest density, whereas strongly aromatised materials, e.g. coal tar and vacuum asphalt, give a resinous coke of high density. These differences have been confirmed by X-ray examination of the structure.

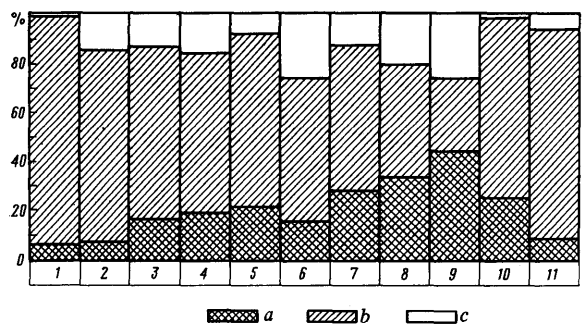

Figure 5. Material balance—(*a*) coke; (*b*) distillate; (*c*) gases—in the coking of: 1) petroleum; 2) mazut; 3) vacuum asphalt; 4) acid asphalt; 5) mazut from bituminous shales; 6) gas-works tar; 7) resin from gas-works tar; 8) coke-oven tar; 9) resin from coal tar; 10) beechwood tar; 11) stearin pitch.

Table 2. Physical constants of resinous coke.

Raw material	Density		Porosity, %	Hardness, s
	apparent	true		
Petroleum (Tyulenovskii)	0.75	1.23	39.0	180
Mazut from Tyulenovskii petroleum	0.84	1.50	44.6	190
Vacuum asphalt from Tyulenovskii petroleum	0.96	1.67	42.6	200
Acid asphalt	0.75	1.30	40.0	235
Mazut (from oil shales)	0.77	1.40	27.5	165
Gas-works tar	0.63	1.08	41.7	125
Resin from gas-works tar	1.01	1.53	33.4	300
Coal tar	0.99	1.74	43.0	170
Resin from coal tar	1.26	1.46	15.0	240
Beechwood tar	0.39	1.55	75.0	85
Stearin pitch	0.65	1.09	39.5	305

In order to elucidate the chemistry and the mechanism of the formation of coal-tar coke, systematic investigations have been made of the changes in properties and chemical composition of coal tar during its oxidative degradation and coking[47,48] (Figs. 6–8). The microstructure of the coke obtained at 450°C shows no significant changes from the initial material. A sharp change ensues at 500°C, when a bright, light-coloured coke is obtained which has strong anisotropy and a secondary structure. Such coke contains many round and oval pores. The most important physicochemical data on coal-tar coke are given in Table 3. This shows that compounds containing functional carboxyls undergo especially intense decarboxylation between 450° and 500°C, and the coal-tar coke obtained at 550°C no longer contains any carboxy-groups. The hydroxyl content increases, reaches a maximum at 500°, and falls to zero at 550°C. The hydroxy-groups are formed by the rupture of ether bonds and disappear as a result of polycondensation processes, which lead to formation of the coal-tar coke.

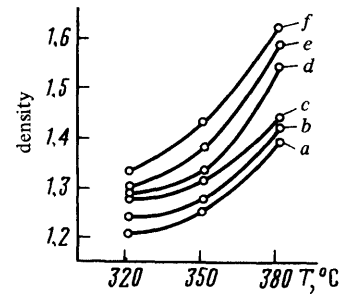

Figure 6. Temperature variation of density of pitch from (air flow, litres kg^{-1} h^{-1}/duration of heating, h): *a*) petroleum (20/3); *b*) vacuum asphalt (50/3); *c*) acid asphalt (80/3); *d*) mazut from oil shales (20/6); *e*) coke-oven tar (50/6); *f*) gas-works tar (80/6); *g*) semicoke tar.

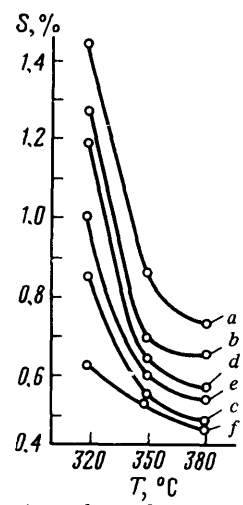

Figure 7. Temperature dependence of mean pitch content (units as in Fig. 6): *a*) 20/3; *b*) 50/3; *c*) 80/3; *d*) 20/6; *e*) 50/6; *f*) 80/6.

The course of such processes has been demonstrated by thermogravimetric examination of individual and high-molecular model compounds. The chemical structure of coal-tar coke is characterised by functional carbonyl groups, whose content steadily increases over the temperature range investigated, whereas they were not

detected at all in the original tar[48]. The infrared spectrum of the coal-tar coke obtained at 450°C shows a considerable weakening of bands in the range 770–960 cm^{-1}, and the maxima at 1450 and 1613 cm^{-1} almost disappear. This confirms that polycondensation of benzene rings has occurred.

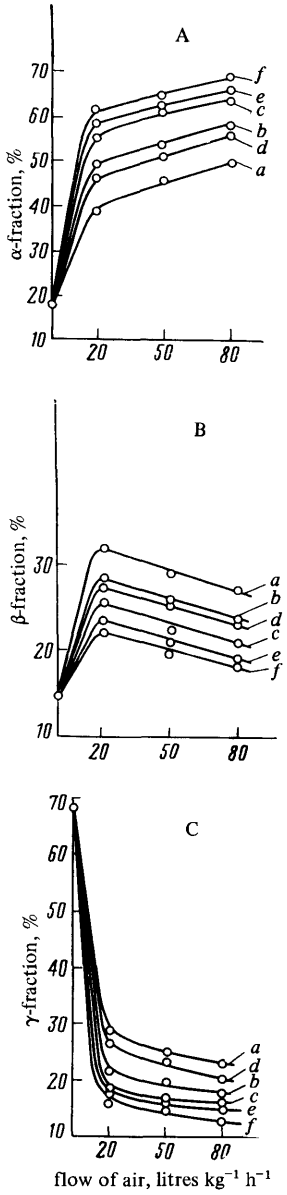

Figure 8. Effect of flow of air on contents of different fractions in the pitch for different temperatures (°C) and durations of heating (h): *a*) 320/3; *o*) 320/6; *c*) 320/9; *d*) 350/3; *e*) 350/6; *f*) 380/3.

The investigations have shown that the yield of coal-tar coke, its apparent and true densities, and its hardness increase with the molecular mass and the proportion of compounds containing a fused aromatic system (asphaltenes, carbenes, etc.) among the products undergoing coking. Pores are formed between 450° and 500°C to give a coal-tar coke varying in porosity from 15 to 75%, also depending on the chemical composition of the products. Formation of a coal-tar coke involves the decarboxylation of existing carboxy-groups with the gradual formation of new hydroxy-groups (with a maximum at 450°C) as a result of rupture of existing ether groups and the polycondensation of hydroxy-groups. Carbonyl groups, whose content increases with rise in temperature, are characteristic of the chemical structure of coal-tar coke.

Table 3. Physicochemical parameters of resinous coke obtained at various temperatures.

Analytic results	Final coking temperature, °C		
	450°	500°	550°
Yield of volatiles, %	18.30	10.40	6.35

4. PLASTIC STATE, CAKING, AND DEGREE OF METAMORPHISM

Investigations of the plastic state and the caking of coals with different degrees of metamorphism[49-51] have yielded very interesting results contributing to a general theoretical explanation of the processes involved in coking. Several specimens of coal were selected from the Balkan coal-field. Pyrolysis results showed that the yield of volatile substances varied between 40.7% and 13.7% with a plastic layer varying in thickness from 23 mm to zero. Petrological analysis showed[52] that vitrinite predominated (69–76%) in the initial coals, the inertinite content varied from 8% to 12%, and very little exinite (trace to 1%) was present.

The variation in petrogaphic composition observed during the step-by-step coking of gas coal from the Lev mine showed that the vitrinite (the main mass) remained homogeneous and isotropic (up to 400–430°C). A secondary pitted structure was detected in it at 470°C, it acquired a bright greyish-white colour, and above 600°C pleochroism and anisotropy developed. The cuticles began to change even before appearance of the plastic state (400–430°C), gradually becoming thinner and difficult to detect, and they finally disappeared at 470°C. Fusain and semifusain remained unchanged even at 625°C: they played no active part in formation of the plastic phase or in caking of the coal. Between 570° and 625°C the boundaries separating these inert ingredients from the main vitrinised mass began to become obscure.

Single pores already begin to appear at 400°C, but pore formation becomes especially intense from 470° to 500°C, when the plastic phase passes into a semicoke phase.

The percentage content of pores is especially high at 570–625°C, when closely situated, large, and mostly shapeless pores are observed, probably formed by the coalescence of several smaller pores.

The coking of a fat coal releases a considerable quantity of liquid products up to 400°C, and thermal degradation is largely complete by 460°C (Fig. 9*A*). The plastic phase formed is of low viscosity and exerts a great resistance (up to 1320 mmH_2O) to gases passing through it (curve *1* in Fig. 9*A*). Pyrolysis becomes especially intense between 400° and 430°C, with maximum evolution of volatile products (curve *2*). The quantity of gases able to diffuse through the plastic phase is considerably smaller than the total quantity evolved, so that pores already begin to form at 400°C. Larger pores are produced by the union of small pores separated by thin walls of softened plastic material (Fig. 10*a*). Hardening of the plastic phase at 452°C coincides with the maximum of a large endothermic effect (Fig. 9*A*, curve *4*). It is significant that formation of a solid semicoke phase from the softened coal coincides with a maximum increase in carbonyl groups (curve *7*). It had earlier been found that these functional groups are especially characteristic also of the chemical structure of coal-tar coke. When heated above 600°C coal forms a coke possessing clearly defined anisotropic properties (Fig. 10*b*).

In the pyrolysis of a typical coking coal thermal degradation and the appearance of liquid products ensue at considerably higher temperatures, so that the initial softening is observed at 403°, and hardening of the plastic phase at 470°C (Fig. 9*B*). The maximum resistance offered by this mass to diffusing gases is considerably smaller (curve *1*). Hardening of the plastic phase is in this case accompanied by a well defined endothermic effect (curve *4*). The quantity of carbonyl groups also increases, as is indicated by the well-defined maximum (0.76 mg-equiv. g^{-1}) at 500°C, lying within the range of the newly formed solid semicoke phase (curve *7*).

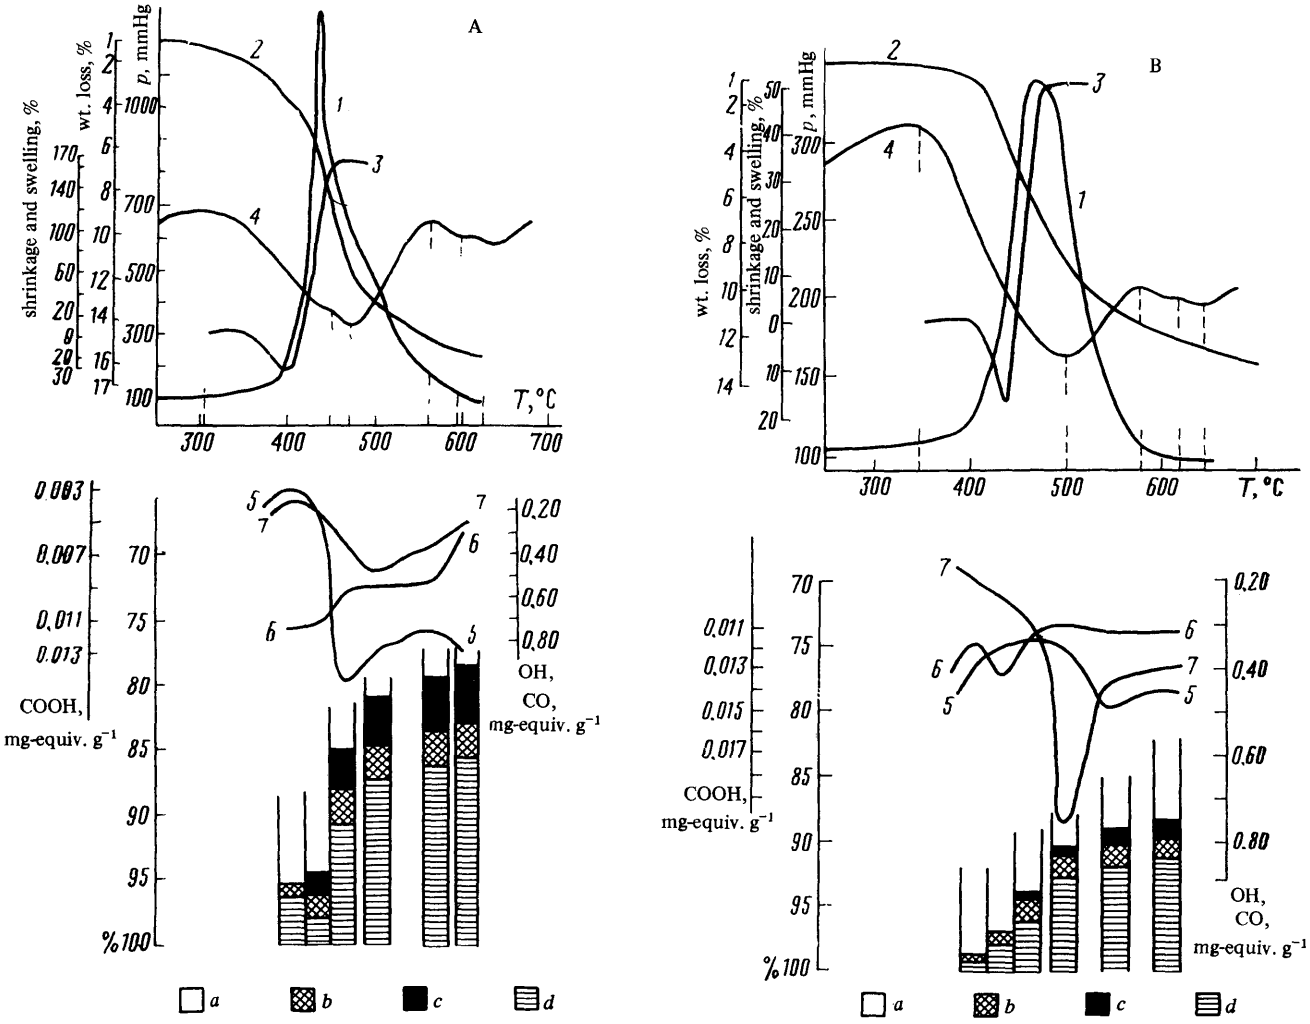

Figure 9. Investigations of plastic state of: A) fat coal from Kachulka mine; B) coking coal from Sheshkingrad mine: 1) Foxwell curve; 2) thermogravimetric curve; 3) dilatometric curve; 4) differential curve; 5) carboxy-groups; 6) hydroxy-groups; 7) carbonyl groups; *a*) semicoke; *b*) pyrogenous water; *c*) coal tar; *d*) gas.

The processes involved in the thermal degradation of, the appearance of a plastic phase in, and the caking of a fat and coking coal are clearly presented in Fig. 11. At every stage the individual phases undergo complicated pyrolytic processes associated with the formation of new products—solid (S), liquid (L), and gaseous (G)—which yield the corresponding phases of the subsequent stage. Fusain and semifusain do not pass into a plastic state, and are occluded directly into the solid coke phase. Hardening of the plastic phase is associated with the appearance of an endothermic effect, whose maximum coincides with the maximum increase in carbonyl groups. Pore formation begins approximately at 400°, and is especially intense between 470° and 500°C. Thermal degradation involves rupture of ether, ester, and other bonds, with the production of exceptionally reactive compounds of low and high molecular weight, which undergo complicated polymerisation and polycondensation processes leading to gradual formation of the continuous three-dimensional structure of high-temperature coke.

5. COKING OF COAL–OIL MIXTURES

The value and the role of liquid products in the appearance of a plastic phase and the formation of coke were revealed by a study of the coking of mixtures of a weakly caking lean coal with various petroleum, tarry, and resinous products[53–57]. Table 4 gives some of the characteristics of the crucible coke obtained. These investigations show how great an influence the chemical composition and the quantity of liquid additives have on the appearance, density, porosity, hardness, and other properties of coke.

Table 4. Characteristics of crucible coke from weakly caking coal with various additives.

Additive	Density		Porosity, %	Hardness, s
	apparent	true		
None	0.56	1.78	68.6	27
Stearin pitch	0.55	1.66	66.8	84
Coke tar	0.32	1.77	81.9	19
Gas-works tar	0.56	1.73	67.6	45
Anthracene oil	0.52	1.71	69.6	37
Petroleum	0.55	1.93	71.5	30
Semicoke tar	0.63	1.74	63.9	35
Acid asphalt	0.51	1.77	71.2	36
Mazut	0.56	1.65	66.1	19
Coke-oven tar (8%)	0.52	1.77	70.8	27
Coke-oven tar (14%)	0.46	1.72	74.6	25
Coke-oven tar (25%)	0.40	1.69	76.4	23
Coke-oven tar (33%)	0.32	1.74	79.9	18
Coke-oven tar (40%)	0.29	1.79	83.8	10
Coke-oven tar (45%)	0.24	1.73	86.1	—

Especially interesting results were obtained in plastometric investigations of mixtures of a weakly caking coal with additions of 5%, 10%, and 15% of petroleum and tar products. Several plastometric curves are shown in Fig. 12, while Table 5 gives the plastometric parameters (x and y) and the strength of the coke obtained from these mixtures. The relation between the quantity x (%) of additives and the thickness y (mm) of the plastic layer can be represented approximately by the equation

$$y = a \cdot x^2 + b \cdot x + c .$$

Such an equation enables us to calculate the quantity of an additive necessary to convert a given weakly caking, lean coal into a coking or fat coal (Fig. 12).

The heavier is an additive and the richer in asphaltic–resinous compounds, the smaller the quantity required to obtain a plastic layer of maximum thickness. Coke-oven tar changes not only the thickness but also the temperature limits within which the plastic layer appears (Fig. 12), which occurs at considerably lower temperatures (360–460°C) on the addition of 10–15% of this material. The addition of gas-works and beechwood tars has no significant effect on the thickness of the plastic layer or on the temperature range of its formation.

Excessive increase of the additives causes intense cracking of the coke, so that its strength diminishes (Table 5). The optimum quantity of additives increases the strength of the coke by factors of 2–4. The strength is diminished by the addition of beechwood tar, which can be attributed to the large quantity of oxygen compounds present in such tar[58].

In order to establish the effect of the chemical and fractional composition of additives on the thickness of the plastic layer and the strength of the coke, coke-oven and gas-works tars were fractionally distilled, and the fractions isolated (10%) were added to a weakly caking coal (Table 6).[59] It was found that the addition of fractions rich in phenols (42–55%) and in naphthalene (80%) caused the plastic layer to break down, and an unstable coke was obtained. The thermogravimetric coking of model compounds has established[35] that naphthalene has escaped almost completely by 210°C (Fig. 1*b*), and cannot influence either formation of the plastic phase or caking. The greatest influence on the increase in the plastic phase and the strength of the coke is exerted by residues of coke-oven and gas-works tars rich in asphthaltic–resinous substances boiling above 350°C.

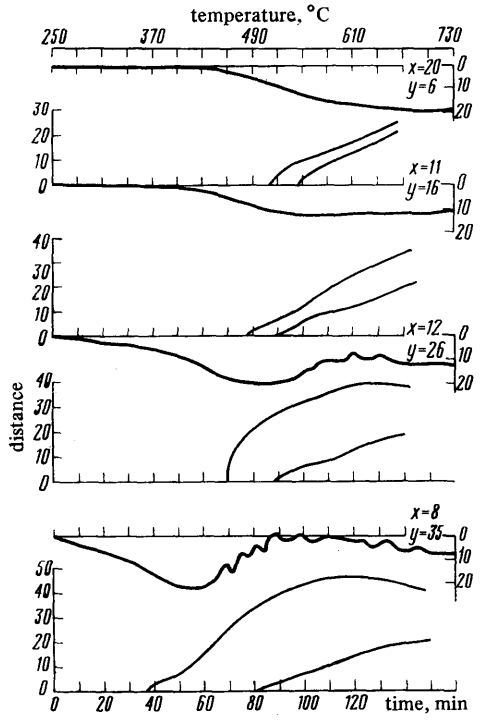

Figure 12. Plastometric curves of coal with various percentages of coke-oven tar: *a*) 0; *b*) 5; *c*) 10; *d*) 15.

Investigations of the coking of model mixtures of a weakly caking coal with various types of tar and fractions thereof revealed the mechanism of caking and coking[60,61]. On the addition of coke-oven tar and its resin the coal is readily dissolved and dispersed in silica-gel resins and asphaltenes, which leads to a great increase in the plastic layer, as a consequence of which the resulting coke is fused, light grey, and lustrous. Gas-works tar and the resin from it hardly affect the thickness of the plastic layer, since coal is insoluble in the petrolenes and kerogens that predominate in its composition. The coke obtained by cementation is grey and dull. Despite the differences in the physical processes accompanying formation of the coke, its strength is almost the same. It has thus been demonstrated that coke formation involves the dissolution and dispersion of coal and the cementation of particles of the resinous coke.

Table 5. Plastometric indices and strength of coke from coal with various additions.

Addition	Plastometric parameters, mm		Strength of coke, kg cm^{-2}	Addition	Plastometric parameters, mm		Strength of coke, kg cm^{-2}

6. CAKING OF LIGNITES AND COKING OF MIXTURES OF COAL AND BROWN COAL WITH OILY ADDITIVES

All brown coals are non-caking, so that they do not form a monolithic coke residue. Karavaev[62] found that Bulgarian lignites showed a slight tendency to cake, which he explained by an increased content of bitumens and sulphur. Investigation of Eastern Maritsa lignitic coal[63–68]

established that only xylite and vitrinised lignite are capable of caking, independently of the sulphur content. The differential thermal curves of these components (Fig. 13) clearly show that thermal degradation processes are closely similar in caking xylite and vitrinised lignite, but differ significantly from processes in which a caked coke residue is not formed.

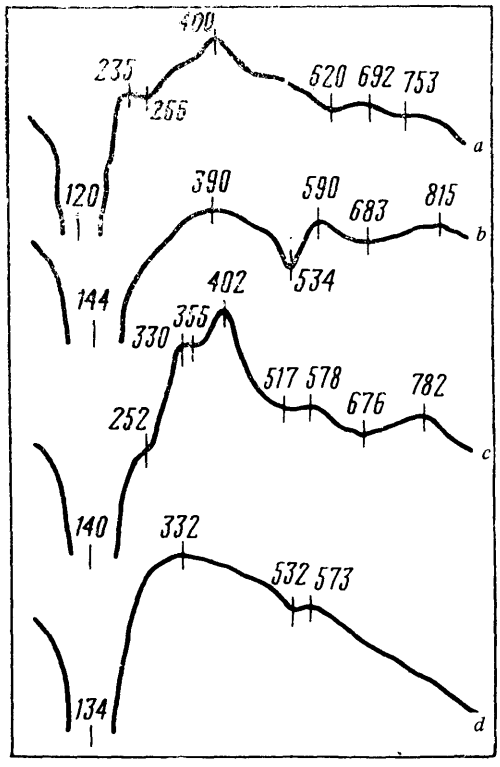

Figure 13. Differential thermal curves of: *a*) xylite; *o*) earthy mass; *c*) vitrinised lignite; *d*) fusinite.

Xylite was subjected to a combined chemical analysis[69,70] to reveal the reason for its caking. Fig. 14 gives differential thermal curves for the debituminised xylite, the residual carbon, and the humic acids liberated. The formation of a caked coke residue from the debituminised xylite (from which 16.2% of bitumens had been isolated) shows that caking is not due to the presence of bitumens. The humic acids yield a well caked crucible coke, whereas the residual coal forms an uncaked coke. This shows that the humic acids are responsible for the tendency of xylite to cake. Extraction of the humic acids leads to fundamental changes in the structure of the organic mass, involving loss of caking power, as is shown by the differential thermal results (*c* and *d* in Fig. 13).

Many investigators in various countries have worked on the use of brown coals to extend the raw-materials base of the coal-tar chemical industry. Our own researches have established the great importance of the age, origin, and previous heat-treatment of brown coals for the physicomechanical properties of the mixed coke[71-76]. A young lignitic coal, a shiny old brown coal, and a bituminous humic–sapropelic coal were used. The results show that replacing a lignitic coal by its semicoke improves the strength of the mixed coke. The best results were given by a semicoke obtained at 400°C, from which 12% of volatiles were isolated (Table 7).

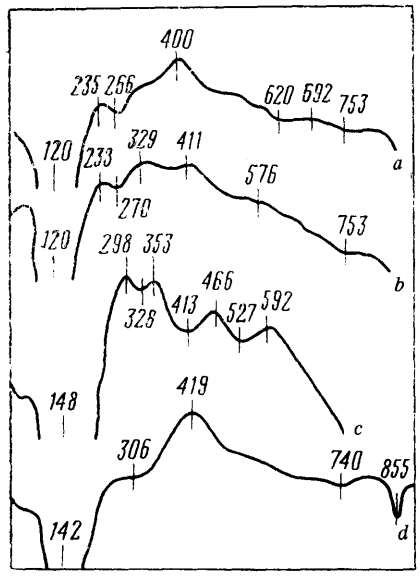

Figure 14. Differential thermal curves of: *a*) initial xylite; *b*) after evolution of bitumens; *c*) humic acids; *d*) isolated humic acids.

Table 7. Effect of semicoking temperature of lignitic coal on plastometric characteristics and strength of coke.

Mixture	Composition, %		Plastometric parameters, mm		Strength of coke, kg cm^{-2}
			x	*y*	
A	Lignites	100	54	0	—
B	Lignites	90	38	0	—
	coke-oven tar	10			
C	Coking coal	100	25	14	107
D	Coking coal	90	12	28	165
	coke-oven tar	10			
E	Coking coal	70

	semicoke from lignite (450°C)	20			
I	Coking coal	70			
	coke-oven tar	10			
	semicoke from lignite (510°C)	20	49	12	320

Analogous investigations with other brown coals[77,78] showed that a stronger mixed coke is formed when the older, bright brown coals are used without the addition of coke-oven tar. If the brown coals are replaced by the semicoke from them, a less stable mixed coke is formed.

When 10% of coke-oven tar is added to the charge, replacement of the coal by the semicoke almost doubles the strength of the mixed coke. A similar rule has been established also for a young lignitic coal. Replacing bituminous humous–sapropelic coals by semicoke produces no significant impairment of the strength of the mixed coke, independently of whether or not the charge contained a coke-oven tar.

Table 8. Physicomechanical characteristics of mixed coke.

Composition of mixture, %				Properties			
coking coal	brown coal	semicoke from brown coal	coke-oven tar	gas permeability Γ	total strength π	abrasion resistance π_{ab}	crushing strength π_{cr}
					kg rev. dm^{-2}		
100	—	—	—	277	19.7	114.0	22.4
young lignitic coal							
80	20	—	—	204	7.4	12.5	14.3
70	20	—	10	211	10.9	19.4	25.0
70	—	20	10	250	30.2	58.0	63.0
old bright brown coal							
80	20	—	—	229	25.9	82.5	3.8
70	20	—	10	271	6.0	197.0	6.2
70	—	20	10	263	18.7	95.0	23.3
bituminous humic-sapropelic brown coal							
80	20	—	—	225	8.3	33.4	11.0
70	20	—	10	278	11.6	58.1	1.5
70	—	20	40	234	7.7	3.8	8.1

The coking of ternary mixtures in a Nikolaev laboratory furnace showed (Table 8) that the addition of 20% of young humic lignites to a coking coal sharply impairs the characteristics of the mixed coke (gas permeability Γ = 204), which cannot be appreciably improved even after the addition of 10% of coke-oven tar (Γ = 211). If semicoke with the same content of oils in the charge is added instead of the lignitic coal, the gas permeability of the mixed coke is considerably increased, reaching 250, while other strength parameters are improved two- to three-fold. The strength characteristics Π and Π_{cr} even exceed the corresponding values for coke obtained from 100% coking coal. A test on the effect of additions of xylitic coal from the Chukurov mine[79] fully confirmed the rule.

If 20% of an older brown coal is added to a coking coal, a mixed coke of very poor physicomechanical characteristics is obtained. However, the quality of the mixed coke can be considerably improved by adding 10% of coke-oven tar, when the gas permeability is changed from 229 to 271, and both the abrasion resistance and the crushing strength are approximately doubled. Replacement of the brown coal by its semicoke leads to some decrease in gas permeability and to increases in total and crushing strengths. A sharp improvement in all the characteristics of the coke is observed if the young humic lignite is replaced by its semicoke.

The addition of 20% of a bituminous humic–sapropelic coal to a coking coal impairs all the physicomechanical characteristics of the mixed coke, and they cannot be improved by the addition even of 10% of coke-oven tar. It is interesting that replacement of this brown coal by its semicoke produces a sharp deterioration both in the gas permeability coefficient and in the strength characteristics of the mixed coke. This confirms the great value of bitumens of humic–sapropelic brown coal in caking. Coke-oven tar pitch, mazut, and vacuum and acid asphalts were also tested as additives[79]. The results showed that bitumens are as important in caking and coking as are brown coal and its semicoke.

7. YIELDS OF CHEMICAL PRODUCTS FROM COAL–PROPERTIES AND STRUCTURE OF COKE

The theoretical investigations of caking and coking enabled formulae to be deduced for calculating the yields of chemical products[80–83] and for predicting the qualitative indices and the physical structure of the resulting coke[84–90]. Examination of the coking of individual types of coals and their mixtures has established graphical relations (Fig. 15) and formulae for calculating the yields of ammonium sulphate, hydrogen sulphide, and pyrogenous water as functions of the contents of nitrogen, sulphur, and oxygen in the original coal[90,91]. Table 9 lists the most important physicochemical and structural indices of the coke obtained in these investigations[92].

Box coking[93,94] has been based on preliminary experiments on the use of Scheffe's simplex-grid plan for predicting the properties of coke. The scheme of experiments is shown in Fig. 16, and the results are listed in Table 10. Mathematical processing of the data on an electronic computer has given the equations below for calculating the most important chemical and structural characteristics of the coke.

1. For the ash (A^c,%)

$$Y_1 = 13.44X_1 + 20.32X_2 + 10.79X_3 + 22.8X_1X_2 + 0.86X_1X_3 + 0.22X_2X_3 + 2.4X_1X_2 \cdot (X_1 - X_2) + 4.2X_1X_3(X_1 - X_3) - 0.13X_2X_3(X_2 - X_3) - 8.8X_1X_2 \times (X_1 - X_2)^2 - 6.2X_1X_3(X_1 - X_3)^2 + 12.9X_2X_3(X_2 - X_3)^2 + 92.8X_1^2X_2X_3 + 47.1X_2X_3 - 1.7X_3X_2^2.$$

2. For the total sulphur in the coke (A^a, total %)

$$Y_2 = 1.03X_1 + 1.87X_2 + 2.16X_3 - 0.08X_1X_2 - 0.14X_1X_3 - 0.06X_2X_3 - 1.01X_1X_2(X_1 - X_2) + 0.08X_1X_3(X_1 - X_3) - 0.93X_2X_3(X_2 - X_3) + 1.49X_1X_2 \times (X_1 - X_2)^2 - 1.47X_1X_3(X_1 - X_3)^2 + 9.52X_1^2X_2X_3 + 0.88X_2X_3(X_2 - X_3)^2 - 3.92X_1X_2^2X_3 (8; 38X_1X_2X_3^2).$$

3. For M_{40} in micuum drum

$$Y_3 = 67.0X_1 + 50.0X_2 + 77.0X_3 + 8.0X_1X_2 + 12.8X_1X_3 + 48.0X_2X_3 + 34.7X_1X_2 \times (X_1 - X_2) - 12.8X_1X_3(X_1 - X_3) - 1.1X_2X_3(X_2 - X_3) + 10.7X_1X_2(X_1 - X_2)^2 - 49.1X_1X_3(X_1 - X_3)^2 - 13.9X_2X_3(X_2 - X_3)^2 - 462.5X_1^2X_2X_3 + 635X_1X_2^2X_3 + 54.8X_1X_2X_3^2.$$

4. For M_{10} in micuum drum

$$Y_4 = 8.0X_1 + 43.8X_2 + 8.3X_3 - 15.2X_1X_2 + X_1X_3 + 69.0X_2X_3 - 9.6X_1X_2 \times (X_1 - X_2) + 18.9X_1X_3(X_1 - X_3) - 16.2X_2X_3(X_2 - X_3) + 43.2X_1X_2(X_1 - X_2)^2 + 46.1X_1X_3(X_1 - X_3)^2 + 56.3X_2X_3(X_2 - X_3)^2 + 262.1X_1^2X_2X_3 - 320.1X_1X_2^2X_3 + 55.4X_1X_2X_3^2.$$

5. For the structural strength

$$Y_5 = 79.8X_1 + 68.4X_2 + 80.1X_3 + 5.4X_1X_2 - 2.4X_1X_2 + 32.2X_2X_3 + 89.6X_1X_2 \times (X_1 - X_2) - 2.9X_1X_3 - X_3 - 14.1X_2X_3(X_2 - X_3) - 258.1X_1X_2(X_1 - X_2)^2 + 4.0X_1X_3(X_1 - X_3)^2 - 96.8X_2X_3(X_2 - X_3)^2 + 354.3X_1^2X_2X_3 - 66.6X_1X_2^2X_3 - 186.3X_1X_2X_3^2.$$

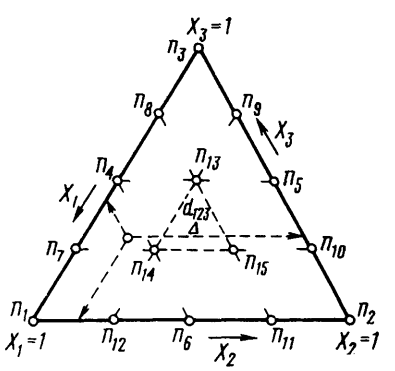

Figure 16. Plan of box experiments used to obtain a fourth-power model.

The equations were checked for five points in Fig. 16: one of the points lies at the centre of the diagram ($X_1 = X_2 = X_3 = 0.333$), while the others correspond to the compositions of the coal charges which are promising for the by-product coke plant at the Kremikovtsy mining complex. Values calculated for M_{40} by means of Eqn. Y_3 differ from the experimental values by ±1.5%, and those for M_{10} (from Eqn. Y_4) by ±1.0% (absolute). Very good agreement was obtained also for the ash, total sulphur, and structural strength.

Table 10. Results of planned experiments.

Advances in the Synthetic Chemistry of Aminoglycosides

S.E.Zurabyan and A.Ya.Khorlin

Data on the methods for the formation of the aminoglycosidic linkage in the synthesis of alkyl and aryl aminoglycosides and oligosaccharides containing 2-amino-2-deoxyglycosyl residues are reviewed systematically.
The bibliography includes 229 references.

I. INTRODUCTION

Aminosugars and in the first place 2-amino-2-deoxyhexoses play a significant role in vital processes, being important structural components of polysaccharides and mixed biopolymers. The central problem of the chemistry of biopolymers containing aminosugar residues is that of the nature of the chemical bond joining the monomeric units of the macromolecules. Since the aminosugar residues in polysaccharides and other carbohydrate-containing polymers are as a rule linked by the aminoglycosidic linkage, the development of methods for its formation and the study of its properties constitute the most important problem in the chemistry of aminosugars.

The present review deals with methods of synthesis of aminoglycosides, including the formation of a new aminoglycosidic linkage, but not with the chemical reactions of glycosides and oligosaccharides without the formation of glycosidic linkages. The methods for the formation of the aminoglycosidic linkage are considered from the standpoint of the main requirements which must be met by glycoside synthesis in general, namely (1) the reaction must be structurally specific and stereospecific, (2) in view of the lability of the protecting groups for the "aglycone" component, the reaction must proceed under fairly mild conditions, and (3) the protecting groups of the glycosylating agent must be fairly stable under the conditions of the glycosylation reaction and at the same time must be removed easily and selectively from the final products without alteration of their structure.

From the chemical point of view, the synthesis of the glycosides of 2-amino-2-deoxysugars is of special interest, since it exhibits many important differences from glycoside synthesis with neutral sugars and other aminosugars. These differences are due to the location of the amino-group in the immediate vicinity to the glycosidic centre.

We have surveyed the studies in which the foundations were laid for the method of synthesising aminoglycosides, their reactions were investigated, or significant improvements were introduced into methods already known. Attention was concentrated on the synthesis of acetamidoglycosides, including oligosaccharides containing acetamidoglycoside residues, since in most cases aminosugars are encountered in nature as *N*-acetyl derivatives.

The problems of aminoglycoside synthesis were considered in previous reviews[1-3], but the intense development of this branch of carbohydrate chemistry, particularly the synthetic chemistry of aminosugar oligosaccharides, led us to write the present review, which covers the literature up to the middle of 1973.

II. THE SYNTHESIS OF ALKYL AND ARYL AMINOGLYCOSIDES

1. Alcoholysis of Monosaccharides

Fischer's method, which is widely used in the synthesis of alkyl glycosides of neutral sugars, is sometimes employed to obtain mixtures of anomeric glycosides of *N*-protected 2-amino-2-deoxysugars. Thus treatment of *N*-acetyl-*D*-glucosamine with alcohols in the presence of hydrogen chloride, toluene-*p*-sulphonic acid, ion-exchange resins in the H^+-form, or Lewis acids[4-13] leads to a mixture of alkyl 2-acetamido-2-deoxy-α-*D*-glucopyranosides and the corresponding β-*D*-glucopyranosides in which the α-anomers predominate. Glycosylation of benzyl alcohol with *N*-acetyl-*D*-glucosamine also leads to a mixture of anomeric glycosides from which benzyl 2-acetamido-2-deoxy-α-*D*-glucopyranoside, used in the synthesis of many 2-amino-2-deoxysugar derivatives, was isolated[14-16]. Treatment of *N*-acetyl-*D*-galactosamine (or its acetate) by lower alcohols gives analogous results[11,17-19]. Since, regardless of the nature of the aglycone, aminogalactosides are formed under the same conditions as aminoglucosides, special attention will not henceforth be devoted to their synthesis.

2-Amino-2-deoxysugars with a free amino-group do not form glycosides under the conditions of the Fischer synthesis in consequence of the electrostatic repulsion of cationic groups from the glycosidic centre by the NH_3^+ group[4].

2. The Helferich Synthesis of Aryl Aminoglycosides

The Helferich method (see the review of Conchie et al.[20]), which consists of fusing together peracetylated aminosugars with phenols in the presence of catalytic

amounts of toluene-*p*-sulphonic acid or zinc chloride, has been used in the synthesis of aryl aminoglycosides[20-25]. Toluene-*p*-sulphonic acid catalyses the preferential formation of 1,2-*trans*-aminoglycosides, while in the presence of zinc chloride a mixture of anomeric aryl aminoglycosides is formed. This method is relatively unsuitable for the synthesis of aminoglycosides with an aglycone having a complex structure and particularly for the glycosylation of labile compounds.

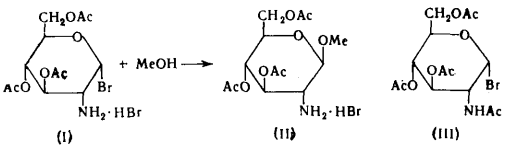
3. The Action of Alkylating Agents

N-Acetyl-D-glucosamine (or its acetate) reacts with methyl iodide in dimethylformamide (DMF) in the presence of barium oxide and hydroxide and is converted into methyl 2-acetamido-3,4,6-tri-*O*-methyl-2-deoxy-β-D-glucopyranoside[26]. When derivatives of *N*-acetyl-D-glucosamine are alkylated with dimethyl sulphate, derivatives of both α- and β-D-glycosides are formed, depending on the reaction conditions[27,28]. A very mild alkylation method was proposed by Kuhn and Baer[29], involving the treatment of *N*-acetyl-D-glycosamine and also its *N*-formyl and *N*-benzyloxycarbonyl analogues with diazomethane in aqueous methanol, which leads to methyl β-D-glycosides. The methods quoted here are specific and their preparative value is apparently small.

III. THE KOENIGS–KNORR REACTION AND ITS MODIFICATIONS IN THE SYNTHESIS OF AMINOGLYCOSIDES

1. Acylhalogeno-derivatives of Aminosugars in the Koenigs–Knorr Reaction

The Koenigs–Knorr reaction (see reviews[20,30,31]), which is based on the reaction of acylhalogenosugars with alcohols and phenols in the presence of hydrogen halide acceptors, has found extensive applications also in the synthesis of aminoglycosides. (The information about acylhalogenosugars of the 2-amino-2-deoxysugar series accumulated at the present time is summarised in Table 1.) As early as 1911, it was shown[32] that the hydrobromide of 2-amino-3,4,6-tri-*O*-acetyl-2-deoxy-α-D-glucopyranosyl bromide (I) is converted into the glycoside hydrobromide (II) on reaction with methanol:

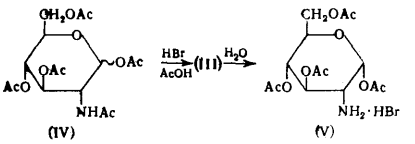


(I) (II) (III)

However, the bromides of fully acetylated 2-amino-2-deoxysugars differ significantly from the bromides of the corresponding neutral analogues[31], and for this reason the structures and properties of the acylated bromides and chlorides of 2-amino-2-deoxysugars must be specially considered.

The bromide (I) and the corresponding chloride are quite stable and resemble the acylhalogeno-derivatives of neutral hexopyranoses. Compared with tetra-*O*-acetyl-α-D-glucopyranosyl bromide, the bromide of the acetylated D-glucosamine (III) is significantly more reactive. The explanation is that in the heterolysis of the C–Br bond the acetamide group at 2-C is more involved in the formation of a stable intramolecular cyclic derivative with the 1-C atom than the acetoxy-group at 2-C in the D-glucose derivative. The reactivity can be reduced (and hence the stability and the acylhalogeno-derivatives increased) by increasing the electronegativity of the substituents in the acylamino-group.

The extreme sensitivity of the bromide (III) to moisture remained for a long time an obstacle to its isolation in a pure state. When hydrogen bromide in acetic acid was allowed to react with the acetate (IV), the expected bromide (III) was not obtained[4]; instead, as shown subsequently[33-35], the hydrobromide (V) was isolated:

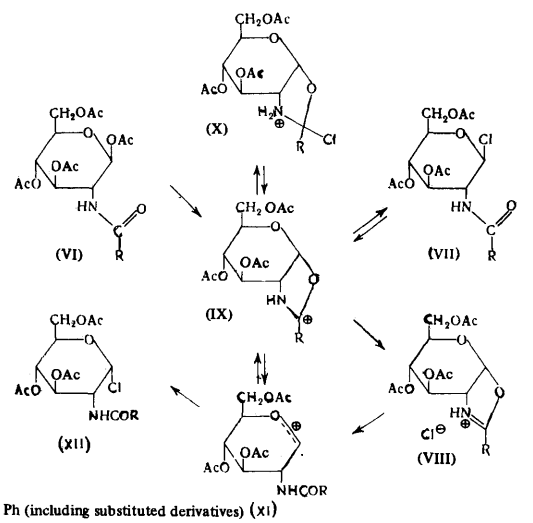


(IV) (V)

However, the bromide (III), formed in this reaction, and also the bromide of the D-galacto-series obtained under similar conditions[19], were used without purification in aminoglycoside synthesis, as will be described below. The bromide (III) was obtained much later in a pure state by treating the acetate (IV) with a limited amount of hydrogen bromide in acetic acid, taking precautions to prevent contact of the product with moisture[36] (cf. Fodor and Ötvös[37]).

Osawa[38] characterised in detail the processes occurring when hydrogen chloride, titanium tetrachloride, or aluminium chloride are allowed to act on 1,2-*trans*-acetylated derivatives of 2-amino-2-deoxysugars (VI). Initially the acetoxy-group at 1-C is eliminated rapidly with participation of the adjoining acylamino-group, which leads to the unstable β-D-glycosyl halide (VII). In this stage the *N*-aroyl derivative is rapidly stabilised as the result of the formation of a salt of the oxazoline derivative (VIII) in which the C=N bond is conjugated with the aromatic ring. If R is an alkyl group, the intermediate cation (IX) formed can react with hydrogen halide to form the oxazolidinium cation (X). Powerful electronegative acyl residues such as *p*-nitrobenzoyl or chloroacetyl favour the rapid formation of the oxonium ion (XI)—the direct precursor of the α-D-glycosyl halide (XII) (see Scheme 1). The mixture of anomeric acetates reacts with hydrogen bromide in acetic acid in a more complex manner[36].

Scheme 1



(VI) (VII) (VIII) (IX) (X) (XII)

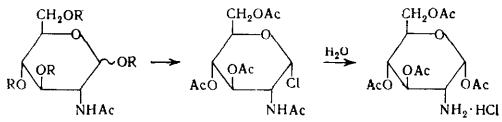
R = Me or Ph (including substituted derivatives) (XI)

The stability of the acylated bromides of 2-amino-2-deoxysugars can be enhanced not only by the introduction of electronegative substituents into the acylamino-group but also by the introduction of aryl or arylalkylidene substituents at the amino-group of the 2-amino-2-deoxysugars, since such groups at 2-C are incapable of forming the intermediate cyclic cation. *O*-Acylated α-D-glycosyl bromides were obtained in this way with the following *N*-protecting groups: benzoyl[39,40], toluene-*p*-sulphonyl[41,42], phenylmethanesulphonyl[43], 2,4-dinitrophenyl[44-46], diphenylphosphoryl[47], anisylidene[47], benzyloxycarbonyl[47], trifluoroacetyl[48,49], dichloroacetyl[50-52], and certain others[47,49,53-58]. These compounds were subsequently used in the synthesis of aminoglycosides.

The stability of acylhalogeno-derivatives of the 2-amino-2-deoxysugar series depends also on the nature of the halogen atom and increases in the sequence Br < Cl < F. Iodides are still unknown and fluorides are so inactive that they can be deacetylated in the presence of sodium methoxide with retention of the C–F linkage[42].

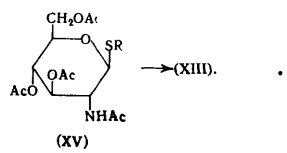
Among aminosugar chlorides, the greatest interest attaches to the peracetylated 2-amino-2-deoxy-α-D-glycosyl chlorides formed when 2-acetamido-2-deoxysugars (or their acetates) are treated with hydrogen chloride[34,54,59-62], acetyl chloride[63,64], both hydrogen chloride and acetyl chloride[65], and titanium tetrachloride[19,33,34]. The chlorides of *N*-acetylated aminosugar di- and tri-saccharides were also obtained by these methods[62,65,66].

The chloride (XIII) is fairly stable and is only slowly converted into the hydrochloride (XIV), which permits its isolation even when moist solvents are employed[33,34,38]:



R = H or Ac (XIII) (XIV)

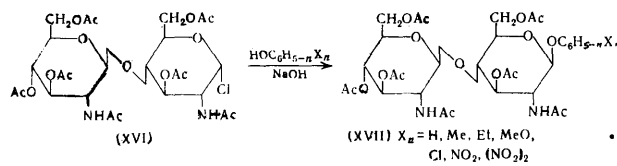
Another method for the synthesis of acetylated aminoglycosyl chlorides[67], including furanosyl chlorides[68], consists of the chlorination of *S*-substituted 1-thioanalogues (XV, R = Et, CSOEt, COMe) (cf. Bonner[69]), for example:



However, from the preparative point of view this method can hardly compete with that discussed above.

The use of the stable bromide (I) in the synthesis of aminoglycosides is restricted to the formation of glycosides from lower alcohols[32] and certain phenols[70] owing to the low solubility of (I) in solvents used in the Koenigs–Knorr reaction. When unstable bromides of acetylated aminosugars (which have as a rule not been isolated in a pure state) or stable but insufficiently reactive chlorides were used, 2-acetamido-2-deoxy-β-D-glucopyranosides and the corresponding β-D-galactopyranosides derived from lower alcohols[19,34,60,63,71,72], phenols[34,60,65,73-77], and monoterpene[78,79], steroid[80], and certain other alcohols[59,81,82] were obtained. Different monofunctional hydroxy-compounds have been glycosylated by bromides with other *N*-protecting groups[38-48,55-57,83-92]. Although the yields of the desired products increased in such cases, the employment of bromides in which the substituents at 2-C are not involved in the reaction led in a number of instances[45,89,92] to a mixture of anomeric glycosides.

The stereospecificity of the glycosylation is apparently a key problem of glycoside synthesis. The isolation of a particular anomer from the reaction mixture (which is frequently very complex, particularly in the case of glycosides with an aglycone having a complicated structure) does not alone demonstrate the stereospecificity of the reaction. Since an answer to this question can be obtained only by a detailed analysis of all the reaction products, the data on the stereospecificity of glycosylation must be treated with caution.



To obtain alkyl or aryl glycosides derived from oligosaccharides containing 2-acetamido-2-deoxy-β-D-glucopyranosyl residues at the reducing end, the Koenigs–Knorr method[62,72] or its modifications were also used. When the disaccharide chloride (XVI) was allowed to react with phenols, aryl β-chitobioside acetates (XVII) were obtained[65,66,93-98].

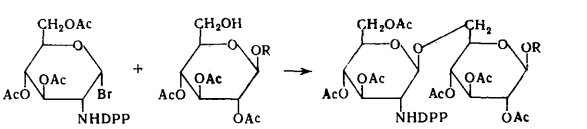
c With decomposition.

2. Synthetic Oligosaccharides†

Among the known methods for the synthesis of di- and oligo-saccharides the only ones available for oligosaccharides with 2-acetamido-2-deoxyglycopyranosyl residues remained for a long time those based on the Koenigs–Knorr reaction and its various modifications. When a freshly prepared solution of the bromide (III)[33] or its *N*-benzoyl analogue (XVIII) was allowed to react with partly substituted derivatives of D-glucose (XIX)[97,98], D-galactose (XX)[97], *N*-acetyl-D-glucosamine (XXI, R′ = acetyl or *p*-nitrophenyl)[93,99], and *N*-acetylmuramic acid (XXII)[12,100–102] under the conditions of the Koenigs–Knorr reaction, a number of disaccharide derivatives (XXIII)–(XXXI) with β-(1→6)-aminoglycosidic linkages between the monosaccharide units were synthesised. The employment of the bromide (III) resulted in a low yield also of the acetate of the non-reducing disaccharide 2,2′-diamino-2,2′-dideoxy-ββ-trehalose[33].

It is noteworthy that in all cases the yield of the desired compounds was significantly lower than in the glycosylation of the same (or similar) aglycone components of the acylhalogeno-derivatives of neutral sugars by the Koenigs–Knorr reaction.

In connection with the high lability of the bromide (III), which is the cause of the low yields of the disaccharide derivatives (XXIII)–(XXXI) (see Scheme 2), subsequently more stable glycosyl halides were used in the synthesis of disaccharides. Zervas and Konstas[47] were the first to use the stable bromide (XXXII) in the synthesis of disaccharides and, when the reaction was carried out in the presence of mercury cyanide, they obtained the protected disaccharide (XXXIV) in 60% yield. An analogous disaccharide derivative (XXXV) was synthesised subsequently[103] with the same yield by the glycosylation of (XXXIII):



(XXXII) DPP = P(O)(OPh)$_2$ (XIX, R = Ac) (XXXIII, R = CH_2Ph) (XXXIV, R = Ac) (XXXV, R = CH_2Ph)

† See Table 2, where the available information about synthetic oligosaccharides and their derivatives is summarised.

Table 2 continued...

[a] The following abbreviations not indicated in Ref. 225 were used: Xyl = D-xylose, GlcN = D-glucosamine, GlcNAc = *N*-acetyl-D-glucosamine, GalNAc = *N*-acetyl-D-galactosamine, ManN = D-mannosamine, MurNAc = *N*-acetylmuramic acid, TalN = D-talosamine, and 3-NH_2-3-deGlc = 3-amino-3-deoxy-D-glucose.

[b] E = enzymatic synthesis, K = Koenigs–Knorr reaction and its modifications, N = nitrosochloride method[174,176], and Z = oxazoline method. The yields are quoted only for the glycosylation stages.

[c] In the reduction stage of the corresponding hydroxyimino-derivative.

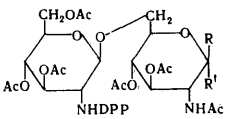
[d] Softening temperature.

[e] Solvated by ethanol.

[f] Obtained by the acid reversion of *N*-acetyl-D-glucosamine.

[g] Including the stage involving the removal of protecting groups.

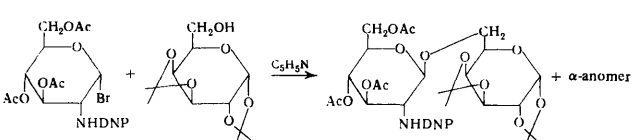
Satisfactory results in the glycosylation stage were achieved[104] when the bromide (XXXII) was allowed to react with the partly protected *N*-acetyl-D-glucosamine derivatives with a free hydroxy-group at 6-C. The yield of the glycosylation products (XXXVI) and (XXXVII) was 41–65%:



(XXXVI, R = OAc, R′ = H)
(XXXVII, R = H, R′ = OCH_2Ph)

The diphenylphosphoryl group is removed either by catalytic hydrogenation in the presence of platinum[47] or (less effectively) by alkaline hydrolysis[103].

When the bromide (XXXVIII) reacts with 1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose (XXXIX), the glycosylation is non-stereospecific and depends on the nature of the solvent and the hydrogen bromide acceptor[105,106]. As in the synthesis of alkyl aminoglycosides from the bromide (XXXVIII)[89], in the presence of pyridine the α-anomer is formed preferentially (30%) and only 15% of the β-linked disaccharide (XL) is produced. When the reaction was carried out in the presence of silver carbonate, only the β-anomer (XL) was isolated in 29% yield. The dinitrophenyl group was removed by treatment with anion-exchange resins in the basic form[46]:

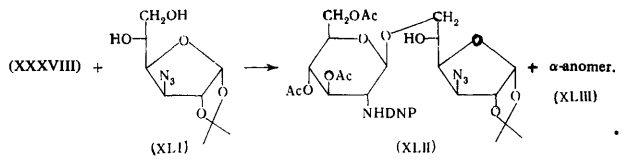


(XXXVIII) (XXXIX) (XL)

DNP = 2,4-dinitrophenyl

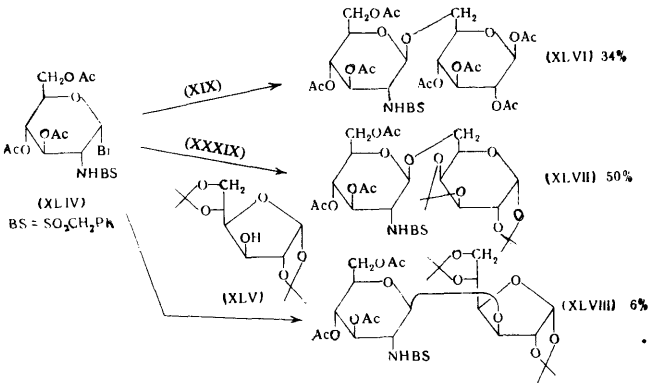
The glycosylation of compound (XLI) with the bromide (XXXVIII) in the presence of mercury salts also led[107] to a mixture of anomeric disaccharide derivatives (XLII) and (XLIII) with an overall yield of 50%, the anomers being formed in proportions of 1 : 3. On the other hand, when

compound (XLI) was glycosylated with 3,4,6-tri-*O*-acetyl-2-deoxy-2-trifluoroacetamido-α-D-glucopyranosyl bromide in the presence of mercury cyanide, only one disaccharide, analogous to (XLII), was isolated:



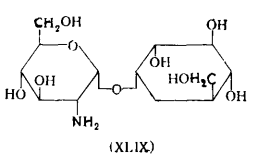
The use of the bromide (XLIV) as the glycosylating agent in the Koenigs–Knorr reaction has been described[43]. The disaccharide derivatives (XLVI)–(XLVIII), in which the phenylmethanesulphonyl group was removed by catalytic hydrogenation in the presence of Raney nickel, were obtained (Scheme 3).

Scheme 3



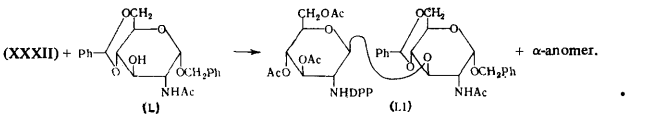
Thus the examples of the synthesis of disaccharides with the (1→6)-linkage already demonstrated the advantage of stable glycosyl bromides with electronegative and other substituents in the amino-group, which consists of a significant increase of the yield of the glycosylation products. However, the preparative value of this procedure was at the same time reduced by the large number of stages involved, particularly in the synthesis of *N*-acetylated disaccharide analogues and in many cases by the loss of stereospecificity in the glycosylation reaction.

Among the few synthetic non-reducing disaccharides containing 2-amino-2-deoxysugar moieties, mention should be made of trehalosamine (XLIX) obtained[108] by the reaction of 3,4,6-tri-*O*-acetyl-2-deoxy-2-(*p*-methoxybenzylideneamino)-α-D-glucopyranosyl bromide with 2,3,4,6-tetra-*O*-benzyl-D-glucopyranose in 18% yield after the removal of protecting groups.

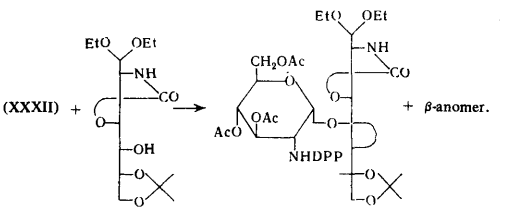


In the glycosylation of secondary hydroxy-groups of sugars difficulties arose for a long time not only because of the lack of effective glycosylating agents in the amino-sugar series but also owing to the limited choice of "aglycone" components with sufficiently reactive functionable groups capable of being glycosylated. This problem was solved, on the one hand, by employing stable bromides as the glycosylating agents. On the other hand, "aglycone" components derived from pyranose[51,109–113] and acyclic[114–116] forms of monosaccharides, in which the hydroxy-groups, particularly at 4-C, are more reactive than in the pyranose form in the 1-C conformation, were proposed recently in a number of studies.

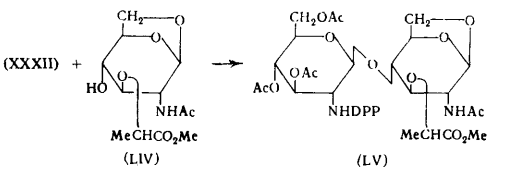
A mixture of protected disaccharides with β-(1→3)-[compound (LI)] and α-(1→3)-aminoglucosidic linkages and containing about 85% of (LI) was obtained in 31% yield by the condensation of the bromide (XXXII) with the benzylidene derivative (L)[115,117]:



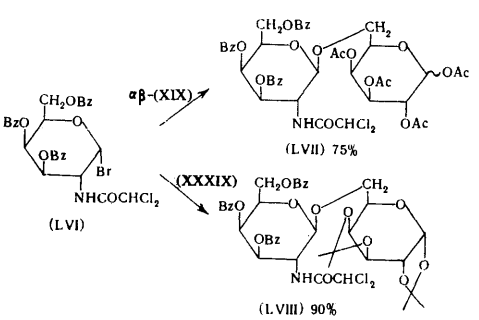
A mixture of anomers derived from disaccharides with α-(1→4)-[compound (LIII)] and β-(1→4)-glycosidic linkages was obtained similarly, in yields of 35 and 10% respectively, from the bromide (XXXII) and the acetal (LII)[115,116]:



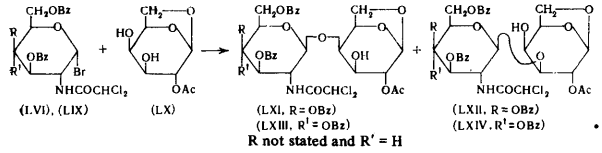
However, Merser and Sinaÿ[113] (cf. Iwamoto and Ymanaga[103] and Bundle and Shaw[104]) failed to observe the formation of a disaccharide with an α-linkage in the glycosylation of the anhydro-derivative (LIV) by the bromide (XXXII) and isolated in 15% yield the protected disaccharide (LV):



The synthesis of di- and oligo-saccharides, which form part of the carbohydrate determinants of glycoproteins and gangliosides and which contain 2-acetamido-2-deoxy-β-D-galactopyranosyl residues, was achieved recently using the reactive and relatively stable bromide (LVI)[50,52]. This version of the Koenigs–Knorr reaction leads to derivatives (LVII) and (LVIII) with a β-glycosidic linkage and with only traces of α-anomers according to infrared spectroscopic data[52]:



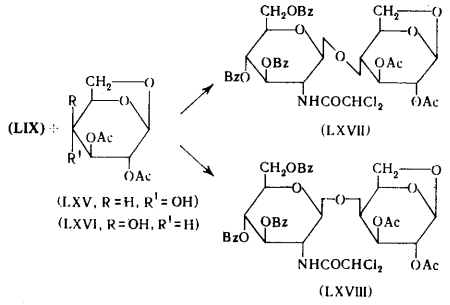
The bromide (LVI) and its D-gluco-analogue (LIX) react with the 1,6-anhydrosugar (LX) to form mixtures of isomeric disaccharide derivatives with β-(1→4)-[compounds (LXI) and (LXIII)] and β-(1→3)-glycosidic linkages [compounds (LXII) and (LXIV)] in overall yields of 45 and 47% respectively[51,118]. In both cases the isomer ratios (LXI) : (LXII) and (LXIII) : (LXIV) were close to 3 : 2. The glycosylation products (LXI) and (LXII) were separated chromatographically. In another instance the product (LXIII) was isolated from the mixture after the degradation of the (1→3)-isomer under mild alkaline conditions.



(LVI), (LIX) (LX) (LXI, R = OBz) (LXIII, R' = OBz) (LXII, R = OBz) (LXIV, R' = OBz)

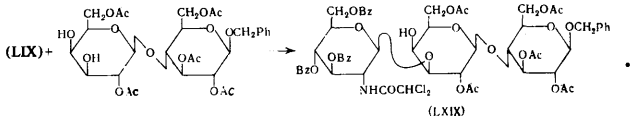
R not stated and R' = H

It is interesting to note that the glycosylation of the 2,3-di-*O*-acetates of the 1,6-anhydrosugars (LXV) and (LXVI) leads under the same conditions[51,110] to the disaccharide derivatives (LXVII) and (LXIII) in yields of only 9–10%. However, the glycosylation of the anhydride (LXV) or its analogue 1,6-anhydro-2-acetamido-3-*O*-acetyl-2-deoxy-β-D-glucopyranose with acylhalogeno-derivatives of neutral sugars is much more effective, leading to derivatives of lactose, *N*-acetyl-lactosamine, and *N*-acetylcellobiosamine in yields of 50–80%.[109,112]



(LIX) + (LXV, R = H, R' = OH) (LXVI, R = OH, R' = H) (LXVII) (LXVIII)

The same group of workers[119] achieved the synthesis of the protected trisaccharide (LXIX) in 19% yield:

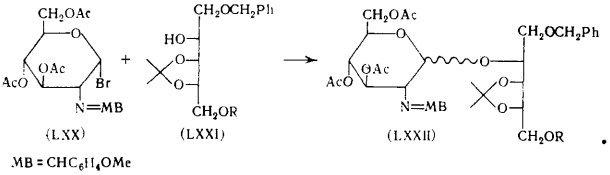


(LIX) + (LXIX)

The most convenient method for the conversion of the *N*-dichloroacetyl group into the *N*-acetyl group proved to be catalytic hydrogenation in the presence of palladium. Another procedure, involving the hydrolysis of the *N*-dichloroacetyl group to the amino-group by barium hydroxide with subsequent *N*-acetylation, is suitable only for derivatives with the β-(1→4)-aminoglycosidic linkage [for example, compounds (LXI) and (LXIII)], since the β-(1→3)-aminoglycosidic linkage in compounds (LXII) and (LXIV) is cleaved even by the action of sodium methoxide in methanol. This finding can be explained by the high electronegativity of the dichloroacetyl group, which withdraws electrons from the glycosidic centre, and this in turn facilitates the degradation of the β-(1→3)-isomer via the β-elimination mechanism.

3. Glycosylation of Polyols and Hydroxyaminoacids

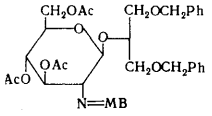
The products of the glycosylation of polyols and hydroxyaminoacids are interesting as model compounds for the investigation of the properties of glycolipids and glycoproteins. Derivatives of 2-amino-2-deoxy-D-glucopyranosyl-D-ribitol and the corresponding glycerol derivative were obtained by the Koenigs–Knorr reaction from glycosyl bromides and partly protected polyols. The glycosylation of D-ribitol derivatives (LXXI, R = CPh_3 or COPh) by the bromide (LXX) in the presence of silver carbonate led to a 15% yield of a mixture of the anomeric aminoglycosides (LXXII, R = CPh_3 or COPh), in which the α-anomers predominated[90]:



(LXX) (LXXI) (LXXII)

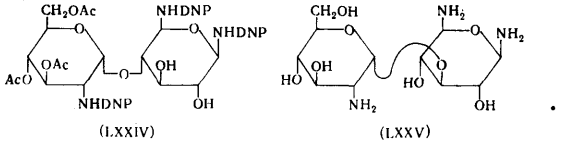
MB = CHC_6H_4OMe

The reaction of the bromide (LXX) with 1,3-di-*O*-benzylglycerol led to the formation under the same conditions[120] of the aminoglucoside (LXXIII) and its α-anomer in proportions of 1 : 0.39 and in an overall yield of 25%. In the glycosylation of 1,3-di-*O*-benzylglycerol with the bromide (XXXII) in the presence of mercury cyanide only the β-anomer, analogous to (LXXIII), was isolated in 55% yield[120].



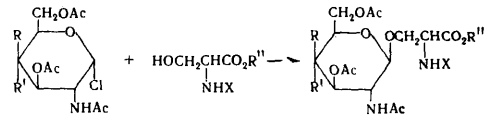
(LXXIII)

The employment of the bromide (XXXVIII) in the glycosylation of di-*N*-protected 2-deoxystreptamine resulted in the formation of a mixture of glycosides from which the isomer (LXXIV) was isolated in a low yield[121–123]. The related compound (LXXV) was also synthesised[124].



(LXXIV) (LXXV)

The Koenigs–Knorr reaction served for a long time as the main method for the synthesis of 2-acetamido-2-deoxyglycosides derived from hydroxyaminoacids. The condensation of the chloride (XIII) or its D-galacto-analogue (LXXVI) with esters of *N*-benzyloxycarbonyl- or *N*-(2,4-dinitrophenyl)-L-serine in the presence of silver carbonate or mercury cyanide led to the formation of the corresponding β-aminoglycosides [LXXVII, R and R' = H or OCOMe, R'' = Me or CH_2Ph, X = $COOCH_2Ph$ or 2,4-$(NO_2)_2.C_6H_3$] in yields up to 49%.[125–128] The glycosylation of the amide of *N*-benzyloxycarbonyl-DL-threonine with the chloride (XIII) was achieved under the same conditions[129]. It is noteworthy that the isolation of the glycosylation products is fairly laborious in many cases.

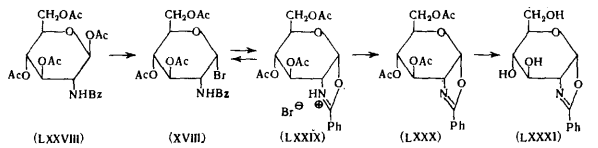


(XIII) or (LXXVI) (LXXVII)

Thus, despite the large number of studies enumerated above in which the classical version of the Koenigs–Knorr reaction or its modifications were employed, there have been virtually no systematic studies on the glycosylation by this method of partly protected saccharides and other "aglycone" components with a complex structure. Therefore, although the method can be regarded as fairly thoroughly developed, it is necessary to find special reaction conditions in each specific instance.

IV. 2-SUBSTITUTED GLYCO[2′,1′:4,5]-2-OXAZOLINES

The oxazoline derivatives of hexopyranoses, which are aza-analogues of sugar orthoesters, have been known for a long time as compounds obtained as side products when hydrogen bromide is allowed to react with acylated 2-amino-2-deoxysugars. The "oxazoline" derivative described by White[130] (cf. Micheel et al.[35]) was shown subsequently[34,131,132] to be 2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-D-glucopyranose. Micheel and coworkers[63,133] succeeded for the first time in isolating the hydrobromide of 2-phenyl-(3,4,6-tri-*O*-acetyl-1,2-dideoxy-α-D-glucopyrano)[2′,1′:4,5]-2-oxazoline (LXXIX), formed when the *N*-benzoate (LXXVIII) is treated with hydrogen bromide in acetic acid. The bromide (XVIII) formed initially is rapidly converted into the oxazoline derivative (LXXIX):

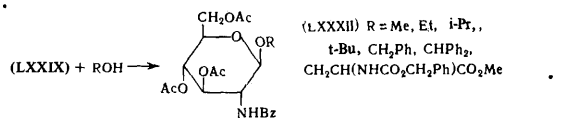


(LXXVIII) (XVIII) (LXXIX) (LXXX) (LXXXI)

Later it was established[134] that this process is reversible and that the equilibrium depends to a large extent on the solvent [as for the *O*-benzoylated analogue of the bromide (XVIII)]. In the instances described the α-chloride does not give rise to the oxazoline derivative[135]. It follows from Osawa's data[38] (see Scheme 1) that oxazoline derivatives are intermediates in the synthesis of *O*-acetylated 2-aroylamino-2-deoxy-α-D-glucopyranosyl chlorides from the corresponding β-acetates. After the acetates have been treated briefly with aluminium chloride or titanium tetrachloride in chloroform and also with hydrogen chloride in acetic anhydride, 2-arylgluco[2′,1′:4,5]-2-oxazolines were obtained in yields up to 75%; with increase of reaction time, the yield of the oxazoline derivatives fell and that of the α-chlorides increased.

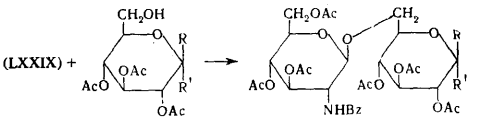
On treatment with pyridine, the hydrobromide (LXXIX) is converted into the free base (LXXX), which can be deacetylated to the oxazoline (LXXXI) without the rupture of the heterocyclic ring[135].

The oxazoline derivatives (LXXIX) and (LXXX) proved to be effective glycosylating agents in the synthesis of 1,2-*trans*-2-benzamido-2-deoxy-D-glucopyranosides. The reaction of compound (LXXIX) with primary, secondary, and tertiary alcohols and also with the methyl ester of *N*-benzyloxycarbonyl-L(D or DL)-serine in the presence of silver carbonate gave a 37–73% yield of the acetates of 2-benzamido-2-deoxy-β-D-glucopyranosides (LXXXII)[133,135,136]:



(LXXXII) R = Me, Et, i-Pr, t-Bu, CH_2Ph, $CHPh_2$, $CH_2CH(NHCO_2CH_2Ph)CO_2Me$

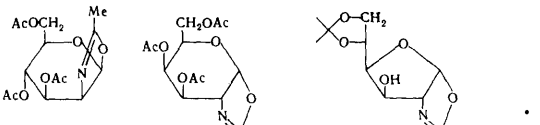
The possibility of using the oxazoline derivatives of sugars in the synthesis of disaccharides with 2-benzamido-2-deoxy-β-D-glucopyranosyl residues, for example (LXXXIV) and (LXXXV), was demonstrated for the first time in the reaction of the oxazoline (LXXIX) with glucose tetra-acetate (XIX) and the glucoside tri-acetate (LXXXIII)[137]:



(XIX, R = OAc) (LXXXIII, R′ = OMe) (LXXXIV, R = OAc), 55% (LXXXV, R′ = OMe), 51% R not specified and R′ = H

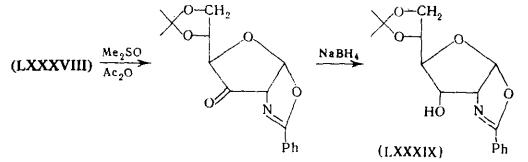
Despite the initial successes in the employment of oxazoline derivatives of sugars in the synthesis of *N*-benzoylaminoglucosides the development of the oxazoline method for the formation of the 1,2-*trans*-aminoglycosidic linkage was held back by the lack of reliable and general methods for the synthesis of the glycosylating agents themselves and in the first place of 2-methylglyco[2′,1′:4,5]-2-oxazolines which would open the way to glycosides and oligosaccharides containing 2-acetamido-2-deoxy-β-D-hexopyranosyl residues. The existing methods for the synthesis of oxazoline derivatives of sugars remained non-general for a long time.

A 2-methyl-substituted oxazoline of the D-manno-series (LXXXVI) was obtained by treating acetylated D-mannosamine with hydrogen bromide in acetic acid[133]. Fletcher and coworkers[138] observed the formation of the oxazoline (LXXXVI) and its D-galacto-analogue (LXXXVII), in yields of 11 and 26% respectively, as side products in the acetylation of *N*-acetyl-D-mannosamine and *N*-acetyl-D-galactosamine with acetic anhydride in the presence of a large amount of zinc chloride.



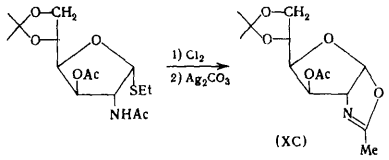
(LXXXVI) (LXXXVII) (LXXXVIII)

The oxazoline derivative of D-glucofuranose (LXXXVIII) was obtained by treating *N*-benzoyl-D-glucosamine with acetone in the presence of hydrogen chloride[139–141]. The oxazoline (LXXXVIII) was converted into the corresponding analogue of the D-allo-series (LXXXIX) by epimerisation at 3-C[142]:



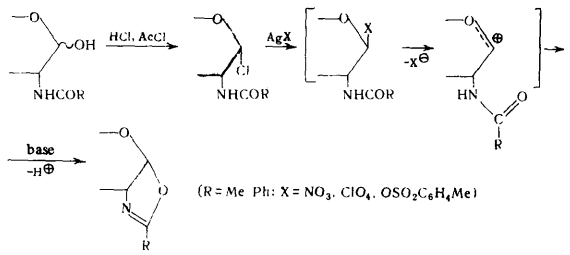
(LXXXIX)

2-Methyl-(3-*O*-acetyl-5,6-*O*-isopropylidene-1,2-dideoxy-α-D-glucofurano)[2′,1′ :4,5]-2-oxazoline (XC), which is the 2-methyl analogue of the oxazoline (LXXXVIII), was obtained for the first time by Wolfrom and Winkley[143] in 56% yield:

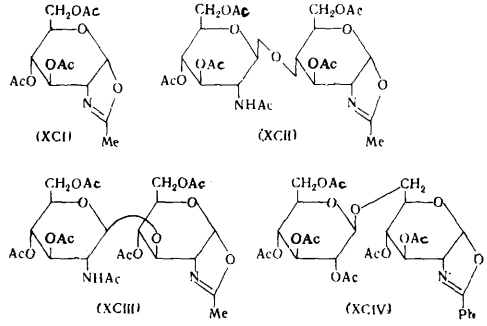


Examples of the employment of oxazoline derivatives of sugar in glycoside synthesis still remained few and were limited to the synthesis of aminoglycosides (including furanosides) derived from lower alcohols and phenol[140,142-145]. The oxazoline group was mainly used to protect the substituents at 1-C and 2-C in the synthesis of muramic acid and its derivatives[141,146-148].

A general method for the preparation of 2-substituted glyco[2′,1′ :4,5]-2-oxazolines was developed in 1968 in the authors' laboratory[149,150]. The starting compounds were *O*-acetylated 2-acylamino-2-deoxyglycosyl chlorides formed in high yields when *N*-acyl derivatives of 2-amino-2-deoxysugars are treated with hydrogen chloride in acetyl chloride[65]. Treatment of the chlorides with silver salts (nitrate, perchlorate, toluene-*p*-sulphonate) in anhydrous acetone or acetonitrile[151] in the presence of organic bases (pyridine, collidine) leads to the corresponding oxazoline derivatives. The reaction probably proceeds via the intermediate formation of a carbonium ion, which is then stabilised by conversion into an oxazoline. Best results were achieved when silver nitrate and collidine were used.



Oxazoline derivatives of mono- and di-saccharides [(LXXX), (LXXXVI), (LXXXVII), and the previously unknown compounds (XCI)–(XCIV)] were obtained by this method in 50–80% yields relative to the free *N*-acylamino-sugar.



It must be emphasised that this method of synthesis rules out the isolation of the intermediate aminoglycosyl chlorides. Some of the oxazoline derivatives obtained [(LXXX), (LXXXVI) and (XCI)] were deacetylated in methanol in the presence of triethylamine[150].

[a] The yields are quoted only for those derivatives in which the oxazoline ring is formed.

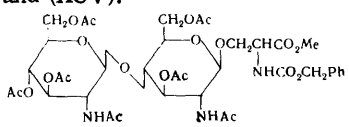
A modification of the method of Fletcher and co-workers[138], consisting of the treatment of the peracetates of 2-amino-2-deoxy-β-D-glucose and 2-amino-2-deoxy-β-D-galactose with anhydrous iron(III) chloride in methylene chloride, was proposed recently[152,153] (cf. Salo and Fletcher[154]). The high yields of the products—the oxazolines (LXXXVII) and (XCI)—and the simplicity of the process evidently make this method extremely promising.

Data for the oxazoline derivatives of sugars synthesised hitherto are summarised in Table 3.

V. OXAZOLINE SYNTHESIS OF 1,2-*trans*-2-ACETAMIDO-2-DEOXYGLYCOSIDES

2-Methylglyco[2′,1′:4,5]-2-oxazolines, which have become available recently, were investigated as glycosylating agents mainly in the glycosylation of "aglycone" components with complex structures. A detailed study was made of the employment of oxazoline derivatives of sugars in the synthesis of acetamidoglycosides, including aminosugar oligosaccharides, in the presence of acid catalysts—mainly toluene-*p*-sulphonic acid as well as other acids[155,156]. Alkyl[135,151,153,155-157] and aryl 2-acetamido-2-deoxy-β-D-hexopyranosides[158,159] are formed in high yields when alcohols and phenols are treated with the oxazolines (LXXXVII) and (XCI) in the presence of the above catalysts. Similarly the glycosylation of monoterpene alcohols with the oxazoline (XCI) led to the formation of (-)-bornyl and (-)-menthyl 2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-β-D-glucopyranosides in yields of 40–43%.[159]

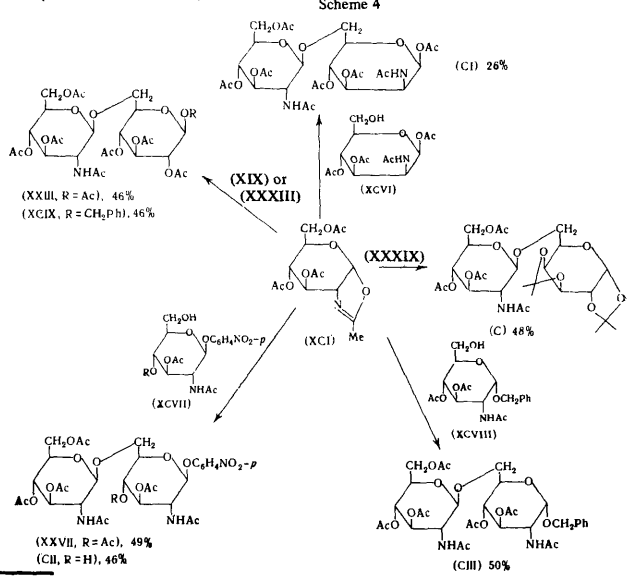
The effectiveness of the oxazoline method in the synthesis of compounds simulating the glycopeptide fragments of biopolymers was demonstrated in the glycosylation of *N*-benzyloxycarbonyl-L-serine esters by mono-[151,155] and disaccharide derivatives[160]. This led to the formation of high yields (55–75% for the monosaccharide and 40% for the disaccharide) of protected L-serine *O*-glycosides (LXXVII, R and R′ = H or OCOMe, R″ = Me or CH_2Ph, X = CO_2CH_2Ph) and (XCV).



(XCV)

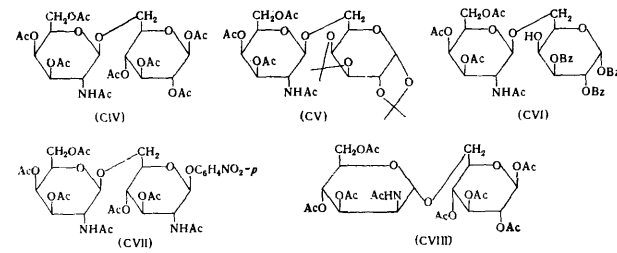
The results obtained using the oxazoline method in the synthesis of oligosaccharides ‡ are of greatest interest and value. Glycosylation of the primary hydroxy-group of derivatives of D-glucose [(XIX) and (XXXIII)][103,161], D-galactose (XXXIX)[161], D-mannose (XCVI)[152], and acetamido-D-glucose [(XCVII, R = H or COMe) and (XCVIII)][16,149,162] with the aid of the oxazoline (XCI) led to the formation of the corresponding disaccharide derivatives (XXIII), (XXVII) and (XCIX)–(CIII) in high yields—mainly about 50% (see Scheme 4).

Scheme 4



‡ See Table 2.

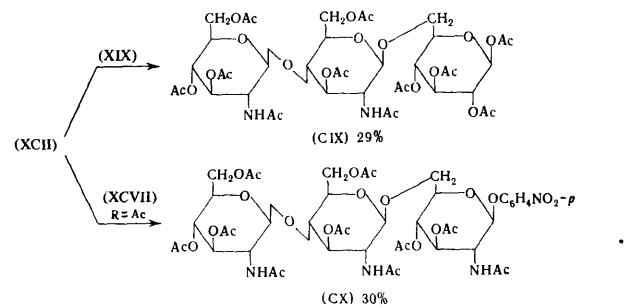
The oxazoline derivatives of the D-galacto-[151,153,157] and D-manno-series[161] proved just as effective in the synthesis of (1→6)-linked disaccharides. The protected disaccharides (CIV)–(CVIII) were obtained from them in 44–81% yield.



(CIV) (CV) (CVI)

(CVII) (CVIII)

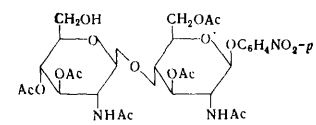
Glycosylation of the disaccharide (XCII) by oxazoline derivatives made it possible to increase the length of the oligosaccharide chain by two aminosugar residues in a single stage, as shown in the synthesis of the trisaccharide derivatives (CIX)[161] and (CX)[162]. This had not been achieved before by other glycosylation procedures.



(CIX) 29%

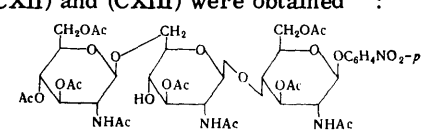
(CX) 30%

Like other glycosylating agents, oxazoline derivatives exhibit a higher reactivity in reactions with the primary hydroxy-groups of sugars than with the secondary groups, so that branched oligosaccharides, when the possibility of their formation was not ruled out altogether, were detected only in trace amounts[162,163]. This factor made it possible to employ as the glycosylated components derivatives of oligosaccharides with unprotected hydroxy-groups at 4-C and 6-C in the terminal monosaccharide residue [for example in compound (CXI)], which are readily obtained from the corresponding 4,6-*O*-benzylidene derivatives.

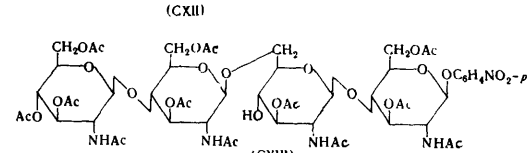


(CXI)

When oxazoline derivatives of the monosaccharide (XCI) and the disaccharide (XCII) were allowed to react with compound (CXI), the tri- and tetra-saccharide glycosides (CXII) and (CXIII) were obtained[164]:



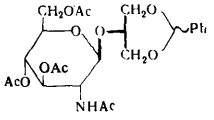
(CXII)



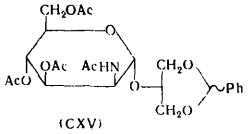
(CXIII)

The low yields of these products (not exceeding 15%) can be explained by the extremely low solubility of the glycosylated component (CXI) even in a polar solvent such as nitromethane. On the other hand, in highly polar solvents toluene-*p*-sulphonic acid catalyses the isomerisation of 2-methylglyco[2′,1′:4,5]-2-oxazolines to 2-acetamido-glycals[154], which apparently constitutes a competing process in the cases under consideration.

The effectiveness of the oxazoline method has been clearly demonstrated in the glycosylation of the secondary hydroxy-groups of polyols and monosaccharides. When the oxazolines (LXXXVI) and (XCI) were condensed with 1,3-*O*-benzylideneglycerol, protected 1,2-*trans*-aminoglycosides derived from benzylideneglycerol, (CXIV) and (CXV), were obtained[165,166] in yields which amounted to 34 and 31% respectively after the removal of the *O*-acetyl and benzylidene groups:



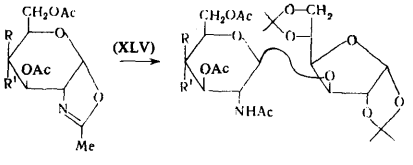
(CXIV)



(CXV)

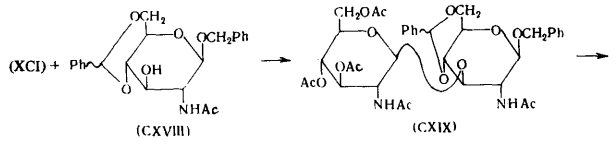
Derivatives of β-(1→3)-linked disaccharides (CXVI) and (CXVII) were obtained in yields of about 50% but the reaction of the oxazoline derivatives (LXXXVII) and (XCI) with diacetoneglucose (XLV)[151,157,166].

The glycosylation of the sterically hindered hydroxy-group at 3-C in the derivative (CXVIII) by the oxazoline (XCI) led to the protected disaccharide (CXIX) in 81% yield. The latter served as the starting compound in the synthesis of the oxazoline derivative of the β-(1→3)-linked disaccharide (XCIII).



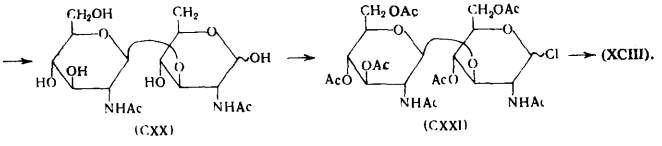
(LXXXVII) or (XCI)

(CXVI, R = OAc, R′ = H)
(CXVII, R = H, R′ = OAc)



(CXVIII)

(CXIX)

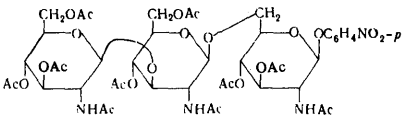


(CXX)

(CXXI)

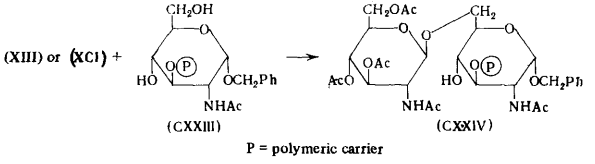
(XCIII).

The disaccharide (CXX) was obtained by standard methods from (CXIX) and was then converted into the chloride (CXXI) and further into the oxazoline (XCIII) in an overall yield of 53% relative to (CXX).[166] The trisaccharide derivative (CXXII) was obtained in 78% yield by the glycosylation of *p*-nitrophenyl 2-acetamido-3,4-di-*O*-acetyl-2-deoxy-β-D-glucopyranoside by the oxazoline (XCIII).[166] The above sequence of transformations demonstrates the possibility of synthesising oligosaccharides with different combinations of 1,2-*trans*-glycosidic linkages between aminosugar residues.



(CXXII)

The recently published study of Vignon and coworkers[163], who achieved the synthesis of a disaccharide on a polymeric carrier, made a significant contribution to the development not only of the oxazoline synthesis of aminoglycosides but also to the synthesis of oligosaccharides in general. The glycosylation by the oxazoline (XCI) [or the chloride (XIII) under the conditions of the Koenigs–Knorr reaction] of the acetamido-D-glucose derivative (CXXIII) linked to a polymeric carrier via an ester bond led to a high yield of the disaccharide derivative (CXXIV) on the carrier. After the treatment of the latter with sodium methoxide in methanol, the disaccharide glycoside was liberated.



(CXXIII) (CXXIV)

P = polymeric carrier

Apart from the advantages of solid-phase synthesis, known from the synthesis of peptides, this version of the oxazoline method for the preparation of aminoglycosides will probably make it possible to solve successfully the problem of synthesising higher oligosaccharides, the difficulties of which are associated with the low solubility of the glycosylated components[164].

In summing up the discussion of the oxazoline method for the synthesis of 1,2-*trans*-2-acetamido-2-deoxyglycosides, we may note that oxazoline derivatives of sugars permit the glycosylation of various types of hydroxy-compounds—alcohols, phenols, hydroxyaminoacids, polyols, and partly protected mono- and oligo-saccharides [as well as thiols (see below)]. The general nature of the reactions has been demonstrated for a number of important classes of natural aglycones. The application of glycosylating agents with a wide variety of structures and a series of different alcoholic components makes it possible to infer the stereospecificity of the reaction. On the other hand, one can conclude on the basis of these data that all the protecting groups tested are stable under the conditions of glycosylation with oxazoline derivatives of sugars, namely the acyl, alkylidene, and benzyl glycoside groups as well as the *N*-benzyloxycarbonyl group used in peptide synthesis.

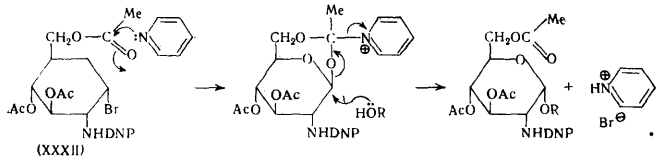
The results taken as a whole show that the oxazoline method is a general procedure for the formation of the 1,2-*trans*-aminoglycosidic linkage.

VI. STEREOSPECIFIC SYNTHESIS OF 1,2-*cis*-2-AMINO-2-DEOXYGLYCOSIDES

As in the series of neutral sugars, methods for the stereospecific synthesis of 1,2-*cis*-aminoglycosides are now in the stage of development only. Above it was stated that the formation of 1,2-*cis*-glycosides from acyl-halogeno-derivatives of sugars is prevented by the involvement of the acetoxy- or acylamino-groups. In those cases where this effect was suppressed by the introduction of "non-participating" substituents into the amino-group of the sugar, the stereospecificity of the glycosylation reaction was lost and the proportions of the anomeric glycosides formed varied within wide limits.

The separation of anomeric alkyl or aryl aminoglycosides presents no difficulties at present and is carried out by chromatographic methods[167-169]. Chromatography is also used to separate anomeric aminoglycosides with aglycones having a complex structure (including disaccharide derivatives), formed in the synthesis by different versions of the Koenigs–Knorr reaction. However, its scope is sharply reduced with increase in the length of the oligosaccharide chain, this effect being already observed for trisaccharide derivatives. For this reason, only stereospecific glycosylation permits the solution of the problem of synthesising higher oligosaccharides having the 1,2-*cis*-aminoglycosidic linkage.

The preferential formation of 1,2-*cis*-aminoglycosides was observed only in a few instances, for example in glycosylation by the bromide (XXXII) in the presence of pyridine[89,92], which the authors explain by the involvement of the acetoxy-group at 6-C:

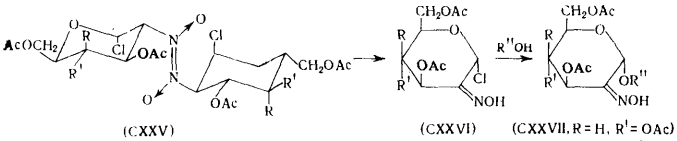


(XXXII)

Indeed, when 3,4-di-*O*-acetyl-2-deoxy-2-(2,4-dinitrophenylamino)-6-*O*-methyl-α-D-glucopyranosyl bromide was used as the glycosylating agent, the dominant reaction product was the 1,2-*trans*-glycoside[92] and in addition the reaction was significantly retarded. The replacement of the acetoxy-groups at 3-C or 4-C in the bromide (XXXII) by methyl groups does not alter the stereospecificity and rate of the reaction.

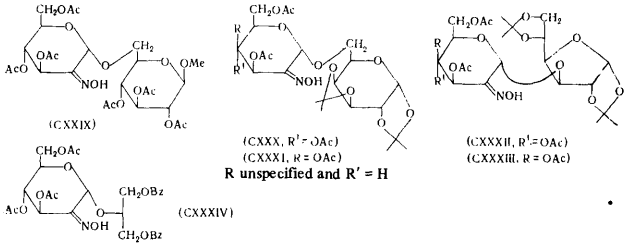
A similar effect of the involvement of the acetoxy-substituent at 4-C was observed recently[170] in a series of neutral sugars. Glycosylation by 2-*O*-benzyl-3,4-di-*O*-(*p*-nitrobenzoyl)-α-L-fucopyranosyl bromide led to α-L-fucosides with a high degree of stereospecificity.

The most promising method for the synthesis of 1,2-*cis*-aminoglycosides was proposed very recently by Lemieux and coworkers. The available[171,172] dimeric D-gluco- and D-galacto-nitrosyl chlorides (CXXV), which dissociate and isomerise in dimethyl formamide (DMF) to the corresponding hydroxyiminochlorides (CXXVI)[173], react with alcohols and phenols in the presence of pyridine to form high yields of 3,4,6-tri-*O*-acetyl-2-hydroxyimino-α-D-arabinohexopyranosides (CXXVII) and the corresponding α-D-lyxohexopyranosides (CXXVIII)[174-176]—the precursors of 2-amino-2-deoxy-α-D-glycosides:



(CXXV) (CXXVI) (CXXVII, R = H, R' = OAc)
(CXXVIII, R = OAc, R' = H)
(R'' = alkyl or aryl)

This method is suitable[174,176,177] also for the synthesis of 2'-hydroxyimino-derivatives of disaccharides [(CXXIX) – (CXXXIV)], which are formed in yields of 50–80%. The β-anomer was isolated in 9% yield only in the synthesis of (CXXXI).



(CXXIX) (CXXX, R' = OAc) (CXXXI, R = OAc) (CXXXII, R' = OAc) (CXXXIII, R = OAc)
R unspecified and R' = H
(CXXXIV)

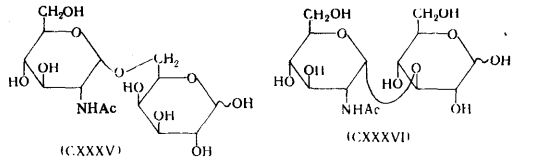
On the other hand, in the remaining cases the authors failed to observe the formation of β-anomers (but they did not rule out this possibility[176]).

The results of Miyai and Jeanloz[175] conflict with these data. They failed to observe the stereospecificity of the glycosylation of benzyl 2,3,4-tri-*O*-benzyl-β-D-galactopyranoside by the chloride (CXXV, R = H, R' = OCOMe) and obtained a mixture of α- and β-(1→6)-linked disaccharides in approximately equal amounts.

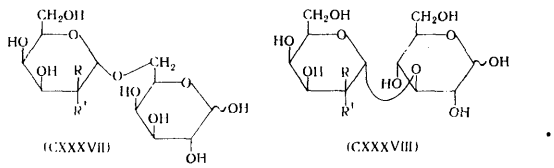
The preparative value of the method is reduced to some extent by the inadequate stereospecificity of the reduction of the hydroxyimino-derivatives to the corresponding 2-amino-2-deoxysugars. Depending on the conditions of the reduction of (CXXVII) and (CXXVIII), the ratio of the amino-α-D-glycosides formed, epimeric at 2-C, varied within a fairly wide range[175,178,179]. A high stereospecificity of the reaction was noted only in the hydrogenation of (CXXVII) on palladium in the presence of hydrazine or in the reduction of the *N*-acetate of compound (CXXVII) by diborane in tetrahydrofuran (THF), as a result of which the product contained 92–95% of the amino-α-D-glucoside and 5–8% of the amino-α-D-mannoside. The reduction of (CXXVII) or (CXXVIII) (as well as its *N*-acetate) by diborane or lithium tetrahydroaluminate in THF led to a mixture of the D-gluco- and D-manno-epimers [from (CXXVII)] and the D-galacto- and D-talo-epimers [from (CXXVIII)] in comparable amounts.

The same behaviour was noted[180] also in the reduction of the hydroxyimino-derivatives of disaccharides [(CXXX)–(CXXXIV)] by diborane in THF. The individual disaccharides (CXXXV) and (CXXXVI) were obtained in high yields only from compounds (CXXX) and (CXXXII) (after the removal of the protecting groups and *N*-acetylation). The reduction of (CXXXI) and (CXXXIII) under the same conditions led to mixtures of disaccharides [(CXXXII) and (CXXXVIII) with R = R' = H or NHCOMe) in which products with the D-talo-configuration of the aminosugar component predominated. They were separated by chromatography.

The reduction of (CXXIX) also leads to the formation of a mixture of disaccharide derivatives with the D-gluco- and D-manno-configuration of the non-reducing monosaccharide residue in proportions of approximately 1 : 1.[178]



(CXXXV) (CXXXVI)



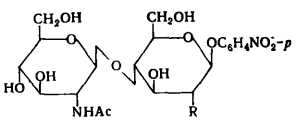
(CXXXVII) (CXXXVIII)

Despite the non-specific reduction of 2-hydroxyimino-derivatives of sugars in many cases, the method described is at present perhaps the only procedure for the synthesis of 1,2-*cis*-aminoglycosides with an aglycone having a complex structure. It is noteworthy that 2-hydroxyimino-2-deoxy-α-D-glycosides are the precursors of not only amino-α-D-glycosides but also of α-D-glycopyranosides[177,181], α-D-hexopyranosides[179], and 2-deoxy-α-D-glycosides[182], including disaccharide derivatives.

VII. ENZYMATIC SYNTHESIS OF AMINOSUGAR OLIGOSACCHARIDES

A detailed description of the synthesis of oligosaccharides containing aminosugar residues by enzymatic systems is outside the scope of this review. We wished to consider only those enzymatic methods for the formation of aminosugar oligosaccharides which are of interest from the preparative point of view. They are based on the well known transglycosylating ability of the lysozyme from hen egg protein (EC 3.2.1.17).

When lysozyme was allowed to act on di-*N*-acetylchitobiose in the presence of methanol, methyl 2-acetamido-2-deoxy-β-D-glucopyranoside was isolated[185]. Subsequently the same workers[186] obtained disaccharide glycosides (CXXXIX), which are formed when lysozyme acts on tetra-*N*-acetylchitotetraose in the presence of *p*-nitrophenyl β-glycosides derived from *N*-acetyl-D-glucosamine, D-glucose, and 2-deoxy-D-glucose as acceptors (see also van Eikeren and Chipman[187]). When penta-*N*-acetylchitopentaose was used as the donor of glycosyl residues and cellobiose as the acceptor, oligosaccharides with the formula $(GlcNAc)_nGlcGlc$§ (n = 1–3) were obtained[188,189].



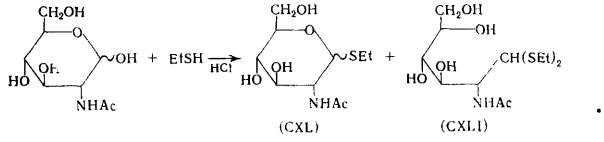
(CXXXIX, R = NHAc, OH, H)

The tetrasaccharide from the cell wall of the bacterium *Micrococcus lysodeikticus*, $(GlcNAc\text{-}MurNAc)_2$, is an active donor of glycosyl residues in lysozyme-catalysed reactions. When it was allowed to react with monosaccharide acceptors (*N*-acetyl-D-glucosamine, D-glucose, D-galactose, and D-xylose), the following trisaccharides were isolated[190–192]: GlcNAc-MurNAc-GlcNAc, GlcNAc-MurNAc-Glc, GlcNAc-MurNAc-β-(1→2)-Glc, GlcNAc-MurNAc-β-(1→2)-Gal, GlcNAc-MurNAc-Xyl, GlcNAc-MurNAc-β-(1→2)-Xyl, and GlcNAc-MurNAc-β-(1→3)-Xyl, the yield of the transglycosylation products reaching 15% (with respect to the donor). The transfer of the same glycosyl residue to oligosaccharides (di-*N*-acetylchitobiose and cellotetraose) proceeds similarly[188,192] and leads to the formation of the oligosaccharides GlcNAc-MurNAc-$(GlcNAc)_2$ and GlcNAc-MurNAc-$(Glc)_4$.

Transglycosylating activity is a characteristic property of glycosidases and endoglycanases, i.e. *O*-glycoside hydrolases, which catalyse the hydrolytic cleavage of the *O*-glycosidic linkage with retention of the configuration at the anomeric glycosidic centre of the substrate. An enhanced affinity of the active centres for the glycone part of the substrate is characteristic of enzymes of this type, and is responsible for the attachment of the activated glycosyl residue to them. The latter is then transferred to the acceptor. Apart from lysozyme, which has already been mentioned, in the preparative synthesis of aminoglycosides employing transglycosylating activity it is possible to use also other enzymes which cleave the aminoglycosidic linkage, for example α- and β-hexosaminidases. However, the available information on this subject is extremely limited.

VIII. SYNTHESIS OF *S*- AND *N*-AMINOGLYCOSIDES

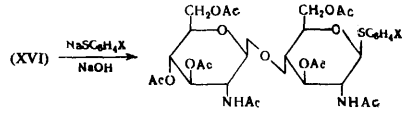
In contrast to neutral monosaccharides, *N*-acetyl-D-glucosamine is capable of giving rise to thioglycosides under the conditions of the Fischer synthesis of glycosides. Thus the anomeric ethyl 2-acetamido-2-deoxy-1-thio-D-glucopyranosides (CXL) were obtained in a low yield under controlled conditions[193], but the main reaction product was the mercaptal (CXLI):



(CXL) (CXLI)

Aminosugar *S*-glycosides are mainly synthesised by the methods used to prepare their neutral analogues[194]. The hydrolysis of the mercaptal (CXLI) in the presence of mercury(II) chloride and mercury(II) oxide gives a mixture of anomeric ethyl 2-acetamido-2-deoxy-1-thio-D-glucofuranosides, with the α-anomer predominating[195].

Different alkyl and aryl 2-amino-3,4,6-tri-*O*-benzoyl-2-deoxy-1-thio-β-D-glucopyranosides (in the form of the hydrobromides)[196] and their *N*-benzoyl analogues[39] have been obtained from the corresponding acylhalogeno-derivatives and thiols. Phenyl 1-thioglycosides of the disaccharide (CXLII, X = H, Me, or NO_2) and their 1-seleno-analogue[197] were synthesised similarly from the chloride (XVI)[197,198]:



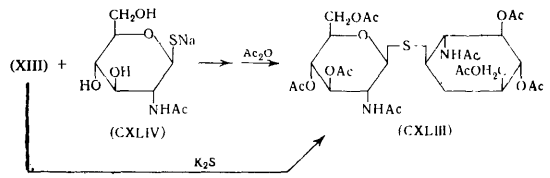
(CXLII)

§ For the significance of the abbreviations, see the footnote to Table 2. The unspecified positions of the glycosidic linkages are β-(1→4).

Ethyl 2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-1-thio-β-D-glucopyranoside is formed in the mercaptolysis of α-D-glucosamine peracetate in the presence of zinc chloride[183]. In this case the stereospecificity is due to the cooperative effect.

The oxazoline method is promising for the synthesis of 1-thioaminoglycosides. Phenyl 2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-1-thio-β-D-glucopyranoside and the thioglycoside (CXLII, X = H) were obtained in this way[158] in yields of 68 and 43% respectively.

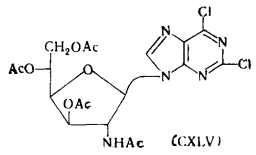
The thio-analogue of the non-reducing disaccharide (CXLIII) was obtained[61] in 50% yield by the reaction of the chloride (XIII) with the sodium salt of (CXLIV) or by treating the chloride (XIII) with potassium sulphide:



Either direct condensation of monosaccharides with aromatic amines[200-203] or aminoacids[203,204] or different versions of the Koenigs–Knorr reaction are used in the synthesis of the *N*-glycosides of 2-amino-2-deoxysugars, as for the *N*-glycosides of neutral sugars[199]. The use of acylhalogenosugars as glycosylating agents involves the same difficulties as in the synthesis of *O*-glycosides of 2-amino-2-deoxysugars.

O-Acylated glycosyl chlorides and bromides with different substituents at the nitrogen atom have been used in the synthesis of aminosugar nucleosides[205-218]. Mixtures of anomeric *N*-substituted aminoglycosides are formed as a rule from bromides with "non-participating" substituents at 2-C.

The synthesis of the nucleoside (CXLV) is so far the only instance[143] of the preparation of *N*-glycosides by the oxazoline method[135].



(CXLV)

---o0o---

The data described permit the conclusion that the synthesis of 1,2-*trans*-aminoglycosides, including 2-amino-2-deoxysugar oligosaccharides, has now been developed in fair detail and there are a number of methods whereby they can be obtained on a preparative scale, among which the oxazoline method is the most convenient. Methods for the synthesis of 1,2-*cis*-aminoglycosides have been much less satisfactorily developed and the synthesis of polysaccharides made up of aminosugar residues has remained completely untouched. In this respect the synthetic chemistry of aminoglycosides still lags behind the synthetic chemistry of their neutral analogues[172,219].

The Mechanism of Non-adiabatic Bimolecular Reactions

E.E.Nikitin

The dynamics of bimolecular non-adiabatic elementary process in gases are discussed. The inelastic processes occurring in collisions between atoms and dia-atomic molecules and exchange and decomposition reactions are considered within the framework of the semiclassical description of collisions based on the instantaneous jump model of the reacting system between adiabatic potential energies surfaces.
The bibliography includes 121 references.

1. INTRODUCTION

This review discusses the mechanisms of elementary non-adiabatic bimolecular gas-phase reactions, i.e. reactions involving a change in the electronic states of reactant molecules. These processes have been attracting increasing attention in connection with new research possibilities which have arisen as a result of applying the techniques of molecular beams and laser fluorescence which yield extremely detailed information about the initial states of the reactants and products. Non-adiabatic processes are much more common than might be supposed on the basis of the space devoted to them in recent books and reviews on elementary processes[1-3].

This paper is an attempt to fill part of the existing gap in the review literature on the mechanisms of elementary non-adiabatic reactions. The author has restricted the treatment to a discussion of the simplest (and therefore the best studied) non-adiabatic reactions—the reactions of atoms with diatomic molecules.

The review has been arranged as follows. Initially (Section 2) there is a brief discussion of the classification of non-adiabatic processes and general information about the mechanisms of non-adiabatic interaction is presented. The next section (Section 3) deals with the influence of non-adiabatic effects on the exchange of rotational and vibrational energies in processes without a redistribution of atoms. Sections 4 and 5 are devoted to non-adiabatic exchange and collisional dissociation reactions. The literature references include mainly recent studies associated directly with research on specific non-adiabatic processes. Instead of direct references to studies in the past years, recent books[1-4] in which the relevant processes are discussed and the original literature is given, are referred to.

2. DEFINITION OF NON-ADIABATIC PROCESSES

Adiabatic Potential Energy Surfaces

In the general case where an atom A collides with a diatomic molecule BC, the following elementary processes are possible:

$$A + BC \begin{cases} \rightarrow A + BC - \text{(elastic and inelastic collisions)} \\ \rightarrow AB + C \text{ (exchange)} \\ \rightarrow AC + B \text{ (exchange)} \\ \rightarrow A+B+C \text{ (dissociation).} \end{cases} \quad (1)$$

Analysis of the mechanism of any of these processes in the gas phase is based on the study of the dynamics of the elementary collision step. Such investigation yields the reaction cross-section which, together with the distribution of the reactant molecules between initial states, fully determines the rate of reaction (see Kondrat'ev and Nikitin[1], §8). The calculation of the cross-section constitutes a fairly difficult problem in classical or quantum mechanics and simplifying assumptions are always made. These simplifications concern two aspects of the problem. The first is associated with the attempt to exclude from consideration the dynamics of electron motion in the reacting system of atoms and molecules and to formulate the problem in terms of the motion of atomic nuclei alone. This is achieved by employing the adiabatic approximation[1,4], within the framework of which one introduces the concepts of the potential energy surfaces of the nuclei $U_n(R)$, which depend on the set of nuclear coordinates R and refer to a given electronic state n. Since the creation of the quantum theory of molecules, the calculation of potential energy surfaces has been one of its most important tasks (see the relevant reviews[5,6]).

Another aspect of the problem consists of the study of the dynamics of the motion of the nuclei of the reacting molecules, which is usually treated in terms of the motion of the characteristic point of the system along the specified potential energy surface from the region corresponding to the initial molecules (reactants) to that of the reaction products. This approach to the theory of elementary processes has developed strongly during the last 10–15 years and a major proportion of the important results have been obtained by computer calculations of reaction probabilities and cross-sections.

However, there is a whole class of chemical reactions which cannot, in principle, be interpreted in terms of the motion of the system along *one* fixed potential energy surface, i.e. a significant feature of the mechanism of these reactions is a change in the electronic state of the system. To investigate the dynamics of these reactions, called non-adiabatic, it is necessary to go beyond the framework of the adiabatic approximation. The theory corresponding to this generalisation can be formulated as follows. One of the formulations employs the adiabatic potential energy surfaces $U_n(R)$ as the zeroth approximation with additional allowance for the transitions between them (non-adiabatic transitions). This approximation will in fact be employed below.

Adiabatic potential energy surfaces are defined as the eigenvalues of the electronic Hamiltonian H_{el} of a system ABC with a fixed configuration of the nuclei. However, in terms of this general formulation, the problem of finding $U_n(R)$ and the corresponding adiabatic electronic functions φ_n usually cannot be solved. Any approximate solution is equivalent, in a certain sense, to the solution of the exact problem with a Hamiltonian H^0_{el} differing from H_{el}. The corresponding eigenfunctions φ^0_n and the eigenvalues $U^0_n(R)$ are associated with the so-called rough adiabatic approximation. If the difference between H_{el} and H^0_{el} is not great, then the $U^0_n(R)$ constitute a satisfactory approximation to the $U_n(R)_0$ in those regions of the configuration space of the nuclei where the difference $U^0_n(R) - U^0_{n'}(R)$ is appreciably greater than the matrix element $\delta H_{nn'}$ for the interaction ($\delta H = H_{el} - H^0_{el}$). Hence it follows that the regions of the intersections of the states of the rough adiabatic approximation, where the above condition is known not to hold, must be specially investigated since such an intersection can either also occur for adiabatic surfaces or be replaced by a close approach of the adiabatic surfaces (the so called quasi-intersection).

The general theory[7,8] and also its specific application to a three-atom system[4,9] establishes the characteristics of the intersection of the $U_n(R)$ and $U^0_n(R)$ states.

Depending on the effects which it is desirable to include in the study of the reaction dynamics, the Hamiltonian H^0_{el} is chosen with different degrees of approximation and the possibility of neglecting certain terms in H_{el} when specifying H^0_{el} is determined by the condition that these terms have little influence both on the structure of the adiabatic surfaces and on the probability of non-adiabatic transitions. In this connection we may mention the following approximations.

a. Neglect of magnetic interactions (spin–orbit and spin–spin). The energy of such an interaction varies from several hundredths of an electron-volt to 1 eV for heavy atoms (for example the iodine atom). In this approximation the overall electron spin is conserved so that any processes described by relation (1) should follow the Wigner rule: among the possible spin states of the products, there should be a state identical with one of the spin states of the initial reactants. Magnetic interactions can be neglected in constructing the potential energy surfaces for a system of light atoms. However, they must almost always be taken into consideration (systems comprising H and He atoms are an exception) in calculations of the probabilities of non-adiabatic transitions.

b. Neglect of electron correlation effects. Within the framework of this approach, based on the one-electron approximation, it is possible to formulate a number of simple rules for the qualitative construction of surfaces (for example the Woodward–Hoffmann principle of the conservation of orbital symmetry[11–13] or the employment of correlation diagrams for molecular orbitals[14]). Since the electron correlation energy is of the same order of magnitude as the energy of the splitting of the atomic states which arise from a single configuration (1–2 eV), the one-electron approximation is not applicable in a quantitative calculation of the surfaces. Nor can it be used to calculate the probability of non-adiabatic transitions.

c. Neglect of the change in electron correlation on mutual approach of the initial reactants. In constructing H^0_{el} within the framework of this approach account is taken first of the electron correlation in isolated atoms and molecules and the interaction between the colliding species is taken into account only in the following stage. This method, which is a generalisation of the Heitler–London method to include many-electron systems, yields the correct type of adiabatic states for large intermolecular distances[15]. We may note that the employment of this approximation for smaller distances leads to a qualitative proof of the familiar Polanyi–Semenov correlation[1] between activation energies and heats of reaction in a series of similar reactions.

Although for a fairly small perturbation δH the U_n^0 and U_n surfaces proved to be close in most of the configuration space of the nuclei, the corresponding states are specified by *different* sets of electronic quantum numbers. Therefore the classification of processes as adiabatic or non-adiabatic within the framework of any rough adiabatic approximation can frequently change when the approximation is refined. The consequent ambiguity in the definition of non-adiabatic reactions must be always borne in mind. However, the final result of the study of the dynamics—the calculation of the reaction probabilities or cross-sections—is independent of the ambiguity of the definition, provided that non-adiabatic transitions have been taken into account correctly in the solution of the problem.

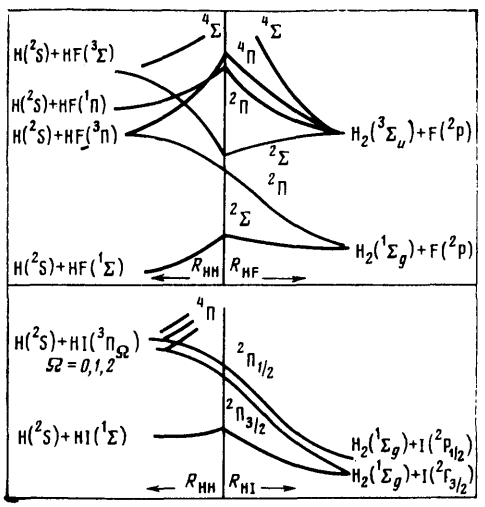

Figure 1. Correlation diagrams for the electronic terms of the reaction H + HF → H_2 + F (weak spin—orbital interaction, upper Figure) and H + HI → H_2 + I (strong spin—orbital interaction, lower figure) with a linear configuration of the nuclei.

Numerous examples of the correlation of the electronic states of a three-atom system are quoted in a review[16]. Here we shall mention only one example illustrating the influence of the spin-orbital interaction on the structure of the surfaces for an HHX system (X is a halogen atom). Fig. 1 presents the cross-sections of the surfaces of the linear HHF system which have been calculated by the semiempirical method of diatomic complexes in molecules[17]. The left-hand side of the Figure corresponds to the pathway $\infty > R_{HH} \geq R^{\circ}_{HH}$, $R_{HF} = R^{\circ}_{HF}$ and the right hand side corresponds to the pathway $R_{HH} = R^{\circ}_{HH}$, $R^{\circ}_{HF} \leq R_{HF} < \infty$. When the linear configuration of the nuclei breaks down, the $^2\Sigma$ and $^4\Sigma$ states (in the calculation of which the spin-orbital interaction is neglected, as in the case of the Π states, because it is small for the F atom) are classified as the $^2A'$ and $^4A'$ states in the C_S symmetry group, the corresponding energies being somewhat altered.

The $^2\Pi$ and $^4\Pi$ states are split as well as displaced and are classified as $^2A'$, $^2A''$, and $^4A'$, $^4A''$.

On passing from F to heavier halogens, account must be taken of the spin-orbit interaction in plotting the diagrams. The lower part of Fig. 1 illustrates qualitatively these changes in the disposition of the states for the HHI system which arise under these conditions. For example, the degeneracy of the state $^2\Pi$ is lifted; instead there arise two components $^2\Pi_{1/2}$ and $^2\Pi_{3/2}$, which are correlated with different states of the I atom. When the linear configuration is distorted, the states are not split further: they remain doubly degenerate with respect to the spin projections as a consequence of Kramers theorem[7].

Description of Non-adiabatic Transitions

Non-adiabatic transitions between potential energy surfaces are due to the dynamic interaction of electrons and nuclei. A consistent quantum theory formulates the problem of describing the transitions in terms of a system of coupled wave equations. In this formulation the problem can be solved (and has been solved successfully) for collisions of two atoms when the potential energy surfaces simplify into potential energy curves (a system of equations in a single variable R). The minimum dimensionality of the equations whose solution is significant in connection with the study of the dynamics of non-adiabatic reactions is two (linear collision of an atom with a diatomic molecule). However, this problem cannot be solved at present even on the best computers: the quantum solution has been obtained so far only for the two-dimensional adiabatic problem of the reaction of a hydrogen atom and an H_2 molecule. This factor and also the fact that even the solution of a real multidimensional adiabatic problem can be obtained only within the framework of the classical description necessitates the employment of semiclassical methods for calculating the probabilities of non-adiabatic transitions, the essential features of which are as follows.

The study of the problem of non-adiabatic transitions shows that the dynamic interaction is most vigorous in the region corresponding to the approach or intersection of the states. The main parameter determining the extent of the interaction is the ratio of the frequency of the oscillation of electrons between the levels, $\omega(R) = |U_n - U'_n|/\hbar$, to the "frequency" $1/\tau$ characterising the rate at which the nuclei traverse the region of interaction. If the parameter $\xi = \omega\tau$ is large, it is possible to neglect the non-adiabatic transitions[4,18,19]. Non-adiabatic transitions must be taken into account only in the regions of the configuration space of the nuclei where $\xi \leq 1$ or ξ becomes zero. The extent l of this region is then important. If the extent is small, i.e. l is appreciably smaller than the characteristic dimensions L which define the region of interaction of the three-atom system, then the semiclassical approximation suggests the following method for describing non-adiabatic transitions which makes maximum use of the simplicity of the classical description of the motion of the representative point in adiabatic regions. The representative point moves along the potential energy surface corresponding to the initial electronic states of the initial reactants until the attainment of the region of strong non-adiabatic coupling. In this region the system executes a jump from the initial surface to a neighbouring surface with a probability P_1, which depends on the parameters of the surfaces in this region; the probability that the system remains on the initial surface is $1 - P_1$. Subsequently the motion is

continued on two surfaces—the first and second surfaces—the probabilities $1 - P_1$ and P_1 being associated with the corresponding trajectories. The motion continues until each trajectory again reaches the non-adiabatic regions. In these regions each trajectory "branches" once more. The consecutive repetition of the steps involving the adiabatic motion on the surfaces and the corresponding jumps yields the semiclassical picture of the process. Clearly the trajectories characterised by different "histories" of the jumps between the potential surfaces and having different probabilities P_k contribute to the set of final states (for example to the energy range $\hbar\omega$ near the vibrational energy E_{vibr} of the molecule formed), which is identified in the semiclassical approximation with the population of the quantum level. Then the overall probability of the process is defined by the sum of the probabilities P_k.

Two general objections may be raised against the semiclassical method: (a) failure to include quantum effects in the adiabatic motion of the system on the surface, (b) inaccurate definition of the concept of the trajectory in the non-adiabatic region where the jump takes place, and (c) failure to consider interference effects in adding the probabilities (and not the probability amplitudes) in the final state. All these objections also apply to the semiclassical description of atomic collisions, the limits of applicability of which are well known. The information accumulated so far concerning the accuracy of the semiclassical method and ways for improving it[22] suggests that the semiclassical approach is the most promising in the study of the dynamics of non-adiabatic processes.

For a specific calculation of the overall probability of a non-adiabatic process, it is necessary to know the probabilities P_k of the individual transitions. The calculation of these quantities reduces to the solution of the system of equations for non-adiabatic coupling, which can be incorporated in a single computer program. However, it is possible to simplify the dynamic calculation significantly using in the transition probabilities calculated independently within the framework of specific models. A number of such models are known at present[18]. The simplest of these is the Landau—Zener model[1,4,19], which can be used to calculate P provided that the cross-sections of the adiabatic surfaces along the part of the projectory $\mathbf{R} = \mathbf{R}(t)$ in the region of the interaction can be fairly satisfactorily approximated by two coupled hyperbolae. States of this kind are known to arise naturally[1,4] when the surfaces U_1 and U_2 are obtained by diagonalisation of the second-order matrix in a basis set of the intersecting states of the rough adiabatic approximation. Then the expression for the probability of non-adiabatic transition is

$$P = \exp[-2\pi a^2/\hbar\,|F_{1R} - F_{2R}|\,v_R] \quad , \qquad (2)$$

where $2a$ is the minimum distance between the states U_1 and U_2, F_{1R} and F_{2R} are the slopes of the lines asymptotic to the hyperbolae along the section of the trajectory $\mathbf{R}$, and v_R is the rate of motion of the system in the region of the transition. It is seen from Eqn. (2), that, for low values of the parameter $2\pi a^2/\hbar\,|F_{1R} - F_{2R}|\,v_R$, the system executes transitions between the adiabatic states with a high degree of probability. Hence follows the usefulness of the concept of diabatic states or diabatic surfaces, defined as surfaces which are followed by the system with a high probability when the velocity is sufficiently high. Evidently the probability P' of the transition between the diabatic states is expressed in terms of P by the relation $P' = 1 - P$, so that we obtain for the Landau–Zener model

$$P' = 1 - \exp[-2\pi a^2/\hbar\,|F_{1R} - F_{2R}|\,v_R] \quad . \qquad (3)$$

For high velocities, the probability of the transition between the diabatic states is low and is given approximately by

$$P' = 2\pi a^2/\hbar\,|F_{1R} - F_{2R}|\,v_R \quad . \qquad (4)$$

In practical calculations upper and lower limits are imposed on the parameter $2\pi a^2/\hbar\,|F_{1R} - F_{2R}|\,v_R$, since unduly low probabilities of the transition (and hence of branching) between adiabatic or diabatic surfaces usually need not be taken into consideration. Bearing in mind these limitations and using the available estimates of the extent of the transition regions l,[18] it is possible to show that the condition $l \ll L$, for which the description of the transitions in terms of jumps is satisfactory, holds when the energies are less than 10 eV.

3. EFFECT OF NON-ADIABATIC CONDITIONS ON THE EXCHANGE OF ROTATIONAL AND VIBRATIONAL ENERGY

Energy exchange processes in the collisions between an atom A and a diatomic molecule BC are usually considered in terms of the trajectory on the potential energy surface, which for $R_{A\text{-}BC} \to \infty$ correlates with the electronic state of the uncoupled system A + BC. If the electronic states of A and BC are non-degenerate, such a correlation defines a single potential energy surface, which is used subsequently in the dynamic calculation. On the other hand, even if only one of the two species has a degenerate electronic state, the interaction between A and BC lifts the degeneracy. Thus several closely spaced potential energy surfaces arise and in the limit $R_{A\text{-}BC} \to \infty$ these are correlated with the degenerate electronic state of the uncoupled system A + BC. If is found that the existence of several close surfaces alters significantly the probabilities of the rotational and vibrational transitions compared with the simplest case of a single surface, where it is possible to employ the adiabatic approximation.

Rotational Transitions

Recent experiments on rotational transitions in the $Na_2^*(^1\Pi)$ [21,22] and $Li_2^*(^1\Pi)$ [23,24] molecules, induced by collisions with inert gas atoms, showed that, together with the $j' - j = \Delta j = \pm 2$ transitions (the usual selection rules for rotational transitions in diatomic molecules with identical nuclei), there is a high probability of transitions with $\Delta j = \pm 1$, and the cross-sections of the one-quantum transitions depend strongly on the sign of Δj. A quantum interpretation of this effect has been given[25,26]. Here we shall consider the simpler semiclassical interpretation based on symmetry considerations alone.

One of the integrals of motion of the moving atom + diatomic molecule system is the overall angular momentum J. In the semiclassical approximation the vector J is identified with the vector of the relative angular momentum l, which is valid subject to the condition $l \gg j$, where j is the angular momentum of the molecule. In this approximation the trajectory of the relative motion of A and BC must be regarded as planar and a reflection in this plane is an operation which commutes with a non-stationary Hamiltonian.

If the electronic state of the molecule BC is defined in such a way that it has a certain symmetry ϵ ($\epsilon = 0, 1$) with respect to reflection in the plane passing through the molecular axis [i.e. the electronic wavefunction acquires the multiplier $(-1)^{\epsilon}$ on reflection in this plane], then the overall wave function (the electronic-rotational function) acquires the multiplier $(-1)^{j-m+\epsilon}$ on reflection in the collision plane[7]. Since the reflection in this plane is an exact symmetry operation, the collision can give rise to transitions between states with the same symmetry relative to the collision plane. Therefore the initial quantum numbers j, m, and ϵ and the final numbers j', m', and ϵ' are linked by the relation $j - m + \epsilon = j' - m' + \epsilon' + 2p$, where m denotes a projection of j onto the axis perpendicular to the collision plane and $2p$ is an even number.

If the electronic state of the molecule is non-degenerate, then ϵ is defined unambiguously and $\epsilon = \epsilon'$. This condition does not alone impose any limitations on the variation of j and therefore for low anisotropy of the interaction the most probable transitions correspond to the minimum change in j, i.e. $\Delta j = \pm 1$. If the molecule BC contains identical atoms (B = C), then the interaction potential of A and B_2 has an additional symmetry, which forbids transitions involving a change in j by an odd number. It follows from this selection rule with respect to m and from the relations quoted above that j can change only by an even number. Therefore the minimum permissible change in j for diatomic molecules with identical nuclei in a non-degenerate electronic state is ± 2.

If the molecule BC is in a degenerate electronic state, then there are always two components of the electronic eigenfunction with different ϵ. Therefore, even for molecules with identical nuclei, transitions with $\Delta j = \pm 1$ are allowed, provided that ϵ changes simultaneously: under these conditions, the symmetry of the overall wavefunction remains unchanged in the transition.

Thus the degeneracy of the electronic state leads to a major effect in the rotational relaxation of diatomic molecules with identical nuclei—the appearance of transitions with $\Delta j = \pm 1$ as well as transitions with $\Delta j = \pm 2$.

Vibrational Transitions

An experimental study of the vibrational relaxation of diatomic molecules revealed a number of instances of "anomalously" rapid deactivation of vibrations in collisions. In this case the standard defining the "normal" rate of deactivation is the average probability $\langle P_{10} \rangle$ of the transition (the $v = 1 \rightarrow v = 0$ transition) for diatomic molecules with identical nuclei or for molecules with a low asymmetry in a single gas-kinetic collision with the molecules of the heat reservoir which are all of the same type. The theory of the vibrational–translational energy exchange ($T - V$ processes) (see, for example, Refs. 1, 3, and 4) predicts the following approximate relation between $\langle P_{10} \rangle$ and the temperature T of the heat reservoir, the frequency ω of the vibrations of the molecule being deactivated, the reduced mass μ of the colliding molecules, and the radius $1/\alpha$ of the action of the intermolecular potential:

$$\ln \langle P_{10} \rangle = -\frac{3}{2}(4\pi^2\omega^2\mu/\alpha^2 kT)^{1/3} + A , \qquad (5)$$

where A is a function of the above parameters, which shows a smaller dependence on them than the first term on the right-hand side of Eqn. (5). This relation constitutes the basis for the widely used semiempirical correlation of the $\langle P_{10} \rangle$ for different molecules over a wide temperature range[1]. Naturally, under these conditions a high accuracy is not achieved, but even approximate validity of Eqn. (5) is sufficient for subsequent discussion.

An illustration of "normal" VT processes may be provided by the following reactions which have been fairly fully investigated over a wide temperature range:

$$\begin{aligned} &N_2(v=1) + N_2(v=0) \rightarrow N_2(v=0) + N_2(v=0) , \\ &O_2(v=1) + O_2(v=0) \rightarrow O_2(v=0) + O_2(v=0) , \\ &CO(v=1) + CO(v=0) \rightarrow CO(v=0) + CO(v=0) . \end{aligned} \qquad (6)$$

The $\langle P_{10} \rangle$ for all these processes, summarised in Fig. 42 in Kondrat'ev and Nikitin's book[1], fall within the shaded band in Fig. 2, whose width makes it possible to estimate the accuracy of Eqn. (5). In this figure $-\lg \langle P_{10} \rangle$ is plotted as a function of the dimensionless parameter $(\omega^2\mu a_0^2/kT)^{1/3}$, where a_0 is the Bohr radius. According to Eqn. (5), the slope of the band should be $(\lg e)\frac{3}{2}(4\pi^2)^{1/3} \cdot (a_0\alpha)^{-2/3}$. Comparison of this quantity with the average slope shown in Fig. 2 yields $\alpha \simeq 3.2/a_0$, which is the usual value adopted in the theory of the vibrational relaxation of diatomic molecules.

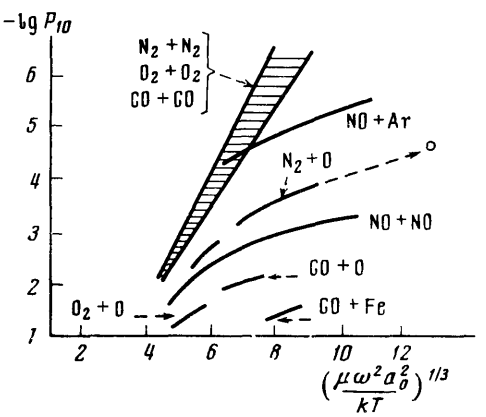

Figure 2. Probabilities of vibrational deactivation in "normal" and "anomalous" processes.

The experimental points for "anomalous" processes lie appreciably below this band. A number of anomalies have been explained by the contribution of VR processes, i.e. the transformation of the vibrational energy of the molecule into rotational energy (see Nikitin[4], §9). However, this explanation, which retains Eqn. (5) but alters the sense of the reduced mass μ, can be adduced only for processes where the reduced mass of the colliding species is much greater than the reduced mass of the molecule being deactivated. Finally, rapid relaxation can be caused by an exchange reaction if the latter is characterised by a low activation energy.

The processes with anomalously rapid relaxation known at present for which the VR mechanism is not effective are listed below (the references to the relevant experimental studies are indicated in square brackets):

$$\begin{aligned} &NO(v=1) + Ar \rightarrow NO(v=0) + Ar , && [27] \\ &NO(v=1) + NO \rightarrow NO(v=0) + NO , && [28, 29] \\ &CO(v=1) + Fe \rightarrow CO(v=0) + Fe , && [30] \\ &N_2(v=1) + O \rightarrow N_2(v=0) + O , && [31, 32, 33] \\ &O_2(v=1) + O \rightarrow O_2(v=0) + O , && [34] \\ &CO(v=1) + O \rightarrow CO(v=0) + O . && [33, 35] \end{aligned} \qquad (7)$$

The experimental $\langle P_{10} \rangle$, taken from the above investigations, are also illustrated in Fig. 2. Evidently the $\langle P_{10} \rangle$ for reactions (7) are much higher than the corresponding values for reaction (6). Thus the usual *VT* exchange model must be abandoned for reactions (7).

The only significant difference between reactions (6) and (7) is that in the first group both species involved are in a non-degenerate electronic state and in the second group one of the species has a degenerate electronic ground state. Accordingly, purely vibrational transitions are possible for the first group, while for the second group there is a possibility of both purely vibrational transitions and electronic-vibrational transitions in which the change in the vibrational state is accompanied by a transition from one adiabatic surface to another. The difference between the mechanisms of the purely vibrational and electronic-vibrational transitions can be understood most simply in terms of the model of an oscillator (molecule BC) excited by an external force (time dependent interaction between A and BC). The external force $F(t)$ acting on the oscillator consists of two components. The first component $F_a(t)$, which is comparatively large and varies with the characteristic collision time τ_c, is due to the relative adiabatic motion of A and BC. The second component $F_n(t)$, which is small and oscillates at the frequency of the splitting of the adiabatic states, arises from non-adiabatic transitions associated with the relative motion of the species. The effectiveness of these two components in exciting the oscillator is determined not only by their magnitude but also by their spectral composition, since only the Fourier component with the frequency ω excites (or deactivates) the oscillator.

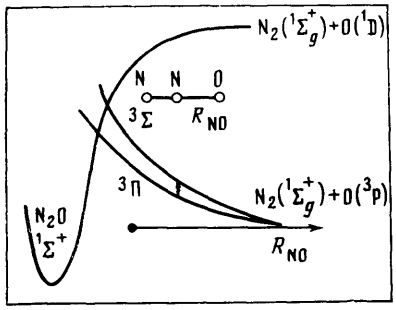

Figure 3. Electronic states of the N_2O system for a linear approach of N_2 and O.

The Fourier spectrum $f_a(\omega)$ of the component $F_a(t)$ may be bell-shaped with a characteristic width $\Delta\omega_c \simeq 1/\tau_c = \alpha u$ (u is the relative velocity of the molecules) and for $\omega \gg \alpha u$ the function $f_a(\omega)$ decreases exponentially:

$$f_a(\omega) = \int_0^\infty F_a(t)\cos\omega t\,dt \sim \exp[-\pi\omega/\alpha u] \text{ when } \frac{\omega}{\alpha u} \gg 1 \qquad (8)$$

The characteristic width of the Fourier spectrum of the component $F_n(t)$ is not determined by the condition that the frequency be equal to the reciprocal of the collision time (as for F_a) but by the maximum frequency ω_m corresponding to the transitions between the adiabatic states when A and BC move along a specific trajectory.

If the uncoupled A + BC system is in a non-degenerate state, then $F(t)$ has only one component $F_a(t)$. Under these conditions, the transition probability P_{10}, proportional to $|f_a(\omega)|^2$, varies approximately exponentially with the velocity subject to the condition $\omega/\alpha u \gg 1$. Such variation of P_{10} with the velocity in fact leads to the temperature variation of $\langle P_{10} \rangle$ in Eqn. (5), which is obtained after averaging P_{10} with respect to the relative velocities according to the Maxwell distribution. Then the parameter $(\mu\omega^2 a_0^2/kT)^{1/3}$, against which $\lg \langle P_{10} \rangle$ is plotted in Fig. 2, is equal to $(2\pi)^{-1/3}\omega a_0/u^*$, where u^* is the relative velocity of A and BC making the maximum contribution to the average transition probability.

If the uncoupled state A + BC is degenerate, it is necessary to take into account the contributions of $F_a(t)$ and $F_n(t)$. It is found[4] that, for fairly large values of $\omega\alpha/u^*$, the contribution of the force $F_a(t)$, which has a large absolute magnitude, is smaller than the contribution of $F_n(t)$, i.e. at fairly low temperatures the vibronic transitions prevail over the purely vibrational transitions. With increase of temperature (and hence with decrease of the parameter $\omega a_0/u^*$), the two contributions begin to compete and ultimately the purely vibrational transitions become more effective. Thus the theory explains the temperature variation of the "anomalous probabilities", which at high temperatures go outside the limit for the normal relation of the type of Eqn. (5).

Details of specific calculations of P_{10} for reaction (7) are quoted in the literature: NO + Ar,[37] NO + NO (Nikitin[4], §21), CO—Fe,[38] N_2 + O and O_2 + O,[39] and are discussed by Nikitin and Umanskii[40]. Here we shall mention only the following feature of the last two processes, in which there is a possibility of the formation of the intermediate complexes N_2O and O_3.

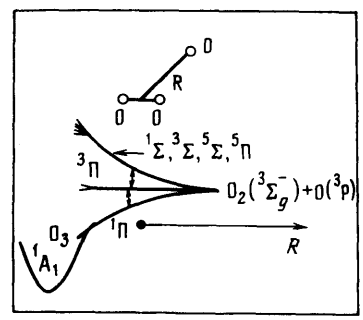

Figure 4. Electronic states of the O_3 system for a non-linear approach of O_2 and O.

The form of the states for the N_2O system (Fig. 3) shows that the vibronic transitions occur in the region where the vibration frequency is equal to the splitting of the electronic states (this region is designated by an arrow in Fig. 3), that is for energies appreciably lower than that of the intersection of the triplet states with the singlet ground state of NO_2. This rules out the possibility of forming a complex with an appreciable contribution of non-adiabatic effects in the region of the intersection of the state $^1\Sigma$ with the states $^3\Sigma$ and $^3\Pi$. This therefore throws doubt on the non-adiabatic relaxation mechanism proposed by Fisher and Bauer[41].

The form of the states for the system $O_2 + O$ (Fig. 4) shows that there is a state correlated adiabatically with the ^1A state of ozone. Therefore, in addition to adiabatic and non-adiabatic vibrational transitions involving the surfaces corresponding to the repulsion of O_2 and O, it is necessary to consider the energy redistribution as a result of the formation of the O_3 complex. Examination of the competition between various channels[39,40] based on different results[39,40] of numerical calculations on the dynamics of the O_3 system on the lower potential energy surface[42] shows that even at low temperatures the non-adiabatic and adiabatic mechanisms [but not described by Eqn. (5)] make comparable contributions.

In the CO + O system there is probably a situation intermediate between $N_2 + O$ and $O_2 + O$: the initial CO + O electronic state differs in spin from the CO_2 ground state (analogy with N_2O), but the CO + O interaction does not correspond to repulsion but to weak attraction (analogy with O_3). Clearly the theory of the relaxation of CO to O must take into account all the characteristics of this system, shown in the CO_2 decomposition reactions and in the recombination of CO and O (see, for example, Kondrat'ev and Nikitin[1] and Troe and Wagner[43]) as well as in isotope exchange reactions[44].

4. NON-ADIABATIC EXCHANGE REACTIONS

When the reacting molecules have a specified energy, he exchange reaction can usually be classified as one of he main types: the direct reaction (ricochet or explosive) or a reaction proceeding via a complex[1]. As a rule, the time of reaction is correlated with the general properties of the potential energy surface on which the reaction takes place. Since the involvement of several potential energy surfaces, frequently of completely different types, is characteristic of non-adiabatic reactions, the angular and energy distribution of the products can correspond to the existence of several reaction types. This was demonstrated for the first time in the reaction

$$Ba + Cl_2 \rightarrow BaCl + Cl\ , \qquad (9)$$

investigated spectroscopically[45,46] and by the method of molecular beams[47]. The product distribution was interpreted by postulating two potential energy surfaces correlated with the ground and excited states of the BaCl molecule.

The reactions proceeding via the formation of a long-lived complex can be described within the framework of a statistical approximation (see Kondrat'ev and Nikitin[1], Nikitin[4], and Nikitin and Umanskii's review[48]). In the simplest version of this approximation it is assumed that the distribution of the products between different electronic states, transitions between which are not forbidden by general conservation laws, is determined by a random redistribution law. However, this hypothesis is probably not valid. Calculation of the potential energy surfaces for the simplest reactions proceeding via a complex, such as

$$M + XM' \rightarrow MX + M' \qquad (10)$$

and

$$M + M'M'' \rightarrow MM' + M''\ , \qquad (11)$$

indicates a possible contribution of non-adiabatic effects (M, M', and M'' are alkali metal atoms and X is a halogen atom). In the first case[49] the surface leading to the excited state approaches very closely (to within 2–5 kcal mole^{-1}) the surface leading to the ground state and in the second case intersections actually occur. However, the relative contribution of the transition regions is very small, so that one cannot expect a statistical population of different electronic states. Similar processes can probably be described within the framework of a theory combining a statistical approach to the energy redistribution between different degrees of freedom for the motion of nuclei with a dynamic approach to the description of non-adiabatic transitions. Hitherto such a theory has not been developed. In this connection a purely dynamic approach is described below, in which reactions proceeding with and without a change in total spin are considered.

Reactions without a Change in Total Spin

The simplest reactions in which non-adiabatic effects are significant and which proceed in accordance with the Wigner rule are those between the inert gas atoms A^+ (A = He, Ne, Ar, Kr, or Xe) and hydrogen molecules. In these processes there may be competition between the exchange reaction

$$A^+ + H_2 \rightarrow AH^+ + H \qquad (12)$$

and the charge-transfer reaction

$$A^+ + H_2 \rightarrow H_2^+ + A\ . \qquad (13)$$

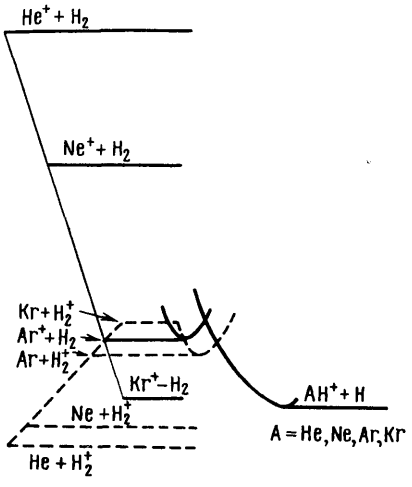

Figure 5. Correlation diagram for the electronic terms of the reactions $A^+ + H_2 \rightarrow A + H_2^+$ and $A^+ + H_2 \rightarrow AH^+ + H$.

The energy levels of the products and reactants are given in Fig. 5, where the energy minimum of the $AH^+ + H$ system (the continuous lines on the left refer to the $A^+ + H_2$ systems and the dashed lines to the $A + H_2^+$ systems) was chosen as the common zero for all the reactions. The correlation between the states on moving from left to right corresponds to motion along the reaction coordinate (12); the reaction pathway profiles then correspond to the rough adiabatic approximation. The parabolic rises on the left-hand side of the diagram correspond to the increase of energy on extension of the H—H bond (the rises for the $Ar^+ + H_2$ and $Ar + H_2^+$ systems are shown).

The potential energy surfaces for the system with A = He have the simplest structure because in this case the initial states are not degenerate and reactions (12) and (13) differ markedly in their energetics. Non-empirical[51,52] and semiempirical[53] calculations of the lowest surface yield a profile for the reaction pathway

$$He + H_2^+ \rightarrow HeH^+ + H, \qquad (14)$$

characterised by a shallow potential well (about 5 kcal mole^{-1}) and a rise equal to the endothermic heat of reaction. The calculations do not yield any indications concerning possible non-adiabatic effects. Experimental studies of reaction (14) in beams have shown[54,55] that the rise is overcome by the kinetic energy for low impact parameters and by the H_2^+ vibrational energy for high impact parameters. The theoretical study of the dynamics has been largely limited to a statistical approximation (see Nikitin and Umanskii's review[48]).

In his discussion of the cause of the low efficiency of the exothermic reaction (12) compared with the highly effective endothermic reaction (13) for A = He, Mahan[14] adduced general arguments showing that reaction (12) is non-adiabatic and that the potential surfaces which correlate with the initial states of the reactants and products, never approach one another. The same arguments remain in force also for A = Ne.[56]

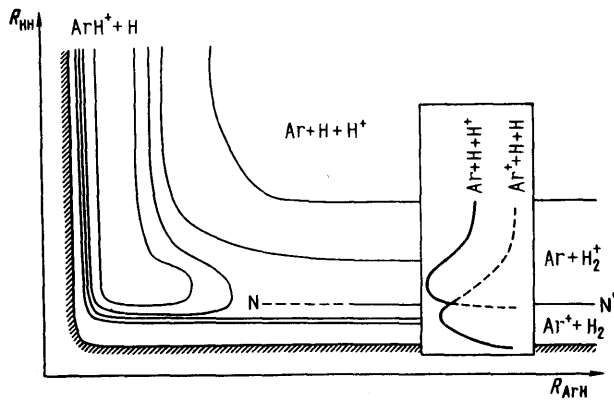

Figure 6. Schematic illustration of the potential energy surface for the collinear system ArH_2^+.

The situation changes significantly on passing to Ar and Kr. In this case the potential energy surfaces for reactions (12) and (13) are close, so that the Ar + H_2^+ and Ar^+ + H_2 diabatic states intersect when R_{HH} is varied and in the limit $R_{Ar-H} \rightarrow \infty$ the intersection is converted into a quasi-intersection for finite R_{Ar-H}. This is shown schematically in Fig. 6, where the lower adiabatic surface for the Ar—H—H linear system is illustrated. The insert illustrates the cross-sections of the surfaces of the ground and first excited states along the H—H coordinate. In adiabatic motion along this coordinate following the lowest surface the system reaches the Ar + H + H$^+$ plateau and for small H—H distances the profile of the cross-section yields the potential curve for the H_2 ground state in the repulsive region. In fact, for large R_{ArH}, the trajectory follows diabatic surfaces. In Fig. 6 this is reflected by the fact that, on approaching and intersecting the N—N′ line (which indicates the region of strong non-adiabatic interaction), the trajectory disappears from the figure or appears on it, depending on whether it approaches this line via the ground or excited state.

With decrease of R_{ArH}, the diabatic motion is increasingly replaced by adiabatic motion: in the region where the N—N′ line is shown dashed the trajectory continues to follow the lowest surface with an appreciable probability $1 - P_{12}$ also after passing through the region of non-adiabatic coupling. Finally, in the region of strong interaction, where the descent begins, the splitting between the states is high, P_{12} is close to zero, and the trajectory follows the lowest energy surface with a very high probability. Thus the dynamics is fully defined if the probability P_{12} of the non-adiabatic transition on the N—N′ line is specified. This treatment, proposed in a qualitative form by Gislason for the reactions discussed[58], was recently used as the basis for a more exact investigation of the dynamics by Chapman and Preston, who obtained a very good agreement with experiment for the cross-sections of reactions (12) and (13) (quoted by Tully[59]). When the energy is 3.36 eV, the charge-transfer cross-section appreciably exceeds the exchange cross-section (17.8 and 3.8 Å^2 respectively). However, Fig. 6 shows that the trajectories reflected from the region of turning of the dip, i.e. not leading to a reaction, result in charge transfer. Therefore dynamic calculations[60], carried out for a model adiabatic surface without taking into account non-adiabatic transitions and also the kinematic abstraction model[61] can be compared with the experimental results for the angular and energy distribution of the products.

A more complex situation arises in a reaction of the type

$$D^+ + DH \rightarrow H^+ + D_2 \qquad (15)$$

and in similar reactions for other hydrogen isotopes. Polanyi and coworkers[62] investigated the dynamics of this reaction on a non-empirical adiabatic surface. It was found, in agreement with the simplest ideas postulating the mechanism of a reaction proceeding via a stable intermediate complex, that the angular and energy distribution of the products agrees qualitatively with the predictions of the statistical theory. However, subsequent experiments[63] did not confirm the expected symmetry in the distribution of products with respect to forward and back scattering. A more detailed investigation of the structure of the surfaces showed that the surface employed in Polanyi's calculations[62] is in fact diabatic far from the potential well. It is necessary therefore to take into account the two lowest surfaces, as was done recently within the framework of semiempirical[64] and non-empirical[65] approximations. The adiabatic surface for the ground state of the H_3^+ linear system is illustrated qualitatively in Fig. 7, where the inserts show the cross-sections of the lowest (continuous line) and the first excited (dashed line) surfaces in directions perpendicular to the reaction coordinate. A surface of this type was used in recent calculations of the total and differential cross-sections of all the reactions pathways[59,66,67]:

$$D^+ + DH \begin{cases} \rightarrow H^+ + D_2 \text{ (channel } a \rightarrow b) \\ \rightarrow D + DH^+ \text{ (channel } a \rightarrow a^*) \\ \rightarrow H + D_2^+ \text{ (channel } a \rightarrow b^*) \end{cases} \qquad (16)$$

A satisfactory agreement was achieved with all the available experimental results for the differential cross-sections and the energy variation of the total cross-sections[59]. The calculated variation of the cross-sections

with the relative energy E_{transl} and for the zero-point DH level is shown in Fig. 8. This relation is simply correlated with the structure of the surfaces. The decrease of the cross-section $\sigma_{a\rightarrow b}$ of the adiabatic exchange reaction with increase of E_{transl} can be explained, by analogy with the usual adiabatic reactions, by an increase in reflection in the region of the turning of the trajectory. This effect is also shown by an increase of the charge-transfer cross-section $\sigma_{a\rightarrow b^*}$. Finally, the increase of $\sigma_{a\rightarrow b^*}$ for the non-adiabatic exchange reaction is due to the increase in non-adiabatic effects with increase of E_{transl}. If E_{transl} is sufficiently small, then the $a \rightarrow b^*$ pathway is unattainable according to the classical treatment. In this case the usual semiclassical description of the non-adiabatic transition is inapplicable and one must go outside the limits of this approximation in order to calculate the probability of the $a \rightarrow b^*$ reaction. One of the methods for extending the theory employs complex trajectories which can reach the non-adiabatic region at complex times. The probabilities of the $D^+ + DH \rightarrow H + D_2^+$ reaction were calculated in this way for low energies[68].

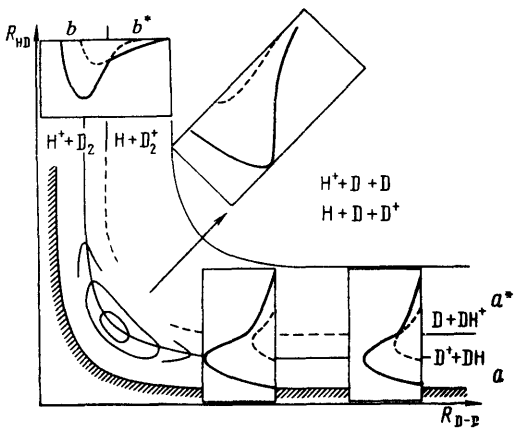

Figure 7. Schematic illustration of the potential energy surface for the collinear system HD_2^+.

Analysis of the dynamics of these reactions revealed the following important factor. Since the calculation of even the most detailed characteristic of the reaction (the differential cross-section) involves averaging with respect to at least two collision parameters (the initial phase of the vibrations and the azimuthal angle), the final result is comparatively insensitive to the transition probabilities along the lines of the quasi-intersection of the adiabatic surfaces. Therefore even comparatively rough estimates of the transition probabilities, carried out subject to the condition that the regions of the non-adiabatic transitions are unattainable on classical grounds, can yield satisfactory accuracy in the calculation of the cross-sections. This constitutes a significant difference between non-adiabatic processes involving three species and non-adiabatic atomic collisions; in the latter case the differential cross-section depends only on a single parameter (the impact parameter), which bears a single-valued (sometimes two-valued or three-valued) relation to the scattering angle[20]. Thus, whereas in the theory of non-elastic atomic collisions the main difficulty of the calculation of the cross-sections consists of the calculation of the transition probabilities, in molecular collisions the main problem involves the investigation of the motion of the system in the adiabatic regions of the configuration space.

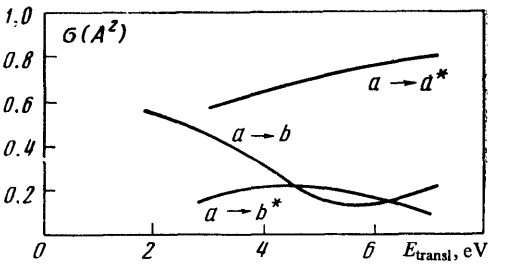

Figure 8. Variation of the cross-sections for reactions (16) with energy.

Another important difference between molecular non-adiabatic processes and atomic processes is that the vibration energy (and not the translational energy) can effectively induce transitions in molecular processes. With the potential energy surfaces for the H_3^+ ion, this is particularly clearly demonstrated by the calculation on the competition between the exchange and charge-transfer reactions[69]:

$$H + D_3^+ \begin{cases} \nearrow DH^+ + D \\ \searrow D_2 + H^+ \end{cases} . \qquad (17)$$

In this process the trajectory begins from the upper half of the pathway followed by the reactants (Fig. 7) subject to the condition that D_2^+ has undergone fairly intense vibrational excitation. Otherwise the trajectory of the reactants is not shown in Fig. 7 at all and their mutual approach, resulting in a transition from the diabatic to adiabatic D_2^+ vibrations, completely prevents the transition from the higher (dashed line) to the lower surface. Thus the probability of charge transfer, described by the transition of the system from the upper half of the reactant valley to the lower half, depends critically on the degree of vibrational excitation of D_2^+. The exchange process can proceed either adiabatically via singlet and triplet excited energy surfaces adjoining the D_2^+ diabatic terms in the initial process or via a non-adiabatic pathway along the lowest surface. In the first pathway it is necessary to overcome an energy barrier, which is not present in the second, but the latter includes a non-adiabatic transition. The competition between these possible processes determines ultimately the efficiency of the exchange.

Reactions Proceeding with a Change in Total Spin

If the set of the possible total spins of the reactants does not include any of the possible values of the total spin of the products, then the spin state of the system necessarily changes along the reaction pathway. The converse assertion is in general not valid: even if the

reaction satisfies Wigner's rule, the most effective reaction pathway need not necessarily correspond to an unchanged spin. An example of the latter process may be provided by the exothermic ion-molecule reaction

$$O^+(^4S) + N_2(^1\Sigma_g) \rightarrow NO^+(^1\Sigma) + N(^4S), \qquad (18)$$

which formally satisfies Wigner's rule.

In contrast to the majority of exothermic ion-molecule reactions, which usually proceed with large cross-sections and at low kinetic energies, the cross-section of reaction (18) is small for low energies and increases sharply with increase of E_{transl} and E_{vibr}. These features of the reaction can be understood qualitatively on the basis of correlation diagrams of electronic states (Fig. 9).

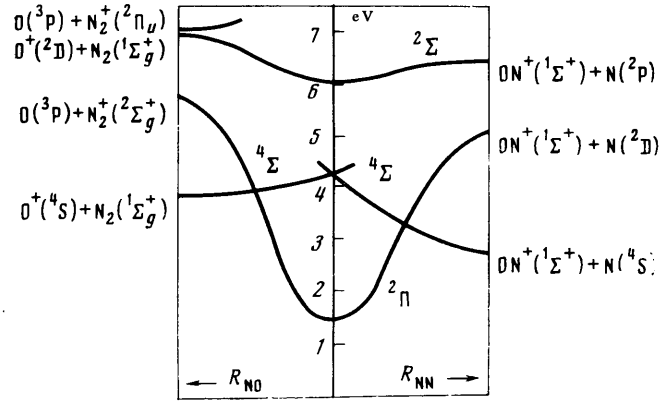

Figure 9. Correlation diagram for the electronic terms of the reaction $O^+ + N_2 \rightarrow NO^+ + N$.

The absence of activation energy in ion-molecule reactions is usually attributed to the fact that the repulsion of reactants due to the exchange interaction is fully compensated by polarisation attraction. However, if the repulsion is sufficiently marked, it can lead to a barrier even against the background of a strong polarisation interaction. Precisely this situation occurs in reaction (18). A non-empirical calculation of the cross-sections of the energy surfaces for the NNO^+ system has indeed shown[70] that in the initial and final pathways with a linear configuration the initial reactants and products repel one another ($^4\Sigma^-$ states). Possibly these two states are interconverted at short interatomic distances. The trajectory along the reaction pathway in an adiabatic mechanism (Fig. 9) requires that an activation barrier be overcome. The non-adiabatic pathway $^4\Sigma^- \rightarrow {}^2\Pi \rightarrow {}^4\Sigma^-$, in which the multiplicity of the system changes twice, can in principle compete with the above pathway. In this reaction mechanism the increase of the cross-section with the energy in the region of low energies can be explained by the existence of a small potential barrier at the point of intersection of the $^4\Sigma^-$ and $^2\Pi$ states in the initial pathway. After the N_2O^+ system has passed to the bonding state $^2\Pi$, it decomposes almost exclusively to the final state by a non-adiabatic transition at another point of intersection of the $^2\Pi$ and $^4\Sigma^-$ states[70].

With increase of the energy, the attainment of the region of the quasi-intersection of the $^4\Sigma^-$ states becomes possible. In this region the increase of the cross-section can be simply related to the increase of the transition probability with increase of E_{transl} and E_{vibr}. A rational calculation of the probability is possible only when the dynamic problem is solved. Since, however, the surface in this region is unknown, O'Malley[71] suggested that the system follows mainly the diabatic states and that the transition probability can be estimated by means of the first order perturbation theory in terms of the interaction corresponding to the quasisplitting. The change in the NN bond length is treated as the coordinate of the diabatic motion. In this case the profile of the reaction pathway has the form of a parabolic potential (the initial diabatic term corresponding to the N_2 vibrations), which is intersected by a monotonically decreasing potential (the final diabatic term describing the relative motion of N and NO^+) (Fig. 10). Within the framework of this one-dimensional model, the reaction probability $P(E_{transl}, E_{vibr})$ is proportional to the square of the overlap of the vibrational eigenfunctions and the wavefunctions for the continuous spectrum. For very low (thermal) energies, the overlapping of the functions of the vibrational ground state and those of the continuous spectrum is so slight that the entire diabatic mechanism is masked by the non-adiabatic mechanism $^4\Sigma^- \rightarrow {}^2\Pi \rightarrow {}^4\Sigma^-$.

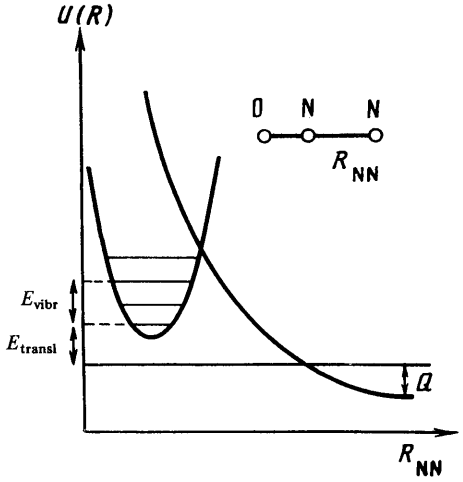

Figure 10. Illustration of the non-adiabatic mechanism of the reaction $O^+ + N_2 \rightarrow NO^+ + N$.

With increase of E_{vibr}, the overlapping will also increase and this is reflected in a sharp increase of the cross-section as a result of the contribution of the diabatic mechanism. On the other hand, the overlapping also increases with increase of E_{transl}. In the ground vibrational state, the cross-section reaches a maximum for values of E_{transl} such that the parabolic term intersects the repulsive term in the region of the minimum of the former. Finally, for a fixed E_{transl}, this mechanism predicts a less marked increase of the cross-section with

increase of E_{vibr} the higher the value of E_{transl}. All these conclusions, based on a simple model, were confirmed experimentally[72,73], which throws doubt on the adiabatic direct dislodgement mechanism put forward by Golubkov and Ivanov[74].

The mechanism of reaction (18) discussed above makes it possible to understand why the isotope exchange reaction

$$N'(^4S) + N_2(^1\Sigma_g) \rightarrow N'N(^1\Sigma_g) + N(^4S)\,, \qquad (19)$$

which is isoelectronic with reaction (18), occurs very slowly if at all[75]. Despite the existence of the stable complex N_3, transition to the latter is probably forbidden by the spin. On the other hand, isotope exchange reactions such as

$$\begin{aligned} O' + O_2 &\rightarrow OO' + O\,, \\ O' + CO &\rightarrow CO' + O \end{aligned} \qquad (20)$$

are very rapid: the first proceeds on the singlet surface of the O_3 ground state and the second on the triplet surface of CO_2. In many cases, for example for the reaction

$$N + NO \rightarrow N_2 + O\,, \qquad (21)$$

it is at present still impossible to interpret the mechanism unambiguously in view of the competition between the adiabatic and non-adiabatic pathways[76]. In general one may expect that, in reactions involving C, N, and O atoms and ions, non-adiabatic mechanisms should be extremely common (see, for example, Tully et al.[77] in connection with the reaction $N^+ + O_2 \rightarrow NO^+ + O$).

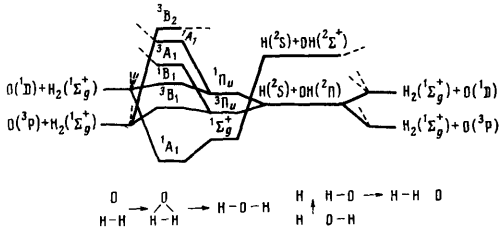

Figure 11. Correlation diagram for the electronic states of the reaction $O + H_2 \rightarrow OH + H$.

A dependence of the rate constant on the spin–orbit interaction in a number of similar reactions might constitute direct proof of a non-adiabatic mechanism infringing Wigner's rule. Unfortunately the activation energy also varies in many such series, so that it is fairly difficult to isolate the pure effect of the spin–orbit interaction. A reaction of the type

$$O(^3P) + HX(^1\Sigma) \rightarrow OH(^2\Pi) + X(^2P)\,, \qquad (22)$$

where X = Cl, Br, or I atoms, may be quoted as the only example which probably indicates the involvement of spin–orbit interaction[78]. Although formally there exists an adiabatic pathway along a triplet surface for these reactions, the correlation diagram for the states shows[79] that in the case of the non-linear configuration OHX the singlet surface lies below the triplet surface on the product side and the preferred reaction pathway at low temperatures involves a transition from the triplet surface $^3A'$ to the singlet surface $^1A'$. The transition probability for a fairly weak spin–orbit interaction is proportional to the square of the perturbation, which is determined by the fine splitting of the $^2P_{1/2}$ and $^2P_{3/2}$ states of the atoms X.[79] Thus the theory predicts a quadratic increase of the pre-exponential factor with increase of the splitting of the ^2P state, which is in qualitative agreement with experiment. For a more detailed investigation of the mechanism of reactions (22), it is necessary to have information about the details of the potential energy surfaces.

From this standpoint, the most complete information is available about the energy surfaces for the $O(^3P)$, $O(^1D) + H_2(^1\Sigma_g^+)$ system[80,81] (Fig. 11).

The study of the possible reaction pathways has shown that, although in the linear configuration the abstraction reaction

$$O(^1D) + H_2(\Sigma_g^+) \rightarrow OH(^2\Pi) + H(^2S) \qquad (23)$$

has a comparatively high activation energy (about 25 kcal mole^{-1}), there is probably no barrier for non-linear collisions. This instance of abstraction can be represented as decomposition of the vibrationally excited H_2O molecule in its ground electronic state, formed when $O(^1D)$ is inserted in the H–H bond. On the other hand, the abstraction reaction on the triplet surface,

$$O(^3P) + H_2(^1\Sigma_g^+) \rightarrow OH(^2\Pi) + H(^2S) \qquad (24)$$

has a potential barrier for all the configurations. If the $O(^3P) + H_2$ system reaches the line of intersection of the triplet and singlet surfaces before the region of the saddle point on the triplet surface, then, providing there is a fairly high transition probability, reaction (24) would occur without a change in spin. However, this probability is low for the H_2O molecule, as shown, in particular, by studies on the reaction

$$O^+(^4S) + H_2(^1\Sigma_g^+) \rightarrow OH(^2\Pi) + H^+ \qquad (25)$$

in molecular beams[82]. It has been found that reaction (25) proceeds via the direct mechanism, i.e. the H_2O^+ complex is not formed in the ground electronic state (Fig. 12).

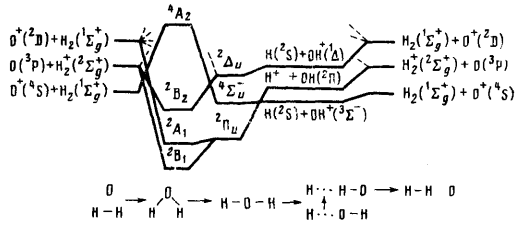

Figure 12. Correlation diagram for the electronic states of the reaction $O^+ + H_2 \rightarrow OH + H^+$.

For reactions involving heavier atoms, the spin–orbit interaction can be sufficiently strong to induce transitions between surfaces of different multiplicity [as happens in reaction (22)]. In this connection we may point to the reaction

$$O(^3P) + Br_2(^1\Sigma) \rightarrow OBr(^2\Pi) + Br(^2P)\,, \qquad (26)$$

which was recently investigated by the molecular beam method[83]. The angular and energy distribution of the

products shows that the reaction proceeds via the formation of the long-lived complex OBr_2. However, this complex can be formed only in its singlet state, so that the dynamic characteristics of the reaction show directly that the mechanism is non-adiabatic. A non-adiabatic mechanism should also be expected for reactions of excited oxygen atoms (see, for example, Pravilov and Vilesov's review[84]).

5. NON-ADIABATIC IMPACT DISSOCIATION

The impact dissociation of molecules BC in reaction (1) is understood as decomposition as a result of a single A + BC collision step. In this respect impact dissociation differs from thermal decomposition, which occurs as a result of many consecutive collisions of BC with the atoms or molecules of the heat reservoir. Many thermal non-adiabatic decomposition processes of triatomic molecules have now been studied[43] together with certain processes involving the thermal non-adiabatic decomposition of diatomic molecules into ions[85-87]. All these processes proceed via the stage of spontaneous non-adiabatic decomposition of an isolated molecule in the state which it attains after excitation. In this respect thermal non-adiabatic decomposition processes are analogous to processes involving spontaneous predissociation of molecules[88]: the only difference between them merely involves the excitation mechanism (by collision or by absorption of light), which has no direct bearing on decomposition.

In non-adiabatic impact dissociation the transitions take place between the potential energy surfaces of the system ABC and not between the terms of an isolated diatomic molecule BC, so that the excitation and decomposition cannot be treated independently.

Among all the non-adiabatic impact dissociation processes, the simplest is the predissociation of diatomic molecules induced by collisions. Molecules in an excited vibrational level of a bound excited electronic state, whose surface intersects that of the antibonding electronic state, usually undergo induced predissociation. If these states differ in parity or symmetry relative to reflection in the plane passing through the nuclei of BC, then spontaneous predissociation is impossible. Transitions between these states are induced by an external perturbation, which removes a corresponding symmetry operation of the Hamiltonian of an isolated molecule.

The induced predissociation of iodine in the $B^3\Pi(0_u^+)$ state has been investigated in greatest detail (see Mulliken[89] and the references quoted therein). The interpretation of the I_2 spectrum[89] and also non-empirical asymptotic calculations[90] yield the following pattern of states. The $0_u^+(B^3\Pi)$ state, which correlates with the $^2P_{1/2}$ and $^2P_{3/2}$ atomic states, is crossed by the $3_u(^3\Delta_u)$, $0_u^-(^3\Sigma_u^+)$, $0_g^+(^3\Sigma_g^-)$, $1_g(^3\Pi_g)$, and $2_g(^3\Pi_g)$ states on the side of the dissociation limit and by the $1_u(^1\Pi_u)$ and $0_u^-(^3\Pi_u)$ states on the side of the repulsive limb (all these states are correlated with the atomic states $^2P_{1/2}$ and $^2P_{3/2}$). The intersection with the 1_u state is responsible for the spontaneous dissociation of I_2 and the intersection with the states $0_u^-(^3\Sigma_u^+)$ and $0_u^-(^3\Pi_u)$ is responsible for the predissociation induced by the magnetic field; the intersection with the 0_g^+ state probably makes the main contribution to the predissociation induced by collisions. If it is supposed that the perturbing effect of the third particle reduces solely to the removal of the prohibition of the transition between the states†, which should now be regarded as diabatic from the standpoint of the classification adopted here, and that the transition probability is low, then the dissociation rate constant k should be correlated with the average parameter $2\pi a^2/\hbar|F_{1R} - F_{2R}|v_R$ in Eqn. (4). Calculations show that, for a fixed vibrational state of I_2, the constant k is proportional to $\alpha_A^2 R_0^{-9}$, where α_A is the polarisability of the other species A involved in the I_2 + A collision and R_0 is the gas-kinetic radius of the pair (in one of the earlier studies[92] it was erroneously suggested that k be correlated with the parameter $I_A\alpha_A\mu^{1/2}R_0^{-3}$). The available experimental results confirm this correlation.

However, this type of treatment is not sufficiently general, since no account is taken of the perturbing effect of the A species on the motion of the I atoms. Allowance for this perturbing effect in fact implies the solution of the dynamic three-particle problem, which was recently investigated within the framework of the classical[93] and semiclassical[94] approximations without taking into account non-adiabatic transitions.

Whereas the phenomenon of induced predissociation has been known for a comparatively long time, the study of non-adiabatic impact dissociation of molecules, which are in the lowest vibrational states before collision, is only just beginning. These processes include the dissociation of the salts NaBr,[95] CsI,[96] and TlX [97,98] (X = halogen atom) into ions in collisions with inert gas atoms and also the dissociation of the molecules X_2 in collisions with caesium[99] and potassium[100-103] atoms. The competition between the different possible non-adiabatic channels was also investigated for the latter processes[102,103]:

$$M + XY \rightarrow \begin{cases} M^+ + XY^- \\ M^+ + X + Y^- \\ M^+ + X^- + Y, \end{cases} \qquad (27)$$

(here M is an alkali metal atom and X and Y are halogen atoms). For relative kinetic energies exceeding the thresholds of the chemi-ionisation processes (27), these channels are the main ones and the competing exchange association processes involving the formation of neutral products,

$$M + XY \rightarrow \begin{cases} MX + Y \\ MY + X \\ M + X + Y, \end{cases} \qquad (28)$$

are comparatively ineffective. The main characteristics of the dynamics of reaction (27) and (28) can be explained qualitatively by the electronic harpooning mechanism[1]. Within the framework of this concept, two functions of the rough adiabatic basis—the function of the covalent state ψ_c (M + X_2 system) and the function of the ionic state ψ_i ($M^+ + X_2^-$) system‡—are adduced in the description of the reaction. Two potential energy surfaces correspond to these wavefunctions—the covalent (U_c) and ionic (U_i) surfaces. If the energy of the unbound system M + X + X is adopted as the starting point of the calculation, then, for large distances R between M and the centre of gravity of XX, the potentials U_c and U_i are

$$U_c = c(r, \gamma)/R^6 + \ldots$$
$$U_i = [I_M - A_{X_2}(r)] - e^2/R + \ldots \qquad (29)$$

† In terms of this approximation, the induced predissociation of diatomic molecules is analogous to the radiationless transitions induced by collisions in polyatomic molecules[91].

‡ For simplicity, the case where X = Y will be considered henceforth.

(where r is the internuclear distance in XX, γ is the angle between the vectors **r** and **R**, and $A_{X_2}(r)$ is the electron affinity of XX). The U_c and U_i surfaces intersect along a line given by the following equation when all interactions other than Coulombic are neglected:

$$e^2/R = I_M - A_{X_2}(r) \ . \qquad (30)$$

If account is taken of the interaction between the covalent and ionic states, the intersection is replaced by a quasi-intersection, so that the line defined by Eqn. (30) gives the location of the region of the possible non-adiabatic coupling. The minimum splitting between the states is equal to twice the matrix element of the interaction

$$V_{ic} = C(R, r, \gamma)\exp[-(A_{X_2}(r)/I_n)^{1/2} \cdot R/a_0]\cos^2\gamma \ . \qquad (31)$$

The variation of V_{ic} with the coordinates is specified mainly by the last two multipliers of this expression, which depend on their arguments to a greater extent than does the coefficient $C(R_r, \gamma)$.[104] A characteristic feature of the interaction is the equality of V_{ic} to zero when $\gamma = \pi/2$, i.e. when MX_2 has the configuration of an equilateral triangle. This corresponds to the familiar case of the conical intersection of the states[4,7].

In the products channel the interaction between the states rapidly attains its asymptotic value corresponding to the interaction of the covalent and Coulombic states of an isolated molecule. In terms of the coordinates R_{MX} and R_{XX}, the line of the quasi-intersection in the products channel,

$$R_{MX} = R^0_{MX} \ , \qquad (32)$$

on which the splitting of the adiabatic terms is constant, becomes straight.

In the region of strong interaction of all three particles, the line of the quasi-intersection, defined by Eqn. (30), is continually converted into the straight line defined by Eqn. (32). The position of this line and the general characteristics of the two lowest U_c and U_i surfaces for the collinear configuration of the M + X + X atoms are illustrated in Fig. 13. As in the previous Figures, the inserts show the cross-sections of the lowest (continuous lines) and highest (dashed line) adiabatic surfaces. The quasi-intersection line is represented by a continuous curve in the output channel in conformity with the fact that, for energies such that chemi-ionisation is possible, the system in this channel is characterised by diabatic behaviour (the trajectory of the representative point does not cross the continuous line). In the initial channel, part of this line is shown dashed (there is an appreciable probability of adiabatic motion of the system), which when produced yields the limit of the sharp descent on the adiabatic surface. In this region non-adiabatic transitions are unlikely, since the splitting of the states is large.

Various approximations for the description of the energy surfaces of the ground state of the MXX system are now known[105-108] and also semiempirical[109] and non-empirical calculations have been made for the simple LiFF system[110,111].

The dynamics of adiabatic reactions (28) was investigated in a series of studies with an exact solution of the classical dynamic problem[105-108,112], as well as within the framework of simplified approaches[113,114]. The qualitative dynamic pattern corresponds to the vertical transition $X_2(r) \rightarrow X_2^-(r)$ in the field of the ion M^+ retained in the vicinity of X_2^- by Coulombic attraction ("the electron harpoon"). The stripping mechanism with participation of the spectator[1], which was proposed in earlier investigations and was shown by subsequent investigations, not to be fully justified, constitutes the limiting simplification of the mechanism described above.

The relevant studies on the dynamics of non-adiabatic reactions (27) are only just beginning. Important information about the variation of the adiabatic terms can be derived from the study of non-elastic and atomic collisions accompanied by the formation of ions[115-117]:

$$M + X \rightarrow M^+ + X^- \ . \qquad (33)$$

In particular the matrix element for the interaction between the ionic and covalent terms[116], which determines the oscillatory structure of the differential cross-section of reaction (33), can be estimated in this way. The interpretation of the differential cross-section of the reaction involving charge transfer to the molecule [the first reaction (27)] is more difficult, since it is then necessary to take into account the effect of the rotation and vibration of the molecule X_2. It is found that the characteristics of the differential cross-sections can be understood if rotation alone is taken into account[118].

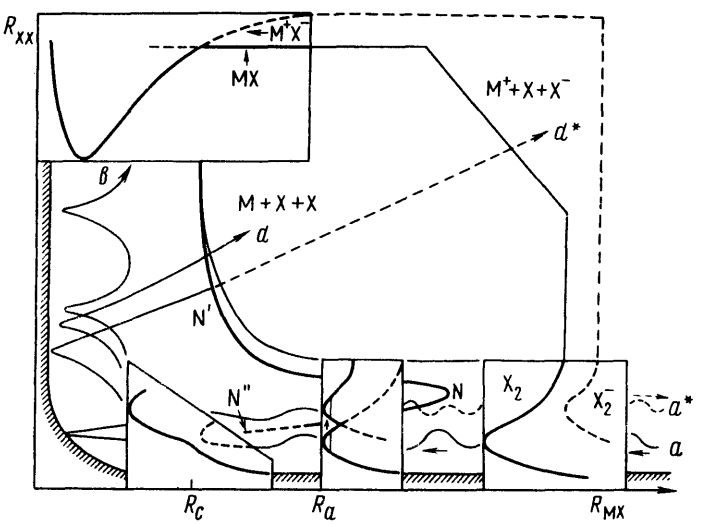

Figure 13. Schematic illustration of the potential energy surface for the collinear system MX_2.

However, the energy dependence of the total charge-transfer cross-section near the threshold depends significantly on the vibrations of X_2. The experimental threshold for the formation of the ion is equal to the difference between the ionisation potential of M and the adiabatic electron affinity A_a of the molecule X_2. This is at first sight inconsistent with the hypothesis of the vertical transition $X_2 \rightarrow X_2^-$ leading to the formation of ions subjected to a strong vibrational excitation. The non-vertical transition corresponding to the affinity A_a also corresponds to the transition between the potential minima of X_2 and X_2^-. This is possible, for example, as a result of tunneling between two potential wells (the potentials of the X_2 and X_2^- vibrations) for distances between the reactants such that the energy levels of the ground vibrational states in the diabatic potentials of the molecule and ion are the same. This transition, occurring when $R \simeq R_a$,

is indicated by an arrow in Fig. 13. Its probability is proportional to the Franck-Condon factor $S_{00}[X_2(v = 0) \rightarrow X_2^-(v = 0)]$ and determines the cross-section directly above the threshold. The energy dependence of the cross-section should be correlated with the variation of the overlap integrals S_{0v} with the number v of the vibrational level of X_2^-, which may be excited on electron transition[119].

However, it is possible to put forward also another mechanism to account for the threshold variation of the cross-section[120-121]. According to this mechanism, involving the classical approximation, the trajectory follows the minimum in the reactant valley (the initial trajectory a), reaching a sharp break in the states at $R \simeq R_C$ in the region of the quasi-intersection of the covalent and ionic states [the coordinate of the break R_C corresponds to the vertical transition $X_2 \rightarrow X_2^-$ when the reactants approach one another, and is determined from Eqn. (30) in which one must put $r = r_e$]. After reaching the break, the trajectory corresponds to the extension of the bond in the ion X_2^-, i.e. to the onset of dissociation of the ion. However, before this process reaches completion the collision of M^+ with one of the atoms of X_2^- leads to marked deactivation of X_2^- as a result of which the ion loses energy and M^+ is strongly accelerated. The ion M^+ begins to move along the reactant valley in the opposite direction and can intersect the line N'NN" of the quasi-intersection of the surfaces in the region where the motion is almost diabatic. The final result of such collision (the trajectory a^* corresponding to the highest state) is the formation of the ions M^+ and X_2^-, the reaction threshold being determined by the adiabatic electron affinity of X_2 despite the fact that the electron transition is a vertical process. This mechanism predicts a correlation between the energy dependence of the cross-section and the probability of the deactivation of the ion X_2^- on collision with M^+ as a result of the brief exchange interaction. Naturally, elucidation of the true mechanism of the formation of ions requires a more thorough investigation of the collision dynamics.

With increase of the energy above the molecular ion formation threshold, the atomic ion formation threshold is reached. One of the trajectories (trajectory d^*) leading to such products is illustrated in Fig. 13. The velocity along the quasi-intersection line N'N is so high that the probability of the non-adiabatic transition is close to unity. Under these conditions, the formation of neutral atoms in adiabatic dissociation (trajectory d) and of neutral molecules in adiabatic exchange (trajectory d) is unlikely.

Possibly a large number of surfaces must be adduced in order to refine further the mechanism of such reactions. This is indicated by the results of a study of processes involving the formation of the products $X + Y^-$ and $X^- + Y$ in reaction (27).[103] Moreover, if one is dealing with impact dissociation under the influence of an inert atom (for example the reaction $TlCl + Ar \rightarrow Tl^+ + Cl^- + Ar$), then it is absolutely essential to take into account several potential surfaces for a correct interpretation of the experimental results.

The Chemisorption of Oxygen on Group IB Metals and Their Surface Oxidation

V.E.Ostrovskii

The modern views on the kinetics and mechanism of the chemisorption of oxygen on group IB metals and their surface oxidation (up to the appearance of an oxide phase) are described. Processes occurring in the temperature range from 0° to 300-400°C, which are of interest in connection with problems of catalysis and radioelectronics, are mainly considered. The bibliography includes 123 references.

I. INTRODUCTION

Group IB metals are catalysts of mild, partial oxidation[1,2]. Catalytic oxidation processes are usually regarded as occurring in stages and it is believed that one of the stages is chemisorption of oxygen[1-4]. The overall rate of the catalytic process on metallic catalysts in general and on group IB metals in particular usually depends significantly on the rate of adsorption of oxygen[5]. This is one of the reasons why much attention is being devoted to the study of the kinetics and mechanism of the chemisorption of oxygen on copper, silver, and gold. Another reason is the requirement for pure materials in the radioelectronics industry[6] and the consequent necessity for assessing the possible contamination of the metals by oxygen under various conditions and also for assessing the effect of the chemisorption of oxygen on the properties of the finished articles. The third reason for studying the above processes is the effect of small amounts of oxygen on various mechanical characteristics such as creep (see, for example, Ostrovskii et al.[7]), strength (see, for example, Gupta[8] and Ahlers[9]), the self-diffusion coefficient (see, for example, Cabane[10]), etc. The chemisorption of oxygen on gold is also of special importance in connection with the problem of reference electrodes in measurements of the changes in contact potentials during the adsorption of oxygen on various surfaces.

II. CERTAIN CHARACTERISTICS OF THE SURFACE INTERACTION OF COPPER, SILVER, AND GOLD WITH OXYGEN

The phase interactions of copper, silver, and gold with oxygen differ sharply in the thermodynamic sense. Table 1 presents the standard free energies of formation ΔG_{f_0} and the standard heats of formation ΔH_{f_0} of copper, silver, and gold oxides from the elements, both at 25°C.[11] It follows from the table that, in the temperature range considered, the metal-oxygen equilibrium involving copper is sharply displaced towards the formation of the oxide and in the case of gold towards the metal. The equilibrium position for silver depends on the oxygen pressure and temperature. Thus the equilibrium oxygen pressure over Ag_2O at 201°C is 1.526 atm, while at 174°C it amounts to 0.596 atm.[12] Nevertheless oxygen is chemisorbed on the pure surfaces of all the metals considered even at pressures much lower than 1 mmHg. The problem of the chemisorption of oxygen on gold remained open for a long time. It had been concluded[13] that oxygen is not chemisorbed, but subsequently it was shown[14] that the method of measurement used in the earlier study[13] was insufficiently sensitive. The widely held view that oxygen is not chemisorbed on gold was also supported by other results[15,16], where the degree of adsorption was not measured directly but it was observed that the electronic work function of gold does not change when the latter is in contact with oxygen at room temperature. However, it was shown later[17-22] and also in earlier studies[23,24] that gold in powder form[18,19,22-24] and in the form of a wire[17], films[20], and foil[21] can chemisorb oxygen.

Table 1. Thermochemical parameters of the oxidation processes.

Oxide	State	ΔH_{f_0}, kcal mole^{-1}	ΔG_{f_0}, kcal mole^{-1}	Remarks
CuO	crystalline	−37.1	−30.4	See also Refs.37 and 38
Cu_2O	ditto	−39.84	−34.98	See also Refs.37 and 38
Ag_2O	»	−7.31	−2.59	See also Ref.12
Ag_2O_2	»	−6.3	—	
Au_2O_3	»	19.3	39.0	

For many years it was not established reliably whether or not oxygen is chemisorbed on gold, since studies of the chemisorption of oxygen on group IB metals encounter a number of the difficulties described above, one of which is common to many metals and others are specific to the metals of the given Group.

1. The presence of admixtures of light elements, in the first place hydrogen and oxygen, and also of catalyst and

adsorption poisons such as sulphur, chlorine, etc. Oxygen may be present owing to the contact of the specimen with air before its introduction into the apparatus or as a result of its contact with the residual gas in the evacuated apparatus. In order to remove oxygen from copper[25], silver[26-28], or gold[19], prolonged treatment by heating with hydrogen or carbon monoxide is necessary. However, there is then a risk of the contamination of the surface layer of the specimen with hydrogen or carbon. At the same time the presence of oxygen on the surface lowers the degree and the initial rate of its adsorption and the presence of hydrogen can lead to an unduly high value of the observed degree of adsorption, since some of the oxygen is consumed in the oxidation of hydrogen. The presence of very small amounts of catalyst poisons as impurities on the surface can also alter its adsorption properties[29,30]. It is then necessary to take into account the ability of many non-metallic impurities in metals to migrate rapidly towards the surface[31-34].

2. The presence of small amounts of impurities comprising other metals. For example, it is known that the addition of very small amounts of nickel to copper sharply enhances its catalytic properties[35], while mercury vapour can alter sharply the adsorption and other properties of gold[36].

3. The possibility of the oxidation of lubricant vapour during the experiments on the adsorption of oxygen[19]. An impression may be created that oxygen is adsorbed to a greater extent than is in fact the case if one does not take into account the fact that part of it is consumed in the formation of water and carbon dioxide. The physical properties of the adsorbent such as the electron work function, electrical conductivity, etc. can also change as a result of the oxidation of the lubricant on the surface.

The need to work under the conditions of high purity leads to a sharp decrease of the specific surface. This imposes more stringent requirements for the purity of the adsorbant and gas employed and for the sensitivity of the method of measurement.

III. KINETICS OF THE PROCESSES

Here we shall consider mainly adsorption and surface oxidation, where the rate of absorption of oxygen is limited by adsorption and not by diffusion in the solid specimen. These processes can occur under different conditions. Such an approach makes it possible to assess the magnitude of the adsorption rate constants. These constants are needed in the derivation of kinetic equations for heterogeneous catalytic oxidation processes involving a mechanism comprising a number of stages and also for the calculation of the degree of contamination of the test metals by oxygen under the conditions of contact with the latter.

1. The Copper–Oxygen System

Above 0°C, copper can sorb irreversibly more than one monolayer of oxygen. Even at −195°C a very thin oxidised layer is formed on copper as a result of the chemisorption of oxygen[39]. This implies that the process is not limited to chemisorption alone, but that oxygen can penetrate also deeper layers of the metal. Thus the rate of sorption of oxygen can depend on at least two processes: the adsorption process proper as a result of which oxygen appears on the surface and another process leading to the generation of copper atoms on the surface capable of adsorbing new portions of oxygen. On contact between copper and oxygen, an induction period is initially observed, during which the formation of the oxide phase cannot be observed on the surface with the aid of the electron microscope[40]. During this period, oxygen is adsorbed and dissolved in the metal phase. The solubility of oxygen in the massive metal (s, in parts per million) up to 750°C is given by the equation[41]

$$\lg s = 2{,}2875 - (956.4/T). \qquad (1)$$

Solubilities close to those given by Eqn. (1) have been published[42]. The standard enthalpy of solution of oxygen in copper $\Delta H^{\circ}_{298} = -10$ kcal mole^{-1} [43] and the free energy of the process up to 750°C can be calculated from the equation $\Delta G = 4360 \pm 14.18\,T$.[41]

The appearance of nuclei of the oxide phase with dimensions less than 100 Å can be observed on the copper surface at the end of the induction period. Copper(I) oxide or Cu_2O_3, which has the structure of the former with a large number of defects, are mainly formed at temperatures up to 600–800°C.[44-47] At higher temperatures copper(II) oxide is also produced[48,49].

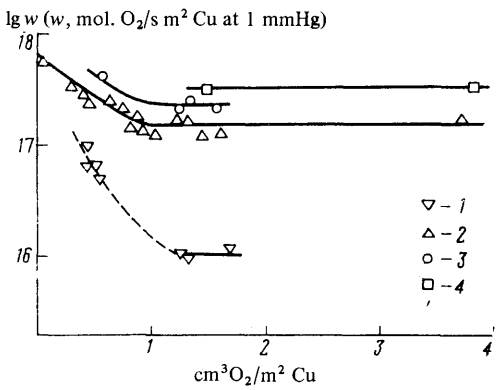

Figure 1. Variation of the rate of sorption of oxygen by copper with the degree of oxidation at different temperatures[18,50] (°C): 1) 55; 2) 105; 3) 125; 4) 135.

There have been comparatively few studies on the rate of adsorption of oxygen in the stages corresponding to the very beginning of the oxidation. Table 2 presents the results of those where measurements were made of the rate per unit surface of the specimen. It also includes the results of the determination of the activation energy. The kinetics of the earliest stage in the sorption of oxygen by copper have been investigated[18,50]. The preliminary reduction of the copper(II) oxide powder was carried out for 190 h at 300–330°C, with subsequent evacuation for 80 h at 350–400°C. Fig. 1 shows results from the study of the dependence of the rate of oxygen sorption on the degree of oxidation at different temperatures. Oxygen was admitted in portions at an initial pressure of 0.13 mmHg. The kinetics of the sorption of oxygen are described by the equation

$$r_i = 4.1 \times 10^{23} \sqrt{\frac{T}{273}} \cdot P_{O_2}\, e^{-11800/RT} \qquad (2)$$

Table 2. Kinetic data for the copper–oxygen system.

[a] Pressure 76 torr. Copper sheet specimen subjected to preliminary oxidation to give a content of about 10 cm^3 O_2/mm^2 Cu.
[b] With decrease of σ from 1.0 to zero, the activation energy and k both fall.
[c] In the range $\sigma < 1.0$ cm^3 O_2/m^2 Cu the rate of adsorption decreases with increase of σ.
[d] In the range $\sigma < 0.2$ cm^3 O_2/m^2 Cu the rate of adsorption decreases with increase of σ.
[e] The average rate of adsorption for adsorption from zero to about 20 cm^3 O_2/m^2 Cu.
[f] Specimen oxidised to give a content of about 35 cm^3 O_2/m^2 Cu.

for degrees of oxidation in the range 1–4 cm^3 O_2/m^2 Cu. On further sorption of oxygen, the kinetics change sharply. When the degree of oxidation σ is less than 1 cm^3 O_2/m^2 Cu, the activation energy and the pre-exponential factor diminish with decrease of the degree of oxidation in such a way that the rate of sorption of oxygen increases at the same time (Fig. 1). Qualitatively similar behaviour was observed in another investigation[51]. The quantitative discrepancies between the results of the two studies[50,51] are probably due to the fact that in the investigation of Shakhovskaya et al.[51] the copper was cleaned in a different way before the oxygen sorption experiments (treatment for several hours at 250°C). The kinetic parameters obtained in the remaining studies whose results are presented in Table 2 are known to refer to surface-oxidised copper specimens which usually contained nuclei of the oxide phases.

The effective activation energies listed in Table 2 for such cases were influenced by diffusion phenomena; these results will be discussed in the section on the mechanism of oxygen sorption. At the end of the induction period the kinetics for the surface-oxidised specimens are no longer described by a simple equation of type (2) and as a rule the process is treated within the framework of the theory of Cabrera and Mott[52], although this does not account for a number of the observed phenomena and relations, for example the discontinuity of the oxidised layer, the differences between the rates of oxidation on different crystal faces, etc.[42] According to the kinetic measurements of Ostrovskii and Kalistratova[50], up to the sorption of 4 cm^3O_2/m^2 Cu (2.5×10^{19} mol./g Cu) the rate of sorption is proportional to the oxygen pressure (the specific surface of copper was 0.3 m^2g^{-1}). This suggests that in these experiments the diffusion of oxygen did not limit the rate of the process, i.e. oxygen was sorbed until the instant of the appearance of the oxide phase. In a study[40] on non-porous copper about 35 cm^3 O_2/m^2 (5×10^{16} mol./g Cu) was sorbed during the induction period at 150°C. This value is close to the solubility of oxygen in massive copper. Comparison of the results of Ostrovskii and Kalistratova[50] with those of Ertl[53] shows that porous copper can sorb (per unit weight of the metal) several orders of magnitude more oxygen than massive specimens. However, when the limiting degree of sorption of oxygen, occurring up to the formation of a new phase, is referred to unit surface area, this quantity differs much less. Although the specific surfaces differ by a factor of several thousands, in the case under consideration the degrees of sorption of oxygen referred to 1 m^2 differ by less than an order of magnitude. This is evidence for unusual properties of the surface layer of copper with respect to the sorption of oxygen. The main bulk of the oxygen dissolved in copper at low temperatures is probably located in the layer near the surface.

The rates of sorption of oxygen by different copper faces are different, but not as a rule by more than an order of magnitude. Gwathmey and Lawless[54] and later others[48,50] concluded that the (100) face sorbs oxygen fastest. Jardinier–Offergeld and Bouillom[56] observed the highest rate constant for the sorption of oxygen and the shortest induction period at 511°C for the (111) face. The induction period for the (110) face was longer than for the (111) face and for the (100) face it was longer still. The information available about the relative rates of sorption of oxygen by the (100) and (110) faces is contradictory[56–58]. Since the results were obtained at different temperatures, it may be that the discrepancies are due to marked differences between the activation energies for the sorption of oxygen on different faces[59].

2. The Silver–Oxygen System

Table 1 shows that the decrease of free energy in the oxidation of massive silver under standard conditions is small. In the oxidation of a cryptocrystalline powder the decrease of free energy may be somewhat greater, but, when the crystal size exceeds 10^{15} Å^3, which is usually the case for silver powders of films, comminution has little influence on the equilibrium position. At an oxygen pressure of the order of several mmHg or below only a two-dimensional adsorption structure is observed on the silver

surface[60], but no oxide phase. At temperatures above 0°C silver strongly sorbs considerable amounts of oxygen. Together with chemisorption, oxygen may dissolve in the bulk of the metal. The dissolution of oxygen in massive silver has been investigated[63-66]. The rate of dissolution and the solubility of oxygen are proportional to the square root of pressure. The heat of solution of oxygen in silver is about 12 kcal mole^{-1}.[67,68]

The formation of a monolayer adsorbed on non-porous specimens requires less oxygen than can dissolve in the specimen according to solubility data. However, the corresponding values have comparable orders of magnitude. The volume of oxygen corresponding to the formation of a monolayer on porous specimens can be much greater than the volume corresponding to the solubility, measured per unit weight of massive specimens. Nevertheless there are data[69] showing that, even at an oxygen pressure of about 0.2 mmHg, the decrease of oxygen pressure on contact with silver corresponds to the sorption of several oxygen monolayers. It is believed[69] that the surface layers of silver can sorb additional amounts of oxygen in the tetrahedral vacancies of the crystal lattice. Possibly the sorption of oxygen by the surface layers of copper described above is of the same type. The rate of the process described in the literature[69], which has been called "deep adsorption", is two–three orders of magnitudes lower than the rate of chemisorption of oxygen on silver. For this reason, the experimental rate of chemisorption should not be significantly influenced by this process.

The main results of the studies of the chemisorption of oxygen on silver are presented in Table 3. In selecting the studies quoted in the table the same criteria were applied as in the selection of the studies in Table 2. Comparison of the data in Tables 2 and 3 shows that the rate of sorption of oxygen by silver is two–three orders of magnitudes lower than the rate of sorption by copper. The rates of sorption of oxygen by silver obtained in different studies differ within the limits of a single order of magnitude when the comparison is made at the same temperature and degree of oxidation. Examination of the complete set of investigations of the chemisorption of oxygen on silver lead to the conclusion that three adsorption regions should be distinguished as a function of the degree of oxidation. The adsorption in these three regions is probably described by different kinetic equations. The first region corresponds to a change in the degree of oxidation σ up to 0.10–0.12 cm^3 O_2/m^2 Ag, i.e. within the limits of surface coverage by an oxygen monolayer constructed in such a way that an oxygen atom is bound to two silver atoms (AgS_2O, where Ag^S is a silver atom on the surface). The second region corresponds to $0.12 < \sigma < 0.22$–0.26, i.e. extends up to the adsorption of an oxygen monolayer in which an oxygen atom is bound to one silver atom (Ag^SO or $Ag^S{}_2O_2$). The third region corresponds to the adsorption of a greater amount of oxygen. The absorption in the first region was investigated in greatest detail in three studies[63,70,71], where measurements were made from σ = 0.05 cm^3 O_2/m^2 Ag. Other workers[71,72] described the results of studies on the kinetics in this region obtained at a pressure of about 10^{-2} mmHg, in terms of an equation of the type

$$r = Ce^{-b\Gamma}Pe^{-E/RT}, \qquad (3)$$

where $C = 10^{-9}$ mole s^{-1} cm^{-2} and $b \simeq 2.6 \times 10^{10}$ cm^2 mole^{-1} at 20°C. The rate of adsorption is proportional to the pressure. According to Temkin and Kul'kova[69], the activation energy for adsorption in this region is 7–8 kcal mole^{-1}, increasing to 10 kcal mole^{-1} when σ = 0.135 cm^3 O_2/m^2 Ag. According to other results[70], the activation energy depends in a complex way on temperature and on the degree of oxidation. The adsorption in the second region has also been studied[28,70]. According to the present author's results[28], the adsorption kinetics in the range $0.14 < \sigma < 0.21$ are described by the simple equation

$$r = kP(1-\theta)\cdot e^{-E/RT}, \qquad (4)$$

where $\theta = 0$ when σ = 0.13 cm^3 O_2/m^2 Ag and $\theta = 1$ when σ = 0.26 cm^3 O_2/m^2 Ag and $k = 7 \times 10^{11}$ mol. O_2 s^{-1} cm^{-2} mmHg^{-1} at 110°C. The activation energy for adsorption in this region, estimated[28] from the theory of the absolute rates of heterogeneous reactions[72], is 12 kcal mole^{-1}. In the third region the rate of adsorption is limited by surface diffusion[70] or diffusion in the surface layer[69]. The activation energy for the adsorption of oxygen is 22–29 kcal mole^{-1}.[70,73]

f $0.1 < \theta < 1.0$; $\theta = 0.1$ when σ = 0.143 and $\theta = 1.0$ when σ = 0.26.

The rate of adsorption of oxygen and the maximum degree of adsorption are significantly influenced by the presence of electronegative elements as impurities in the silver. Thus 25% surface coverage of silver by chlorine reduces the rate of subsequent adsorption of oxygen[30] and surface coverage by sulphur even to the extent of several percent greatly reduces the degree and rate of adsorption of oxygen[29,74]. A theory of these phenomena has been discussed from the standpoint of the effect of mutual influence in chemisorption[75]. With the aid of added sulphur,

chlorine, selenium, and tellurium labelled with radioactive isotopes, it was established[31-33,76] that admixtures of electronegative elements (10^{-4}–10^{-1} at.%), uniformly distributed throughout the bulk of silver, diffuse to the surface during the pelleting of the catalyst at 200–300°C. Therefore, even when the concentration of the impurities is of the order of 10^{-3} at.% with respect to the specimen as a whole, the surface concentration can be of the order of several per cent, which, as stated above, influences significantly the adsorption of oxygen.

The total amount of oxygen which can be sorbed by pure silver per unit surface area is about one order of magnitude less than the amount of oxygen which can be sorbed by copper. At the same time oxygen hardly oxidises silver at pressures below 100–200 mmHg, but diffuses fairly rapidly through it. Therefore diffusion through silver can be used for the thorough separation of small amounts of oxygen[7] from hydrogen, nitrogen, and the inert gases, which are not adsorbed on silver.

3. The Gold–Oxygen System

The solubility of oxygen in gold at 300–900°C is only 5×10^{-4} cm^3 O_2 per gram of gold[78]. This is nevertheless more than the volume of oxygen required to adsorb a monolayer on the surface of 1 g of the massive metal. On the other hand, for porous gold with a specific surface of the order of 0.1 m^2g^{-1} the solubility is orders of magnitude smaller than the volume of oxygen needed to form a monolayer. The chemisorption of oxygen at 100–150°C corresponds to the formation of a surface monolayer with one oxygen atom for each gold atom[19]. Therefore in the study of the chemisorption of oxygen its dissolution can be virtually ignored. The results of the few studies on the kinetics of the chemisorption of oxygen on gold are presented in Table 4, which shows that similar rates of chemisorption are obtained in different investigations[14,19,22] at low surface coverages. The rate is two orders of magnitude lower than the rate of sorption of oxygen by copper at the same temperature and is close to the rate of sorption of oxygen by silver. With increase in the degree of adsorption, the rate of the latter decreases sharply. The adsorption of oxygen on gold containing not more than one silver atom for each 2000 gold atoms has been studied[19]. Thus the adsorption of oxygen on gold cannot be attributed to adsorption on the silver impurity. In order that gold can adsorb oxygen, it is very important to prevent contact with mercury vapour, since otherwise the capacity to adsorb oxygen is lost[36]. Preliminary treatment of gold before the study of the adsorption of oxygen is important, since the adsorbed oxygen and water, present apparently in the form of hydroxy-groups, are removed with much difficulty. Treatment with hydrogen for 100 h at 350°C and then evacuation at the same temperature and for the same period proved convenient for the purification of the adsorbant[19]. The treatment with hydrogen was carried out at low pressures to facilitate the diffusion of the resulting water to the trap where it was frozen out. The activation energy for the chemisorption of oxygen at a low degree of adsorption does not exceed 3–5 kcal $mole^{-1}$ as can be seen from the data in Table 4 and as has been shown by Endow et al.[21] With increase in the degree of adsorption, the activation energy rises[19,21,22]. The kinetics of the adsorption of oxygen up to the sorption of the amount corresponding to about 0.7 of a monolayer are described by the equation

$$r = kP(1-\theta)^4\left(\frac{2}{2-\theta}\right)^3, \qquad (5)$$

where $k = 2 \times 10^{16}$ mol. O_2 s^{-1} m^{-2} at a pressure of 1 mmHg, $\theta = 0$ when $\sigma = 0$, and $\theta = 1$ when $\sigma = 0.13$ cm^3 O_2/m^2 Au. Eqn. (5) was derived[81] for the case where the adsorbate molecule occupies four sites in adsorption on a homogeneous surface. In the adsorption of oxygen on gold this corresponds to the formation of Au_2SO. At a higher surface coverage the rate of adsorption is limited by the rate of rearrangement of the surface oxide layer, the observed activation energy for adsorption increases, and the reaction order with respect to oxygen pressure gradually falls. When the volume of the adsorbed oxygen approaches that corresponding to the formation of a monolayer of the surface oxide AuSO, the rate virtually ceases to depend on the pressure[19].

IV. CHANGES IN CERTAIN PHYSICAL PARAMETERS OF THE METALS DURING THEIR SURFACE OXIDATION

1. Heat of Adsorption

The heat of adsorption of oxygen on copper has been studied using powders[25,82] and films[83,84]. Russell and Bacon[82] observed a slow decrease in the heat of adsorption at 0°C in a Bunsen calorimeter from 92 kcal/mole O_2 with increased degree of adsorption. However, the portions of oxygen used were too large to determine the dependence of the differential heat of adsorption Q_d on the degree of adsorption. Later the variation of Q_d with surface coverage was investigated[83] with the aid of a Beeck calorimeter at 25°C and in another study[25] with the aid of a FOSKA calorimeter[85] at 100–130°C. The results obtained in these two studies[25,83] are presented in Fig. 2. The initial heat of adsorption at 25° and 100°C is about 115 kcal $mole^{-1}$. It then falls to the level of 82–90 kcal/mole O_2. At 25°C the decrease occurs at $\sigma = 0.08$ cm^3 O_2/m^2 Cu and 100°C at a degree of adsorption as low

as $\sigma = 0.04$ cm^3 O_2/m^2 Cu. After this the heat of adsorption remains almost constant both at 25° and 100°C up to the adsorption of a monolayer or a little more. Then at 25°C it falls to 58 kcal mole^{-1} when $\sigma = 1.0$ cm^3 O_2/m^2 Cu.

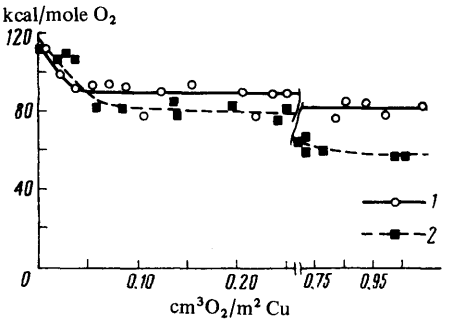

Figure 2. Variation of the heat of sorption of oxygen by copper with the degree of oxidation: 1) to the left of the discontinuity at 100° or 110°C; to the right of the discontinuity at 130°C according to Ostrovskii[25]; 2) at 25°C according to Starostina et al.[80]

It is believed[83] that the decrease is caused by the adsorption of oxygen on a surface layer of copper(I) oxide. At 100–110°C[25] the heat of adsorption decreases to only 82 kcal mole^{-1}, which is equal, within the accuracy of measurement, to the heat of oxidation of copper to the Cu_2O phase (Table 1). Thus at 100–110°C, where the rates of diffusion processes in the copper specimen undergoing oxidation are much higher than at 25°C, the region of enhanced heat of adsorption is narrower than at 25°C and after the oxidation of 1–2 copper monolayers the heat of reaction corresponds to the heat of oxidation to the oxide phase. It has been found that the heat of adsorption of oxygen on a copper film at room temperature is 110 kcal mole^{-1} regardless of the surface coverage[84]. The heat of adsorption of oxygen on silver has been determined calorimetrically[29,86,87] and also from the adsorption-chemical equilibrium involving water vapour[88,89], from the difference between the activation energies for adsorption and desorption[90], and from adsorption isosteres[73]. The results obtained in different studies agree. Fig. 3 presents the results of direct calorimetric measurements[87] at 110°C. Evidently the initial heat of adsorption is about 125 kcal mole^{-1}. Similar values were obtained in studies on the adsorption-chemical equilibrium involving water vapour: 108 kcal mole^{-1} [88] and 115 kcal mole^{-1}.[89] The heat of adsorption corresponding to almost complete monolayer coverage is about 15 kcal mole^{-1} according to Benton and Drake[90], which is close to the value obtained by Kul'kova and Temkin[89]. The isosteric heat of adsorption of oxygen on silver is 21 kcal mole^{-1},[91] and on silver containing 0.08% Ni and 0.13% Cu at oxygen pressures of several hundred mmHg it increases from 17 kcal mole^{-1} as the equilibrium pressure is reduced. For comparison, we may note that the heat of decomposition of Ag_2O is 14.7 kcal mole^{-1}.[12,92] It has been shown[87] that the heat of adsorption decreases appreciably in the presence of even small amounts (of the order of 1% of the monolayer) of a sulphur impurity on the surface of silver.

The heat of chemisorption of oxygen on gold has been determined in only two studies[18,19]. It was shown[19] that, in contrast to the heats of chemisorption on copper and silver, the heat of chemisorption of oxygen on gold is independent of the degree of surface coverage within the limits of experimental error (about 4%) and amounts to about 103 kcal/mole O_2.

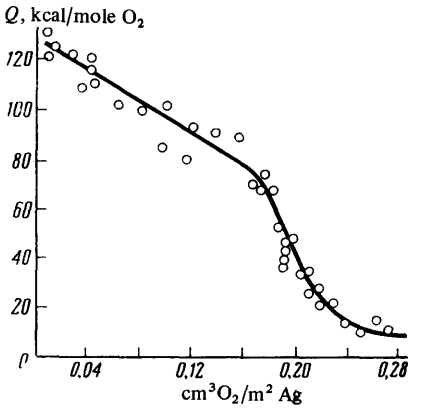

Figure 3. Variation of the heat of sorption of oxygen by silver with the degree of oxidation[84].

Thus almost all the oxygen adsorbed on a carefully cleaned gold surface is very firmly bound to the surface. It has been shown[19] that it can be removed only with much difficulty in the form of water after treatment by hydrogen with heating.

2. The Electronic Work Function

Table 5 presents the results of measurements of the maximum change in the electronic work function following the adsorption of oxygen on copper, silver, and gold. Evidently the electronic work function increases with adsorption or remains unchanged (on gold). The increase is evidence that the oxygen becomes negatively charged on adsorption. The maximum change in electronic work function after the adsorption of oxygen on this metal apparently depends on temperature, the amount of adsorbed oxygen, and to a large extent on the method of measurement employed. With increase of the amount of oxygen, the electron work function initially rises and then either remains unchanged or actually falls somewhat. If the oxygen is admitted onto the surface in portions, then after the introduction of each portion there is initially a rapid increase in the electronic work function and then a decrease. The decrease can actually amount to more than half of the initial rapid increase of the electron work function for the given portion of oxygen. The decrease in the electronic work function is usually explained by the diffusion of oxygen into the bulk of the specimen. However, one cannot rule out the possibility that it is partly due to the desorption from the surface of the water formed because the metals can contain hydrogen in the form of hydroxy-groups, owing to their previous history. Moreover the slow changes can be caused in many

instances by the processes occurring at the reference electrode. Table 5 shows that the smallest differences between the maximum changes in the electron work function on interaction with oxygen are observed for copper.

Table 5. Maximum increase in electron work function after the chemisorption of oxygen on Group IB metals.

Metal	Maximum increase in electron work function, V	Temperature of measurements, °C	Method	References
Copper	0.30	+20	d.	107

[a] At a pressure below 1 mmHg.
[b] At a pressure of 50 mmHg.
Methods: d. = diode; ph. = photoelectric emission; v.c.(Au) = vibrating condenser with gold reference electrode; v.c.(W) = ditto with tungsten reference electrode; v.c.(Mo-gl.) = ditto with molybdenum electrode enclosed in glass.

In this case the electron work function amounts to 0.30–0.55 V close to room temperature when the oxygen pressure is below 1 mmHg. The increase in the electronic work function following an increase in oxygen pressure to 50 mmHg may be because at this high pressure and 25°C the surface is completely saturated by oxygen which cannot diffuse sufficiently rapidly into the bulk of the specimen and at low pressures part of the surface remains free as a result of the dissolution of oxygen. The results of measurements of the changes in the electron work function after the adsorption of oxygen on silver in different investigations differ very considerably. For example, when the adsorption of oxygen and the measurements of the change in electron work function were carried out at room temperature, the observed change in the electron work function ranged from 0.3 V in some studies [93,94] to about 1.0 V in others [95,96]. The results obtained at 100°C agree somewhat better, ranging from 0.65 to 1.1 V (except for the results of Enikeev et al. [93]). The measurements of the electronic work function of gold on contact with oxygen do not yet yield a final conclusion as to whether or not oxygen influences the electron work function. This is aggravated by the fact that the failure to take into account various experimental characteristics may have a decisive influence on the result for gold. For example, the formation of a gold film by atomising gold in an atmosphere of hydrogen [20], can lead to the occlusion of the gas by the film with subsequent formation of water when the film interacts with oxygen, whereas inadequate reduction of the initial gold hydroxide may lead to a distortion of the results for the adsorption of oxygen by the desorption of water, etc. According to the theory of the role of the surface electron gas in adsorption phenomena developed by Temkin and coworkers [27,98], the heat of adsorption being independent of the degree of surface coverage, as observed by Dobrovol'skii and Ostrovskii [19], should correspond to a constant electron work function in adsorption of oxygen on gold, which was in fact observed in careful investigations [16,19].

3. Electrical Conductivity and Other Properties

The electrical conductivity of thin copper, silver, and gold films decreases as a result of their contact with oxygen. The temperature coefficient of the resistance of copper decreases after the admission of oxygen [100-102]. At 0°C the introduction of oxygen into the space over degassed copper leads to a rapid increase of resistance. After some time the resistance ceases to change or begins to decrease. With increase of oxygen pressure above a certain limit, a slow increase of the resistance is again observed. The changes are irreversible, the electrical conductivity of the film is not restored after evacuation. Similar changes were observed also when oxygen was brought into contact with silver [102-104]. After a film 255 μm thick was exposed at 0°C to oxygen at a pressure of 0.1 mmHg, the resistance increased rapidly by 0.4% and then by a further 0.4% over 1 h. [104] At 200–300°C the resistance of a thin silver film increases in oxygen in proportion to the square of the time [103].

After the exposure of gold films 182 μm thick to oxygen at a pressure of 0.1 mmHg and 0°C, their resistance increases slowly to an extent reaching 2‰ after 1 h. [104] A decrease of the conductivity of gold in the presence of oxygen is observed also at higher temperatures (150–200°C) [105].

The adsorption of oxygen on copper or silver films about 50 Å thick alters the Hall potential [106]. As stated above, the oxygen impurity in copper and silver at a concentration of the order of 10^{-4}% greatly increases the self-diffusion coefficient of the metal [10].

V. THE MECHANISM OF THE PROCESSES IN THE SURFACE OXIDATION OF METALS

1. The Problem of Creating Clean Surfaces

A discussion of the problem of creating clean surfaces cannot be separated from a discussion of the oxidation mechanism, since the explanation of the phenomena observed in the sorption of oxygen is frequently determined by the presence of impurities in the specimens or at any rate depends significantly on them. The problem of the elimination from copper, silver, or gold of heavy element impurities which may influence the sorption of oxygen can now be solved comparatively readily because of the availability of sensitive and reliable analytical methods such as spectroscopic analysis, activation analysis, etc. Moreover, this is facilitated by the fact that,

in the storage and preparation of the specimens in vacuum apparatus, they are as a rule not subjected to additional contamination by heavy element impurities. It is much more difficult to determine the content of light element impurities, in the first place such as hydrogen, nitrogen, oxygen, and their compounds. In Group IB metals the problem is somewhat facilitated by the fact that these metals hardly sorb nitrogen and hydrogen. However, compounds of the above elements, including their oxides, can be adsorbed by Group IB metals.

Table 6. Heats of adsorption of the vapours of the principal impurities contaminating copper, silver, and gold.

Metal	Heat of adsorption, kcal mole^{-1}			
	CO	H_2O	CO_2	H_2S
Copper	16—17[83] 17.5[114] 9.3[115]	12[116]		
Silver		14.9[117]	17.5[118] (on Ag_2O)	78 ± 10*[29]
Gold	8.7[115]	14[19,86] 14.5[117]	14[19,86]	

* The interaction of the silver surface with hydrogen sulphide at 100°C proceeds in accordance with the equation $H_2S + (\ ) = H_2 + (S)$, where ( ) is a bivalent adsorption centre on the surface and (S) a chemisorbed sulphur atom[29].

Table 6 presents the heats of adsorption of certain substances contaminating the above adsorbents. Evidently the heats of adsorption are low and it would seem that *in vacuo* the surface should be rapidly cleaned. However, the problem is more difficult. Impurities in amounts greatly exceeding the volume of one monolayer can be present within the bulk of the crystals whence they can diffuse over a long period to the surface and contaminate it. Various sulphur- and chlorine-containing impurities, etc. diffuse rapidly to the surface on heating[32], but cannot be desorbed on heating *in vacuo*, since the bond energy between them and the surface is high (for example the bond energy of the sulphur atoms adsorbed on the surface of silver is 78 ± 10 kcal mole^{-1}).[29] The specimens obtained by reducing salts precipitated from aqueous solutions can contain considerable amounts of water and the acid residues of the salts undergoing decomposition, which are eliminated slowly owing to kinetic barriers which hinder their rapid diffusion to the surface. For example, the removal of residual water from gold obtained by the reduction of gold hydroxide at 350°C *in vacuo* takes place over hundreds of hours[19]. The elimination of oxygen present in the metal during the cleaning of the surface before the study of the adsorption of oxygen constitutes a special problem. Usually the metal is treated for this purpose with hydrogen or carbon monoxide and the water or carbon dioxide formed are evacuated. The cleaning of powdered copper in a static apparatus at 170°C requires treatment with hydrogen for hundreds of hours[25] and the cleaning of gold at 350°C requires many tens of hours[19]. The study of adsorption in an ultrahigh vacuum on sputtered metal films facilitates the solution of some of the problems enumerated above, but new problems are created because the surface of the films is very small compared with the surface of the powders and therefore very small amounts of impurities are sufficient to contaminate it (see, for example, Savchenko[119]). Nevertheless, the present review has shown that in those cases where sufficient attention was devoted to the cleaning of the specimens, the results obtained in the study of the oxidation of the surface of powders were analogous to those obtained in the study of the oxidation of the surface of thin films.

2. The Mechanism of the Sorption of Oxygen

The nature of the interaction of oxygen with copper, silver, and gold surfaces is in many respects similar, but each of the three systems has its specific features. The most striking common feature is that a definite amount of oxygen is sorbed by the metals above room temperature with a heat exceeding significantly the heat of formation of the corresponding oxides. Moreover, copper and silver can sorb considerable amounts of oxygen in their surface layers (deep adsorption) without the formation of an oxide phase. With increase of the specific surface, the maximum amount of such oxygen per unit weight of the metal increases and for specimens with a high surface area can be several orders of magnitude greater than the amount corresponding to the solubility of oxygen in the given metal determined for non-porous specimens. Even if the heat of deep adsorption exceeds that of the oxidation of the metal to an oxide phase, it does not do so by more than 10%. Most of the oxygen estimated in the determination of its solubility in such metals is probably concentrated in the surface layers. At the same time some oxygen can be present also in the bulk of the copper and silver, since its diffusion through a layer of the metal can be observed. The sorption of oxygen by porous gold is limited to a monolayer. The initial specific rates of sorption of oxygen on the metals under consideration have similar orders of magnitude when the comparison is made at 100–200°C. The initial heat of adsorption lies between 100 (gold) and 125 (silver) kcal/mole O_2 with an average error of the measurements in the range 5–7 kcal mole^{-1}. At the same time the variation of the rate of sorption of oxygen on copper, silver, and gold with the amount sorbed and the dependence of the heat of sorption on the amount sorbed on these metals are specific to each metal.

The sum total of the above results for the sorption of oxygen by copper shows that on clean copper oxygen is adsorbed and passes into the bulk of the metal. The collision of oxygen molecules with a surface coated by a layer of adsorbed oxygen probably stimulates an endothermic activated transfer of oxygen to the surface layer of the specimen with further adsorption on the liberated site. The heat of adsorption greatly exceeds the heat of oxidation to an oxide phase, while the heat of transfer of oxygen from the gas phase to the surface layer is close to the heat of oxidation of copper to an oxide phase. Therefore the initial heat of sorption of oxygen corresponds to the heat of adsorption, but, as the surface is covered, the heat of sorption approaches the heat of oxidation of copper to an oxide phase (Fig. 3). An increase of temperature increases the probability that the oxygen colliding with an unoxidised surface site is transferred directly to the surface layer. This explains why more oxygen is sorbed with a heat significantly exceeding the heat of oxidation of copper to an oxide phase at room temperature[83] than at 100°C.[25] Thus, in order to explain all the results obtained for the sorption of oxygen by copper up to the formation of nuclei of a new phase, it is necessary to assume that three processes can occur when oxygen molecules collide with the copper surface. In the collision

between an oxygen molecule and unoxidised surface sites there is a possibility of (1) the adsorption of the oxygen on the surface and (2) deep adsorption. When an oxygen molecule collides with oxidised surface sites, a third process is possible—the adsorption of the molecule with transfer of another molecule previously adsorbed to the surface layer. The rates of each of these processes are proportional to the oxygen pressure in the gas phase. The rates of the first two processes decrease with decrease of the fraction of unoxidised surface. The rate of the third process increases as the surface monolayer is oxidised and can fall slowly as oxygen is sorbed after the completion of the oxygen monolayer when diffusion in the surface layers begins to have an effect. The second process does not require an additional activation energy as compared with the first (the energy liberated in the adsorption step at any temperature is sufficient to transfer oxygen to the surface layer and the fate of a given species is determined solely by the direction of the impulse), since otherwise the decrease of the rate, illustrated in Fig. 1, would cease for different amounts of sorbed oxygen at different temperatures. The activation energy for adsorption is much lower than the activation energy for the third process. Thus on polycrystalline materials it amounts to 7.5 kcal mole^{-1} for the sorption of 0.6 cm^3 O_2/m^2 Cu [18,50] and to 7.3 kcal mole^{-1} for the sorption of between 0.25 and 0.80 cm^3 O_2/m^2 Cu [51]; on the (110) face, under the conditions of the formation of the adsorption layer, the activation energy is 3.5 kcal mole^{-1} [53]. Fig. 1 shows that, as oxygen is sorbed up to 1 cm^3 O_2/m^2 Cu, the activation energy rises. Extrapolation of the curves to the initial conditions yields very similar rates at different temperatures, i.e. the initial activation energy for adsorption is close to zero. The activation energy for the third process is 11.5 kcal mole^{-1} in the sorption of 1–4 cm^3 O_2/m^2 Cu [18,50] or 15.5 kcal mole^{-1} in the sorption of about 10 cm^3 O_2/m^2 Cu. [61] Under these conditions, the rate of sorption of oxygen is still proportional to the pressure. On further sorption of oxygen, the activation energy rises to 21.8 kcal mole^{-1} [44] or 21 kcal mole^{-1} [40] on sorption of about 35 cm^3 O_2/m^2 Cu. Within the limits of experimental error, these activation energies are equal to the activation energy for the diffusion of copper ions in the surface oxide film (20.1 kcal mole^{-1}). [120] The activation energies quoted in some studies [40,44,120] were obtained under conditions where the rate of sorption of oxygen is almost independent of its pressure in the gas phase. In other words, under these conditions, the rate of reaction is limited by diffusion in the solid. On further oxidation, nuclei of the oxide phase appear and an increased rate of sorption of oxygen characteristic of this stage is observed.

On silver as well as on copper, oxygen is adsorbed and passes into the bulk metal. As for copper, the heat of adsorption on silver greatly exceeds the heat of oxidation to an oxide phase and the heat of deep adsorption is close to the heat of oxidation of the metal. However, the difference between the initial heats of adsorption of oxygen on silver (about 125 kcal/mole O_2) and the enthalpy of formation of Ag_2O (about 15 kcal/mole O_2) is in this case much greater than the difference between the corresponding values for copper. The dependence of the differential heat of adsorption of oxygen on the degree of adsorption (Fig. 3) shows that the heat of adsorption of oxygen greatly exceeds the heat of oxidation to an oxide phase up to almost complete surface coverage, in which there is one oxygen atom for each surface silver atom (0.26 cm^3 O_2/m^2 Ag). An increase in the electronic work function of silver following the adsorption of oxygen is also observed up to virtually monolayer surface coverage [111]. The rate of deep adsorption of oxygen on silver at 250°C is three orders of magnitude slower than the average rate of monolayer adsorption [69] and deep adsorption should not affect the results of the study of the adsorption of oxygen up to the limit of one monolayer. At the same time deep adsorption can influence the catalytic properties of silver in oxidation reactions. The results of studies of the adsorption of oxygen on silver are described in terms of the hypothesis that adsorbed oxygen exists in two forms, one of which corresponds to the formation of a two-dimensional surface oxide Ag_2SO and the other to the formation of $AgSO$ (or Ag_2SO_2). Many workers have used ideas of this type [5,73,77,81]. In this connection we may point to the existence of the compound AgO, which is not a peroxide [121], and of the surface compound of silver and oxygen, which was identified as a superoxide [122]. Oxygen is adsorbed initially with formation of the surface oxide Ag_2SO. The adsorption of oxygen as Ag_2SO has the highest heat and involves the main change in the electronic work function. The adsorption of oxygen as $AgSO$ begins only after the surface has been largely covered by oxygen as Ag_2SO. The adsorption of oxygen on a reduced surface proceeds in accordance with the equation

$$4\,Ag^S + O_2 \rightarrow 2\,Ag^S\!\!<\!\!\overset{O}{}\!\!>\!\!Ag^S, \qquad (6)$$

and on a surface coated by Ag_2SO according to the equation

$$2\,Ag^S\!\!<\!\!\overset{O}{}\!\!>\!\!Ag^S + O_2 \rightarrow 4\,\overset{O}{\|}\,Ag^S. \qquad (7)$$

In the intermediate range of coverages the following reactions can also occur:

$$2\,Ag^S + O_2 \rightarrow 2Ag^S \xrightarrow{+2Ag^S} 2\,Ag^S\!\!<\!\!\overset{O}{}\!\!>\!\!Ag^S, \qquad (8)$$

$$Ag^S\!\!<\!\!\overset{O}{}\!\!>\!\!Ag^S Ag^S + O_2 \rightarrow 3\,\overset{O}{\|}\,Ag^S \xrightarrow{+2Ag^S} 3\,Ag^S\!\!<\!\!\overset{O}{}\!\!>\!\!Ag^S. \qquad (9)$$

The maximum degree of adsorption of oxygen on silver before the rate drops by 2–3 orders of magnitude corresponds to the saturation of a monolayer with one oxygen atom per surface silver atom. Thus it was possible to assume that oxygen is adsorbed in the form of $AgSO$ (or Ag_2SO_2). However, the heat of adsorption of oxygen on an oxygen-free surface differs from the heat of adsorption at monolayer coverage by more than 100 kcal mole^{-1}, a sharp decrease of the heat of adsorption being observed near the degree of adsorption corresponding to one oxygen atom per silver atom on the surface. Moreover, as adsorption proceeds until the attainment of the above surface coverage, the electronic work function of silver rises, but subsequent adsorption has little influence on it; the depolarisation of dipoles cannot explain this type of variation of electronic work function with surface coverage. Under conditions close to complete surface coverage by oxygen with one oxygen atom per two silver atoms, there is also a change in the kinetics of the adsorption of oxygen (Table 3). These findings can be explained by assuming that oxygen is adsorbed on the surface in the two forms indicated above. The existence of two forms of oxygen on silver was also postulated to account for its catalytic properties. The heat of adsorption of oxygen in the form of Ag_2SO is high, decreasing with surface coverage (Fig. 3). The rate of adsorption decreases exponentially under these conditions [71,80]. The bond between oxygen and silver in the surface oxide Ag_2SO is polar with the negative end of the

dipole directed to oxygen (Table 5). Further adsorption of oxygen, leading to the conversion of adsorbed oxygen from Ag_2SO into $AgSO$, involves a small heat change and the electronic work function of silver does not alter. Under these conditions, the rate of adsorption of oxygen falls linearly, to a first approximation, as the concentration of Ag_2SO on the surface decreases[28]. The adsorption terminates when the surface is covered by an $AgSO$ monolayer. Further sorption of oxygen proceeds slowly and is due to deep adsorption†. The introduction onto the surface of impurities comprising electronegative elements such as sulphur, selenium, etc. reduces the rate of adsorption of oxygen[29,30,74], and the heat of its adsorption[28], via the mechanism of the mutual influence of adsorbed species. Admixtures of the above elements, introduced into the bulk of the specimen, act similarly, since they can migrate rapidly to the surface[32].

The oxygen adsorbed on gold hardly penetrates into the bulk of the crystal lattice at temperatures below 150°C. The sorption of oxygen is limited to a monolayer. To describe the results of adsorption studies, it is assumed, as for the adsorption on silver, that the oxygen can exist in two forms on the surface: as Au_2SO and $AuSO$. The heat of adsorption of oxygen on a clean gold surface with formation of Au_2SO is equal, within the limits of experimental error, to the heat of adsorption of oxygen with formation of $AuSO$ on a surface coated by Au_2SO. A clean gold surface is homogeneous with respect to the adsorption of oxygen. The heat of adsorption is constant over a wide range of variation in the extent of surface coverage by a monatomic oxygen layer. It amounts to about 100 kcal $mole^{-1}$, while the enthalpy of oxidation of gold to an oxide phase is positive (Table 1). Up to 70% surface coverage by the Au_2SO species, the adsorption kinetics are described by Eqn. (5), which corresponds to the adsorption of each O_2 molecule on four adjacent atoms of the homogeneous gold surface. Subsequent adsorption involves mainly the formation of $AuSO$. Only two surface sites are required for the adsorption of an oxygen molecule in the form of $AuSO$. Therefore the rate of adsorption depends less strongly on the degree of surface coverage than the rate of adsorption in the form of Au_2SO. The rate of adsorption remains proportional to pressure, but Eqn. (5) does not hold. On further increase of the degree of adsorption, the order of the adsorption process with respect to oxygen pressure diminishes, since the observed rate of adsorption begins to depend on the rate of surface migration. Data on the electronic work function of gold in the adsorption of oxygen are contradictory, as can be seen from Table 5. In studies[16,99] carried out under the cleanest conditions using different methods for the measurement of the electronic work function, no changes in the latter were observed when gold came into contact with oxygen. The change in surface potential observed[20] on bringing gold into contact with oxygen can be attributed to the fact that the fusion of gold and the sputtering of the film were carried out in an atmosphere of hydrogen. The adsorbed oxygen might interact with the occluded hydrogen on the surface of the film, generating a charge on the latter.

† In a recently published study[123] the hypothesis of the existence of Ag_2SO and Ag_2SO_3 was used to explain the results of an investigation of the heteroexchange of oxygen on silver.

Surface Properties of Aqueous Salt Systems

A.I.Rusanov and E.A.Faktor

Use of the Gibbs method and of a layer of finite thickness to calculate the thermodynamic characteristics of surface layers is examined. The chief properties of surface layers have been calculated for 35 aqueous salt systems from experimental data. The influence of the nature of the dissolved salt on the properties of solutions and surface layers is discussed on the basis of the calculated results. A list of 87 references is included.

I. INTRODUCTION

Considerable experimental information has been accumulated on the surface tension of aqueous salt systems, but its processing is far from complete. Calculation is usually confined to finding the adsorption, although modern thermodynamics enables the composition and the entropy characteristics of the surface layer also to be calculated from sufficiently complete surface-tension data. These characteristics in turn make it possible to elucidate the effect of the nature of the ions on the structure and the properties of the surface layers.

The aim of the present paper is to generalise available published information from unified points of view by basing the thermodynamic calculations on a rigorous scheme and comparing characteristics of the same type for various aqueous salt systems. The most reliable published data on the surface tensions of solutions containing singly and multiply charged ions have been used for the calculations. A total of 35 aqueous salt systems have been considered.

II. SURFACE PHENOMENA IN AQUEOUS SALT SYSTEMS

1. Experimental Investigations of Surface Tension

Nearly linear increases in the surface tension of the solution with salt concentration were observed [1-6]. Quincke [2] formulated the empirical rule that solutions of different chlorides have roughly the same surface tension at the same volume concentration of the chloride ion. An attempt to extend this rule to other halides was less successful.

Whatmough [4] suggested that, when several salts were present together in solution, they made additive contributions to the surface tension.

More accurate results [7-9] revealed a fairly complicated relation between surface tension and solution composition. The earlier empirical relations were found to lack generality and be applicable only to dilute solutions. Nevertheless, the hypothetical linear composition dependence of the surface tension of a salt solution was used [10] to estimate by extrapolation the surface tension of a supercooled melt of the pure salt. This hypothesis, which is only an approximation, has been used also to solve several applied problems requiring no great accuracy in the calculation of surface tension [11,12].

An important contribution to developing ideas on the structure of the surface layer was made by Langmuir [13]. He assumed that the surface of a salt solution is covered by a film of water, below which the salt concentration is constant, and calculated the thickness of the film by means of the formula

$$\tau = -1000\,\Gamma_{1(2)}/c \qquad \text{(II, 1)}$$

where $\Gamma_{1(2)}$ is the adsorption of the salt and c the molar concentration of the solution. Extension of similar calculations to various aqueous salt systems showed [9,14,15] that the film thickness depends on the nature of the salt, but in all cases examined diminishes from 5–3 Å at low concentrations to 2 Å at high concentrations. Comparison with the size of a water molecule led to the important conclusion that the ions of a dissolved salt enter the surface monolayer when the solution is sufficiently concentrated.

Adsorption of a solute changes the potential difference between the solution and the surrounding medium. The dependence of this potential difference on solution composition was investigated by Frumkin [16,17], who discovered that most salt solutions give a small potential difference at their air interface, with the outer region of the double layer charged negatively. This indicates that anions are arranged on the average closer to the air than are cations. With solutions of the same concentration the negative charge increases in the sequence of anions

$$F^- < Cl^- < Br^- < I^- < CNS^-.$$

The reason is that less strongly hydrated ions pass more readily (and hence in greater quantity) into the surface layer, thus conferring a higher charge on the surface. According to Frumkin the nature of the cation has little effect on the surface charge.

Comparison of the adsorptions calculated by means of the relation

$$RT\Gamma_{1(2)} \approx 0.5\,(\sigma_0 - \sigma) \qquad \text{(II, 2)}$$

(in which R is the gas constant, T is the temperature, and σ and σ_0 are the surface tensions of the salt solution and pure water respectively) with the results of electrometric measurements indicated that the greater the adsorption of the salt the more strongly charged was the surface of the solution.

Pavlov [18] used empirical relations to calculate the surface tensions of salt solutions, and in many cases observed satisfactory agreement with experimental values obtained

by other workers. Having used incorrect premises in calculating the adsorption of the salt, he obtained positive values of $\Gamma_{1(2)}$.

In a study of the surface properties of aqueous salt systems Rebinder[19] directed attention to the behaviour of water as a surface-active compound. He obtained the complete surface-tension isotherm for the aqueous silver thallium(I) nitrate system at 90°C (the salt $AgTl(NO_3)_2$ melts at 82.5°C, above which temperature it is completely miscible with water). The surface-tension isotherm is well described by Shishkovskii's equation

$$\sigma - \sigma_0 = b \ln (ac + 1) \qquad \text{(II, 3)}$$

where a and b are constants, c is the concentration of water, and σ and σ_0 are the surface tensions of the molten salt and of the solution respectively.

Yashkichev[20] suggested a qualitative interpretation of results for the surface tension of salt solutions according to which the effect of the salt was governed by two factors acting in different directions. The first such factor was the effect of ions in disrupting the mutual order of the water molecules, which with negatively hydrated ions would tend to diminish surface tension. The other factor was the negative adsorption of ions, interaction of whose fields with water molecules of the surface layer should strengthen the tendency of the molecules to be drawn into the interior of the solution, which would correspond to an increase in surface tension. Such an explanation is, of course, greatly oversimplified and insufficiently informative, since negative adsorption of a salt is the starting point of the argument, but this does not provide sufficient grounds for such an assumption.

A series of studies[21-25] on foams, films, and drop entrainment from electrolyte solutions has shown that the stability of a foam depends on the nature of the dissolved salt and is increased by the presence of strongly hydrated ions. The critical rupture thickness on the spontaneous thinning of films of electrolyte solutions is inversely proportional to the concentration and energy of hydration of the ions. In several cases separation of electrolytes has been observed during drop entrainment[25].

2. The Jones–Ray Effect

A prolonged controversy ensued from the papers by Jones and Ray[26-28], who discovered by the capillary-rise method a minimum in the surface-tension isotherms for 13 aqueous salt systems. A depression of surface tension reaching 0.02 dyn cm^{-1} was observed in all cases in dilute solutions (below 0.002 N). The positive adsorption of the salt corresponding to this depression was explained by preferential attraction between salt ions and water molecules on the solution surface (at higher concentrations the forces retaining ions in solution increase more rapidly and the adsorption becomes negative).

According to Langmuir[29] the Jones–Ray effect is a consequence of the experimental technique: a film of water which may be several hundreds of ångströms thick would be present on the internal surface of the capillary, and would be thicker for salt solutions than for pure water. Such a film leads to a change in the effective radius of the capillary, which influences the measured results.

Langmuir's view was criticised[30], and the Jones–Ray effect was then confirmed[31] for aqueous potassium chloride by the ring-detachment method. Dole[32] also tried to obtain theoretically an equation for a surface-tension isotherm passing through a minimum. The deduction involved the postulated presence, on the surface of a dilute solution, of a monomolecular layer of water, whose interaction with the ions of the salt was far stronger than the interionic interaction in the solution. In order to bring into line with the experimental results, furthermore, it was postulated that only negative ions could be adsorbed and only on certain active centres (one per 10^5 water molecules). The calculated surface tensions were close to the experimental values, but Dole's postulates were too arbitrary to serve as evidence.

Bikerman[33] discussed the Jones–Ray effect in terms of the surface tension as the sum of three contributions. The work required for a water molecule to escape to the surface was assumed to be independent of concentration. The second term resulted from the lower salt concentration at the surface than in the bulk of the solution, so that formation of a surface layer entailed an increase in the bulk concentration of the solutions; this process was replaced in the calculations by compression of the ionic gas, and the corresponding work was computed solely on the basis of electrostatic interaction. The third term represented the work required to separate positive and negative ions. Calculations based on this scheme gave minimum surface tension for dilute potassium chloride solutions, but the third term was calculated from Jones and Ray's results. Moreover, the postulates involved (e.g. the assumed concentration independence of the first term) restrict considerably the concentration range in which the formulae might be applied.

The phenomena associated with the Jones–Ray effect was carefully examined by Passoth[34], who measured the surface tension by a modified maximum bubble pressure method enabling the time of formation of the bubble to be varied within wide limits. When the bubble formed slowly, the effect was observed with sodium and potassium chloride solutions, but no effect was observed when the rate was increased. Passoth concluded that the inner walls of the capillary were coated with a liquid film, whose thickness depended on solution concentration with slow formation of the bubble. Estimated thicknesses of this film were consistent with Langmuir's results.

A recent examination of the thermodynamic conditions of concentration buffering has shown that the Jones–Ray effect is impossible. It must thus be accepted that the effect is spurious, and is connected with the method adopted for measuring surface tension[34,36].

3. Use of Thermodynamics in the Analysis of Surface Phenomena in Aqueous Salt Systems

Two chief methods—the Gibbs method and the method of a layer of finite thickness—can be distinguished in the thermodynamics of surface phenomena. The former is based on the concept of a geometric surface, and utilises excess functions[37]. The excess entropy $\bar{S}$ and the excess mass of the ith component $\bar{m}_i$ are defined by the relations

$$\bar{S} \equiv S - s_v^{(\alpha)} V_\alpha - s_v^{(\beta)} V_\beta \qquad \text{(II, 4)}$$

$$\bar{m}_i \equiv m_i - \rho_i^{(\alpha)} V_\alpha - \rho_i^{(\beta)} V_\beta \qquad \text{(II, 5)}$$

where S is the entropy of the system, m_i is the mass (or the number of moles) of the ith component, $\rho_i^{(\alpha)}$ and $\rho_i^{(\beta)}$ are the densities of the ith component in the coexisting α and β phases, $s_V^{(\alpha)}$ and $s_V^{(\beta)}$ are the bulk entropy densities in these phases, and the sum of the volumes of regions of the system mutually separated by a dividing surface gives the total volume $V = V_\alpha + V_\beta$. The values of the excess

quantities depend on the position chosen for the dividing surface. The surface density of the excess of mass is termed the absolute adsorption

$$\Gamma_i \equiv \bar{m}_i/A \qquad \text{(II, 6)}$$

(in which A is the area of the dividing surface); while the combination

$$\Gamma_{i(j)} \equiv \Gamma_i - \Gamma_j \frac{\rho_i^{(\beta)} - \rho_i^{(\alpha)}}{\rho_j^{(\beta)} - \rho_j^{(\alpha)}} \qquad \text{(II, 7)}$$

is the Gibbs relative adsorption, which is invariant with respect to displacement of the dividing surface. The relative adsorption $\Gamma_{i(j)}$ is numerically equal to the absolute adsorption Γ_i for a dividing surface corresponding to the condition $\Gamma_j = 0$. Gibbs obtained the adsorption equation

$$d\sigma = -\bar{s}_{(j)}dT - \sum_{i \neq j} \Gamma_{i(j)}\, d\mu_i \qquad \text{(II, 8)}$$

where σ is the surface tension, μ_i is the chemical potential of the ith component, and $\bar{s}_{(j)}$ is defined by the relation

$$\bar{s}_{(j)} \equiv \frac{\bar{S}}{A} - \Gamma_j \frac{s_v^{(\beta)} - s_v^{(\alpha)}}{\rho_j^{(\beta)} - \rho_j^{(\alpha)}} \qquad \text{(II, 9)}$$

In the case of electrolyte solutions Eqn. (II, 8) contains electrode potentials instead of chemical potentials.

The chief merit of the Gibbs method is its mathematical simplicity. An important disadvantage, however, is that the use of geometric surfaces excludes consideration of the thickness of the surface layer, which is one of the principal problems of the theory of surface phenomena. An important role in the discussion of this problem was played by the method of a layer of finite thickness[38-40], an account of whose development and a modern presentation will be found in a monograph[41].

Displacement of the equilibrium in a two-phase n-component system with a planar surface is described by the set of equations[41]

$$\begin{cases} a\,d\sigma = s_{a\sigma}\,dT + v_{a\sigma}\,dP - \sum_{i=1}^{n-1}\sum_{k=1}^{n-1} (x_i^{(\sigma)} - x_i^{(\alpha)})\, g_{ik}^{(\alpha)} dx_k^{(\alpha)} \\ a\,d\sigma = (s_{a\beta} - s_{a\sigma})\,dT - (v_{a\beta} - v_{a\sigma})\,dP - \sum_{i=1}^{n-1}\sum_{k=1}^{n-1} (x_i^{(\alpha)} - x_i^{(\beta)})\, g_{ik}^{(\alpha)} dx_k^{(\alpha)}, \end{cases} \qquad \text{(II, 10)}$$

where

$$\bar{s}_{a\sigma} \equiv s^{(\sigma)} - s^{(\alpha)} - \sum_{i=1}^{n-1} (x_i^{(\sigma)} - x_i^{(\alpha)}) \left(\frac{\partial s}{\partial x_i}\right)^{(\alpha)} \qquad \text{(II, 11)}$$

$$v_{a\sigma} \equiv v^{(\sigma)} - v^{(\alpha)} - \sum_{i=1}^{n-1} (x_i^{(\sigma)} - x_i^{(\alpha)}) \left(\frac{\partial v}{\partial x_i}\right)^{(\alpha)} \qquad \text{(II, 12)}$$

$$s_{a\beta} \equiv s^{(\beta)} - s^{(\alpha)} = \sum_{i=1}^{n-1} (x_i^{(\beta)} - x_i^{(\alpha)}) \left(\frac{\partial s}{\partial x_i}\right)^{(\alpha)} \qquad \text{(II, 13)}$$

$$v_{a\beta} \equiv v^{(\beta)} - v^{(\alpha)} - \sum_{i=1}^{n-1} (x_i^{\beta} - x_i^{(\alpha)}) \left(\frac{\partial v}{\partial x_i}\right)^{(\alpha)} \qquad \text{(II, 14)}$$

$$g_{ik} \equiv \left(\frac{\partial^2 g}{\partial x_i\, \partial x_k}\right)_{P,T}^{(\alpha)} \qquad \text{(II, 15)}$$

a is the molar surface, x_i is the mole fraction of the ith component, g is the molar Gibbs thermodynamic potential, and the s and v are molar entropies and volumes. The superscripts α and β denote the coexisting bulk phases, and σ indicates the surface layer. Physically the quantities $s_{a\sigma}$ and $s_{a\beta}$ represent entropy effects, and $v_{a\sigma}$ and $v_{a\beta}$ volume effects of transitions from the α phase to the surface layer and to the β phase respectively, i.e. effects accompanying formation of 1 mole of surface layer and of phase β from an infinite quantity of phase α. The quantities $s_{a\sigma}$ and $v_{a\sigma}$ are differential molar effects of adsorption. In the case of a liquid–vapour (α–β) equilibrium the quantities $s_{a\beta}$ and $v_{a\beta}$ are differential molar effects of vaporisation.

III. CALCULATION OF THERMODYNAMIC PROPERTIES OF SURFACE LAYERS

1. Calculation of Relative Adsorptions

For a strong uni-univalent electrolyte dissolved in water (the KA–H_2O system) the equation to the Gibbs adsorption isotherm is

$$-d\sigma = \Gamma_K + d\bar{\mu}_{K^+} + \Gamma_{A^-} d\bar{\mu}_{A^-} + \Gamma_{H^+} d\bar{\mu}_{H^+} + \Gamma_{OH^-} d\bar{\mu}_{OH^-} + \Gamma_{H_2O} d\mu_{H_2O} \qquad \text{(III, 1)}$$

where σ is the surface tension, Γ and $\bar{\mu}$ are the absolute adsorption and the electrochemical potential of the corresponding ion, and Γ_{H_2O} and μ_{H_2O} are the absolute adsorption and the chemical potential of undissociated water. Besides taking into account the phase equilibrium conditions, we should consider Eqn. (III, 1) in combination with the condition of equilibrium in the dissociation of water

$$\mu_{H_2O} = \bar{\mu}_{H^+} + \bar{\mu}_{OH^-} \qquad \text{(III, 2)}$$

and the condition of electrical neutrality

$$\Gamma_{H^+} + \Gamma_{K^+} = \Gamma_{OH^-} + \Gamma_{A^-} \qquad \text{(III, 3)}$$

According to thermodynamics the number of components in a given mixture is strictly defined, but their choice is arbitrary. For convenience we shall henceforward select as components the neutral substances HA and KA (almost completely absent from the bulk of the solution), and introduce for them, by analogy with (III, 2), the conditions

$$\mu_{KA} = \bar{\mu}_{K^+} + \bar{\mu}_{A^-};\ \mu_{HA} = \bar{\mu}_{H^+} + \bar{\mu}_{A^-} \qquad \text{(III, 4)}$$

From Eqns. (III, 1–4) we then obtain

$$-d\sigma = (\Gamma_{A^-} - \Gamma_{K^+})\, d\mu_{HA} + \Gamma_{K^+} d\mu_{KA} + (\Gamma_{OH^-} + \Gamma_{H_2O})\, d\mu_{H_2O} \qquad \text{(III, 5)}$$

and after allowing for the phase equilibrium conditions and eliminating $d\mu_{KA}$ we find that

$$-d\sigma = \Gamma_{A^-(K^+)} d\mu_{HA} + (\Gamma_{OH^-(K^+)} + \Gamma_{H_2O(K^+)})\, d\mu_{H_2O} \qquad \text{(III, 6)}$$

where the additional subscript (K^+) indicates conversion to relative adsorptions (with respect to the cation K^+).

The coefficient of $d\mu_{HA}$ in Eqns. (III, 5 and 6) represents the non-equivalence of adsorption of cation and anion of the dissolved electrolyte. If the compound HA is volatile, this coefficient can in principle be evaluated from the dependence of the surface tension on the vapour pressure of HA. When the non-equivalence of adsorption of the ions can be neglected, the first term on the right-hand side of (III, 5 and 6) vanishes, and the coefficient of $d\mu_{H_2O}$ becomes equal to the total adsorption of water in molecular and dissociated forms. These two adsorption equations then become formally identical with those for systems of non-electrolytes:

$$-d\sigma = \Gamma_1 d\mu_1 + \Gamma_2 d\mu_2 \qquad \text{(III, 7)}$$

$$-d\sigma = \Gamma_{2(1)} d\mu_{(2)} \qquad \text{(III, 8)}$$

where $\Gamma_1 \equiv \Gamma_{KA} = \Gamma_{K^+}$ and $\Gamma_2 \equiv \Gamma_{H_2O} + \Gamma_{OH^-}$. Analogous formulae are obtained also for a solution of a weak electrolyte (when Γ_1 becomes the total adsorption of the electrolyte in molecular and dissociated forms). Formulae (III, 7 and 8) are obviously valid not only for an aqueous uni-univalent electrolyte but also for electrolytes of any type.

From (III, 8) the relative adsorption of water $\Gamma_{2(1)}$ can be calculated by means of the formula

$$\Gamma_{2(1)} = -\frac{1}{RT}\left(\frac{d\sigma}{d\ln a_2}\right)_T \qquad \text{(III, 9)}$$

where a_2 is the activity of water. If the salt is non-volatile and the vapour approximates to an ideal gas, we can use isothermal data on the vapour pressure P over the solution to calculate

$$\Gamma_{2(1)} = -\frac{P}{RT}\left(\frac{d\sigma}{dP}\right)_T \qquad \text{(III, 10)}$$

The relative adsorption of the salt $\Gamma_{1(2)}$ is easily found from formula (II, 8):

$$\Gamma_{1(2)} = -x_1^{(\alpha)}\Gamma_{2(1)}/(1-x_1^{(\alpha)}) \qquad \text{(III, 11)}$$

where $x_1^{(\alpha)}$ is the mole fraction of the salt in the solution. In Eqn. (III, 10) the vapour is regarded as ideal, but in (III, 11) the vapour density is neglected, so that both relations are valid only far from the critical point.

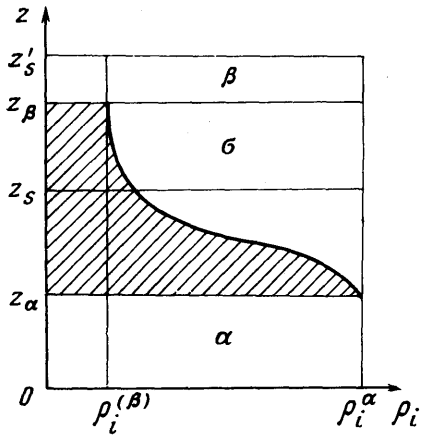

Figure 1. Density profile of ith component in surface layer.

2. Calculation of Composition of Surface Layer

Relation between adsorption and composition of surface layer

If the z-axis is directed perpendicularly to the surface from phase α towards phase β, the quantity $m_1^{(\sigma)}/A$ (the shaded area in **Fig. 1**) in a surface layer of thickness $\tau \equiv z_\beta - z_\alpha$ will be given by

$$m_1^{(\sigma)}/A = {}^{(\sigma)}_{m}x_1^{(\alpha)}/A = \Gamma_1 + \rho_1^{(\alpha)}\tau - (\rho_1^{(\alpha)} - \rho_1^{(\beta)})(z_\beta - z_s) \qquad \text{(III, 12)}$$

and similarly

$$m_2^{(\sigma)}/A = m^{(\sigma)}(1-x_1^{(\alpha)})/A = \Gamma_2 + \rho_2^{(\alpha)}\tau - (\rho_2^{(\alpha)} - \rho_2^{(\beta)})(z_\beta - z_s) \qquad \text{(III, 13)}$$

where

$$m^{(\sigma)} = m_1^{(\sigma)} + m_2^{(\sigma)},\quad x_1^{(\sigma)} = m_1^{(\sigma)}/m^{(\sigma)};$$

$m_i^{(\sigma)}$ is the number of moles of the ith component in the surface layer, and z_S is the coordinate of the dividing surface. These relations hold for any position of the dividing surface, not necessarily within the surface layer.

Passing to the relative adsorption

$$\Gamma_{2(1)} \equiv \Gamma_2 - \Gamma_1(\rho_2^{(\alpha)} - \rho_2^{(\beta)})/(\rho_1^{(\alpha)} - \rho_1^{(\beta)}) \qquad \text{(III, 14)}$$

and remembering that $A/m^{(\sigma)} = v^{(\sigma)}/\tau$, we obtain from (III, 12 and 13) the required relation

$$x_1^{(\sigma)} = \frac{x_1^{(\alpha)} - x_1^{(\beta)}\varkappa}{1-\varkappa}(1 - v^{(\sigma)}\Gamma_{2(1)}/\tau) - \frac{v^{(\sigma)}(x_1^{(\alpha)} - x_1^{(\beta)})}{v^{(\beta)}(1-\varkappa)} \qquad \text{(III, 15)}$$

where

$$\varkappa \equiv \rho^{(\beta)}/\rho^{(\alpha)} = v^{(\alpha)}/v^{(\beta)},\quad \rho = \rho_1 + \rho_2;$$

and v is the molar volume. Equation (III, 15) shows that conversion from relative adsorptions to mole fractions in the surface layer necessitates specification of the thickness and the molar volume of the latter—two parameters which characterise unambiguously the situation of the surface layer in the system.

In the case of equilibrium between solution and vapour with neglect of the density of the latter $\varkappa \to 0$ formula (III, 15) simplifies to[42,43]

$$x_1^{(\sigma)} = x_1^{(\alpha)}(1 - v^{(\sigma)}\Gamma_{2(1)}/\tau), \qquad \text{(III, 16)}$$

which coincides also with the expression for adsorption from a binary liquid solution at its interface with a solid[44].

Use of thermodynamic equations to calculate composition of surface layer

In order to calculate $x_1^{(\sigma)}$ by means of Eqn. (III, 16) it is first necessary to find the Gibbs relative adsorption. However, it can be calculated also by use of the thermodynamics of surface layers, e.g. from the constant-pressure temperature dependence of surface tension, an equation for which is obtained by fixing the pressure in Eqns. (II, 10) and eliminating one of the derivatives, e.g. $(dx_{n-1}/dT)_P^{(\alpha)}$. For a binary system we then have

$$a\left(\frac{d\sigma}{dT}\right)_P = -s_{\alpha\sigma} + \frac{x_1^{(\sigma)} - x_1^{(\alpha)}}{x_1^{(\beta)} - x_1^{(\alpha)}}s_{\alpha\beta} \qquad \text{(III, 17)}$$

which holds in practice even in the presence of a foreign gas (e.g. air[45]) in the system. In the case of a non-volatile salt ($x_1^{(\beta)} = 0$) we find from (III, 17) that

$$x_1^{(\sigma)} = x_1^{(\alpha)} - \frac{(d\sigma/dT)_P \cdot v^{(\sigma)}/\tau + s_{\alpha\sigma}}{s_{\alpha\beta}}x_1^{(\alpha)} \qquad \text{(III, 18)}$$

where $v^{(\sigma)} = a\tau$, which enables the composition of the surface layer of a binary solution to be calculated from the constant-pressure temperature dependence of surface tension. The differential molar entropy effects in (III, 18) are defined[41]

$$s_{\alpha\sigma} = -(d\sigma/dT)^{(\alpha)}_{x_1}\, v^{(\sigma)}/\tau;\quad s_{\alpha\beta} = RB/T$$

the constant B being evaluated from the temperature dependence of the vapour pressure $\ln P = A - B/T$. Surface-tension isobars are found from the composition dependence of σ and P, and are then differentiated to determine $(d\sigma/dT)_P$.

The composition of a surface layer of given thickness can be calculated also from isothermal data on the dependence of surface tension on solution composition. For a binary system the surface-tension isotherm

$$a\,d\sigma = \left[(x_1^{(\beta)} - x_1^{(\alpha)})\frac{v_{\alpha\sigma}}{v_{\alpha\beta}} - (x_1^{(\sigma)} - x_1^{(\alpha)})\right]g_{11}^{(\alpha)}dx_1^{(\alpha)} \qquad \text{(III, 19)}$$

follows from (II, 10).[46] When liquid–vapour (α–β) equilibrium is established far from the critical point, it can be assumed that

$$|v_{\alpha\beta}| \gg |v_{\alpha\sigma}| \qquad \text{(III, 20)}$$

and the first term in square brackets can be neglected. From (III, 19) we then obtain

$$x_1^{(\sigma)} = x_1^{(\alpha)} \frac{(d\sigma/dx_2^{(\alpha)})_T v^{(\sigma)}}{g_{11}^{(\alpha)} \cdot \tau} \qquad \text{(III, 21)}$$

The quantity $g_{11}^{(\alpha)}$ is calculated by means of the formula

$$g_{11}^{(\alpha)} = \frac{RT}{1 - x_1^{(\alpha)}} \frac{\partial \ln a_1}{\partial x_1^{(\alpha)}},$$

where a_1 is the activity of the first component. The molar volume is determined to a first approximation with no salt present in the surface layer. On the assumption of the same composition dependence of molar volume in the surface layer and in the solution, the calculated values of $x_1^{(\sigma)}$ are then used to make a second approximation refining the value of $v^{(\sigma)}$, and so on.

It follows from formulae (III–16, 18, and 21) that calculation of the composition of the surface layer requires that its thickness τ should be specified. Thermodynamics imposes certain restrictions on the choice of this quantity.

3. Estimation of Minimal Possible Thickness of Surface Layer

It has been shown[44,47] in the thermodynamics of surface phenomena that conditions of stability impose limitations on the thickness of the surface layer. These conditions can be used to find the minimum possible thickness for every mixture composition at every temperature. The requirement that the compositions of solution and surface layer should vary in parallel

$$(dx_1^{(\sigma)}/dx_1^{(\alpha)}) \geqslant 0$$

can be used as such a condition for binary systems. Application of this inequality to Eqn. (III, 15) and the assumption that molar volumes are additive yield

$$\tau \geqslant \Gamma_{2(1)} [v^{(\alpha)} - x_1^{(\alpha)}(v_1 - v_2)] + x_1^{(\sigma)} d\Gamma_{2(1)}/dx_1^{(\alpha)} \qquad \text{(III, 22)}$$

On the other hand, it follows from the self-evident inequality $0 \leqslant x_1^{(\sigma)} \leqslant 1$ that

$$\tau \geqslant \Gamma_{2(1)} v_2 \qquad \text{(III, 23)}$$

where v_1 and v_2 are the molar volumes of the components, and

$$v^{(\alpha)} \equiv v_2 + (v_1 - v_2) x_1^{(\alpha)}$$

is the additive molar volume of phase α. Analogous relations (but written for an equimolecular surface) were obtained for films adsorbed on a solid[44].

Use of other stability conditions for surface layers of finite thickness also leads to inequalities of the type (III, 22 and 23). The minimum possible thickness is then found directly from data on the composition of the surface layer[41,46].

4. Calculation of Excess Entropy

Considerable interest attaches not only to relative adsorption and the composition of the surface layer but also to the entropy characteristics of the latter, especially in connection with its structure. Calculations of these characteristics for binary liquid solutions were first published by the Reviewers[43,45]. The excess entropy depends by definition (II, 4) on the position of the dividing surface. However, the quantity $\bar{s}(j)$, introduced by analogy with the relative adsorption, is invariant with respect to displacement of the dividing surface and according to (II, 9) is equal to the excess entropy for a surface corresponding to the condition $\Gamma_j = 0$.

To obtain a relation for calculating the excess entropy we make use of an equation linking the molar entropies of solution and surface layer of finite thickness $s^{(\alpha)}$ and $s^{(\sigma)}$ with the temperature derivative of the surface tension. For a liquid–vapour equilibrium in a binary system, with the density of the vapour phase neglected, this equation becomes[41]

$$s^{(\sigma)} = s^{(\alpha)} - \frac{A}{m^{(\sigma)}} \left(\frac{d\sigma}{dT}\right)_{x_1^{(\alpha)}} + \left(\frac{\partial s}{\partial x_1}\right)^{(\alpha)} (x_1^{(\sigma)} - x_1^{(\alpha)}) \qquad \text{(III, 24)}$$

According to a general rule[41] a similar relation should apply to the excess functions. On passing to the latter $m^{(\sigma)}/A$ is replaced by the sum of the absolute adsorptions $\Gamma_1 + \Gamma_2$, and $x_1^{(\sigma)}$ by $\Gamma_1/(\Gamma_1 + \Gamma_2)$. Hence the entropy of the surface layer $s^{(\sigma)} \equiv S^{(\sigma)}/m^{(\sigma)}$ is replaced by $\bar{s}/(\Gamma_1 + \Gamma_2)$, where $\bar{s}$ is the excess entropy per unit surface. From this we obtain

$$\bar{s} = s^{(\alpha)}(\Gamma_1 + \Gamma_2) - (d\sigma/dT)_{x_1^{(\alpha)}} + (\partial s/\partial x_1^{(\alpha)})[\Gamma_1 - x_1^{(\alpha)}(\Gamma_1 + \Gamma_2)] \qquad \text{(III, 25)}$$

Passing to relative adsorptions, we find from (III, 25) that

$$\bar{s}_{(1)} = -(d\sigma/dt)_{x_1^{(\alpha)}} + [s^{(\alpha)} - (\partial s/\partial x_1)^{(\alpha)} x_1^{(\alpha)}]\,\Gamma_{2(1)} \qquad \text{(III, 26)}$$

$$\bar{s}_{(2)} = -(d\sigma/dT)_{x_1^{(\alpha)}} + [s^{(\alpha)} + (\partial s/\partial x_1)^{(\alpha)}(1 - x_1^{(\alpha)})]\,\Gamma_{1(2)} \qquad \text{(III, 27)}$$

whence

$$\bar{s}_{(2)} = \bar{s}_1 + \bar{s}^{(\alpha)}(\Gamma_{1(2)} - \Gamma_{2(1)}) \qquad \text{(III, 28)}$$

In the practical application of formulae (III, 26 and 27) to the calculation of excess entropies from experimental values of $(d\sigma/dT)_{x_1(\alpha)}$ the molar entropy of the solution is first calculated by means of the formula

$$s^{(\alpha)} = s_1 x_1^{(\alpha)} + s_2(1 - x_1^{(\alpha)}) + (\Delta h - \Delta g)/T \qquad \text{(III, 29)}$$

where Δh is the molar heat of mixing, which can be determined from calorimetric data, and Δg is the molar Gibbs free energy of mixing.

5. Calculation of Molar Entropy of Surface Layer

Calculation of molar entropy of surface layer from data on excess entropy

As in the calculation of composition, the entropy of the surface layer can be calculated either from excess Gibbs functions or directly by means of formulae relating to the surface layer. To obtain relations between the excess entropy and the molar entropy of the surface layer we return to Fig. 1, replace the density profile by the entropy profile, and write down the consequent self-evident relation

$$\bar{s} = S^{(\sigma)}/A - s_v^{(\alpha)}\tau + (s_v^{(\alpha)} - s_v^{(\beta)})(z_\beta - z_s) \qquad \text{(III, 30)}$$

Considering (III, 30) together with (III, 12) and passing to molar quantities

$$S^{(\sigma)} = s^{(\sigma)} m^{(\sigma)},\ s_v^{(\alpha)} = \frac{s^{(\alpha)}}{v^{(\alpha)}},\ s_v^{(\beta)} = \frac{s^{(\beta)}}{v^{(\beta)}},\ \rho_1^{(\alpha)} = \frac{x_1^{(\alpha)}}{v^{(\alpha)}},\ \rho_1^{(\alpha)} = \frac{x_1^{(\beta)}}{v^{(\beta)}}$$

we find from (II, 9) that

$$s^{(\sigma)} = \frac{v^{(\sigma)}}{\tau}\bar{s}_{(1)} + \frac{\varkappa\,(x_1^{(\alpha)}s^{(\beta)} - x_1^{(\beta)}s^{(\alpha)})\,v^{(\sigma)}/v^{(\alpha)} + (s^{(\alpha)} - s^{(\beta)\varkappa})\,x_1^{(\sigma)}}{x_1^{(\alpha)} - x_1^{(\beta)\varkappa}} \quad \text{(III, 31)}$$

where $x_1^{(\sigma)}$ is defined by (III, 15) with the same meaning of κ. Thus formula (III, 31), when considered in combination with (III, 15), enables the molar entropy of the surface layer to be calculated from its excess entropy. We again stress that the thickness and the molar volume of the surface layer must be specified: these two parameters define unambiguously the position of the surface layer in the heterogeneous system.

On passing to a solution–vapour ($\alpha-\beta$) system and neglecting the vapour density, we find from (III, 15 and 31) that

$$s^{(\sigma)} = s^{(\alpha)} + (\bar{s}_{(1)} - \Gamma_{2(1)}s^{(\alpha)})\,v^{(\sigma)}/\tau \quad \text{(III, 32)}$$

which can be used to calculate the molar entropy of the surface layer from the excess functions.

Calculation of molar entropy of surface layer from entropies of coexisting phases

The molar entropy of the surface layer $s^{(\sigma)}$ can be calculated directly from the thermodynamic equations for a layer of finite thickness. A suitable formula can be obtained from the definition (II, 11) of the differential molar entropy effect of adsorption. For a binary system we have

$$s_{\alpha\sigma} = s^{(\sigma)} - s^{(\alpha)} - (\partial s/\partial x_1)^{(\alpha)}\,(x_1^{(\sigma)} - x_1^{(\alpha)}) \quad \text{(III, 33)}$$

Taking into account the above expression for $s\alpha\sigma$, we hence obtain Eqn. (III, 24), which is quite convenient for calculating $s^{(\sigma)}$ from the entropy of the solution $s^{(\alpha)}$ and the temperature variation of surface tension.

The entropy of the surface layer can be calculated also by means of the formula

$$s^{(\sigma)} = s^{(\beta)} - s_{\alpha\beta} + s_{\alpha\sigma} - (\partial s/\partial x_1)^{(\alpha)}\,(x_1^{(\beta)} - x_1^{(\sigma)}) \quad \text{(III, 34)}$$

obtained by subtracting (II, 11) from (II, 13). Since the salt is non-volatile, $x_1^{(\beta)} = 0$, and we finally obtain[45]

$$s^{(\sigma)} = s^{(\beta)} - RB/T - (d\sigma/dT)_{x_1^{(\alpha)}}v^{(\sigma)}/\tau + (\partial s/\partial x_1)^{(\alpha)}x_1^{(\sigma)} \quad \text{(III, 35)}$$

The molar entropy of the vapour $s^{(\beta)}$ is evaluated from the formula

$$s^{(\beta)} = s_0^{\beta} - R\ln P \quad \text{(III, 36)}$$

where $s_0^{(\beta)}$ is the entropy of 1 mole of water vapour at 1 atm, and P (in atm) is the aqueous vapour pressure over the solution.

Among Eqns. (III–24, 32, and 35) the most convenient for practical application is (III, 24), which gives the smallest calculated error[43,48]. However, the use both of this equation and of (III, 32) requires the availability of calorimetric data, from which $s^{(\alpha)}$ can be calculated, and then the entropy of the surface layer. Adsorption data are also required when Eqn. (III, 34) is applied. However, formula (III, 36), which involves calculating the entropy of phase β and the entropy effect $s\alpha\beta$, can be used in approximate form (neglecting the last term) even in the absence of calorimetric data.

IV. EFFECT OF NATURE OF DISSOLVED IONS ON PROPERTIES OF SURFACE LAYER

In this Section we shall discuss results calculated by means of the above formulae for binary aqueous salt systems studied hitherto. Calculations have been made at one or more temperatures depending on the completeness and quality of the experimental data. The calculated thermodynamic characteristics of surface layers of various aqueous salt systems at the same temperature permit the systems to be compared and the effects of cations and anions on the structure and properties of the surface layer to be elucidated. The temperature 25 °C was chosen for this purpose. Most published surface-tension data relate to the range 10–30 °C, which permits interpolation for 25 °C. Furthermore, heats of mixing[49–51] as well as activity coefficients[52] are most often given for this temperature. Calculations at other temperatures are also important for revealing the temperature dependence of these properties of surface layers.

The Table summarises the published sources used. The second column gives references to determinations of surface tension, and the third column the sources of data on activity coefficients or vapour pressures. The molar entropies of the pure components have been taken from Refs. 53 and 54.

1. Dependence of Relative Adsorption on Energy of Hydration of Ions of Dissolved Salt

When calculating relative adsorptions in aqueous salt systems, we must bear in mind that the concentrations of hydroxide and hydrogen ions are far smaller than those of the ions of the dissolved salt. From the electrical neutrality of the surface layer (III, 3) we may then suppose that the condition of equivalent adsorption of cation and anion of the salt is a quite good approximation. Formulae (III, 9–11) have therefore been used to compute relative adsorptions.

The calculated adsorptions show (Figs. 2–15) that the relative adsorption of water $\Gamma_{2(1)}$ is positive in all the systems examined. The adsorption isotherms pass through an extremum in aqueous potassium, rubidium, and caesium chlorides, aqueous lithium and zinc nitrates, and aqueous ammonium sulphate (in potassium chloride solution it is perceptible only at 40 °C [61]). The relative adsorption of the salt $\Gamma_{1(2)}$ is negative, and in most cases increases numerically with concentration.

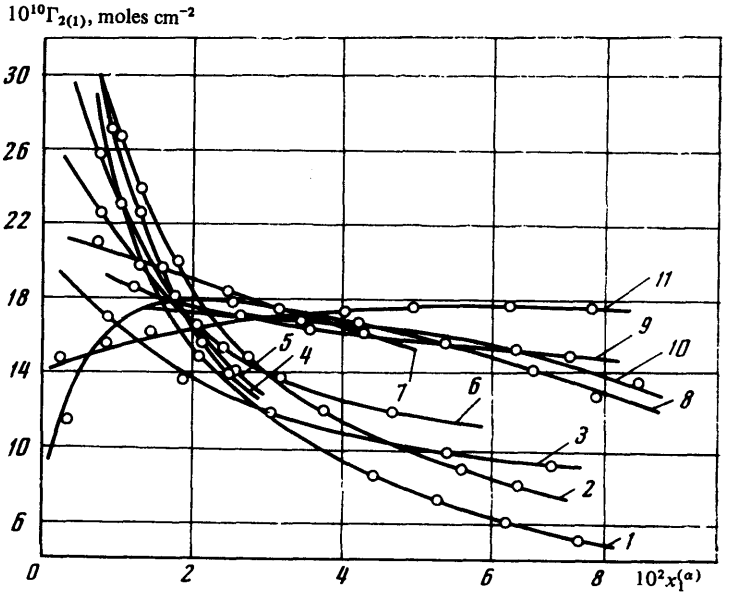

Figure 2. Relative adsorption of water at 25°C in aqueous solutions of: 1) $MgCl_2$; 2) $CaCl_2$; 3) LiCl; 4) $BaCl_2$; 5) $SrCl_2$; 6) $MnCl_2$; 7) CsCl; 8) RbCl; 9) KCl; 10) NaCl; 11) NH_4Cl.

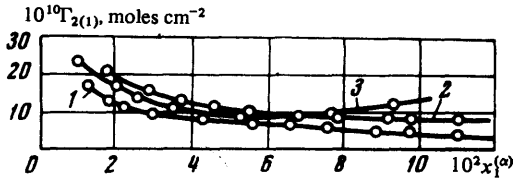

Figure 4. Relative adsorption of water at 25°C in aqueous solutions of: 1) LiBr; 2) NaBr; 3) KBr.

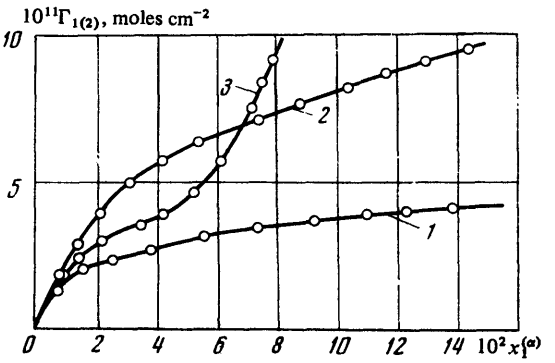

Figure 5. Relative adsorption of salt at 25°C in aqueous solutions of: 1) LiBr; 2) NaBr; 3) KBr.

In order to interpret the adsorption data we must consider the relation between the relative adsorption and the nature of the ions adsorbed. Consideration is usually given to published ionic hydration energies when adsorption isotherms for different salts are compared[82,83]. Indeed, the ability of an ion to pass from the bulk of the solution to the surface layer is largely determined by the strength of bonding of the ion with solvent molecules, i.e. by its hydration. However, data on the energy of hydration of individual ions generally relate to infinite dilution[49,84], so that the concentration dependence of this energy must be taken into account when discussing adsorption over a wide concentration range. Use for this purpose of Mishchenko's qualitative theory[49], which classifies solutions of electrolytes according to the form of isotherm for their integral heats of distribution, shows that substances whose dissolution becomes continuously less exothermic exhibit the most substantial change (weakening) of hydration with increase in solution concentration. Among the systems examined, aqueous solutions of lithium chloride, bromide, iodide, and nitrate, magnesium chloride and sulphate, calcium and barium chlorides, and zinc nitrate and sulphate belong to this group.

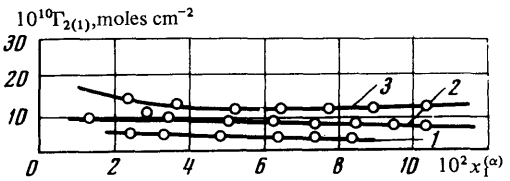

Figure 6. Relative adsorption of water at 25°C in aqueous solutions of: 1) LiI; 2) NaI; 3) KI.

A similar conclusion concerning the variation of hydration with concentration can be reached by comparing values of df/dc (where f is the mean activity coefficient and c the concentration). Positive values of df/dc indicate partial dehydration of the ions. Comparison of these derivatives for solutions of alkali-metal chlorides shows that, with increase in concentration, ionic dehydration is most significant with lithium chloride solution[20].

As example we shall examine in detail the series of solutions of alkali-metal chlorides. In infinitely dilute solutions the hydration energies $-\Delta H_0$ of the lithium, sodium, potassium, rubidium, caesium, and ammonium cations are respectively 127, 101, 81, 75, 67, and 78 kcal g-ion^{-1}.[49] However, the above discussion shows that bonding with water molecules becomes weaker with increase in concentration (energetic and coordinative dehydration) more noticeably with the lithium ion, which is most strongly hydrated at infinite dilution, than with the other cations, which facilitates transfer of these ions from the bulk of the solution to the surface layer. In sufficiently concentrated solutions the adsorption may thus become greater (numerically less) than that from solutions of the other chlorides.

The above considerations apply also to solutions of lithium bromide, iodide, and nitrate, magnesium chloride and sulphate, calcium and barium chlorides, and zinc nitrate and sulphate, and correspond to results obtained over a considerable concentration range. Fig. 3 shows that at concentrations $x_1^{(\alpha)} = 0.03$ and above the numerical value of the adsorption is significantly smaller from solutions of lithium, magnesium, and calcium chlorides than from solutions of other chlorides. Similarly, with the alkali-metal bromides (Fig. 5) adsorption from lithium bromide solution is greater (numerical value smaller) than from sodium and potassium bromide solutions beginning from $x_1^{(\alpha)} = 0.01$. The conclusions reached are supported also by the adsorption isotherms for solutions of iodides (Fig. 7), nitrates (Fig. 9), and sulphates (Fig. 11).

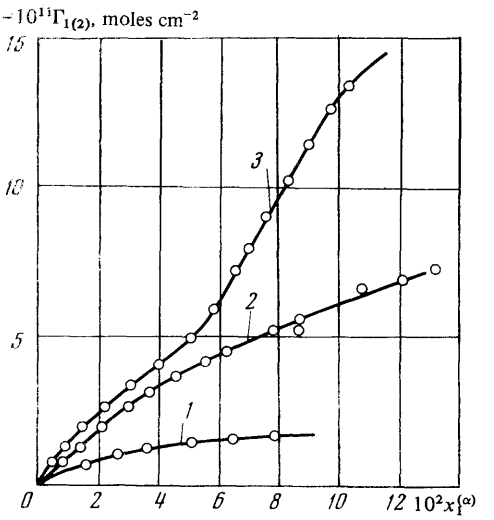

Figure 7. Relative adsorption of salt at 25°C in aqueous solutions of: 1) LiI; 2) NaI; 3) KI.

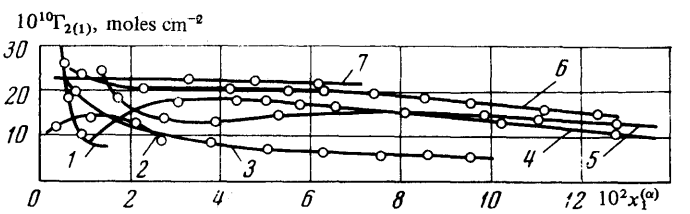

Figure 8. Relative adsorption of water at 25°C in aqueous solutions of: 1) $Ba(NO_3)_2$; 2) $LiNO_3$; 3) $Zn(NO_3)_2$; 4) $NaNO_3$; 5) NH_4NO_3; 6) $AgNO_3$; 7) KNO_3.

In very dilute solutions, however, it must be expected that the relative positions of the isotherms will correspond to the hydration energies for infinite dilution. The diagrams show, nevertheless, that the adsorption isotherms almost coalesce at low salt concentrations. Additional calculations were therefore made for the chlorides of various metals. With $x_1^{(\alpha)} = 0.004$ adsorption of the salt at 25°C (expressed as -10^{-11} mole cm^{-2}) is respectively 0.4, 0.6, 0.8, and 0.9 in aqueous rubidium, ammonium, lithium, and barium chlorides. Thus at such concentrations adsorption decreases with increase in the energy of hydration of the cation. In the above series it is

least with the barium ion, which is the most vigorously hydrated in infinitely dilute solution[49] ($-\Delta H_0$ = 320 kcal g-ion^{-1}).

For nitrate solutions calculations were made of the adsorption with $x_1^{(\alpha)}$ = 0.002 at 25°C. The values obtained for aqueous caesium, lithium, and zinc nitrates (respectively 0.3, 0.6, and 0.9 measured in -10^{-11} mole cm^{-2}) are also consistent with the energies of hydration of the cations at infinite dilution[49] ($-\Delta H_0$ = 67, 127, and 496 kcal g-ion^{-1}).

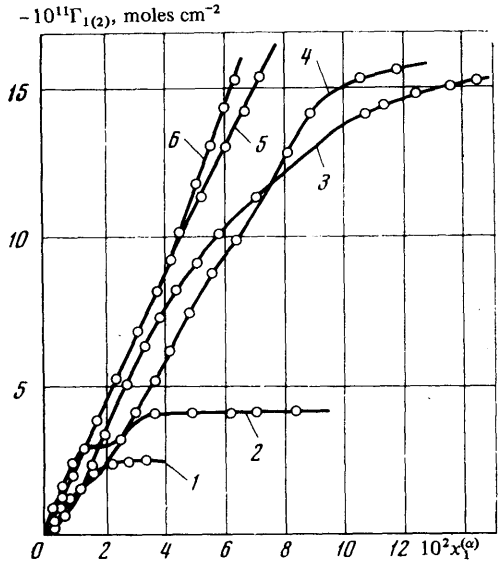

Figure 9. Relative adsorption of salt at 25°C in aqueous solutions of: 1) $LiNO_3$; 2) $Zn(NO_3)_2$; 3) $NaNO_3$; 4) NH_4NO_3; 5) $AgNO_3$; 6) KNO_3.

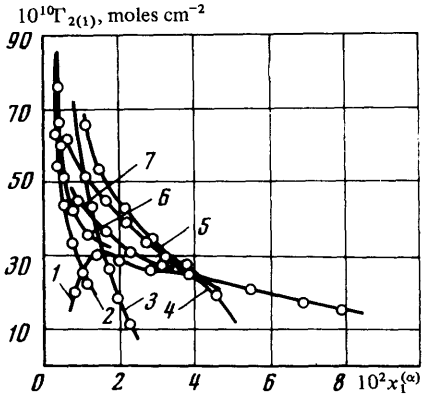

Figure 10. Relative adsorption of water at 25°C in aqueous solutions of: 1) $(NH_4)_2SO_4$; 2) $Al_2(SO_4)_3$; 3) $CuSO_4$; 4) $MgSO_4$; 5) $ZnSO_4$; 6) K_2SO_4; 7) Na_2SO_4.

In other cases (when the salts exhibit no marked difference in the concentration dependence of the hydration energy) the relative positions of the salt-adsorption isotherms correspond throughout the concentration range to the hydration energies at infinite dilution, e.g. for lithium, sodium, and potassium halides (Figs. 13–15). In conformity with Mishchenko's classification, solutions of lithium chloride, bromide, and iodide are of the same type according to the form of the isotherms for the integral heats of dissolution, while solutions of the sodium halides belong to another type, and those of the potassium halides to a third type. This means that the variation (increase or decrease) in the energy of hydration of the anions is roughly the same in each of the three cases. The relative positions of the adsorption isotherms should then correspond to these hydration energies at infinite dilution. For the chloride, bromide, and iodide ions we have[49] $-\Delta H_0$ = 84, 76, and 67 kcal g-ion^{-1}. The diagrams show that the numerical value of the adsorption diminishes in this sequence in all three cases.

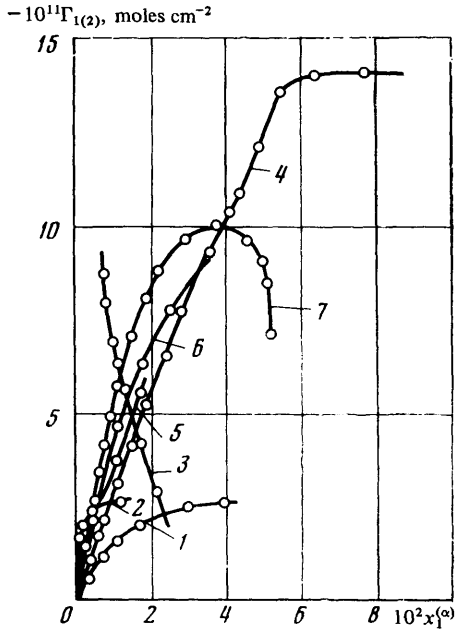

Figure 11. Relative adsorption of salt at 25°C in aqueous solutions of: 1) $ZnSO_4$; 2) K_2SO_4; 3) $CuSO_4$; 4) $(NH_4)_2SO_4$; 5) $Al_2(SO_4)_3$; 6) Na_2SO_4; 7) $MgSO_4$.

As already mentioned, calculations of adsorption have been made for several temperatures where suitable data on surface tension and activity coefficients were available. Comparison of results for 25° and 40°C indicates only a slight change (in most cases within the limits of error of the calculation) in the relative adsorption with temperature[43,61]. Only in aqueous ammonium chloride is a significant increase in $\Gamma_{1(2)}$ produced by raising the temperature from 25° to 40°C.[55] The evident reason is that the energy of hydration of the ammonium ion diminishes more rapidly with rise in temperature than do those of metal ions.

Increase in the numerical adsorption of surface-inactive non-volatile substances is accompanied by an increase in the surface tension of the solution (a direct consequence of the Gibbs adsorption equation). However, the surface

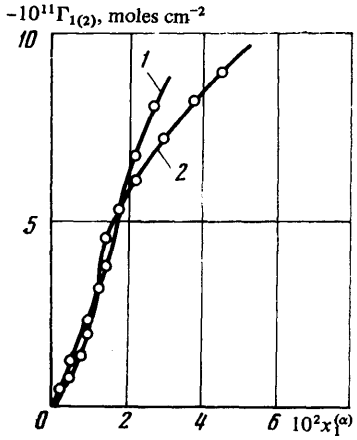

Figure 12. Relative adsorption of carbonates at 25°C from aqueous solutions of: 1) Na_2CO_3; 2) K_2CO_3.

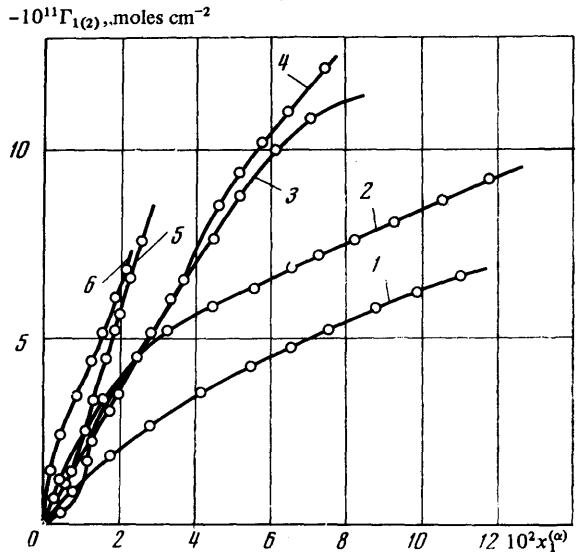

Figure 13. Relative adsorption of sodium salts at 25°C from aqueous solutions of: 1) NaI; 2) NaBr; 3) NaCl; 4) $NaNO_3$; 5) Na_2CO_3; 6) Na_2SO_4.

tension depends also on structural changes occurring in the solution under the influence of ions of the dissolved salt (this fact is reflected in the Gibbs equation by the activity coefficients). On the one hand, disruption of the structure of water by ions facilitates the transfer of water molecules to the surface layer and thus tends to diminish surface tension. On the other hand, the fields due to the ions, whose concentration in the solution may exceed considerably their concentration in the surface layer, promote the transfer of molecules into the interior of the solution and increase surface tension[20]. The presence of opposing tendencies provides an explanation for the fairly closely similar surface tensions exhibited by solutions of salts containing markedly different ions. For example, the presence of lithium ions structures a solution[85] and hinders the transfer of water molecules to the surface layer, which corresponds to an increase in surface tension relative both to pure water and to potassium chloride solution (potassium ions are known to loosen the structure of water[85]). But Fig. 3 shows that the adsorption of potassium chloride is numerically greater than that of lithium chloride. Hence on this basis the presence of potassium chloride in solution should produce a greater increase in surface tension. As a result, the surface-tension isotherms of these two solutions are quite close (Fig. 16).

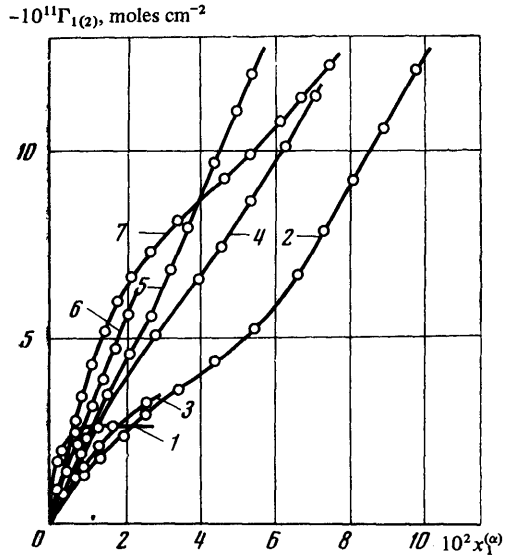

Figure 14. Relative adsorption of potassium salts at 25°C from aqueous solutions of: 1) K_2SO_4; 2) KI; 3) KBr; 4) KCl; 5) KNO_3; 6) $K_3[Fe(CN)_6]$; 7) K_2CO_3.

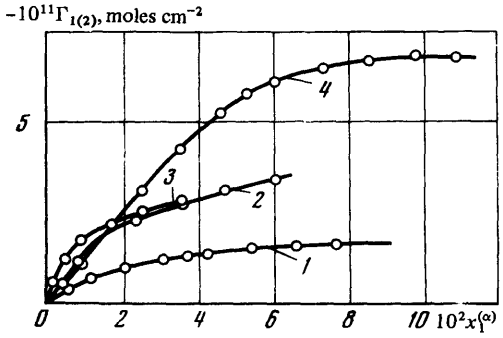

Figure 15. Relative adsorption of lithium salts at 25°C from aqueous solutions of: 1) LiI; 2) LiBr; 3) $LiNO_3$; 4) LiCl.

2. Composition and Minimum Possible Thickness of Surface Layer in Aqueous Salt Systems

A value of τ exceeding the minimum possible thickness must be specified in order to calculate the composition of the surface layer by means of formulae (III—16, 18, and 21), as in the calculation of its molar entropy. Thus the choice of thickness for the calculation entails estimation of its minimum possible value.

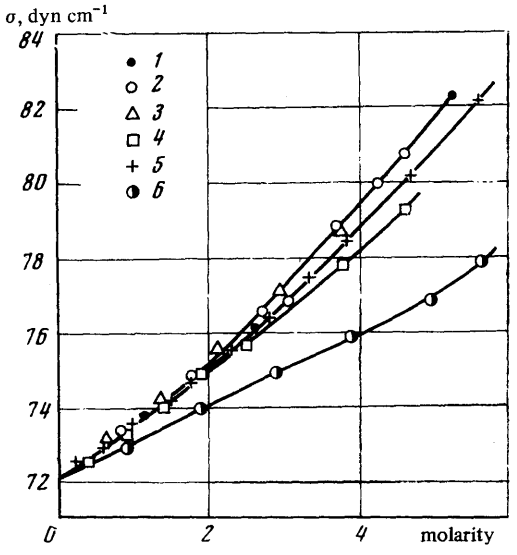

Figure 16. Surface tension at 25°C of solutions of ammonium and alkali-metal chlorides[48,55,61]: 1) LiCl; 2) NaCl; 3) KCl; 4) RbCl; 5) CsCl; 6) NH_4Cl.

The estimation has been based on the inequalities (III, 22 and 23). The larger of the two values of τ_{min} obtained from these inequalities are plotted against composition in Figs. 17–20. In most cases the minimum possible thickness decreases with increase in solution concentration. The diagrams show also that, with the exception of solutions of sulphates and carbonates, τ_{min} does not exceed 5 Å even at low salt concentrations. It is noticeable also that the minimum possible thickness falls more rapidly with concentration in solutions of sulphates.

The inequality (III, 23) can be used also to make the interesting estimation of the maximum possible thickness of a layer of pure water on the surface of the solution if such a layer can exist (an analogous method has already been applied to aqueous sodium chloride[14]). Another possibility for estimating the thickness of a film of water on the surface of a salt solution is to solve Eqns. (III, 18 and 21 [sic]) for τ with $x_1^{(\sigma)} = 0$. The hypothetical absence of salt in the surface layer implies a transition from a real surface layer to a model in which vapour and salt solution are separated by a film of water of thickness τ.

Calculations by different methods for solutions of lithium and sodium chlorides show (Fig. 21) that the film of water becomes thinner with increase in solution concentration, and that the water present on the surface of concentrated solutions is insufficient to form a monolayer. This implies that in these systems the ions of the salt enter a monolayer at the solution—vapour interface—a conclusion which is consistent with earlier results[8,9,15,16,45].

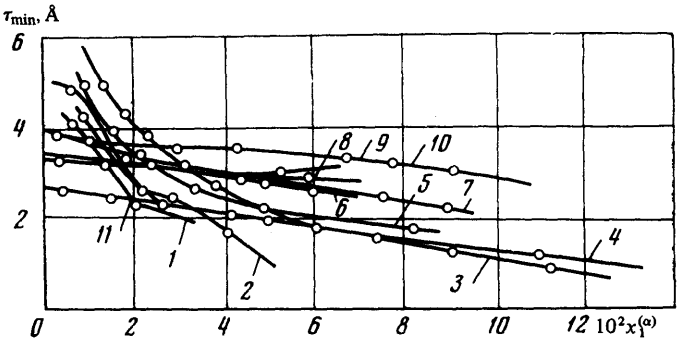

Figure 17. Concentration dependence of minimum possible thickness of surface layer at 25°C in aqueous solutions of chlorides: 1) $SrCl_2$; 2) $MgCl_2$; 3) $CaCl_2$; 4) LiCl; 5) $MnCl_2$; 6) RbCl; 7) NaCl; 8) KCl; 9) CsCl; 10) NH_4Cl; 11) $BaCl_2$.

Estimation of the minimum possible thickness was followed by calculation of the composition of the surface layer. In the case of carbonate and sulphate solutions the calculations were based on a layer 10 Å thick, and in the remaining cases 5 Å was chosen. These values are acceptable on purely thermodynamic grounds, since they deliberately exceed the minimum possible thickness.

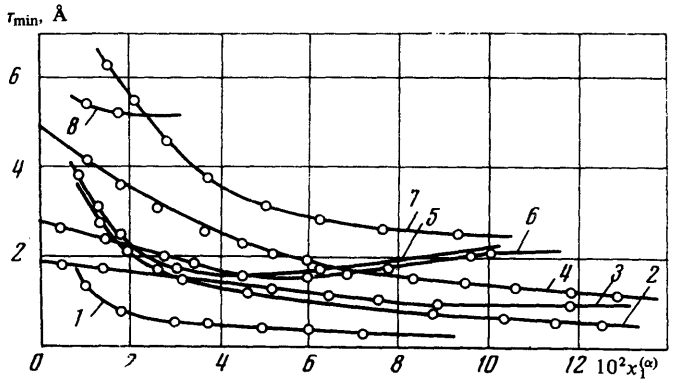

Figure 18. Concentration dependence of minimum possible thickness of surface layer at 25°C in aqueous solutions of alkali-metal halides and carbonates: 1) LiI; 2) LiBr; 3) NaI; 4) NaBr; 5) KBr; 6) KI; 7) Na_2CO_3; 8) K_2CO_3.

Choice of the same thickness (e.g. 5 or 10 Å) for the surface layers of several salt solutions helps to reveal several regularities indicating a relation between the nature of the ions and the properties of the surface layer.

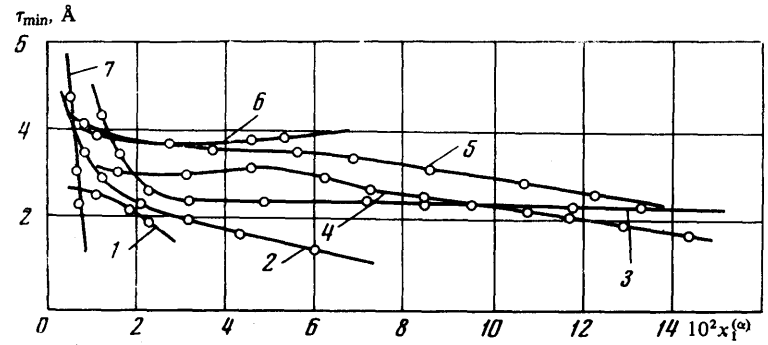

Figure 19. Concentration dependence of minimum possible thickness of surface layer at 25°C in aqueous solutions of nitrates: 1) $LiNO_3$; 2) $Zn(NO_3)_2$; 3) NH_4NO_3; 4) $NaNO_3$; 5) $AgNO_3$; 6) KNO_3; 7) $Ba(NO_3)_2$.

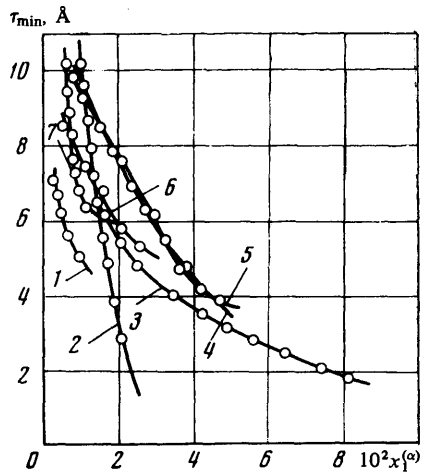

Figure 20. Concentration dependence of minimum possible thickness of surface layer at 25°C in aqueous solutions of sulphates: 1) K_2SO_4; 2) $CuSO_4$; 3) $(NH_4)_2SO_4$; 4) $MgSO_4$; 5) $ZnSO_4$; 6) Na_2SO_4; 7) $Al_2(SO_4)_3$.

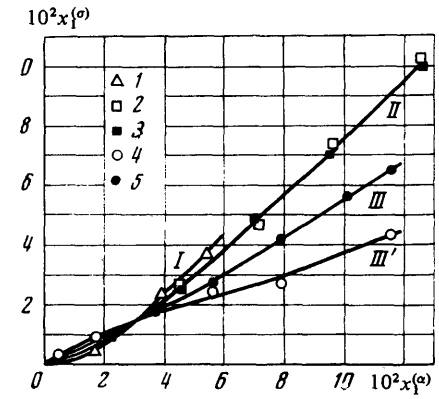

Figure 22. Composition of surface layer 5 Å thick in aqueous solutions of chlorides of: I) calcium; II) lithium; III, III′) ammonium at: 1,2,4) 25°C; 3,5) 40°C.

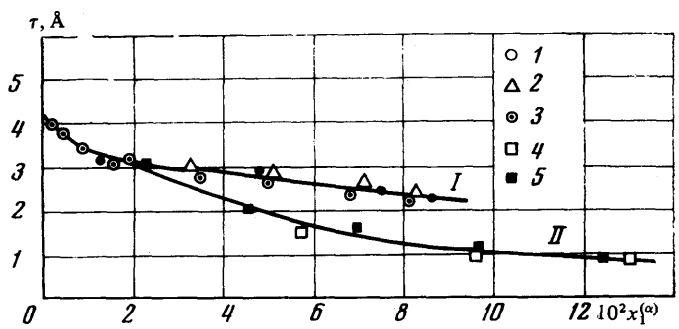

Figure 21. Thickness at 25°C of layer of water on surface of solutions of: I) sodium chloride; II) lithium chloride from: 1) formula (III, 17); 2) inequality (III, 22); 3) Ref. 14; 4) formula (III, 17); 5) inequality (III, 22).

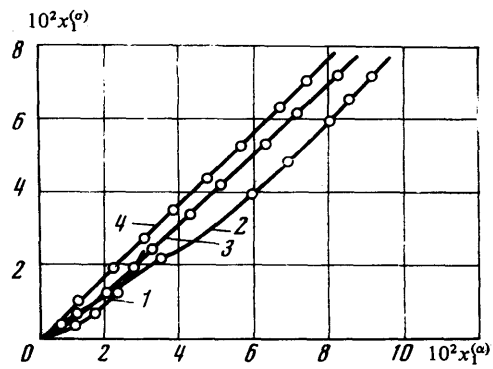

Figure 23. Composition of surface layer 5 Å thick in aqueous solutions at 25°C of lithium salts: 1) nitrate; 2) chloride; 3) bromide; 4) iodide.

Parallel calculations of composition by means of Eqns. (III–16, 18, and 21) for solutions of alkali-metal and ammonium chlorides showed good agreement [43,55,61], so that composition in the remaining systems was calculated only by means of (III, 16). Plots of the results show (Figs. 22–27) that the surface layer is in all cases depleted in salt relative to the solution, which corresponds to negative relative adsorption of the salt. This is a natural and necessary feature, since the parameters are directly related by formula (III, 16).

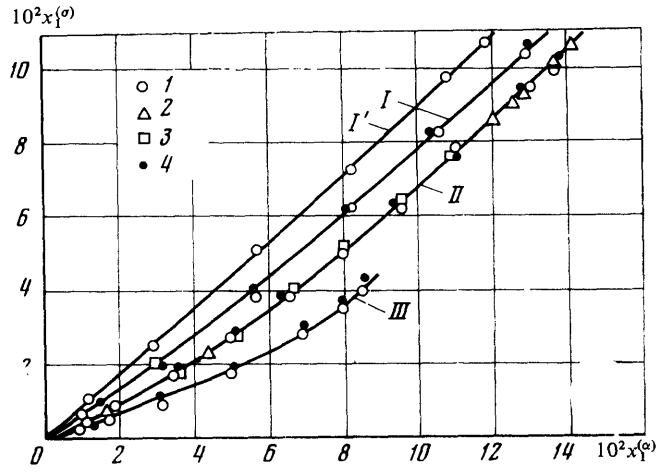

Figure 24. Composition of surface layer 5 Å thick in aqueous solutions of sodium halides: I) iodide; I') iodide (10 Å); II) bromide; III) chloride at: 1–3) 25°C; 4) 40°C.

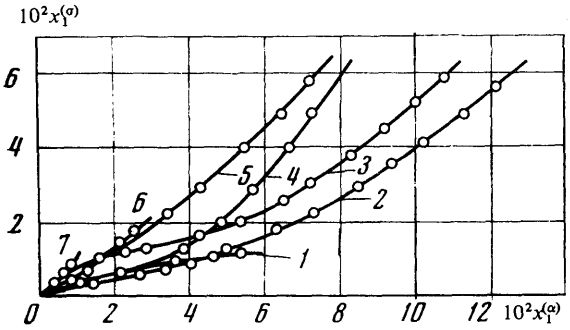

Figure 25. Composition of surface layer 5 Å thick at 25°C in aqueous solutions of nitrates: 1) KNO_3; 2) $AgNO_3$; 3) $NaNO_3$; 4) NH_4NO_3; 5) $Zn(NO_3)_2$; 6) $LiNO_3$; 7) $Ba(NO_3)_2$.

Comparison of the isotherms for the lithium halides shows (Fig. 23) that, for solutions of the same composition, the salt content of the surface layer diminishes in the sequence LiI > LiBr > LiCl throughout the concentration range. A similar pattern is exhibited by the halides of sodium (Fig. 24) and of potassium [55]. Thus the results obtained for adsorption and composition indicate that iodides penetrate into the surface layer more readily than do bromides and chlorides (and bromides in turn more readily than chlorides). As already mentioned, the increase in salt contents of lithium, sodium, and potassium halides in the sequence—chloride < bromide < < iodide—corresponds to the hydration energies of these ions.

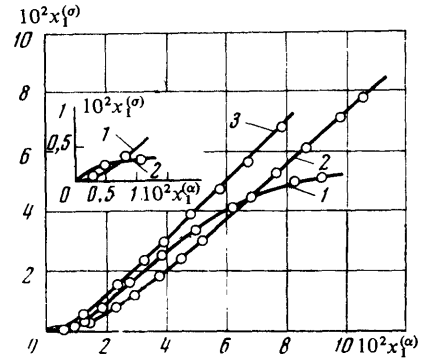

Figure 26. Composition of surface layer 5 Å thick at 25°C in aqueous solutions of alkali-metal bromides: 1) KBr; 2) NaBr; 3) LiBr.

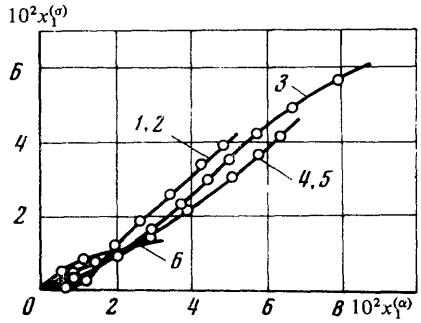

Figure 27. Composition of surface layer 10 Å thick at 25°C in aqueous solutions of sulphates and carbonates: 1) $CuSO_4$; 2) $ZnSO_4$; 3) K_2CO_3; 4) $(NH_4)_2SO_4$; 5) Na_2SO_4; 6) Na_2CO_3.

The isotherms for the composition of the surface layer in solutions of lithium, calcium, and ammonium chlorides show (Fig. 22) that at low concentrations ($x_1^{(\alpha)} < 0.03$) the quantity of salt in the surface layer diminishes in the sequence $NH_4Cl > LiCl > CaCl_2$, i.e. with increase in the energy of hydration of the cation at infinite dilution ($-\Delta H_0 = 78$, 127, and 386 kcal g-ion^{-1}). [49] The relative positions of the isotherms change in more concentrated solutions, which is explained by differences in the concentration dependence of the hydration energy for these ions [49].

A similar situation is observed with the surface layers of solutions of alkali-metal bromides and of sulphates (Figs. 26 and 27). The concentration of salts containing

the most strongly hydrated cations (lithium bromide and copper and zinc sulphates respectively) is lower in the surface layers of dilute solutions than are those of the other bromides and sulphates. For the above reasons the relative positions of the composition isotherms change with increase in concentration of the solution.

In conclusion we note that rise in temperature from 25° to 40°C has little effect on the composition of the surface layer in solutions of salts having a metal cation (Figs. 22 and 24).

3. Entropy of Surface Layers

Excess entropy

After the molar entropy of the solution $s^{(\alpha)}$ and the relative adsorption have been calculated, formulae (III, 26–28) can be used to estimate the excess entropies $\bar{s}_{(1)}$ and $\bar{s}_{(2)}$. The first calculations of excess entropy in binary systems were published by the Reviewers[43] (with unary systems excess entropy can be determined by means of the Gibbs adsorption equation).

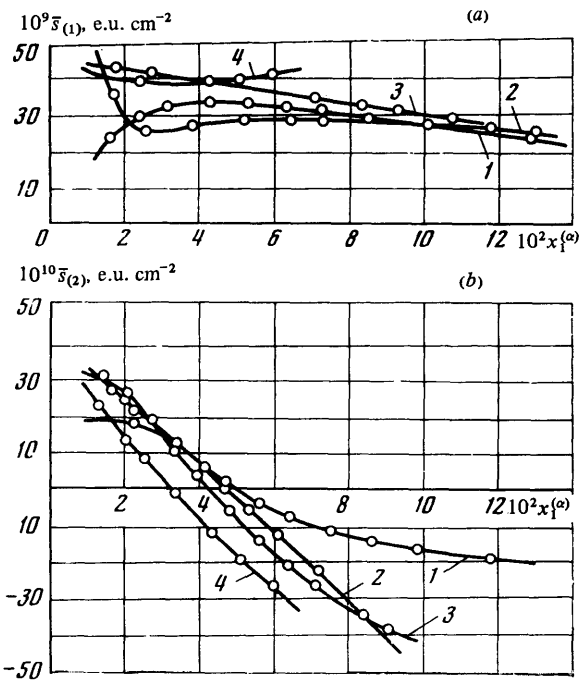

Figure 28. Excess entropies at 25°C in aqueous solutions of: 1) $NaNO_3$; 2) NH_4NO_3; 3) $AgNO_3$; 4) KNO_3.

The calculated results show that $\bar{s}_{(1)}$ is positive and in all cases exceeds $\bar{s}_{(2)}$ (e.g. Figs. 28 and 29 together with Refs. 43, 55, 61, and 68). Since $\bar{s}_{(1)}$ and $\bar{s}_{(2)}$ represent the excess entropies for the surfaces $\Gamma_1 = 0$ and $\Gamma_2 = 0$ respectively, the fact that $\bar{s}_{(1)} > \bar{s}_{(2)}$ implies that the dividing surface, for which $\Gamma_1 = 0$, is located below the surface corresponding to the condition $\Gamma_2 = 0$ (Fig. 1).

In all the systems examined the quantity $\bar{s}_{(2)}$ diminishes with increase in concentration, in some cases (e.g. nitrate solutions) becoming negative. Such a negative value (with $\bar{s}_{(1)} > 0$) does not necessarily mean that the molar entropy of the surface layer is smaller than the entropy of the solution. It may be due merely to variation in the position of the surface $\Gamma_2 = 0$ with concentration. Upward movement of this surface (increase in its coordinate z_S in Fig. 1) corresponds to a decrease in $\bar{s}_{(2)}$ down to negative values.

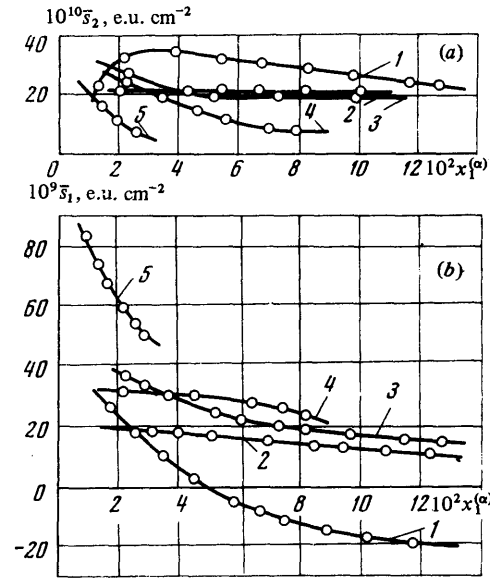

Figure 29. Excess entropies at 25°C in aqueous solutions of: 1) $NaNO_3$; 2) NaI; 3) NaBr; 4) NaCl; 5) Na_2SO_4.

Molar entropy of Surface layer

The molar entropy of a surface layer 5 Å thick was calculated by means of formulae (III—24, 32, and 35) for solutions of alkali-metal halides and ammonium chloride at 25° and 40°C (the calculation for aqueous sodium iodide was repeated with $\tau = 10$ Å); the results showed satisfactory agreement[43,45,55,61]. For the remaining systems Eqn. (III, 24) was used to calculate entropy at 25°C, since this method is the most accurate. Figs. 30–35 illustrate (*a*) the dependence of the entropy of the surface layer $s^{(\sigma)}$ on the composition of the layer and (*b*) the molar entropies of the solutions $s^{(\alpha)}$ as a function of solution composition.

The entropy of the solution is in all cases smaller than that of the coexisting surface layer: $s^{(\sigma)} > s^{(\alpha)}$. However, this difference is not entirely attributable to surface phenomena, since the solution shows a substantial difference in composition in bulk and at the surface. It is therefore of interest also to compare the entropy characteristics of solution and surface layer having the same salt concentration. Even in this case $s^{(\sigma)} > s^{(\alpha)}$. In aqueous lithium chloride with $x_1^{(\alpha)} = 0.045$, for example, $s^{(\alpha)} = 16.1$ e.u. mole^{-1}. With the same salt concentration in the surface layer, however, the entropy of the latter is $s^{(\sigma)} = 16.8$ e.u. mole^{-1}. In aqueous caesium chloride with $x_1^{(\alpha)} = 0.020$ we have similarly $s^{(\alpha)} = 17.5$ e.u. mole^{-1},

whereas with the same salt concentration in the surface layer $s^{(\sigma)} = 18.6$ e.u. mole^{-1}. Comparison of the entropies of surface layer and solution both containing 1 mole % of the salt gives for $s^{(\alpha)}$ and $s^{(\sigma)}$ the respective values 17.0 and 17.6 e.u. mole^{-1} (Figs. 30–34).

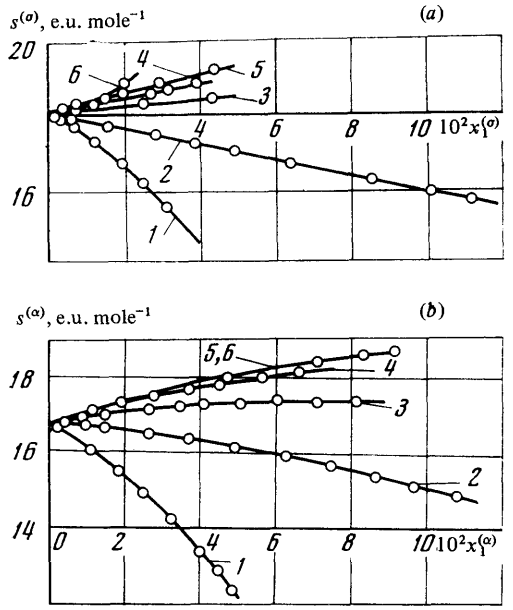

Figure 30. Composition dependence of molar entropy at 25°C in: *a*) surface layer 5 Å thick; *b*) solution for aqueous: 1) $MgCl_2$; 2) LiCl; 3) NaCl; 4) KCl; 5) RbCl; 6) CsCl.

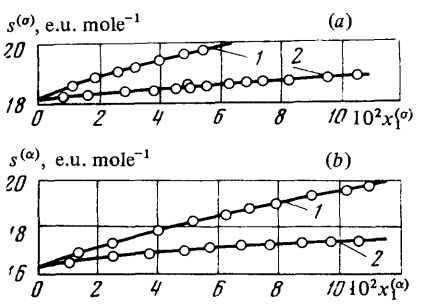

Figure 31. Composition dependence of molar entropy at 25°C in: *a*) surface layer 5 Å thick; *b*) solution for aqueous: 1) KI; 2) NaI.

The above examples show that the greater entropy of the surface layer is due not only to depletion with the salt but also to definite structural changes in the layer (with loosening of the surface structure on passing to the vapour). Nevertheless, a parallel variation in the entropies of solution and surface layer must be noted: increase in the salt concentration is accompanied by decreases in $s^{(\sigma)}$ and $s^{(\alpha)}$ in aqueous lithium chloride, magnesium chloride, and lithium nitrate, and by increases in the remaining cases. Such variation of entropy with concentration seems reasonable: increase in the content of the positively hydrated lithium and magnesium ions orders both the solution and the surface layer [85] with a consequent decrease in entropy; but accumulation of the large, weakly hydrated rubidium, caesium, and ammonium ions produces an increase in entropy.

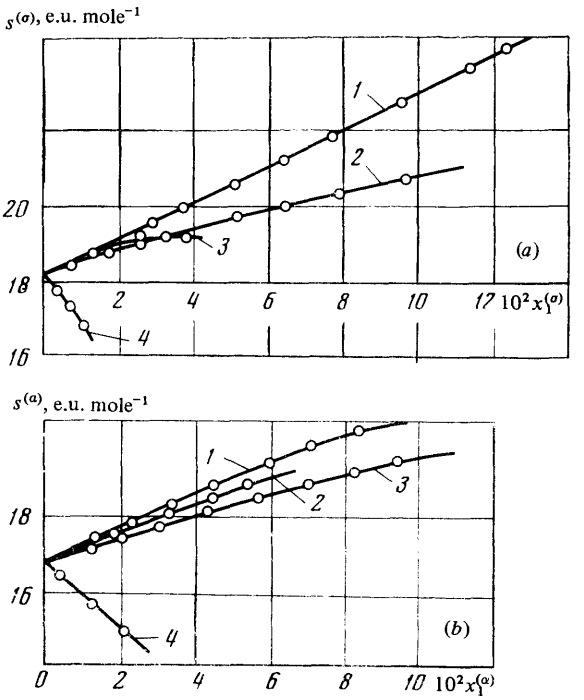

Figure 32. Composition dependence of molar entropy at 25°C in: *a*) surface layer 5 Å thick; *b*) solution for aqueous: 1) NH_4NO_3; 2) $NaNO_3$; 3) $AgNO_3$; 4) $LiNO_3$.

Comparison of the entropies of surface layers in different aqueous salt systems will reveal the effects of individual ions on the structure of the solution. Change in structure is due firstly to reorientation of water molecules by ion–dipole interaction. Among ions of the same valency the smallest will be the most effective. Secondly, the introduction of ions would tend to distort and disrupt the structure of water, and the more strongly the larger their size. Bonner [87] has concluded from ample experimental data that the combined effect of the above two factors would be minimal with sodium among singly charged ions. This conclusion is fully supported by the results obtained (Figs. 30 and 33). The entropy isotherm for the surface layer in aqueous sodium chloride is very nearly horizontal, which means little increase in entropy with the accumulation of salt in the surface layer: i.e. the introduction of sodium ions in fact causes minimal disruption of the structure on the surface layer.

Fig. 33(*a*) illustrates the molar entropies $s^{(\sigma)}$ as functions of composition of surface layer for aqueous solutions

of sodium chloride, bromide, iodide, and nitrate. At low salt concentrations the entropies are almost identical. But with increase in the salt content of the surface layer ($x_1^{(\sigma)} > 0.03$) the difference in behaviour among the halide ions affects the entropies of the surface layer (the chloride ion has less effect than have bromide and iodide ions on the structure of water [49]). Differences in the entropies of the solutions $s^{(\alpha)}$, however, are observed (Fig. 33*b*) at far higher concentrations ($x_1^{(\alpha)} > 0.08$). We reach the same conclusion from the molar entropies of solutions and surface layers in aqueous potassium chloride and iodide (Fig. 34).

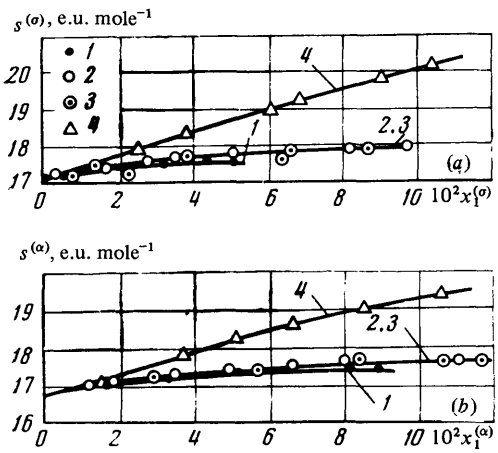

Figure 33. Composition dependence of molar entropy in: *a*) surface layer 5 Å thick; *b*) solution for aqueous: 1) NaCl; 2) NaBr; 3) NaI; 4) $NaNO_3$.

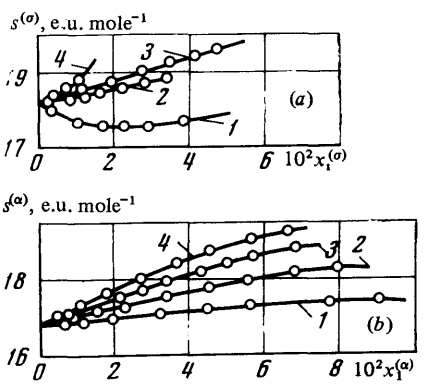

Figure 34. Composition dependence of molar entropy in: *a*) surface layer 5 Å thick; *b*) solution for aqueous: 1) KBr; 2) KCl; 3) KI; 4) KNO_3.

The entropy characteristics of solutions of rubidium and caesium chlorides (Fig. 35) are especially interesting. The isotherms of the molar entropies of the solutions coincide throughout the concentration range. Beyond the concentration $x_1^{(\sigma)} = 0.02$ the entropy of the surface layer increases more rapidly with the concentration of caesium chloride in the layer than with that of rubidium chloride.

The examples cited show that in several cases differences in behaviour among ions are more strongly developed in the surface layer than in the solution. The differences in the values of the corresponding thermodynamic functions of the systems therefore become appreciable sooner (at lower concentrations) in the surface layer than in the solution.

In conclusion we note that, among all the properties of surface layers, the entropy is most sensitive to variation in temperature, and increases appreciably on passing from 25° to 40°C. [43,45,55,61]

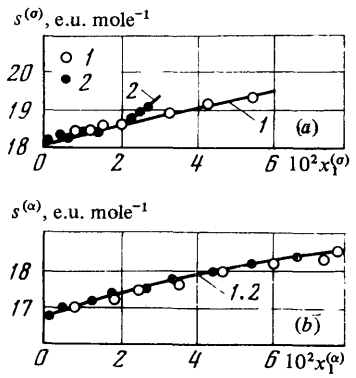

Figure 35. Composition dependence of molar entropy at 25°C in: *a*) surface layer 5 Å thick; *b*) solution for aqueous: 1) RbCl; 2) CsCl.

The Review has shown that thermodynamic calculations based on experimental data for surface tension and discussion of the thermodynamic characteristics obtained for surface layers are useful for studying the structure of aqueous salt systems and the effect of the nature of dissolved ions on the properties of solutions and surface layers.

Advances in the Chemistry of Triptycene

V.R.Skvarchenko, V.K.Shalaev, and E.I.Klabunovskii

Information is presented on the preparation of triptycene, its homologues, and substituted derivatives. The spectroscopic, X-ray, optical, and other physical properties of these compounds are discussed. A systematic account is given of the behaviour of substituents located at a bridgehead, and of the differing reactivities of α- and β-positions in the aromatic rings on nucleophilic and electrophilic substitution. Reactions involving opening of the bridge system, the polarographic reduction of triptycenequinones, and the catalytic hydrogenation of triptycene are considered. The list of references contains 247 items.

I. INTRODUCTION

Triptycene, which was first described in 1942,[1] has now become readily available thanks to the well known work of Wittig[2-9] on the preparation of dehydrobenzene and its interaction with anthracene.

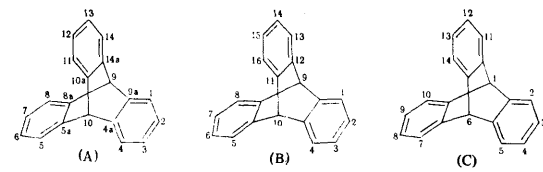
The specific properties of triptycene—the low mobility of bridge substituents, the difference in reactivity towards substitution between α- and β-positions in aromatic rings, steric peculiarities due to the rigidity of the molecule—attracted the attention of research workers. The large number of differently substituted isomeric compounds is due to the presence of three equivalent aromatic rings in the triptycene molecule. The bulky structure of the thermally stable triptycene suggests that certain polymers containing a triptycene fragment may possess valuable specific properties.

The chemistry of triptycene has been studied in comparative detail. A considerable quantity of interesting work of fundamental character has appeared during recent years, but only one review paper has hitherto been published on triptycene, which is small in scope and not readily accessible to a wide range of readers[10]. The present Review examines methods for constructing the triptycene system, together with the reactivity, spectral characteristics, and certain physicochemical properties of compounds of this series.

II. CONSTRUCTION OF TRIPTYCENE SYSTEM

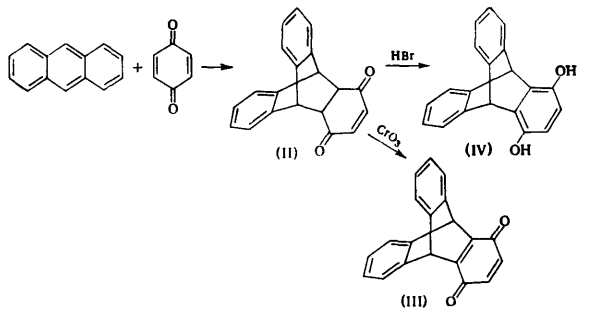
The most general method for building up the polycyclic triptycene system—9,10-*o*-benzo-9,10-dihydroanthracene† (I)—is diene synthesis between anthracene or a substituted derivative and a sufficiently active six-membered carbocyclic dienophile. Thus Clar[14] was the first to isolate the adduct (II) of anthracene with *p*-benzoquinone,

† A nomenclature which regards triptycene as a derivative of dihydroanthracene is now generally accepted[11,12], with the carbon atoms numbered as in (A) (used in the present Review) or (B):

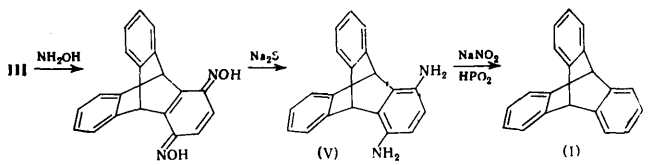


In some publications triptycene compounds have been regarded as substituted bicyclo[2,2,2]octanes, with the carbon atoms numbered as in (C).[1,13]

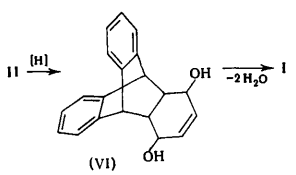
which he converted into triptycene derivatives—triptycenequinone (III) and triptycenequinol (IV):



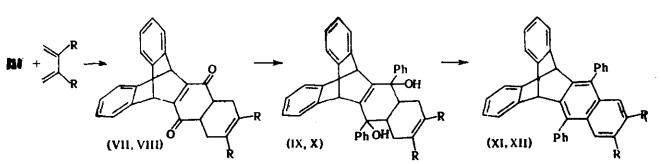
from which, however, he was unable to obtain triptycene. Bartlett et al.[1,15] extended Clar's scheme, and were the first to accomplish the multistage synthesis of triptycene:

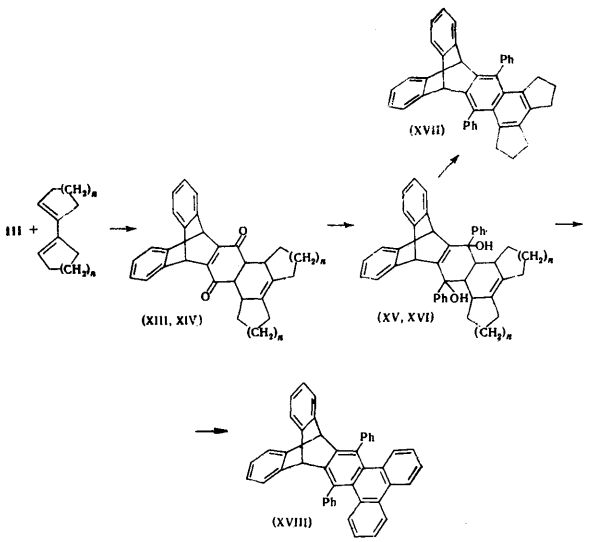


Triptycene was obtained also by dehydration of the dion (VI) (by boiling with alcoholic hydrogen chloride[16] or with a mixture of phosphorus trichloride and phosphoryl chloride), which is readily formed by direct reduction of the adduct (II) with lithium tetrahydroaluminate[16] or with aluminium isopropoxide in propan-2-ol:[11]

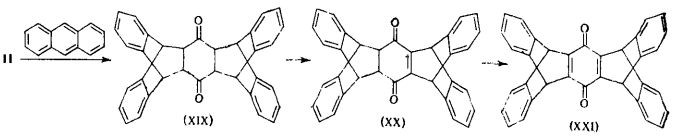


Triptycenequinone (III), which was used by Bartlett in the preparation of triptycene (I),[1,15] later served as the starting compound for the synthesis of several more complicated structures containing a triptycene fragment. Thus a detailed study was made of the dienophilic reactivity of triptycenequinone (III) with aliphatic dienes (butadiene, 2,3-dimethylbutadiene) and bicyclic dienes (1,1'-bicyclohexenyl, 1,1'-bicyclopentenyl) (an adduct of triptycenequinone (III) with acecyclone had been described earlier)[17]. The action of phenyl-lithium on the adducts obtained (VII, VIII, XIII, XIV) gave the corresponding diols (IX, X, XV, XVI), whose dehydration produced quantitative yields of 5,12-diphenyltetrahydro-6,11-benzonaphthacenes, which on subsequent dehydrogenation are converted into hydrocarbons of complicated structure—1,4-diphenyl-2,3-benzotriptycenes (XI, XII, XVII, XVIII):[18-20]



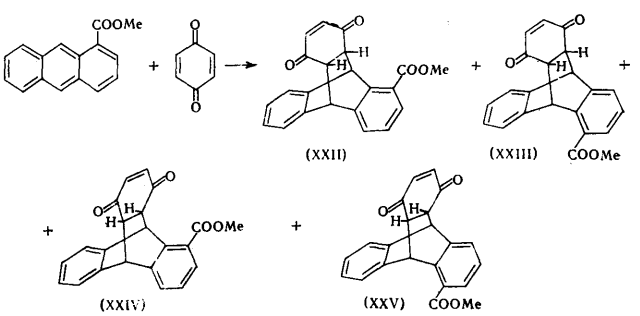


Other dienophiles which have been made to react with anthracene are derivatives of *p*-benzoquinone[21-27] and 1,4-naphthaquinone[28-31], 1,4-anthraquinone[32], quinones of the triptycene series[33-35] and bicyclo[2,2,1]heptadiene-2,3-dicarboxylic anhydride[36], but no attempts were made to obtain from these adducts the corresponding hydrocarbons having a triptycene structure. Depending on the conditions the reaction between anthracene and *p*-benzoquinone yields not only the adduct (II) but also other compounds. Thus with excess of anthracene the double adduct (XIX) is formed; at 140–165°C this is dehydrogenated first to the diketone (XX), and at 165°C to the quinone (XXI):[11]

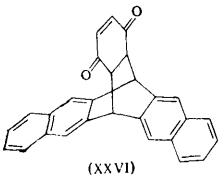


In the presence of aluminium chloride the adduct (II) is formed in high yield even at room temperature, and with excess of anthracene the double adduct (XIX).[37]

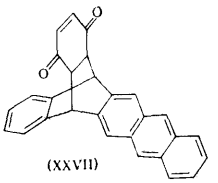
With substituted anthracenes *p*-benzoquinone forms isomeric compounds. Thus with methyl 1-anthroate adducts of *exo*- and *endo*-configuration are obtained, each of which in turn is a racemic mixture of stereoisomers (XXII–XXV):[13]



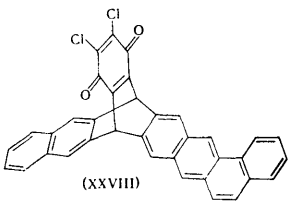
Other acenes react similarly to anthracene with *p*-benzoquinone. Thus pentacene undergoes diene synthesis with the formation of two adducts, of symmetrical (XXVI) and unsymmetrical (XXVII) structure[38].



(XXVI)



(XXVII)

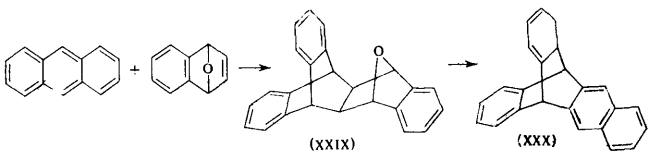


(XXVIII)

Pentacene reacts similarly with chloranil[14], and the latter has been reported to react with 7,14-dihydro-1,2-benzohexacene to yield the adduct (XXVIII).[39]

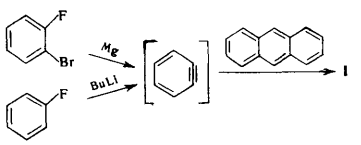
Hydrocarbons having a partly hydrogenated triptycene structure are obtained by diene synthesis between anthracene and cyclohexene[40], 1,4-dihydronaphthalene[28], 1,4-dihydro-1,4-methanonaphthalene[41], and bicyclo[2,2,1]-heptadiene[42,43].

An original route to 2,3-benzotriptycene (XXX) was suggested by Wittig et al.[41], who applied the Diels–Alder reaction to anthracene and 1,4-epoxy-1,4-dihydronaphthalene (in turn obtained by diene synthesis from furan and dehydrobenzene), and heated the resulting adduct (XXIX) in acetic acid[44]:



(XXIX) (XXX)

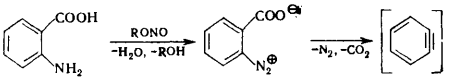
The direct method of preparing triptycene by diene synthesis from anthracene and dehydrobenzene, proposed by Wittig in 1956,[2] is at present time the simplest and the most convenient. Its development has made triptycene readily available as a subject for many interesting investigations. Various processes have been described for generating dehydrobenzene from numerous monosubstituted and *ortho*-disubstituted benzene derivatives‡, as well as procedures for conducting the diene synthesis. Triptycene is obtained in various yields depending on the method of producing dehydrobenzene and on the conditions of its reaction with anthracene. Thus Wittig et al. obtained a 30% yield by the action of magnesium on *o*-bromofluorobenzene (in oxolan or ether) in the presence of anthracene[2,3,6]; reaction of anthracene with dehydrobenzene generated by treating fluorobenzene with *n*-butyllithium in oxolan gave only a 10% yield of triptycene[5]:



‡ A special monograph[45] was devoted to dehydrobenzene and arynes.

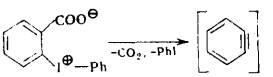
Triptycene has been obtained also from dehydrobenzene generated from fluorobenzene by the action of lithium hexaphenylantimonate[7], from halogenobenzenes by the action of potassium t-butoxide[46,47], by the decomposition of *N*-nitrosoacetanilides[47-52], by the oxidation of 1-aminobenzotriazole[53], by the decomposition of *N*-*o*-carboxyphenyl-*N'*-toluene-*p*-sulphonyldi-imide *N*-oxide[54], by heating benzo-1,2,2-thiadiazole dioxide in oxolan[8,9], and by decomposing *o*-diiodobenzene with zinc in the gas phase (at 550°C).[55]

The most convenient mode of generating dehydrobenzene for the preparation of triptycene is to decompose *o*-diazonium benzoate (a betaine obtained by diazotising anthranilic acid) by heating in an aprotic solvent[56,57]:



In the improved method of Friedman and Logullo[58,59] anthranilic acid dissolved in acetone (oxolan, butan-2-one, or diglyme) is added to a boiling solution of anthracene and pentyl (or butyl) nitrite in dichloromethane (chloroform or 1,2-dichloroethane). The yield of triptycene is 50–60%, but with simultaneous mixing of the reactants it sometimes falls to 10%; use of a molar excess of anthracene or anthranilic acid tends to raise the yield to 70–80%. With difficulty accessible substituted anthracenes it is sometimes better to use a modified method involving intermediate isolation of *o*-diazonium benzoate[60]. Dioxan[61] and *p*-xylene[62] have also been used as high-boiling solvents in the preparation of substituted triptycenes.

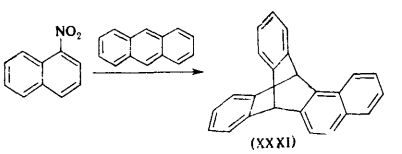
The use in certain cases of dehydrobenzene formed by the decomposition of iodonium *o*-benzoate (in boiling diglyme[63] or triglyme[64], sometimes in the presence of catalytic additions of iodine or copper sulphate or acetate[65])



has no significant advantages over the above method[58,59].

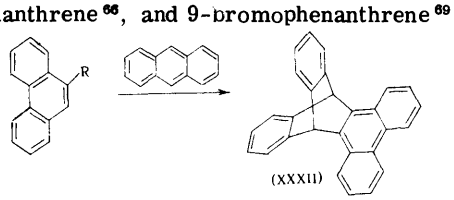
Not only dehydrobenzene and its substituted derivatives but also other arynes—2,3-dehydronaphthalene[58], 9,10-dehydrophenanthrene[66], 2,3-dehydro-9,10-anthraquinone[67], and dehydro[2,2]paracyclophane[68]—have been used in diene syntheses with anthracene.

Many reactions yielding benzotriptycenes (XXX–XXXII) also involve the intermediate formation of arynes—e.g. the reaction of anthracene (at 300°C) with 1-nitronaphthalene[28]



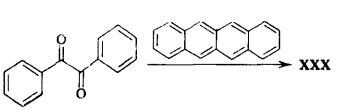
(XXXI)

9-nitrophenanthrene[66], and 9-bromophenanthrene[69]

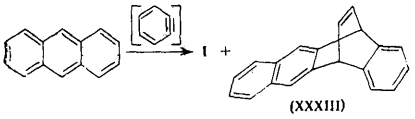


(XXXII)

and the pyrolysis of benzil in the presence of naphthacene[70].

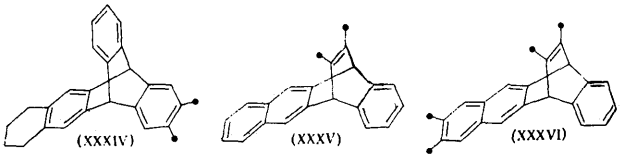


Dehydrobenzene adds to anthracene not only at the *meso*(9,10)-positions but also partly at the 1,4-positions, so that triptycene is accompanied by traces of 5,12-dihydro-5,12-ethenonaphthacene (XXXIII):[71]



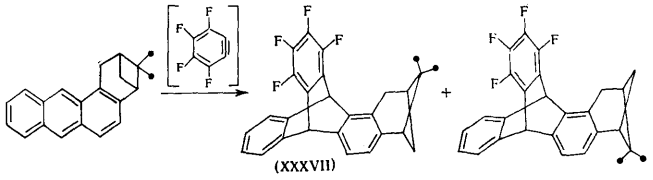
(XXXIII)

Substituted anthracenes react similarly, with the nature of the substituents and their positions in the anthracene molecule determining the proportions of isomeric adducts formed. Electron-accepting or sufficiently bulky substituents diminish appreciably the diene activity of the anthracene system towards dehydrobenzene and orient its addition predominantly to the unsubstituted rings[53,72]. Thus the presence of two *meso*-nitrile groups deactivates both the middle and the outer rings, so that isomeric adducts are obtained in equal quantities but with a very low total yield (4%).[71] The activity of 9,10-diphenylanthracene is only 20% of that of anthracene, while the ratio of products of addition at positions 9,10 and 1,4 falls to 8%.[53] Electron-donating substituents direct the addition of dehydrobenzene predominantly to the substituted ring, at the same time increasing the diene activity of the anthracene system[72]. Depending on the structure of the initial methylanthracenes the addition of dehydrobenzene takes place either solely at the 9,10-positions with formation of a triptycene compound (XXXIV from 1,2,3,4-tetrahydro-8,9-dimethylnaphthacene) or also at the 1,4-positions with the formation of substituted ethenonaphthacenes (XXXV and XXXVI from 2,3-di- and 2,3,6,7-tetra-methylanthracenes).



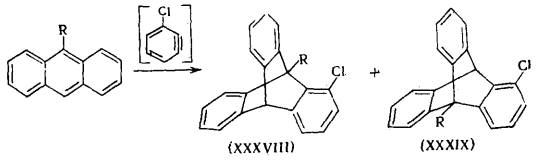
(XXXIV) (XXXV) (XXXVI)

Reaction between dehydrotetrafluorobenzene[74] and 1,2,3,4-tetrahydro-3,3-dimethyl-2,4-methanobenz[*a*]-anthracene yields a mixture of two isomeric compounds:



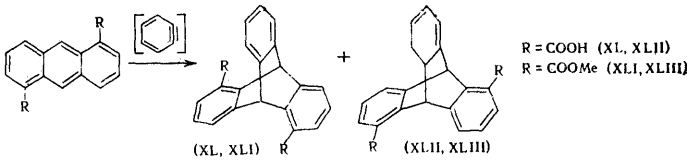
(XXXVII)

where the products (XXXVII) of addition on the sterically most hindered side of the initial anthracene molecule predominates[75]. Several substituted anthracenes form mixtures of *quasi-cis*- and *quasi-trans*-isomers (XXXVIII and XXXIX) by diene synthesis with substituted dehydrobenzenes:



(XXXVIII) (XXXIX)

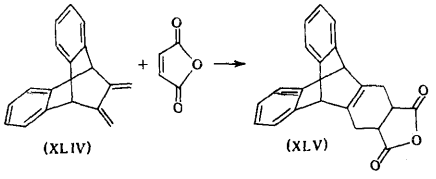
The reactions of 9-substituted anthracenes with 3-chloro-dehydrobenzene show that the ratio of the isomers formed depends mainly on the inductive effect of the substituent R, not on its size[76]. Anthracene derivatives substituted in the outer rings give with dehydrobenzene racemic mixtures of optical enantiomers. Thus stereoisomeric disubstituted triptycenes (XL–XLIII) have been obtained from 1,5-disubstituted anthracenes[77]:



(XL, XLI) (XLII, XLIII)

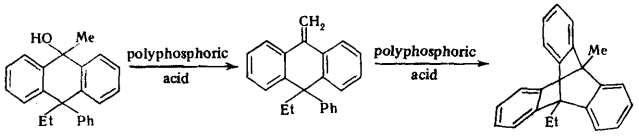
Other reactions of substituted dehydrobenzenes with substituted anthracenes have also been reported[78–80].

A specific method for building a partly hydrogenated triptycene system by diene synthesis is the action of maleic anhydride on the compound (XLIV), which gives 1,2,3,4-tetrahydrotriptycene-2,3-dicarboxylic anhydride (XLV):[81]



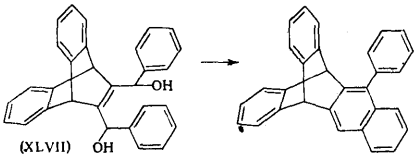
(XLIV) (XLV)

Cyclisation has been used to synthesise certain substituted triptycenes. For example, 9-ethyl-10-methyl-triptycene (XLVI) was obtained in theoretical yield by the action of polyphosphoric acid on 10-ethyl-9,10-dihydro-9-methyl-10-phenyl-9-anthrol:[82]



(XLVI)

1-Phenyl-2,3-benzotriptycene has been obtained by the cyclodehydration of (XLVII):[44]



(XLVII)

III. STRUCTURE AND PHYSICAL PROPERTIES OF TRIPTYCENE COMPOUNDS

Triptycene is a colourless substance, melting at 254.03°C when 99.999 mole % pure and readily soluble in the usual organic solvents[83]. It crystallises in the orthorhombic system with a unit cell belonging to the $P2_12_12_1$ space group and having the parameters 0.822, 2.064, and 0.816 nm, number of formula units $z = 4$, and volume 1.384 nm^3; the crystallographic density is 1.227 g cm^{-3}, and the symmetry of the molecule $\bar{6}m2$.[84,85]

Changes in the enthalpy of triptycene correspond to the integral of heat capacity with respect to temperature between 429° and 519°K, and the temperature dependence of heat obeys Debye's law. The large difference in heat

capacity between solid and liquid triptycene (11.48 cal deg^{-1} $mole^{-1}$) indicates strong bonding of the molecules in the crystal lattice; movement of the molecules is restricted at temperatures somewhat above the melting point. The heat capacity of triptycene is well approximated by that of a model in which three benzene rings are superposed on bicyclo[2,2,2]octane.[83]

The highly symmetrical structure of the triptycene molecule is confirmed by infrared, ultraviolet, and proton magnetic resonance spectroscopy. The infrared spectrum is characterised by absorption bands having wavenumbers (νmax, cm^{-1}) of 3040 (stretching vibrations of aromatic carbon–hydrogen bonds), 2960 (aliphatic carbon–hydrogen bonds of bridging methine groups), 1470 to 1450 (aromatic carbon–carbon bonds), and 755–740 (deformation vibrations of carbon–hydrogen bonds in *ortho*-disubstituted benzenes)[65,86,87]. The ultraviolet spectra of triptycene and its 9,10-substituted derivatives are characterised by bands having λmax (in nm) (and $\lg\epsilon$)—263 (3.25), 271 (3.56), and 278 (3.66)[87-92]—and can be interpreted[89] by the superposition of three benzene chromophores, which is supported by calculation of the intensities of the bands of longest wavelength for several chlorinated triptycenes[76] and benzo-derivatives[67]. The ultraviolet spectra reveal only an inductive effect of substituents in the bridges, since their conjugation with the aromatic rings is impossible[87].

The ^1H n.m.r. spectrum of triptycene contains a multiplet of aromatic protons (with its centre δ = 7.05 ppm) and a singlet of bridge protons (δ = 5.21 ppm).[93,94] The measured transition frequencies in the multiplet agree well with those calculated for the four-spin system AA'BB'.[93,95] A certain broadening of the AA' part of the spectrum is due to interaction between α-protons and bridge protons[95].

The ^1H n.m.r. spectra of triptycenes substituted in an aromatic ring differ markedly depending on the position of the substituent. Thus β-substituents have almost the same effect on the chemical shifts of the two bridge protons, since their signals appear in the spectrum as one singlet. Probably the only exception is provided by the nitro-group: the signal due to one bridge proton in 2-nitrotriptycene is displaced 3 Hz from that due to the other[96], and with 2,7-dinitrotriptycene the separation is 5 Hz.[97] The ^1H n.m.r. spectra of α-monosubstituted triptycenes always contain two singlets due to the bridge protons (because of the non-equivalence of the latter relative to the α-substituent)[44]. Analysis of the spectra has shown that the signal due to the bridge proton adjacent to the substituent is usually displaced down-field[44,62,76,96,98].

In the series—1-chloro-, 1,8-dichloro-, and 1,8,14-trichloro-triptycenes—the average increase in the difference between the chemical shifts of the signals due to the bridge protons is 0.43 ppm. This quantity is the sum of the contributions by magnetic anisotropy, the electrical field, and the van der Waals effect, among which the field effect makes the main contribution (0.29 ppm).[76] Triptycene derivatives are thus convenient compounds for the study of magnetic anisotropy[76].

In 1,4-diphenyltriptycene steric factors hinder a coplanar arrangement of the phenyl substituents, which is also apparent in their spectra[98].

The isomeric vinyltriptycenes have been the simplest convenient models for studying several structural features of differently substituted unsaturated triptycene derivatives. Thus the ^1H n.m.r. spectra indicate that the protons of a 2-vinyl group in triptycene are less shielded than are those of a vinyl group in position 1 and of course 9. The coplanarity of vinyl group and benzene ring in 1- and 2-vinyltriptycenes is confirmed by an analysis of spectroscopic results (ultraviolet and n.m.r.).[99]

The structure of triptycene has been reliably confirmed by X-ray diffraction[84,85,100-102]. The molecule possesses a threefold axis of symmetry and a plane of symmetry perpendicular to this axis. The aliphatic carbon–carbon bonds in the bicyclo[2,2,2]octane system and also the carbon–carbon bonds in the aromatic rings have the normal length, but the $C_{(4a)}-C_{(9a)}$ bond, which is common to the bicyclic system, is somewhat elongated. The presence of a strained bicyclic system is evident also in the variation in the bond angles. Thus the angles between the aliphatic carbon–carbon bonds are 105° (instead of 109°47′), and those between aliphatic and aromatic carbon–carbon bonds common to the bicyclic system are 113° (instead of the usual 120°). The distortion of the angles produces corresponding changes in hybridisation of the orbitals bonding atoms of the bicyclic system and the neighbouring atoms of the aromatic rings.

Certain distortions are observed in triptycene derivatives with substituents at positions 9 and 10. Thus internuclear distances are somewhat increased for atoms in the vicinity of the bridge substituents in 9-bromotriptycene[100] and 9-2′-chloroethyltriptycene[101]; the angles between the aliphatic carbon–carbon bonds in the former molecule are 107°. Rotation of the chloroethyl group in the latter molecule is retarded by the spatial proximity of α-hydrogen atoms of the aromatic rings, which in turn causes a general distortion of structure and non-equivalence of the aromatic rings[101]. Retarded rotation of a chloromethyl group attached to a bridging carbon atom is also definitely revealed in the ^1H n.m.r. spectra of 9-chloromethyl- and 9,10-bischloromethyl-triptycenes. The activation energy of rotation of such a chloromethyl group determined from the spectroscopic results (~16 kcal $mole^{-1}$) was about treble that for an ordinary σ-bond.[103]

The ^1H n.m.r. spectra of several other 9-substituted triptycenes have been studied[104]. The spectrum of the adduct of *p*-benzoquinone with 9,10-di-t-butylanthracene reveals the methyl protons as three separate singlets[105]. Stable rotational isomers may be formed in the presence of sufficiently bulky bridge substituents. Thus two conformers have been isolated and characterised in the reaction of dehydrobenzene with anthracene-9,10-bis-$\alpha\alpha$-dimethylacetonitrile; their equilibrium interconversion occurs at 200°C.[106]

Certain features of the chemical behaviour of 9-substituted triptycenes are due to the steric hindrance of substituents in this position. Examples are the stability of triptycen-9-yl iodoformate, the impossibility of obtaining ditriptycen-9-yl oxalate, the low reactivity of triptycen-9-ol towards alkali metals[107], and the difficulty of the formation of 9,9′-bitriptycenyl[15] (although ditriptycen-9-ylmercury has been obtained in good yield by the mercuration of triptycen-9-yl-lithium[108]). The low yield of α-nitrotriptycene obtained by the nitration of triptycene has been attributed[97] to steric hindrance of the α-positions in the aromatic rings. The difficulty of the solvolysis of compounds containing halogenomethyl bridge groups is also explained by peculiarities of the three-dimensional structure of the triptycene system[109,110].

The mass spectra of triptycene have been discussed in several papers[111-113], but the interpretation of the experimental results is ambiguous.

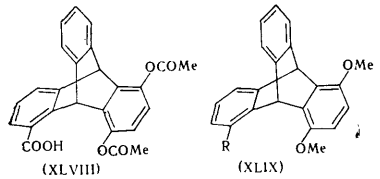
Studies have been made also of the electron spin resonance spectra of triptycene[12,114-121], its substituted derivatives[121-125], and semiquinones[126-130]. The absence

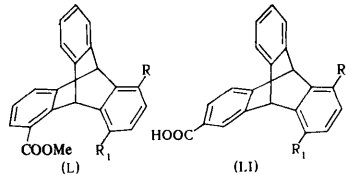
of fine structure from the e.s.r. spectrum in the last case indicates that the bridge carbon atoms completely interrupt conjugation of electrons between the benzene rings and the quinonoid portion of the molecule [129].

The hypothesis that transannular interactions may occur between the aromatic rings in the triptycene molecule, which appeared in several publications [88,95,98], was not subsequently confirmed [67,97,131].

Thus the factors responsible for the peculiarities of chemical behaviour are probably the strain in the bicyclic structural fragment and the three-dimensional structure of the triptycene system.

The molecule of a substituted triptycene having three non-equivalent rings is chiral, which leads to the appearance of optical isomers. Such a system is an ideal model for studying the effect of substituents on optical activity, since the rigid structure of the molecule excludes the possibility of interaction between its various parts, and conversions can be accomplished without racemisation or inversion of configuration [13].





Optical activity in the triptycene series was first shown for 5,8-diacetoxytriptycene-1-carboxylic acid (XLVIII), obtained by conversion of the isomeric compounds (XXII–XXV) and resolved into enantiomers [13]. A series of 5-substituted (+)-1,4-dimethoxytriptycenes (XLIX) were obtained [77,132–134] from (+)-(XLVIII), and from these the the absolute configuration 9*R*, 10*S* was established for (+)-5-*NN*-dimethylamino-1,4-dimethoxytriptycene hydrobromide [XLIX: R = $N(CH_3)_2$.HBr] by X-ray structural analysis by Bijvoet's method [102]. This configuration is possessed by other members of the (XLIX) series, as well as by 5,8-disubstituted methyl triptycene-1-carboxylates (L), [135] for which the optical rotatory dispersion was also studied [132]. The structure of the isomeric methyl 5-hydroxy-8-methoxy- and 8-hydroxy-5-methoxytriptycene-1-carboxylates was established from the measured dipole moments [136]; in the latter ester infrared spectroscopy reveals an intramolecular hydrogen bond between the spatially contiguous methoxycarbonyl and hydroxyl groups.

Other optically active triptycene derivatives have been obtained from enantiomeric 5- and 8-substituted triptycene-1-carboxylic acids [137]. The absolute configuration of the chiral centres (9*R*, 10*R*) has been determined by chemical correlation with (+)-(XLIX) in (+)-5-methoxytriptycene-1-carboxylic acid, and confirmed by comparison of the circular dichroic spectrum with that of (+)-methyl 5-acetoxy-8-methoxytriptycene-1-carboxylate (L). The absolute configuration of (−)-5-methoxytriptycene-1-carboxylic acid (9*S*, 10*S*) was established by X-ray structural analysis and chemical correlation; the configuration of (+)-5-chlorotriptycene-1-carboxylic acid was also determined. The chiral 5,8-disubstituted triptycene-2-carboxylic acids (LI) and esters have been studied; the absolute configuration (9*R*, 10*S*) has been determined by chemical correlation for the dextrorotatory enantiomers [138]. Chiral 1,5- and 1,8-disubstituted triptycenes have also been obtained. Chemical correlation has established the absolute configuration 9*R*, 10*R* for the dextrorotatory enantiomer of 8-methoxytriptycene-1-carboxylic acid, and the inverse configuration for the laevorotatory enantiomer [77,139].

Determination of the absolute configuration of 1,5-disubstituted triptycenes by means of circular dichroism gave results [140] directly opposite to those obtained earlier by X-ray and chemical methods. However, these conclusions [140] were revised a little later [141].

Polorgraphic characteristics of quinones of the triptycene series (in 0.1 *N* KNO_3 in dimethylformamide).

Quinone	First wave K'	First wave $-E'_{1/2}$, mV	Second wave K''	Second wave $-E''_{1/2}$, mV	$\overline{E}$, mV	E^0, mV	$\lg K_{sq}$
 (III)	1.55	644	1.34	1248	946	666	10.237
 (LII)	1.62	877	1.33	1473	1175	437	10.169
 (LIII)	1.53	944	1.28	1400	1172	440	7.728
 (LIV)	1.09	673	1.14	1280	977	635	10.305
 (LV)	1.11	806	0.92	1352	1079	533	9.254
 (LVI)	1.06	819	0.91	1350	1085	527	8.983
 (XXI)	1.57	665	1.56	1342	1004	608	11.592
 (LVII)	1.42	633	1.31	1260	947	667	10.644

A study has been made of the polarographic reduction of triptycenequinone (III) and benzotriptycenequinones (XXI and LII–LVII) containing different numbers of annelated benzene rings in the quinonoid and triptycene moieties [32,34,142–148]. Quinones are characterised by two one-electron polarographic waves on reduction in dimethylformamide. Reduction occurs reversibly, with

intermediate formation of the semiquinone to yield the dianion of the quinol (or the quinol itself at sufficient hydrogen-ion concentrations):

$$Q + e^- \overset{K_{sqn}}{\rightleftarrows} S; \quad S + e^- \rightleftarrows Q^{-2} .$$

The Table[148] illustrates the effect of annelation on the redox potentials of the quinones E°, the constants of the diffusion currents K, the half-wave potentials, and the effective formation constants of the semiquinone

$$K_{sqn} = \left[10^{\frac{0.5(E'_{1/2}-E''_{1/2})F}{RT}} - 3 \cdot 10^{-\frac{0.5(E'_{1/2}-E''_{1/2})F}{RT}} \right]^2,$$

where $E'_{1/2}$ and $E''_{1/2}$ are the first and second half-wave potentials. The constant of the diffusion current seemed to vary little for the triptycenequinones (III, LII, LIII) and also for the dibenzotriptycenequinones (LIV–LVI). The ratio of these constants K''/K' is about 0.85 for all quinones, indicating partial protonation of the semiquinone, which is further reduced at the same potential. On annelation in the quinonoid part of the molecule the negative potentials $E'_{1/2}$ and $E''_{1/2}$ increase in all these compounds, while Ksqn decreases and reduction is hindered only at the first stage. Annelation in the hydrocarbon part of the quinone molecules produces negative shifts in $E'_{1/2}$, $E''_{1/2}$, and $1/2(E'_{1/2} - E''_{1/2})$, accompanied by increase in Ksqn and in the hindrance to catalytic hydrogenation (cf. quinones III and LIV). With the quinones (LII) and (LV), as well as with (LIII) and (LVI), annelation displaces $E'_{1/2}$ and $E''_{1/2}$ to more positive potentials; the former pair of quinones show a decrease in Ksqn with increase in annelation, whereas the latter pair shown an increase. With the quinones (XXI) and (LVII) annelation makes the half-wave potentials more positive and diminishes both the constant of the diffusion current and Ksqn: i.e. in this case reduction occurs more easily as the structure becomes more complicated. Comparison of quinones (III) and (XXI), however, shows that reduction becomes more difficult with complication of the structure. This effect is almost completely absent with the quinones (III) and (LVII).

IV. REACTIVITY OF BRIDGE ATOMS

The early work on the chemistry of triptycene showed that the halogen at the bridgehead in 9-halogenated triptycenes is inert towards various nucleophilic reagents. Thus Bartlett and his coworkers were unable to make 9-bromotriptycene[88,149] or 9-iodotriptycene[15] react with sodium ethoxide, tin(II) chloride, sodium sulphide, or silver nitrite even under severe conditions. Nucleophilic substitution at a bridging carbon atom in the triptycene molecule is difficult for structural reasons. Reactions having an S_N1 mechanism are improbable, since intermediate formation of a carbonium cation would have required transition of the bridging carbon to an sp^2-hybridised state and a coplanar arrangement of the aliphatic carbon–carbon bonds§ in the already strained bicyclic fragment of triptycene; furthermore, such a carbonium ion could not have been stabilised by conjugation with the aromatic rings but, on the contrary, would have been destabilised by the negative inductive effect of the three *o*-phenylene substituents[88,152]. An unsuccessful attempt to generate a bridging carbonium ion from triptycen-9-yl iodoformate by the action of silver tetrafluoroborate has been reported[107]: only triptycen-9-yl fluoroformate was isolated from the reaction products.

Reactions occurring by an S_N2 mechanism are also impossible, since carbon atoms at a bridgehead are shielded from attack by nucleophilic reagents[88,152]. This confirmed the S_N2 rule, according to which substitution by an S_N2 mechanism always involves inversion of configuration[153].

As already remarked above[84–86], distortion of the tetrahedral angle at a bridging carbon atom in the triptycene molecule produces a change in hybridisation of the corresponding orbitals, and the carbon–carbon bonds acquire a greater p-character, while the bridge carbon–hydrogen bond is enriched with the s-component, approximating in character to bonds having sp^2-hybridisation of the carbon orbitals. This is accompanied by an increase in electronegativity of the bridging carbon atom, while the hydrogen atom becomes the positive pole of the dipole of the carbon–hydrogen bond, thereby becoming more acidic (in comparison with the methine hydrogen atoms in alkanes[86]). These structural peculiarities of triptycene find confirmation in its infrared spectrum[86,87]: the frequency of the absorption band due to the bridge carbon–hydrogen bond approaches that of a carbon–hydrogen bond in an alkene (3000 cm^{-1}). X-Ray examination shows that the bridge carbon atom has $sp^{2.26}$-hybridisation (the $J_{^{13}C-H}$ interaction constant gives $sp^{2.45}$-hybridisation). The smaller hybridisation calculated from crystallographic data was attributed[154] to curvature of the aliphatic carbon–carbon bonds in the triptycene molecule.

Nevertheless, halogenated triptycenes react with organometallic compounds under conditions under which nucleophilic attack at a bridging carbon atom is impossible. For example, 9-bromotriptycene reacts with n-butyllithium to give triptycen-9-yl-lithium[4,108,155]; 9-bromo- and 9,10-dibromo-2,3-benzotriptycenes react similarly[41]. The transition state leading to triptycen-9-yl-lithium may be four-membered with little carbanion character, and the lithium compound itself largely covalent[152]. Triptycen-9-yl-lithium undergoes substitution with intermediate formation of a carbanion bridge, and reacts in the usual way with carbon dioxide, benzophenone, triphenylboron, benzenediazonium tetrafluoroborate, mercury(II) chloride, and selenium chloride; it can be hydrolysed to triptycene[108].

Formation of a tetrahedral carbanion bridge, in contrast to a carbonium ion bridge, does not obstruct the structural peculiarities of the triptycene molecule. The straining of the bond angles at the carbon bridge should destabilise the carbanion, but this effect may be balanced by increase in the electronegativity of the bridging carbon atom. The stability of the carbanions would also be increased by the $-I$ effect of the three *o*-phenylene groups (although stabilisation by conjugation is excluded).

The comparatively ready formation of a bridging carbanion in triptycene is confirmed by a study of the kinetic acidity of the attached hydrogen atom[154,156]. Triptycene is similar to aromatic hydrocarbons in its ability to split off a bridge proton: the acidity of the hydrogen atom is closely similar to that of an *o*-hydrogen in toluene, and

§ The adamantyl cation with a tertiary carbonium atom at the bridgehead, for which a planar configuration is also impossible because of the three-dimensional structure, nevertheless is formed and exists in SbF_5-SO_2 solution[150]. In this case stabilisation is attributed to polarisation of the electrons of the carbon–hydrogen bonds of the tertiary carbon atoms (at positions 3, 5, and 7), which are attracted to the cationoid centre inside the adamantane skeleton[151].

far higher than in cyclohexane. According to Streitwieser and Ziegler [154] the enhanced acidity of the bridge hydrogen in triptycene is two-thirds due to the $-I$ effect of the three *o*-phenylene groups and only one-third due to strengthening of the *s*-character of the bridge carbon–hydrogen bond. This conclusion is consistent with the kinetic acidities of the bridge hydrogen atoms in triptycene and in 2,3-benzotriptycene [157]. Furthermore, the acidity of the 9-hydrogen atom in 2-methyltriptycene, in which the bicyclic part of the molecule has remained unchanged, is one-half, and that of the 10-hydrogen one-third, of the acidity of the hydrogen atoms in triptycene [154].

9-Bromotriptycene reacts with magnesium in ether [88] or oxolan [158], but the triptycen-9-ylmagnesium bromide formed, which can be hydrolysed to triptycene, cannot be carbonylated [88]. 9-Bromotriptycene is unaffected by sodium in boiling toluene, but reacts with the metal when heated in mineral oil to 140°C (even in an atmosphere of carbon dioxide), being converted almost quantitatively into triptycene [88]. This reaction probably involves intermediate formation of the triptycen-9-yl radical.

Barlett et al. showed [15] that the thermal decomposition of triptycen-9-ylcarbonyl peroxide was about two-thirds due to homolytic rupture of the oxygen–oxygen bond. Free-radical breakdown was accompanied by inversion of the carboxyl, yielding on subsequent hydrolysis triptycen-9-ol and triptycene-9-carboxylic acid:

$$\mathrm{Tr{-}COO{-}OOC{-}Tr \rightarrow 2\,Tr{-}COO\cdot;\ Tr{-}COO\cdot \rightarrow Tr\cdot + CO_2;}$$

$$\mathrm{2\,Tr\cdot \rightarrow Tr{-}Tr;\ Tr\cdot + C_6H_6 \rightarrow TrH + Ph\cdot;\ 2\,Ph\cdot \rightarrow Ph{-}Ph;}$$

$$\mathrm{Tr{-}CO{-}O{-}O{-}CO{-}Tr \rightarrow Tr{-}CO{-}O{-}CO{-}O{-}Tr \rightarrow TrOH + TrCOOH + CO_2.}$$

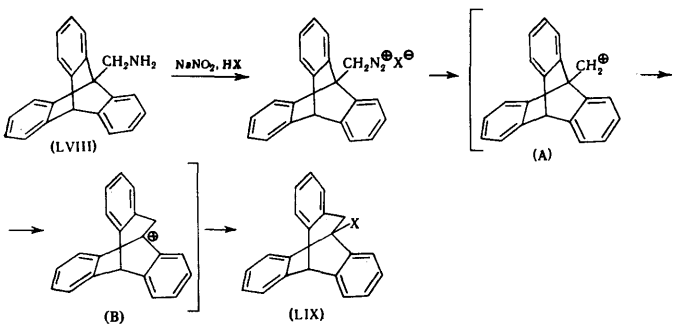
The free radical formed by decomposition of the peroxide possessed great affinity for hydrogen and iodine. The formation of triptycene in the reactions of triptycen-9-yllithium with halides of transition metals (silver, copper, cobalt, nickel) and of 9-bromotriptycene with metallic silver probably involves the triptycen-9-yl radical as an intermediate stage [108]. A small yield of a substance of high melting point, regarded as 9,9′-bitriptycenyl in view of its infrared spectrum, was isolated on decomposition of the peroxide. (9,9′-Bitriptycenyl obtained by addition of dehydrobenzene to 9,9′-bianthryl melted at 577°C and had a similar infrared spectrum [159].) In other reactions in which the radical occurred as an intermediate stage formation of a dimer was not observed (e.g. in the decomposition of ditriptycen-9-ylmercury of ditriptycen-9-yl diselenide in the presence of metallic silver or copper) [108].

Thermal decomposition of t-butyl triptycene-9-peroxycarboxylate gave triptycene in the high yield of 92%, attributable to the fact that the t-butyl groups in the original ester and in the decomposition products of the t-butoxyl radical are active donors of hydrogen. Decomposition of the same ester in chlorobenzene gave an 80% yield of triptycene (with traces of triptycene-9-carboxylic acid) [160].

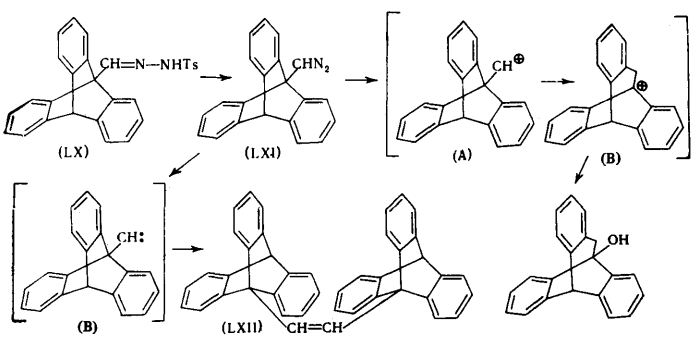
Decomposition of triptycen-9-al in the presence of t-butyl peroxide in carbon tetrachloride led to the isolation, after treatment with methanol, of 9-chlorotriptycene and methyl triptycene-9-carboxylate [160]. The results established that detachment of a chlorine atom from the solvent greatly predominated over decarbonylation. The thermal decomposition of triptycen-9-yl iodoformate to give 9-iodotriptycene (in 52% yield) is a peculiar substitution of the bridge oxygen function by homolysis of the carbon–oxygen bond [107]. 9-Iodotriptycene has been obtained also by irradiation of triptycene-9-carboxylic acid in the presence of iodine and lead tetra-acetate [155].

The ability of the bridge positions in triptycene to undergo radical substitution is thus a well established fact. The radical formed obviously has a tetrahedral configuration and is not stabilised by conjugation with the aromatic rings. Triptycen-9-yl is closely similar to the 1-norbornyl radical in stability [160], which supports Bartlett's suggested analogy [15] in the properties of the bicyclo[2,2,1]-heptane and triptycene bicyclic systems, which exhibit closely similar angular strains. It is also obvious that destabilisation of the triptycenyl radical due to the negative inductive effect of the three aromatic rings is slight [150].

The enhanced acidity of hydrogen atoms and the reactivity of halogen atoms at a bridgehead in the triptycene molecule make the bridging carbon atoms like aromatic carbon atoms. Among other reactions of 9-substituted triptycenes several transformations have been reported of the 9-nitro, [161] 9-nitroso, [161,162] and 9-bromo [163–165] derivatives, as well as reactions of 9-aminotriptycene-1,4-quinone [166], triptycene-9-carboxylic acid [167], and triptycen-9-ylmethylamine [168]. Diazotisation of this amine (LVIII) yields derivatives of a homologue of triptycene—homotriptycene (tribenzobicyclo[3,2,2]nonatriene (LIX)—formed by a Dem'yanov rearrangement involving expansion of the ring [168]:



Studies have been made [169] of the reactions of 9-diazomethyltriptycene (LXI), obtained by treating triptycen-9-al toluene-*p*-sulphonylhydrazone (LX) with sodium methoxide in pyridine. Decomposition of the hydrazone (LX) at 80° to 90°C involved intermediate formation of the carbonium ions (A) and (B) together with the carbene (C); decomposition of the dry sodium derivative of the hydrazone in a vacuum at 170–200°C involved preferential formation of the carbene (C), which was converted into a high yield of the hydrocarbon (LXII):



Unsuccessful attempts have been made to prepare a bridge iodonium salt of triptycene [155] and also to solvolyse a chloromethyl group located at a bridgehead in triptycene [109]. The bromine atom in 9-bromomethyltriptycene is also unreactive [110].

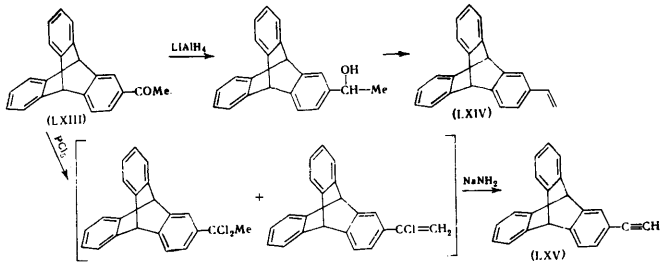
Functional substituents distant two or more methylene units from the bridging carbon atoms develop their normal reactivity [61].

Results obtained for the dissociation constants of several 10-substituted triptycene-9-carboxylic acids and for their esterification with diazodiphenylmethane were analysed by means of the linear free-energy equation. As was to be expected, the acidity and the rate of esterification of these acids are determined mainly by the inductive effect of the substituent [170].

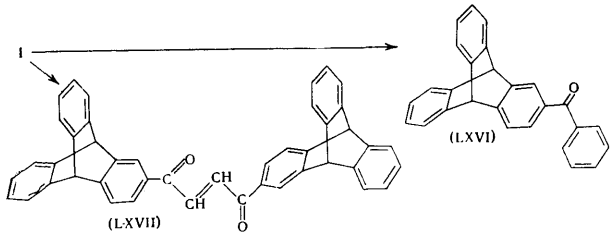
9-Vinyltriptycene [99,171] and 9-ethynyltriptycene [172] have been prepared, and their properties studied. Many 9- and 9,10-substituted triptycenes have been obtained with the aim of studying their physiological activity [61,173,174]. Certain amines of this series possess anti-inflammatory activity [61]; triptycene itself binds nucleosides weakly [175]. Several 9,10-disubstituted triptycenes have been subjected to polycondensation; the resulting polyesters were thermostable, in several cases also plastic, and could be processed into films and fibres [42,43,60]. A film based on a polyamide containing triptycene fragments enables hydrogen and helium to be separated from methane [176].

V. REACTIVITY OF AROMATIC RINGS

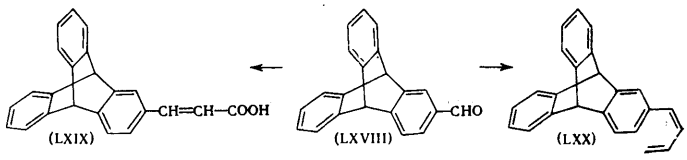
Electrophilic substitution usually occurs preferentially at the β-position in the aromatic rings of triptycene. Thus treatment of triptycene with acetyl chloride in the presence of aluminium chloride (at $-20°C$) gives a high yield of 2-acetyltriptycene (LXIII). [96] This compound has been used as a readily accessible starting material for the preparation of unsaturated hydrocarbons of the triptycene series—the 2-vinyl (LXIV) [99] and 2-ethynyl (LXV) [177] derivatives:



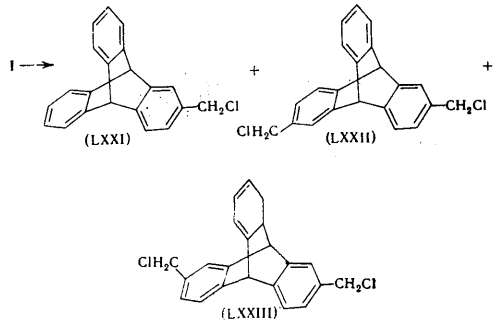
Triptycene is acylated by benzoyl and fumaroyl chlorides also exclusively at position 2 to form the corresponding ketones (LXVI and LXVII): [178]



The direct formylation of triptycene with excess of dichloromethyl methyl ether in the presence of aluminium chloride (at $-20°C$) gives a 51% yield of triptycen-2-al (LXVIII). [179] This aldehyde had previously been obtained from 2-acetyltriptycene (LXIII) in several stages [180]. Triptycen-2-al (LXVIII) has been used for the preparation of 2-butadienyltriptycene (LXX) [179] and β-triptycen-2-ylacrylic acid (LXIX): [180]



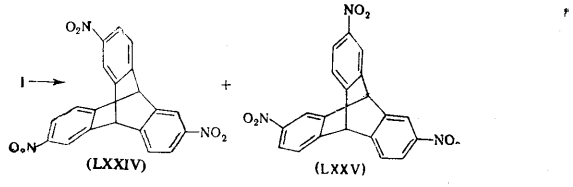
Triptycene undergoes chloromethylation under comparatively severe conditions with the formation of three products—the 2-chloromethyl (LXXI, 15%), 2,6-bis-chloromethyl (LXXII, 52%), and 2,7-bischloromethyl (LXXIII, 16%) [181] derivatives:



Treatment of triptycene with concentrated nitric acid in acetic anhydride led to isolation of the 2-nitro (44%), 2,6- and 2,7-dinitro, and traces of the 1-nitro (2.3%, identified from the ^{1}H n.m.r. spectrum) compounds [97].

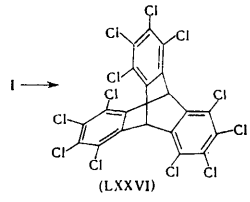
The formation of isomeric dinitro- and bischloromethyl-triptycenes and the presence of unchanged triptycene in the reaction mixture indicate that a substituent in one aromatic ring has little effect on the reactivity of unsubstituted rings towards sufficiently active electrophilic reagents.

A mixture of isomeric 2,6,12- and 2,7,13-trinitrotriptycenes (LXXIV and LXXV) containing no α-substituted isomers is formed when triptycene is treated with fuming nitric acid [182]:



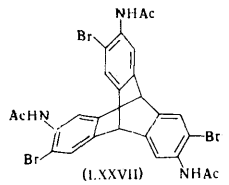
Preparation of a hexanitrotriptycene of undetermined structure has been reported in the patent literature [183].

The action of a combined chlorinating agent (sulphuryl chloride in the presence of sulphur monochloride and aluminium chloride) gave dodecachlorotriptycene (LXXXVI) in high yield [184]:

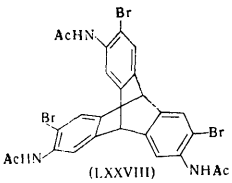


Among other compounds of the series 9,10-dimethyltriptycene has been most thoroughly studied in relation to

electrophilic substitution[185]; β-monosubstituted derivatives are obtained on bromination, acylation, and nitration[186]. Monosubstituted derivatives of undetermined structure were obtained by the nitration and acylation of 1,2-benzotriptycene, but this hydrocarbon could not be brominated[28]. The chloromethylation of 2-chloromethyltriptycene (**LXXI**) gives the 2,6-bischloromethyl derivative (**LXXII**) in theoretical yield[181]. The bromination of isomeric triacetamidotriptycenes (obtained by reducing a mixture of trinitrotriptycenes in acetic acid) gives a mixture of isomeric triacetamidotribromotriptycenes

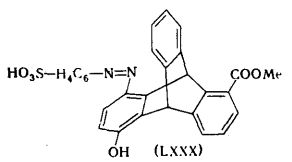


(LXXVII)

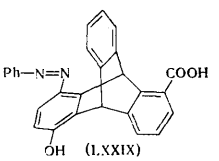


(LXXVIII)

in high yield[182]. The reaction of 5-hydroxytriptycene-1-carboxylic acid with benzenediazonium chloride and that of its methyl ester with diazotised sulphanilic acid yield the corresponding azo-compounds (**LXXIX** and **LXXX**).[137]



(LXXX)



(LXXIX)

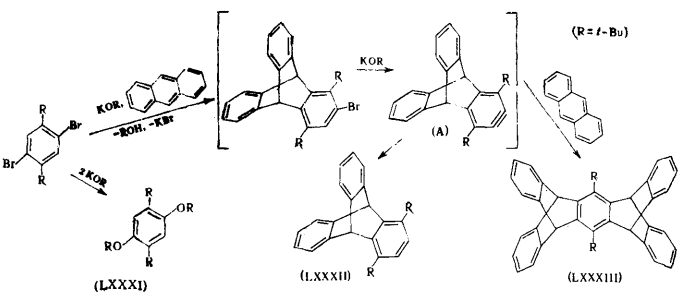
The reactivity of α- and β-positions in the aromatic rings of the triptycene molecule towards electrophilic and nucleophilic reagents has been studied quantitatively by deuterium exchange in the presence of trifluoroacetic acid[187,188] and caesium cyclohexylamide[188] respectively. In the former case exchange of a hydrogen atom was more rapid in the β- than in the α-position by factors of 7–8; but isotopic exchange in the presence of the amide was more rapid in the α- than in the β-position by factors of 7.3–7.5. Under conditions of electrophilic isotope exchange a hydrogen atom in either position was less mobile than in *o*-xylene or 9,10-dihydroanthracene[187]; but under conditions of nucleophilic isotope exchange it was more mobile than in benzene[154].

Differences in reactivity between α- and β-positions in the aromatic rings of the triptycene molecule are attributed to strain in the bicyclo[2,2,2]octane system[188], which distorts the angles between aromatic and aliphatic carbon–carbon bonds[84,85]. This results in changes in the hybridisation of the orbitals and the lengths of the carbon–carbon bonds in the aromatic ring. The bond common to the bicyclic system and the aromatic ring acquires an enhanced *p*-character like an aliphatic carbon–carbon bond, and the remaining orbitals of the bounding carbon atoms acquires a greater *s*-character, while becoming more electronegative. Therefore the α-carbon atom attached by the electronegative orbital is less reactive towards electrophilic substitution than is the β-carbon atom (which remains unaffected by the strained ring); as a consequence the α-hydrogen atom develops enhanced acidity.

An attempt was made to explain the preferential β-substitution on electrophilic attack also by the Mills–Nixon effect[189]—by the fixation of multiple bonds at the 1–9a, 2–3, and 4–4a positions in the aromatic rings of triptycene because of the strain in the bicyclic system—indirect support for which was obtained by comparing the oxidation potential of triptycenequinone with those of other *p*-quinones[38]. Dynamic factors may also determine the final results of electrophilic substitution and the differently strained σ-complexes formed on α- and β-substitution[190].

Nucleophilic substitution in an activated aromatic ring in triptycene has been accomplished with 2,3-dichlorotriptycene-1,4-quinone, which is analogous to 2,3-dichloro-1,4-naphthaquinone in chemical behaviour. This triptycene derivative reacted with amines to form quinonoid compounds, but the latter did not dye cellulose acetate fibre, probably owing to non-coplanarity of the structure[191,192].

Nucleophilic substitution in an unactivated aromatic ring of triptycene involves intermediate formation of 1,2-dehydrotriptycene, indicated by the reactions of 2-bromotriptycene with potassamide and lithium piperidide, as well as that of 1-chlorotriptycene with the latter, which yield mixtures (~1 : 3) of 1- and 2-substituted triptycenes. Phenyl-lithium reacts similarly with 2-fluoro- and 2-chloro-triptycenes, but with 2-bromotriptycene under these conditions the bromine atom is exchanged for lithium[193]¶. The intermediate formation of 1,2-dehydrotriptycene appears at first glance to be inconsistent with the distribution of bond lengths in the aromatic ring[84,85], since it should have been more strained than 2,3-dehydrotriptycene. For this reason, however, 1,2-dehydrotriptycene is obviously the more reactive, which probably explains the composition of the reaction products[193]. Formation of an sp-hybridised $C_{(2)}-C_{(3)}$ bond in triptycene compounds (2,3-dehydrotriptycene, A) has been postulated[47] only for the action of potassium t-butoxide on 1,4-dibromo-2,5-di-t-butylbenzene in the presence of anthracene, when 1,4-di-t-butoxy-2,5-di-t-butylbenzene in the presence of anthracene, when 1,4-di-t-butoxy-2,5-di-t-butylbenzene (**LXXXI**), 1,4-di-t-butyltriptycene (**LXXXII**), and the adduct (**LXXXIII**) were isolated, which suggested the reaction scheme.



Homolytic substitution in an aromatic ring of triptycene has not been studied. A substance containing a little chlorine and of undetermined structure was isolated from the products of the radical chlorination of triptycene[1].

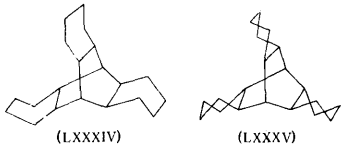
Triptycene derivatives containing functional substituents in the aromatic rings exhibit no significant difference in properties from other aromatic compounds[1,96,99,133,135,137,139,178–182,193–195]. Thus 2-chloromethyltriptycene (**LXXI**) is comparable in reactivity with benzyl chloride: it undergoes nucleophilic substitution (solvolysis, cyanolysis) and reduction and also forms an organomagnesium compound, under the same conditions as benzyl chloride.

¶ Triptycen-2-yl-lithium was formed also by the reaction of 2-bromotriptycene with n-butyl-lithium[96]. Triptycene was obtained on hydrolysis of this compound[193], but treatment with acetonitrile gave 2-acetyltriptycene[96].

The hydrolysis rate constant of 2-chloromethyltriptycene (LXXI) (in 40% aqueous acetone) exceeds that of benzyl chloride by a factor of 2.73, which indicates that the dihydroanthrylene fragment of triptycene exerts a positive inductive effect [109].

More severe conditions are required for the nucleophilic substitution of 1-chloromethyltriptycene. Its hydrolysis rate constant is smaller than that of 2-chloromethyltriptycene by a factor of 5.8. [194] Isomeric α- and β-carboxylic acids differ in acidity: triptycene-1-carboxylic acid is stronger than the 2-isomer, which is weaker than benzoic acid (as established by potentiometric titration in non-aqueous solvents—acetonitrile and dimethylformamide) [196]. This is also consistent with the general rule that substituents in α- and β-positions in the aromatic rings of triptycene differ in behaviour and with the change in hybridisation of the orbitals of the corresponding carbon atoms.

Triptycene is hydrogenated over palladium or ruthenium on carbon (under 30–100 atm at 100–200°C), either partly or completely depending on the conditions [197]. Exhaustive hydrogenation gives iso-*cis*-perhydrotriptycene (LXXXIV) rapidly and iso-*trans*-perhydrotriptycene (LXXXV) far more slowly (in 60% yield after 1 month).



(LXXXIV) (LXXXV)

In triptycenequinol (IV) either the substituted or an unsubstituted ring is reduced depending on the conditions [1]. Variously annelated quinones of the triptycene series undergo very rapid catalytic hydrogenation by an electronic mechanism [198–205]. Steric factors have a slight effect on the rate of hydrogenation. The rate usually increases with the degree of annelation of the quinones. Comparison of results for the catalytic hydrogenation of quinones over nickel and palladium on carbon with those for polarographic reduction (see Table in Section III) revealed the linear relation $\lg k_1 - \lg k_2 = \chi(E_1^\circ - E_2^\circ)$, where k_1 and k_2 are the hydrogenation rate constants for two members of the series, E_1° and E_2° are their standard potentials, and it was found that $\chi = 1.7\ V^{-1}$. The rate of catalytic hydrogenation should thus increase as the standard potential of the quinone falls (as a result of the diminished stability of the intermediate semiquinone). On hydrogenation over nickel, furthermore, the first-order rate constant increases with the activation energy owing to an increase in the entropy factor.

The hydrogenation of adducts of anthracene and pentacene with *p*-benzoquinone was investigated on the basis of the multiplet theory of catalysis [206–214]. Since successive complication of the structure of the non-reacting part of the molecule (II, XXVI, XXVII) has no significant effect on the rate or the extent of the process, it was deduced that the catalyst (nickel) surface contained projecting active centres, on which the indicial group of the reactant molecule was superposed (hydrogenation of the $C_{(2)}-C_{(3)}$ bond). The results enabled a model of the active complex to be constructed and permitted determination of the number of active centres (1.20^{20} [sic] g^{-1} Ni) and their optimum dimensions (height not exceeding 3.9 Å).

Hydroaromatic compounds of the triptycene series are dehydrogenated by sulphur or palladium on carbon with the formation of substituted triptycenes [18,19,28,215].

A high-melting complex of triptycene with tricarbonylchromium was obtained and found to be soluble in organic solvents and to decompose on fusion, sublimation, or illumination. Its proton magnetic resonance spectrum indicated that the chromium atom was coordinated with one of the aromatic rings [216].

Several substituted triptycenes readily form clathrates [30,34,35,38,98,139]. For example, 1,4-diphenyltriptycene gives with carbon tetrachloride and cyclohexane stable clathrates containing one solvent molecule per two hydrocarbon molecules [98].

It has been reported that quinols of the triptycene series can be used as photographic developers [217,218] and stabilisers for synthetic elastomers [219,220]. The reactivity of 2-vinyltriptycene (LXIV) is close to that of styrene under conditions of radical homo- and co-polymerisation, whereas 9-vinyltriptycene, in which the vinyl group is sterically hindered and is not conjugated with the ring system, is inert under these conditions and does not polymerise. Polymerisation of 2-vinyltriptycene (LXIV) occurs at the vinyl bond to give a linear polymer containing the triptycene fragment in the side-chain, which is less thermostable than polymers containing a triptycene residue in the main chain [220].

VI. REACTIONS INVOLVING OPENING OF THE BRIDGE SYSTEM

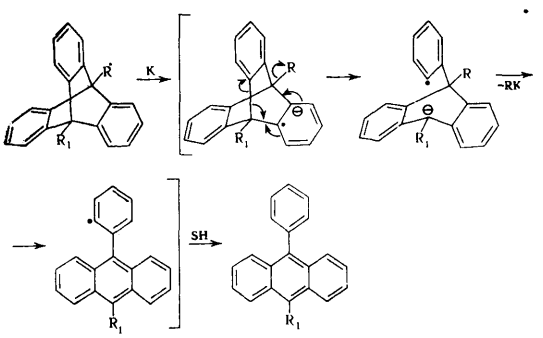
Triptycene is comparatively readily oxidised by strong oxidants such as chromium trioxide or potassium permanganate in acetic acid with the formation of anthraquinone, which resists further oxidation under these conditions [1]. Formally oxidation involves cleavage of the bicyclic system, but initial attack by the oxidant on one of the aromatic rings is not excluded. Intermediate oxidation products could not be isolated (probably because of their enhanced activity under the reaction conditions).

Triptycenequinone (III) is also oxidised to anthraquinone [14]. The latter compound and 1,4-diphenylanthraquinone (2 : 1) have been isolated from the oxidation of 1,4-diphenyltriptycene, the ratio of the products being obviously determined not only by statistical factors (otherwise the inverse ratio would have been obtained) [98]. The oxidation of 1,2-benzotriptycene [28] and 9,10-dibromo-2,3-benzotriptycene [41] also yielded anthraquinone, and no other reaction products could be identified. Thus derivatives of anthraquinone are the most usual oxidation products of compounds of the triptycene series. Nevertheless, the oxidation of substituted triptycenequinones with ammonium persulphate leads to cleavage of the quinonoid ring with the formation of substituted 9,10-dihydro-9,10-ethenoanthracenes [134].

Under milder conditions functional groups can be oxidised while the triptycene structure is preserved. Thus triptycenequinol (IV) can be oxidised to triptycenequinone (III), [1] 9,10-bishydroxymethyltriptycene to triptycene-9,10-dicarboxylic acid [60], 2-acetyltriptycene (LXIII) to triptycene-2-carboxylic acid [178], and triptycen-2-ylmethanol to triptycen-2-al (LXVIII). [180] Triptycene compounds with substituents containing multiple bonds can be ozonised without affecting the triptycene structure [178,222].

The bridging system of triptycene is opened up by reduction under severe conditions. Thus triptycene-1,4-quinol (IV) and triptycenequinone (III) give 9,10-dihydroanthracene when distilled with zinc dust [14]; 1,2-benzotriptycene breaks down into naphthalene and 9,10-dihydroanthracene [28].

Triptycene hydrocarbons undergo an interesting cleavage reaction under the influence of potassium in oxolan [223] or a potassium–sodium alloy in ether [224]. The electron spin resonance spectra of the reaction products indicate intermediate formation of a radical-anion of anthracene. Study of the effect of a substituent group on the stability of the intermediate radical-anion suggested the reaction mechanism. [223]



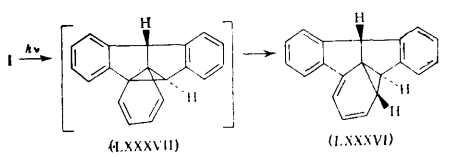
The detachment of 9,10-substituents accelerates in the sequence

$$CH_3 > C_6H_5 < H, C_6H_5CH_2$$

which confirms that one of the substituents leaves as an anion. Metallic sodium has a slight effect on the cleavage of 9-phenyltriptycene, and does not interact at all with other hydrocarbons of the series [223].

The previously mentioned diazotisation of triptycen-9-ylmethylamine (LVIII) [168] and decomposition of 9-diazomethyltriptycene (LXI) [169] also involve cleavage of the bicyclic system.

The product of the photochemical isomerisation of triptycene, in contrast to the related barrelene and benzobarrelene (which are converted into a mixture of semibullvalenes and cyclo-octatetraenes) [225], is the hydrocarbon (LXXXVI), which has been regarded [226] as formed by the sigmatropic rearrangement of the intermediate semibullvalene (LXXXVII):



(LXXXVII) (LXXXVI)

---o0o---

Papers have appeared recently on the chemistry of triptycene. Thus it has been synthesised from dehydrobenzene generated from 1,1-dimethyl-3-phenyltriazen in the presence of sodium trichloroacetate and trichloroacetic acid [227], and the preparation of deuterotriptycene has been reported [228]. The enthalpy of formation and the energy of strain of triptycene have been determined [229]. The high-resolution ^1H n.m.r. spectrum of triptycen-2-amine exhibits signals due to non-equivalent bridge protons [230]. The electron spin resonance and optical spectra of the radical-ions of certain derivatives have been studied [231]. Hindered rotation of the methyl group has been detected in tetra- and octa-chloro-9-methyltriptycenes [232,233]. The optical activity of 5-substituted 1,4-dimethoxytriptycenes has been investigated [234]. 9-Butadienyltriptycene has been prepared [235], and several reactions of 9-bromo- and 9,10-dibromo-triptycenes have been accomplished [236]. β-Substituted mono-, di-, and tri-nitrotriptycenes are formed by the action of acetyl nitrate [237], and the bromination of triptycen-2-amine gives 3-bromotriptycen-2-amine [238].

Tetrahydrodi-*o*-benzopentacene has been obtained by the reaction of 2-bromo-3-fluorotriptycene with magnesium in the presence of anthracene in oxolan, which indicates the intermediate formation of 2,3-dehydrotriptycene [238]. The photoisomerisation of triptycene in methanol involves an intermediate carbene stage [239]. Other publications have also appeared [240–247].

Advances in and Problems of Solid-phase Peptide Synthesis

G.P.Mishin, G.A.Korshunova, and Yu.P.Shvachkin

The present state of the solid-phase method of peptide synthesis is considered, its advantages and disadvantages are analysed, and the trends in and prospects of its further development are described. Attention has been concentrated on problems of improving polymeric carriers, of obtaining aminoacyl polymers, and also the problem of the formation of erroneous sequences in solid-phase peptide synthesis.
The bibliography includes 376 references.

I. INTRODUCTION

In 1973 ten years elapsed since the publication of Merrifield's report [1] of the synthesis of peptides on an insoluble polymeric carrier. The method proposed, called the solid-phase method, has been widely used in the synthesis not only of peptides but also of a number of compounds of other classes. About 500 papers have already been published on the solid-phase synthesis of peptides, among them several reviews, the most complete of which are those of Merrifield [2] and Losse and Neubert [3] as well as the monograph of Stewart and Young [4], which has been translated into Russian.

The above reviews [2-4] cover the literature until the beginning of 1969, representing a survey of approximately 150 experimental papers. It is useful to review the literature from 1969 to the beginning of 1972. The available reviews of Marglin and Merrifield [5], Geiger [6], Wünsch [7], Waki and Izumiya [8], Kishida and Sakakibara [9,10], and Losse [11] deal only with separate aspects of solid-phase peptide synthesis. There is only one review in Russian, that of Vesa, which was published in 1968. Later investigations are described in the monograph of Stewart and Young [4] and the reviews of Merrifield [2] and Losse and Neubert [3]. We regard the present publication as a continuation of these reviews.

Abbreviations Adopted

The abbreviations used for the names of aminoacids are those recommended by the IUPAC–IUP Commission on Nomenclature [Biochemistry, 5, 2485 (1966)].

AOC	= t-amyloxycarbonyl †;
BOC	= t-butyloxycarbonyl;
BMV	= *N*-(2-benzoyl-1-methylvinyl);
DVB	= *p*-divinylbenzene;
BPOC	= 2-(*p*-biphenylyl)isopropyloxycarbonyl;
DMSO	= dimethyl sulphoxide;
DME	= dimethylformamide;
DNP	= 2,4-dinitrophenyl;
DCHA	= dicyclohexylamine (or dicyclohexylammonium);
DCC	= *NN'*-dicyclohexylcarbodi-imide;
Z	= benzyloxycarbonyl;
CDI	= *NN'*-carbonyldi-imidazole;
MBZH	= di-(4-methoxyphenyl)methoxy-(4,4'-dimethoxybenzhydryl);
MZ	= *p*-methoxybenzyloxycarbonyl;
NPS	= *o*-nitrophenylsulphenyl;
THF	= tetrahydrofuran;
TFA	= trifluoroacetyl;
FOC	= furfuryloxycarbonyl;
Pht	= phthalyl;
P	= polymeric carrier.

†POC = cyclopentyloxycarbonyl is quoted in the IUPAC–IUB Report (Ed. of Translation).

II. POLYMERIC CARRIER

The polymeric carrier is the main component in solid-phase peptide synthesis. Clearly the selection of the carrier is extremely important for the success of the process.

The copolymer of styrene and 1–2% DVB proposed by Merrifield[1] is completely insoluble in the usual solvents but swells satisfactorily in methylene chloride, DMF, dioxan, and chloroform. This is extremely important, since it makes it possible to employ virtually the entire bulk of the polymeric bead for the reactions[13].

The above carrier[1,14] is still most frequently used. The same may be said of the "anchor" group with the aid of which the first aminoacid is added to the polymeric carrier: as can be seen from the data quoted in Table 1, the chloromethyl group clearly predominates.

Although in the vast majority of studies[15–227] the authors used the chloromethylated copolymer of styrene and 1–2% DVB, a considerable proportion of studies on solid-phase peptide synthesis in fact dealt with the modification of the "anchor" group. This is due to a number of difficulties involved in the preparation of the aminoacyl polymer by Merrifield's method (see the next section of the present review).

[a] Copolymer of styrene and 5% DVB.
[b] "Popcorn" type of copolymer of styrene and 0.5 DVB.

Attempts have been made to employ bromomethylated and iodomethylated styrene–DVB copolymers. However, such carriers can be prepared only in two stages‡. Thus Tilak[228] initially condensed the chloromethylated polymer with a carboxylic acid and then decomposed the resulting ester linkages with a solution of hydrogen bromide or iodide in acetic acid. The comparatively rare employment of such carriers, particularly of the iodomethylated polymer[143,229–233], is probably in fact due to the difficulties in their preparation. Therefore the method of the intermediate formation of iodomethylpolystyrenes by the reaction of chloromethylated derivatives of *N*-protected aminoacids in the presence of sodium iodide as the catalyst[234] is extremely attractive. Subsequently this method was successfully applied in a number of other laboratories[229,235–238].

Weygand[239] and, independently, Mizoguchi[240,241] suggested that a halogenoacetyl polymer be used. It improves the conditions governing the addition of the first aminoacid to the polymeric carrier but precludes the employment of acid reagents for the separation of the peptide from the carrier. The alkaline reagents used for this purpose[239–243] increase the risk of racemisation of the peptide. For this reason, halogenoacetyl polymers are usually employed to synthesise amides, hydrazides, and esters of protected peptides[240,241,244,245]. The same may be said also of the α-bromopropionyl polymer proposed by Mizoguchi and coworkers[240,241].

The polymeric carriers examined suffer from the same disadvantages as the chloromethylated Merrifield copolymer nitrated in the aromatic rings[1]. The enhanced resistance of the ester linkage of the peptide to acid reagents makes the nitrated carrier more suitable for the synthesis of protected amides and hydrazides of peptides[246]. Thus, using ammonia or amines for the separation of peptides from the polymeric carrier, Takashima et al.[247,248] obtained a number of oxytocin analogues.

The benzhydryl polymer proposed by Southard and coworkers[249–251] permits the employment of mild acid reagents for the separation of the peptide from the carrier but requires the use in the synthesis of extremely acid-labile protective groups, which also involves certain difficulties.

An interesting version of the synthesis of aminoacyl polymers without using condensing agents and tertiary amines was proposed by Dorman and coworkers[252]. The dimethyl(arylmethyl)sulphonium polymer employed by these workers was subsequently used to synthesise a number of biologically active peptides[218,253].

The polymeric carriers in which a hydroxyl forms part of the "anchor" group are of undoubted interest. This is primarily the hydroxymethylated polymer of styrene proposed by Bodanszky and Sheehan[254], which has been frequently used in solid-phase peptide synthesis despite a number of important disadvantages[65,209,233,250–260]. The hydroxyhexamethylene polymer proposed by Bayer et al.[261], the *p*-hydroxyphenylacetoxy polymer investigated by Blake and Li[262], and the t-hydroxyalkyl polymer of Wang and Merrifield[263] belong to the same group of carriers. The hydroxyalkylamino-polymer, developed by Tilak and Hollinden[264], is also suitable; it can be used successfully in combination with the Z-protected α-amino groups of aminoacids. The hydroxybutyryl polymer has similar properties[264,267]. The impossibility of using acid reagents in the stage involving the removal of the peptide from the carrier must be regarded as a disadvantage of these carriers.

Many of the hydroxyl-containing carriers make it possible to convert the peptidyl polymer into a polymeric activated peptide ester at the end of the synthesis, which leads to many possibilities in its subsequent use (see Section VII). This is primarily the polymer with hydroxyphenyl sulphide groups proposed by Marshall and Liener[268] and independently by Flannigan and Marshall (G.R. Marshall)[269]. The oxidation of the sulphide group to the corresponding sulphone leads to the formation of an activated peptide ester. A carrier with analogous properties was obtained by Wieland et al.[270] by the reaction of 4′-aminomethyl-2,2-diphenylmethanediol with a chloromethylated carrier. It can be converted by dehydration into an activated vinyl ester of the peptide. The polymeric carrier containing the sulphonamide group has similar properties[271]. *N*-Alkylation of the sulphonamide group facilitates the alkaline hydrolysis, ammonolysis, and hydryzinolysis of the "anchor" linkage.

Special carriers whose "anchor" sections already contain the appropriate functional groups are used to synthesise the amides and hydrazides of peptides under the conditions of the acid cleavage of peptidyl polymers. These are the t-alkyloxycarbonylhydrazide polymer of Wang and Merrifield[263,272] and the benzhydrylamino-polymer proposed by Pietta and Marshall[273]. Monahan, Rivier, and coworkers[274–279] as well as other investigators[280–282] frequently used the benzhydrylamino-polymer to obtain a number of biologically active peptide amides.

Together with polymeric carriers whose functional groups are capable of interacting with the carboxyl of the combined aminoacid, carriers permitting the synthesis of peptides from the terminal NH_2 group are sometimes used. Thus Letsinger and Kornet[283] proposed a carrier of the alkyloxycarbonyl chloride type capable of interacting with the α-amino-group of an aminoacid. However, the suggested approach has not been widely used in solid-phase synthesis owing to the risk of racemisation in the activation of the carboxy-group of the peptide. Nevertheless a carrier of the alkyloxycarbonyl chloride type has been used effectively to add to a polymeric carrier peptides containing ω-amino-groups in diaminoacid residues[284–286]. The peptidyl polymers thus obtained can be cyclised directly on the carrier[284,285].

A novel method for solid-phase peptide synthesis from the terminal NH_2 group was developed by Felix and Merrifield[287], who suggested that aminoacid BOC-hydrazides can be used for the synthesis. The activation of the carboxyl of the peptide being synthesised by the azide method virtually rules out the possibility of racemisation in the peptide formation stage. Dahlmans and coworkers[288,289] also suggested that a polymeric carrier containing sulphonyl chloride groups be used for the synthesis of peptides from the terminal NH_2 group, the aminoacid residues being introduced into the chain in the form of their t-butyl esters. However, like the entire approach of this kind, this method has not so far become widely used.

‡There exists a little known but extremely simple method of synthesising iodomethylated styrene polymers and copolymers by treating the chloromethylated polymer with NaI [see V. V. Korshak, S. V. Rogozhin, and V. A. Davankov, Izv. Akad. Nauk SSSR, Ser. Khim., 1912 (1965); Vysokomol. Soed., 8, 1686 (1966)] (Ed. of Translation).

Not only the anchor group of the carrier but also the physicochemical properties of the polymeric matrix itself are important for the solid-phase synthesis. The polymeric carrier proposed by Merrifield ensures the diffusion of the dissolved reactants within the grains as a result of swelling in many organic solvents, which permits the employment of the entire bulk of the polymeric bead and at the same time its mechanical strength is fairly high. On the other hand, it is not free from many disadvantages. Studies of the structure of styrene–DVB copolymers are being continued [290–293]. The variation of the swelling of the gel polymeric carrier as a function of the chemical nature of the solvent and also the inadequate dimensions of the cells of the polymeric network complicate the diffusion process. To improve the diffusion of the solutes into the polymeric grain and to stabilise the polymer structure, some investigators suggest the employment of macroporous rigidly cross-linked carriers based on polystyrene. The advantages of the latter were noted a long time ago [294], but their practical application began later [173,199,295–297]. A comparative assessment of different carriers [173] suggests that macroporous carriers are extremely promising.

A higher rate of diffusion of solutions into the carrier beads can be achieved by employing fine-mesh polymers, but such carriers are inconvenient to handle. Therefore Bayer et al. [53] suggested that glass beads coated by a thin layer of polymers be used as the carrier. The possibility of employing such hybrid carriers was also demonstrated by other investigators [173,199,298,299]. The disadvantages of these carriers are their low specific capacity and the possibility of the gradual disruption of the outer organic layer, which leads to an appreciable loss of the peptide synthesised. The latter disadvantage is to a large extent eliminated when the anchor organic molecules are fixed on the glass beads by covalent bonds [60,300–304]. According to the authors, such pellicular carriers can be used for column solid-phase peptide synthesis.

The effectiveness of the interaction of the polymeric carrier with reactant solutions is low owing to the presence of a heterogeneous system. Here the advantages of the solid phase synthesis give rise to a significant disadvantage. A way out of this difficulty can be found by combining the possibilities of the solid-phase synthetic method with the synthesis of peptides in solution. For this purpose, Shemyakin, Ovchinnikov et al. [305] developed a method of peptide synthesis on a soluble polymeric carrier. It was suggested that polystyrene ($M = 2 \times 10^5$), soluble in organic solvents and insoluble in water, be employed. This makes it possible to carry out the peptide synthesis in a homogeneous medium and the peptidyl polymer can be purified in a heterogeneous medium. However, under these conditions there are losses of the peptidyl polymer in its precipitation from solution and also certain other complications. Nevertheless a number of biologically active peptides, including gramicidin S could be synthesised by this method [306–309].

The proposed approach is now being developed by the group of Bayer and coworkers [310–312] using poly(ethylene glycol) ($M = 1 \times 10^4$–2×10^4) as the carrier. The authors use ultracentrifugation and ultrafiltration through membranes to purify the intermediates.

Apart from poly(ethylene glycol), which differs in its nature from the traditional carriers based on polystyrene, attempts have been made to use other polymers in the solid-phase synthesis, in particular graft polychlorotrifluoroethylene, chloromethylated polystyrene [313], various polyphenols [269,314,315], and also resitol methylated in the phenolic hydroxyl and chloromethylated in the aromatic ring [93,115,316]. Polymers based on dextrans [2], for example Sephadex LH-20 and G-25, were also tried for this purpose [317,318].

III. THE ADDITION OF THE FIRST AMINOACID TO THE POLYMERIC CARRIER

The method of adding *N*-protected aminoacid to the chloromethylated polymeric carrier in organic solvents in the presence of tertiary amines is most commonly used. To reduce the possibility of the formation of ionogenic groups on the carrier as a result of the interaction of the tertiary amine with the chloromethyl polymer via the mechanism

$$Et_3N + Cl{-}CH_2{-}\textcircled{P} \longrightarrow Cl^- \cdot Et_3N^+{-}CH_2{-}\textcircled{P},$$

it is suggested that triethylamine be replaced by other bases, for example by ethyldi-isopropylamine [23]. An even greater effect is achieved when quaternary tetramethylammonium bases, proposed for this purpose by Loffet [133,152], are used. A definite effect is also observed on changing the solvent in which the ester is formed. t-Butyl alcohol is most promising for this purpose [207,208].

The standard methods of preparation of aminoacyl polymers presuppose interaction between the components at high temperatures (50–80°C), which is not always acceptable. Thus Marglin [176] observed a number of side effects under these conditions and suggested that they can be eliminated by synthesising aminoacyl polymers in DMF with triethylamine in the course of 24 h at 25°C. The results were somewhat unexpected, since hitherto DMF could be used at this stage only at 50–75°C. [23,220]

Since the nature and conditions of the interaction of the *N*-protected aminoacid with the polymeric carrier are determined primarily by the nature of the "anchor" group of the latter, clearly all the above considerations are applicable also to all other carriers containing the chloroethyl group in the aromatic ring.

N-Protected aminoacids add to bromo- and iodomethylated carriers under milder conditions. The reaction is usually carried out with triethylamine in DMF at 20 to 30°C in the course of 36–72 h. [228,230–233] Dicyclohexylamine is sometimes used instead of triethylamine [231,232]. A *C*-terminal aminoacid is added to a chloromethylated carrier in the presence of sodium iodide as the catalyst under still milder conditions [234,236–238].

Analogous conditions are required for addition also in the case of halogenoacetylated carriers. Ethyl acetate, methylene chloride, or DMF are usually employed as solvents [239–245] and the bases are normally triethylamine or ethyldi-isopropylamine [239,242].

In conjunction with the benzhydryl polymer, Southard and coworkers [249,250] used DCHA salts of BMV-aminoacids and other *N*-protected aminoacids for the preparation of aminoacyl polymers. The reaction was carried out by refluxing in chloroform for 12 h [249] or in methylene chloride at 20°C for 4 days [250].

Using a dimethyl(arylmethylene)sulphonium polymer, an aminoacyl polymer was obtained under very mild conditions without a tertiary amine [252]:

$$Me_2S + Cl{-}CH_2{-}\textcircled{P} \longrightarrow Cl^- \cdot Me_2S^+{-}CH_2{-}\textcircled{P} \xrightarrow{HCO_3^-}$$

$$\longrightarrow HCO_3^- \cdot Me_2S^+{-}CH_2{-}\textcircled{P} \xrightarrow[2.\ \text{drying}\ 3.\ \text{heating}]{1.\ \text{BOC-aminoacid}}$$

$$\longrightarrow BOC{-}NH{-}CHR{-}COO{-}CH_2{-}\textcircled{P} + CO_2 + Me_2S\ .$$

The yield of reaction product is then 87–96%, [218,253] while with chloromethylated carriers it does not as a rule exceed 25–30%.

Condensing agents such as CDI and DCC are used for the addition of the first aminoacid to carriers whose "anchor" group incorporates a hydroxyl. It is then necessary to block the remaining free hydroxy-groups when condensing agents are used in the peptide formation stage, which is not always very convenient.

Toluene-*p*-sulphonyl chloride is sometimes used as the condensing agent in the stage involving the formation of the aminoacyl polymer [263,265,266].

Condensing agents are also employed for the addition of the first aminoacid to carriers whose "anchor" groups contain an amino- or a hydrazino-group. DCC is most frequently used for this purpose [263,273–282]. The corresponding 2,4,5-trichlorophenyl esters of aminoacids have been used with the sulphonamide carrier [271].

In the synthesis of peptides from the terminal NH_2 group different aminoacids are added to the polymeric carrier in the form of an ester, amide, or another involving the carboxy-group in the presence of trimethylamine [283–289].

An interesting modification of the addition of the aminoacid to the carrier involves a functional side group. Thus Glass et al. [226] used the imadazole ring of histidine for the interaction with a fluorodinitrophenyl group of the polymeric carrier.

In those cases where the carrier pore size changes in the course of the synthesis, the aminoacids can add to sections of the polymer which subsequently become appreciably inaccessible to chemical attack by other reagents [13]. As a result of screening by the carrier, these aminoacids do not enter into peptide formation reactions, which leads to the appearance of erroneous sequences. The amount of such inaccessible residues can reach 40%. [319]

One of the ways of overcoming these disadvantages is the addition to the polymeric carrier of short peptides, incapable of passing into the very small carrier pores, instead of the individual aminoacids. Attempts were made to employ for this purpose polymers with modified functional groups, in particular halogenoacetyl [239,242] and bromomethyl [230–232]. It proved possible to use a chloromethylated carrier only in the reaction with depsipeptides on refluxing in ethyl acetate [320,331] or with the simple dipeptide BOC-Gly-Gly-OH. [227] We believe that the employment of sodium iodide in conjunction with a chloromethyl polymer is very promising. It is then possible to add to the carrier di-, tetra-, and penta-peptides in amounts of the order of 0.12–0.32 millimole g^{-1}. [237,238]

IV. PROTECTION AND DEBLOCKING OF α-AMINO-GROUPS

The benzyloxycarbonyl protecting group, employed initially by Merrifield [1], proved to be relatively unsuitable under the conditions of solid-phase synthesis [4]. Therefore its application is limited if one disregards studies where Z-aminoacids were used to introduce the *N*-terminal residue of the peptide being synthesised. Under there conditions, the benzyloxycarbonyl group is removed in the acid separation of the peptide from the carrier or leads to more stable derivatives when the peptidyl polymer is subjected to ammonolysis, hydrazinolysis, or transesterification.

Z-Aminoacids can be used in combination with a hydroxyalkylamino-polymer [264–266,296] and a hydroxybutyryl polymer [264,267]. The benzyloxycarbonyl group is then removed with a 30% solution of hydrogen bromide in acetic acid without loss of peptide and carrier. Z-Aminoacids are also suitable for peptide synthesis on a polymer of the sulphonamide type [271]. The polymeric carrier based on poly(ethylene glycol) [310,312] has an interesting property, i.e. the benzyloxycarbonyl group can be removed by hydrogenation, which could not be done when insoluble carriers were used.

Nevertheless the main substituent used to protect the α-amino group in the synthesis of peptides on a polymeric carrier continues to be the BOC group (Table 2). The availability and stability of BOC-aminoacids, the possibility of removing the BOC group by mild acid reagents, and many other advantages make it virtually irreplaceable at the present stage of development of solid-phase peptide synthesis.

The BOC-group is usually removed with a 1 *N* solution of hydrogen chloride in acetic acid [14], despite the possible risk of acetylation of the peptide amino-groups by trace amounts of acetic acid in the last stage of peptide formation. However, careful neutralisation and washing reduce this risk to a minimum.

A 4 *N* solution of hydrogen chloride in dioxan, proposed for the first time by Stewart and Woolley [322], is beginning to be increasingly employed for the elimination of the BOC group. Dioxan promotes the swelling of the polymer, which improves the efficiency of the deblocking. This is important, since the incomplete removal of the *N*-protecting group can be one of the causes of the omission of aminoacid residues from the chain [169].

Trifluoroacetic acid [242,323] or its 50% solution in ethylene chloride were proposed in 1966–1967 for the removal of the BOC group. The methyl chloride solution was used by Gutte and Merrifield [324] in the synthesis of ribonuclease A. In addition trifluoroacetic acid prevents the formation of the pyroglutamic acid residue from the BOC-glutamine residue at the instant of the removal of the BOC group, which happens when a 1 N hydrogen chloride solution in acetic acid is employed [325]. A 4 *N* solution of hydrogen chloride in dioxan can also be used for this purpose. The present authors successfully applied this procedure in the solid-phase synthesis of a number of fragments of the insulin A-chain [126].

A mixture of standard reagents with mercaptoethanol is used to remove the BOC-group from the tryptophan residue. The possibility of employing for this purpose a 20% solution of mercaptoethanesulphonic acid in acetic acid [162] and also of a 0.1 *N* solution of hydrogen chloride in formic acid [221] has been demonstrated.

Special studies have been made on problems of the removal of the BOC group [60,97]. The possibility of employing at this stage hydrogen chloride solutions in propionic acid [97], in a methylene chloride–DMSO mixture [134], and in methanol [206] was investigated. Chou et al. [134] obtained interesting results demonstrating the dependence of the degree of removal of the BOC group on the chain length of the peptide synthesised, the nature of the deblocked aminoacid residue, and its location in the peptide chain, which the authors believe to be the most important factor.

The AOC group, whose chemical properties are similar to those of the BOC group, was employed in the solid-phase synthesis for the first time by Inukai et al. [314]. It will probably be used on a wider scale with increase in the manufacture of AOC-aminoacids.

The NPS group, which is readily removed by solutions of hydrogen chloride in an inert solvent [328] and also by thioacetamide in a mixture of acetic acid and methanol [327], was introduced almost simultaneously into the solid-phase

Table 2. N^{α}-protecting groups and methods for their removal in solid-phase peptide synthesis.

[h] 25% CF_3COOH in chloroform.

synthesis in three laboratories[326–328]. The group is extremely useful in many special cases owing to its high lability[71,99,131,222,235,284,285].

The BPOC group, proposed by Sieber and Iselin[329], is even more labile. It is two thousand times more sensitive than the BOC group to acid cleavage and can be removed with 75% trichloroacetic acid in 1.5 h,[329] with 0.5–1.5% solution of trifluoroacetic acid in methylene chloride[42,263,272], with 0.05–0.1 *N* hydrogen chloride solution in chloroform in 8–10 min,[191,197,262] and also with glacial acetic acid in 8 h.[156,159]

Mention should also be made of the BMV group, proposed by Southard and coworkers[249,250] in conjunction with a benzhydryl polymer. It can be removed with 0.4 *N* aqueous hydrogen chloride solution in THF or with 1 *N* solution of toluene-*p*-sulphonic acid in the same solvent. The FOC group[115,330] and MZ group[149,232], whose stabilities are similar to those of the BOC group, are also used in solid-phase peptide synthesis. The employment of the Pht group in conjunction with the hydroxy-t-alkylpolymer[263] and also of the trimethylsylyl group[309], which is suitable for the synthesis of peptides using aminoacid-*N*-carboxy-anhydrides, has been reported.

In selecting the N^{α}-protecting group, investigators devoted special attention to the deblocking stage[99].

V. PROTECTION AND DEBLOCKING OF THE FUNCTIONAL GROUPS IN THE SIDE CHAINS OF TRIFUNCTIONAL AMINOACIDS

Fairly convenient protecting groups, satisfying the requirements of the solid-phase method, which in general are the same as the requirements of the classical method for the synthesis of peptides, are now available for all trifunctional aminoacids.

Arginine. Nitroarginine[18,22,24,36,37,42,44,51,52,54,59,69,88,95,120,124,128,129,131,139,140,142,144,145,148,160,161,165,168,175,186,191,193,200,201,206,211,215,216,218,220,223,225,233,250,263,268,275–278,280,281] is usually employed with subsequent hydrogenation of the peptide when separated from the carrier. When the peptidyl polymer is treated with anhydrous hydrogen fluoride, this stage can be eliminated. For peptides containing cysteine and methionine, N^{G}-tosylarginine is usually employed[70,71,76,92,107,121,172,179,191,194,197,212,262].

Aspartic and glutamic acids. The ω-carboxy-groups of these aminoacids are successfully protected by the formation of benzyl esters[19–21,24,27,32,36,37,42,44,51,55,57,59,76,78,88,94,124,127–129,142,143,145,148,161,167,172,175,188,190,197,198,206,220,231,233,250,263,268,282], which are readily cleaved on treatment of the peptidyl polymer with acid. t-Butyl esters, which are more labile in an acid medium but are resistant to hydrazinolysis, are sometimes used[95,100,102,151,156,159,205,209,238,262]. In order to keep the ω-carboxy-group protected even after the separation of the peptide from the polymeric carrier by acid treatment, nitrobenzyl esters of the aminoacids are employed[90,113,126,194].

Asparagine and glutamine. The *p*-nitrophenyl esters of the BOC derivatives of asparagine and glutamine are usually employed to introduce their residues into the peptide, since the use of DCHA leads to the formation of the corresponding nitriles. On the other hand, if DCHA has to be used, the amide groups of asparagine and glutamine must be protected, for example by the MBZH group, which can be removed by refluxing with trifluoroacetic acid[131].

Histidine. The N^{Im}-benzyl group is most often used to protect the histidine imidazole ring. It can be removed either by catalytic dehydrogenation or by sodium in liquid ammonia[21,33,37,44,59,76,80,81,82,95,96,100,102,117,120,121,137,139,140,142,157,161,169,172,175,188,190,192,194,198,201,211,212,215,216,225,233,262,263]. The N^{Im}-group of histidine can be deblocked simultaneously with the separation of the peptide from the polymeric carrier when N^{Im}-tosylhistidine is employed[183,186,200,277,278].

The DNP group, which can be removed by treatment with thiols at pH 8 and room temperature, must be regarded as the most convenient protecting group for the histidine side chain[47,63,124,146,153,165,181,196,206,281,282,332]. The possibility of removing this group under the conditions of alkaline hydrolysis, aminolysis, and hydrazinolysis of peptidyl polymers has also been demonstrated[181]. The choice of the protecting group for the histidine imidazole ring has been the subject of a special examination by Losse[331,332].

Lysine. The benzyloxycarbonyl group, which can be readily removed by the acid cleavage of the peptidyl polymer but is entirely stable in combination with the N^{α}-BOC protecting group, is usually employed to protect the N^{ϵ}-amino-group of lysine[16,29-31,33,44,47,49,50,63,76,87,88,102,124,127,128,129,144,145,148,151,153,155,156,159,161,172,176,182,188,194,196,197,206,220,221,231,253,275,280,282]. There are, however, data demonstrating the partial elimination of the N^{ϵ}-Z group when the N^{α}-BOC group is removed. In this respect the *p*-Br-Z protecting group is more reliable[213]. The tosyl group[40,92,114,117,179,194,203,262], which can be removed by treatment with sodium in liquid ammonia, and also the TMA group[24,36,37,45,51,296], which is eliminated by treatment with 1 *N* piperidine solution, are sometimes used to protect the lysine side chain.

Methionine. Methionine is usually used without protecting the functional group in the side chain, but special protecting agents must be used in the stage involving the separation of the peptide from the carrier (which is not always successful). For this reason BOC-Met(O)-OH is sometimes employed to synthesise methionine-containing peptides[124,128,145].

Ornithine. As in the case of lysine, the amino-group of ornithine in the side chain is protected by the benzyloxycarbonyl[275,284,285] or tosyl[93] group; MZ-Orn(p-NO_2-Z)-OH has also been used[149].

Serine and threonine. Simple benzyl esters[21,24,33,36-38,51,52,76,92,94,104,112,124,128,129,132,143-145,148,151,153,156,159,161,168,172,174,176,186-188,193,194,196-198,200,206,212,213,215,216,220,223,241,253,262,268,276-287,282], which are cleaved under the conditions of the acid treatment of the peptidyl polymers, are normally used to protect the hydroxy-groups of serine and threonine. When activated esters are used in the peptide formation stage, serine and threonine are introduced into the peptide chain without protecting the hydroxyl. The employment of Weygand's protecting group (1-benzyloxycarbonylamino-2,2,2-trifluoroethyl) for the serine and threonine side chains has been reported[38].

Tyrosine. The tyrosine hydroxy-group is usually protected in the form of the benzyl ether[20,24,32,33,36,39-41,43,44,47,48,51,57,59,63,74,76,80,92,104,110,112,114,120,121,124,126,128,137-140,142,143-145,155,156,159,167,170,172,174,175,181,186,188,193,197,200,203,205-208,210,212,213,233,235,237,238,240,241,243,247,248,262,263,275-278,282]. The latter is readily cleaved by hydrogen bromide in trifluoroacetic acid or by hydrogenation, but, in contrast to the analogous serine and threonine derivatives, it is relatively stable in anhydrous hydrogen fluoride, which is not very convenient. It is suggested that the *p*-methoxybenzyl and *m*-bromobenzyl groups are more suitable in this respect[213].

Cysteine. In most cases the benzyl group, which can be removed from the cysteine residue only with sodium in liquid ammonia under rigorously controlled conditions (owing to the possibility of side reactions), is used to protect the SH functional group of cysteine[33,39,41,43,44,48,70,71,74,76,79,81,104,107,110,112,128,129,131,138,143,155,167,170,172,174,184,194,196,203,236-238,247,248,255].

The employment of anhydrous hydrogen fluoride can also be made difficult by N → S acyl migration. It has been suggested that *S*-*p*-methoxybenzylcysteine be used to prevent this[69,81,145,151,220,282].

Sometimes the SH group of cysteine is protected with the trityl[15,81] and benzyloxycarbonyl[235] groups, but at the present time two approaches are of greatest interest for the synthesis of crysteine peptides. These are in the first place the employment of different protecting alkylthio-groups (for example, the ethylthio-group), proposed by Weber and coworkers[20,32,57,150]. These groups are removed by sulphitolysis. The second approach to the solution of the problem is based on the suggestion of Lunkenheimer and Zahn[61,111] that bis-BOC-cysteine be used for the peptide synthesis, which eliminates the need for special protection of the SH group. Both approaches still require further investigation, like the problem of the protection of the SH group as a whole.

The studies of Zahn and coworkers[81] and of Weber and coworkers[144,150] have been devoted to these problems.

VI. METHODS FOR THE FORMATION OF THE PEPTIDE BOND

The peptide formation stage is of key importance in peptide synthesis, which is particularly true of the solid-phase method. The absence of intermediate stages involving the purification of the peptide synthesised necessitates the attainment of 100% yield in this stage.

DCC remains the most common condensing agent (Table 3). All the protein aminoacids (except asparagine and glutamine) can be successfully introduced with the aid of this agent into the peptide chain joined to the polymeric carrier. Difficulties are sometimes encountered in the introduction of valine and isoleucine residues into the peptide chain[167] owing to their steric structure. The structure of the polymeric carrier also has a definite influence on the degree of the peptide formation reaction[199].

The nature of the solvent is likewise very important; it must be of relatively low polarity. Therefore methylene chloride, sometimes with small amounts of added DMF, is usually employed in the condensation stage. Under these conditions, a 2.5-3-fold excess of the reactants is used, the reaction being carried out in the course of 2-4 h with stirring in a minimal volume of the solvent. Sometimes the condensation with DCC is performed in other organic solvents, in particular in chloroform[101,103,160,250] or THF.[30,31,49,50,87] The method of activated esters has been frequently attempted in the solid-phase synthesis, but without success. Thus Bodanszky and Sheehan[246,254] investigated the employment of *p*-nitrophenyl esters of aminoacids. However, despite a number of advantages compared with the carbodi-imide method, this procedure is as a whole more laborious, since it requires a longer

condensation time and the preliminary synthesis of amino-acid derivatives. Nevertheless many important peptides, including the insulin A-chain and its analogues, have been obtained using *p*-nitrophenyl esters[333,334]. Beyerman et al.[335] investigated the catalytic effect of 1,2,4-triazole when activated esters are used. This approach was employed also by a number of other investigators[116,117,161,215,216], despite the claim of Ragnarsson et al.[136] that 1,2,4-triazole has no catalytic effect.

Table 3. Methods for peptide formation in solid phase synthesis.

Method	Condensation conditions	References
Dicyclohexylcarbodi-imide	CH_2Cl_2, 25°C, 2-4 h	17,19,21,24,25,28,29,32—48,51,53—55,57,59—61,63,65,69—71,73,74,76—83,85,86,88—94,96,97,99,104,107,108,110,112,114—118,120—124,126—129,131,132,135,137—146,148,149,153—157,159,161,163,164,166,167,169,171,172,174,175,177—179,182—184,186,188,190—193,196—201,205—207,209—216,218,220,222,223,225,227,233,235,236,238,240,247—249,253,255—257,259—263,268,269,272,273,275—277,280—282,286,289,296,297,299—301,303,304,312,313

[a] 5 h. [b] 72 h. [c] 12 h. [d] $CHCl_3$ instead of DMF. [e] 1-Hydroxybenzotriazole instead of 1,2,4-triazole.

N-Hydroxysuccinimide esters, used for the first time by Shemyakin, Ovchinnikov, and coworkers[305] in combination with a soluble carrier, are being increasingly applied in the peptide formation stage. This method has proved suitable also for insoluble polymers[44,70,106,107,116,192,318]. The esters are frequently obtained directly at the instant of condensation, using *N*-hydroxysuccinimide and DCC.[78,117,127,242,284,285]

Instances where trichloro- and pentachloro-phenyl esters were employed (Table 3), sometimes with added 1,2,4-triazole[157], *N*-methylmorpholine[226], and 2,6-lutidine[271], are also known. The use of 2-pyridyl esters has also been reported[170]. Some of the methods enumerated above have been compared by Bodanszky and Bath[56].

Among other procedures for the formation of the peptide bond, mention should be made of the method of mixed anhydrides with isobutyl chlorocarbonate, which has been used for the synthesis both from the *N*-end[283] and from the *C*-end[27,310-312]. The employment of the mixed anhydride of *N*-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline and a BOC-aminoacid has also been reported[168]. The possibility of employing symmetrical anhydrides of BOC-aminoacids[158,207] and aminoacid *N*-carboxyanhydrides is likewise possible[16]. Admittedly in this case it is still impossible to control exactly the number of combined aminoacid residues, which limits the applicability of this method. The possibility of the interaction of *N*-carboxyanhydrides with *N*-trimethylsilyl derivatives of aminoacids joined to a non-cross-linked polystyrene has been demonstrated[309].

When poly(ethylene glycol) is used in the solid-phase synthesis, the peptide chain may be grown using the water-soluble carbodi-imide[310].

VII. THE PROBLEM OF THE FORMATION OF ERRONEOUS SEQUENCES IN SOLID-PHASE PEPTIDE SYNTHESIS

It is noteworthy that none of the methods of peptide formation discussed above can guarantee 100% condensation. The situation is increasingly complicated with increasing growth of the chain being synthesised. To ensure an adequate degree of condensation, it is necessary to employ an increasing excess of the aminoacids. Thus in the synthesis of the 104-member analogue of the apoprotein of cytochrome c from horse heart, a 30–70-fold excess of BOC-aminoacids was used in the last stages[44,88]. The yields are somewhat improved, but the fundamental difficulties are not eliminated, by repeated condensations[104,112,121,148,169,198,207,209,211,233,259,260]. All this leads to the omission of individual aminoacid residues from the chain. Bayer, Hagenmaier, and coworkers[53,62,86] devoted much attention to the problem of the formation of erroneous sequences associated with the omission of aminoacid residues due to the incomplete occurrence of the deblocking and peptide formation stages. They estimated not only qualitatively but also quantitatively the possible related peptide impurities and suggested a number of methods for detecting such side reactions, in particular methods based on mass spectroscopy and ^{19}F NMR[132,302,312]. Baas et al.[336] actually proposed a special formula for the quantitative estimation of possible impurities, taking into account the yield at each peptide formation stage.

The foregoing considerations obviously demonstrate the importance of increasing the yield in the condensation stage and the necessity for careful and clear-cut monitoring of this stage as well as the stage involving the removal of N^{α}-protecting groups. There are a number of methods for following these processes. The most traditional are quantitative hydrolysis of the peptidyl polymers with subsequent aminoacid analysis[1], the separation of the intermediate peptides from the polymeric carrier and analysis of their homogeneity by various procedures, and spectrophotometric determination of any one reaction

product whose amount is proportional to the yield at the condensation or deblocking stages. For example, it is possible to determine the *p*-nitrophenol formed when one uses *p*-nitrophenyl esters of aminoacids[254,308,333], *o*-nitrophenylsulphenyl chloride, where NPS-aminoacids are employed[284,285], or benzoylacetone when the BMV protecting group is used[250].

The dansylation or dinitrophenylation method is sometimes employed to determine free amino-groups[73,185,215,216,312], but these procedures are laborious, which hinders their wide-scale employment.

The extent of the condensation reaction has also been analysed by determining the chloride ions in the triethylamine hydrochloride formed in the stage involving the neutralisation of the aminopeptidyl polymer (Table 4). However, it is then impossible to establish whether the reduced content of chloride ions is due to the incomplete condensation reaction or whether it is due to the incomplete deblocking of the α-amino-groups.

Table 4. Methods for the determination of free amino-groups in solid-phase peptide synthesis.

Bromocresol Purple (indicator)	337
Potentiometric titration with $HClO_4$ + AcOH	58,68,195,214

Dorman's method[35], in which the reaction mixture is treated with pyridine hydrohalide after the peptide formation stage in order to form the hydrohalides of the amino-groups which failed to condense, is more convenient in this respect. (The BOC group of the aminoacid introduced remains unaffected under these conditions.) The resulting salt of the aminoacyl polymer is treated with triethylamine, washed, and the filtrates are analysed for chloride ions[62,67,78,86,132,151,164,198,199,253]. Instead of pyridine hydrohalide, one can use, for example, picric acid[258–260]. The picrate formed is decomposed by a suitable amine and the solution is analysed spectrophotometrically for picric acid.

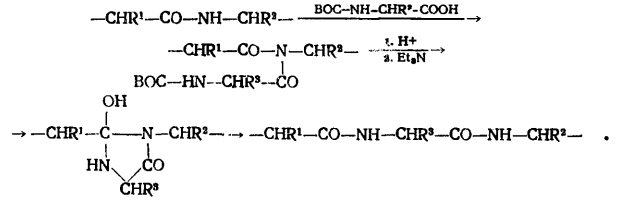
There are a number of other qualitative and quantitative methods whereby free amino-groups can be estimated. These include the use of 2-hydroxy-1-naphthaldehyde[60,77,84,99,129,191,257], 2-amino-1-naphthaldehyde[223], the Bromocresol Purple indicator[337], and also ninhydrin (Table 4).

Some of the methods quoted for estimating free amino-groups have been assessed in special investigations[164,338]. We believe that the procedure which is fastest, most accurate, and, what is most important, susceptible to automation is that proposed by Brunfeldt and coworkers[58,68,195,214], involving the potentiometric titration of the free amino-groups with perchloric acid in the presence of acetic acid.

Together with the problem of determining the extent of the condensation reaction, the problem of the blocking of the amino-groups which failed to enter into the peptide formation reaction merits examination. Thus, after each condensation stage, Merrifield[1] acetylated with acetic anhydride the amino-groups which failed to react, a procedure which is frequently employed also at the present time[62,86,91,92,116,117,139,148,179,197,198,212,215,216,260,281,313]. *N*-Acetylimidazole is also used for this purpose[91,282].

In order to create large differences between the acid–base properties of the required peptide and the side products, it is convenient to employ 3-nitrophthalic[55,177,203,207] and 3-sulphopropionic[131] anhydrides as blocking agents. The derivatives of shorter peptides formed under these conditions contain an additional acid group which facilitates their separation from the desired peptide.

Whereas the problem of monitoring the solid phase synthesis has to some extent been solved, that of increasing the yield of the peptide formation stage still remains entirely open. The duplication of the condensation stages and the employment of a large excess of *N*-protecting aminoacids do not provide a solution. Moreover, a large excess of BOC-aminoacids can lead to an additional number of erroneous sequences owing to the incorporation of the aminoacid residues within the peptide chain being synthesised[46], in accordance with the following mechanism:



It is inconvenient to employ an excess of *N*-acylated aminoacids also for purely economical reasons, since their regeneration is relatively ineffective and requires further development[339].

From this point of view, the most interesting method of economical solid-phase peptide synthesis is that of Esko and Karlsson[77], which is based on the sorption of the BOC-aminoacid by the aminoacyl polymer. The amount of sorbed reactant is sufficient to carry out the peptide formation stage and the excess BOC-aminoacid can be removed from the reaction vessel even before adding the condensing agent. The sorption phenomenon was used by Elliott et al.[218] in the synthesis of bradykinin analogues.

The low efficiency of the condensation reaction is probably related to the fact that, as the chain being synthesised grows in length, there is a possibility that it may roll up on the carrier into a disordered coil, which leads to the screening of the *N*-terminal amino-group. Hydrogen bonds can play a significant role in this process. This hypothesis is confirmed by the fact that the addition of urea, which dissociates hydrogen bonds, to the reaction mixture results in an increase of the rate and degree of deblocking of the BOC groups[134] and also in an increase of the yield in the peptide formation stage[97,148,282].

We believe that one of the possible methods of preventing the coiling of the peptide chain may be the additional (segmental) fixation of the individual sections of the growing peptide chain on the carrier as a result of the interaction with the latter of the functional side groups of the peptide [236].

Nevertheless the problem of the solid-phase synthesis of long peptide chains remains open. At the present stage the most rational procedure in this respect involves a combination of the possibilities of the solid-phase method (the synthesis of short chains) and the classical procedure for joining them together in solution. This approach has been called the solid phase-fragment method.

Furthermore, one should bear in mind the possibility of the block version of peptide synthesis on a carrier. This method was investigated for the first time by Weygand and Ragnarsson [340] and in greater detail by Omenn and Anfinsen [341]. Subsequently block synthesis in different versions was used also in other laboratories [96,102,117,127,147,215,227,231,232,257,297]. However, block condensation on a polymeric carrier involves a number of specific difficulties which so far restrict the application of this method in practice.

VIII. METHODS FOR THE SEPARATION OF PEPTIDES FROM THE POLYMERIC CARRIER

The commonest method for the separation of peptides from the polymeric carrier involves the use of hydrogen bromide in trifluoroacetic acid (Table 5). A number of protecting groups, other than the *S*- and N^{Im}-benzyl, N^{G}-nitro-, tosyl, and *O*-*p*-nitrobenzyl groups, are removed at the same time. A 1:1 mixture of trifluoroacetic acid and methylene chloride has been used recently fairly frequently as a solvent in this process [65,77,128,168,176,179,188,194], which increases the swellability of the polymer.

When the peptide does not contain serine and threonine residues, it is possible to separate it from the carrier by treatment with hydrogen bromide in acetic acid [116,260,284,285,301]. To protect the residues of certain other amino-acids (cysteine, methionine, and tyrosine) from the alkylating action of the benzyl bromide formed in the reaction, protecting agents such as anisole, ethyl methyl sulphide, or methionine are added to the reaction mixture.

Peptides are being increasingly separated from the polymeric carrier by treatment with anhydrous hydrogen fluoride, which was used for this purpose for the first time by Lenard and Robinson [342]. All protecting groups, other than the N^{Im}-benzyl group, are also removed at the same time.

Among other acid agents, one must mention the use of a 50% solution of trifluoroacetic acid in methylene chloride and a solution of boron trifluoride in ether, which are used in special cases (Table 5). The employment of hydrogen bromide in trifluoroacetic acid for a long period (more than 1h) can lead to partial degradation of the peptide, particularly when the chain contains proline residues [116,343,344].

Alkaline agents, for example a solution of sodium hydroxide in aqueous alcohols, are also used in the stage involving the cleavage of the peptidyl polymer [1,30,31,49,50,87]. Water–dioxan or water–alcohol–dioxan solutions of sodium hydroxide are likewise employed [25,171,238,240,241,310–312]. The use of sodium methoxide [312] and sodium thiophenoxide [241,242] has been described.

In order to obtain peptide amides, peptidyl polymers are treated with ammonia under different conditions

Table 5. Methods for the separation of peptides from the polymeric carrier.

(Table 5). The possibility of interchain aminolysis, which may lead to the occurrence of erroneous sequences, has been reported [227]. Intrachain aminolysis is sometimes also observed, particularly in the dipeptide stage, with formation of dioxopiperazines. This process is facilitated when the *C*-terminal aminoacid is proline or an *N*-methylated aminoacid [202,214,233,259,260].

Hydrazine or hydrazine hydrate is frequently used to separate the peptide from the carrier, particularly in the synthesis of fragments for subsequent azide block condensation in solution (Table 5).

The transesterification method in the presence of tertiary amines or a strongly basic anion-exchange resin has been applied quite recently in the stage involving the cleavage of the peptidyl polymer (Table 5). In this connection there is a risk of partial loss of the peptide from the polymeric carrier when the peptidyl polymer is washed with alcohol after the neutralisation stage [64] and also of the conversion of ω-benzyl esters into ethyl or methyl esters [345].

A comparative assessment of the various methods for the separation of peptides from the polymeric carrier has been carried out [346] and the effect of various solvents on the extent of separation of the peptide has been investigated [98].

Hydrogen bromide in trifluoroacetic acid in the case of a polymer of the alkyloxycarbonyl chloride type [287] and alkaline agents or a 36% solution of hydrogen bromide in acetic acid in the case of a polymer treated with sulphonyl chloride [289] are used to separate peptides attached to the carrier via the *N*-terminal amino-group.

Peptides joined to the carrier via a side chain amino-group are separated under similar conditions [284-286].

As already mentioned in Section II, there are many carriers whereby the peptidyl polymer can be converted at the end of the synthesis into an activated polymeric ester [268-271]. This ester can react with any amino-component, for example with the ester of the *C*-terminal aminoacid [268] or with the deblocked α-amino-group of the peptide synthesised (cyclisation on the carrier) [269]. A similar situation arises also when the hydrazides and 4-carboxyphenylhydrazides are used in the stage involving the formation of the aminoacyl polymer [108]. The above derivatives can be activated also at the end of the synthesis.

IX. AUTOMATION OF SOLID PHASE PEPTIDE SYNTHESIS

The absence of non-standard operations in the solid-phase synthesis makes it possible to mechanise and automate the entire process. The first automatic synthesisers were reported as early as 1965–1966. [347,348] A discussion of the design characteristics of such automatic apparatus can probably serve as the subject of a separate review and therefore we shall confine ourselves here to the examination of the principal trends in the construction of apparatus of this kind.

An interesting version of an automatic synthesiser with a perforated tape programming unit was proposed by Brunfeldt and coworkers [349-351], who also suggested a special apparatus whereby one can monitor automatically the synthesis by potentiometric titration [68,214]. A number of studies have been made on the development and improvement of individual units of the automatic device. Thus, a fundamentally new design for the reaction vessel was developed by Birr and Lechinger [166,352]. They made the reactor in the form of a rotor with porous walls, which made it possible to separate the solvent from the carrier by centrifugal filtration. The systems for the metering and supply of solutions, the methods of stirring the reaction components in the vessel, etc. are also being improved [211,219,353-356].

It is still difficult to specify the optimal version of the automatic synthesiser. However, it is already clear that such apparatus will become available to many investigators in the immediate future.

---o0o---

Summarising the foregoing one can conclude that solid-phase peptide synthesis is in a state of intense development. While having many important advantages over classical methods of synthesis, it is not free from disadvantages which limit its practical applications. In assessing its present state and the prospects for its development, both undue enthusiasm and excessive skepticism would be inappropriate. A sorber, critical approach to this problem is particularly necessary. However, the data examined above show that many imperfections of the solid-phase method are typical growing pains, which are normally cured eventually. This is shown particularly by the recent publications on the improvement of the conditions for peptide formation [357], on the development of new protecting groups for trifunctional aminoacid residues [358], and on the application of modified polymeric carriers [359]. The methods for the addition of the first aminoacid to the polymeric carrier are also being improved [360,361] and the solid-phase-fragment method of synthesising peptides is being successfully developed [362].

The above trends have been reflected also in certain very recent publications [363-376] which appeared during the preparation of this review for the press.

All this leads to the hope that the existing versions of solid-phase peptide synthesis will be rapidly improved and that the serious disadvantages from which the method still suffers will be overcome.

On the whole, the solid-phase method can be regarded as an extremely promising procedure for peptide synthesis.

Aminoalkyl Organophosphorus Compounds

K.A.Petrov, V.A.Chauzov, and T.S.Erokhina

Data on the methods of preparation of aminoalkyl compounds of phosphorus (by transformation of functional groups and by aminoalkylation of tervalent phosphorus compounds) and their physical and chemical properties are presented and the practical applications of substances of this type are briefly described.
The bibliography includes 528 references.

I. INTRODUCTION

Aminoalkyl organophosphorus compounds are used as complex-forming agents with chelating properties, extractants, herbicides, insecticides, wetting agents, pharmaceutical preparations, ion exchangers, etc. A number of novel methods have now been proposed for their synthesis. However, there are no reviews dealing with compounds of this class either in Soviet or foreign literature. These considerations and also the potential practical and theoretical value of these compounds led to the publication of this review.

II. METHODS OF SYNTHESIS

A wide variety of numerous methods of synthesis have been proposed for amino-substituted organophosphorus compounds, some of which are simple and can be used to prepare such compounds in large amounts. The methods of synthesis can be usefully divided into two groups in terms of the starting materials and the mode of introduction of the amino-group. The first group includes methods analogous to those used for the introduction of the amino-group into any organic compounds. They are based on the transformation of various functional groups in organophosphorus compounds into amino-groups, these reactions are classified as amination of organophosphorus compounds without the formation of new phosphorus–carbon bonds.

The second group includes methods specific to organophosphorus compounds, leading to the formation of phosphorus–carbon bonds. These are classified as aminoalkylation of phosphorus compounds with formation of phosphorus–carbon bonds.

1. Amination of Organophosphorus Compounds without the Formation of New Phosphorus–Carbon bonds

The method of conversion of carboxy- and carbonyl groups into the amino-group (the Curtius, Hofmann, Lossen, and Beckmann reactions) has been frequently used to synthesise amino-substituted organophosphorus compounds. By treating phosphonocarboxylic acid esters in succession with hydrazine and nitrous acid, one obtains azides, which are converted into aminophosphonic acids after the Curtius rearrangement, alcoholysis, and hydrolysis [1,2]:

$$\begin{aligned} &R{-}\underset{\underset{COOEt}{|}}{CH}{-}P(O)(OEt)_2 \xrightarrow{N_2H_4} R{-}\underset{\underset{CONHNH_2}{|}}{CH}{-}P(O)(OEt)_2 \xrightarrow{HNO_2} \\ &\rightarrow R{-}\underset{\underset{CON_3}{|}}{CH}{-}P(O)(OEt)_2 \xrightarrow{H_2O,H^+} R{-}\underset{\underset{NCO}{|}}{CH}{-}P(O)(OEt)_2 \xrightarrow{EtOH} \\ &\rightarrow R{-}\underset{\underset{NHCOOEt}{|}}{CH}{-}P(O)(OEt)_2 \xrightarrow{HCl,H_2O} R{-}\underset{\underset{NH_2}{|}}{CH}{-}PO_3H_2 , \end{aligned} \quad (1)$$

where R = H, Me, $PhCH_2$, or $Me(CH_2)n$ and n = 9–15. The yields of the desired products in this procedure are 31–83%. [1-4]

The Schmidt rearrangement, which is of a similar type, has been used to synthesise ω-aminodecylphosphonic acid [5]:

$$HO_2C(CH_2)_{10}PO_3H_2 \xrightarrow{HN_3} H_2N(CH_2)_{10}PO_3H_2 + CO_2 + N_2 . \quad (2)$$

The synthesis of diethyl α-aminobenzylphosphonate by the Hofmann degradation of α-(*OO*-diethylphosphono)phenylacetamide has been described [6]:

$$\underset{\underset{CONH_2}{|}}{PhCHP}(O)(OEt)_2 \xrightarrow{NaBrO} \underset{\underset{NH_2}{|}}{PhCHP}(O)(OEt)_2 . \quad (3)$$

This method is applicable also to the synthesis of β-aminoalkylphosphonates and phosphonic acids [7,8]. For example, 2-aminoethylphosphonic acid has been obtained by this method in 71% yield.

NN'-Bisdiphenylphosphinylmethylurea and *N*-diphenylphosphinylmethylurethane were obtained by the Lossen reaction, which has a mechanism similar to those described above, in 20 and 29% yields respectively [9]:

$$\begin{aligned} &Ph_2P(O)CH_2C(O)NHOH \xrightarrow{(EtO)_3CH} Ph_2P(O)CH_2NCO \rightarrow \\ &\xrightarrow{EtOH,H_2O} [Ph_2P(O)CH_2NH]_2CO + Ph_2P(O)CH_2NHCOOEt . \end{aligned} \quad (4)$$

The Beckmann rearrangement has been used to synthesise *N*-acyl-$\alpha\alpha$-dimethyl-β-aminoethyldiphenylphosphine oxides [10,11]:

$$R{-}\underset{\underset{NOH}{\diagdown}}{C}{-}CH_2CMeP(O)Ph_2 \xrightarrow{\text{polyphosphoric acid or } PCl_5} R{-}CONHCH_2CMe_2P(O)Ph_2 , \quad (5)$$

where R = Me, or $Ph_2P(O)CMe_2CH_2$.

Other methods of synthesis of the substances under consideration are based on the reduction of nitrogen-containing organic compounds of phosphorus. Thus α-aminobenzylphosphonic acid has been obtained[12,13] in yields up to 50% by the reduction of the *p*-nitrophenylhydrazone of diethyl benzoylphosphonate with sodium sulphide or, better, with aluminium amalgam and subsequent hydrolysis:

$$p\text{-}NO_2C_6H_4NH-N=\underset{\underset{Ph}{|}}{C}-P(O)(OEt)_2 \xrightarrow[2)\ HCl,H_2O]{1)\ Na_2S\ or\ Al/Hg} H_2NCHPO_3H_2 \cdot \quad (6)$$
$$\qquad\qquad\qquad

have been introduced into the reaction with potassium phthalimide in dimethylformamide:

$$\longrightarrow (H_2NCH_2)_nP(O)Ph_{3-n}\cdot \qquad (13)$$

(n = 2, 3; X = Cl; n = 1, X = OTs)

The corresponding phthalimidomethylphosphine oxides, which are formed in 46–81% yields, can be readily converted by treatment with hydrazine into aminomethylphosphine oxides in 70–95%.

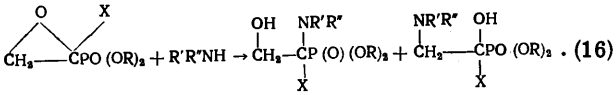
Phosphonoethylation of the sodium derivative of diethyl β-acetamidomalonate led after hydrolysis to γ-amino-γ-carboxypropylphosphonic acid in 46% yield [1]:

$$BrCH_2CH_2P(O)(OEt)_2 + Na^+C^-(COOEt)_2NHCOMe \rightarrow$$
$$\rightarrow (EtO)_2P(O)CH_2CH_2C(NHCOMe)(COOEt)_2 \xrightarrow{H^+,H_2O} H_2O_3PCH_2CH_2CH(CO_2H)NH_2 . \qquad (14)$$

The addition of amines to vinylphosphonates constitutes a specific method for the synthesis of β-aminoalkylphosphonates [57,61,63,74–79]. Thus the corresponding diethyl β-aminoethylphosphonates have been obtained in 53–83% yields by the reaction of diethyl vinylphosphonate with a number of amines in the presence of sodium ethoxide as the catalyst or in its absence on heating [74,76]:

$$CH_2{=}CH{-}P(O)(OEt)_2 \xrightarrow{HNR_2} R_2NCH_2CH_2P(O)(OEt)_2 , \qquad (15)$$

where R = H or Me and $R_2 = (CH_2)_2$ or $(CH_2)_5$. The esters of vinylphosphonothioic acid [80], the amides of vinylphosphonic and vinylphosphonothioic acids [81], acid esters of vinylphosphonous acid, vinylphosphonites [82], vinylphosphinates, vinylphosphines [82–84], vinylphosphine oxides [83–86], and trialkyl(aryl)vinylphosphonium salts [87–89] have also been used in this reaction. In all cases, the amino-group adds to the β-carbon atom of the vinyl group and an increase of the electron-donating properties of the substituents at the phosphorous atom significantly reduces the rate of reaction. The addition of lithium amides to diphenylvinyl- and diphenylallyl-phosphines, 1-phenylphosphorin-3-ene and 3,4-dimethyl-1-phenyl-3-phospholene also leads after hydrolysis to β-aminoalkylphosphines [90]. Epoxyethylphosphonates and the corresponding diphosphonates readily react with amines to form mixtures of 1-amino-2-hydroxy- and 2-amino-1-hydroxy-isomers [91,92]:



(X=H, P(O)(OR)$_2$)

Phosphonates with an active methylene group readily add to azomethines in the presence of acid or basic catalysts with formation of β-aminoalkylphosphonates [93–98]. The yields obtained by this method [93,94], which resembles the first stage of the addition of olefins to the P–O group, amount to 32–88%:

$$RCH_2P(O)(OR')_2 + PhCH{=}NAr \xrightarrow{R_2NNa} ArNHCH(Ph)CH(R)P(O)(OR')_2 . \qquad (17)$$

(R=Ph, COOEt CN; R'=Et, *i*-Pr; Ar=Ph, C_6H_4Cl-*p*,*m*, C_6H_4OMe-*p*, *m*)

Diphenylbenzylphosphine oxide reacts similarly with Schiff bases [99]. Alkylation of benzylphosphonate carbanions with dialkyl-2-chloroethylamines yielded the corresponding α-(γ'-aminopropyl)-α-phenylphosphonates [100]:

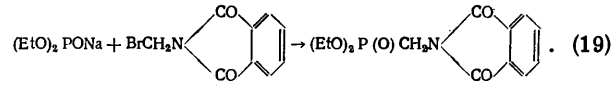
$$PhCH_2P(O)(OEt)_2 \xrightarrow[2.\ R_2N(CH_2)_2Cl]{1.\ NaNH_2} PhCH(C_2H_4NR_2)P(O)(OEt)_2 . \qquad (18)$$

2. Aminoalkylation of Phosphorus Compounds with Formation of Phosphorus–Carbon Bonds

A common feature of this group of methods for the formation of aminoalkyl organophosphorus compounds is the employment of phosphorus(III) compounds, including tautomeric P–H acids, as one of the reactants. The mechanisms of these reactions probably resemble those of Michaelis–Becker and Arbuzov reactions and the addition of phosphorus(III) compounds to systems with multiple bonds, which are widely used in phosphorus chemistry.

The Michaelis–Becker and Arbuzov Reactions

The reactions of dialkyl phosphites and sodium or potassium phosphites with ω-halogenoalkylamines and the corresponding amides proceed via the usual Michaelis–Becker mechanism and lead to the corresponding ω-aminoalkylphosphonates [5,55,101–105]. Thus diethyl phthalimidomethylphosphonate was obtained in 40% yield by the reaction of sodium diethyl phosphite with *N*-bromomethylphthalimide [101]:

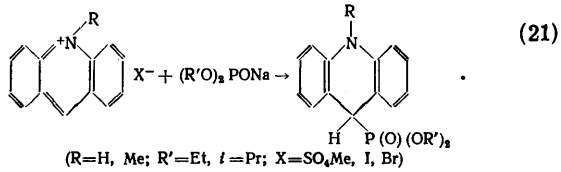


The more reactive α-chloroalkylamines can react directly with dialkyl phosphites to form the hydrochlorides of aminophosphonates in 47–95% yields [102,106]:

$$R_2NCH(R')Cl + (R''O)_2PHO \rightarrow R_2NCH(R)P(O)(OR'')_2 \cdot HCl , \qquad (20)$$

where $R_2 = (CH_2)_4$ or $(CH_2)_5$, R' = H, Et, i-Pr, or $CONC_5H_{10}$, and R'' = Me or Et.

The reaction of diaryl phosphites with diphenylbromoethyl isocyanate in the presence of triethylamine led to the formation of diaryl isocyanatodiphenylmethylphosphonates [107] in 32–88% yields. Sodium dialkyl phosphites readily react with acridinium salts to form dihydroacridylphosphonate esters [108] (yield 63–68%):



(R=H, Me; R'=Et, *i*=Pr; X=SO_4Me, I, Br)

The reaction of lithium, potassium, sodium, and magnesium phosphides with ω-chloroalkylamines has been proposed as a general method for the synthesis of ω-aminoalkylphosphines [109–116]. 2-Diethylaminoethyldialkyl(phenyl)phosphines have been obtained in this way in 40–65% yields [110]:

$$Et_2NCH_2CH_2Br + MPR_2 \rightarrow Et_2NCH_2CH_2PR_2 \cdot$$
$$(M=Li, K;\ R=Et, Ph, C_6H_{11}\text{-cyclo.}) \qquad (22)$$

The Arbuzov reaction is widely used for the synthesis of aminoalkyl organophosphorus compounds. Triethyl phosphite readily reacts with *N*-chloromethylpiperidine to form piperidinomethylphosphonate in 52% yield [117]:

$$(EtO)_3P + ClCH_2NC_5H_{10} \rightarrow (EtO)_2P(O)CH_2NC_5H_{10} + EtCl . \qquad (23)$$

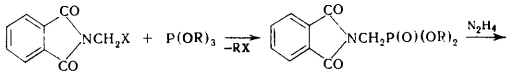
Aminoalkylation of neutral phosphites by halogenoalkyl amines has been used successfully to synthesise aminoalkylphosphonates with various functional groups [103,104,106,118–123]: aminomethyltriphosphonates were obtained in

71–77% yield by the reaction of trichloromethylamines with triethyl phosphite in chloroform at −40°C:[121]

$$3\,(EtO)_3P + R_2NCCl_3 \xrightarrow{CHCl_3,\,-40^\circ} [(EtO)_2P(O)]_3CNR_2 + 3\,EtCl \qquad (24)$$

where R = Me and $R_2 = (CH_2)_5$.

The reaction of *N*-halogenomethylphthalimides with trialkyl phosphites gave rise to the formation of phthalimidomethylphosphonates in 82–94% yields[55,124–128]. Treatment of the latter with hydrazine leads to aminomethylphosphonates:



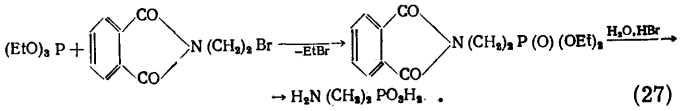
$$\longrightarrow H_2NCH_2P(O)(OR)_2\,. \qquad (25)$$

(X = Cl, Br; R = Me, Et)

When dialkyl phosphonites and alkyl phosphinites are used instead of trialkyl phosphites, the products are aminoalkylphosphinic acids and aminoalkylphosphine oxides[129–131]. The reactions of chloromethyl isocyanate with trialkyl phosphites and alkyl phosphinites takes place similarly. Isocyanatomethylphosphonates and isocyanatomethylphosphine oxides were obtained by this procedure in 7–40% yields[132]:

$$R_2P(OR') + ClCH_2NCO \rightarrow R_2P(O)CH_2NCO + R'Cl\,. \qquad (26)$$
(R=OR', Pr)

Dialkyl phosphorochloridites and phosphorofluoridites and alkyl phosphorodichloridites and phosphorodifluoridites also react with chloromethyl isocyanate[133–135]. When di- and tri-chloromethyl isocyanates instead of chloromethyl isocyanate are used in the reaction with phosphites, products phosphorylated to different extents are obtained, depending on the ratio and reactivities of the reactants[135–138]. The method has been used also to synthesise ω-aminoalkylphosphonates[12,55,105,139–141]: 2-aminoethylphosphonic acid has been synthesised in 50% yield by the reaction of *N*-(2-bromoethyl)phthalimide with triethyl phosphite and subsequent hydrolysis[12]:

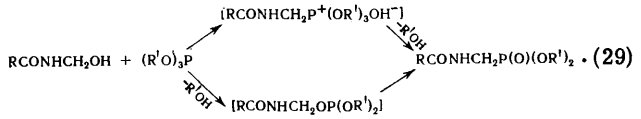


$$\rightarrow H_2N(CH_2)_2PO_3H_2\,. \qquad (27)$$

Apart from halogenoalkylamines and the corresponding amides, *N*-trimethylammoniummethylformamide[142], *N*-acetoxymethylamides[143], and the corresponding amines[144] have also been introduced into this reaction. Trialkyl phosphites[142,143], triphenyl phosphite, and phosphorous hexaethyltriamide[144] have been used as the phosphorus-containing components. In the reactions with triphenyl phosphite and phosphorous hexaethyltriamide the desired products were isolated in 54 and 73% yields respectively:

$$PX_3 + MeCOOCH_2NEt_2 \rightarrow [X_3P^+CH_2NEtMeCOO^-] \rightleftarrows [X_3P^+CH_2NEt_2(OCOMe)\,X^-] \rightarrow$$
$$\rightarrow X_3P(O)CH_2NEt_2 + MeCOX\,. \qquad (28)$$
(X=OPh, NEt_2)

N-Hydroxymethylamides are also capable of aminoalkylating trialkyl phosphites at 100–160°C with a 30–59% yield of the desired products[145,146]. It is suggested that under these conditions the phosphite is either alkylated directly or there is a preliminary transesterification and a subsequent Arbuzov rearrangement[145]:



(R = Me, Ph; R' = Me, Et, Pr, Bu)

A mixture of an amide and paraformaldehyde can be introduced into the reaction instead of *N*-hydroxymethylamides[147]. Aminophosphonates have been obtained under the same conditions from secondary amines, aldehydes, and trialkyl phosphites in 21–94% yields[147–150]:

$$RR'NH + R''CHO + (R'''O)_3P \rightarrow RR'NCH(R'')P(O)(OR''')_2 + R'''OH\,, \qquad (30)$$

where R and R' = Me or Et, RR' = $(CH_2)_5$, R'' = H or Ph, and R''' = Et, Pr, or Bu.

In the presence of acetic acid at 100–160°C trialkyl phosphites are capable of being aminomethylated by aminoacetals of formaldehyde and by diethylaminoacetonitrile[151,152]:

$$(RO)_3P + R'R''NCH_2X \xrightarrow{MeCOOH} R'R''NCH_2P(O)(OEt)_2 + MeCOOEt + HX\,. \qquad (31)$$
(X=CN, OR; R=Me, Et, Pr, Bu; R', R''=Me, Et, Ph)

The yields of aminophosphonates are 50–65%. The authors believe[151,153] that the role of acetic acid reduces either to an increase of the polarity of the medium, which promotes the ionisation of the aminoalkylating agent, or to transesterification of the latter and a subsequent reaction of type (28).

N-Aminomethyl- and *N*-alkoxymethyl-amides of carboxylic acids are also capable of reacting under these conditions with trialkyl phosphites to form carbamoylmethylphosphonates in 52–85% yields[153,154].

N-Aminomethylamides of carboxylic acids containing a hydrogen atom at the amide nitrogen atom readily react with trialkyl phosphites also in the absence of acetic acid, forming acetamidomethylphosphonates[154] (50–70%); a secondary amine and an alcohol have been isolated as side products:

$$RCONHCH_2NR'_2 + P(OR'')_3 \rightarrow RCONHCH_2P(O)(OR'')_2 + HNR'_2 + R''OH + R''NR'_2\,, \qquad (32)$$

where R = Me, Ph, or $CH_2{=}C(CH_3)$–, R' = Me or Et, and R'' = Et or Bu.

The authors suggest that this is caused by acid catalysis due to the imidine form (I).

In the presence of acid agents, trialkyl phosphites are capable of being aminoalkylated by Schiff bases[155,156]. Thus trialkyl phosphites react with benzylideneaniline in the presence of phenol at 100–130°C, giving rise to 20–30% yields of aminophosphonates[155]:

$$(RO)_3P + ArN{=}CHPh \xrightarrow{PhOH} (RO)_2P(O)CH(Ph)NHAr + PhOR\,. \qquad (33)$$
(Ar=Ph, C_6H_4Me-*p*; C_6H_4Cl-*m*; R=Et, Pr).

When aminoacetals are treated with PCl_3, aminoalkylphosphonates are also formed ultimately[157,158]. It is suggested that the reaction proceeds via the formation of α-chloromethylamine and a phosphite[157]:

$$3\,R'_2NCH_2OR + PCl_3 \rightarrow 3\,R'_2NCH_2Cl + P(OR)_3\,, \qquad (34)$$
$$P(OR)_3 + R'_2NCH_2Cl \rightarrow R'_2NCH_2P(O)(OR)_2 + RCl\,,$$

where R = Et, R' = Et, and $R'_2 = (CH_2)_5$.

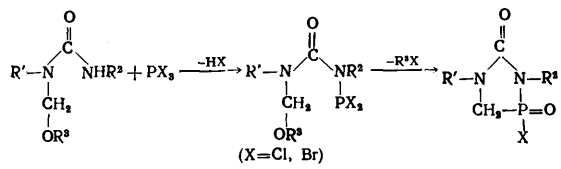
The occurrence of the first stage was demonstrated by the isolation of α-chloromethylamines[117]. Phosphorochloridites[119,159] and chlorophosphines react similarly with aminoacetals[160]. An analogous mechanism probably

operates in the reactions of diaminals and aminoacetals of formaldehyde with mixed anhydrides of diethylphosphorus acid on the one hand and acetic, benzoic, and diethylphosphoric acids on the other and with tetraethyl pyrophosphite [161]:

$$(EtO)_2POY + R_2NCH_2X \rightarrow X(EtO)P(O)CH_2NR_2 + YOEt\ , \qquad (35)$$

where Y = COMe, COPh, $P(OEt)_2$, or $P(O)(OEt)_2$, X = OBu, NMe_2, or NEt_2, R = Me, and $R_2 = (CH_2)_5$. The yields of aminophosphonates in these reactions amount to 43–65%.

1,3-Dialkyl-4-halogeno-2,4-dioxo-1,3,4-diazaphospholans have been obtained in 40–86% yields by the reaction of phosphorus trihalides with *NN'*-dialkylalkoxyalkylureas [162]:



(X=Cl, Br) . (36)

The reaction of *N*-hydroxymethylamides with phosphorus trichloride, which probably proceeds via the formation of the corresponding phosphorochloridite and its rearrangement, leads to amidomethylphosphonic acids after hydrolysis [101,163–167] (yields 20–34%):

$$RCON(R')CH_2OH + PCl_3 \rightarrow [RCON(R')CH_2OPCl_2] \rightarrow$$

$$\rightarrow [RCON(R')CH_2P(O)Cl_2] \xrightarrow{H_2O} RCON(R')CH_2PO_3H_2\ , \qquad (37)$$

where R = Me, $Me(CH_2)n$ (n = 10–16), or β-pyridyl and R' = H, alkyl, or aryl.

The reaction of diethyl phosphorochloridite and chlorodiphenylphosphine with *N*-hydroxymethylamidine, which is similar to those already discussed, leads to amidomethylphosphonates and amidomethylphosphine oxides in yields up to 80% [37,145]:

$$R_2PCl + HOCH_2NHCOR' \xrightarrow{NEt_3} R_2P(O)CH_2NHCOR'\ . \qquad (38)$$

(R=OEt, Ph; R'=Me, Ph)

The reaction of dialkyl phosphorochloridites with 4-(*NN*-diethylamino)but-2-yn-1-ol in the presence of bases proceeds with isomerisation and the formation of dialkyl-(α-*NN*-diethylaminomethyl)allenylphosphonates [168,169]:

$$(RO)_2PCl + HOCH_2C\equiv CCH_2NEt_2 \xrightarrow[-NR_3\cdot HCl]{NR_3} [(RO)_2POCH_2C\equiv CCH_2NEt_2] \rightarrow$$

$$\rightarrow CH_2=C=CP(O)(OR)_2\ . \qquad (39)$$

$$\quad\quad CH_2NEt_2$$

(R=Et, Pr)

The α-aminoalkylation of tertiary phosphines, leading to α-aminoalkylphosphonium salts, can be carried out only when effective α-aminoalkylating agents, such as α-halogenoalkylamines and the corresponding amides [102,170–173] and ureas [174,175], are used:

$$R_2NCH(R')X + R''_3P \rightarrow R_2NCH(R')P^+R''_3X^-\ . \qquad (40)$$

The yields of the α-aminoalkylphosphonium salts are 40–98%.

Reactions of Dialkyl Phosphites and Their Analogues with Amines and Carbonyl Compounds

In 1952 Kabachnik and Medved' [176] and Fields [177] proposed independently a new general method for the synthesis of α-aminophosphonates by the reaction of dialkyl phosphites and aldehydes or ketones† with ammonia (Kabachnik and Medved') and amines (Fields):

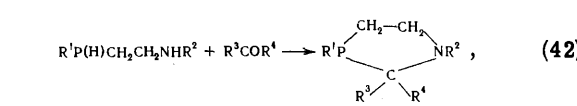
$$(RO)_2PHO + HN\langle + \rangle C=O \rightarrow (RO)_2P(O)\overset{|}{\underset{|}{C}}-N< + H_2O\ . \qquad (41)$$

Aminophosphonates are obtained after only brief heating of the reactants in solvents (water, alcohol) or in their absence. The yields of aminophosphonates vary within wide limits and depend on the structures of the initial reactants. The desired products are isolated from the reaction mixture by distillation in the form of hydrochlorides or picrates.

By varying the amines, aldehydes, ketones, and the phosphorus-containing component, it is possible to obtain by this method a wide variety of α-aminoalkyl phosphorus-containing compounds. The following amines (or ammonia) were introduced into the reaction: ammonia [176,178–189]‡, aliphatic primary and secondary amines [86,177,180,187,190–202], aromatic and heterocyclic amines [177,203–207], alkylenediamines and alkylenepolyamines [78,208–213], and hydroxyalkylamines [214–221].

$$(EtO)_2PHO + CH_2O + NH_3 \rightarrow [(EtO)_2P(O)CH_2]_2NH + [(EtO)_2P(O)CH_2]_3N\ .$$

Aziridine [57] and carboxamides [147] could not be made to undergo this reaction. Formaldehyde [86,214][114 ? (Ed. of Translation)] [177,180,187,190–193,195–197,199–204,209,211,218,219,221] as a 40% aqueous solution or paraformaldehyde, aliphatic and alicyclic aldehydes and ketones [78,177,178,180,181,183,186,188,194,199,206–208,210–213], and aromatic and heterocyclic aldehydes and ketones [176,178,179,183,185,189,190,205,210] have been used as the carbonyl components. Apart from dialkyl or diaryl phosphites [76,176–179,181–184,187–189,194,198,199,203,204,208–214,216–222], other compounds with a phosphorus-hydrogen bond readily enter into the reaction: dialkyl phosphorothioites [186,189], monoalkyl phosphonites [211], dialkyl(aryl)-phosphine oxides [86,180,196,200], dialkylphosphine sulphides [192], hypophosphorus acid [185,193,205–207,223–227]§, and phosphines [71,115,190,195,201,228]. In all cases the reaction proceeds via mechanism (41), i.e. with formation of a product resulting from the substitution of a hydrogen atom at the phosphorus atom by an α-aminoalkyl residue. 2-Aminoethylphosphines with hydrogen atoms at nitrogen and phosphorus readily react with carbonyl compounds to form intramolecular aminoalkylation products—1,3-azaphospholidines [114,115,229,230] (yields 47–91%):



(42)

where R^1 = H, Et, Bu, or Ph, R^2 = H or Et, R^3 and R^4 = H, Me, Et, or Ph, and $R^3R^4 = (CH_2)m$ (n = 4–6) or

---

†Kabachnik and Medved' studied this reaction in relation to ketones somewhat later [178].

‡When ammonia, a primary amine, and a sterically unhindered aldehyde are used, products substituted to different extents at the nitrogen atom are obtained, depending on the reactant ratio and the reaction conditions [182,187,209,220].

§The aminoalkylation of hypophosphorous acid with a mixture of an amine and an aldehyde leads to mono- and bis-aminoalkylation products—aminoalkylphosphonic and di(aminoalkyl)phosphinic acids respectively [193,206,223]:

$$H_3PO_2 + CH_2O + R_2NH \rightarrow R_2NCH_2P(O)(H)OH \xrightarrow{R_2NH+CH_2O} (R_2NCH_2)_2POOH\ .$$

R=Me, Et; $R_2 = (CH_2)_5$, $(CH_2)_2O(CH_2)_2$; $R_2N{=}N(CH_2CH_2)_2N$.

$(CH_2)_2O(CH_2)_2$. *o*-Aminophenylphosphines[231], 3-aminopropylphenyl(butyl)phosphine[232-234], and 4-aminobutylphenylphosphines[233] react similarly with aldehydes and ketones.

Compounds containing a phosphorus–phosphorus bond are readily aminoalkylated under these conditions with formation (among other products) of mixtures of organophosphorus compounds with different degrees of aminoalkylation and oxidation of the phosphorus atom[191,197,202,235-238]. Thus the reaction of tetraphenyldiphosphine with formaldehyde and diethylamine yields diethylaminomethyldiphenylphosphine and phosphine oxide together with other products[235,236]:

$$Ph_2P{-}PPh_2 + CH_2O + HNEt_2 \xrightarrow{H_2O} Ph_2PCH_2NEt_2 + Ph_2P(O)CH_2NEt_2 + Ph_2PH + Ph_2PHO . \quad (43)$$

An even more complex mixture of products is formed in the aminoalkylation of white phosphorus[191,202,236]:

$$P_4 + CH_2O + HNR_2 \xrightarrow{H_2O} R_2NCH_2PO_2H_2 + (R_2NCH_2)_2PO_2N + (R_2NCH_2)_3PO + (R_2NCH_2)_2PH + (R_2NCH_2)_3P + (HOCH_2)_2PO_2H + HOCH_2PO_2H_2 , \quad (44)$$

where R = Me, Et, Bu, or cyclo-C_6H_{21} and R_2 = $(CH_2)_4$, $(CH_2)_5$, or $(CH_2)_2O(CH_2)_2$.

Depending on the reactant ratio and the type of amine employed, the main product (trisdialkylaminomethylphosphine oxide) is obtained in yields up to 47%.[191,236] It is believed that the dialkylhydroxymethylamine, formed from formaldehyde and a secondary amine, initially cleaves the phosphorus–phosphorus bond and then aminoalkylates the dissociation products[202,236]:

$$R_2NH + CH_2O \longrightarrow R_2NCH_2OH ,$$

$$Ph_2P{-}PPh_2 + R_2NCH_2OH \longrightarrow \begin{matrix} Ph_2P{-}PPh_2 \\ | \quad\quad | \\ R_2NCH_2{-}O{-}H \end{matrix} \longrightarrow$$

$$\longrightarrow Ph_2POCH_2NR_2 + Ph_2PH , \quad (45)$$

$$Ph_2POCH_2NR_2 \xrightarrow{+H_2O} Ph_2PHO + HOCH_2NR_2 ,$$

$$Ph_2PHO + HOCH_2NR_2 \longrightarrow Ph_2P(O)CH_2NR_2 ,$$

$$Ph_2PH + HOCH_2NR_2 \longrightarrow Ph_2PCH_2NR_2 .$$

The aminoalkylation of phosphorus acid must be considered in connection with the practical importance of aminoalkylphosphonic acids formed by this method in high yields in a single stage and readily isolated from the reaction mixture[239]:

$$H_3PO_3 + H{-}N\!\!<\!\!\!> + CH_2O \xrightarrow{H^+} H_2O_3PCH_2N\!\!<\!\!\!> + H_2O . \quad (46)$$

A significant difference between the method for the aminoalkylation of phosphorous acid and those discussed above is that a satisfactory reaction is achieved only in strongly acid media (pH 1–3). The reaction is carried out with heating to 120–150°C in the course of 1–2 h and goes a most to completion. The yields of the products of exhaustive phosphonomethylation amount to 49–96% when primary amines and polyamines are used[239]. Ammonia (in the form of ammonium salts)[239-241], primary amines[239,242-245], ethanolamine[239,246], glycine[239,247], diethanolamine[239,246], iminodiacetic acid[239,247], alkylenediamines[239,248], polyethyleneimines[245], and other amines[78,250-254] were used in the reaction. Apart from formaldehyde (in the form of the 40% solution), other aldehydes and ketones can be made to react[242-244,250-253,255,256]. A promising method for the aminomethylation of phosphorous acid is its reaction at 100–160°C with aminopolyacetic acids[257-259]. For example, nitrilotri(methylphosphonic) acid was obtained in 93% yield by heating phosphorous acid with nitrilotriacetic acid[259]:

$$N(CH_2COOH)_3 + H_3PO_3 \xrightarrow{160^\circ} N(CH_2PO_3H_2)_3 . \quad (47)$$

In the presence of phosphorus trichloride, the reaction proceeds under milder conditions.

Two views have been expressed about the mechanism of reaction (41), which in many respects resembles the Mannich reaction[260]. One of these is based on a study of the reactions of diethyl phosphite with benzaldehyde and ammonia: it is suggested that in the first stage the dialkylphosphite adds to the carbonyl compound [reaction (48a)] under the influence of the catalyst (ammonia) and then the hydroxy-group in the α-hydroxyalkylphosphonate is substituted by the amino-group[179,180] [reaction (48b)].

$$(RO)_2PHO + R'R''CO \xrightarrow{NH_3} (RO)_2P(O)CR'R''OH , \quad (48a)$$

$$(RO)_2P(O)CR'R''OH + NH_3 \rightarrow (RO)_2P(O)CR'R''NH_2 + H_2O . \quad (48b)$$

This hypothesis was put forward because the main product of the reaction of diethyl phosphite with ammonia and benzaldehyde in the cold is α-hydroxybenzylphosphonate $(EtO)_2P(O)CH(Ph)OH$; the formation of α-aminobenzylphosphonate $(EtO)_2P(O)CH(Ph)NH_2$ is observed only on heating the reaction mixture[179]. Stage (48a) constitutes the addition of dialkyl phosphites to carbonyl compounds in the presence of a base (in the present case ammonia), which has been thoroughly investigated[261]. The possibility of the second stage—the nucleophilic substitution of the hydroxy-group by the amino-group—has been demonstrated by the formation of α-aminobenzylphosphonate on heating α-hydroxybenzylphosphonate with an alcoholic solution of ammonia[179].

The second view is based on the reaction of dialkyl phosphites with formaldehyde and secondary amines; it is suggested that the first stage involves the addition of the amine to formaldehyde with formation of hydroxymethylamine [reaction (49a)] and the subsequent interaction of the latter with the dialkyl phosphite, leading to the dialkylaminomethylphosphonate[177] [reaction (49b)]:

$$R_2NH + CH_2O \rightleftarrows R_2NCH_2OH , \quad (49a)$$

$$(R'O)_2PHO + R_2NCH_2OH \rightarrow (R'O)_2P(O)CH_2NR_2 + H_2O . \quad (49b)$$

This hypothesis arose in view of the absence of the exchange of the hydroxy-group for the dialkylamino-group on heating diethyl hydroxymethylphosphonate with diethylamine[177]. The possibility of stage (49b) was demonstrated by the formation of aminophosphonates in high yields on reaction of dialkyl phosphites with bisaminals and aminoacetals of formaldehyde[177,198]:

$$R_2NCH_2X + (EtO)_2PHO \rightarrow R_2NCH_2P(O)(OEt)_2 + HX . \quad (50)$$
$$(R=Et, i\text{-}Pr, Bu;\ X=OMe, NR_2)$$

Thus on the basis of this mechanism the reaction can probably be regarded as a process of the Michaelis–Becker type in which the amine catalyses the formation of a highly nucleophilic dialkyl phosphite anion and the dissociation of α-hydroxyalkylamines at the C–O bond leads to a stable carbonium–immonium ion[262-264]:

$$R_2N{-}CH_2OH \rightleftarrows [R_2N{-}CH_2^+ \longleftrightarrow R_2N^+{=}CH_2] + OH^- , \quad (51)$$

$$(R'O)_2P(O)H \overset{B}{\rightleftarrows} [(R'O)_2PO]^- + BH^+ ,$$

$$[(R'O)_2PO]^- + R_2N^+{=}CH_2 \rightarrow (R'O)_2P(O)CH_2NR_2 .$$

There are at present no data for the mechanism of the reactions of phosphorous acid with formaldehyde and

amines [reaction (46)] in a highly acid medium. One can only suppose that in this case the aminoalkylating species is the carbonium-immonium ion and the object of electrophilic attack is phosphorous acid [containing phosphorus(III)], the reversible formation of which is promoted by the high acidity of the medium.

In conclusion one should note that, despite the conflict between mechanisms (48) and (49) although there is evidence in support of each), the proposed versions of reaction (41)—amination of the α-hydroxyalkyl organophosphorus compounds [reaction (48)] and aminoalkylation of organophosphorus compounds with a phosphorus–hydrogen bond by aminoacetals and bisaminals [reaction (50)]—are of preparative value. The first version—the amination of α-hydroxyalkylorganophosphorus compounds¶—has been investigated mainly for hydroxymethyl derivatives of phosphines and for hydroxymethylphosphonium salts. The value of this method is due to the availability of such compounds, which obviates the necessity for the employment of the relatively inconvenient phosphines: heating of hydroxymethylphosphines with diethylamine in a sealed tube at 150–160°C for 8 h leads to diethylaminoethylphosphines in 57–88% yields [265]:

$$Pr_nP(CH_2OH)_{3-n} + (3-n)\,Et_2NH \rightarrow Pr_nP(CH_2NEt_2)_{3-n} + (3-n)\,H_2O\,. \quad (52)$$

When tri(hydroxymethyl)phosphine is treated with aniline under the conditions of azeotropic distillation of water, tri-(*N*-phenylaminomethyl)phosphine is formed in 81% yield [266]:

$$P(CH_2OH)_3 + 3\,PhNH_2 \rightarrow P(CH_2NHPh)_3 + 3\,H_2O\,. \quad (53)$$

Acetoxymethylphosphines can be used in the reaction instead of hydroxymethylphosphines. In this case the reaction is carried out in an aqueous or aqueous alcoholic medium in the presence of potassium hydroxide and involves the preliminary hydrolysis of the acetoxymethylphosphines to the corresponding hydroxymethylphosphines [267,268]. An advantage of this method compared with those described above is the ease of the purification of the initial acetoxymethylphosphines, which has a significant influence on the purity of the desired products [267]. The use of hydroxymethylphosphonium salts instead of hydroxymethylphosphines leads to aminomethylphosphines [269,270]. This method is used also to synthesise aminomethylphosphine oxides: diethylaminomethyldiphenylphosphine oxide was obtained in a quantitative yield by heating hydroxymethyldiphenylphosphine oxide with diethylamine [271]:

$$Ph_2P(O)CH_2OH + HNEt_2 \rightarrow Ph_2P(O)CH_2NEt_2 + H_2O\,. \quad (54)$$

There are patent data concerning the condensation of hydroxymethylphosphonium salts and tri(hydroxymethyl)-phosphine oxide with amines to form high-molecular-weight compounds [272–274].

The second version of reaction (41) (aminoalkylation of compounds with a phosphorus–hydrogen bond by bisami als and aminoacetals) has also found applications in the synthesis of a wide variety of aminoalkyl derivatives of phosphorus. The high yields of the desired substances, the absence from the reaction mixture of water which is difficult to remove, and the possibility of employing aminals with different functional groups make this synthetic procedure extremely useful and in many cases the only one possible. Aminophosphonoacetate esters have been obtained in yields of 73–82% from the aminoacetals of glyoxylic acid esters [106]:

$$R_2NCHCOOMe + (EtO)_2PHO \rightarrow (EtO)_2P(O)CHCOOMe + MeOH\,. \quad (55)$$
(OMe; NR$_2$)

(R=Me; R$_2$= (CH$_2$)$_5$)

The reaction of the dimethylacetal of dimethylformamide with diethyl phosphite leads to a 62% yield of aminomethylenediphosphonate [275,276]:

$$Me_2NCH(OMe)_2 + 2\,(EtO)_2PHO \rightarrow [(EtO)_2P(O)]_2CHNMe_2 + 2\,MeOH\,. \quad (56)$$

Cyclic bisaminals and aminoacetals readily react with dialkyl phosphites, forming aminophosphonates containing amino- and hydroxyalkyl substituents at the nitrogen atom [277–280]:

$$(EtO)_2PHO + \begin{array}{c} CH_2-X \\ | \\ CH_2 \\ \diagdown \\ N \\ \diagup \\ R' \end{array} \begin{array}{c} | \\ CHR \end{array} \rightarrow (EtO)_2P(O)CH(R)N(R')CH_2CH_2XH\,. \quad (57)$$

(R=H, Me; R'=H, CH$_2$CH$_2$OH; X=O, NH)

Aminoalkylphosphonamides were obtained by this method from phosphoramidites in 35–79% yields [281–283]:

$$(R_2N)_2PHO + (R'_2N)_2CHR'' \xrightarrow{Na} (R_2N)_2P(O)CH(R'')NR'_2 + R'_2NH\,. \quad (58)$$
(R=Me, Et, Bu; R$_2$= (CH$_2$)$_5$; R'=Me, Et; R''=H, Ph)

Apart from dialkyl phosphites and phosphorodiamidites, hypophosphite esters [284,285], dialkyl(aryl)phosphine oxides [180,286], alkylphosphonous and phosphonothious acids [287], and phosphines [265] react readily with bisaminals and aminoacetals.

The Addition of Compounds with a Phosphorus–hydrogen Bond to Multiple Carbon–nitrogen and Carbon–carbon Bonds

Dialkyl phosphites readily add to aromatic Schiff bases, forming α-aminoalkylphosphonates in 67–91% yields [288,289]:

$$(RO)_2PHO + ArHC{=}NAr' \rightarrow (RO)_2P(O)CH(Ar){-}NHAr'\,. \quad (59)$$

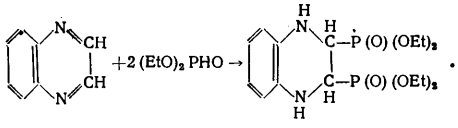
The reaction proceeds slowly even when the reactants are mixed in the cold in the absence of a solvent and is rapid in the presence of catalytic amounts of alkali metal alkoxides [288,289] or acids (HCl, $SnCl_2$) [290–293] in alcohol. When carefully purified reactants are used, the desired products can be obtained in nearly quantitative yields by the reaction without a solvent and without heating [294].

The above method of synthesis is of undoubted interest, although its applications are limited to the formation of *N*-monosubstituted α-aminoalkyl derivatives of phosphorus. Its usefulness is primarily due to the ready availability of the aromatic Schiff bases and the high yields of the desired products.

Under the conditions described above, dialkyl phosphites readily add not only to Schiff bases obtained from aromatic amines, aldehydes, and ketones [288–299] but also to those synthesised from aromatic amines and heterocyclic aldehydes [300–303], from heterocyclic amines and aromatic aldehydes [304,305], from aliphatic amines and diamines and aromatic aldehydes [306–311], and from aliphatic amines and aldehydes [310,312–314]. Certain heterocyclic compounds containing multiple carbon–nitrogen bonds are capable of combining with dialkyl phosphites to form phosphorus-containing heterocycles [315,316]. For example,

¶ This method is probably not general, since in many cases the corresponding α-aminoalkyl compounds could not be obtained by treating hydroxyalkyl organophosphorus derivatives with amines [177,185,196].

the addition of two dialkyl phosphite molecules to quinoxaline in sodium ethoxide leads to 1,4-dihydro-2,3-bis-(diethoxyphosphinyl)quinoxaline in 77% yield[315]:



(60)

Imines containing functional groups at the nitrogen and carbon atoms also readily combine with dialkyl phosphites, forming α-aminoalkyl phosphonates with different functional groups in 23–84% yields[317–320]†:

$$PhN{=}CXY + (RO)_2PHO \rightarrow PhNHC(X)(Y)P(O)(OR)_2 , \quad (61)$$

where X = H, P(O)(OEt)$_2$ or P(O)Ph$_2$ and Y = P(O)(OEt)$_2$ or P(O)Ph$_2$.

The synthesis of optically active α-aminobenzylphosphonic acid by the addition of diethyl phosphite to the Schiff base derived from benzaldehyde and α-phenylethylamine enantiomers has been described. The reaction proceeds with asymmetric induction; subsequent hydrolysis and hydrogenolysis of the addition product resulted in the formation of the enantiomers of α-aminobenzylphosphonic acid[322]‡:

$$PhCHO + PhC^*H(Me)NH_2 \rightarrow PhCH{=}NC^*H(Me)Ph \xrightarrow{(EtO)_2PHO} \underset{(II)}{\rightarrow (EtO)_2P(O)C^*HPhNHC^*HMePh} \xrightarrow{HCl,\ H_2O} H_2O_3PC^*HPhNHC^*HMePh \xrightarrow{H_2,\ Pd/C} \rightarrow H_2O_3PC^*HPhNH_2 . \quad (62)$$

$[\alpha]_D = -18{,}1°$ [from (+) - II];
$[\alpha] = +18{,}1°$ [from (−) - II].

Apart from dialkyl phosphites, other organophosphorus compounds with a phosphorus–hydrogen bond readily add to azomethines: diaryl phosphites[291,324–326]; monoalkyl phosphites[327], dialkyl phosphorothioites[328–332], phosphorodiamidites[281], hypophosphorous acid[205,206,227,333–336], alkylphosphonites[337], dialkyl(aryl)phosphine oxides[180,318,320] and sulphides[338,339], dialkyl(aryl)phosphines[318,340], and triphenylphosphine hydrobromide[318]. Instead of diaryl phosphites, the more readily available triaryl phosphites can be introduced into the reaction in the presence of water and hydrochloric acid[341]. The imides of α-aminoalkylphosphonates have been synthesised in 36–95% yields by the addition of the anilides and phenylhydrazides of dialkylphosphorous acids to Schiff bases[342–345]:

$$(EtO)_2PNHX + PhCH{=}NC_6H_4R \rightarrow (EtO)_2P(=NX)CH(Ph)NHC_6H_4R . \quad (63)$$
(R=H, Me, NO$_2$; X=C$_6$H$_4$R, NHC$_6$H$_4$R)

α-Aminoalkyl organophosphorus compounds are formed also following the addition of compounds with a phosphorus–hydrogen bond to enamines[346–348]; for example, the reaction of diphenylphosphine oxide with 2-dialkylaminovinyldiphenylphosphine oxides resulted in the formation of tetraphenyldialkylaminoethylenediphosphine dioxides in 67–75% yield[347]:

$$Ph_2P(O)CH{=}CHNR_2 + Ph_2PHO \rightarrow Ph_2P(O)CH_2CH(NR_2)P(O)Ph_2 . \quad (64)$$
(R=Me, Et)

It is noteworthy that the mode of addition to 1-acetamidoacrylic acid is determined by the presence of an electron-accepting substituent and leads after hydrolysis to β-amino-β-carboxyethylphosphonic acid in 50% yield[1]:

$$CH_2{=}\underset{NHCOMe}{C}{-}COOH + P(OMe)_3 \rightarrow CH_2{=}\underset{NHCOMe}{C}COOMe + (MeO)_2PHO \rightarrow \rightarrow (MeO)_2P(O)CH_2{-}\underset{NHCOMe}{CH}COOMe \xrightarrow{HCl,\ H_2O} H_2O_3PCH_2\underset{NH_2}{CH}COOH . \quad (65)$$

The addition of dialkyl phosphites and phosphorothioites to aziridine has been proposed as a method for the synthesis of 2-aminoethylphosphonates and 2-aminoethylphosphonothioates[349]:

$$(RO)_2PHX + \underset{NH}{CH_2{-}CH_2} \longrightarrow (RO)_2P(X)CH_2CH_2NH_2 \quad (66)$$
(X = O, S; R = Et, Pr, *i*-Pr, Bu)

Phosphine[350,351], alkyl(phenyl)phosphines[232,234,352–355], and dialkylphosphines[350] add to allylamines in the presence of radical catalysts contrary to the Markovnikov rule with formation of 3-aminopropylphosphines.

Several studies have been made on the mechanism of the addition of compounds with a phosphorus–hydrogen bond to Schiff bases. The following mechanism has been proposed for reaction (59) catalysed by alkoxides[289]:

$$(RO)_2PHO + RONa \rightleftarrows (RO)_2PONa + ROH , \quad (67)$$
$$(RO)_2PONa + R'R''C{=}NR''' \rightarrow (RO)_2P(O)C(R')(R'')N(Na)R''' ,$$
$$(RO)_2P(O)C(R')(R'')N(Na)R''' + (RO)_2PHO \rightarrow (RO)_2P(O)C(R')(R'')NHR''' + (RO)_2P(O)Na .$$
etc.

Recently this mechanism was confirmed by kinetic investigations[356]. The catalytic effect of acids in reaction (59) has been explained both by the enhancement of the electrophilicity of the Schiff base and by an increase of the dialkyl phosphite content in the reactive symmetrical [with phosphorus(III)] form[357].

The employment of an equimolar mixture of the amine and the carbonyl compound instead of the complete Schiff base[291,319,324,325], i.e. the reaction carried out under conditions analogous to those described in the preceding section, constitutes a modification of the process discussed above. This evidently shows that the methods are related: one cannot rule out the possibility of the occurrence of reactions of type (41) employing primary amines and ammonia, via a stage involving the formation of an azomethine and their subsequent course in accordance with Eqn. (59).

Synthesis of α-Aminoalkylphosphorus Derivatives by the Reaction of Phosphoramidites with Carbonyl Compounds

The full ester-amides and triamides of phosphorus(III) acids react with carbonyl compounds to form α-aminoalkylphosphorus derivatives in many instances. Such a reaction was investigated for the first time§ in relation to dialkyl *NN*-dialkylphosphoramidites, aldehydes[361], and ketones[362]. In such cases the desired products are formed in 9–53% yields[361–364]:

$$(RO)_2PNR'_2 + R''(R''')CO \rightarrow (RO)_2P(O)C(R'')(R''')NR'_2 , \quad (68)$$

where R = Pr, Bu, or Pe, (RO$_2$) = C$_2$H$_4$O$_2$, R′ = Me or Et, R″ = H, Me, or Et, R‴ = H, Et, Pr, C$_6$H$_{13}$, or Ph, and R″R‴ = (CH$_2$)$_4$ or (CH$_2$)$_5$.

†Subsequently it was concluded on the basis of spectroscopic data that the reverse order of addition obtains for X, Y = P(O)(OEt)$_2$ and P(O)Ph$_2$ [Eqn. (61)].[321]

‡Diethyl α-aminobenzylphosphonate was resolved into its enantiomers by the fractional crystallisation of its salt with dibenzoyltartaric acid[323].

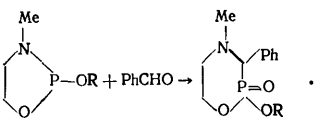
§The formation of an adduct in the reaction of *o*-phenylene *N*-phenylphosphoramidite with benzaldehyde was described as early as 1959.[358,359] Later it was shown that the proposed structure of the adduct is incorrect and that the reaction product is an aminophosphonate[360].

It has been shown that reaction (68) probably does not involve the preliminary hydrolysis of the initial phosphoramidite by traces of water to the dialkyl phosphite and the amine with subsequent interaction via mechanism (41).[361] Dialkyl *N*-arylphosphoramidites[360,365], propyl *NN*-diethylphenylphosphonamidite[366,367], phosphorous triamides[364], and diphenylphosphinamidous acids[365,368] react similarly with aldehydes. Acid alkylphosphoramidites can also react with aldehydes and ketones to form the acid esters of phosphonamidic acids[369] (45–65%):

$$(RO)(R'_2N)PHO + R''(R''')CO \rightarrow HO(RO)P(O)C(R'')(R''')NR'_2, \qquad (69)$$

where R = Me, Et, Pr, or Bu, R′ = Me or Et, R″ = H or Me, R‴ = Me or Ph, and R″R‴ = $(CH_2)_5$.

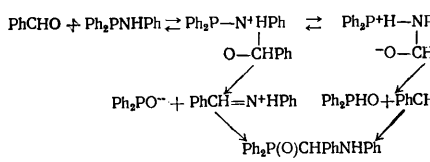
The reaction of benzaldehyde with 2-alkoxy-3-methyl-1,3,2-oxazaphospholans takes place with ring expansion and leads to 2-alkoxy-2-oxo-3-phenyl-4-methyl-1,4,2-oxazaphosphorinanes[370]:



(70)

It is noteworthy that the formation of aminophosphonates in reactions of phosphorus(III) amides and carbonyl compounds is by no means observed in all cases and frequently other processes take place[371]. This factor and also the relatively low availability of the initial amines reduce the practical value of this method.

Several hypotheses have been put forward concerning the mechanism of reaction (68). Some workers suggest a preliminary nucleophilic attack by the phosphorus atom on the carbonyl carbon atom with a subsequent series of rearrangements[360,361], while others believe, on the basis of experimental data, that nucleophilic attack by the nitrogen atom (analogous to that in the Wittig and PO–olefin addition reactions) is most likely with a subsequent rearrangement of the adduct in accordance with mechanism (71) to an aminoalkyl compound[365]:



(71)

The catalytic effect of amine hydrochlorides in reactions of type (68) can also be accounted for[364] within the framework of a mechanism analogous to mechanism (71).

Synthesis of Aminoalkyldiphosphonic Acids by the Reaction of Phosphorus(III) Trihalides with Nitriles

When nitriles are heated with phosphorus trihalides in the presence of organic and inorganic oxygen-containing acids with subsequent hydrolysis of the reaction mixture, aminoalkyldiphosphonic acids are formed[372–375]:

$$R{-}CN + P(Hal)_3 \xrightarrow[2.H_2O]{1.t^\circ} (H_2O_3P)_2C(R)NH_2. \qquad (72)$$

The desired products were obtained in yields of 28 and 51% respectively by the reaction of phosphorus tribromide with acetonitrile (R = Me) and benzonitrile (R = Ph)[374]. If instead of being hydrolysed, the reaction mixture is subjected to alcoholysis, acid esters are formed[372,373]. The reaction of cyanomethylated polystyrene copolymers with phosphorus trihalides and phosphorous acid in the presence of carboxylic acids leads after hydrolysis to phosphorus-containing complex-forming ion-exchange resins[376]. The reactions with phosphorous acid of the adducts of HCl or HBr and nitriles $[(H_2N{-}CRHal)^+Hal^-]$ or the products of the interaction of PCl_5, $COCl_2$, $(COCl)_2$, etc. with carboxamides $[(RR''N{=}CRHal)^+Hal^-]$ are modifications of the method under consideration. These also lead to aminoalkyldiphosphonic acids (4–78%); in the latter case nitrogen-substituted aminoalkyldiphosphonic acids are produced[377]. Formamides react directly with PCl_3 to form aminomethyldiphosphonic acids, which are or are not substituted at the nitrogen atom[378,379].

III. PHYSICAL AND CHEMICAL PROPERTIES

PHYSICAL PROPERTIES

The first members of the series of aminomethylphosphonates $[RR'NCH_2PO(OR'')_2$, R,R′ = H, Me, or Et and R″ = Me or Et) are soluble in water[177]; their salts (hydrochlorides, hydrobromides, and picrates) are much more soluble in water and are sparingly soluble in organic solvents (alcohol and ether). The latter properties are frequently used for their isolation and purification. Aminophosphinates and phosphine oxides are oily liquids or solids which dissolve in organic solvents and are sparingly soluble in water; they are isolated from the reaction mixture by distillation, crystallisation, or in the form of salts.

Acid esters of aminophosphonic acids and aminophosphonic and aminophosphinic acids are to some extent soluble in water and much less so in organic solvents. The surfactant properties of these compounds have been investigated[2,380]. Infrared spectroscopic and NMR data for many substances of this class have been published[3,124,201,267,320,363,381–385].

CHEMICAL PROPERTIES

The chemical properties of aminoalkyl organophosphorus compounds are determined by the presence in their molecules of the phosphorus-containing residue, the amino-group, and the methylene or methylidyne groups linked directly to nitrogen and phosphorus atoms. In many reactions these groups behave in the same way as in the corresponding compounds with a single heteroatom, exhibiting in a few instances certain chemical properties due to the mutual influence resulting from the close proximity of the nitrogen- and phosphorus-containing fragments.

Reactions Involving the Organophosphorus Fragment

One of the most important reactions involving the organophosphorus fragment is hydrolysis of α-aminoalkylphosphonic acid esters to the free acids on heating the esters with hydrochloric acid at 100–140°C for several hours:

$$H_2NC(R)(R')P(O)(OR'')_2 \xrightarrow{HCl,H_2O} H_2NC(R)(R')PO_3H_2. \qquad (73)$$

Aminoalkylphosphonic acids[178,179,181] are obtained in 35–85% yields. The hydrolysis of *N*-mono- and *N*-disubstituted α-aminoalkylphosphonates[187,203,210,386] and the analogous phosphinates[310,387], β- and γ-aminoalkylphosphonates[17,20], and ω-trialkylammoniumalkylphosphonates[388]

proceeds similarly. α-Aminoalkylphosphonothionates are converted into aminoalkylphosphonic acids under these conditions[186]. To remove hydrogen chloride from the hydrochlorides of aminoalkylphosphonic acids, the latter are treated in some cases with silver oxide and then with hydrogen sulphide[208] or epoxyalkanes[1,208].

The method described above has been used to eliminate both alkyl groups from dialkylaminoalkylphosphonates. The method involving the thermal decomposition of the hydrochlorides and hydrobromides of aminoalkylphosphonates until the complete elimination of the alkyl halide has proved convenient for the removal of only one alkyl group, i.e. for the preparation of the acid ester[389-391]. Thus acid esters were obtained in 78–97% yields by heating the hydrochlorides and hydrobromides of dialkylaminomethylphosphonates[389]:

$$R_2NCH_2PO(OR')_2 \cdot HX \rightarrow R_2NCH_2PO(OR')(OH) + RX. \quad (74)$$
(X=Cl, Br; R=Me, Et; R'=Et, Bu)

This method proved to be unsuitable for aminophosphonates containing aromatic substituents at the nitrogen atom and at the α-carbon atom owing to their complete cleavage in an acid medium. Such aminophosphonates are hydrolysed in an alkaline medium[299,392,393], since under these conditions both the esters themselves and their hydrolysis products are fairly stable[297]. The hydrolysis is usually carried out in an aqueous or alcoholic solution of alkali; the acid is isolated from the resulting salt by acidification[392,393]. It is noteworthy that in the alkaline hydrolysis of alkyl esters it is possible to obtain only the acid esters[299,392]. Phenyl esters, which are completely hydrolysed under severe conditions in an alkaline medium, are used for the synthesis of the free acids[393]:

$$ArNHCH(Ar')P(O)(OR)_2 \xrightarrow{KOH} \begin{cases} \xrightarrow{R=Alk} ArNHCH(Ar')P(O)(OR)OH \\ \xrightarrow{R=Ph} ArNHCH(Ar')PO_3H_2. \end{cases} \quad (75)$$
(Ar=Ph, *m*, *p*-C_6H_4Me; Ar'=Ph, *p*-$C_6H_4CHMe_2$)

Acid esters and acids are obtained in 63–92% yields. This method is also suitable for the synthesis of acid esters of *N*-alkylaminoalkylphosphonic acids[392]. The resulting ω-aminoalkylphosphonic acids have three dissociation constants corresponding to the protonation of the phosphonate anion in the titration with an acid (pK_1), the second dissociation of the phosphonate group (pK_2), and the dissociation of the betaine proton in the titration with alkali (pK_3):[394]

$$\begin{aligned} &H_3N^+(CH_2)_nPO_3^-H + H^+ \rightleftarrows H_3N^+(CH_2)_nPO_3H_2 \quad pK_1, \\ &H_3N^+(CH_2)_nPO_3^-H \rightleftarrows H_3N^+(CH_2)_nPO_3^{2-} + H^+ \quad pK_2, \\ &H_3N^+(CH_2)_nPO_3^{2-} \rightleftarrows H_2N(CH_2)_nPO_3^{2-} + H^+ \quad pK_3. \end{aligned} \quad (76)$$
(n=1, 2, 4, 5, 10)

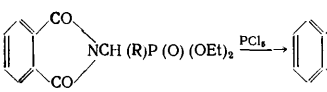
For the compounds under consideration, the above dissociation constants are $pK_1 = 2.35–2.6$, $pK_2 = 5.9–8.0$, and $pK_3 = 10.8–11.25$.[394] For comparison, we may quote the first and second dissociation constants of alkylphosphonic acids: $pK_1 = 2.35–2.6$ and $pK_2 = 7.1–8.25$ for $Me(CH_2)_{n-1}PO_3H_2$ (n = 1, 2, 6, or 12). Owing to the high pK_3 values of such acids, due to the high basicity of the amino-residue, they are titrated as mono-basic acids in the presence of indicators[395]. γ-Anilinopropylphosphonic acid also has the betaine structure, but, owing to the low basicity of the nitrogen atom, it is titrated as a dibasic acid [$pK_1 = 2.10$, $pK_3 = 4.25$, and $pK_2 = 7.15$ for $PhNH_2^+(CH_2)_3PO_3^-H$].[394] The same observations have been made also for the acid esters of aminophosphonic acids: whereas the acid esters of dialkylaminomethylphosphonic acids are neutral in an aqueous medium[389,392], the acid esters of *N*-arylaminophosphonic acids behave as acids themselves[392]. Owing to this difference, the former acid esters do not form stable salts with many metals[392]. The acid properties of polyaminopolyalkylphosphonic acids and mixed polyaminopolyalkylphosphonic and polyacetic acids are characterised by a large set of dissociation constants whose values are determined both by the nature of the dissociating functional groups and by their mutual influence¶.

Other reactions involving the phosphorus atom have been well investigated. Thus aminophosphonic acids are esterified by expoxyalkanes[397] and orthoformates[123].

Phenyl *N*-arylaminobenzylphosphonates are readily transesterified by alcohols in the presence of alkoxides[393]:

$$ArNHCH(Ar')PO(OPh)_2 \xrightarrow[-PhONa]{ROH,\ RONa} ArNHCH(Ar')PO(OR)_2. \quad (77)$$
Ar=Ph, *m*, *p*-C_6H_4Me, *p*-C_6H_4Cl, *p*-$C_6H_4CHMe_2$; Ar'=Ph, *p*-C_6H_4Me; R=Me, Pr, Bu.

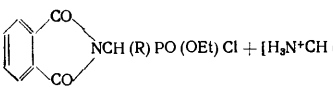
Treatment of diethyl ω-dialkylaminomethyl(ethyl)phosphonates with phenyl-lithium leads to ω-dialkylaminomethyl(ethyl)diphenylphosphine oxides[398]. Phthalimidobenzyl(methyl)phosphonates are quantitatively converted into ester-acid chlorides by reaction with phosphorus pentachloride[128,399]:



(78)

(R=H, Ph)

The resulting acid chlorides were used to synthesise peptides containing aminoalkylphosphonic acid moieties in 70–88% yields[128,399]:

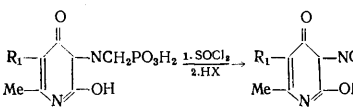


(79)

(R=H, Ph; R'=H, *d*, *l*-Me, *l*-CH_2Ph)

β-Phthalimidoethylphosphonyl chloride, obtained by treating the corresponding acid with thionyl chloride or its diethyl ester with phosphorus pentachloride, has been used to synthesise lipids and kephalins containing aminoethylphosphonic acid residues[400,401].

The conversion of pyrimidinylmethylphosphonic acids into the dimethyl and dibutyl esters and *NN'*-diphenyldiamide in 29–50% yields by successive treatment with thionyl chloride, methyl or butyl alcohol, and aniline has been described[54,402]:



(80)

(R_1=H, Br; X=OMe, OBu, NHPh)

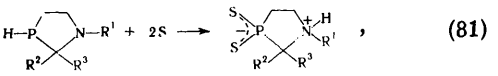
Treatment of *N*-substituted α-aminobenzylphosphonates with thionyl chloride and then with *p*-nitrophenol and triethylamine is accompanied by the cleavage of the phosphorus–carbon bond and leads to di(nitrophenyl)phosphate[403]. Phosphorus pentachloride completely cleaves nitrilotri(methylphosphonic)acid to tri(chloromethyl)amine and phosphoryl chloride; the hexaethyl ester is cleaved similarly[123].

¶Detailed data on their acid dissociations are quoted in the review of Kabachnik et al.[396]

Like other phosphines, ω-aminoalkylphosphines are converted into the corresponding sulphides and oxides on treatment with sulphur or hydrogen peroxide [24,110,111,114,230,234,265,267,340,352,353,355].

Phosphinic and phosphinodithioic acids are formed under these conditions from di-(β-aminoethyl)phosphines and β-aminoethylphenylphosphines [114,115].

1,3-Azaphospholidines containing a hydrogen atom at the phosphorus atom are converted into inner salts of phosphinodithioic acids in 71–81% yields by treatment with sulphur in benzene [230]:



(81)

where R^1 = H or Et, R^2 = H, R^3 = Ph, and R^2R^3 = $(CH_2)_5$.

The oxidation of *NNN'N'*-ethylenediaminetetra(methylenephosphonous) acid with mercury(II) chloride to the phosphonic acid has been proposed as a method of synthesising the latter in an analytically pure form [404].

The alkylation of β-diethylaminoethyldialkyl(aryl)phosphines by ethyl iodide involves the phosphorus atom and results in the formation of aminophosphonium salts in 74–87% yields [110]:

$$Et_2NCH_2CH_2PR_2 + EtI \rightarrow [Et_2NCH_2CH_2P^+(R_2)Et]\,I^- . \quad (82)$$
(R=Et, Ph, cyclo-C_6H_{11})

Aminoalkylphosphonimidates readily exchange the imino-residue for oxygen and sulphur on treatment with carbon dioxide and carbon disulphide; treatment with acids leads to ester-amides [343]:

$$(EtO)_2PCH(Ph)NHAr' \xrightarrow{NAr} \begin{cases} \xrightarrow{CO_2} (EtO)_2P(O)CH(Ph)NHAr' \\ \xrightarrow{CS_2} (EtO)_2P(S)CH(Ph)NHAr' \\ \xrightarrow{AcOH} (EtO)(ArNH)P(O)CH(Ph)NHAr' . \end{cases} \quad (83)$$

Reactions Involving the Nitrogen Atom

The amino-group of aminoalkyl phosphorus derivatives enters into many of its characteristic reactions. *N*-Alkyl-substituted and unsubstituted aminoalkyl organophosphorus compounds form stable salts with acids. In contrast to alkylation, the protonation of aminoalkylphosphines also takes place at the nitrogen atom [23,231]. The alkylation of the nitrogen atom is of preparative interest. Thus, on reaction with dimethyl sulphate (DMS) in an alkaline medium and subsequent acidification, *NN*-di(carboxymethyl)aminomethylphosphonic acid is converted into its *N*-methylbetaine [26]:

$$H_2O_3PCH_2N(CH_2COOH)_2 \xrightarrow[2.\ H^+]{1.\ NaOH,\ Me_2SO_4} HO_3^-PCH_2N^+Me(CH_2COOH)_2 . \quad (84)$$

Depending on the methylating agent, aminoalkylphosphonic acid containing an unsubstituted amino-group are converted into dimethylaminoalkylphosphonic acids (formaldehyde and formic acid) or into fully methylated derivatives—betaines (DMS in an alkaline medium or methyl iodide in methanol) [395,405]. It has been suggested that polyaminoalkylpolyphosphonic and polyaminoalkylpolyphosphonicpolyacetic acids be obtained by alkylating aminoalkylphosphonic acids with alkylene dihalides and chloroacetic acid in an alkaline medium [48,406–410].

The full esters of dialkylaminoalkylphosphonic acid are readily alkylated by alkyl halides and DMS even at room temperature in inert solvents (dioxane, ether) or in the absence of a solvent on heating with formation of salts of trialkylammoniumalkylphosphonates [63,75,411–414].

Thus alkylation of diethyl ω-dimethylaminoalkylphosphonates with methyl iodide in ether at 0°C leads to the corresponding methiodides in 61–81% yields [388]:

$$Me_2N(CH_2)_nP(O)(OEt)_2 \xrightarrow{MeI} Me_3N^+(CH_2)_nP(O)(OEt)_2I^- . \quad (85)$$

A characteristic feature of these compounds is their tendency to undergo dealkylation to the betaines—slowly at room temperature and rapidly on heating [411,414,415]. For example, when trimethylammoniummethylenediphosphonate is refluxed for 3 h in benzene, the betaine is formed in 97% yield [411]:

$$(EtO)_2P(O)CHP(O)(OEt)_2 \xrightarrow{t^\circ} (EtO)(O)PCHP(O)(O)(OEt)_2 + EtI . \quad (86)$$
($^+NMe_3I^-$; $-O^+NMe_3$)

It has been noted that the tendency towards betaine formation depends not only on the type of substituent in the alkoxy-group (increases with decrease of the length of the substituent) but also on the nucleophilic properties of the anion: the perchlorates and methyl sulphates are more stable than the bromides and iodides [414].

A simple method for the synthesis of such betaines is the coupled *N*-alkylation and *O*-dealkylation of aminophosphonates occurring when these are heated [346,415]: a betaine was obtained in 50% yield by heating dimethyl α-dimethylaminoisobutylphosphonate [346]:

$$(MeO)_2P(O)CH[CHMe_2]NMe_2 \xrightarrow{t^\circ} (MeO)O_2^-PCH[CHCMe_2]N^+Me_3 . \quad (87)$$

Toluene-*p*-sulphonic acid is used as a catalyst for this process [415]. The *N*-dealkylation of aminoalkyl phosphorus derivatives has been less thoroughly investigated. *N*-Benzylaminoalkylphosphonic and the analogous phosphinic acids are readily dealkylated [310] by hydrogenolysis in glacial acetic acids over a palladium catalyst at a temperature as low as 20°C, the yields being 92–98%:

$$PhCH_2NHCH(R)P(O)(OH)X \xrightarrow{AcOH,H_2/Pd-C} H_2NCH(R)P(O)(OH)X . \quad (88)$$
(X=OH, Ph; R=Me, Et, Pr, Bu, Ph)

When the iodide of diethyl triethylammoniummethylphosphonate is heated with triethylphosphite, the latter is alkylated and an ethyl group is removed from the nitrogen atom [416]. The ethyl esters of *N*-t-butylaminomethylphosphonic and *N*-t-butyliminodi(methylphosphonic) acids are hydrolysed and cleaved by hydrochloric acid to aminomethylphosphonic and iminodi(methylphosphonic) acids respectively [312,314].

Aminoalkyl organophosphorus compounds, both unsubstituted and mono-substituted at the nitrogen atom, are readily acylated. Thus, on heating with acetic anhydride, aminomethylphosphonic acid is converted into acetamidomethylphosphonic acid in 57% yield [417]:

$$H_2NCH_2PO_3H_2 + (MeCO)_2O \rightarrow MeCONHCH_2PO_3H_2 . \quad (89)$$

Fusion of this acid with phthalic anhydride leads to phthalimidomethylphosphonic acid [417]. In this case the chlorides of chloroacetic, benzoic, and *p*-nitrobenzoic acids are also effective acylating agents in an alkaline medium [417,418]. The full esters of aminoalkylphosphonic and aminoalkylphosphonothioic acids are smoothly acylated by acetic anhydride [417,418], acyl chlorides in the presence of pyridine and by the Schotten–Baumann reaction [329,418,419], aryl isocyanates [420], keten [421], mixed anhydrides of aminocarboxylic and carbonic acids [422,423], phthalimidoacetic acid in the presence of dicyclohexylcarbodi-imide [399], and phosgene [424]. The acylation of aminoalkylphosphinates and phosphine oxide has also been described [72,387].

Phosphonic acids containing a tertiary nitrogen atom can be converted by treatment with hydrogen peroxide in alkaline or neutral aqueous and aqueous alcoholic media

into the *N*-oxides of aminophosphonic acids and into their salts[425-432]; for example, the oxidation of nitrilotri-(methylphosphonic) acid with hydrogen peroxide leads to the *N*-oxide in 49% yield[425]:

$$N[CH_2PO_3H_2)_3 \xrightarrow{H_2O_2} ON(CH_2PO_3H_2)_3 . \quad (90)$$

The oxidation of *NN*-disubstituted aminomethylphosphine oxides takes place similarly[86,433]. The oxidation of aminoalkylphosphonic acids and their esters, containing a primary amino-group, with sodium hypochlorite leads to azodi(alkylphosphonic) acids and their esters[434]:

$$2\,(RO)_2P(O)C(R')(R'')NH_2 \xrightarrow{NaOCl} (RO)_2P(O)C(R')(R'')N{=}NC(R')(R'')P(O)(OR)_2 . \quad (91)$$
(R=H, Alk)

The diazotisation of aminoalkyl organophosphorus compounds with a primary amino-group is of considerable preparative interest. The reaction with α-aminoalkylphosphonic acids proceeds with evolution of nitrogen and the formation of α-hydroxyalkylphosphonic acids[28,183,387]:

$$H_2O_3PCH(R)NH_2 \xrightarrow{HNO_2,\ \text{nitrogen oxides}} H_2O_3PCH(R)OH + N_2 . \quad (92)$$
(R=H, Ph)

Aminomethylphosphonate esters are converted into diazomethylphosphonates in 46–64% yields on diazotisation with sodium nitrite in aqueous acetic acid[125-127]:

$$(RO)_2P(O)CH_2NH_2 \xrightarrow{HNO_2} (RO)_2P(O)CHN_2 . \quad (93)$$
(R=Me, Et)

α-Diazoalkylphosphine oxides were obtained similarly in 45–90% yields by the diazotisation of α-aminoalkylphosphine oxides[18,36,127]:

$$R_2P(O)CH(R')NH_2 \xrightarrow{HNO_2} R_2P(O)C(R')N_2 . \quad (94)$$
(R=Ph, CH_2Ph, R'=H; R=Ph, R'=Ph)

The possibility of such diazotisation of aminophosphonates and phosphine oxides is probably due to their high α-C–H acidity and the considerable stability of the resulting α-diazoalkyl derivatives of organophosphorus compounds: comparison of the thermal stabilities of α-diazoalkyl organophosphorus compounds with those of the carbonyl analogues showed that the former are just as stable and in some cases even more stable than the latter[435].

The diazotisation of β-amino-αα-dimethylethyldiphenylphosphine oxide takes place with deamination and is accompanied by the isomerisation of the intermediate carbonium ion, to a large extent owing to the migration of the diphenylphosphinyl group[10]:

$$Ph_2P(O)CMe_2CH_2NH_2 \xrightarrow[\text{or } C_5H_{11}ONO]{NaNO_2,\ H_2SO_4} [Ph_2P(O)CMe_2CH_2^+] \longrightarrow$$
$$\longrightarrow Ph_2P(O)CH_2{-}C(Me){=}CH_2\ (25\%) + Ph_2P(O)CH{=}CMe_2\ (8\%) +$$
$$+ Ph_2P(O)CH_2CMe_2OH\ (38.8\%) + Ph_2P(O)CMe_2CH_2OH\ (6.8\%) +$$
$$+ Ph_2P(O)C(Me)\begin{matrix}CH_2\\ \diagdown\\ \diagup\\ CH_2\end{matrix}\ (14.7\%) . \quad (95)$$

The primary amino-group in aminomethylphosphonates and aminomethylphosphine oxides is converted in the usual way into the isonitrile group in 72–80% yield[142,436]:

$$R_2P(O)CH_2NHCHO \xrightarrow[NEt_3]{COCl_2} R_2P(O)CH_2N{=}C . \quad (96)$$
(R=Ph, CH_2Ph, OEt)

Reactions Involving the α-Carbon Atom

These reactions are usually accompanied by the dissociation of carbon–nitrogen and phosphorus–carbon bonds or the elimination of an α-hydrogen atom and the formation of phosphorylated nitrogen yields.

When the carbon–nitrogen bond in aminoalkyl derivatives of organophosphorus compounds is broken, the amino-group is substituted by other organic residues. For example, heating of tri(dimethylaminomethyl)phosphine with aniline leads to tri(anilinomethyl)phosphine in 45% yield[266]:

$$(Me_2NCH_2)_3P + 3\,H_2NPh \xrightarrow[-3Me_2NH]{} (PhNHCH_2)_3P . \quad (97)$$

The substitution of the diethylamino-group in *NN*-diethylaminomethylphosphines by the diphenylphosphine residue has been suggested[190] as a method for the synthesis of compounds with a P–C–P bond system (yields 31–100%):

$$Ph_nP[CH_2NEt_2]_{3-n} + m\,HPPh_2 \xrightarrow[Et_2NH]{} Ph_nP[CH_2NEt_2]_{3-n-m}[CH_2PPh_2]_m . \quad (98)$$
($n=0-2$, $m=1-3$)

The formation of a cyclic product in 76% yield on dehydrochlorination of tetra(anilinomethyl)phosphonium chloride with triethylamine probably proceeds via a mechanism involving the cleavage of the P–C and C–N bonds[266]:

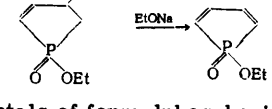
$$(PhNHCH_2)_4P^+Cl \xrightarrow[-Et_3N\cdot HCl]{Et_3N} \left[\begin{matrix}PhNCH_2 & & CH_2NHPh\\ & P^+ & \\ PhNHCH_2 & & CH_2NHPh\end{matrix}\right] \longrightarrow$$
$$\longrightarrow \left[\begin{matrix}PhNCH_2 & & CH_2NHPh\\ & CH_2\ \ P & \\ PhN: & \longrightarrow & CH_2{-}NHPh\\ H & & \end{matrix}\right] \longrightarrow \begin{matrix}Ph\\ N{-}CH_2\\ CH_2\ \ \ PCH_2NHPh + PhNH_2\\ N{-}CH_2\\ Ph\end{matrix} . \quad (99)$$

The removal of the amino-group from aminoalkyl derivatives of phosphorus is facilitated in the presence of an acid hydrogen atom in the β-position[122,348]. For example, α-amino-γ-oxophosphonates are spontaneously deaminated to the corresponding vinylphosphonates in 18–44% yields even at room temperature[122]:

$$(EtO)_2P(O)CH[NMe_2]CH_2COR \xrightarrow[-Me_2NH]{} (EtO)_2P(O)CH{=}CHCOR , \quad (100)$$

where R = *p*-C_6H_4X (X = Br, H, or OMe) or CH = CHPh.

1-Ethoxyphosphole 1-oxide has been synthesised by treating the iodide of 1-ethoxy-4-trimethylamino-2-phospholen 1-oxide with sodium ethoxide[437]:



(101)

The aminoacetals of formylphosphonic acid esters and formyldiphenylphosphine oxides react with diethyl phosphite and diphenylphosphine oxide to form diphosphorylated trimethylamines[103] in 52–60% yields:

$$R_2P(O)\begin{matrix}CH(OMe)\\ \diagdown\\ \diagup\\ NMe_2\end{matrix} + R'_2P(O)H \xrightarrow{-MeOH} [R_2P(O)][R'_2P(O)]CHNMe_2 . \quad (102)$$
(R,R'=OEt, Ph)

NNO-Trimethylaminoacetal of formyldiethylphosphine readily disproportionates on heating to bisdiethylphosphinyldimethylaminomethane and the dimethyl acetal of dimethylformamide (DMF)[116]:

$$2\,Et_2PCH(OMe)NMe_2 \rightarrow (Et_2P)_2CHNMe_2 + HC(OMe)_2NMe_2 . \quad (103)$$

Immoniumphosphonates were synthesised by treating aminoacetals of formylphosphonic acid esters with thionyl chloride[103]:

$$(RO)_2P(O)CH\langle^{OMe}_{NMe_2} \xrightarrow{SOCl_2} (RO)_2P(O)CH{=}N^+Me_2Cl^- + SO_2 + MeCl \quad (104)$$

(R=Me, Et)

The products are very reactive with respect to compounds with a mobile hydrogen atom[122]:

$$(EtO)_2P(O)CH{=}N^+Me_2Cl^- + RH \xrightarrow[-NEt_3\cdot HCl]{NEt_3} (EtO)_2P(O)CH(R)NMe_2 \quad (105)$$

(R=R'S, R'_2N, R' O, $R'_2P(O)$, $(MeCO)_2CH$, $ArCOCH_2$)

The chemical and thermal instability of certain aminoalkyl organophosphorus compounds is due to the lability of their phosphorus–carbon bond. The lability is manifested most clearly in α-aminoalkylphosphonium salts[170–173]: *NN*-disubstituted aminomethyltriphenylphosphonium halides are unstable even at room temperature and are fully hydrolysed by water[173]:

$$Ph_3P^+CH_2NR_2X^- \rightleftarrows Ph_3P + CH_2{=}N^+R_2X^- \xrightarrow{H_2O} Ph_3P + CH_2O + H_2NR_2X \quad (106)$$

X=Cl, Br; R=Me; $R_2 = (CH_2)_5$, $(CH_2)_2O(CH_2)_2$

The replacement of the phenyl groups at the phosphorus atom by alkyl groups[171,173] (i.e. an increase of the basicity of the initial phosphine) and a decrease of the stability of the carbonium-immonium ion by the introduction of acyl groups at the nitrogen atom[172] appreciably stabilise such compounds, but they too decompose in an alkaline medium or under the influence of powerful nucleophilic agents (MeONa, NEt_3, MeLi, t-BuOK) with formation of trialkyl(aryl)phosphines[171–173]. The introduction of substituents stabilising the positive charge (for example, the *p*-dimethylaminophenyl group) at the α-carbon atoms reduces sharply the thermal and hydrolytic stability of α-aminoalkylphosphonium salts[170]. An ethynyl group at the phosphorus atom is cleaved[438]:

$$Bu_3PC{\equiv}CH + HOCH_2NEt_2 \rightarrow [Bu_3\overset{+}{P}(C{\equiv}CH)CH_2NEt_2]OH^- \rightarrow Bu_3P(O)CH_2NEt_2 + C_2H_2 . \quad (107)$$

The stability of the carbonium-immonium ion formed determines also the lability of the carbon–carbon bond in β-aminoalkylphosphonium salts[89]:

$$[Ph_3PC(Ph){=}CH_2]Br^- + HNC_5H_{10} \rightleftarrows [Ph_3\overset{+}{P}CH(Ph)CH_2NC_5H_{10}]Br^- \rightarrow$$
$$\rightarrow Ph_3P{=}CHPh + [CH_2{=}\overset{+}{N}C_5H_{10}]Br^- . \quad (108)$$

On heating (distillation), certain α-aminoalkylphosphonates undergo partial cleavage of the phosphorus–carbon bond with formation of enamines and dialkyl phosphites[102,363]:

$$R_2NCHP(O)(OR'')_2 \xrightarrow{t^\circ} R_2NCH{=}CR'R'' + (R''O)_2PHO , \quad (109)$$

(CHR'R'')

where $R_2 = (CH_2)_4$, R'R'' = Me, and R''' = Et or $R_2 = (CH_2)_5$, R' = H, R'' = Me, and R''' = Me.

Aminophosphonates containing aromatic groups at the nitrogen and α-carbon atoms are relatively stable in an alkaline medium[297], but, when treated with acetic or hydrochloric acid at 40–60°C, they are fully decomposed into an amine, aldehyde, alcohol, and phosphorus acid[291,439]:

$$ArNHCH(Ar')P(O)(OR)_2 \xrightarrow{HCl \text{ or } MeCOOH} ArNH_2 + Ar'CHO + H_3PO_3 + 2\,ROH \quad (110)$$

β-Aminoalkylphosphonates, which are intermediates in the PO–olefin addition reaction (17), undergo a further conversion into an olefin and a phosphoramidate in the presence of bases[94] or acids[98]:

$$PhCHP(O)(OEt)_2 \xrightarrow[-NH_3]{NaNH_2} PhCH + PhN(Na)P(O)(OEt)_2 . \quad (111)$$

(CHPh, NHPh; HCPh)

Like α-aminocarboxylic acids, aminomethylphosphonic acid is cleaved by ninhydrin with formation of a blue dye and a mixture of phosphates[440].

The phosphonate carbanions obtained from aminophosphonates readily enter into the PO–olefin addition reaction[275,319,441]. For example, phosphorylated enamines were obtained in 60–75% yields by treating dimethylaminoethylenediphosphonates with sodium hydride in dioxane and then with aldehydes (ketones do not enter into this reaction)[275]:

$$[(EtO)_2P(O)]_2CHNMe_2 \xrightarrow[2.RCHO]{1.NaH} (EtO)_2PO_2Na + RCH{=}CP(O)(OEt)_2 , \quad (112)$$

(NMe$_2$)

where R = Ph, *p*-$C_6H_4NO_2$, PhCH=CH, or 3,4-(OCH_2O)Ph. When nitroso-compounds are introduced into this reaction instead of aldehydes, amidines are formed in 45–97% yields[319,324,441]:

$$(PhO)_2P(O)CH(NHR'')R \xrightarrow[2.\ R'NO]{1.NaH \text{ or } KOH} (PhO)_2PO_2Na + R'N{=}C(R)NHR'' .$$

(R=Ph, *p*-$C_6H_4NO_2$; R' = Ph, *o*-C_6H_4Me; R''=Ph, *p*-$C_6H_4NO_2$, *o*-C_6H_4Me, *p*-C_6H_4OMe) (113)

Phosphorylated nitrogen ylides have been obtained by the reaction of α-ammoniumalkylphosphonates with bases[414,442]:

$$(RO)_2P(O)CH(R')N^+R''_3X^- \xrightarrow[-B\cdot HX]{B} (RO)_2P(O)C^-(R')N^+R''_3 . \quad (114)$$

In this case, where R' is a group capable of stabilising the negative charge [COR', COOR', PO(OR')$_2$], the formation of the ylide is observed even on treatment with potassium carbonate[414,442], whereas stronger bases (sodium hydride or dimsyl sodium) are needed when R' = H.[443] The chemical properties of these compounds have been little investigated: only alkylation with methyl iodide leading to a *C*-methylated ammoniumalkylphosphonate[414] and PO–olefin addition on treating *N*-diphenylphosphinylmethylpyridinium salts with aromatic aldehydes in the presence of diethylamine[444] have been described. The carbanions obtained by the reaction of diethylphosphinylmethyl isocyanide with butyl-lithium also react with carbonyl compounds to form vinyl isocyanides[142] (68–84%).

IV. APPLICATIONS OF AMINOALKYL ORGANOPHOSPHORUS COMPOUNDS

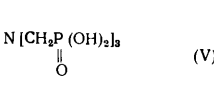
Owing to their ready availability and their chemical properties, compounds of this class can find extensive applications in various branches of science and engineering. Much interest is shown at present in the employment of aminoalkylphosphonic acids as effective complexones with electron-donating functions of the nitrogen atoms and the oxygen atoms in the phosphoryl groups, which are capable of forming chelate rings and of assuming various conformations depending on the configurations of the metal ions being chelated. Numerous publications have been devoted to this problem and have been described exhaustively in the review of Kabachnik et al.[396] Here only some data on the employment of these compounds as complexones are quoted.

Polyaminoalkylpolyphosphonic acids [for example (III)–(VI)], which are analogous of polyaminoalkylpolyacetic acids, are capable of effective complex formation with many metal ions:

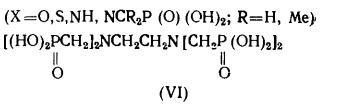
$(HO)_2PCNH(CH_2)_nNHCP(OH)_2$ (III)

(*n*=2 – 5; R=H, Me)

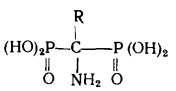
$(HO)_2PCNHCH_2CH_2XCH_2CH_2NHCP(OH)_2$ (IV)



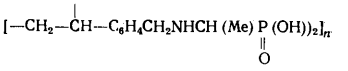
(V)



(VI)



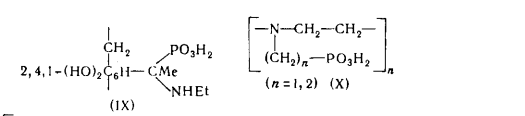
(VII)



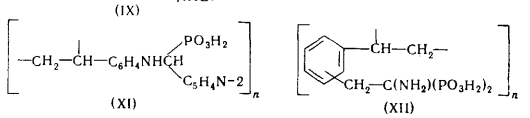
(VIII)

However, owing to their stereochemical characteristics and the high electron-donating capacity of the phosphonate group, they form relatively unstable complexes with alkaline earth metal ions, while their complex-forming capacity with respect to transition metal, lanthanide, and beryllium ions is very high [78,104,375,396,445-450]. An important feature of organophosphorus complexones is the formation of very stable "acid" or "hydrogen" complexes at low pH in which the metal is not coordinated to the nitrogen atom owing to the protonation of the latter [396]. This property is of undoubted interest in studies with readily hydrolysable salts. For these reasons, certain organophosphorus complexones [for example (III) and (VI)] can be used for the extraction of valuable elements and for the separation of lanthanides and actinides within their respective groups [448-452].

The high complex-forming capacity of these compounds is used also in the ion-exchange resins (VIII)-(XII) containing aminophosphonic acid residues [50,79,249,376,453-459]. For example, ion exchangers of the type (VIII)-(XI) effectively extract Cu^{2+} ions from an acetate buffer (capacity 1.1-1.4 mequiv. of Cu^{2+} per gram of resin) [453,459]:

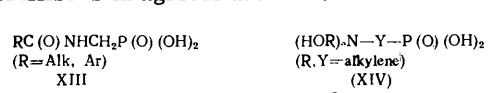


(IX) (n = 1, 2) (X)

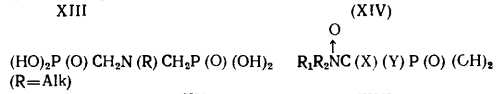


(XI) (XII)

Aminophosphonic acids can also find application in most cases where it is necessary to bind metal ions giving rise to undesirable effects. It has been suggested that they be used for water softening and to prevent the formation of scale [375,460] [compounds of type (V) and (VII)], as antioxidants [compounds (XIII)] [167] and as corrosion inhibitors [461], for the removal of rust and for the etching of aluminium alloys [compounds (VII) and (XIV)], [53,462] for the passivation of metals [253] [compounds (V), (VI) and (XV)], and as metal deactivating additives to lubricating oils [compounds (XIII)]. [45,167] The effective dispersing and deflocculating properties of salts (Li, Na, K, NH_4) of aminophosphonic acids [240,244,253] permit their employment for the formation of oil gels [164] [compounds (XIII)], as components of a boring solution [compound (V)], [182] for the prevention of ice formation in water-containing hydrocarbon fuels [compounds (XV)], [242] and in detergent compositions [45,240,243] [compounds (V) and (XV)]. Their manganese, copper, zinc, etc. salts can be used as microfertilisers in agriculture [53,373].

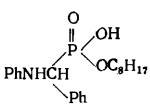


(XIII) (XIV)

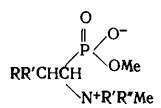


(XV) (XVI)

Aminophosphonic acid N-oxides [of the type of compound (XVI)] and their salts have been suggested as complexones [425,428,431], stabilisers of peroxide compounds, antioxidants for oils and soaps, water softening agents, metal corrosion inhibitors, and metal passivators [428-432]. In view of its ability to form complexes soluble in ligroin with a number of metal atoms, mono-octyl anilinobenzylphosphonate (XVII) has been proposed as an effective extractant at the interface between organic and aqueous phases [385,463-465].



(XVII)



(XVIII)

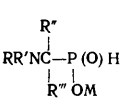
Inner salts of aminophosphonates (XVIII) are suitable as stabilisers of esters [415].

Aminophosphonates obtained from hydroxyalkylamines and polyamines [for example (XIX)] and also the hydroxyalkyl esters of aminophosphonic acids [for example (XX)], which contain hydroxy- and amino-groups, have been suggested as fire-resistant polyhydroxy-components in the manufacture of polyurethanes [213,215,218-220,277,279,280,397,466,467].

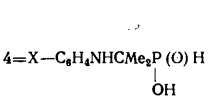
(XIX) (XX)

Their non-combustibility and thermal and chemical stability permit the employment of certain aminophosphonates as hydraulic liquids, heat exchangers, lubricators, and plasticisers [146,194,466,468]. These compounds can also be used as surfactants, emulsifying agents [194,222], and extractants [469].

Aminoalkylphosphonous acids and their salts of the general type (XXI) have been suggested as surfactants, antioxidants, and complex-forming agents [33,205,206,223].



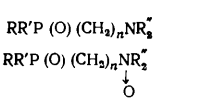
(M=H, Na, NH_4) (XXI)



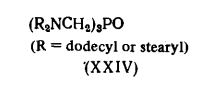
(X=HO, RR'N) (XXII)

Compounds of the general type (XXII) have been patented as photographic developers which are stable in air, readily soluble, and free from allergic effects [225].

Aminoalkylphosphine oxides and N-oxides of type (XXIII) are promising extractants suitable for the extraction of uranium and for the separation of lanthanides and actinides within their respective groups [86,286,433,470]:



(n=1, 2) (XXIII)

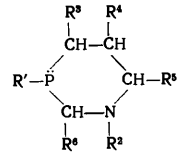


(XXIV)

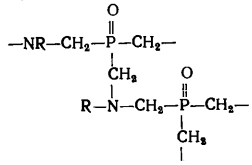
(XXV)

Tri(aminomethyl)phosphine oxides (XXIV) have been proposed as additives which reduce the static electric charge of synthetic fibres and impart fire resistance to them [237]. Aminoalkylphosphine sulphides (XXV) are suitable as lubricating materials and additives to oil [338].

Aminoalkylphosphines of the general type (XXVI) can be employed to modify carbonyl catalysts in oxo synthesis[471].

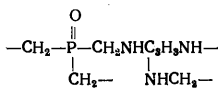


(XXVI)

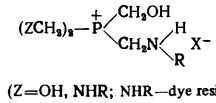


(XXVII)

Products obtained by the condensation of tetra(hydroxymethyl)phosphonium halides, tri(hydroxymethyl)phosphine and the corresponding phosphine oxide with nitrogen-containing compounds (primary amines, ammonia, urea, guanidine, melamine, etc.) of type (XXVII) and (XXVIII) are thermostable non-combustible resins suitable for impregnating veneers, wool, textiles, etc.[272-274,472-477].



(XXVIII)



(Z=OH, NHR; NHR—dye residue

(XXIX)

When the aim was to make fabrics non-combustible, best results were obtained by condensation directly on the fibre[478]. Dyes with amino-groups give rise to wear-resistant colours on cellulose fibres on treatment with tetra(hydroxymethyl)phosphonium halides (XXIX).[479] Certain polyamides based on di(aminoalkyl)phosphine oxides and phosphinic acids have the self-quenching property and exhibit an enhanced adhesion to metals[355,480-482].

The biological activity of aminoalkyl organophosphorus compounds has been comparatively little studied. It has been established that 2-aminoethylphosphonic acid and some of its derivatives enter into the composition of the proteins and polysaccharides of some marine animals and lower organisms[483-488]. Many aminoalkyl organophosphorus compounds exhibit a low toxicity to warm-blooded animals[489]. Their much higher toxicity to plants and insects permits the employment of some of them [for example (V), (XVI), (XXI), (XXX)–(XXV)] as insecticides, fungicides, antiparasite agents, herbicides, growth regulators, and defoliants[33,194,203,209,431,490-492]. The chelate complexes formed by aminoalkylphosphonic acids with iron(III) ions are suitable for the protection of plants from chlorosis[52,59]. The low toxicity of aminoalkylphosphonous acids (XXI) and ammoniumalkylphosphonates (XXXII) to warm-blooded animals permits their use as antibacterial agents[58,205,224,334-336]. It has been suggested that salts of aminophosphonic acids of the type (V) and (XIII) be used to improve the contrast of X-ray photographs[493] and to increase the concentration of 5-hydroxytetracycline in blood[494]; their salts with microelements are suitable for the introduction of the latter into the organism[165]. The high complex-forming capacity of polyaminoalkylpolyphosphonic acids [for example (III), (IV), and (VI)] with respect to beryllium and certain heavy elements gives rise to the possibility of using them for the effective treatment of intoxications caused by the presence of these metals in the organism[396].

---o0o---

After the review had been sent to the editors, a number of publications dealing with methods for the synthesis and properties of aminoalkyl organophosphorus compounds appeared.

β-Dialkoxyphosphinylethyl isocyanate was obtained by the Curtius rearrangement of the azide of β-dialkoxyphosphinylpropionic acid[495].

A number of α-aminophosphonic acids were synthesised by the Hofmann degradation of the amides of α-diethoxyphosphinylcarboxylic acids[496,497].

α-Aminophosphonates, tri-(γ-aminopropyl)phosphine, and the corresponding phosphine oxide were obtained by reducing the oximes of α-ketophosphonates[498], tri-(β-cyanoethyl)phosphine, and the corresponding phosphine oxide[499].

1-Alkyl-4-alkoxy-4-oxo-1,4-azaphosphorinanes and silicon-containing β-aminoethylphosphonic acid esters have been synthesised by the addition of primary amines and silicon-containing amines to divinylphosphinic[500] and vinylphosphonic[501] acid esters.

The interaction of alkali metal derivatives of benzyl phosphonates and phosphine oxides with β- and γ-chloramines led to the formation of a number of phosphorus analogues of methadone and their analgesic activity was studied[502].

The synthesis of dialkylphosphinobis(dimethylamino)methanes by the reaction of *NNN'N'*-tetramethylformamidinium chloride with lithium dialkyl phosphites and their disproportionation to bis(dialkylphosphino)dimethylaminomethane and tris(dimethylamino)methane have been described[503].

The condensation of trialkyl(aryl) phosphites with thiourea and urea has been suggested as a general method of synthesising α-ureidophosphonates[504].

Methods have been patented for the synthesis of nitrilotri(ethylenephosphonic) acid by the reaction of sodium and potassium dialkyl phosphites with tri-(2-chloroethyl)amine[505] and for the synthesis of ureidomethylphosphonyl halides by the reaction of phosphorus trihalides with alkoxymethylureas[506]. They have been suggested as fire resistant agents.

New polydentate *PN*-ligands have been obtained by the reaction of *N*-substituted ethylenediamines with diphenylphosphine and formaldehyde and their properties have been investigated[507].

The phosphonomethylation of silicon-containing[508,509] and heterocyclic[510] amines and glycine[511] with phosphorous acid and formaldehyde in hydrochloric acid has been described. The compounds thus obtained have been suggested as inhibitors of corrosion and scale formation and as complex-forming agents.

Dialkyl 1-(*N*-acylamino)-2,2,2-trichloroethylphosphonate esters have been obtained by treating *N*-1,2,2,2-tetrachloroethylbenzamide and *N*-acetyltrichloroacetaldimine with trialkyl phosphites and dimethyl phosphite[512,513].

It has been shown that magnesium derivatives of phosphorodiamidites readily add to Schiff bases[514];

N-allyl- and *N*-pyridyl-aminophosphonates have been synthesised by the reaction of dialkyl phosphites with Schiff bases [515,516]. A new method has been proposed for the synthesis of α-aminobenzylphosphonates by heating benzaldazines with an excess of diethyl phosphite in the presence of sodium diethyl phosphite—in the course of the reaction two molecules of diethyl phosphite add to the C=N bonds with subsequent reduction of the resulting 1,2-bis(diethoxyphosphinylbenzyl)hydrazine [517].

The kinetics and mode of the reactions of dialkyl(phenyl) phosphites with Schiff bases have been discussed [518,519].

The chromatographic determination of many aminophosphinic acids has been described [520,521], and it is suggested that they be identified with the aid of crystalline *N*-di- and *N*-tri-nitrophenyl derivatives [522]; the infrared and ^{1}H NMR spectra of certain aminoalkyldiphosphonic acids have been investigated [523,524].

It has been shown that the deamination of 2-amino-1-hydroxy-1-phenylethylphosphonic acid involves appreciable rearrangement with formation of phenylacylphosphonic acid [525].

Ion-exchange resins based on chloromethylated styrene-divinylbenzene copolymers containing β-aminoethylphosphonic [526] and (−)-α-aminobenzylphosphonic [527] acid groups have been synthesised and investigated; the synthesis and polymerisation of *N*-methacryloyl-β-aminoethylphosphonic acid has been described [528].

Gas Chromatography in the Functional Group Analysis of Organic Compounds

V.G.Berezkin, V.S.Tatarinskii, M.V.Pal'yanova, and M.M.Fedyachkin

The role and trends in the development of chromatographic methods for the functional group analysis of organic compounds are discussed. Attention is concentrated on the analytical possibilities of using chemical reactions of the test compounds together with gas-chromatographic separation (chemical-chromatographic method).
The bibliography includes 192 references.

I. INTRODUCTION

With the introduction of gas-chromatographic methods appreciable changes have occurred in recent years in methods for functional group analysis, particularly for the functional group analysis of volatile organic compounds. The application of combined methods in conjunction with gas chromatography has revealed a number of new possibilities. These include the following: (1) an improvement of the resolving power of methods for functional group analysis which have been transformed from methods for group identification into methods for the identification of individual compounds: this has permitted the successful solution of problems which could hardly be solved by earlier methods[1,2]; (2) an improvement in the reliability of the method, in particular a decrease of the errors associated with the stage involving the intermediate isolation of the pure substance; (3) reduction of the time required for analysis; (4) decrease in the amount of substance necessary for functional group analysis.

The application of gas chromatography is useful and justified also in combination with any traditional methods for functional group analysis. For example, the employment of physical (spectroscopic and electroanalytical) methods, which are used at the outlet from the chromatographic column for the analysis of the eluate, makes it possible to proceed from group identification to the identification of individual compounds; the employment of chemical methods in combination with chromatographic procedures makes it possible to increase greatly the range of reactions studied, whose products may be not only coloured or gaseous substance but in general any volatile compounds; this of course greatly extends the scope of the method. In combination with chemical methods for functional group analysis, gas-chromatographic procedures can be used also as kinetic techniques, since the reactivities of isomers are frequently different.

II. RETENTION PARAMETERS

The retention parameter of a compound is its chromatographic constant, which is directly proportional to its distribution constant between the gas and stationary phases (the determination of this constant taking into account adsorption interactions has been discussed, for example, by Berezkin[3]). The retention parameters depend on the structure of the molecule of the compound, in particular on the size and number of functional groups present in the molecule. Various workers have successfully used additive schemes to calculate the retention parameters[4-8]. The possibility, in principle, of detecting certain functional groups on the basis of retention indices should be noted[9]; however, this is possible only provided that the structure of the carbon skeleton of the compound being analysed is first established and the procedure is not very reliable[10]. We may note that, in order to improve the accuracy, the relative rather than absolute retention characteristics (relative retention time, relative retention index, etc.) are usually employed in such cases.

The properties of retention parameters can be used for functional group analysis. For example, the linear variation of the logarithm of the retention parameter with the number of methylene groups in a molecule is generally known for homologous series[11,12]. This permits a relatively simple solution of one of the complex problems of functional group analysis—the determination of the number of carbon atoms in the hydrocarbon group. The solution of this problem by other methods is much more difficult. Sakharov and coworkers[13,14] have shown that fractional-linear functions can be usefully employed to characterise the variation of the retention parameters.

In assigning the components of the mixture under analysis to a particular class of organic compounds, the variation of the retention volumes on two[15,16] or more[17,18] stationary phases of different polarity can be of significant assistance: $\lg V_{1i} = A \lg V_{2i} + B$, where V_{1i} and V_{2i} are the retention volumes of the ith compound in a particular homologous series on the first and second phases and A and B are constants.

It has been suggested that organic compounds of different types can be characterised by graphical relations for differences between logarithmic functions of relative retention parameters, for example relations of the type $\Delta I_{12} = f(\Delta I_{34})$, where ΔI_{12} and ΔI_{34} are the differences between the retention indices of the given compound on phases 1 and 2 and phases 3 and 4 respectively. The points corresponding to compounds of a given class are located on the above graphs in specific characteristic regions, which can be

usefully employed to identify the functional groups in organic compounds[19].

The method of identification based on the variation of the retention time with the reciprocal of the absolute temperature in one chromatographic column, proposed by Arakelyan et al.[20], is fairly laborious but relatively reliable.

All the methods indicated above have been used successfully in analytical practice and have been described in detail in monographs on chromatography[21–24].

III. INVERSE GAS CHROMATOGRAPHY

Inverse gas chromatography (IGC) is based on the use of a direct interaction between standard compounds and the test substance and the establishment of definite relations between the chromatographic characteristics of the standard compounds and the structure of the compounds used as the stationary phase. IGC is particularly useful in the study of involatile compounds (high-molecular-weight compounds and compounds unstable at elevated temperatures).

The IGC method permits the group identification of compounds used as the stationary phase. When the relative retention times of substances of different polarity (methanol, heptane, and toluene) are plotted in a triangular coordinate system using straight-chain paraffins, aliphatic alcohols, and acids as the stationary liquid phase, each of the above homologous series is characterised by a distinct range of values of the retention times for the standard compounds. We may note that certain isomeric compounds can also be distinguished with the aid of this method. Thus the spectra of the volatile standard compounds 1,3-butylene glycol and 1,4-butylene glycol and those of primary and secondary octyl alcohols are different. The above data indicate a fairly high sensitivity of the IGC method with respect to the nature and structure of the compounds. Similar results can be obtained also for polymeric systems.

The extensive factual data accumulated in gas chromatography on the application of polymers as stationary liquid phases for the separation of mixtures of volatile compounds lead to the conclusion that polymers can also be identified by the IGC method. Thus the retention volumes of phosphine are 1.75, 1.58, and 2.52 cm^3 on columns with silicone oils 702, VKZh-94 V, and PFMS-4 respectively[25]. In another example two polymeric compounds of the same type —poly(propylene glycol) with M = 1760 and poly(ethylene glycol) with M = 1540 — are characterised by markedly different retention parameters[26], which permits their identification by the IGC method.

The IGC method has been developed in greatest detail to characterise (identify) asphaltenes (M = 500–1000)[27].

Dorrence and Peterson[28] demonstrated the usefulness of employing in IGC chemical reactions with the stationary liquid phase investigated. In order to study the functional groups in asphaltenes, the asphaltene test specimen in the column was silylated, as a result of which the active hydrogen atoms in the hydroxy- and carboxy-groups were replaced by trimethylsilyl groups. Treatment of asphaltene with *NN*-bis(trimethylsilyl)acetamide at 160°C led to a sharp decrease in the specific coefficients for the interaction with the chosen volatile standards (phenol and propionic acid). This method can be used to characterise various polymeric compounds with functional groups.

We may note that, whereas the amount of test substance required for the IGC method on a packed column is about 0.4 g, it decreases to 3–4 mg when a capillary column is used[27]. The microversion of IGC is particularly important for polymers which are difficult to synthesize and in general for compounds which are difficult to obtain.

Since the problem of identifying polymers in may cases reduces to the determination of their molecular weights, we may mention the possibility of employing the relation between the retention parameters of volatile standard compounds and the molecular weight of the stationary liquid phase[29].

IV. SELECTIVE DETECTORS

One of the major requirements which must be met by detecting systems in gas chromatography, namely their universality, i.e. equal sensitivity to all the mixture components emerging from the chromatographic column, is a disadvantage in the identification of organic compounds. In functional analysis the main requirement which must be met by the detector is its selectivity and an ideal system would be one having specific sensitivity only to compounds of specified classes, whose signal would be proportional to the content of the corresponding functional group.

The automatic titrator[11] and the spectrofluorimetric detector[30] meet this requirement most closely. The first is designed for the selective determination of acids and bases in the eluate and is based, as its name suggests, on the automatic maintenance of a specified pH in the titration cell. The operation of the spectrofluorimetric detector, which is designed for the detection of aromatic groups, is based on the employment of the fluorescence[30] or ultraviolet light absorption[31] characteristic of aromatic compounds.

The detector with selective sensitivity to compounds having multiple bonds is of undoubted interest[32]. The detection principle involves passing the mixture of saturated and unsaturated compounds to be analysed through an ionisation chamber together with krypton, which is excited to a metastable state by radioactive emission. The metastable krypton atoms are capable of ionising the molecules of the unsaturated compound and in the presence of the latter an ionisation current is generated.

The electron capture detector, proposed for the first time by Lovelock and Lipsky[33], exhibits an enhanced sensitivity to alkyl halides, sulphides, carbonyl compounds with conjugated double bonds, organometallic compounds, nitriles, and nitro-compounds. The sensitivity of the detector to many types of compound reduces its value for the purpose of identification, but makes it irreplaceable in the determination of certain compounds present in nanogram amounts.

Other selective detectors, which can be divided into three main groups, exhibit a much higher specificity. Thermionic detectors, based on the increased conductivity of the flame in a flame-ionisation detector on combustion of organic compounds containing heteroatoms in the presence of alkali metal or alkaline earth metal salts, were used in early investigations mainly for the selective detection of halogen- and phosphorus-containing compounds[34,35]. When rubidium and potassium salts are used[36], the sensitivity for nitrogen-containing compounds increases, but the greatest sensitivity is achieved when caesium bromide is employed[37]. In the presence of caesium the thermionic detector may be used for the highly sensitive determination of silicon, tin, and lead compounds[38]. It has also been shown[39] that the signal of the thermionic detector with rubidium sulphate is proportional to the content of heteroatoms in the molecules of the substances being analysed and a formula has been proposed whereby it is possible to calculate the content of the heteroatoms (halogens, sulphur, phosphorus, and nitrogen).

The coulometric detector[40], which exhibits selective sensitivity to compounds containing halogens, sulphur, nitrogen and phosphorus, may prove to be of significant assistance in the identification of organic compounds. The detector design was developed further in studies by Stepanenko and Krichmar[41–44]. The ion-selective electrodes, which have recently come to be widely used in analytical chemistry, have also found applications in coulometric detectors for the determination of fluorine[45], sulphur, and chlorine[46]. Among other electrochemical detecting systems, mention should be made of a selective galvanic detector[47], which is sensitive to alcohols and aromatic and unsaturated hydrocarbons.

The group of spectroscopic detectors, a major advantage of which is (apart from a fairly high sensitivity in the determination of heteroatoms) a very high selectivity, has been developed vigorously in recent years. The simplest example of this group is the halogen detector based on the Beilstein effect, i.e. on the green light emission arising when halogen-containing compounds are introduced into the flame through a copper mesh[48]. The flame-photometric detector, which was initially proposed for the selective determination of phosphorus and sulphur[49], has been modified to determine many other elements. The operation of the detector is based on the measurement of the intensity of the characteristic emission lines of the flame in the presence of heteroatoms using a photo-multiplier. In the determination of sulphur- and phosphorus-containing compounds, 394 and 526 nm light filters are usually employed, but it has also been stated that the positions of these maxima have been determined inaccurately[50]. When the flame-photometric detector is sensitised by indium salts, its sensitivity to halogen atoms is increased selectively with a maximum in the region of 360 nm[51,52] or at 409.9 nm, which corresponds to the maximum in the emission spectrum of indium iodide[53]. The photometric recording of the flame emission from an alkali metal thermionic detector made it possible to distinguish chlorine, bromine, and iodine atoms[54] and the employment of metallic calcium ensures a selective determination of fluorine in the region of the spectrum near 529.9 nm.[55] Organomercury[56,57] and boron[58] compounds can also be analysed. It has been suggested that the disadvantage of the flame photometric detector, due to the mutual interference of the heteroatoms present (and also of their concentrations) on the observed emission, be eliminated[59] by measuring the ratios of the spectral line intensities for the elements being determined (at 256 nm for chlorine, 206.2 nm for iodine, 253.3 nm for phosphorus, 182.04 nm for sulphur, and 292 nm for bromine) to the intensity of the spectral line of the carbon atom at 247.9 nm, which is almost independent of the structure of the compound and the elements present in it[60].

Many other detectors are used for identification purposes (the mass-spectrometric detector has been particularly successful); selective detectors were surveyed in detail in an earlier review[61].

One should note that almost all specific detectors (with the exception of those mentioned at the beginning of this section) have only an indirect bearing on functional analysis, since they cannot show unambiguously within which functional group the given heteroatom is located. Therefore their application is more effective in elemental analysis of organic compounds, particularly when it is necessary to determine substances present in microamounts. However, there is no doubt that the detecting systems developed so far have assisted in the identification of unknown compounds. The preliminary introduction into the test compounds of a specific heteroelement using reactions characteristic of the given functional group (for example the introduction of bromine at the site of a double bond) with subsequent employment of a detector selective for the element introduced can probably be of some interest. When the given heteroatom is detected in the compound being identified, the presence of the expected functional group may be postulated with considerable certainty.

V. CHEMICAL-CHROMATOGRAPHIC METHODS

The combination of chemical and gas-chromatographic methods appears to be the most effective and flexible procedure in functional group analysis. There has been a steady increase in the proportion of studies involving chemical-chromatographic methods among all the investigations on gas chromatography. Fig. 1 shows that the contribution of these methods increased in 1972 almost by a factor of 1.5 compared with 1966 (data quoted in the bibliographic section of the Journal of Chromatography were used to plot this graph).

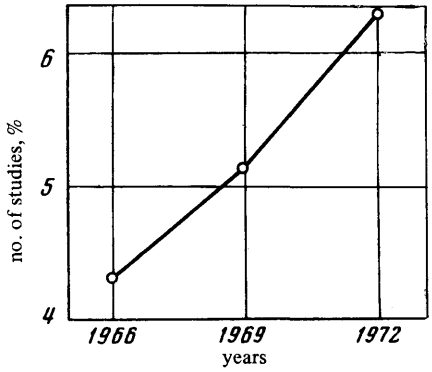

Figure 1. The number of studies on chemical-chromatographic analytical methods in relation to the total number of publications on gas chromatography.

Various methods are used to carry out the chemical reactions: reactions carried out outside the chromatographic system, reactions before the column, reactions in the column, and reactions after the chromatographic column. The choice of the reactions and of the conditions governing their occurrence is governed by the problem to be solved.

The effect of the reaction of the analytical mixture before the chromatographic process, involving a selective removal of components, makes it possible to assign the latter to specific classes by comparing the chromatograms obtained with and without the treatment of the sample by the selected reagents. This method has been called the substraction method.

The substraction process is carried out in a small column (reaction loop) filled with the selected chemical reagent, usually deposited on an inert carrier, like the stationary liquid phase. Under these conditions, it is even possible in many cases to use volatile reagents when the latter are deposited on a strongly adsorbing carrier[62,63].

If the sample analysed is introduced simultaneously into two columns connected in parallel having detector cells operated in a differential mode (the reaction loop is used in series with only one of the columns), then the chromatograph will show only the components eliminated[64]. The system suffers from the disadvantage that it is necessary to achieve an absolutely exact reproducibility in all the working parameters of both chromatographic columns; this can be obviated by including the reaction loop between the two detector cells[65] and by employing one column. The main requirement which the system must meet in this case is a small volume, which should be comparable to the peak width.

It is quite unnecessary that the compounds removed should be fully retained in the reactor in the form of involatile compounds. Even if reactions result in volatile products, the latter will have different elution times from those of the initial compounds, which can be clearly shown by subsequent chromatography. Moreover, the incomplete adsorption in the reaction column may be used to secure additional information about the structure of the compounds analysed. Thus the incomplete removal of *cis*-dienes in a reactor with maleic acid chloride makes it possible to distinguish them from the *trans*-isomers, which react faster and are completely eliminated in the reactor[66]; the employment of a reactor with boric acid ensures the separation of primary and secondary alcohols from their tertiary isomers[67,68].

The fillers in the reaction loops, used for the selective removal of a wide variety of different classes of compounds, have been described in detail in the literature[69,70].

Tricyclohexyl borate has been suggested for the selective absorption of alcohols[71]; metal hydrides can be used for the same purpose[72–74] and it has been noted[73] that aluminium hydride and lithium tetrahydroborate remove all compounds with oxygen-containing functional groups, except ethers. The complete elimination of aldehydes from the mixture analysed is achieved when *o*-dianisidine[74], sodium tetrahydroborate[73], or hydroxylamine hydrochloride[72] are used. The difference in the reactivity of boric acid towards various alcohols has been used to separate tertiary alcohols from primary and secondary alcohols[73,74] and the employment of sodium tetrahydroborate, which reacts slowly with ketones, makes it possible to distinguish the latter from aldehydes[73]. Prokopenko et al.[75] showed that the selectivity in the elimination of different oxygen-containing substances in reactors containing boric acid and lithium tetrahydroaluminate depends on the amount of the reagent. Thus tertiary alcohols can be completely removed in a reactor with a high boric acid content.

The method for the preliminary absorption of alcohols and carbonyl compounds in a reactor filled with 40% of 3-nitrophthalic anhydride and semicarbazide on Celite-545, placed directly before the separating chromatographic column[76], is also of interest.

The formation of adducts with urea is a characteristic reaction for the removal of n-alkanes[77,78] and methyl esters of aliphatic acids[79]. Ohtaki et al.[80] showed that all hydrocarbons with a straight-chain structure can be removed by the reaction with urea. In the subsequent treatment (reactions with hydroborates and oxidation) the olefins can be isolated in the form of the corresponding alcohols and can be determined gas-chromatographically. The overall olefin content in the initial mixture can probably be found also by determining the amount of hydroborate which has reacted.

Columns with *NN*-di-(2-cyanoethyl)formamide[81], mercury perchlorate[82], and alumina[83] have been used for the selective retention of aromatic hydrocarbons. Mercury perchlorate is also an effective absorber for unsaturated compounds[82,83]. It has been suggested that the group isolation of organomercury compounds be carried out either by including in the chromatographic system a short reactor with a powdered metal or by removing them by reaction with various sulphur-containing compounds[84].

A novel method has been proposed for the determination of the overall admixture of involatile organic substances[85].

In many instances it is useful to employ a reaction column with phosphoric acid, which permits the selective removal of nitrogen-containing organic bases from complex mixtures[86].

Examples of the determination of alcohols, ketones, aldehydes, esters, and aromatic hydrocarbons by reactions in a syringe have been described[87].

Qualitative chemical tests after chromatographic separation constitute a less common way of identifying the components of complex mixtures. One of the reasons for this is the low sensitivity of colour reactions, so that considerable amounts of the substance analysed, not less than 20–100 μg, have to be used[88]. It is possible to specify the two most interesting procedures for rapid qualitative tests. The first consists of the subdivision of the eluate from the chromatographic column into several approximately equal streams which are directed to test-tubes with group reagents for a specific class of compounds[88]. A colour change in one of the test tubes at the instant of the emergence of the peak is evidence that the substance belongs to the given class. The second method provides for the employment of a sorbent layer impregnated with the reagent for the given functional group and moving continuously relative to the stream of eluate from the column[89]. If the eluate contains a compound of the given class, then a coloured spot appears on the sorbent layer. By changing the reagent impregnating the sorbent and by comparing the results of the chemical study with the separation chromatograph, it is easy to determine the class of the compound corresponding to each peak. The advantages of the first method are the possibility of testing each peak for several functional groups and also the possibility of determining the nature of the components present at microconcentrations insufficient for the appearance of an appreciable colour by the successive introduction of several samples (provided that the colour of the solution remains stable for a sufficiently long time). The sensitivity of the method based on the subdivision of the eluate stream can be improved significantly by concentrating the substances in short porous glass traps filled with alumina[90]. When the flow rate through the trap is of the order of 5 ml min^{-1}, the majority of compounds investigated (aldehydes, ketones, alcohols, ethers, and aromatic and sulphur-containing substances) are trapped by the layer of packing 2–3 mm thick in the form of a concentrated band, which makes it possible to reduce the detection limit to the level of 0.1–1 μg. The specific reagents used for qualitative tests after chromatographic separation have been discussed[69,70].

All the methods for group analysis described above are applicable only to mixtures of volatile compounds which can be subjected to gas-chromatographic separation. In order to separate the components of mixtures of involatile or high-boiling compounds and assign them to specific groups, special procedures are used, many of which are also carried out in non-chromatographic reactors. Thus a number of procedures (esterification, decarboxylation, silylation, etc.) have been developed or applied in the gas chromatography of involatile compounds and also of highly polar substances whose separation is difficult. In particular, acetylation[91], silylation[91,92], and methylation[93] are used in the gas-chromatographic analysis of hydroxy-compounds; carboxylic acids are converted into the more volatile methyl esters or decarboxylated, etc. Without going into the details of these procedures (reactions of this kind for many classes

of compounds have been described in the literature[94]), we may say that the chemical reactions themselves can be regarded as one of the methods for group identification. In fact, the reagents employed are usually highly selective, for instance, when aldehydes or ketones are identified among the reaction products on treatment of the solid mixture with, for example, iodic acid and subsequent chromatography[95,96], it is possible to conclude with a high degree of certainty that the initial mixture contains α-hydroxycarboxylic acids.

Yet another useful feature of the above procedures should be indicated, namely the possibility of securing additional information about the qualitative composition of the mixture analysed on the basis of gaseous side products which are at present disregarded. Thus, in the conversion of phenols into methyl ethers by the reaction with diazomethane[97] nitrogen is evolved, ammonia is a side product in the silylation of involatile hydroxy-compounds[98], and in the decomposition (described above) of α-hydroxycarboxylic acids by iodic acid to yield the corresponding ketones or aldehydes[95,96] (which are not always convenient for chromatography) an equivalent amount of carbon dioxide is formed, etc.

Pyrolytic methods give rise to extensive possibilities for the identification of unknown compounds. Compounds which permit qualitative and quantitative inferences concerning the presence of specific functional groups in the specimen are as a rule formed in the pyrolytic decomposition of the substance analysed.

The thermal decomposition of organic compounds in the presence of sulphur vapour at 850–880°C gives products which yield information for the identification of many functional groups[99]. Thus the products formed in the pyrolysis of aldehydes, ketones, ethers, esters, alcohols, sulphonic acids, amino-compounds, and acids have been investigated in this way. The nature and ratios of the volatile pyrolysis products (nitrogen, hydrogen sulphide, carbon monoxide, carbon dioxide, carbon disulphide, and sulphur dioxide) are largely determined both by the structure of the initial compounds and by the presence of functional groups in the molecules.

The pyrolysis products (hydrogen, carbon monoxide and dioxide, methane, water, etc.) of substances in an inert gas atmosphere and their ratios also characterise the functional groups in the initial specimen[100–102]. Thus ketones and aldehydes give rise to CO, alcohols to CO_2 and H_2O, esters to CO_2, H_2O, and CO, acids to CO_2, mercaptans to hydrogen sulphide, halogen-containing compounds to the corresponding hydrogen halides, and the decomposition of amines results in the evolution of ammonia[101]. However, since the quantitative aspects of the formation of characteristic products were not determined in the published investigations, the methods based on pyrolytic decomposition are at present applicable mainly to qualitative analysis only.

On thermal decomposition in the presence of a catalyst [copper(II) oxide], hydrazine derivatives evolve methane; this made it possible to devise a method for their quantitative chromatographic determination[103].

The possibility of employing the effects of electron impact and of electric discharges in functional analysis has been studied[104,105]. It has been shown that, by decomposing the specimen analysed in an electric discharge, it is possible to assign the substance to a particular homologous series[104]. The study of the products formed in the decomposition of alcohols, aliphatic and aromatic hydrocarbons, ethers, esters, ketones, and aldehydes in an electric discharge established that methane is formed from all the test compounds and acetylene is generated by compounds with an ethyl group. The decomposition products of all aromatic compounds contain benzene and carbon monoxide and dioxide are present in those of oxygen-containing compounds.

Examples of the employment of thermal decomposition methods for the analysis of certain other groups will be discussed below.

It is necessary to consider especially methods for the quantitative determination of functional groups. In principle any classical gas-volumetric analytical method can be modified for chromatography but it would be very wrong to assume that the only problem is to replace one method by another, even if the latter is more up to date and more automated (although these advantages are important, particularly in routine determinations). Chemical-chromatographic methods give rise to distinctly new possibilities. These include simultaneous qualitative (from the retention time) and quantitative (from the signal intensity) determination of the desired reaction product in the complex reaction mixture, the possibility of the simultaneous determination of several reaction products with similar chemical properties, which in chemical methods can be determined only as a single group, the separation of the desired reaction product from side products, which is frequently a potential source of errors in classical methods, the possibility, in principle, of employing reversible reactions, since one of the products is continually removed from the reaction system by the carrier gas, a high sensitivity of the determination, which makes it possible to carry out a complete analysis of microspecimens, rapidity of the determinations, and finally the possibility of complete automation of the entire analytical process.

The use of chemical reactions (or specific thermal decomposition), leading to reaction systems of two types, has now been described for the quantitative analysis of functional groups in organic compounds. If the reaction products are compounds with physicochemical properties similar to those of the other ingredients of the reaction mixture, then an aliquot part of the latter is chromatographed. This procedure involves a decrease of the sensitivity of the determination (only part of the mixture is analysed), the possibility of loss of the required product and hence of a decrease in the accuracy of the analysis, and also additional difficulties in the automation of the analytical process. It is more convenient although not always possible to employ reactions which lead to the formation of either a gaseous or a volatile product, which characterises specifically the functional group being determined. The final product (or products) are in this case directed to chromatographic analysis either immediately from the reactor or after intermediate concentration.

The employment of chemical-chromatographic methods for the quantitative determination of specific functional groups is discussed below.

1. Determination of Active Hydrogen

The quantitative determination of active hydrogen is based on the known reactions of the compounds analysed with a Grignard reagent or with lithium tetrahydroaluminate. In the first case the reaction results in the evolution of methane, the gas-chromatographic determination of which is fairly simple. It is noteworthy that all the errors of the classical method[106], associated with additional gas evolution (for example, the evolution of ethane appearing as a result of the decomposition of the Grignard reagent) can be readily eliminated in the final chromatographic step[107–110].

The employment of lithium tetrahydroaluminate[111–114], which reacts with active hydrogen atoms in several seconds even at room temperature, is of considerable interest. Methyl, ethyl, n-propyl, and n-butyl ethers, tetrahydrofuran

(THF), dioxane, and ethylmorpholine[115] can be used as solvents, which greatly extends the range of applications of the method compared with the classical chemical determination. THF is a particularly satisfactory solvent for many organic compounds[111,118].

The method for determining active hydrogen was largely the same in all the studies mentioned. A solution of lithium tetrahydroaluminate in a suitable solvent is poured into the reaction cell, a sample of the substance analysed is positioned without coming into contact with the solution (for example the specimen can be put in a dish resting on the reactor stopper[114]), the reaction cell is flushed with the carrier gas and then disconnected from the chromatographic system, and the sample is plunged into the solution. After the completion of the reaction, the cell is reconnected to the chromatograph and the hydrogen evolved is determined in a column with activated charcoal or molecular sieves. A cell designed as a standard attachment of a chromotograph[117], which we believe to be the most convenient for the analysis of liquid substances, has been described for reactions with lithium tetrahydroaluminate.

However, we may note that the high reactivity of lithium tetrahydroaluminate can in many cases constitute a disadvantage, since certain compounds which do not contain active hydrogen are converted into substances containing such hydrogen as a result of the reduction by the reagent.

In this connection we may mention the methods for the determination of active hydrogen linked to a silicon atom, based on the hydrolysis of the organosilicon compound in the presence of potassium hydroxide for 15s and accompanied by the evolution of an equivalent amount of hydrogen, which is determined gas-chromatographically[118].

2. Determination of Amino-groups

Various modifications of the gas-chromatographic method for the determination of primary amino-groups in organic compounds, based on the well-known deamination reaction first used for the quantitative determination of amines by Van-Slyke[124], have now been proposed[119–123]. The nitrogen evolved as a result of the reaction can be readily separated from the accompanying gases in a column with 5 Å molecular sieve for routine analyses, reaction systems[122,123] are preferable in which provision is made for the stirring of the solution during the deamination reaction, a bubbler-type reactor is used (which guarantees freedom from errors associated with the solubility of nitrogen in the reaction mixture), and provision is also made for the absorption of nitrogen oxides which corrode the metallic components of the chromatograph. The duration of analysis does not usually exceed 15 min, the error is not more than ±0.3–0.4%, and the sensitivity of the determination reaches 0.07 mg of amino-nitrogen.

A modification of the method[125], in which solid sodium nitrite deposited on Celite C-22 is suggested instead of the nitrite solution normally employed, is of interest. In addition an internal standard (THF) is introduced into the reaction solution, which obviates the necessity of daily calibration of the apparatus.

The reaction with acrylonitrile has been suggested for the determination of amino-groups[126]; the excess of acrylonitrile which has failed to react is determined gas-chromatographically on a column with poly(ethylene glycol)-300 at 100°C. A similar method, also based on determination of an excess of the reagent which has failed to react, has been proposed for the analysis of relatively involatile primary amines by reaction with benzaldehyde[127]. All the characteristics of the method for the determination of amino-groups with a final gas-chromatographic step are superior to those of the classical Van-Slyke method. An important advantage of the former is also that it fully eliminates errors associated with the presence in the gas mixture of nitrogen oxides and other gaseous substances[128–130] which are not absorbed by an alkaline potassium permanganate solution and which constitute a potential cause of unduly high results.

3. Determination of Alkoxy-groups

The determination of alkoxy-groups in the form of the corresponding alkyl iodides, which are formed by the Zeisel reaction[131] when the compound analysed is refluxed in hydriodic acid, constitutes the basis of almost all gas-chromatographic methods. The classical chemical analysis of alkoxy-compounds is one of the most time-consuming and laborious methods in functional group analysis and yields only the overall content of alkoxy-groups. The ease of gas-chromatographic separation and quantitative determination of alkyl iodides (for example, the separation of 24 C_1–C_{10} alkyl iodides has been described[132]) from the very beginning indicated the likely usefulness of chromatography in analysis, which has been reflected also in the number of publications on this problem[133–147]. In early investigations the alkyl iodides were usually subjected to intermediate concentration in cooled traps with the liquid solvent (n-heptane) and as early as 1961 the contents of C_1–C_4 alkoxy-groups were determined by this procedure[137]. Silica gel[139,141], kieselguhr[140], and Apiezon L on silica gel[143] were employed to concentrate the mixture using high-temperature desorption at 150–170°C. Ehrenberger[140] was able to determine as many as five C_1–C_4 alkoxy-groups present simultaneously. To improve the accuracy of the analysis, the gas-chromatographic separation was employed together with gravimetric[139] and iodometric[140] determination of the amount of alkyl iodide, the accuracy of determination improving to ±0.05 abs.%. The overall duration of analysis is determined by the duration of the reaction with hydriodic acid and ranges from 1 to 3 h.

In 1968 Chumachenko and Kolesnik[148] showed that, in the reaction of organic substances with hydriodic acid in a hermetically sealed tube at 130°C, alkyl iodides are quantitatively split off in the course of 5–10 min, which made it possible to develop methods for the rapid determination of methoxy-[145] and ethoxy-groups[146] in organic compounds. The apparatus is illustrated schematically in Fig. 2. The sample of the substance (1–2 mg) was placed in a 10 × 0.8 cm test tube, 0.3 ml of hydriodic acid (or a mixture of 50 mg of potassium iodide and 0.05 ml of orthophosphoric acid) was poured in, the tube was closed, and kept at 130°C for 10–15 min in the determination of ethoxy-groups or 5 to 12 min in the case of methoxy-groups. The stream of nitrogen was then switched to flush the reactor and the alkyl iodides split off were transferred by the carrier gas to a column with Polysorb-1, where they were separated. Absorption tubes with potassium carbonate and calcium chloride were used to absorb moisture and the acid vapour. The entire apparatus was made of glass and Teflon. The overall duration of the analysis was 15–20 min or 25–30 min in the determination of methoxy- and ethoxy-groups respectively and the accuracy was at least to within 0.2 abs.%. The determination of the relatively volatile methyl and ethyl iodides was possible when these were transferred directly by the carrier gas from the reactor to the chromatographic

column, but in the analysis of C_3-C_5 alkoxy-groups intermediate concentration will probably be a necessary step.

The method for the determination of alkoxy-groups in carboxylic acid esters which are difficult to hydrolysed, based on their alkaline fusion at 240–360°C in the presence of sodium alkoxide, merits consideration[149]. The alcohols evolved in this process are trapped in a cooled trap and then analysed gas-chromatographically. Fig. 3 presents a chromatogram for the separation of the alcohols formed in the analysis of a mixture of polychloroacrylates. Calculation showed that the reaction proceeds with quantitative liberation of the alcohols from the corresponding esters. The alkaline fusion method has been used also to determine the alkoxy-groups in polysiloxane[150].

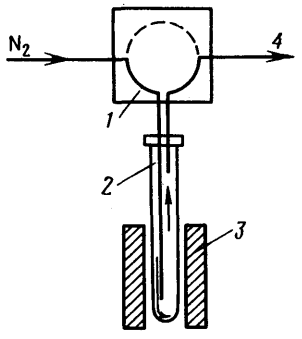

Figure 2. Apparatus for the determination of alkoxy-groups[148]: *1*) diaphragm valve; *2*) reactor; *3*) heater; *4*) outlet to chromatographic column.

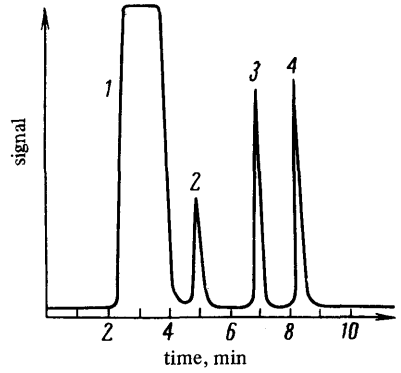

Figure 3. Chromatogram of the products of the alkaline fusion of poly(methyl α-chloroacrylate), poly(ethyl α-chloroacrylate), and poly(isopropyl α-chloracrylate)[149]: *1*) water; *2*) methanol; *3*) ethanol; *4*) isopropyl alcohol.

A method has been described for the determination of ethoxy-groups by oxidising the specimen with CrO_3 and subsequent analysis of an aliquot part of the reaction solution for acetic acid[151].

Among other methods, mention should be made of the determination of hydroxy-ethyl groups in the form of acetanilide, formed quantitatively from the initial specimen on pyrolysis carried out at 400°C for 10 min[152], and also the determination of alkoxy-groups by a hydrogenation method[141]. The latter procedure is particularly attractive, since the alkoxy-groups are eliminated in a flow reactor, which significantly reduces the duration of the determination and the saturated hydrocarbons formed on hydrogenation can be extremely conveniently separated and detected. The substance analysed enter a hydrogenation tube containing 2.0–2.5 ml of the catalyst (5% of platinum on kieselguhr or 1.5% of platinum on porous glass) and heated to 325°C. On hydrogenation, the alkoxy-groups are split off in the form of hydrocarbons, which either enter a 5 cm column with activated charcoal at 20°C (determination of C_1-C_2 alkoxy-groups) or a 50 cm column with silica gel (determination of C_3-C_5 alkoxy-groups).

It is noteworthy that, despite their inadequate reproducibility, the gas-chromatographic methods for the determination of alkoxy-groups are fairly widely used nowadays and in the immediate future may completely replace classical chemical analytical methods.

4. Determination of *S*-, *N*-, and *Si*-Alkyl Groups

The rupture of C–N, C–S, and C–Si bonds is many times more difficult than the rupture of the C–O bond. Therefore much more severe conditions than those described above are used for the determination of the corresponding alkyls. At the same time the different reactivities of the alkyls bound to S, N, and Si atoms can be used for their separate determination. Thus a method has been proposed for the quantitative determination of alkoxy- and *N*-alkyl groups present together[153]. In the first stage the alkoxy-groups are split off and determined under conditions analogous to those already described, after which the reactor is heated to 300°C (20 min) and then to 350°C (10 min). Under these conditions, the N–C bonds are broken and the resulting alkyl iodides are determined gas-chromatographically with intermediate concentration at a low-temperature.

The dissociation of C–S bonds in organic sulphides can be achieved with the aid of a suspension of Raney nickel in ethyl, n-butyl, or cyclohexyl alcohol[154]. The reaction is carried out in a simple microreactor (Fig. 4) consisting of a test-tube with two syringes for the injection of the reactants and for the removal of the gaseous reaction products. The corresponding hydrocarbons formed from the alkyl groups are separated and identified in a gas chromatograph connected to the reaction cell.

A similar reaction system was used also to determine alkyl groups linked to a silicon atom[155,156]. In this case the reaction with concentrated sulphuric acid in the presence of a vanadium catalyst was employed. Heating of the organosilicon compound being analysed to 175°C for 15 to 20 min in the above medium leads to the elimination of alkyl groups linked to silicon in the form of the corresponding hydrocarbons (methane from methyl groups, benzene from phenyl groups, etc.), the gas-chromatographic separation and identification of which presents no difficulty. Ethyl and phenyl groups can also be determined quantitatively by their thermal dissociation from the silicon atom with formation of ethane and benzene[157]. The reaction is carried out in the presence of phosphorus pentoxide in water, with the temperature raised from 20° to 500–580°C (depending on the group being determined).

A method has also been described for the determination of alkyl groups in aromatic compounds by their catalytic abstraction in a stream of hydrogen to yield saturated hydrocarbons[158–159].

It was shown recently[158] that the alkoxy-groups in organosilicon compounds can be identified by determining the products of the reaction of the substances analysed with boron tribromide. The alkoxy-groups are split off in the form of alcohols (which are then converted into unidentified compounds).

5. Determination of Acyl Groups

Virtually all the methods developed so far are based on the transesterification of the initial specimen with sulphuric acid, a mixture of methanol with hydrochloric or toluene-*p*-sulphonic acid, and a mixture of toluene-*p*-sulphonic acid and its methyl ester[160–165]. In the first gas-chromatographic method described[160] the simultaneous qualitative and quantitative determination of formyl and acetyl groups on a single sample was already achieved. The sample of the test substance, toluene-*p*-sulphonic acid, and methanol were introduced into the reactor and the reaction was carried out at 70–80°C for 30 min. The reaction products were then collected in a cooled trap and an aliquot part of the distillate was analysed. Methyl formate and methyl acetate were separated from one another and from methanol in a column with Carbowax-1500.

The gas-chromatographic separation of acyl groups up to butyryl and isobutyryl groups was described later[164,165]. The transesterification was carried out in a mixture of toluene-*p*-sulphonic acid and its methyl ester at 225–230°C for 20 min and the substances evolved were chromatographed on compound columns with poly(ethylene glycol adipate) and a T-1 emulsifier by passing the carrier gas through the reactor. In this analytical method the accuracy, reproducibility, and sensitivity are naturally higher than in the analysis of only part of the solution. It was noted[164] that the yield of methyl acetate in the transesterification reaction is 90% and therefore an appropriate correction factor must be applied in the calculation.

Alkaline hydrolysis[162] with subsequent gas-chromatographic determination of acetic acid can also be used to identify the acetyl group.

6. Determination of Hydroxy-, Carboxy-, and Carbonyl Groups.

The quantitative determination of hydroxy-groups can be achieved by estimating the active hydrogen[166]. The methane evolved in the reaction between a hydroxyl-containing polymer and a Grignard reagent is determined with the aid of a column containing a 5 Å molecular sieve connected directly to a column filled with 10% of *N*-methylpyrrolidinone on alumina, in which methane is separated from the solvent. The authors showed that the gas-chromatographic method permits the determination of hydroxy-groups at concentrations so low that chemical methods are inapplicable.

A more specific method for the determination of primary and secondary alcohols is based on the reaction of the specimen being analysed with acrylonitrile and the determination of the excess of the latter by chromatography on a 3 m column filled with Chromosorb containing 10% of poly(ethylene glycol)-3000.[167]

The microdetermination of carboxy-groups can be achieved by decarboxylating organic acids by pyrolysis in helium in the presence of copper carbonate and quinoline, the specimen being heated for 45 min in a reactor at 225°C.[168] The carbon dioxide evolved is determined gas-chromatographically. To increase the productivity of the method, it is recommended that a system of three reactors, connected in parallel, be used.

The reaction of α-aminoacids with ninhydrin serves as the basis of a method for the determination of carboxy-groups in aminoacids from the amount of carbon dioxide evolved[169]. The reaction is carried out in a system consisting of an attachment to a standard chromatograph. The sample of the substance (3–5 mg), a buffer mixture at pH 4.7, and about 50 mg of ninhydrin are placed in the cooled reaction vessel, which is flushed with the carrier gas, whereupon the latter is disconnected and the system is heated to 100°C. When the reaction is complete (after 3 min), the reaction system is again connected to the chromatograph and the carbon dioxide evolved is determined on a column with AG-3 activated charcoal. The duration of analysis is 10–15 min and the standard deviation of the determination is ±0.39%.

The method for the determination of carboxy-groups by the pyrolysis of the specimen at 1000–1100°C in sulphur vapour is very interesting[170]. The carboxy-groups are then quantitatively split off in the form of carbon disulphide, which is determined using silica gel.

The pyrolytic method has been successfully applied also in the determination of carbonyl groups[171]. The analysis is based on the fact that in the pyrolysis of different ketones and methyl esters of aromatic acids dissolved in carbon tetrachloride in an atmosphere of argon, carbon monoxide is formed in an amount equivalent to the content of the group being determined. The pyrolysis is carried out in a reactor filled with crushed quartz at 800–860°C.

7. Determination of Sulphur-containing Groups

It is recommended that alkane- and arene-thiols be determined quantitatively by reaction with acrylonitrile and

subsequent determination of the excess of the latter which failed to react[167]. The reaction is carried out in a pyknometer for 1–2 min and the solution is analysed gas-chromatographically.

In the determination of sulphate and sulphite groups in organic substances, reductive hydrolysis in phosphoric acid in the presence of a tin(II) salt for 15 min at 300°C can be used[172]. A column with silica gel is employed to separate the hydrogen sulphide evolved from other gases.

It has been suggested that arenesulphonic acids and their salts be determined by alkaline fusion[173] and pyrolysis[174]. In the first case the process is carried out in apparatus (Fig. 5) consisting of a quartz tube part of which is inserted in a cylindrical furnace. Several milligrams of potassium hydroxide and sodium alkoxide are added to the test sample in a platinum boat. The fusion is carried out for 20 min, after which the boat is removed from the hot zone and placed under an outlet with a rubber membrane through which a saturated aqueous solution of maleic acid is injected into the boat from a syringe. The maleic acid displaced phenols from the melt. The boat is then again moved to the heated space and the volatile products are determined chromatographically.

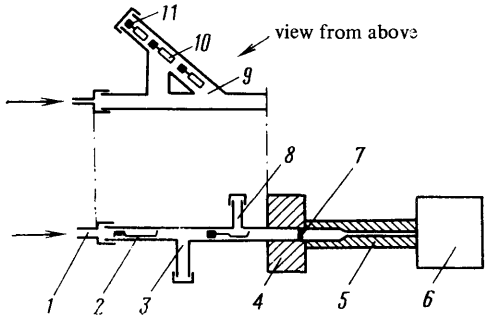

Figure 5. Attachment of alkaline fusion[173]: *1*) inlet for carrier gas; *2*) retraction device; *3*) pocket for the ejection of boats after analysis; *4*) furnace; *5*) heated connection to the chromatograph; *6*) gas chromatograph; *7*) device limiting the travel of boats; *8*) outlet with rubber membrane; *9*) outlet for boats with samples; *10*) platinum boat; *11*) device for moving boats.

Sulphur dioxide in an amount equivalent to the content of the sulpho-groups is evolved by the pyrolysis of arenesulphonic acids and their salts at 710–790°C in the presence of added silicic acid[174]. The pyrolysis products are separated on a column with Porapak Q, which also permits the simultaneous determination of the initial hydrocarbon formed in an amount up to 50% (Fig. 6). The method is particularly interesting, because in certain cases the addition of a hydrogenating agent (for example, a carbohydrazide) to the specimen undergoing pyrolysis increases the yield of the initial hydrocarbon to the theoretical value (thus the yield of benzene from benzenesulphonic acid was 98%), which in principle makes it possible to identify the specimen fully on the basis of a single sample.

8. Determination of Vinyl and Alkyl Groups

The vinyl groups in organosilicon polymers can be determined by the pyrolysis of the initial specimen and subsequent gas-chromatographic determination of the relative amounts of ethylene and methane in the volatile pyrolysis products[175].

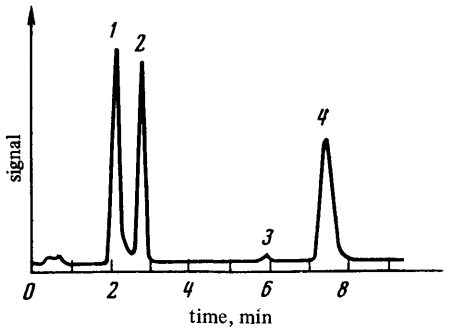

Figure 6. Chromatogram of the pyrolysis products of toluene-*p*-sulphonic acid[174]: *1*) water; *2*) sulphur dioxide; *3*) benzene; *4*) toluene.

The elimination of terminal vinyl groups in the form of ethylene when the specimen of the organosilicon polymer is treated with concentrated sulphuric acid also served as the basis for the development of an analytical method[176]. The sample is placed in a reactor, 450 μl of 90% sulphuric acid is poured in, the solution is heated in a stream of helium from 65° to 250°C (at a rate of 10 deg min^{-1}), and the decomposition products are trapped at low temperatures. When the reaction is complete (after approximately 1.5 h), the trapped volatile products are determined chromatographically. It was shown that vinyl groups are quantitatively converted into ethylene, ethyl groups into ethane, and methyl groups into methane.

Methods have been described for the identification of vinyl groups in the form of ethylene after alkaline hydrolysis[158] and alkaline fusion[150].

It has been suggested that alkyl groups be determined by the degradative decomposition of the test substance in a stream of hydrogen, which serves at the same time as the carrier gas, in the presence of a catalyst: a mixture of aluminium oxide silicate with quartz impregnated by tungsten and molybdenum oxides[177].

9. Determination of Unsaturated Bonds

Before the start of any determination of functional groups, it is important that the investigator knows about the presence and positions of unsaturated bonds for a correct choice of reaction conditions in order to avoid side processes, which frequently involve unsaturated bonds. We therefore feel it useful to consider, if only briefly, the main advances achieved in chromatographic methods in this field.

It is well known that the oxidation of substances containing multiple bonds by oxidising agents such as potassium permanganate and periodate, etc. results in the cleavage of the

molecule at the site of the bond with formation of two or more fragments (depending on the number of unsaturated bonds). Chromatography in all its versions is the most promising procedure for solving the problem of separation and identification of fragments which then arises and this has been reflected in a large number of published studies on chromatographic methods for the determination of the number and location of unsaturated bonds. It is noteworthy that in certain cases involving the formation of complex mixtures of oxidation products identification for the determination of the structure is frequently altogether impossible without a final chromatographic step.

The widely used methods involving oxidation with potassium permanganate in acetic acid[178], frequently resulting in too far reaching oxidation, and with the milder potassium permanganate–potassium periodate mixture[179] have been rapidly giving way recently to the ozonolysis method first proposed by Bon[180]. It is based on the formation of ozonides, their decomposition, and gas-chromatographic identification of the products.

Several types of apparatus, mainly of similar design[181–183], ensuring an ozone concentration of about 2.5–3.0%, have been developed. The usual sequence of steps is as follows[184–188]. The test substance (10–100 μg) in ethyl acetate or carbon disulphide (the use of a solvent for solids is not obligatory[186]) is placed in the reaction tube, the mixture is cooled to a temperature from -70° to 10–15°C (depending on the nature of the substance being analysed), and a stream of oxygen enriched with ozone is passed through the reactor until the initial concentration of ozone is restored at the outlet from the tube. The ozone is detected at the outlet with the aid of a solution of potassium iodide and starch in sulphuric acid. When the reaction is complete (after 0.5–5.0 min), nitrogen is bubbled through the solution and, after the decomposition of the resulting ozonides, the products are analysed gas-chromatographically. Depending on the structure and number of unsaturated bonds, the main products are formaldehyde, acetaldehyde, acetone (in the presence of isopropylidene groups), glyoxal (particularly from compounds with conjugated double bonds), carbon dioxide (in the presence of cumulative bonds), and other aldehydes and aldoesters.

The ozonides are decomposed either with the aid of a triphenylphosphine powder[185,189] or thermally[190,192]. A microreactor in which the specimen with a volume up to 5 μl may be ozonised, decomposed, and injected into the gas chromatograph without any transfer of the test substance and associated losses has been described for the latter case[186].

---o0o---

In this review the authors deliberately did not consider the methods for the determination of the carbon skeleton of organic compounds, which constitute one of the branches of functional group analysis and significantly facilitate identification. The possibilities and achievements of gas chromatography in this field are very great and require special consideration. The determination of the carbon skeleton by hydrogenation has been described in detail in Beroza's review[192].

The survey of the principal achievements of gas chromatography in the qualitative identification of organic compounds and quantitative determination of functional groups leads to the conclusion that, by virtue of the sum total of its advantages, the application of gas chromatography has now resulted in radical changes in one of the most important branches of organic chemistry–functional group analysis, particularly in the study of multicomponent mixtures. We may note that the traditional chemical methods have not lost their value. On the contary, the greatest advances have been achieved precisely in those cases where gas chromatography is used in combination with traditional chemical methods.

It is noteworthy that the growth in the use of gas-chromatographic methods in analytical practice is now held back by the lack of a universal chromatographic apparatus with different reactors designed for functional group analysis with simultaneous employment of chemical and chromatographic procedures.

The Periodic Law and Progress in the Study of the Structure of Matter†

V.I.Gol'danskii

A survey is made of the diverse achievements of Soviet scientists, rising to one of the founders of Russian chemistry—the genius D.I.Mendeleev and his greatest work—the periodic law, which has exerted an immense influence on the development of physics and chemistry at all four conceptual levels in the structure of matter—elementary particles, nuclei, atoms, and molecules. Consideration is given to the fundamental contribution made by Soviet scientists to predicting, discovering, and studying new isotopes and new types of radioactivity, to synthesising new transuranic elements and establishing their valency states (sometimes completely unexpected), and to founding the chemistry of "new atoms", in which proton and electron have been replaced by other elementary particles.

The principal modern methods for studying the structure of matter are based on the recording of hyperfine interactions between electrons and nuclei, electrons of outer and inner shells—i.e. essentially interactions between periodic and monotonic functions of the atomic numbers of the chemical elements. Soviet scientists both discovered the hyperfine interactions and made the most important contribution to their chemical utilisation (the discovery of electron spin resonance, the introduction of e.s.r. and γ-resonance spectroscopy into chemistry, the widespread application of nuclear magnetic resonance to chemistry, the establishment of photoelectronic spectroscopy in the ultraviolet and of accurate X-ray chemical spectroscopy, etc.).

The work of Soviet theoretical chemists in basing the periodicity in the properties of chemical elements on the molecular orbital method is reported, and illustrates how the periodic law preserves its fertility even at the modern quantum-mechanical level of attacking the problem of chemical bonds.

A list of 157 references is included.

The emergence and growth of chemical sciences in our country are indissolubly linked with three great names—M. V. Lomonosov, A. M. Butlerov, and D. I. Mendeleev—which we cannot fail to remember on the anniversary of our Academy. Each of these giants left an indelible mark in the history of science. Among the three, Mendeleev received the fullest recognition during his lifetime. More than 130 honorary titles and diplomas were conferred on him by Russian and foreign scientific societies, universities, and academies. But with all the brilliance of the confirmations of Mendeleev's chief creation—the periodic law—during his lifetime, its immense significance was disclosed still more fully by his successors. Mendeleev's feeling that "... the future will not threaten the periodic law with destruction but will only promise a superstructure and further development..." was realised[1].

For a long time a kind of hierarchy of the natural sciences—mathematics, physics, chemistry, biology—has been established, in which a "senior" science enriches a "junior" science with methods and concepts, thus stimulating its development. The periodic law was a brilliant example of the reverse relation in this hierarchy—an enormous and ramified influence of a chemical discovery on the development of physics.

Rutherford's discovery of the atomic nucleus and Moseley's investigation of X-ray spectra revealed the physical meaning of the serial number of an element in Mendeleev's system as the positive charge on its nucleus. Bohr's theory linked the planetary model of an atom with

† This paper is an expanded text of a lecture at the 250th Anniversary General Meeting of the USSR Academy of Sciences.

the quantum theory, gave a theoretical interpretation of the origin of periodicity in the chemical properties of elements, and enabled the structure of the sixth period in Mendeleev's system and the properties of the then unknown hafnium and rhenium to be predicted. But another consequence of comparing the periodic system with the quantum theory—Pauli's "exclusion principle" formulated in 1925—acquired a special and immeasurable importance. A path could be traced from Mendeleev through the Pauli principle to the Fermi-Dirac statistics and further to the theory of the valency bond, to the theory of atomic nuclei and universal weak interaction, of metals and semiconductors, superconductivity and superfluidity.

Mendeleev's law—or at least his method of systematisation and periodisation of the properties of known materials and extrapolation to new, as yet undiscovered materials—has found and finds wide application at all four levels (elementary particles, nuclei, atoms, molecules) in the science of the structure of matter. All the achievements in revealing a system in what was till recently chaos provide a guarantee of a deeper insight in the future. How clearly the great Mendeleev understood this is evident even from such remarkable words of his: "It can readily be supposed—but cannot yet be proved—that the atoms of elements are composite materials formed by the addition of several still smaller parts, that what we term indivisible (the atom) is indivisible only by ordinary chemical forces, as particles are indivisible under ordinary conditions by physical forces ... Such a view is evidently supported by the periodic relation I have formulated between properties and weight ..."[2].

The present Review will be concerned mainly with the most recent achievements of scientists—especially of Soviet scientists—in studying the structure of matter at the atomic and molecular levels, i.e. chemical structure. But first we must refer to elementary particles, especially to nuclei.

Recent decades have been marked not only by the discovery of a multitude of new elementary particles but also by the first major successes in their systematisation and the prediction of new particles on this basis. The author of the first systematic account of elementary particles, based on the introduction of a new (strangeness) quantum number and on application of the concepts of group theory, the American Nobel prizewinner Gell-Mann, makes a direct reference to the analogy between his work and Mendeleev's discovery of regularities in the properties of the chemical elements. He suggests that the system of particles will lead to a theory explaining their interactions, as the Pauli principle and quantum mechanics arose to explain the regularities and properties of atomic systems found by Mendeleev.

A still closer and still fuller analogy exists between the classification of the elements and the generally accepted classification of atomic nuclei based on the concept of the presence of many neutron and proton shells. This shell model of the nucleus led to the discovery of such an extremely important property of nuclear forces as their well developed dependence on the relative orientation of the spin and the orbital moment of the nucleons (neutrons and protons). Nevertheless, the creation and development of the shell model of the nucleus resulted from advances in the study of radioactivity, in particular the isomerism of artificial radioactive isotopes discovered in the USSR by Kurchatov and his coworkers in 1935.[3]

The fundamental contribution by Soviet scientists to the investigation of radioactivity—the spontaneous transmutation of chemical elements—can be illustrated by Fig. 1, which represents diagrammatically five main elementary types of radioactivity either already observed or predicted. Only two of them—α- and β-disintegration—were known by the end of the nineteenth or the beginning of the twentieth century. The third type—spontaneous fission—was discovered in 1940 in the USSR by Petrzhak and Flerov[4], at that time young students of V. G. Khlopin and I. V. Kurchatov. The fourth type—proton radioactivity—was suggested long ago by Rutherford, but was predicted from modern theories only in the 1950s by Soviet scientists[5-7], and observed experimentally only in 1970 in the cobalt-53m isomer[8]. The fifth and final type—two-proton radioactivity—was predicted in the USSR in 1960[6,9] and has not yet been observed experimentally. An interesting and expected feature of many dozens of nuclei having an even number of protons—the ability to emit a pair of protons together, but not single protons—is due to the pairing of protons having opposite spins, and has its chemical analogue in the formation of coordinate bonds, in which a single atom supplies the pair of electrons.

The coupling of the pairing effect, which is characteristic of all particles having semi-integral spins (electrons, protons, neutrons, etc., to which the general name *fermions* is given), with the presence of a potential barrier around the nucleus even with neutral particles (in this case a purely centrifugal barrier) leads to the possibility,

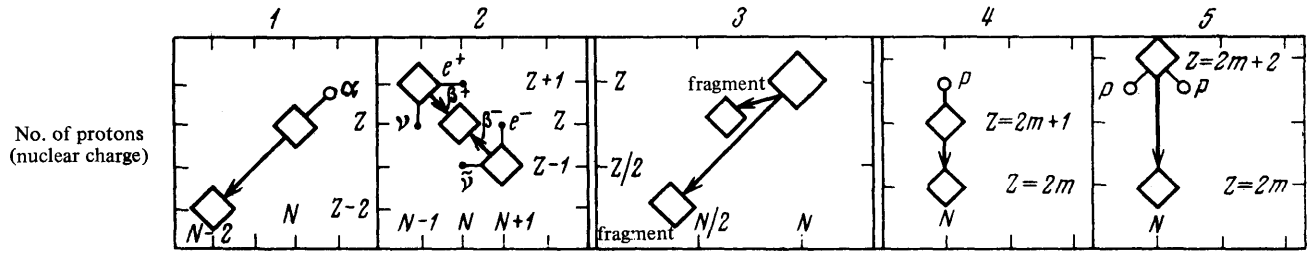

Figure 1. Schemes illustrating the five main types of radioactive disintegration of nuclei—spontaneous transmutation of chemical elements (e^- = electron; e^+ = positron; ν = neutrino; $\tilde{\nu}$ = antineutrino): 1) α-disintegration; 2) β-disintegration (β^-, β^+, and electron capture); 3) spontaneous fission; 4) proton disintegration; 5) two-proton disintegration.

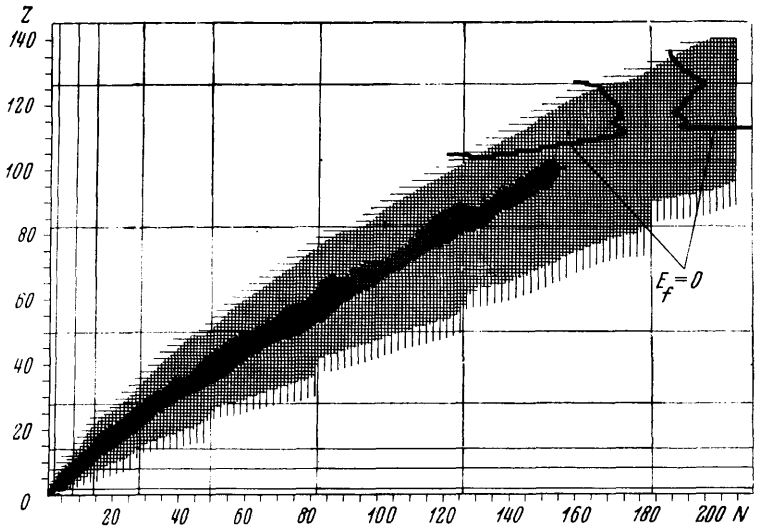

Figure 2. Region of stable and radioactive isotopes known at the present time (Z = No. of protons (atomic No.); N = No. of neutrons). The upper and lower boundaries are determined by the predicted instability for ejection of protons and neutrons respectively. The boundary of a possible "isthmus" of stability to spontaneous fission in the vicinity of $N = 184$ and $Z = 126$, 114 is indicated in the upper right-hand corner. In the absence of shell effects, spontaneous fission would have given a straight horizontal stability boundary near $Z \simeq 110$–112.

recently demonstrated theoretically, of the appearance of a sixth elementary type of radioactive disintegration of nuclei—two-neutron radioactivity, or the emission of a pair of neutrons by long-lived isomeric nuclei[9].

A few two-stage radioactive processes are known or have been predicted, in which the first step is some variant of β-disintegration, which is almost instantaneously followed by escape from an intermediate nucleus of some other particle (excited by part of the energy of β-disintegration) or by its fission. Such processes and the particles emitted in them are said to be *delayed*, the "delay" being due here to the sluggishness of the initial β-disintegration—i.e. not to the disintegration but to the formation of the excited nucleus.

Only delayed α-particles and neutrons were known before the Soviet work. The emission of delayed protons was discovered in the laboratory of G. N. Flerov at Dubna in 1962[10]. Another series of studies showed that the probability of fission of several transuranic nuclei was far higher than that expected from theoretical considerations, which was explained by the delayed fission of uranium and plutonium nuclei produced from neptunium and americium, as a result of slow electron capture from inner shells[11]. Theoretical analysis by Leningrad scientists indicated that tritium and helium-3 nuclei could also be emitted as delayed particles[12].

At the present time around 2000 isotopes of 105 chemical elements are known, of which only 15% are stable isotopes. However, systematisation of the bonding energies of nucleons in nuclei indicates the possibility of detecting almost 4000 more radioactive isotopes with a marked deficiency or a marked excess of neutrons in the nuclei. Fig. 2 shows clearly the relative regions of already known and not yet discovered isotopes. And the question of new isotopes involves not only their number: fundamentally new properties and phenomena await study.

The present stage of research on neutron-deficient and neutron-excess isotopes began in 1959–1960, when Soviet scientists[13,14], in particular Zel'dovich, proposed ways of determining the limits of stability of nuclei based on the shell theory of the nucleus and one of the main properties of nuclear forces—their independence of electric charges—since when dozens of new isotopes even of the lightest elements have been found, and their properties have shown excellent agreement with prediction. An extremely interesting example is the superheavy helium-8, which has double the weight of ordinary helium[15]. The prediction and detection of this isotope by Soviet scientists were marked by a discovery diploma[15]. Helium-8 is a kind of record-holder among atomic nuclei, in which each proton is associated with three neutrons. As a result of three successive radioactive transformations—two β-disintegrations and one α-disintegration (Fig. 3)—each atom of superheavy helium is converted into two atoms of ordinary helium, so that an aerostat filled with helium-8 inflated spontaneously to twice its volume in fractions of a second, without change in the chemical composition of the gas filling it.

In the search for new radioactive isotopes the synthesis of new transuranic elements acquired the widest popularity for understandable reasons, and greatly extended the limits of the Mendeleev periodic system. The first transuranic element (neptunium) was synthesised in 1940 and a fundamental contribution to extending the Mendeleev system was

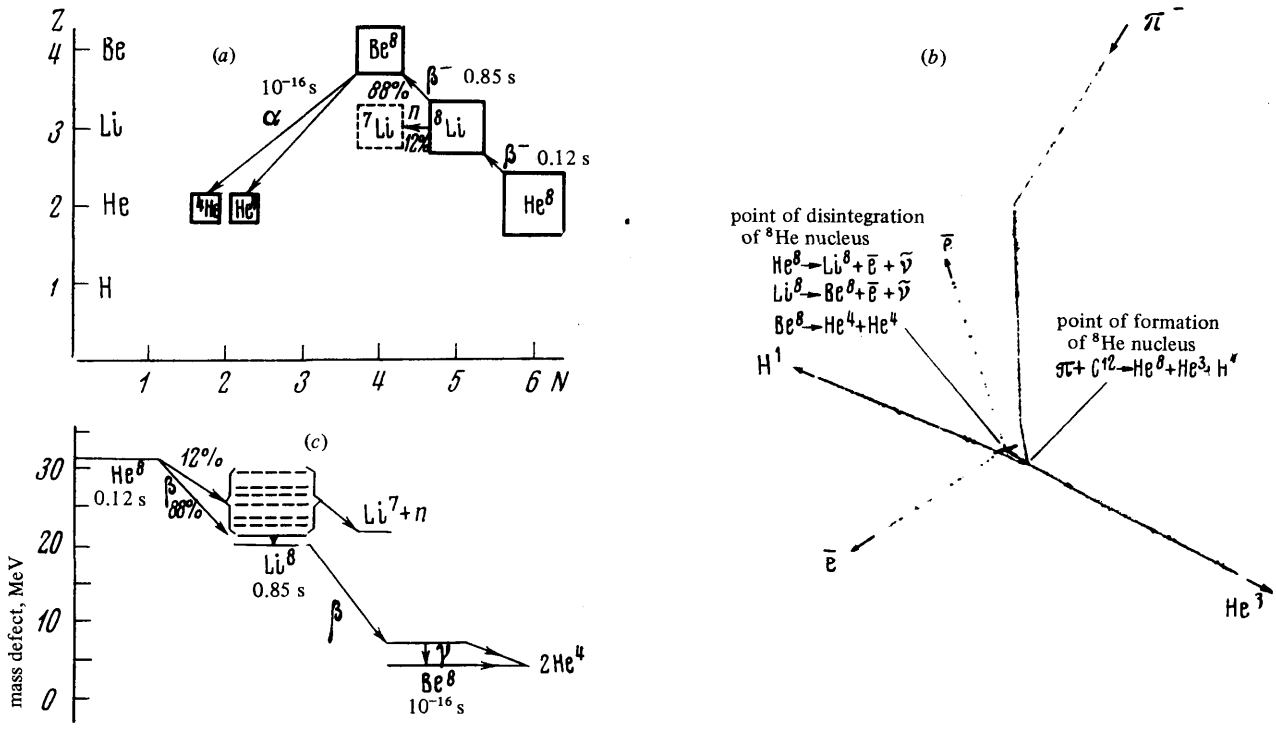

Figure 3. *a*) Illustration of disintegration path of helium-8 nuclei; *o*) pattern of formation of helium-8 nuclei by the bombardment of photographic emulsions with π-mesons ($\pi^- + {}^{12}C \rightarrow {}^1H + {}^3He + {}^8He$) and subsequent disintegration of helium-8 (obtained in the synchrocyclotron in the Laboratory of Nuclear Problems of the Joint Institute of Nuclear Research at Dubna); *c*) scheme of disintegration ($^8He \rightarrow {}^8Li \rightarrow {}^8Be \rightarrow 2{}^4He$).

made by a group of scientists headed by G. T. Seaborg at the Radiation Laboratory in Berkeley (U.S.A.) During 1941–1945 these workers obtained by means of accelerators, nuclear reactors, and nuclear explosions, eight new elements—from plutonium to element No. 101—the last of which they named *mendelevium* "... as a token in recognition of the priority of the great Russian chemist Dmitrii Mendeleev, who was the first to use the periodic system of the elements to predict the chemical properties of then undiscovered elements. This principle is the key to the discovery of almost all the transuranic elements"[16]. In 1958 scientists from Berkeley announced that they had obtained element 102 and in 1961 element 103, which they named respectively *nobelium* and *lawrencium*[17–19].

An enormous contribution to the synthesis and study of transuranium elements has since been made by Flerov's laboratory in Dubna. In 1963 and subsequent years Flerov and his coworkers obtained for the first time many isotopes of elements 102 and 103, which compelled them to revise the mass numbers previously assigned in Berkeley to the isotopes of these elements[20–23]. In 1964 the Dubna scientists achieved the remarkable success of obtaining the first isotope of the new element No. 104, named "kurchatovium Ku".[24] In February 1971 the synthesis was announced in Dubna of the next element 105, for which the name "nielsbohrium Ns" was proposed[25]. Several other isotopes of kurchatovium and of element 105 have since been synthesised in Berkeley.

Some idea of the latest situation is given by Fig. 4, in which are indicated all isotopes of the four newest elements known at the present time and those isotopes of elements 102 and 103 for which the presently accepted characteristics were first established in Dubna. Special emphasis is given to the isotopes discovered there of elements 104 and 105, which were incorporated by Soviet scientists into the Mendeleev system‡.

With regard to the main interest of chemists in the new elements—in their chemical properties—controversies have now continued for nearly thirty years on Seaborg's actinide theory, according to which actinium is followed by completion of a shell of fourteen 5*f* electrons in the elements from thorium to No. 103, analogous to the filling of the 4*f* shell in the rare-earth elements. A tendency sometimes develops to regard the periodic system as analogous not to a geographical atlas but to a plan which must indicate every street and every house, and to see any distinction between actinides and lanthanides as the overthrow of the actinide theory.

Nevertheless, the actual properties of elements in chemical compounds, the greater or lesser stability of their different valency states, are influenced by extremely

‡ In July 1974 the Dubna group announced the synthesis of new isotopes of kurchatovium (mass numbers 255 and 256) and the first isotope of element 106 (apparently A = 259).[25a]

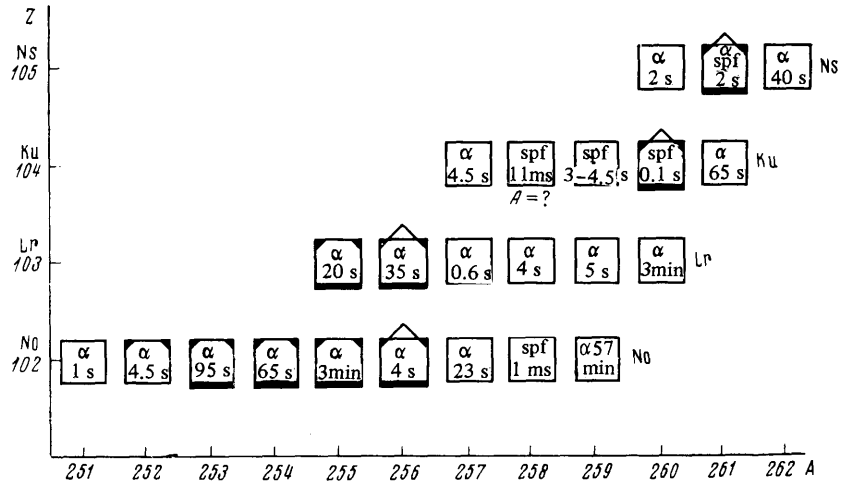

Figure 4. Isotopes of elements 102–105. The shaded corners and underlining denote those isotopes for which the presently accepted characteristics were first established at Dubna in the USSR. The triangles above the boxes indicate the first isotopes of each element, whose properties have not since been revised. The boxes contain the type of disintegration (spf = spontaneous fission) and the half-lives.

diverse factors. The problem can hardly be solved by model calculations. Even calculation of the energetics of the electron configurations of the free atoms and ions requires complicated programmes and high-speed electronic computers (as an illustration, it was thus established that the electron configuration $7s^27p$ for a free lawrencium atom was ~ 0.5 eV more advantageous, because of relativistic effects and spin-orbit splitting, than the lutetium-like configuration $6d7s^2$). No systematic molecular-orbital calculations have yet been made even for isolated molecules of lanthanide and actinide compounds. The same applies to real solutions and solid compounds, where the solvation energy as well as interionic and intermolecular interactions must also be taken into account, and with radioelements also the various effects of autoradiolysis. Here the chemist has the final say: comprehensive chemical investigations would prepare the ground for future calculations, and any new, especially unexpected facts lay the foundations for future general theoretical constructions.

For this reason it is difficult to overestimate the value of research on the chemistry of transuranium elements made during the past seven or eight years under the general direction of V. I. Spitsyn in the Institute of Physical Chemistry of the USSR Academy of Sciences. This led to the discovery of extreme valency states—septivalent neptunium, plutonium[26-29], and americium[30], bivalent californium, einsteinium[31], and fermium[32], and univalent mendelevium[33].

The septivalent states of the three actinides could be achieved by oxidation only in alkaline media, in which neptunium could be oxidised by more than twenty oxidants, and plutonium by more than ten, including ozone, persulphate, hypobromite, and the radical-ion $O^{\cdot-}$, the last being formed by the radiolysis of aqueous alkalis. It was most difficult to obtain septivalent americium: this required the radiolysis of alkaline solutions of americium(VI) cooled almost to 0°C and supersaturated with nitrous oxide, which is an acceptor of the strong reductant—the hydrated electron—produced by radiolysis. Around twenty solid compounds of septivalent neptunium and plutonium have been obtained—mainly perneptunates and perplutonates of alkali and alkaline-earth metals.

Fermium and mendelevium were reduced to the lowest valencies by the action of magnesium in aqueous–ethanolic solutions of chlorides of inert carriers. The lowest valency state of mendelevium was detected with only a few hundred atoms of the mendelevium-256 isotope (half-life 1.5 h) available.

The experimental valency states found by Soviet scientists for the above five actinides are indicated by crosses in Fig. 5, which includes all such states known for lanthanides and actinides (the most stable states are denoted by small squares). Fig. 5 shows both properties common to the two groups and their differences, which are due to the close approach in bonding energy of the ns, np, $(n-1)d$, and $(n-2)f$ electrons that is characteristic of the heavier elements. The results of these investigations by Spitsyn and his coworkers indicate a certain affinity between the far actinides ($Z \geqslant 98$) and the transition d-elements, as well as the possibility of discovering octovalent plutonium, quinque- and sexi-valent curium, and quinquevalent berkelium.

Fig. 5 includes also results obtained at Dubna in the USSR by a group of Soviet and Czechoslovak radiochemists under the general direction of Zvara[34-37]. They developed a method, of record rapidity and sensitivity, for establishing the chemical nature of new elements from the volatility of their anhydrous halides. In 1966 this method was used to demonstrate that kurchatovium and hafnium chlorides were closely similar in volatility, and significantly less volatile than the chlorides of actinides[34]. This decisive experiment, which proved that element 104 is already a member of the titanium subgroup of Group IV, and that element 103 sees the completion of the fourteen-electron $5f$ shell, in conformity with the actinide theory,

needed only 16 atoms of kurchatovium. The properties of this element were subsequently confirmed and refined by isolating and recording the radioactive decay of 60 of its atoms[35]. Furthermore, it was shown that nobelium and lawrencium are at most tervalent in their chlorides[35,36]. An outstanding new achievement was the observation that nielsbohrium chloride is more volatile than hafnium tetrachloride but less volatile than niobium pentachloride, as was to be expected for quinquevalent ekatantalum[37]. It must be emphasised that the experiments were made on isotopes of kurchatovium and nielsbohrium whose lifetimes did not exceed a few seconds.

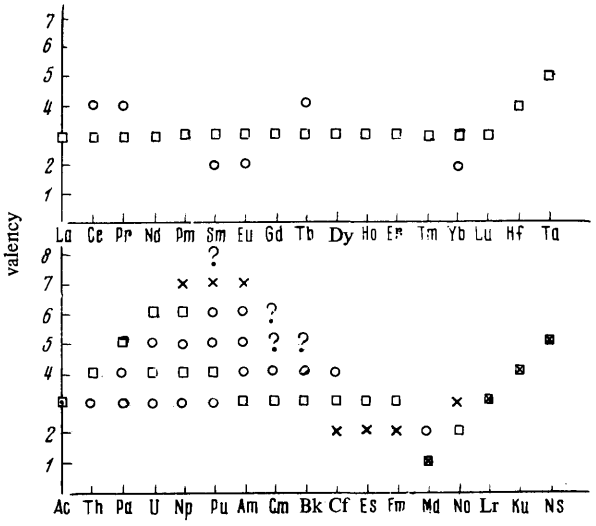

Figure 5. Valency states of lanthanides and actinides (as well as hafnium, kurchatovium, tantalum, and nielsbohrium). The most stable states are indicated by squares, and states first detected in the USSR by crosses (Np, Pu, Am, Cf, Es, Fm, and Md at the Institute of Physical Chemistry of the USSR Academy of Sciences, and No, Lr, Ku, and Ns at Dubna).

Advances in the synthesis and in the study of the properties of the far transuranium elements have enhanced the interest taken in the problem of the limits to which the periodic system can be extended. Only a decade ago it was supposed that spontaneous fission restricts the possibilities of synthesising elements 110–112. However, calculations by Soviet and foreign theoretical nuclear physicists[38–40] indicated that significant stabilisation of nuclei might result from the filling of nuclear shells containing 114, 126, and 164 protons, 184 and 258 neutrons. As a result the "isthmus of stability" shown in Fig. 2 may well appear, and contain many isotopes of elements in the vicinity of positions 114, 126, and even 164 in the Mendeleev system.

With regard to the chemical properties to be expected of these elements, data on the presently known elements and their extrapolation yield the sequence of electron shells depicted in Fig. 6. Each period is represented here by cells containing the symbols of the electron shells filled in the given period: i.e. each cell contains 2, 6, 10, 14, or 18 elements. Element 114 terminates the seventh period, element 164 completes the eighth period, and both are analogues of lead. Element 126 will occur in a new group of 18 elements—"octadecanides", apparently resembling actinium and in whose atoms the 5*g* shell will be completed—forming part of the 50-element eighth period[41–42]. The hypothetical eighth period is completed in Fig. 6 by element 168, and the ninth period by element 218.

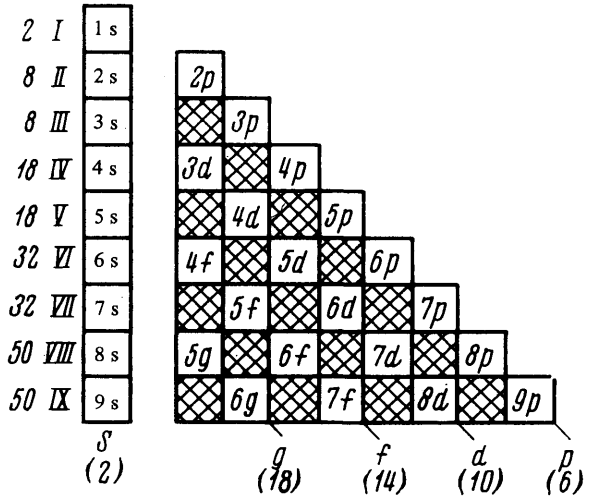

Figure 6. Diagram of sequence in which electron shells are filled in the periodic system. The total number of elements in the period indicated by the Roman numeral (which equals the serial number of the *s*-shell) is listed on the left-hand side. The total numbers of electrons in the various complete shells are given below the diagram.

Quite a number of attempts have been made during recent years to find in Nature or to obtain in accelerators some superheavy elements, but this has not yet been done with sufficient certainty. However, the links between the chemistry and the physics of elementary particles which have appeared recently have opened up completely new prospects for enriching and expanding our ideas on chemical elements. This refers to the numerous examples of so called "new atoms", in which the proton has been replaced by a different positive particle, or the electron by a different negative particle[43]. The possibility of replacing a proton by a lighter positive particle implies that ordinary hydrogen (protium) will cease to be the lightest occupant of the first position in the Mendeleev system. For example, we are now acquainted with kaonium, pionium, and muonium, in which the proton has been replaced respectively by a κ^+, π^+, and a μ^+ meson, and whose atoms are lighter by factors 2, 7, and 9. The lifetimes of these atoms are determined by the decay of the mesons and lie in the range 10^{-8}—10^{-6} s. The lightest conceivable isotope of hydrogen is positronium Ps, whose atom comprises a positron and an electron, and is lighter than hydrogen by a factor of 920. Because a positron has the same mass as an electron, positronium is the only atom completely devoid of a heavy nucleus. Apart from

its extraordinarily small mass, positronium differs from ordinary radioactive hydrogen (tritium) in the most important fact that all the characteristics of its loss by mutual annihilation of the positron and the electron—lifetime, number of γ-quanta emitted on annihilation, their energy and angle of divergence—depend on the properties of the surrounding medium, which permits a completely fresh investigation of these properties. The extremely short lifetime of positronium (10^{-10}–10^{-7} s) hinders its accumulation in concentrations exceeding a few atoms per cubic centimetre, so that none of the classical methods of chemistry can be used to study the reactions of positronium. This can be done only by nuclear methods, which enable the formation and destruction of every single positronium atom to be observed by recording the accompanying γ-quanta. Combining such methods with wide variation in the external conditions—composition of medium, concentrations, temperature, pressure, etc.—has enabled comprehensive quantitative investigations of all types of chemical reactions undergone by positronium to be made in the Institute of Chemical Physics of the USSR Academy of Sciences during the past twelve years[43–45]. Examples are given in Table 1 of oxidation, donor–acceptor interaction, substitution, addition, and conversion. Thus, for the first time in the history of radiochemistry, a detailed study has been made of the chemistry, including the kinetics and the mechanism of the reactions, of atoms which last at most 10^{-7} s.

Table 1. Examples of chemical reactions of positronium.

Type	Example	Method	Medium
Oxidation	$Ps + Fe^{3+} \rightarrow e^+ + Fe^{2+}$	time, angle	aqueous solutions
Donor–acceptor interaction	$Ps + M(C^+ :) \rightleftarrows PsM$ carbonium ion	time	organic solutions
Substitution	$Ps + Cl_2 \rightarrow PsCl + Cl$	time, angle	gases, organic solutions
Addition	$Ps + (CF_3)_2NO \rightarrow (CF_3)_2NOPs$	time, angle	gases, solutions, solid phase
Ortho–para-conversion	$o\text{-}Ps + NO \rightarrow p\text{-}Ps + NO$ (↑↑ ↓ ↑↓ ↑)	time, angle	gases, solutions
"Mixed" interaction (conversion or addition)	$o\text{-}Ps + NO_2 \rightarrow PsNO_2$ / $p\text{-}Ps + NO_2$ (↑↑ ↓ ↑↓ ↑)	time, angle	gases, aqueous and organic solutions

Despite the intrinsic interest of the chemistry of positronium, results obtained by the new positronium method for chemistry as a whole are of greater significance. For example, by using as standard the extremely short "proper" lifetime of positronium (with respect to annihilation), it was possible to measure the rates of several ultra-rapid chemical reactions occurring within fractions of a nanosecond and lifetimes of intermediate products of the order of picoseconds. Varying the temperature and the composition of the solvent in which the reactions of positronium were observed yielded a general technique for delimiting kinetic and diffusion régimes in the kinetics of liquid-phase reactions. Comparison of the rates of various reactions of hydrogen and positronium atoms led to a general conclusion on the mechanism of electron transfer in oxidation by ions of variable valency in solution. Observations on the reactions of positronium with a carbonium ion in different organic structures made it possible to determine the electronic conductance of various groups relative to that of the benzene ring.

Thus the chemistry of positronium has already passed the stage of "fitting" its possibilities to known facts and has entered the second, main stage, when it supplies new information of value to chemistry. The chemistry of other new atoms, sometimes termed in general *mesochemistry*, is still at the first stage, although the results already obtained are extremely promising. Pioneering work on mesochemistry has been done with the synchrocyclotron at the Laboratory of Nuclear Problems (directed by V. P. Dzhelepov) of the Joint Institute of Nuclear Research in Dubna, by the staff of this laboratory and several others, including academic institutes[46–67].

Systematic research on the physicochemical interactions of the hydrogen-like atom of muonium was undertaken at the Institute of Theoretical and Experimental Physics of the USSR State Atomic Energy Commission[43,46–50]. A method was proposed and developed[51–53] for determining the absolute rate constants of the chemical reactions of muonium with organic and inorganic compounds, the mechanism of these reactions was investigated, and quantitative dependences of reactivity on molecular structure were obtained. Known nuclear physical constants of the μ^+ meson and muonium were used as independent time standards, which permitted study of the behaviour of single muonium atoms during times of 10^{-9}–10^{-5} s. Conversion to hydrogen of results for the reactions of muonium in several cases provided more accurate characterisation of the reaction rate for hydrogen atoms themselves than did the corresponding direct experiments. The temperature dependence of the reactivity of muonium was examined, and activation energies of its reaction were determined. A sharp jump in polarisation of the μ^+ meson was revealed for the water–ice phase transition, associated with formation of a closed coordinated system of hydrogen bonds in the ice crystal.

The presence of Larmor precession of triplet muonium was first shown in chemically inert condensed media, and the energy of hyperfine splitting in the muonium atom was determined as a function of the periodic lattice potential of several materials, including semiconductors. Spin-exchange interactions of muonium in solutions of paramagnetic ions have been studied, and a close analogy was shown with results obtained by nuclear magnetic resonance but with substantial broadening of the range of measurements with respect to concentrations and spin–spin relaxation times.

The two-frequency spin precession of the μ^+ meson in the muonium atom, resulting from a quadratic Zeeman effect in the ground-state levels of muonium, was discovered[54] at the Kurchatov Institute of Atomic Energy of the USSR State Atomic Energy Commission. The two-frequency precession was used to study the properties of muonium introduced into the crystalline matrix of several materials. A method for studying diffusion of the μ^+ meson and muonium in a solid was based on the dependence of the interaction between the magnetic moment of the μ^+ meson and those of the nuclei of the medium on the rate of diffusion of the meson in the crystal lattice[55,56]. Spin relaxation of the μ^+ meson caused by dipole–dipole interactions was noted in metals and in light and heavy ice.

The interaction with matter of μ^- and π^- mesoatoms, in which one of the electrons has been replaced by a μ^- or π^- meson, is also of great interest[57-67]. Negatively charged mesons are slowed down in a medium, and ultimately trapped in atomic orbitals to form mesonic atoms and then, in a series of cascade transitions with emission of mesonic X-rays, reach the ground state in the inner K shell. Study of the characteristic X-ray emission spectrum, the lifetimes of the mesons, and their depolarisation enables the interaction of μ^- mesons with matter to be investigated. Observations on the chemical reactions of π^- mesons are based on comparing the specific pattern of their decay on interaction with free protons with the decay within any other π-mesonic atoms. Such work was begun more than ten years ago in the Laboratory of Nuclear Problems of the Joint Institute of Nuclear Research (by Prokoshkin and his coworkers[58,59]); recently the Institute of Chemical Physics of the USSR Academy of Sciences, the State Institute of Applied Chemistry, etc. have taken part in this work.

Since the radii of atomic orbitals are inversely proportional to the mass of the particles occupying them, this radius is minute—around 10^{-11} cm—for atoms of mesohydrogen in the ground state. It would seem that mesonic atoms should not be affected by other chemical bonds at distances of hundreds of mesoatomic dimensions in the molecule. Therefore the discovery of many relations for mesonic atoms which conform to the Mendeleev periodic dependence on atomic number Z was completely unexpected.

Fig. 7 illustrates examples of such regularities for μ^-- and π^--mesonic atoms (given for π^- by the relation

where $W^{exp}_{Z_mH_n}$ is the experimental probability of the nuclear capture of π^- mesons by protons of hydrogen atoms). Such examples led to the so-called "model of large mesomolecules"[60-62] for the properties and transformations of molecules involving excited mesonic atoms, in which the meson is situated not in the ground state but in an orbital remote from the nucleus which has a principal quantum number n and hence a radius increased by a factor n^2, and reaches normal atomic dimensions. Fig. 7 shows that such orbitals are no longer mesoatomic but are mesomolecular. Observations of the formation and the transformations of large mesomolecules yield several conclusions on the properties of other valency bonds in these molecules and on the electronic effects of various functional groups. Furthermore, such observations enable a definite correlation to be established between mesochemical and radiation-chemical reactions and the rate constants of chemical reactions involving mesonic atoms and radicals to be determined.

We have already mentioned the four levels in the structure of matter, and have proceeded from particles through nuclei to atoms and molecules. But the highroad of modern research is based on the synthesis of ideas on

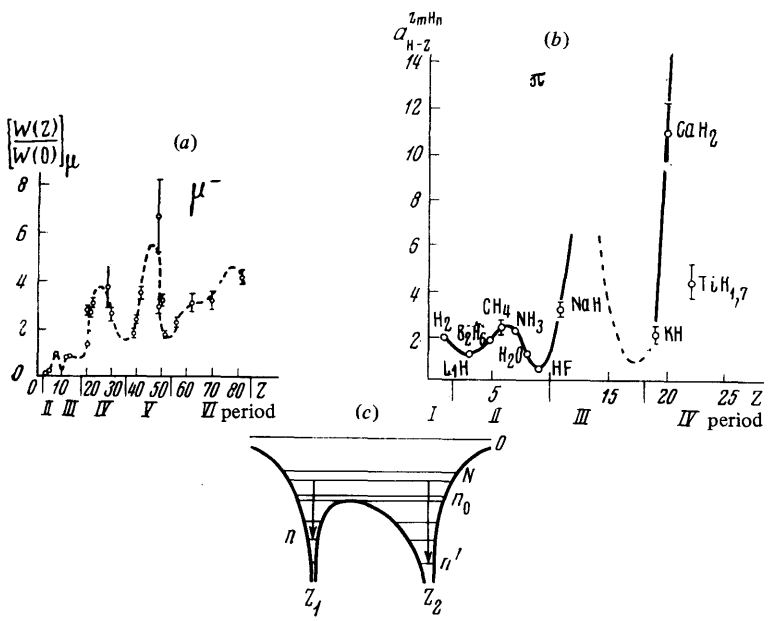

Figure 7. Examples of periodic dependence of certain mesoatomic reactions on atomic number of element Z: *a*) ratio of probabilities of atomic capture of μ^- mesons by element Z and by oxygen chemically combined with it in oxides Z_mO_n;[57] *б*) coefficients $a_{H\text{-}Z} = W(H)/W(Z)$ representing ratio of probabilities of capture of π-mesons by hydrogen and by element chemically combined with it in the saturated hydride Z_mH_n (aggregate of data from several Soviet and foreign papers); *c*) scheme of mesonic levels in diatomic "large mesomolecule" Z^1Z^2. Above n_0 are generalised mesomolecular levels, and below it are located mesoatomic levels Z^1 and Z^2.[60]

the structure of nuclei and electron shells, on the unity of the quantum-mechanical description of the properties of both.

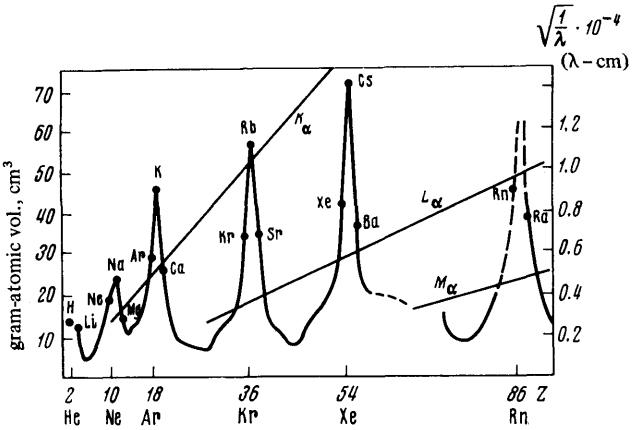

Figure 8. Typical examples of periodic dependence (of atomic volume) and linear dependence (of square root of wave-number of α-lines of K-, Z-, and M-series X-rays—Moseley's law) on atomic number Z of element.

The discovery and interpretation of Mendeleev's periodic law provided for chemistry and physics the two types of dependence of properties of the electron shells on the nuclear charge illustrated in Fig. 8. For the outer, valency shells we have a periodic relation, represented here by the atomic volumes. The relation of the inner, deep shells is a monotonic power dependence represented in Fig. 8 by Moseley's linear law.

The next contemporary stage, to whose establishment and development Soviet scientists have made an enormous contribution, entails the detection, examination, and utilisation in chemistry—and in all other natural sciences—of interactions between outer and inner electrons, outer electrons and nuclei, i.e. interrelations as it were between periodic and power functions of the atomic numbers of the elements (with the atomic numbers themselves as a particular case).

The first example of such interactions, now combined under the name *hyperfine interactions*, was discovered in 1928 by Terenin and Dobretsov[68], and independently by Schüler[69], as a result of accurate investigations on the optical spectra of sodium vapour. It was found that each of the two components of the yellow D-line was split only by 0.02 Å, and this splitting could be explained on the assumption that spins and magnetic moments were present not only in the electrons but also in the nuclei. In the above work, incidentally, Terenin and Dobretsov used for the first time atomic beams—a technique which has since been widely used in various resonance methods.

Table 2 lists the various forms of hyperfine interaction and methods involving their use. One of the main types is the interaction of the electric charges and the magnetic and quadrupole moments of nuclei with the charge of the s-electrons and the intramolecular magnetic and non-uniform electric fields. These hyperfine interactions are used in electron spin resonance (discovered by Zavoiskii[70,71] in 1944) and in other methods of microwave spectroscopy, in particular nuclear magnetic resonance and nuclear quadrupole resonance. Hyperfine interactions play a decisive role also in γ-resonance or Mössbauer spectroscopy, first placed in the service of chemistry by the work of Soviet scientists[72,73]. The hyperfine interaction energy involving valency electrons is in all cases many orders of magnitude smaller than even those of the weakest chemical bonds, and the dependence of this energy on the nuclear charge is represented by most insignificant periodic bumps, as it were, on the background of far stronger periodic or monotonic relations. Fig. 9 shows as example of this situation logarithmic plots of the periodic dependence on atomic number of the density of valency s-electrons in the region of the nucleus and the monotonic increase in total density of all s-electrons on the nuclei of elements from lithium to krypton.

Table 2. Hyperfine interactions and methods of use.

Type of interaction or dependence	Parameter and energy of interaction*	Experimental methods
Magnetic dipole (M1) interaction between nucleus and unpaired ("own" or "foreign") electrons	$\mu_{nucl}H \sim 10^{-6} - 10^{-4}$ eV	microwave spectroscopy—e.s.r., n.m.r.
Electric quadrupole (E2) interaction between nucleus and valency electrons or neighbouring ions	$eqQ \sim 10^{-7} - 10^{-6}$ eV	n.q.r. double resonances, spin echo, etc.
Coulombic (electrostatic—E0) shielding of nuclear charge by s-electrons	$\frac{V_{nucl}}{V} I_1 \sim 10^{-8} - 10^{-7}$ eV	Mössbauer
Coulombic (electrostatic—E0) shielding of charge of inner by outer electrons; dependence of energy of vacant levels on effective charge of atomic core	$\frac{V_{inner}}{V} I_{inner} \sim 0.1 - 10$ eV	X-ray electron and photoelectron spectroscopy or e.s.c.a.
Dependence of Coulombic energy of interaction of electrons with nuclei on nuclear mass (isotope effects in ionisation potentials)	$\frac{m}{M} \cdot \frac{\Delta M}{M} I \sim 10^{-6} - 10^{-2}$ eV	Accurate chemical X-ray spectroscopy, determination of effective charges on atoms
Dependence of energy of vibrational levels on nuclear mass (isotope effects in vibrational levels of molecules)	$\frac{\Delta M}{M} E_{vibr} \sim 10^{-4} - 10^{-3}$ eV	Accurate optical spectroscopy and laser methods for separating isotopes

* μ_{nucl} = magnetic moment of nucleus; H = intramolecular magnetic field on nucleus; e = charge of electron; q = gradient of intramolecular electric field; Q = quadrupole moment of nucleus; V_{nucl} = volume of nucleus; V = volume of atom; V_{inner} = volume of inner shell; I = ionisation potential (I_1 for first electron, I_{inner} for inner electron); m = mass of electron; M = mass of nucleus; ΔM = difference in mass between isotopes; E_{vibr} = energy of vibrational level.

Interaction between the electric charges of the outer and inner electron shells is apparent in changes (of fractions or even a few electron-volts) in the energy of electrons removed from the inner shells of the atoms, and it also leads to the appearance of a specific fine structure in the X-ray spectra. This forms the basis of the so called photoelectron spectroscopy, whose X-ray and ultraviolet forms were established by Siegbahn et al. in Sweden[74,75] and by Terenin et al. in the USSR[76], and also of precision chemical X-ray spectroscopy, founded by workers of the USSR Academy of Sciences at the Vernadskii Institute of Geochemistry and Analytical Chemistry, the Institute of the Mineralogy, Geochemistry, and Crystal Chemistry of the Rare Elements, the Kurnakov Institute of General and Inorganic Chemistry, and the Konstantinov Institute of Nuclear Physics[77-83].

Finally, the isotopic dependence of the vibrational energy levels and the ionisation potentials has recently found most interesting application for the laser separation of isotopes, which has been accomplished in the Institute of Spectroscopy of the USSR Academy of Sciences[84].

A few examples may be cited of the great successes achieved by Soviet scientists in the use of hyperfine interactions in various chemical problems. Some years after the discovery of electron spin resonance by Zavoiskii, and in the same place Kazan, the first observation of hyperfine structure in e.s.r. spectra was made by Kozyrev et al.[85] (and independently in England[86]), which ensured the successful application of the new method in chemistry[86]. Chemical e.s.r. spectroscopy owes its origin largely to Voevodskii[87], who made it a powerful weapon in structural kinetic investigations, in particular the observation of free radicals formed directly during irradiation of various substances, as well as in investigations on so called weak chemical interactions[88,89], whose energy is incomparably smaller than the usual thermal energy but close to the energy of hyperfine interactions. Such interactions are too weak to be observed by methods like optical spectroscopy, measurement of dipole moments, etc.; yet they often control a most important chemical phenomenon—the mutual influence of the reactivities of different functional groups distant from each other—and are apparent in differences (spatial or temporal) in the delocalisation of electrons in the molecules. The e.s.r. method made possible the direct observation of such delocalisation of electrons[90,91], attempts at which had been begun towards the end of the 1950s[90] on radical-anions of the type shown at the top of Fig. 10. But here the left-hand and right-hand rings are not equivalent, owing to the approach of a gegenion (e.g. Na^+, R^+) towards the negative charge, and this prevents delocalisation—"erosion" of the free valency and the negative charge between the two rings. Only quite recently has the exchange of electrons been demonstrated between two distant identical functional groups, in the stable nitroxide biradical shown in the middle of Fig. 10.[91] The e.s.r. spectrum of this biradical in various solvents is characterised by five (bottom right in Fig. 10)—not

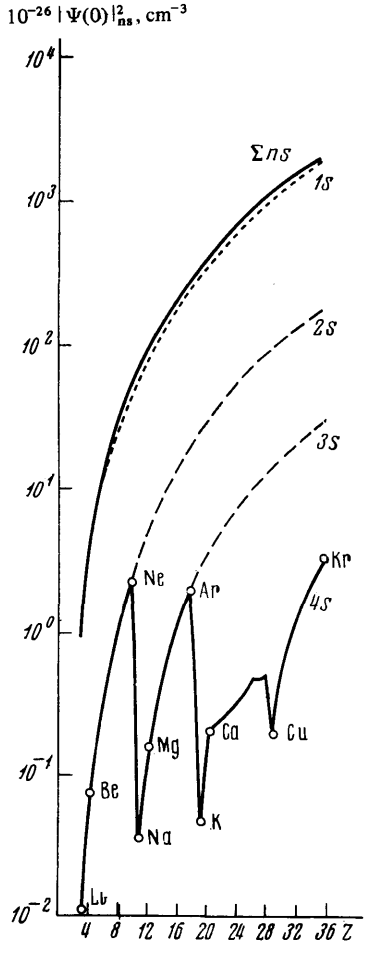

Figure 9. Dependence on atomic number Z of s-electron densities (all calculated per s-electron to a non-relativistic approximation): valency s-electrons $|\Psi(0)|^2_{ns}$ in region of nucleus (bottom full curve); 1s, 2s, and 3s densities (broken curves); total density of all s-electrons (upper full curve).

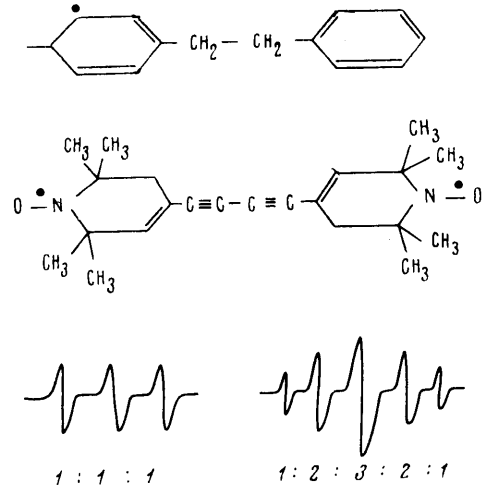

Figure 10. Illustration of e.s.r. investigation of the delocalisation of electrons in molecules: examples of test materials (radical and biradical) (above and centre); typical spectra corresponding to localisation (triplet) and delocalisation (quintet) of electrons in nitroxide biradical (below).[91]

three (bottom left)—hyperfine splitting components, which indicates that each of the unpaired electrons at once undergoes the same interaction with the two (its "own" and the "other") nitrogen-14 nuclei. The frequency of the effective exchange of position by the two electrons here exceeds 10^8–10^9 s^{-1}.

Among other interesting recent chemical applications of e.s.r. we may mention direct observations of the tunnel transfer of electrons in irradiated frozen alkalis at low temperatures, when the distance tunnelled is reckoned in tens of ångströms [92]. The method proved to be sensitive to extremely slow movements of paramagnetic labels, with linear speeds reaching 10^{-7} cm s^{-1} and diffusion coefficients reaching 10^{-17}–10^{-18} cm^2 s^{-1}. [93] It is difficult to overestimate the possibilities which such observations open up for physicochemical biology, the study of molecular kinesis phenomena§, in particular conformational transitions of biopolymer molecules, and various types of motion at molecular, supermolecular, and cellular levels. The e.s.r. method originated in experiments on a condensed phase, to which it was restricted for a long time. Subsequently, however, it found fairly wide application for the study of branched chain reactions in the gas phase [94,95] and from 1967—mainly in the work of Nalbandyan et al. [96–98] and because of the substantial improvement in the sensitivity of e.s.r. instruments—also in the investigation of degenerate branched gas-phase reactions, of particular theoretical and practical interest, such as the oxidation of hydrocarbons, when the concentration of active centres is far smaller.

Further prospects for studying the gas-phase and surface reactions of paramagnetic atoms and free radicals by means of hyperfine interactions are opened up by the maser kinetic method developed by Tal'roze and his coworkers [99,100]. Here, as in e.s.r., use is made of the magnetic hyperfine interaction between electron and nucleus, which in hydrogen atoms causes certain transitions between two hyperfine sublevels of the ground state of wavelength 21 cm. Interaction of a beam of hydrogen atoms from a hydrogen quantum generator (the maser) with various molecules leads to the observed relaxation of the inversion of hyperfine sublevels, so that excellent accuracy can be ensured in the determination of rate constants with around 10^4 improvement in sensitivity relative to e.s.r. in the gas phase.

At the present time about 50% of all e.s.r. spectrometers used in world science are concentrated in the Soviet Union. The widespread introduction of e.s.r. in industry—for rapid analysis or for the optimisation of several technical and in particular catalytic processes using paramagnetic ions of transition metals—promises to have a very considerable economic effect. A theoretical basis for such development may be provided by the comprehensive series of investigations made at the Vernadskii Institute of Geochemistry and Analytical Chemistry [101] on the application of e.s.r. to the study of complex formation by paramagnetic ions in solution. Portable e.s.r. spectrometers suitable for the above purposes have been suggested in the Institute of Chemical Physics [102].

Nuclear magnetic resonance has found extraordinarily wide use by Soviet chemists. Because of the thorough isolation of a system of nuclear magnetic moments from all other degrees of freedom, it is characteristic of this form of microwave spectroscopy that the exchange of energy between this system and the environment in a condensed phase is extraordinarily difficult. Nuclear magnetic spin–lattice relaxation times reach many hours in molecular crystals, and many minutes in pure organic liquids (about the same as the spin–spin relaxation time in liquids). However, the action of the various local fields is averaged out in liquids by Brownian motion, and in the solid phase by the superposition of specially selected external high-frequency fields. Hence under the usual experimental conditions, i.e. with external magnetic fields of $\sim 10^4$ G, when the energy of interaction of the nuclear magnetic moments with the field is of the order of 10^{-7} eV, while the characteristic frequency of precession of these moments $\nu \simeq 10^8$ Hz, n.m.r. lines can be obtained of width reaching $\Delta\nu \simeq 10^{-2}$ Hz. Although the relative width of the n.m.r. spectral lines $\Delta\nu/\nu \simeq 10^{-10}$ is several orders of magnitude larger than for the Mössbauer effect, the n.m.r. method has as yet no peers with respect to absolute line width ($\Delta\nu \simeq 10^{-2}$ Hz corresponds to $\Delta E \simeq 10^{-17}$ eV). Two factors—the chemical shift and indirect spin–spin interaction of nuclei—are responsible for the regular displacement, depending on the molecular structure of the medium, undergone by peaks of such record narrowness. The range of dimensionless chemical shifts varies from 2×10^{-5} for protons to $\sim 10^{-4}$–10^{-3} for heavy atoms. Spin–spin interaction constants vary in absolute value from zero to several kilohertz depending on the density of valency electrons in the region of the nucleus and on the degree of overlap of electrons in the chain of bonds at whose ends are situated the two atoms whose nuclear interaction is under investigation.

The contribution made by Soviet scientists to establishing the theoretical foundations of nuclear magnetic resonance is very great. Work in the Institute of Chemical Physics of the USSR Academy of Sciences, which has acquired a world-wide reputation [103], combined the concepts of a spin temperature and a reservoir of dipole–dipole interactions, and gave widely quoted equations describing the processes in a system of nuclear spins for any value of the saturating field. The Soviet book "Teoriya Yadernogo Magnitnogo Rezonansa" [104], which gave the first general theory of the magnetic shielding of nuclei, became a work of reference for n.m.r. specialists throughout the world.

Studies undertaken in the Institute of Organoelementary Compounds of the USSR Academy of Sciences provide the chief examples of the fundamental experimental results which we have obtained by means of nuclear magnetic resonance. Some time ago Nesmeyanov made a detailed analysis of the close relation between the chemistry of organoelementary compounds and the periodic law [105]. A clear recent confirmation of such a relation was the establishment [106] of periodicity in the shielding of carbon nuclei in cyclopentadienyl ligands of isostructural π-complexes of transition metals (shielding is maximal with the iron subgroup, as shown in Fig. 11). However, n.m.r. reveals far finer regularities. Electronic effects due to different substituents are widely discussed in chemistry, but what occurs at the point of bonding of substituents remained well hidden and was the subject of theoretical speculations, for the key (substituted) atom itself is usually not involved in the range of interactions for which the role of substituents is considered.

Fig. 12 shows the variation in shielding of the key carbon atom in a substituted aromatic system [107]. The effect of substituents on the key atom was found to be stronger in absolute value by factors of 10–10^2 than in the "strictly aromatic" part of the molecule, and furthermore, when the bond with the substituent was weakly polar (with alkyl

§ The term "moleculokinesis", meaning the functional motion of molecules, was introduced by V.A. Engel'gardt.

or methine groups), its sign was opposite to that to be expected from the electron-donor or electron-acceptor character of the substituent. With alternant aromatic systems this alternation of sign is considered also within the region of ring delocalisation of π-electrons; in non-alternant systems the reversed sign of the effect is characteristic only of the key atom. These facts give an experimental guideline for choosing an adequate quantum-chemical description of the electronic effects of weakly polar *C*-substituents. If, however, the bond between the key atom and the α-atom of the substituent is strongly polar, the carbon-13 n.m.r. chemical shifts vary in conformity with the usual views on the inductive effect of a substituent: i.e. alternation of the effect on the key carbon atom is now absent. This is clearly seen from the central portion of Fig. 12, which shows the variation of shielding and the parallel variation of the total electron density of corresponding carbon atoms in a cyclopentadienyl ligand of ferrocene with a carbonium ion as substituent. The lower part of Fig. 12 shows the superposition of effects which is characteristic of substituents of mixed type, e.g. formyl.

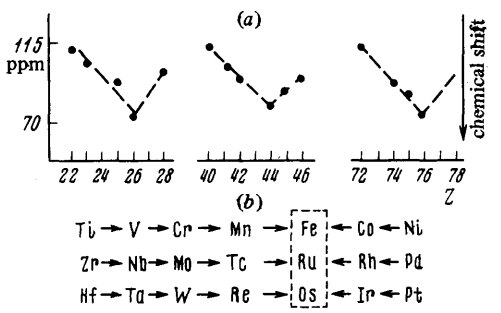

Figure 11. (*a*) Plots of variation in chemical shifts (ppm with respect to tetramethylsilane) of ^{13}C nuclei in n.m.r. spectra of unsubstituted ligands in π-cyclopentadienyl derivatives of transition metals. (*b*) Sequence of increasing shielding of ^{13}C and ^{1}H nuclei in π-cyclopentadienyl derivatives of transition metals.

this applies equally to the two β-atoms; but if an asymmetric atom is adjacent to the ring, spectral differences arise between α- and α'-, and between β- and β'-carbon-13 atoms. Here we are dealing with short-range and long-range intramolecular effects of asymmetric atoms.

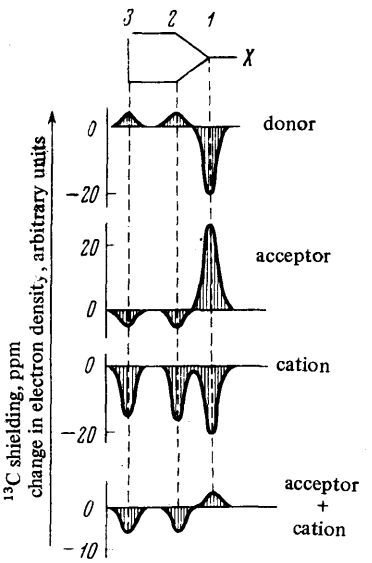

Figure 12. Variation in the shielding of carbon-13 nuclei in a cyclopentadienyl ligand of ferrocene under the influence of substituents attached to the α-carbon atom [107]. Donors (alkyls) increase the electron density at positions 2 and 3, but diminish it on the key atom. Acceptors (cyano and methine) decrease the electron density at positions 2 and 3, but increase it on the key carbon atom. A carbonium ion produces effects of the same sign, by diminishing electron density on all the atoms of cyclopentadiene ring. Substituents of mixed type (formyl, etc.), by producing competing effects of opposite sign at the key atom, cause a slight change in shielding of the key carbon-13 nucleus.

In the current physics of elementary particles fairly complicated views are held on the spatial, charge, and temporal symmetry of their interactions, on the relation between the charge and space parities of particles and antiparticles. As illustration, a neutrino is regarded as a kind of screw with a left-hand thread, and an antineutrino as one with a right-hand thread. Such properties are represented in scientific literature by terms such as "chirality" and "helicity", which imply "handedness" and "twistedness".

Study of the properties and interactions of optically active compounds with asymmetric atoms has revealed many curious new analogies between the chemistry and the physics of elementary particles, which have sometimes already been explained but occasionally still await a strict interpretation based on quantum mechanics and group theory. An example of such a new fact is the interesting phenomenon (Fig. 12) discovered by Kursanov et al. [108] that, when a cyclopentadienyl ring contains a substituent with a symmetrical atom directly adjacent to the ring, the two α-carbon-13 atoms have identical n.m.r. spectra, and

Many other examples of this kind have recently been investigated by Reutov et al. [109] for several classes of organoelementary compounds. A series of papers by Kabachnik and his coworkers [110,111] have demonstrated the effects of the intermolecular interaction of enantiomers, which has become possible only because of the exceptional absolute sensitivity of n.m.r. and the excellent reproducibility of the results. A definite chemical shift in the singlet phosphorus-31 n.m.r. spectrum is observed for a solution of "left-hand" molecules of biologically active phosphoric depsipeptides in an optically inactive solvent (chloroform); exactly the same shift is observed, of course, for a solution of "right-hand" molecules. With the same number of left- and right-hand molecules present an n.m.r. singlet is still observed, but displaced. In general, i.e. in a left–right mixture, two n.m.r. lines are present, whose positions and intensities depend on the relative concentrations of the two forms, as shown in Fig. 14. Thus "homocontacts" and "cross contacts" of left and right molecules in an inert solvent are different,

and their mutual shielding is non-equivalent. A pair of left and right molecules associate to form a diastereomer, which is short-lived on the n.m.r. time scale ($\tau \leqslant 10^{-3}$ s). It is of fundamental importance to investigate not only the analogy of, but also the possible effect of the asymmetry of elementary particles in our world on, the asymmetry at molecular and biological levels.

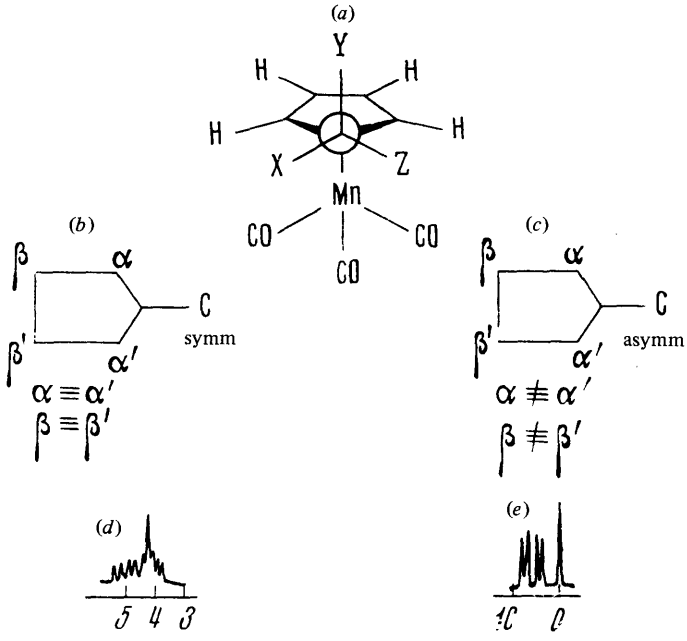

Figure 13. Increase in multiplicity of n.m.r. spectra of (*a*) cyclopentadienyltricarbonylmanganese under the influence of an asymmetric substituent[108,109]: (*b*) α- and β-carbon atoms chemically equivalent in pairs (giving a common n.m.r. signal) if the substituent is optically inactive; (*c*) all four carbon atoms in the substituted ring are chemically non-equivalent if the substituent is optically active; (*d*) ^{1}H n.m.r. spectrum; (*e*) ^{13}C n.m.r. spectrum.

Brief mention must be made of the extremely interesting work of Knunyants[112,113] on organofluorine compounds and of Andrianov[114-117] on organosilicon compounds. Comprehensive correlations between n.m.r. spectra and structure were obtained for both classes of compounds, and the chemical shifts of various fluorine-containing and silicon-containing functional groups were shown to be characteristic. Quantitative aspects of the effect of fluorine atoms on the carbon–mercury spin–spin interaction were obtained by Fourier carbon-13 n.m.r. spectroscopy. In molecules of the type R_2Hg, where R is a fluorine-containing substituent with sp^3 hybridisation of the α-carbon atom, only a small fraction of the observed spin interaction of the carbon-13 and mercury-199 nuclei is due to the usually prevalent Fermi contact mechanism.

A very peculiar reaction involving ring expansion in siloxanes has been discovered by means of n.m.r. spectroscopy. Furthermore, application of the method to organocyclosiloxanes led to a correct formulation of the converse problem, important for the method itself, which arises in interpreting the observed changes in chemical shifts and spin–spin interaction constants.

A clear and extremely important result at the level of the structure of complicated biomolecules has been obtained by Ovchinnikov et al.[118] working at the Shchemyakin Institute of Bio-organic Chemistry. Conformational rearrangements of the antibiotic valinomycin on complex formation with the potassium ion have been demonstrated by Fourier carbon-13 n.m.r. spectroscopy. Complex formation is accompanied by strong shifts (3–5.5 ppm) of the signals of the carbonyl groups to smaller magnetic fields, which is attributed both to the effect of hydrogen bonds and to the involvement of the carbonyl groups themselves in weak ion–dipole interaction retaining the potassium ion in the closed bud of valinomycin. Experiments finally confirmed a pattern of competition between intramolecular and intermolecular hydrogen bonds governing the bonding of ions in the central cavity of these beautiful, flowerlike cyclic molecules and their liberation on conformational opening of the bud, when the effect of the medium ruptures the intramolecular hydrogen bonds shown by double lines in Fig. 15*a*. These results are especially significant for the reason that the conformational rearrangements effect the transport of ions through cell membranes.

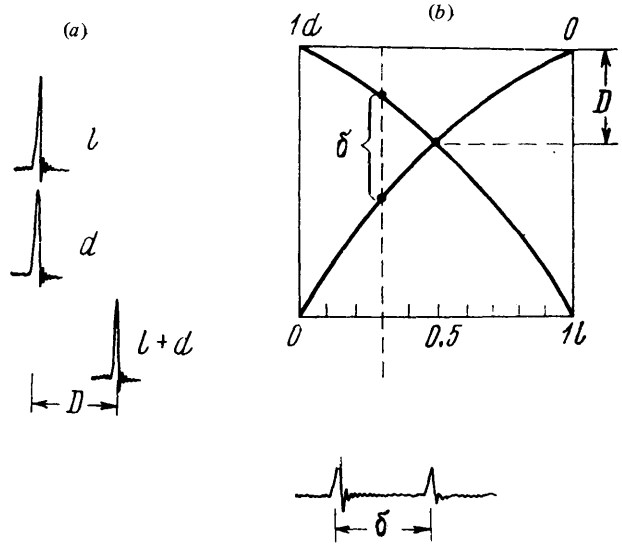

Figure 14. Statistically controlled diastereomeric association in solutions of enantiomers[110,111]: *a*) right-hand and left-hand molecules separately give a singlet n.m.r. signal with an identically coinciding chemical shift, which is displaced if they are mixed in equal quantities (deviation of chemical shift); *b*) with unequal concentrations of left-hand and right-hand molecules in solution the n.m.r. spectrum becomes a doublet, with the intensity ratio of the components equal to the concentration ratio.

Conditions of nuclear magnetic resonance are established by a strong and uniform external magnetic field, but in nuclear quadrupole resonance the three-dimensional quantisation of the magnetic moment of the nuclei is specified by intracrystalline electric field gradients which orient the nuclear quadrupole moments. The limited

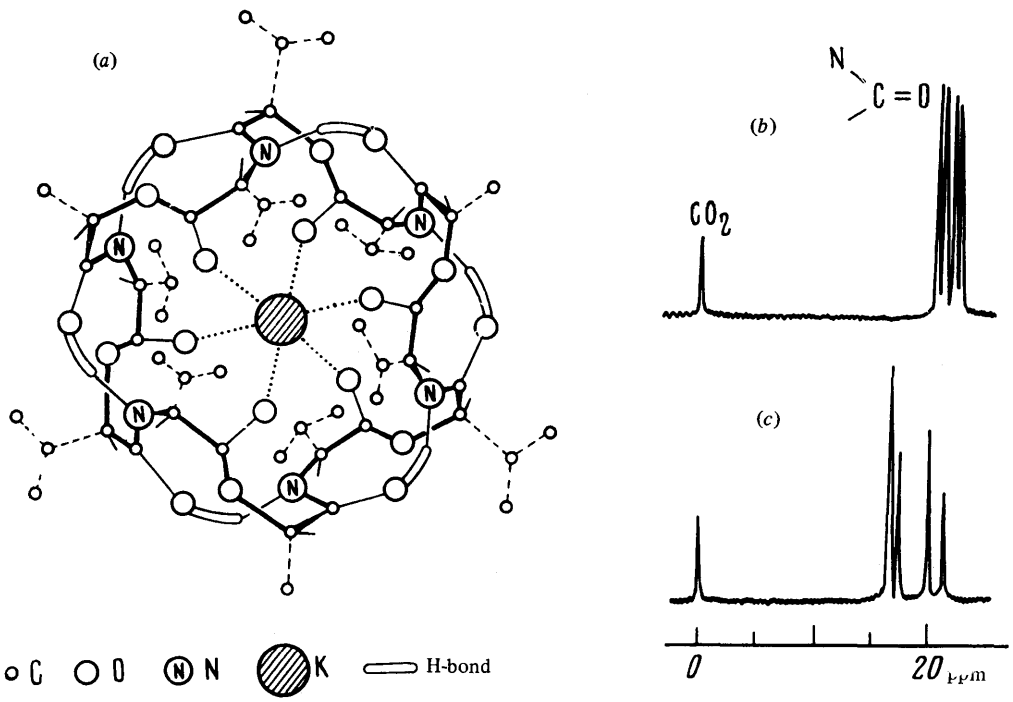

Figure 15. Observation of conformational rearrangement of valinomycin on complex formation with alkali-metal ions[118]: *a*) three-dimensional structure of potassium complex; *b*) position of n.m.r. signals of carbonyl groups in valinomycin; *c*) position in its potassium complex.

scope of the Review does not permit any detailed consideration of the work of Soviet scientists in applying nuclear quadrupole resonance to the study of the chemical structure of matter, although we have obtained the majority of the data on the chemical shifts of n.q.r. frequencies that have now accumulated in the world. Numerous correlations between n.q.r. frequencies and various σ-constants characterising the reactivity of molecules (such as the Hammett, Taft, etc. constants) have been established by the work of the Institute of Organoelementary Compounds[119,120], the Kazan chemical school of A.E. and B.A.Arbuzov[121], and also Voronkov[122]. Limitations have been revealed in the correlation approach, because several factors govern the relations between the electric field gradients on a given nucleus and the activity of the centres in different classes of reactions.

The applications of Mössbauer or γ-resonance spectroscopy to various fields of chemistry are universally associated primarily with the Institute of Chemical Physics. Investigations in this field were presented to the Annual General Meeting of the USSR Academy of Sciences in February 1966, and the lecture was subsequently published[122a], so that the present discussion will be confined to two or three significantly novel aspects. As early as 1962 the asymmetry of the γ-resonance spectra illustrated in Fig. 16 was discovered in the Institute. It permits detection and quantitative description of the anisotropy of bonds and vibrations of atoms in molecules and crystals from the type of spectra for isotropic polycrystalline powders, somewhat as the Debye method in X-ray diffraction gives the structure of single crystals from experiments on powders. During past years more than a hundred publications¶ have appeared on the above effect, which is referred in the world literature to Soviet scientists. A new effect of similar type was reported at the Institute in 1973, involving a difference between components of Mössbauer spectra not in peak area but in shape, whose study will permit characterisation of the anisotropic diffusion of molecular and supermolecular systems[133]. Use of emission γ-resonance spectroscopy, when the atoms are not in the stable form of absorbers but in the radioactive form of emitters of resonance γ-quanta, has opened up rich new possibilities for obtaining both structural and dynamic information.

Use of the iron-57 isotope as a Mössbauer label, with different spectra in all four forms—bivalent and tervalent, in high- and low-spin states—has shown convincingly[134] that the two classic coordination compounds familiar to all chemists since their student days of practical qualitative analysis—the beautiful Prussian Blue and Turnbull's Blue—are in fact the same compound (Prussian Blue), in which the high-spin outer-sphere ion is Fe^{3+}, while the low-spin inner-sphere iron is bivalent. However when these typical coordination compounds have been obtained, an electron escapes from the outer-sphere iron to the central ion of the complex, as illustrated by Fig. 17.

The first experiments by emission γ-resonance spectroscopy, when radioactive cobalt-57 was used as label

¶ Several interesting publications of recent years may be mentioned as example[123-132].

and the chemical state of iron-57 atoms formed by K-capture in the cobalt isotope was determined, supported the above conclusions. Subsequently, however, use was made of the fact that emission of a resonance γ-quantum of energy 14 keV by an excited iron-57 nucleus is preceded by the escape of another, harder quantum (123 keV–Fig. 18), and the time dependence of the form of the Mössbauer spectra of the hexacyanoferrate(II–III) complexes was studied. In this way it was possible to characterise an extremely unstable form of Turnbull's Blue at the instant of its formation[135], and to establish that the time of intramolecular electron transfer converting the complex into Prussian Blue was close to 10^{-8} s.

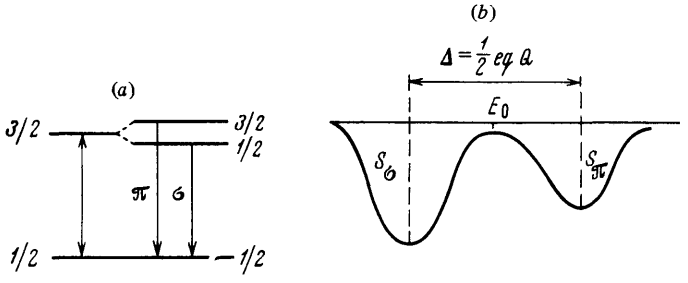

Figure 16. Illustration of effect of asymmetry of hyperfine structure of γ-resonance spectra due to anisotropy of motion of Mössbauer atoms: *a*) scheme of $\frac{3}{2} \rightarrow \frac{1}{2}$ transition in the quadrupole splitting of upper level (π-transition $\frac{3}{2} \rightarrow \frac{1}{2}$; σ-transition $\frac{1}{2} \rightarrow \frac{1}{2}$); *b*) asymmetry of Mössbauer quadrupole doublet for isotropic powdered specimen with different mean square amplitudes of vibration $\overline{x^2}$ and $\overline{z^2}$ perpendicular and parallel to the direction of the gradient q of the electric field in a molecule or in a crystal (s_σ and s_π are the areas of the peaks).

Russian Chemical Reviews, 43 (12), 1974 1035

As a method sensitive both to the electronic structure and to the motion of atoms and electrons, γ-resonance spectroscopy should undoubtedly in future occupy a prominent position in molecular biology for the study of numerous examples of the interrelation between the transport of electrons and changes in electronic states with particular mechanical movements. A most important problem in molecular biology is the mechanism of photoreception—the nature of the action of light on visual pigments and photoreceptor membranes—with which the "rhodopsin" project headed by Yu. A. Ovchinnikov is concerned. An extremely interesting result has recently been obtained in the Institute of Chemical Physics by collaboration between the Structure of Matter Department and N. M. Emanuel's department[136]. This was based entirely on the unique possibilities of simultaneously revealing both the electronstructural and the dynamic properties of a substance by means of γ-resonance spectroscopy. It has been established that the first stage of photolysis of the pigment—conversion of rhodopsin into prelumirhodopsin—is already accompanied not only by photoisomerisation of the chromophore (11-*cis*-retinal → 11-*trans*-retinal) but also by reversible conformational rearrangement of the whole photoreceptor membrane, which occurs even at extremely low temperatures (77°K) and leads to a sharp increase in the rate of spin–lattice relaxation.

The relative accuracy of γ-resonance spectroscopic measurements has no equal: fractional energy changes of the spectral lines of 10^{-15}–10^{-16} have already been recorded; this improves the relative accuracy of nuclear magnetic resonance by factors of 10^5–10^6. However, the energies of the transitions between two nuclear levels

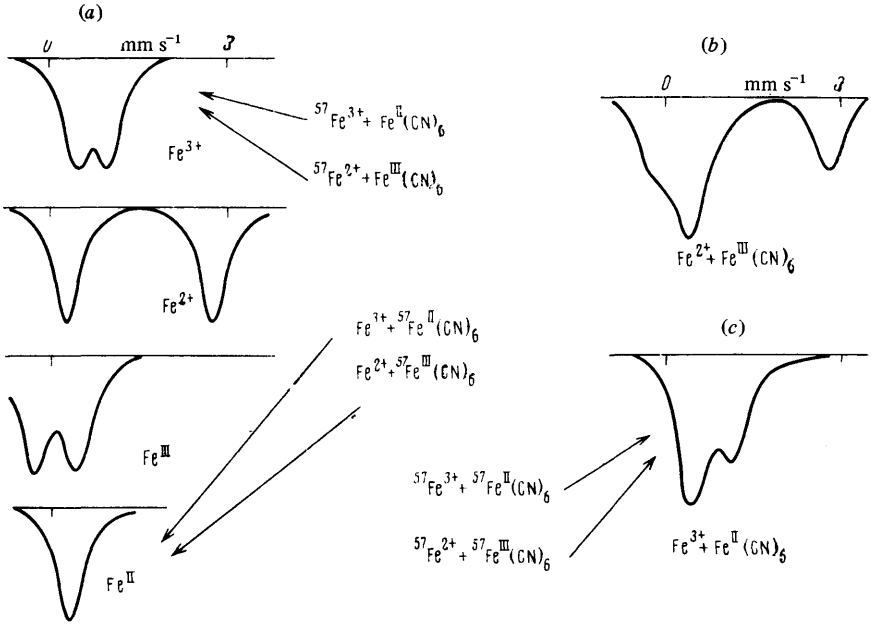

Figure 17. γ-Resonance spectra of hexacyanoferrate(II–III) complexes (only the spectra indicated by the arrows are observed): *a*) high-spin and low-spin forms of bivalent and tervalent iron; *b*) Fe^{2+} + Fe^{III} (Turnbull's Blue); *c*) Fe^{3+} + Fe^{II} (Prussian Blue).

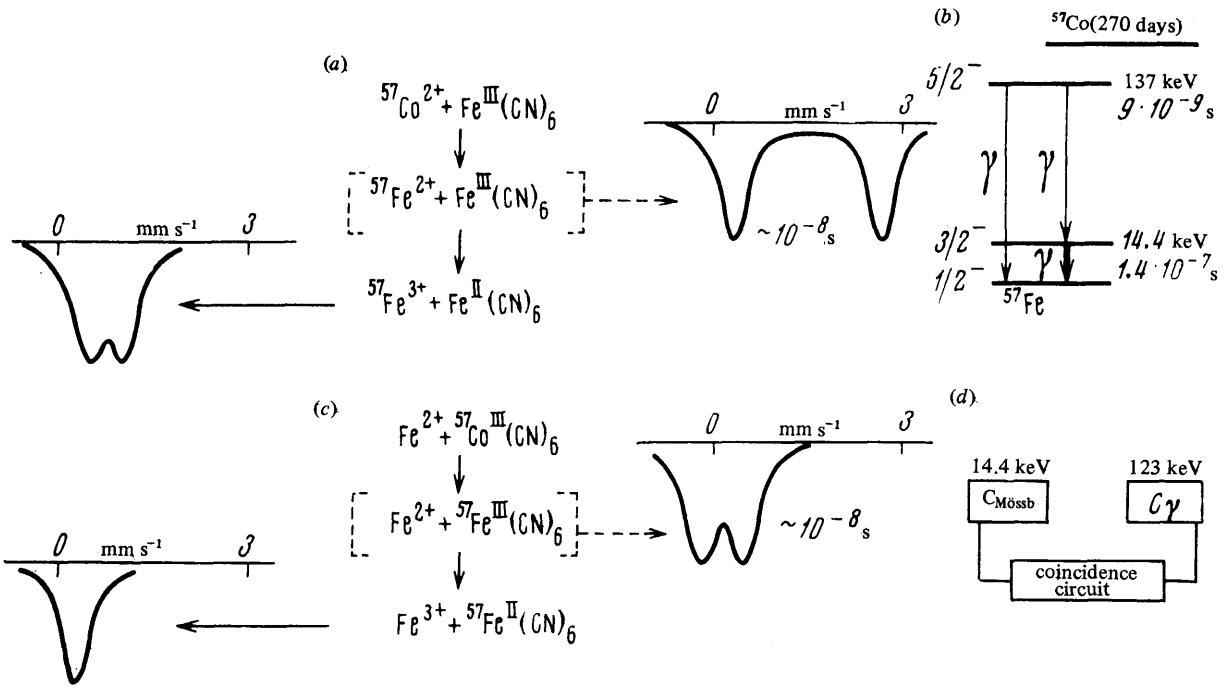

Figure 18. γ-Resonance emission spectra of systems formed by K-capture by cobalt-57 nuclei of: *a*) outer-sphere Co^{2+} with a hexacyanoferrate(III) anion—spectra integrated with time ($> 10^{-7}$ s) after the disintegration $^{57}Co \rightarrow {}^{57}Fe$); *b*) spectra of system (*a*) ~ 10^{-8} s after the disintegration; *c*) hexacyanocobaltate(III) anion with outer-sphere Fe^{2+} cation—spectra integrated with time ($> 10^{-7}$ s) after the disintegration; *d*) spectra of system (*c*) ~ 10^{-8} s after the disintegration.

used in the Mössbauer effect are reckoned in tens of electron-kilovolts, exceeding by almost a billion (10^{12}) the typical energies of n.m.r. transitions. Because of the scatter of local electric and magnetic fields and the presence of all kinds of defects, dislocations, etc., furthermore, the strongest non-uniform broadening of the spectral lines occurs when two different nuclei—an emitter and an absorber of γ-quanta—are involved in the resonance transition. Hitherto, therefore, it has not been possible to observe in Mössbauer spectra absolute line widths below 10^{-10} eV, which is wider than the best n.m.r. lines by a factor of 10^7. This fact played a decisive part in the unsuccessful plans of all kinds to produce a γ-ray laser, abandoned over a decade ago. During the past two or three years, however, fundamentally new ideas have appeared in papers by Soviet scientists—Kagan, Khokhlov, the present Reviewer, and others[137,138]—opening the way to produce γ-ray lasers both on lines of great natural width (i.e. on short-lived nuclei) with neutron pumping and by eliminating various forms of line broadening by combining the methods of γ-ray resonance spectroscopy and nuclear magnetic resonance. Furthermore, an original laser method has been suggested for separating nuclei excited to the Mössbauer levels necessary for stimulating γ-emission from the same nuclei in the ground state[139]. Work aimed at producing a γ-ray laser is of very great interest to physics, chemistry, and biology, for powerful beams of coherent radiation are apparently able to produce direct holographic three-dimensional images of molecules.

We have been considering above the use of hyperfine interactions between electrons and nuclei to study the structure of matter. Considerable successes have also attended quantitative observations of the interaction between electrons of outer and inner shells. The well known phenomenon of the photoeffect—the dislodgment of an inner or a valency electron by a quantum of definite energy—underlies X-ray electron or photoelectron spectroscopy, and the kinetic energy of the electron is measured in the most accurate β-spectrometer. The binding energy of an electron in chemically combined atoms is determined from the difference between the energy of the quantum and the kinetic energy. This quantity is a sensitive characteristic of the chemical bond: with its help we can use data on relative line intensities to construct diagrams of valency and inner electron levels, to determine the degree of oxidation of an element and the donor–acceptor character of a ligand in a complex, to solve many problems of the geometrical structure of a molecule, to estimate the effective charge on an atom, to make a quantitative analysis of elements and functional groups, and to study adsorbed molecules, catalysts, diffusion, the composition of the thinnest surface films, etc. Broad investigations in this field were begun in the Kurnakov Institute of General and Inorganic Chemistry at the end of 1970, and more than 500 simple

and complex inorganic compounds have been examined during the past three years. Some of the most interesting and important results[140] will be noted here.

Examination of specimens of a lunar regolith provided by Soviet automatic stations and by American cosmonauts has shown that the concentrations of elements at the surface of the particles differ appreciably and regularly from the bulk concentrations. A substantial part of the surface consists of metallic iron, coated with only an unusually thin layer of oxide or even in part not oxidised at all after a long time in the earth's atmosphere (Vinogradov, Zhavoronkov et al.[141,142]).

Study of a large number of isostructural series of complex compounds of platinum, palladium, rhodium, iridium, cobalt, and other transition metals has established sequences of ligands according to their ability to withdraw electron density from the central atom[140]. The sequence for acido-ligands is

$$F > NO_3 \gtrsim NO_2 \gtrsim CN \simeq \tfrac{1}{2}C_2O_4 \simeq NCS > Cl > Br \simeq SCN > I$$

the corresponding sequence for neutral ligands is

$$N_2 > CO \simeq C_2H_4 > C_2(C_6H_5)_2 > C_6H_5CN > NH_3 > C_5H_5N > R_2S > P(C_6H_5)_3$$

Buslaev et al.[143] have obtained schemes of molecular valency levels for oxo-anions and fluorides of non-transition elements in Groups II–V, and have established for the first time several regularities in the variation of energy levels of isoelectronic and isovalent series of compounds. These rules are supported by calculations[144]. Detailed consideration has been given to experimental and theoretical aspects of the determination of relative line intensities in an X-ray electron spectrum. A technique developed for the quantitative analysis of thin films on solid surfaces has been used to examine the surface characteristics of catalysts, semiconductors, certain protective coatings, etc.

Although electron spectroscopy for chemical analysis in its X-ray form (X-ray electron spectroscopy) has reached us from abroad, accurate chemical X-ray spectroscopy owes not only its fruitful application but also its actual origin to Soviet scientists. Chemical changes in the energy of X-ray lines, like the ionisation potentials of the inner electrons, are governed by the shielding effect of the outer electron shells on the inner shells. It was established as early as the 1920s that the energies of X-ray transitions are slightly dependent on the chemical bond, but only in the 1960s were methods first proposed, as a consequence of development of the appropriate quantum-chemical techniques in the Institutes of the USSR Academy of Sciences[77-83,145], for determining the effective atomic charges in molecules from the shifts in the lines of the X-ray emission spectrum. These methods are based on the principle that the magnitude of the shift is completely determined by the number and the character of the valency electrons belonging to the given atom. The effective charge on an atom in a compound is found from this relation and the measured shift of the X-ray line. At the present time the X-ray spectroscopic method for determining the effective charge on an atom is probably the most soundly based, and is widely used in Soviet and foreign laboratories. Measurement of the shift of the inner X-ray lines provides solutions in particular to the problems of the degree of oxidation of an element in a compound, the presence of non-equivalent atoms of the same element in a compound, and the coordination numbers of certain elements, and permits the study of several other characteristics of the geometrical structure of molecules.

Extremely important information on the electronic structure of chemical compounds (the ionisation energies of valency levels and the character of their wave functions) can be extracted from the energies and the relative intensities of X-ray transitions from valency levels and bands. For example, the relative intensities of the maxima in the K-spectrum of chlorine can be used to determine the ratio of the squares of the coefficients in the $3p$ orbitals of the chlorine atom in all the wave functions of the valency levels, and the energy position of the maxima to find the relative positions of the valency levels. Since the X-ray spectra of almost all the atoms in a compound can be studied, a fairly detailed picture of the electronic structure of the molecule is obtained. Work on the chemical X-ray spectroscopy of free molecules and isolated groups in crystals, semiconductors, and metals has been done in several Institutes of the USSR Academy of Sciences—the Kurnakov Institute of General and Inorganic Chemistry[146], the Institute of Inorganic Chemistry of the Siberian Division (Nikolaev et al.[147]), and the Institute of Metal Physics of the Ural Science Centre[148]—the Institute of Metal Physics of the Ukrainian SSR Academy of Sciences[149], etc.

The chemical bond has been investigated also by use of the fine structure of the edges of X-ray absorption spectra, which corresponds to electron transitions from inner levels to vacant levels of the discrete and continuous spectrum. These transitions can be used to construct a scheme of vacant levels and to determine the effective charge on the absorbing atom. The first method for such determination was developed in the Vernadskii Institute of Geochemistry and Analytical Chemistry and the Institute of the Mineralogy, Geochemistry, and Crystal Chemistry of the Rare Elements of the USSR Academy of Sciences[77-80], and was based on the dependence of the energy position of the discrete absorption lines and their relative intensity on the effective charge of the absorbing atom. This method stimulated the study of X-ray absorption spectra, and on its basis the problem of the relative intensities of the discrete spectrum and the origin of the continuous absorption spectrum was first posed and solved for the simplest model. Until the mid-1960s accurate chemical X-ray spectroscopy was confined to elements at the beginning and the middle of the periodic system. X-Ray methods for determining effective charges on atoms even of the heaviest elements were subsequently developed from work at the Konstantinov Leningrad Institute of Nuclear Physics of the USSR Academy of Sciences[81-83]. This new type of spectroscopy thereby acquired universal value.

Chemical X-ray spectroscopy provided a very clear demonstration of the particular inadequacy of formal ideas on the oxidation states of atoms. The determination of effective charges from X-ray emission and absorption spectra sometimes led to quite remarkable conclusions[77,78]. For example, whereas the effective charges in high-spin compounds of bivalent iron were only slightly less than the formal valency of the ion (2+), in the analogous compounds of tervalent iron these charges were not simply very far from the formal valency of the ion (3+) but, moreover, even smaller than for bivalent iron, about +1.2. The effective charges on iron in ferrocene and the ferricinium ion (where one electron has been removed) were almost identical (about +0.6). The effective charges of cations are in general always less than their formal valencies, while the charges on anions are numerically less than unity: in other words, Coulombic repulsion prevents the accommodation of more than one extra electron in an atom, after which only a redistribution of electrons

among different molecular orbitals takes place. In just the same way a large positive charge on an ion is balanced by electrons (which "leak" from other parts of the molecule) from other molecular orbitals. Therefore, as in the ferricinium ion it is not the central iron atom but the cyclopentadienyl ring which is ionised; in the ion $[Fe(H_2O)_6]^{3+}$, however, ligands (water molecules)—not the iron itself—lose three electrons. Although the calculation of effective atomic charges in molecules and the significance attributable to these quantities, in particular the volume in which the measured charge is concentrated, continue to be debated†, the positive side of the conclusions is undoubted: the electrostatic description of chemical bonds is decisively rejected even in high-spin compounds having a weak ligand field (which were the most reliable "refuge" of electrostatic concepts); the rightness and also in some measure validity of such an empirical generalisation as Pauling's principle of electrical neutrality are confirmed; and finally the need to apply the currently most popular and fruitful method of quantum chemistry—molecular orbital theory—to almost all chemical structures is convincingly demonstrated.

Modern structural chemistry makes use of radiation covering a range of more than thirty octaves (10^{10} of wavelengths, from fractions of an Ångström unit to decimetres). Different methods give, of course, complementary information, and only the combination of all methods will yield a consistent picture of the electronic structure of atoms and molecules. Owing to the impossibility of obtaining exact solutions to the Schrödinger equation for many-electron systems, chemists are compelled to use only approximate solutions. As a consequence, even in the most favourable case the complete wave function of a many-electron system—atom or molecule—can be sufficiently accurate only in certain of its regions: in other words, a wave function which may be entirely adequate e.g. for analysing the electronic spectrum of a molecule may prove completely unsuitable for describing the n.m.r., e.s.r., or γ-resonance spectrum of the same molecule.

The development of numerous spectroscopic methods enabling the various parts of many-electron systems to be "probed" has seriously tested theoretical methods of obtaining the wave functions of atoms and molecules. During the past decade this has greatly disturbed the coexistence of different approximate theories of the chemical bond, and one of them—the theory of molecular orbitals—has clearly tended to be preferred by research workers. This theory is based on the formation in a molecule of discrete states of individual electrons (molecular orbitals), defined by the self-consistent motion of the electrons in the field produced by the others and all the nuclei in the molecule. Thus the quantum-mechanical model of an atom—the theory of atomic orbitals—now represents the particular case in molecular-orbital theory in which the system contains only one atomic nucleus. Furthermore, the molecular-orbital theory involves the most general physical concepts on molecular structure, and the mathematics used is most suitable for making quantitative calculations on an electronic computer. All this is responsible for the dominant role of this theory in modern quantum chemistry.

One of the first to make wide use of the molecular orbital method and to popularise it in every way possible was Ya. K. Syrkin[150-152], founder of the Soviet school of quantum chemistry. He clearly demonstrated with numerous examples (including the effective charges on atoms in molecules[151]) the need to regard the properties of a molecule not as the simple sum of those of central ion and ligands but as involving all the intramolecular interactions, by no means reducible to small perturbations. Soviet scientists were the first to make systematic calculations by a form of the method which has since found widespread use in the so called zero differential overlap approximation (ZDO)[152,153], also to use the method to describe transition-metal complexes, including sandwich compounds[154,155], and to analyse the band structure of dielectrics and semiconductors[156].

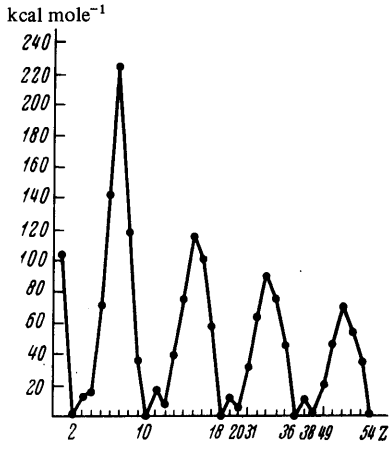

Figure 19. Stabilities (dissociation energies) of homonuclear diatomic molecules Z_2 for elements in the main groups of the first five periods of Mendeleev's system.

In conclusion let us consider briefly the periodicity of the chemical properties of the elements in the light of our modern knowledge of molecules. The molecular-orbital theory, which extends and generalises the atomic-orbital theory, regards the electronic structure of a molecule as resulting from the filling of discrete electron levels forming definitely repeated shells by virtue of the laws of quantum mechanics and the Pauli principle. Thus, just as periodic relations exist in the electronic structure of atoms, so also distinct periodic variations (though more complicated) are found in the electronic structure of molecules. A convincing example is the clear correlation of various properties of homonuclear diatomic molecules (e.g. the stability, i.e. the dissociation energy, of Z_2 in Fig. 19) with the position of the atom Z in the periodic system[157]. Here the sequence of molecular orbitals, bonding and antibonding in character, is almost invariant in Z_2 molecules for all atoms of a given period. The differing properties of these molecules depend on the relative numbers of bonding and antibonding electrons, which is ultimately determined by the total number of electrons

† The concept of the effective charges of atoms is most justified when such charges are compared in series of compounds of the same type, e.g. monosubstituted compounds or complexes of a given element with ligands having weak and strong fields respectively.

in the molecule, i.e. by the atomic number of the element Z. This is yet another of the innumerable confirmations expected by Mendeleev in the future superstructure and development of the periodic law.

---o0o---

We have tried to trace the main line of research on the structure of matter from the establishment of Mendeleev's periodic law until the present time. These investigations provide the clearest evidence of the unity and indissolubility of the whole of modern natural science—primarily physics, chemistry, and biology—most closely linked with ideas on the structure of matter, from elementary particles to the most complicated molecules and cells. Indeed, the properties of elementary particles that have now been found and explained on the Mendeleev path of the development of physics and chemistry, interactions between nuclei and electron shells, have become the basis of methods correctly revealing the structure of molecules and the relation between this structure and their reactivity, i.e. the spatial rearrangement and movement of molecules, which means solving key problems both of theoretical chemistry and of future chemical industry, as well as understanding the molecular nature of the motion of biological materials. Contrary to the view sometimes held, the role of chemistry in this triad (physics, chemistry, biology) has by no means become subordinate, but is even central, for without chemistry a genuine union and mutual enrichment of the main natural sciences are impossible.

Compounds of the Noble Gases

A.B.Neiding and V.B.Sokolov

The results of investigations of the physical and chemical properties of compounds of the noble gases and their structure, stability, and reactivity are given; the principal methods of synthesis are considered. Special attention is paid to the latest achievements in this field—to investigations of complexes, derivatives of xenon fluorides and oxo-acids, xenon hexafluoride, and the study of the electronic structure. Non-empirical methods of calculation on the bonding in noble gas compounds are discussed and their results are compared with experimental results obtained with the aid of photoelectronic and X-ray electronic spectroscopy. Possible practical uses of the compounds of the noble gases are considered on the basis of the material presented. There is a bibliography of 400 references.

I. INTRODUCTION

The development of the new field of inorganic chemistry—compounds of the noble gases—which began not much more than ten years ago is still continuing, although the direction and nature of the investigations has undergone certain changes. Whereas in the first two years after the discovery of this new class of substances (1962–1964) there appeared many papers dealing with their preparation and preliminary study, subsequent years are distinguished by a broadening and simultaneous deepening of the investigations, by the isolation of a series of new, previously unknown compounds, and also by continuation on a more complete basis of the theoretical comprehension of new experimental results. A significant increase in the importance of the work of Soviet scientists is also characteristic for this period of time.

The studies of the first two years were reflected in a review[1] published in 1965. It is now opportune to systematise the many new experimental and theoretical results to create a complete picture of the present state of investigations of the compounds of the noble gases. The present review has this aim and deals with the literature available to the authors in January 1974.

During the years which have elapsed since the first review was published[1] there have appeared several publications[2-12] which treat in more or less detail the particular aspects of the problem being considered. Of these, we think that of Dyatkina[2] merits special attention, in which a detailed analysis is given of all investigations of the nature of the chemical bond in compounds of the noble gases, and also the reviews of Malm and Appelman[3], Holloway[4], and Jha[5]. Because of this, in the present review greater attention is paid to papers published after 1969.

For brevity and also with the aim of simplifying the exposition, the molecular constants and physical properties of the most studied compounds of xenon and krypton are given in Tables 3 and 5, and in the text are given only those data which require explanation or serve for subsequent discussion.

II. XENON COMPOUNDS

A. XENON FLUORIDES

1. The Fluorine–Xenon System

The fluorine–xenon system has been investigated[13] over a wide range of temperature and pressures. The processes taking place in this system are described by the following consecutive-concurrent reactions:

$$Xe + F_2 \rightleftarrows XeF_2;\ K_2 = [XeF_2]/[Xe][F_2];$$
$$XeF_2 + F_2 \rightleftarrows XeF_4;\ K_4 = [XeF_4]/[XeF_2][F_2];\ K_4^* = [XeF_4]/[Xe][F]^2;$$
$$XeF_4 + F_2 \rightleftarrows XeF_6;\ K_6 = [XeF_6]/[XeF_4][F_2].$$

Table 1 gives experimental and calculated (in parentheses) equilibrium constants.

The equilibrium constants showed[16] that XeF_2 and XeF_6 can be easily obtained in the pure form, whereas there are no conditions which would ensure that the XeF_4 concentration in the equilibrium mixture exceeds 91 vol.%. At an initial molar ratio of $Xe : F_2 \geq 1.4$ the equilibrium mixture consists almost solely of the excess of xenon and XeF_2. In every instance the equilibrium is reached rather rapidly above 250°C. The optimal conditions of synthesis of the pure xenon fluorides at various temperatures have been determined[17].

An investigation of equilibria in the fluorine–xenon system showed[13] that a xenon fluoride with the ratio $F:Xe > 6$ does not exist even under conditions of high pressures (500 atm, 250°C). Other work[18] agrees with this result and also refutes a previous report[19] of the synthesis of xenon octafluoride.

Table 1. Equilibrium constants of the reactions for the formation of xenon fluorides[13].

Equilibrium constant	25°	250°	300°	350°	400°	500°
K_2	$(1.23\cdot10^{13})$	$(8.8\cdot10^{4})$	$(1.02\cdot10^{4})$	(1670)	(360)	29.8
K_2[14]	$(7.23\cdot10^{12})$	—	$(7.74\cdot10^{3})$		(285±49)	—
K_4'[15]	$(1.65\cdot10^{24})$	$(1.1\cdot10^{8})$	$(1.49\cdot10^{6})$	$(4.14\cdot10^{4})$	$(1.98\cdot10^{3})$	(14.4)
K_4	$(1.35\cdot10^{11})$	1431	154.9	27.22	4.857	0.5020
K_6	$(8.2\cdot10^{5})$	0.9435	0.2112	0.05582	0.01822	—

The reaction rate in the fluorine–xenon system depends on the diameter of the reaction vessel and the state of its surface[16]. The reactions for the formation of the xenon fluorides are mainly heterogeneous and take place on the fluorinated walls of the reaction vessels or at the surface of certain metal fluorides, for example, CoF_3, NiF_2, or CaF_2. The catalytic influence of these fluorides was investigated[20] at 300–450°C and pressures of 1.5–2.0 atm and is tentatively explained by the formation of the complexes $XeF_6.CoF_3$, $XeF_6.NiF_2$, etc. The existence of such compounds was confirmed[21] by the investigation of interaction in XeF_6–metal fluoride systems: $XeF_6.2CrF_2$, $XeF_6.CoF_2$, and $XeF_6.2FeF_2$ were prepared. Slivnik and coworkers[22,23] investigated the catalytic influence of highly disperse nickel and magnesium fluorides on the reaction between xenon and fluorine (1 : 10) and found that at 120°C XeF_2 is almost the only product in the presence of MgF_2, whereas in the presence of NiF_2 the only reaction product is XeF_6 even at the molar ratio $F:Xe = 5$. Chromium, vanadium, and manganese fluorides also exert a catalytic influence[24].

The catalytic formation of XeF_2 on heated metals has been investigated[25]. This process is catalysed only by metals which form ionic fluorides, for example, Ni, Pd, Co, Cu, Al. Investigation of the adsorption of xenon in the presence of fluorine on nickel and palladium[26] suggested that the stage determining the rate of catalytic formation of XeF_2[25] is the desorption of XeF_2 from the metal surface.

2. Xenon Difluoride

a. Methods of Preparation

Most of the papers on the preparation of noble gas compounds belong to the first period of investigation[1]. No method new in principle has originated in recent years.

Almost pure XeF_2 can be obtained by the interaction of xenon and fluorine ($Xe:F_2 = 1.3–2.0$) in the temperature range 400–500°C at pressures of 0.5–27 atm.[27,28] XeF_2 can also be prepared in a cylindrical flow reactor filled with a nickel packing with a contact surface of 0.2 m^2, when heated to 600°C and at a total pressure of 650 mmHg.[29] XeF_2 is formed in good yield in a mixture of xenon and fluorine (1 : 1 by volume) subjected to a glow discharge[30]. The yield of XeF_2 increases with the rate of flow of the mixture through the reactor.

XeF_2 of high purity has been prepared photochemically[31–34]. Small quantities of XeF_2 can be obtained in quartz or Pyrex vessels by irradiation of mixtures of xenon and fluorine (600–1000 mmHg, $Xe:F_2 = 1:1$) with daylight. However, when the conversion reaches 60% the xenon difluoride begins to be contaminated with the tetrafluoride[33]. The irradiation of a mixture of xenon and fluorine with the light from a high-pressure mercury lamp is recommended[35,36] as a convenient method of obtaining pure XeF_2. The photochemical interaction of xenon with OF_2 leads to the formation of XeF_2.[31]

Xenon difluoride is obtained in 98% yield by the reaction of xenon with an excess of O_2F_2[37] at −118°C and O_4F_2.[38] The reaction of xenon with fluorine in the gaseous and condensed phases under the action of protons with energies of 10 MeV at temperatures from −78° to −180°C can be used for the synthesis of XeF_2.[39] XeF_2 is also formed by the reaction of xenon with fluorine in shock waves[40] at 1100°C.

b. Physical Properties of XeF_2

The vapour pressure of XeF_2 in the temperature range 0–115°C is expressed by the equation[41]

$$\lg P_{mmHg} = -3057.67/T - 1.23521 \lg T + 13{,}969736.$$

The density of liquid XeF_2 in the temperature range 115 to 90°C is given by the expression[42]:

$$\rho_{g\,cm^{-3}} = 3.641 - 3.96\cdot10^{-3}\,t.$$

The heat capacity of XeF_2 was measured[14] by an adiabatic method in the temperature range from −268° to 77°K.

The standard enthalpies of formation of XeF_2, and also XeF_4 and XeF_6, obtained by different methods[13,43–45] are somewhat different. Johnson and coworkers[45] consider the results of the calorimetric investigation of the reaction of solid XeF_n with phosphorus(III) fluoride to be the most reliable.

As an extension of the earlier[1] spectroscopic investigations, the infrared, Raman, and ultraviolet spectra of gaseous and solid XeF_2 have been studied. The high-resolution infrared spectrum of gaseous XeF_2 was investigated in the range of the ν_3 vibrations (544–574 cm^{-1}).[46] An analysis of the spectrum led to the following molecular constants: $\nu_0 = 560.101\ cm^{-1}$, $B_0 = 0.11350\ cm^{-1}$, $\alpha_3 = 3.31\times10^{-4}$, $X_{23} = -1.44\ cm^{-1}$. The B_0 found was used to calculate the bond length $r(Xe–F) = 1.997 \pm 0.0015$ Å.

The laser Raman spectrum of XeF_2 has been obtained and interpreted[47]. The very interesting band at 514.5 cm^{-1} has been assigned to the ν_1 symmetric stretching vibration. The agreement with the predicted $\nu_1 = 515\ cm^{-1}$ (from the composite band $\nu_1 + \nu_3$ at 1070 cm^{-1} in the infrared spectrum of XeF_3)[48] shows the very low anharmonicity of the vibrations of the XeF_2 molecule.

The investigation of the spectra of gaseous and solid (−193°C) XeF_2 in the far ultraviolet range (50–160 eV)[49] enabled information to be obtained about the excited electronic levels of the molecule and to assign the absorption lines in the range 61–73 eV on the basis of a semi-empirical calculation.

Radioelectronic[50,51] and photoelectronic spectroscopy[52–54] have played a large part in the study of the structure of noble gas compounds, especially XeF_2. The results for XeF_2 obtained by these methods are discussed in Chapter V.

NMR and EPR methods have also been used for studying XeF_2. In ^{19}F NMR the variation of the second moment of the rigid XeF_2 lattice with the external magnetic field has been measured [55]. The magnetic screening parameters do not agree with the results of semiempirical calculation [56]. The EPR of γ-irradiated XeF_2 were investigated at 77°K. [57] The spectrum obtained was assigned to the XeF radical; the parameters of the spin-hamiltonian of XeF in the XeF_2 and XeF_4 lattices [58] differ slightly. In connection with the EPR results it is interesting to note that the hypothetical formation of XeF in the gas phase [40, 59-61] has still not been confirmed experimentally [62]. A calculation by the SCF MO method showed that the $^2\Sigma^+$ and $^2\Pi$ states of XeF are repulsive and the XeF radical should not exist in the gas phase in the free state [63].

The deflection of an XeF_2 molecular beam in a heterogeneous electric field has been studied [64]. The results obtained confirmed the structure $D_{\infty h}$ for this molecule. The emission spectrum of a Xe + BF_3 (NaF, LiF) mixture in a microwave discharge [65] is characterised by the existence of two groups of bands of different intensity, assigned to XeF_2: 3510, 2635 and 3080, 2355 Å.

c. Chemical Properties

Behaviour of XeF_2 in Non-Aqueous Solvents

Xenon difluoride dissolves in BrF_3, [66] BrF_5, [67] HF, [68] IF_5, [69] SO_2, [69] and CH_3CN. [70] The solubility of XeF_2 in IF_5 reaches 1538 g per 1000 g IF_5. [71] Different opinions [72-74] have been expressed about the behaviour of XeF_2 in IF_5. The most complete picture of the interaction in the IF_5–XeF_2 system was obtained in investigating the equilibrium diagram [71,75] (Fig. 1). Fig. 1*b* shows the so-called "transitional" equilibrium diagram obtained at temperatures up to 80°C. At 80°C the irreversible conversion of the unstable solvates $XeF_2.nIF_5$ (n = 1.5–9) into $XeF_2.IF_5$ takes place. An attempt [76] to reproduce the earlier results [72-74] led to the production of only $XeF_2.IF_5$, which according to spectroscopic, Raman, and X-ray diffraction results is a molecular compound [76]. $XeF_2.IF_5$ is tetragonal with parameters a = 7.65, b = 10.94 Å, space group $I4/m$. The structure (Fig. 2) shows the existence of the discrete molecules XeF_2 ($D_{\infty h}$) and IF_5 (C_{4v}). [77]

The maximal solubility of XeF_2 in BrF_5 is 1893 g per 1000 g bromine pentafluoride [78]. Xenon difluoride dissolves readily in anhydrous HF; at −2°C the solubility is 6.38 moles XeF_2 per 1000 g HF and increases with the temperature. The enthalpy of dissolution is 2.5 kcal mole^{-1}. The investigation of the electrical conductivity of such solutions, their Raman spectra, and ^{19}F NMR led to a conclusion about the solubility of XeF_2, in molecular form, in HF. [68] The solubility of XeF_2 in 3HF.NOF is unusually high [79]: 73.25 wt.% at 16.8°C.

Xenon difluoride is slightly soluble in Mo and W hexafluorides. According to DTA results [80], the unstable compounds $XeF_2.MoF_6$ and $XeF_2.WF_6$ are formed in the WF_6–XeF_2 and MoF_6–XeF_2 systems.

The solubility of XeF_2 in acetonitrile at 0°C is 16.8 g and that at 21°C 32.0 g per 100 cm^3 solvent [70]. Xenon difluoride is oxidised at the boiling point of acetonitrile [69]. XeF_2 dissolves in dimethyl sulphoxide (DMSO) and pyridine but not in liquid ammonia [69]. XeF_2 forms the complex $XeF_2.2Bipy$ with bipyridyl [72].

The behaviour of XeF_2 in various solvents was investigated by infrared spectroscopy [81]. A shift in the frequency of the vibrations of the Xe–F bond into the longer-wave range with increase in the donor strength of the solvent was noted and this can be regarded as qualitative indication of the weakening of this bond.

The XeF_2–XeF_6 system has a simple eutectic [82].

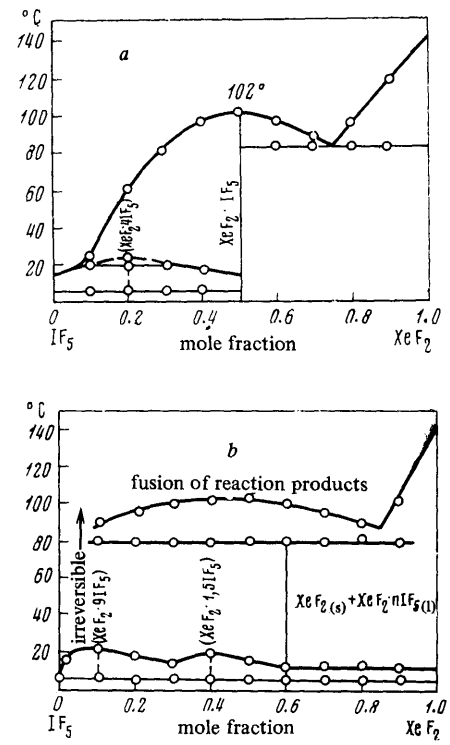

Figure 1. *a*) Equilibrium diagram of the IF_5–XeF_2 system; *b*) "transitional" equilibrium diagram of the IF_5–XeF_2 system.

Redox Reactions of XeF_2

It would seem that in redox fluorination reactions XeF_2 from both the thermodynamic and kinetic viewpoints does not compete with such powerful fluorinating agents as molecular fluorine, oxygen fluorides, certain halogen fluorides, etc. However, this "kinetic inertness" is the merit of XeF_2 and simplifies the practice of oxidising fluorinations.

DTA has shown [83] that at moderate temperatures XeF_2 reacts with many elements: with Mo at −11°, W (21°), Te (16°), S (27°), P (−10°), Ge (−12°), Si (16°), Nb (6°), Ta (22°), Sb (33°), Sn and Ti (28°), etc. In all these reactions higher fluorides of the corresponding elements are formed. XeF_2 reacts with elemental bromine and iodine with the formation of BrF_3 and IF_5. On the basis of the results of an investigation of the reactions of XeF_2, of the calculations of the free energies of the corresponding processes, and also of the relative reactivities of the halogen fluorides [84] a series for the relative fluorooxidising capability of XeF_2 has been compiled [83]:

$$ClF_3 > BrF_5 > IF_7 > ClF > BrF_3 > XeF_2 > IF_5 > BrF\ .$$

The high fluorinating activity of XeF_2 also appears in reactions with WO_3 (27°), U_3O_8 (67°), Nb_2O_5 (49°), V_2O_5 (26°), KBr (21°), KI (12°), KIO_3 (47°), and $NaBrO_3$ (41°), as a result of which higher fluorides, $KBrF_4$, KIF_6, and $NaBrO_2F_2$ are formed[88]. Solid XeF_2 reacts at 20°C with ICl and ICl_3 with the formation of IF_5.[85] Chromium(V) fluoride fluorinates XeF_2 to XeF_4 at 120°C, and at 60°C a mixture of $XeCr_2F_{10}$ and XeF_4 is formed[86].

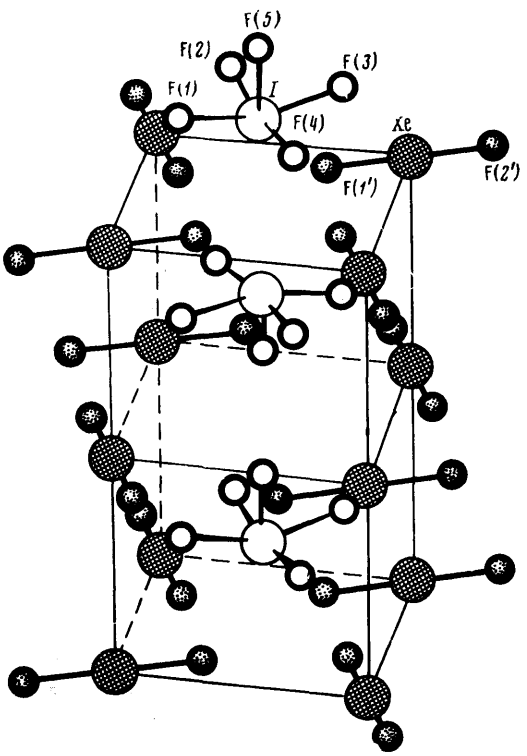

Figure 2. Crystal structure of $XeF_2.IF_5$.

A qualitative investigation of the oxidising power of xenon fluorides was carried out in the case of their interaction with UF_4.[87] The greatest rate of fluorination is observed with XeF_6.

Xenon difluoride is used as fluorinating agent for obtaining the higher fluorides of the rare-earth elements (r.e.e.). When mixtures of XeF_2 and TbF_3 are heated to 300–350°C, TbF_4 is formed[88,89]. The reaction of XeF_2 with the fluoro-complexes of tervalent r.e.e. can be used to obtain compounds of Ce^{IV}, Pr^{IV}, and Tb^{IV} of composition Cs_3LnF_7.[90]

The oxidising reactions of XeF_2 in solutions of non-aqueous solvents are interesting. In acetonitrile, the reactions of XeF_2 with I_2, SO_2, and SO_3 take place with the formation of IF_5, SO_2F_2, and $S_2O_6F_2$ respectively[67]. The reactions are catalysed appreciably by traces of HF and BF_3, which is probably linked with the formation of the cations XeF^+ and $Xe_2F_3^+$ in the solutions[67]. The catalytic influence of certain fluoro-acids on the formation of BrF_3 was investigated[83]; the rate constants observed are characterised by the catalytic activity of certain fluoro-acids in the reactions of XeF_2 with Br_2 in BrF_3 solutions (s^{-1}) at 19°C: 0.0081 (XeF_2), 0.016 ($XeF_2 + TaF_5$), and 0.045 ($XeF_2 + SbF_5$). The order of increase of the rate constants $BrF_3 < TaF_5 < SbF_5$ ($k_{BrF_3} : k_{TaF_5} : k_{SbF_5} = 1:2:6$) agrees with the relative acceptor capability of these fluorides[91]. The reaction of XeF_2 with the oxides of As, P, and Sb in BrF_3 leads to the formation of AsF_5, PF_5, and SbF_5.[66] In the presence of AsF_5, BF_3, PF_5, or TiF_4, xenon difluoride decomposes acetonitrile[92].

Solutions of XeF_2 in CCl_4 are stable up to the boiling point of CCl_4.[93] In the presence of traces of Group V element halides, XeF_2 reacts with CCl_4 with the formation of Freons, SiF_4, Xe, and Cl_2. The reaction of XeF_2 with $SiCl_4$, $TiCl_4$, and $SnCl_4$ leads to the formation of tetrafluorides[93]; when there is an excess of XeF_2 the compounds $2XeF_4.MF_4$ (M = Sn or Ti) are formed. $2XeF_2.ZrF_4$ and $2XeF_2.HfF_4$ are formed in the direct interaction of the fluorides[93].

In HF solutions xenon difluoride reacts with $Re_2(CO)_{10}$ with the formation of ReF_5.[94] Tungsten and molybdenum carbonyl fluorides can be obtained analogously[95]. Marshall and Peacock[96] reported the production of Re, Mo, Ru, and Os carbonyl fluorides by the reaction of XeF_2 with carbonyls and carbonyl chlorides of the corresponding metals. They also obtained the double carbonyl fluorides $Mo(CO)_3F_2.MoF_5$, $Re(CO)_5F.ReF_5$ of tungsten, osmium, iridium, and rhodium[97].

Reactions of XeF_2 in Aqueous Solutions

Xenon difluoride dissolves readily in water but the solutions are unstable[98]. The solubility of XeF_2 in the molecular form has been shown by the ultraviolet spectra[99] and electrical conductivity[100,101] of its aqueous solutions.

The hydrolysis of XeF_2 is a first-order reaction, the rate constant in pure water being 2.8×10^{-5} s^{-1} at 0° and 25×10^{-5} s^{-1} at 25°C.[102] The activation energy of hydrolysis is 18.4 kcal $mole^{-1}$.[103] The rate constant for the hydrolysis of XeF_2 in 0.01 M $HClO_4$ is 42×10^{-5} s^{-1} at 25°; the activation energy is 20.2 kcal $mole^{-1}$.[104] The rate of hydrolysis of XeF_2 in water is minimal in the range pH 4–9.[105] The hydrolysis is strongly catalysed by bases, the anions F^-, NO_3^-, HCO_3^-, CO_3^{2-}, $H_2PO_4^-$, HPO_4^{2-}, PO_4^{3-}, and by the cations Th^{4+}, Al^{3+}, La^{3+}, and Be^{2+}.[104,105] The rate of hydrolysis of XeF_2 also increases with the concentration of HF in the solution[106]. The results obtained in investigating the hydrolysis of XeF_2 in neutral aqueous solutions are explained[104] by the reactions:

$$XeF_2 + H_2O \rightarrow XeO + 2HF;\ XeO + H_2O \rightarrow$$

$$\rightarrow Xe + H_2O_2;\ H_2O_2 + XeF_2 \rightarrow Xe + 2HF + O_2,$$

which have also found experimental confirmation[104,107].

Aqueous solutions of XeF_2 exhibit a pronounced oxidising ability. The redox potential of the XeF_2/Xe couple in acidic medium $XeF_{2(aq)} + 2H^+_{(aq)} + 2e^- = Xe_{(g)} + 2HF_{(aq)}$ is estimated[3] to be 2.64 V ($\Delta G^\circ_{298}XeF_{2(aq)} = -20.35$ kcal $mole^{-1}$). Other results[108] obtained by use of the Powell and Latimer equation for aqueous solutions of non-electrolytes, give $E^\circ_{(XeF_2/Xe)} = 2.3$ V. The bromate ion was oxidised by XeF_2 in aqueous solutions, which enabled previously unknown perbromates to be synthesised, in particularly $RbBrO_4$.[109] Xenon difluoride also oxidises iodates and chlorates[110–112]. In alkaline solutions, XeF_2 oxidises astatides to perastatate[113], Np^V and Np^{VI} to Np^{VII}.[108,114]

Reactions of XeF_2 with Organic Compounds

The use of elemental fluorine in organic chemistry is very limited and requires a special technique [115]. The use of other fluorinating agents, such as HF, certain metal fluorides, or interhalogen compounds, while allowing fluoro-substituted compounds to be obtained, results in low yields and poor selectivity. Xenon fluorides, and XeF_2 in particular, have been investigated recently as promising fluorinating agents.

Xenon difluoride reacts with an excess of benzene in CCl_4 in the presence of small quantities of HF with the formation of fluorobenzene [116] (68% yield on the benzene); with substituted benzenes in CCl_4 or CH_2Cl_2 the corresponding fluorobenzenes are formed [117]. These investigations [116,117] showed that the use of XeF_2 gives a possibility of changing the Balz–Schiemann reaction for obtaining fluorinated aromatic compounds. The conversion is effected in a single stage, which is an advantage in comparison with the usual three-stage process [115].

An investigation of the reactions of XeF_2 with benzene and its derivatives by an EPR method allowed the formation of intermediate *para*-substituted radical-cations of the polyphenyls $R(C_6H_4)_2R^+$, where R is Cl, CH_3, F, or $F-C_6H_4-C_6H_4$, to be established [118]. On this basis it was concluded that XeF_2 initiates the generation of radical-cations, in particular from compounds with a relatively high oxidation potential. The results obtained are explained satisfactorily within the framework of a mechanism [119] which postulates the formation of an intermediate complex and a radical-cation.

Xenon difluoride reacts with 1,1-diphenylethylene in the presence of HF and CF_3CO_2H as catalysts with the formation of 1,2-difluoro-1,1-diphenylethanes (yield 65–95%). [120] Aromatic compounds are fluorinated not just in solutions; XeF_2 readily replaces hydrogen in benzene and its derivatives in the gas phase [121] at 100–200 °C. Pentafluorophenyl peroxide has been isolated [122] by the reaction of XeF_2 with pentafluorophenol in acetonitrile. Ethylene reacts with XeF_2 with the formation of 1,2-di- and 1,1,2-trifluoroethanes with yields of 35 and 20% respectively [123]. XeF_2 reacts with propene with the formation of a multicomponent mixture of volatile substances. Propyne resists the action of XeF_2; only after 100 days at room temperature is 2,2-difluoropropane formed (33% yield) [123].

In acetonitrile, XeF_2 reacts with certain organometallic compounds containing Si–Si, Si–H, Si–C (allyl), or Si–O bonds [124]. With chlorine-containing compounds the following substitutions take place:

$$2\,R_3SiCl + XeF_2 \rightarrow 2\,R_3SiF + Cl_2 + Xe\ [R = CH_3,\ C_2H_5,\ R_3 = C_6H_5(CH_3)_2]\ ,$$

$$R_3SiHCl \xrightarrow{XeF_2} R_3SiHF \xrightarrow{Cl_2} R_3SiClF \xrightarrow{XeF_2} R_3SiF_2\ [R_3 = C_6H_5(CH_3)]\ .$$

An effective oxyacylation of benzene is effected in the presence of XeF_2. [125] Oxyacylation was studied by the example of the reactions of benzene with toluic acid, benzoic acid and its nitro- and fluoro-derivatives; the corresponding phenyl benzoates are formed:

$$RCOOH + C_6H_6 + XeF_2 \rightarrow RCOOC_6H_5 + Xe + 2HF\ .$$

The activation energy of the oxybenzoylation of benzene in the presence of XeF_2 is 16 kcal mole^{-1}. [126] The yield of esters is 50–70%. In the absence of benzene the carboxylic acids in the RCOOH + XeF_2 + CCl_4 mixture undergoes decarboxylation with the formation of hydrocarbons and their fluoro-derivatives.

Xenon difluoride participates in solvolysis with alcohols; reaction with C_1–C_4 primary aliphatic alcohols leads to the formation of aldehydes [127]. The rate constants for the oxidation decrease with increase in the length of the carbon chain. The direct fluorination of pyridine by xenon difluoride in the gas phase at 100 °C leads to rapid polymerisation of pyridine [126]. In the fluorination of liquid pyridine, 2-, 2-, and 4-monofluoro-derivatives are formed in 10% yield (on XeF_2), which then are also polymerised. The fluorination of 2-fluoropyridine allows all the disubstituted products to be synthesised, mainly the 2,5-difluoro-isomer [128].

3. Xenon Tetrafluoride

The principal methods of synthesis of XeF_4 were described in the previous review [1]. Xenon tetrafluoride can be obtained by thermal, photochemical [33], and radiation [39] methods, and also by the action of a glow discharge. The synthesis of comparatively pure XeF_4 can be effected at 400 °C and a total pressure of the mixture of xenon and fluoride of 7 atm ($Xe : F_2 = 1 : 5$). [129] After an hour the yield of XeF_4 reaches 90%. The purification of XeF_4 from the impurities XeF_2 and XeF_6 is effected on metal fluorides, owing to the differing abilities of the xenon fluorides for complex formation [91,130]. XeF_4 is also purified effectively by gas–liquid chromatography [131–133]. This method is recommended as a preparative method for the synthesis of the pure individual fluorides of Xe and for their quantitative analysis [132,133].

Xenon tetrafluoride readily sublimes at room temperature. The vapour pressure over solid XeF_4 is represented by the equation [41]:

$$\lg P_{mmHg} = -3226.21/T - 0.43434\ \lg T + 12.301738\ \ (2-117^\circ)\ .$$

The density of supercooled liquid XeF_4 is described by the equation [42]:

$$\rho(g\ cm^{-3}) = 3.500 - 4.05\ 10^{-3}\ t\ \ (110-50^\circ)\ .$$

The heat capacity of XeF_4 has been measured [15] in the range 5–350 °K. The laser Raman spectrum [47] of gaseous XeF_4 has been interpreted and compared with the Raman spectrum of solid XeF_4. As a result of a study of the spectra of gaseous and solid (−193 °C) XeF_4 in the far ultraviolet range (50–160 eV) [49] information has been obtained about the excited electronic levels of this molecule and the absorption lines in the range 61–73 eV have been assigned on the basis of a semiempirical calculation.

Brundle and coworkers [53] investigated the photoelectronic spectrum of XeF_4 with a high resolution by use of HeI and HeII radiation. The electron-impact excitation method was also used for studying XeF_4. [134]

The ^{19}F NMR method was used to study the variation of the second moment of XeF_4 with temperature and the external magnetic field for a rigid lattice and for higher temperatures, when the molecular motion leads to some narrowing of the absorption lines [135]. The magnetic screening parameters found do not agree with the results of a semiempirical calculation [56]. The results of an investigation of the deflection of an XeF_4 molecular beam in a non-homogeneous electric field [64] confirmed that the structure of this molecule was D_{4h}.

Xenon tetrafluoride dissolves in anhydrous HF [68] and in liquid NOF.3HF. [79] The results of an investigation of the electrical conductivity of the XeF_4 solutions and of their ^{19}F NMR spectra show the solubility of XeF_4 in the molecular form in HF, [68] NOF.3HF, [79] and IF_5. [136] The results obtained by various investigators [69,137] for solutions of XeF_4 in IF_5 disagree. The most reliable results are those of Sladky and Bartlett [76], who found that specially

purified XeF_4 dissolves readily in IF_5 without any reaction even in the presence of AsF_5.

Xenon tetrafluoride reacts[69] with NH_3, AsF_3, CCl_2F–$CClF_2$, C_5H_5N, CH_3CN, and $(CH_3)_2SO$ with the formation of the same products as for XeF_2, but the oxidising properties of XeF_4 in these reactions is more clearly expressed. With perfluoropropene, XeF_4 forms perfluoropropane; 1,2-di and 1,1,2-tri-fluoroethane are formed with ethylene; cyclohexane is fluorinated to fluorocyclohexane. With aromatic compounds, XeF_4 takes part in substitutions[123]: benzene is fluorinated to fluorobenzene; toluene to *o*-, *m*-, and *p*-fluorotoluenes, fluorobenzene to the *o*-, *m*-, and *p*-difluorobenzenes, hexafluorobenzene to perfluorocyclohexane, perfluoro-1,4-cyclohexadiene, and perfluoro-1,3-cyclohexadiene. Unlike those of XeF_2, the reactions of XeF_4 take place in the absence of a catalyst[123].

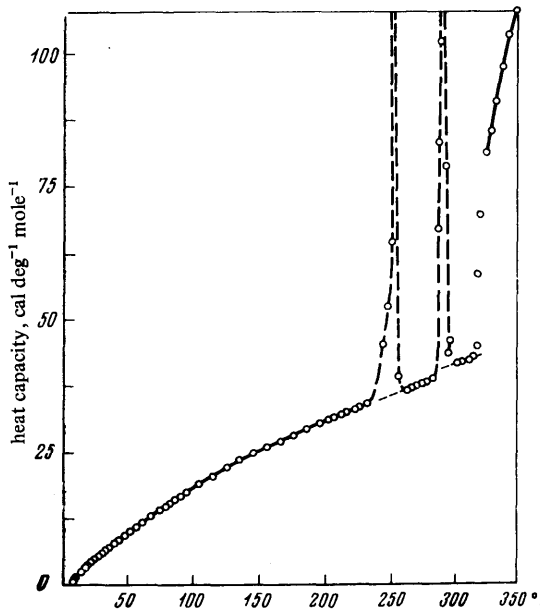

Figure 3. Temperature dependence of the molar heat capacity of xenon hexafluoride.

As a result of the hydrolysis of XeF_4, solutions of XeO_3 are obtained[98,138]:

$$3XeF_4 + 6H_2O \rightarrow XeO_3 + 2Xe + {}^3/_2O_2 + 12HF.$$

Owing to the extremely violent nature of the reaction, the hydrolysis was carried out[139,140] by the slow addition of water to XeF_4 cooled by liquid nitrogen followed by heating the "frozen" mixture.

An attempt to use XeF_4 for obtaining solutions of Pu^{VIII} from Pu^{VII} was unsuccessful[141]. Testing for sensitivity to shock and detonation stability showed that XeF_4 is not an explosion hazard[142]. However, it often explodes when mixed with substances of organic origin.

4. Xenon Hexafluoride

Xenon hexafluoride can be obtained by heating a mixture of xenon and fluorine (1 : 10 or 1 : 20) at 200–300 °C for 15–17 h and a total pressure of 30–50 atm.[17,143] XeF_4 is removed most effectively on sodium fluoride[1]. XeF_6 can also be obtained by a radiation method[39].

The density of XeF_6 was measured[144] over a wide range of temperatures. An equation was derived for the temperature dependence of the molar volume of XeF_6. The following analytical expressions were found[144] for the vapour pressure of XeF_6:

$$\lg P_{mmHg} = -3313.5/T + 12.5923, \quad \text{(from -19° to 18.65°C)};$$

$$\lg P_{mmHg} = -3093.9/T + 11.8397, \quad \text{(from 18.65° to 49.23°C)};$$

$$\lg P_{mmHg} = -6170.88/T - 23.67815 \lg T + 80.77778, \quad \text{(from 49.38° to 76.85°C)}.$$

The second virial coefficient is determined by the relation[144]: $B = -1.143 \times 10^8 T^{-2}$ cm^3 mole^{-1}. The relatively small B (−955 cm^3 mole^{-1} at 73 °C) shows the monomericity of XeF_6 in the gas phase; this agrees with the results of measurements of the vapour density of XeF_6 at 73 °C and 494 mmHg,[144] and at 25 °C and 15 mmHg.[13] Another picture is observed in liquid xenon hexafluoride. In the range from the melting point of XeF_6 (49.48°) to 100 °C the Raman spectra[145] and heat capacities[144] as well as the unusually high entropy of vaporisation at the boiling point clearly show either polymerisation or a high degree of association in the liquid.

Table 2. Crystalline modifications of XeF_6.[149]

Phase and temp. limits of existence, °C	Characteristics of the crystal lattice							
	a	*b*	*c*	angle, deg	*Z*	ρ_{calc}, g cm^{-3}	space group	structural element
Monoclinic, from 49.48 to 18.65	9.33	10.96	8.95	β 91.9	2	3.56	$P2_1/m$ or $P2_1$	2 tetrameric rings of XeF_5^+ groups and F^-
Orthorhombic from 18.65 to −19.35	17.01	12.04	8.57	—	16	3.71	$Pnma$	4 tetrameric rings of XeF_5^+ groups and F^-
Monoclinic below −19.35	16.80	23.93	16.95	α 90.7	64	3.825	$P2_1/b$	16 tetrameric rings of XeF_5^+ groups and F^-
Cubic from −180 to 49.48	25.06	—	—	—	144	3.73	$Fm3c$	24 tetrameric and 8 hexameric rings of XeF_5^+ groups and F^-

The heat capacity of XeF_6 was investigated[144] in the temperature range 5–350 °K. Fig. 3 shows the variation of the molar heat capacity of XeF_6 with temperature. The distinct maxima are due to phase transformations in the solid state. Investigations[146–151] of the crystal structure of XeF_6 made by X-ray diffraction and neutron diffraction methods, confirmed the polymorphism of this compound and the existence of four crystalline modifications (Table 2).

The structure of the cubic phase of XeF_4 has been studied in most detail[147,151]. An X-ray diffraction examination of a single crystal was made at 93 °K. The main structural elements are XeF_5^+ tetragonal pyramide, the five vertices of which are occupied by fluorine atoms. The pyramids are connected with one another by bridges of fluoride ions into tetrameric and hexameric rings (Fig. 4) which are found in the structure in right and left forms; there are for the hexameric rings an ordered, and for the tetrameric rings a disordered, alternation of enantiomorphic forms. The polymeric rings are three-dimensional and also have an almost spherical form.

The tetramer (Fig. 4*a*) is an eight-membered ring consisting of four XeF_5^+ ions and four F^- ions. In the XeF_5^+ ion the interatomic distances are (the F atoms at the vertices are denoted F*a*, and those in the basal plane F*b*): Xe–F*a* = 1.83 Å, Xe–F*b* (mean) = 1.84 Å, F*a*–F*b* (mean) = 2.29 Å, F*b*–F*b* (mean) = 2.54 Å. The mean angles are: F*a*–Xe–F*b* = 77.2°, F*b*–Xe–F*b* = 87.2°. The bridging F^- is 2.23 Å from one Xe and 2.60 Å from the other; the angle in the bridge is 120.7°.

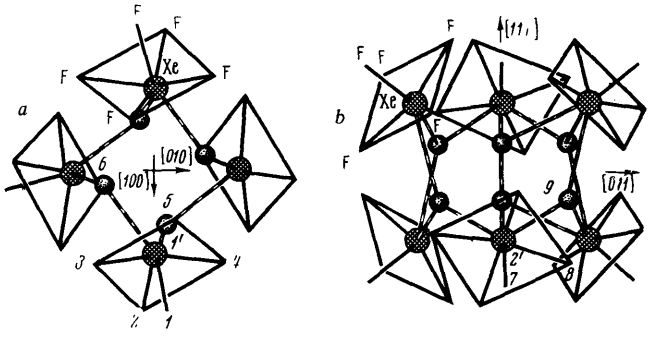

Figure 4. *a*) Structure of the tetrameric rings in the crystal lattice of xenon hexafluoride; *b*) structure of the hexameric rings in the XeF_6 crystal lattice.

The hexamer (Fig. 4*b*) is a twelve-membered ring of six XeF_5^+ ions and six F^- ions. In the XeF_5^+ the distances are: Xe–F*a* = 1.75 Å, Xe–F*b* = 1.88 Å, F*a*–F*b* = 2.33 Å, F*b*–F*b* = 2.62 Å. The angles are: F*a*–Xe–F*b* = 80.0°, F*b*–Xe–F*b* = 88.3°. The bridging F^- are 2.56 Å from each of the Xe; the angle in the bridge is 118.8°.

The polymeric nature of xenon hexafluoride in condensed phases does not allow the structure of the XeF_6 molecule to be found by investigations of, for example, crystal structure, as has been done for XeF_2 and XeF_4. The problem of the structure of XeF_6 is therefore still the subject of discussion and its solution must evidently be sought in an investigation of the gas phase, where the XeF_6 molecules are monomeric.

As even the first investigations of the vibrational spectra showed[1], XeF_6 differs from all the known hexafluorides and evidently exhibits a symmetry other than octahedral. Interest in the structure of XeF_6 has also been aroused by the fact that the first calculation made within the framework of the valence-bond theory predicted a non-octahedral structure for the then still hypothetical XeF_6 molecule, whereas in accordance with a semiempirical calculation by the MO method O_h symmetry is preferable for XeF_6.[1] In discussing these results, Dyatkina[2] suggested that the success of the valence-bond theory in this instance was only apparent, since certain arbitrary assumptions were made in the calculation.

In attempting to explain this difference and also the earlier experimental results, Goodman (see Holloway[5]) advanced a hypothesis according to which these results are completely compatible with the ground state O_h and a low-lying triplet state ^3T_u which can be thermally populated at room temperature. However, measurements of the magnetic susceptibility of XeF_6 showed[152,153] temperature-independent diamagnetism; this signifies that over the entire range of temperatures studied (that is, in the condensed phases) the ^3T_u state is not occupied. An investigation of the deflection of a molecular beam in a non-homogeneous magnetic field[154] led to the same conclusion extended to the gas phase.

An investigation of the deflection of a molecular beam of XeF_6 in a non-homogeneous electric field[64] showed that XeF_6 has a structure with a symmetry-forbidden dipole moment.

After the first electron diffraction investigations[155,156] which showed, as did theoretical results[157,158], that XeF_6 did not have octahedral symmetry, Gavin and Bartell[160] made a careful electron diffraction investigation of gaseous XeF_6 and thoroughly discussed the results in conjunction with the accumulated experimental and theoretical data[159,161].

The results of the investigations[160] seemed incompatible with a regular octahedral configuration for the XeF_6 molecule, in which there are independent normal vibrations. Some asymmetry of the radial distribution in the region of the Xe–F bonds shows the existence of non-equivalent bonds; the mean length of the Xe–F bond is 1.890 Å. The mean square amplitude of the vibrations for non-bonded fluorine atoms l(F...F) = 0.07 Å is somewhat less than l(Xe–F) = 0.08 Å. According to Bartell and Gavin[160,161], the electron diffraction results show either distortion of an octahedral configuration with displacement of the fluorine atoms towards a configuration with C_{3v} or (less probably) C_{2v} symmetry, or that in the XeF_6 molecule there exists an inversion motion (combination of deformation vibrations t_{1u} of very large amplitude and t_{1g}) with a minimum energy at the configuration with symmetry O_h. Theoretical consideration[159,161] showed that in the XeF_6 molecule there can exist conditions under which there appears a pseudo Jahn-Teller effect, brought about by distortion of the O_h configuration as a result of the deformation vibration of type t_{1u} (see Dyatkina[2]).

The results of early investigations of the vibrational spectra of XeF_6[1,162] were discussed by Glass[163] who drew the conclusion that the ground state of gaseous XeF_6 has symmetry O_h but unusual electronic properties affect the width of the bands.

On the basis of a simplified electronic model of XeF_6 derived to explain the "anomalies" of the electronic isomerism hypothesis, Goodman[164] concluded that gaseous XeF_6 at normal temperature is a mixture of three isomers differing in electronic states and geometric configurations (Fig. 5). In addition to the ground state $^1A_{1g}$ (O_h) in the lowest positions, there are also $^3A_{2u}$ (D_3d), and ^3Eu (D_3d) excited states, 450 and 1200 cm^{-1} respectively away from the ground state, due to the Jahn–Teller effect.

The results of an extensive spectroscopic investigation made by Claassen and coworkers[165] were interpreted in the spirit of Goodman's hypothesis. They measured the spectra of gaseous XeF_6 in the visible and ultraviolet ranges, the Raman spectra in the range from the boiling point of XeF_6 (76°C) to 150°C, the infrared spectrum and Raman spectrum in an argon matrix at 4°K, and also reproduced the earlier measurements[162] of the infrared spectrum of gaseous XeF_6.

According to Clarassen and coworkers[165], the temperature dependence of the spectra in the visible and ultraviolet regions confirms Goodman's hypothesis. Using results obtained at 298.1°, 323.6°, and 365.6°K, and the statistical weights of the three isomers calculated according to Goodman, three spectral curves were constructed

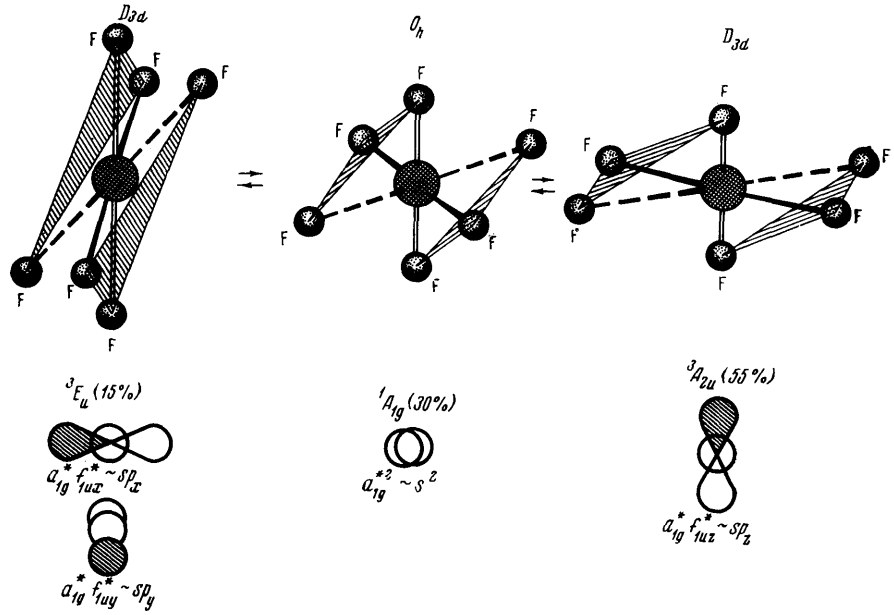

Figure 5. Electronic isomers of xenon hexafluoride; in parentheses, the statistical weights of the isomers.

in this way a spectrum measured at each of these temperatures was resolved into three temperature-independent spectra. The frequencies in these spectra were not assigned in this paper [165].

On the basis of the laser Raman spectra and their temperature dependence it was concluded that gaseous XeF_6 consists of two or more species, the relative concentration of which is a function of temperature. The interpretation of the infrared and Raman spectra, based on the hypothesis of electronic isomerism, led to a satisfactory (in the opinion of these investigators [165]) assignment of the bands to transitions in the isomers or between the isomers.

Mention has been made of the significant influence of preliminary heat treatment of the specimen on the infrared [165,166] and Raman [165] spectra of matrix-isolated XeF_6 molecules. The question of solid-state pseudorotation has been discussed [167].

The dependence of the second moment of polycrystalline XeF_6 on temperature and the external field has been studied by the ^{19}F NMR method [168]. The values found for the magnetic screening parameters are comparable with the corresponding values for UF_6, PuF_6, OsF_6, PtF_6, and MoF_6.

The solubility of XeF_6 in anhydrous HF also shows an anomaly in comparison with other hexafluorides [169]. At room temperature the solubility (moles per 1000 g HF) is: MoF_6 1.50, WF_6 3.14, UF_6 0.49, ReF_6 1.75, OsF_6 0.97, XeF_6 8.6. The results of the measurements of electrical conductivity and of the Raman spectra of solutions show that all the above hexafluorides except XeF_6 dissolve in the molecular form. The anomalously high electrical conductivity of XeF_6 in HF shows strong ionic dissociation in the solution. The solubility of XeF_6 in BrF_5 is ~11 moles per 1000 g BrF_5 at 25°C. [170]

Hydrolysis of XeF_6 takes place with the formation of xenon trioxide [98]:

$$XeF_6 + 3H_2O \rightarrow XeO_3 + 6HF.$$

Hydrolysis can be effected most simply and safely by using argon or helium as carrier [171,172] and also at liquid nitrogen temperature.

5. Complexes of Xenon Fluorides

After the years which have elapsed since the discovery of noble gas compounds, there have been considerable developments in investigations of the interaction of these compounds, especially xenon fluorides, with fluoro-acids and fluoro-bases.

The SbF_5–XeF_2 system has been investigated in detail [173]. Fig. 6 shows the equilibrium diagram of this system. The considerable supercooling (up to 100 deg) of the specimens in composition range 0.1–0.3 mole fraction XeF_2 is due [75] to the formation of XeF and XeF^+. The presence of an EPR spectrum of solutions of $XeF_2.2SbF_5$ in SbF_5 can be confirmation of the occurrence of this type of process [174].

The TaF_5–XeF_2, [175] NbF_5–XeF_2, [175] and VF_5–XeF_2 [176] binary systems have been investigated. In the TaF_5–XeF_2 system $XeF_2.TaF_5$ and $XeF_2.2TaF_5$ are formed, in the XeF_2–NbF_5 system only $XeF_2.2NbF_5$, and in the VF_5–XeF_2 system only $XeF_2.VF_5$. [176,177] The production of $XeF_2.NbF_5$ has also been reported [178].

The UF_6–XeF_2 system [179] consists of mixture with unrestricted mutual solubility of the components in the liquid state and with the crystallisation of $XeF_2.UF_6$ without formation of solid solutions. The degree of dissociation of $XeF_2.UF_6$ in the region of the melting point (120°C) does not exceed 20%. The pressure for the dissociation into constituent components is determined by the relation [180]:

$$\lg P_{mmHg} = 9.30 - 2171/T \quad (20\text{–}100°C).$$

The enthalpy of dissociation of $XeF_2.UF_6$ is independent of temperature (18.6 kcal mole^{-1}); the enthalpy of fusion is −3.5 kcal mole^{-1}.

$XeF_2.RuF_5$, $2XeF_2.RuF_5$, $XeF_2.2RuF_5$, $XeF_2.IrF_5$, $2XeF_2.IrF_5$, $XeF_2.2IrF_5$, $XeF_2.PtF_5$, $XeF_2.OsF_5$, $2XeF_2.OsF_5$, and $2XeF_2.AsF_5$ have been isolated[130] from solutions of XeF_2 and the noble metal pentafluoride in BrF_5. A report[34] of the formation of stable $XeF_2.AsF_5$ was not confirmed subsequently[130]. $XeF_2.OsF_5$ also decomposes[130] at 20°C; with the formation of osmium hexafluoride:

$$3(XeF_2 \cdot OsF_5) \rightarrow 2XeF_2 \cdot OsF_5 + 2OsF_6 + Xe.$$

Bartlett regards this reaction as an intermolecular reaction with the transfer of an electron and the intermediate formation of the XeF radical in the solid phase.

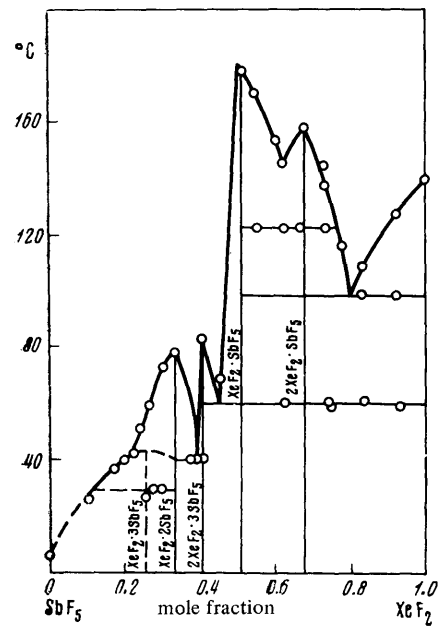

Figure 6. The equilibrium diagram of the SbF_5–XeF_2 system.

The reaction of XeF_2 with MnF_2 leads to the formation of the paramagnetic complex $XeMnF_6$ with an effective magnetic moment[181] of 3.86 μ_B, which shows that Mn is quadrivalent in the compound.

Xenon tetrafluoride reacts in BrF_3 solutions with PBr_5, As_2O_3, and Sb_2O_3 with the formation of the corresponding pentafluorides[182]. Only recently it was found reliably that XeF_4 reacts with fluoro-acids: $XeF_4.2SbF_5$[183] and $XeF_4.SbF_5$[184] are formed during the dissolution of XeF_4 in SbF_5 at 50°C.

When XeF_6 is reduced with uranium tetrafluoride, in addition to XeF_4 and UF_6, $XeF_6.UF_5$ is also obtained[185,186]. This compound can be made also by mixing XeF_6 and UF_5. The magnetic susceptibility of $XeF_6.UF_5$ obeys the Curie–Weiss law in the temperature range from −183° to 17°C, the Weiss constant being 55° and the effective magnetic moment 1.57 μ_B, which confirms that uranium is quinquevalent in the complex.

$XePtF_{11}$ and Xe_2PtF_{17} are formed[187] in the F_2–PtF_5–Xe system at a fluorine pressure of 80 atm and 180–220°C. The magnetic susceptibility of $XePtF_{11}$ obeys the Curie–Weiss law in the temperature range from −183° to 18°C; the Weiss constant is 35° and the effective magnetic moment of $XePtF_{11}$ is 1.97 μ_B.[187]

Under conditions most favourable for the formation of XeF_6, fluorination at 400°C of a mixture of AuF_3 and XeF_2 in the molar ratio 1:6 gave[188] a gold(V) complex $2XeF_6.AuF_5$; this shows that XeF_6 facilitates the stabilisation of the higher degrees of oxidation of the elements. $XeF_6.CrF_4$ was obtained[189] by the reaction of a considerable excess of XeF_6 with CrF_2 at 120°C. The oxidation of Cr^{II} to Cr^{IV} was confirmed by magnetic susceptibility measurements: the effective magnetic moment was 2.76 μ_B. The formation of $XeF_6.CrF_4$ by the reaction of XeF_6 with CrF_5 was also reported[189], although considering the known properties of XeF_6 and CrF_5, the reduction of Cr^V is difficult to explain.

In reactions with alkali metal fluorides[190], NOF,[191] and NO_2F[4,192] xenon hexafluoride acts as a fluoro-acid; in these reactions M_2XeF_8 (M = Cs, Rb, K, Na) and $MXeF_7$ (M = Cs or Rb), $2NOF.XeF_6$ and $NO_2F.XeF_6$ are formed. An X-ray diffraction investigation[193] of $2NOF.XeF_6$ showed the presence in the crystal lattice of the groups NO^+ and XeF_8^{2-}; $a = 8.914$, $b = 5.945$, $c = 12.83$ Å, $\rho_{calc} = 3.354$ g cm^{-3}, $Z = 4$, space group *Pnma*. Fig. 7 shows the structure of XeF_8^{2-}.

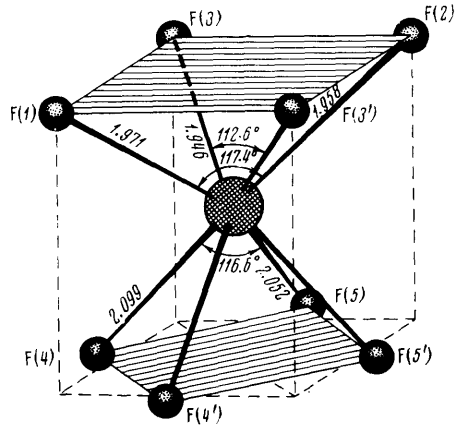

Figure 7. Structure of the XeF_8^{2-} anion in the $2NOF.XeF_6$ crystal lattice.

Reactions of the xenon fluorides in which they act as fluoro-bases (donors of fluoride ions) are interesting. Up till now the following complexes of xenon difluoride have been prepared: $2XeF_2.MF_4$ (M = Sn,[83] Ti,[83,194] Zr,[93] Pd,[195] Mn,[181]), $4XeF_2.PdF_4$,[195] $3XeF_2.PdF_4$,[195] $XeF_2.PdF_4$,[195] $XeF_2.2PdF_4$,[195] $XeF_2.MF_5$ (where M = As,[130] Sb,[173] Ta,[175,178] Nb,[178] V,[177] I,[71,76] Os,[130,178] Ir,[178] Pt,[130] Ru[130]), $XeF_2.2MF_5$ (M = Sb,[173] Ta, Nb,[175,178] Br,[78] Ir, Ru[130]), $2XeF_2.MF_5$ (M = As,[34,130] Sb,[173] Os,[130,178] Ir, Ru[130]), $XeF_2.MF_6$ (M = U,[179] Mo, W[80]), $XeF_2.XeF$,[196,197] $XeF_2.XeOF_4$;[198] xenon tetrafluoride: $XeF_4.SbF_5$,[184] $XeF_4.2SbF_5$;[183,184] xenon hexafluoride: $2XeF_6.MF_4$ (M = Ge,[199] Sn,[200] Pd[195]), $4XeF_6.MF_4$ (M = Ge,[199] Sn,[200] Pd,[195] Mn[201]), XeF_6MF_4 (M = Ge,[199] Pd,[195] Cr[189]), $XeF_6.MF_5$ (M = As,[91,200] Sb,[170] Ir,[190] Ta,[201] Ru,[91] Pt,[187] U[185]), and $2XeF_6.MF_5$ (M = P,[202] As,[91,202] V,[203] Ta,[201] Pt,[187] Au[188]); the ability of the xenon fluorides to supply fluoride ions decreases in the order[91]: $XeF_6 > XeF_2 > XeF_4$.

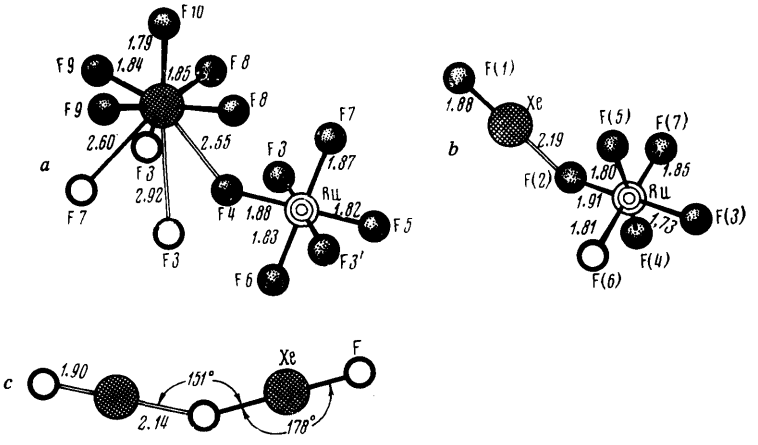

Figure 8. Crystal structure of the complexes of the xenon fluorides: *a*) $XeF_5^+RuF_6^-$; *c*) $Xe_2F_3^+$ in $2XeF_2.AsF_5$.

X-Ray diffraction and spectroscopic investigations of several xenon fluoro-complexes have enabled an understanding of their structure to be approached.

Peacock and coworkers [204] made an X-ray structural diffraction investigation of $XeF_2.2SbF_5$ and although they formally represented the complex in an ionic form ($XeF^+Sb_2F_{11}^-$) they attributed covalent character to the bonds in it. Bartlett and coworkers' X-ray diffraction investigation [205] of $2XeF_2.AsF_5$ led to the opposite conclusion: the structure of $2XeF_2.AsF_5$ is constructed from $Xe_2F_3^+$ cations and AsF_6^- anions. As Fig. 8 shows, the $Xe_2F_3^+$ cation has a planar V-shaped configuration with bridging fluorine atoms.

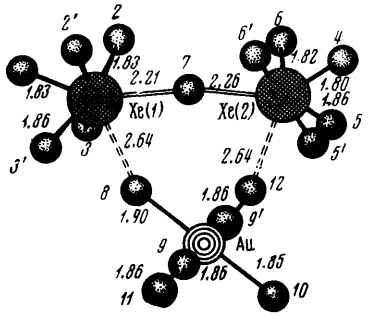

Figure 9. Crystal structure of $Xe_2F_{11}^+AuF_6^-$.

Bartlett and coworkers [130] investigated the Raman spectra of the compounds of XeF_2 with noble metal pentafluorides and calculated the normal vibrations of $XeF_2.IrF_5$ for strong and weak interactions of the XeF^+ and IrF_6^- ions. On the basis of a comparison of calculated and experimental frequencies for the ionic and bridging models they concluded it was possible to describe the compounds $XeF_2.MF_5$ and $XeF_2.2MF_5$ within the framework of the ionic model. An approximate calculation of $XeF_2.SbF_5$ using the frequencies of the Sb–F stretching vibrations of the $SbF_5SO_3F^-$ anion and the "frequency" formulae for a linear triatomic asymmetric molecule also showed that an ionic structure corresponds to the best agreement of the observed and calculated spectra [206]. Infringement of the selection rules for molecules with symmetry O_h, which is observed in the vibrational spectra of xenon fluoro-complexes cannot alter the correctness of ideas about the ionic structure of the compounds and is tentatively explained by a reduction in the symmetry of the anion in the crystal lattice [180,207]. X-Ray diffraction investigations confirmed the conclusion about the ionic structure of these substances.

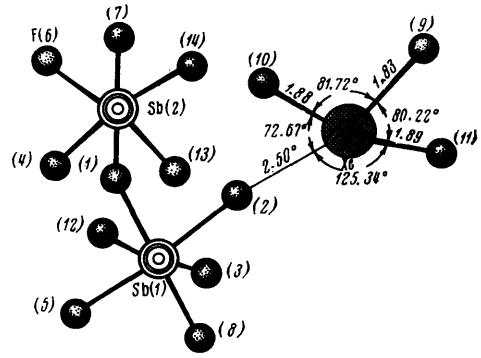

Figure 10. Crystal structure of $XeF_3^+Sb_2F_{11}^-$.

In addition to the molecular constants of the simple xenon compounds, Table 3 gives experimental values of the vibrational frequencies of the cations of certain fluoro-complexes of xenon. Table 4 gives the crystallographic properties of these compounds. Figs. 8–10 show the structures of typical compounds.

Note. *The Raman spectra of the complexes of XeF_2 were investigated in Refs. 130, 206, 209, and 211; the infrared spectra in Refs. 206, 209, 210, and 220; **ν and δ are stretching and deformation vibrations respectively; K is the force constant of the main stretching vibration; the following abbreviations are used in the Table: IR(g) and IR(s), the infrared spectra of the gaseous and solid substances; Ram(g) and Ram(s) the Raman spectra of the gaseous and solid substances respectively. The numbers in parentheses show the degree of degeneracy of the vibrations.

From Table 3, clearly in compounds which contain the XeF^+ cation the frequency of the vibration of the Xe–F terminal bond is shifted to the long-wave part of the spectrum. This shift is explained with semiempirical calculation by the simple LCAO MO method[212], which led to the following series of energies of the xenon–fluorine bond (in kcal mole^{-1}): XeF^+ (~ 50) > XeF_2 (~ 30) > XeF (< 10); consequently for an ionic compound the frequency of the vibration of the Xe–F bond should be higher than for XeF_2, which is also observed experimentally. Since the frequency of the vibrations of the Xe–F bond depends directly on the strength of the fluoro-acid, it can serve as a criterion of the relative acceptor capability of fluoro-acids in reactions with XeF_2:[212]

$$(Sb_2F_{10}) > SbF_5 > (Ir_2F_{10}) > PtF_5 > IrF_5 > (Ta_2F_{10}) > RuF_5 > Ta_{\ldots} > (Nb_2F_{10}) > TiF_4 > SnF_4 > SO_2F > CF_3COO > IF_5.$$

Rüdiger and Meinert[226] showed the possibility of using the MO method in the Hückel approximation for bonding calculations on the complexes of XeF_2 and obtained satisfactory correspondence of the experimental and calculated results for the salts XeF^+ and $Xe_2F_3^+$.

B. Oxygen-containing Compounds of Xenon

1. Xenon Oxide Fluorides

Xenon oxide tetrafluoride can be obtained by controlled hydrolysis of XeF_6 or by reaction of XeF_6 with silicon dioxide [1,98]; XeF_6 is removed on sodium fluoride.

At room temperature $XeOF_4$ is a colourless transparent liquid. The density of liquid $XeOF_4$ is given by the relation [227]:

$$\rho \text{ g cm}^{-3} = 3.168 - 0.0032\ t\ .$$

The similarity of the Raman spectra of $XeOF_4$ and of a solution of $XeOF_4$ in HF indicated [228] that $XeOF_4$ dissolves in molecular form in HF. A study of the change in the form of the peak of the Xe–O stretching vibration with dilution of the solution of $XeOF_4$ in HF suggested molecular association in liquid $XeOF_4$. [229]

The physical properties of $XeOF_4$ were studied rather thoroughly even at an early stage of the investigations [1] and are given in Table 5. The square pyramidal structure (Table 3) is confirmed by the microwave spectrum [233], according to which the Xe–O and Xe–F distances in the $XeOF_4$ molecule are respectively equal to 1.703 and 1.900 Å and the angle O–Xe–F is 91.8°. The results of an electron diffraction investigation [234] of gaseous $XeOF_4$ led to the following values: r(Xe–O) = 1.7109 Å, r(Xe–F) = 1.9010 Å, and the angle O–Xe–F = 91°. The agreement between the two methods is satisfactory.

The Raman spectra of gaseous [47] and liquid [235] $XeOF_4$ were obtained. The infrared and Raman spectra of $XeOF_4$ were interpreted [47] (Table 3).

The ^{17}O NMR spectrum of $XeOF_4$ [236] has the form of a triplet with an intense central peak of width 130 Hz and two symmetric side peaks of width 110 Hz. An analysis of the intensities showed that the side lines are due to the interaction of ^{17}O with ^{129}Xe and the main line to the interaction of ^{17}O with the remaining xenon isotopes. The ^{17}O chemical shift (relative to $H_2{}^{17}O$) is 313 p.p.m. The spin–spin coupling constant ($^{129}Xe-{}^{17}O$) is 629 Hz. Investigations of the ^{19}F NMR spectrum for $XeOF_4$ have continued [237,238]. The relaxation times were measured in the temperature range from −56° to 85°C and the presence of molecular association in liquid $XeOF_4$ was concluded. The high-resolution ^{19}F NMR spectrum [237] is characterised by an intense central line and a doublet with a spin–spin coupling ($^{129}Xe-{}^{19}F$) constant of 1124 Hz. The chemical shift at 25° is 100.27 p.p.m. (relative to CCl_3F). [237]

The interaction of $XeOF_4$ with alkali : metal fluorides leads to the formation of $3KF.XeOF_4$, $3RbF.XeOF_4$, and $CsF.XeOF_4$, [227] which decompose when heated. With NOF, $NOF.XeOF_4$ is formed [227]. With fluoro-acids, $XeOF_4$ forms the unstable $2XeOF_4.AsF_5$, [229] $2XeOF_4.VF_5$, [229] $XeOF_4.SbF_5$, [213,229] and $XeOF_4.2SbF_5$. [213,227] From the Raman spectrum [229], $2XeOF_4.VF_5$ is a molecular compound. The presence of ^{19}F NMR peaks and their position in the spectrum of solutions of $XeOF_4.2SbF_5$ in SbF_5 shows the presence in the solutions of the cation $XeOF_3^+$, in which the electron pair and the F atom occupy an equatorial position of the trigonal bipyramid and two other F atoms are located axially [215]. The chemical shifts at 5° are −195.1 p.p.m. ($F_{eq}-{}^{129}Xe$) and −147.1 p.p.m. ($F_{ax}-{}^{129}Xe$) relative to CCl_3F. The coupling constants ($^{129}Xe-{}^{19}F$) are 938 Hz (F_{eq}) and 434 Hz (F_{ax}). The ionic structure of $XeOF_4.SbF_5$ and $XeOF_4.2SbF_5$ is confirmed by their Raman spectra [213,215] and by X-ray diffraction investigations [213,222] (Tables 3 and 4).

Xenon dioxide difluoride XeO_2F_2 is formed in the interaction of XeO_3 with $XeOF_4$ or with XeF_6. [239] Removal of impurities is most effectively brought about by distillation. XeO_2F_2 forms colourless crystals which melt at 30.8°C to give a colourless liquid. XeO_2F_2 is more stable than XeO_3, but like XeO_3 is explosive; in moist air

The following abbreviations are used in the Table: (g) gaseous state of the substance, (s) solid (crystalline) state of the substance.

it is rapidly hydrolysed to XeO_3. When XeO_2F_2 reacts with XeF_6, $XeOF_4$ is formed [239]. The standard enthalpy of formation of XeO_2F_2 (g) [240] was estimated as 56 kcal $mole^{-1}$.

The Raman spectra of liquid and solid XeO_2F_2 and the infrared spectrum of solid XeO_2F_2 in an argon matrix at 4°K were investigated [214]. It was concluded that the XeO_2F_2 molecules are monomeric in the liquid and possibly the solid phases. According to the vibrational spectra, the XeO_2F_2 molecule has a pseudopyramidal structure of C_{2v} symmetry (Table 3). The normal vibrations of XeO_2F_2 and SO_2F_2, CrO_2F_2, and SeO_2F_2 were compared and it was shown that the frequencies of monotypical vibrations are arranged in a series in accordance with the mass of the central atom [214].

The molecular structure and symmetry of XeO_2F_2 were investigated by neutron diffraction on single crystals [241]. It was found that the XeO_2F_2 structure is orthorhombic, with parameters $a = 6.443$, $b = 6.288$, $c = 8.312$ Å, $Z = 4$, $\rho_{calc} = 4.10$ g cm^{-3}. The structure consists of dimeric layers of XeO_2F_2 molecules linked by weak Xe...O bridges.

The ^{19}F NMR spectrum for XeO_2F_2 and also that for XeO_2F_2–$XeOF_4$ mixtures (1 : 1) have been obtained [237]. The XeO_2F_2 spectrum is characterised by a single peak accompanied by a doublet from the spin–spin coupling ($^{19}F-^{129}Xe$) with constant 1178 Hz. The chemical shift is 105.10 p.p.m. in relation to CCl_3F. Throughout the entire range of temperatures studied (16–70°C) significant broadening of the lines was not observed.

The compound $XeO_2F_2.2SbF_5$ has been prepared [215]. The ^{19}F NMR spectrum of a solution of $XeO_2F_2.2SbF_5$ in SbF_5 shows the formation in the solution of the cation XeO_2F^+, the structure of which is analogous to the isoelectronic XeO_3—a trigonal bipyramid [215]. The chemical shift at 5° is −199.4 p.p.m. relative to CCl_3F; the spin–spin coupling constant ($^{129}Xe-^{19}F$) is 79.7 Hz. The presence of the XeO_2F^+ cation in $XeO_2F_2.2SbF_5$ is confirmed by the Raman spectrum [215] (Table 3).

Xenon trioxide difluoride XeO_3F_2 was isolated in the reaction of XeF_6 with Na_4XeO_6 at room temperature [242]; it was identified by the mass spectrum. The volatility of XeO_3F_2 is comparable with that of XeO_4 but less than that of XeO_2F_2. The infrared and Raman spectra of XeO_3F_2 in an argon matrix at 4°K were investigated [216] (Table 3).

Xenon dioxide tetrafluoride XeO_2F_4 is formed by the reaction [243]:

$$XeO_3F_2+XeF_6\rightarrow XeOF_4+XeO_2F_4\,.$$

Xenon oxide hexafluoride $XeOF_6$ could not be isolated but its compound $XeOF_5^+Sb_2F_{11}^-$ was obtained [184] by the reaction of $KrF^+Sb_2F_{11}^-$ with $XeOF_4$ at −10°C.

2. Xenon Trioxide

The behaviour of XeO_3 in aqueous solutions was discussed in detail by Malm and Appelman [3], and that in non-aqueous solutions by Jaselskis [11].

The method for obtaining pure aqueous solutions of XeO_3 [140] is the hydrolysis of XeF_6 with the subsequent precipitation of fluoride ion with magnesium oxide,

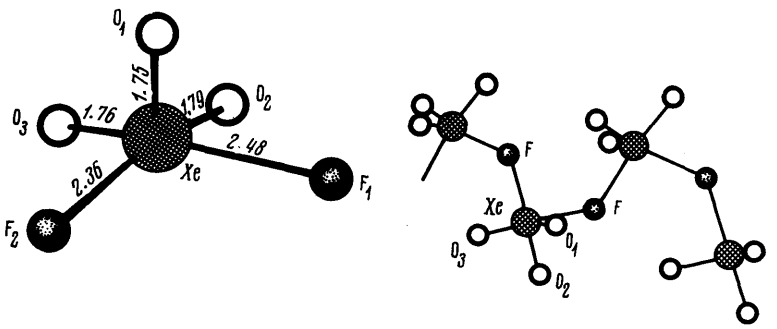

Figure 11. Structure of the XeO_3F^- anion in the $nK^+(XeO_3F^-)_n$ crystal lattice.

removal of Mg^{2+} ions by the action of zirconium phosphate and trace amounts of fluoride ions with the aid of ZrO_2.

Crystalline colourless XeO_3 can be obtained by the evaporation of aqueous solutions of XeO_3 at room temperature[244]; XeO_3 sublimes at 70°C and decomposes under these conditions; in amounts exceeding 20 mg gaseous XeO_3 partly explodes. According to other results[245], the thermal decomposition of XeO_3 starts at 40°C and proceeds without explosion. The properties of XeO_3 are given in Table 5.

The thermodynamic properties of aqueous XeO_3 have been studied[246]. The standard enthalpy of formation $\Delta H^\circ_{298}(XeO_3 \infty H_2O)$ is 99.94 kcal mole^{-1}. The value $\Delta G^\circ_{298}XeO_{3(aq)} = 120.8$ kcal mole^{-1} was used to calculate the redox potential of the couple XeO_3/Xe in acid medium and $HXeO_4^-/Xe$ in alkaline medium:

$$XeO_{3(aq)} + 6H^+_{(aq)} + 6e^- = Xe_{(g)} + 3H_2O,$$

$$HXeO_{4(aq)}^- + 3H_2O + 6e^- = Xe_{(g)} + 7OH^-,$$

equal respectively to 2.10 and 1.24 V.

The kinetics of decomposition of XeO_3 in a neutral aqueous solution has been studied[247]. The variation of the optical density of solutions of XeO_3 with time has been plotted. It has been shown that the decomposition of XeO_3 is described by a first-order equation up to high degrees of conversion. The rate constant is independent of the concentration of the solution in the range 1.01×10^{-3}–3.30×10^{-3} M. The Arrhenius relation has the form:

$$k = 10^{13,4\pm1,1} \cdot \exp(-28\,100 \pm 1900/RT).$$

The results of an investigation[247] of the kinetics of decomposition of XeO_3 in aqueous solutions can be regarded as a quantitative measure of the stability of these solutions As the pH is increased, the stability of the XeO_3 solutions falls[3]. γ-Radiolysis of the aqueous solutions of XeO_3 at room temperature leads to decomposition of XeO_3 into Xe and O_2.[248] The radiation-chemical yield increases with the XeO_3 concentration[249,250]. The possible mechanism of γ-radiolysis has been discussed[249,250].

Aqueous solutions of XeO_3 readily oxidise H_2O_2 to O_2,[251] Pu^{III} to Pu^{IV} in 2 M $HClO_4$,[252,253] Np^V to Np^{VI} in 2 M $HClO_4$,[254] Np^{VI} to Np^{VII} in 1 M KOH[255] and 10–11 M KOH.[108] Many organic compounds, for example, primary and secondary aliphatic alcohols,[256,257] benzyl alcohol,[257,258] benzaldehyde,[258] diphenylmethanol,[257] etc., are decomposed in aqueous solutions of XeO_3 with the formation of CO_2. XeO_3 reacts with t-butyl alcohol only in the presence of transition metal ions, with the formation of Bu^tOXeO_3K. $.Bu^tOH$.[259] In alkaline solutions XeO_3 epoxidises alkenes by electrophilic attack at the double bond[260]. Carboxylic acids are decomposed to CO_2.[261]

3. Xenates and Perxenates

The fluoroxenates $RbF.XeO_3$ and $CsF.XeO_3$ crystallise on the evaporation of a 0.5 M aqueous solution of XeO_3 (containing HF) after its neutralisation to pH 4 by the corresponding hydroxides[262]. $CsF.XeO_3$ can also be made by atmospheric hydrolysis of $CsF.XeF_6$[261] or $CsF.XeOF_4$.[227] Potassium fluoroxenate is formed in the evaporation of a mixture of a 0.5 M solution of XeO_3 and 1 M solution of KOH.[262] The fluoroxenates mentioned are comparatively stable; their decomposition starts to become appreciable above 260°C.[262] $CsCl.XeO_3$ can be obtained[263] by mixing aqueous solutions of XeO_3 and CsCl; unstable $CsBr.XeO_3$ has been isolated[262] from saturated solutions of CsBr at pH 9 and 0°C. The stability of the halogenoxenates falls with increase in the mass of the halogen[262]: $CsF.XeO_3 > CsCl.XeO_3 > CsBr.XeO_3$.

The halogenoxenates are much more stable than XeO_3, which does not agree with the view[227] that they are molecular compounds. Actually, X-ray diffraction investigations[264] showed that the crystal structure of $KF.XeO_3$ is constructed from infinite XeO_3 chains connected by bridging fluorine atoms in such a manner that each link acquires a negative charge, XeO_3F^-. As Fig. 11 shows, the anion has a polymeric structure and the links are connected by potassium ions. Consequently, the correct structural formula of potassium fluoroxenate is $nK^+(XeO_3F^-)_n$. The orthorhombic lattice of $KF.XeO_3$ has the parameters a = 7.354, b = 6.811, c = 8.815 Å, ρ_{calc} = 3.835 g cm^{-3}, Z = 4, space group $Pn2_1a$.[264] The ionic structure of the halogenoxenates has been confirmed by the results of an investigation[217] of the infrared and Raman spectra of $MXeO_3F$ (M = K, Rb, or Cs) and $MXeO_3Cl.MCl$ (M = Rb or Cs), which agree most satisfactorily with C_{3v} symmetry for XeO_3F^-.

Cs, Rb, K, and Na xenates of composition $MHXeO_4$ crystallise from solutions of XeO_3 when the corresponding hydroxides are added[265]. They are all stable up to 150 to 160°C, tend to detonate, and decompose slowly in aqueous solutions. An investigation[266] of the Raman spectra of aqueous 1.1 M solutions of $NaHXeO_4$ showed the presence of $HXeO_4^-$ in them.

In the ozonisation of aqueous solutions of XeO_3 and KOH the stable salt of sexivalent and octivalent xenon is isolated—$K_4XeO_6.2XeO_3$,[267] which tends to denotate and decomposes above 200°C by the reaction:

$$K_4XeO_6 \cdot 2XeO_3 \rightarrow K_4XeO_6 + 2Xe + 3O_2.$$

On the basis of the results of investigations of the thermal stability, infrared spectra, and an X-ray diffraction analysis of $K_4XeO_6.2XeO_3$, it was concluded[267] that in this

compound the XeO_3 molecules are coordinated (by means of two bridging oxygen atoms) to the central group—octahedral perxenate, in such a manner that $K_4Xe_3O_{12}$ is formed.

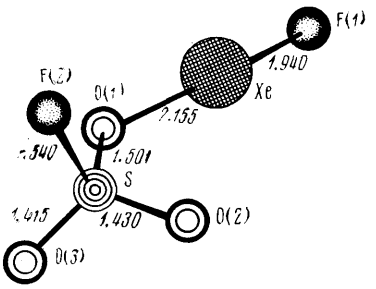

Figure 12. Molecular structure of $FXeOSO_2F$.

The salts of xenon(VIII), the perxenates, are formed in solutions of strong bases in the hydrolysis of XeF_6, the disproportionation of XeO_3, and in ozonation of XeO_3 solutions. Appelman thinks[268] that the ozonation of XeO_3 in 1–2 M alkali is the most effective. Some perxenates, for example, $Na_4XeO_6 . 2.5NaF$, can also be obtained, but in smaller yield, by the hydrolysis of XeF_4 in alkaline solutions[269]. An investigation of the Raman spectra of aqueous solutions of perxenates[266] shows the high concentration of symmetric, evidently octahedral, anions:

$$HXeO_6^{3-} + OH^- \rightleftarrows XeO_6^{4-} + H_2O.$$

Methods of making $Na_4XeO_6.nH_2O$ (n = 2, 4, or 6) of high purity have been developed[270], involving the hydrolysis of mixtures of XeF_4 and XeF_2 in alkaline solutions. The thermal stability of $Na_4XeO_6.6H_2O$ has been investigated[271]. The following parameters of its hexagonal lattice have been found[272] for Na_4XeO_6 by X-ray diffraction: a = 5.63, c = 16.00 Å. At the basis of the structure lies cubic close packing of O atoms with distribution of the Na and Xe atoms in octahedra; here the $Na_2XeO_6^{2-}$ layer lies parallel to the plane bc with distance between them 6.25 Å. Lithium perxenate of composition $Li_4XeO_6.nH_2O$ where $0.6 < n < 2$,[273] is less stable than sodium perxenate.

The rare-earth elements (r.e.e.) form dipole perxenates. In the general instance, the r.e.e. and yttrium form complex salts[270,274] $M_nLn_m(XeO_6)_l.xH_2O$, where M is an alkali metal, Ln is Ho, Eu, Dy, Pr, La, Nd, or Y, with $2 < x < 4$. Analogous compounds are obtained for Th^{IV}, U^{VI}, Np^{VI}, and Pu^{VI}.[275] The compound $3(UO_2)_2XeO_6 . 5Na_4XeO_6.nH_2O$, which is stable up to 100°C and is slowly hydrolysed in water, has also been synthesised. Np^{VI} perxenate decomposes spontaneously with the formation of Np^{VII}.[275] Americium perxenate $Am_4(XeO_6)_3.4OH_2O$ is precipitated from basic solutions of Am^{III}.[276] Cobalt[277], barium and strontium[278], copper, lead, silver, nickel, tin, and zinc[3] perxenates have also been obtained. Their properties have not been studied. In aqueous solutions the perxenates are strong oxidants[3].

4. Xenon Tetroxide

Xenon tetroxide XeO_4 is formed in the reaction of perxenates with sulphuric acid at room temperature, for example[1]:

$$Ba_2XeO_6 + 2H_2SO_4 \rightarrow XeO_4 + 2BaSO_4 + 2H_2O.$$

The standard enthalpy of formation of XeO_4 is 153.5 kcal $mole^{-1}$, which corresponds to a mean thermochemical bond energy of 21.1 kcal $mole^{-1}$.[279]

The molecular structure of gaseous XeO_4 has been determined by electron diffraction[280]; the tetrahedral configuration of the molecule (symmetry Td) has been confirmed; the interatomic distances are: r(Xe–O) = 1.736 Å, r(O...O) = 2.832 Å, and the mean square amplitudes of the vibrations are: l(Xe–O) = 0.046 Å, l(O...O) = 0.086 Å. The results obtained for the bond lengths led Gundersen and coworkers[280] to the conclusion that the bond between xenon and oxygen had considerable double bond character, although the amplitudes of the vibrations are more characteristic of a single bond.

The vibrational spectra of XeO_4 were investigated by Yeranos[281] (infrared spectrum), Huston and Claassen[218] (Raman spectrum), and McDowell and Asprey[219] (infrared and Raman). Table 3 gives the vibrational wavenumbers of XeO_4. The frequencies in the laser Raman spectra of gaseous and solid XeO_4 have been assigned[218] and with the aid of a force field Urey and Bradley calculated the force constants. Unlike most of the tetrahedral molecules and ions studied[282], in XeO_4 the force constant for the interaction of non-bonded atoms is negative (–0.18 mdyn $Å^{-1}$). McDowell and Asprey[219] studied the infrared and Raman spectra of gaseous XeO_4^{16} and XeO_4^{18} and showed the existence of a difference between the force fields of XeO_4 on the one hand and OsO_4,[283] and RuO_4[284] on the other. The negative sign of the coupling constant of non-bonded atoms shows, in complete agreement with Huston and Claassen's work[218], a significant difference between the nature of the bonds in XeO_4 and in the tetroxides of the noble metals.

5. Derivatives of Xenon Fluorides and Oxides

Xenon forms comparatively stable compounds only with the most electronegative elements—fluorine and oxygen. The concept of electronegativity played a positive part in the prediction of the possibility of the formation of compounds with groups more electronegative than fluorine and oxygen.

When XeF_2 reacts with stoichiometric amounts of fluorosulphonic or perchloric acids below –60°C colourless crystalline substances are formed: $FXeSO_3F$, $Xe(SO_3F)_2$, $FXeClO_4$, $Xe(ClO_4)_2$.[285,286] $FXeSO_3F$ melts at 36.6°C to a yellow-green liquid and decomposes on melting:

$$2FXeSO_3F \rightarrow XeF_2 + S_2O_6F_2 + Xe.$$

The reactions of $FXeSO_3F$ are accompanied by the release of xenon. The $FXeSO_3F$ structure consists of discrete $FXeOSO_2F$ molecules (Fig. 12), in which the Xe atom is coordinated linearly with F and O atoms of a distorted tetrahedral fluorosulpho-group[287]. $FXeSO_3F$ has an orthorhombic lattice with parameters a = 9.88, b = 10.00, c = 10.13 Å, Z = 8, ρ_{calc} = 3.30 g cm^{-3}, space group $Pbca$. $Xe(SO_3F)_2$ melts at 43–45° to a yellow liquid, which slowly decomposes[285,286]:

$$Xe(SO_3F)_2 \rightarrow S_2O_6F_2 + Xe.$$

Preliminary investigation[286] of the crystal structure of $Xe(SO_3F)_2$ showed that the crystals are monoclinic with $a = 7.94$, $b = 13.7$, $c = 6.84$ Å, $\beta = 96°$. $FXeClO_4$ melts sharply at 16.5°C with decomposition; $Xe(ClO_4)_2$ melts at 0°C. Xe, O_2, and Cl_2O_7 have been observed[286] in the decomposition products of $FXeClO_4$ and $Xe(ClO_4)_2$.

The reaction of XeF_2 with $HOTeF_5$ leads to the formation of $FXeOTeF_5$ and $Xe(OTeF_5)_2$.[288-291] These compounds decompose above 150°C with the formation of $F_5TeOTeF_5$. The compound $Xe(OTeF_5)_2$ is orthorhombic with the lattice parameters $a = 9.83$, $b = 8.73$, $c = 12.97$ Å, $Z = 4$, $\rho_{calc} = 3.64$ g cm^{-3}, space group *Cmca*.[289] Like the noble gas fluorides, $FXeOTeF_5$ acts as a fluoride-ion donor with the formation[288,292] of $[F_5TeOXe]^+[AsF_6^-]$, is a weaker fluorobase than XeF_6 and XeF_2, but a stronger one than XeF_4. When XeF_2 reacts with $HOSeF_5$, $FXeOSeF_5$ and $Xe(OSeF_5)_2$ are formed[293,294]; their properties are reminiscent of xenon pentafluoro-orthotellurates. The thermal decomposition of these compounds starts at 100°C and leads to the formation of $F_5SeOSeF_5$.

XeF_2 forms $FXeOC(O)CF_3$ and $Xe[OC(O)CF_3]_2$ with trifluoroacetic acid at −24°C; they are pale yellow solid substances which explode when heated above 25°C and detonate under impact[290,295,296]. In addition to the above compounds, the following have been obtained: $FXeOSO_2CF_3$ and $FXeOSO_2CH_3$,[286] and $F_5TeOXeOSeF_5$,[294] which exists in equilibrium with $Xe(OTeF_5)_2$ and $Xe(OSeF_5)_2$, $FXeOPOF_2$ and $Xe(OPOF_2)_2$ are formed by the reaction of XeF_2 with $P_2O_3F_4$ in trichlorofluoromethane at −40°C and are stable up to 20°C.[297]

Investigation of the infrared and Raman spectra of derivatives of XeF_2 in oxo-acids[286-293] gave certain information about the nature of the bonds in the compounds obtained. Comparison of the vibrational frequencies of the Xe–F bond in these compounds and in XeF_2 led to the conclusion that the bonds of the Xe atoms with the ligands in all the compounds are similar[286]. This agrees with the results of the X-ray diffraction investigation of $FXeOSO_2F$:[287] the length of the Xe–F terminal bond in $FXeOSO_2F$ (1.94 Å) is close to the Xe–F distances in XeF_2 (2.01 Å), $Xe_2F_3^+$ (1.90 Å), $FXeFRuF_5$ (1.88 Å), and $FXeFSb_2F_{10}$ (1.84 Å).

The compounds listed are thermodynamically and thermally unstable. There are two points of view concerning the mechanism of their decomposition: according to one of these[286] the decomposition proceeds through the intermediate formation of the free radicals SO_3F and XeF; according to the other[298], the decomposition of $FXeOSO_2F$ takes place through the intermediate formation of XeF_2 and SO_3. Recently published results of experimental investigations of certain products of the reactions of XeF_2 with oxo-acids show the formation of rather stable free radicals during the course of their decomposition. Thus, in the EPR spectra of the yellow solutions of $FXeOPOF_2$ in CCl_4 a line of width 67 G with *g*-factor of 2.0067 is found[297]. This fact, just like the nature of the ultraviolet spectra of such solutions[297], has been interpreted as a sign of the formation of free radicals (evidently, PO_2F_2) in the decomposition of $FXeOPOF_2$ and $Xe(OPOF_2)_2$. The EPR method was also used for studying[294] the intermediate products of the photochemical decomposition of $Xe(OTeF_5)_2$ and $Xe(OSeF_5)_2$; the investigation was made in the solid state and in hexafluoroethane at −150°C. Lines with half-width 10.2 G, *g*-factor 2.00 were observed in the spectra of both solid substances. The appearance of the EPR signals is explained[294] by the formation of the free radicals $OSeF_5$ and $OTeF_5$.

The interaction of $FXeSO_3F$ with AsF_5, SbF_5, and RuF_5 did not lead, as expected[286], to the formation of salts containing the cation $(XeSO_3F)^+$; however, the complex $[(FXe)_2O_2S(O)F]^+[AsF_6]^-$, which decomposes above 60°C, was obtained[286] by the reaction of $FXeSO_3F$ with XeF_2 and AsF_5. An analysis of the Raman spectra of $[(FXe)_2O_2S(O)F]^+[AsF_6]^-$ and $[(FXe)_2F]^+[AsF_6]^-$ showed similar Xe–F bonds in these cations and confirmed the structure given[286].

Xenon tetrafluoride and hexafluoride are also capable of the formation of compounds with oxo-acids[299]. $FXeOSO_2F$ and $Xe(OSO_2F)_2$ are formed in the reaction of XeF_4 with $HOSO_2F$ in the temperature range from −22° to 5°C; under analogous conditions XeF_6 forms the colourless crystalline substance F_5XeOSO_2F, which melts above 73°C with decomposition[298]. The results of the measurement of the ^{19}F NMR spectrum of F_5XeOSO_2F, in HSO_3F at −60° show the existence in the solutions of the cation F_5Xe^+ ($FXeF_4^+$).[298] The data of the NMR spectrum: chemical shift (relative to HSO_3F) −188 p.p.m. (F_{ax}) and −68.9 p.p.m. (F_{eq}), (^{129}Xe–^{19}F) coupling constants 1377 Hz (F_{ax}) and 170 Hz (F_{eq}), agree with the results of earlier investigations[215] of the ^{19}F NMR for XeF_5^+. The ionic structure of F_5XeSO_3F is also confirmed by the Raman spectrum[298], the intense polarised bands at 650 and 595 cm^{-1} in which were assigned[300] to ν(Xe–F) and $\nu_{sym}(XeF_4)$ in XeF_5^+.

C. Other Xenon Compounds

Xenon dichloride $XeCl_2$ can be obtained: (a) by passing a high-frequency discharge (25 MHz, 150–350 mA) through a mixture of xenon, fluorine, and $SiCl_4$ or CCl_4 at −78°C.[300] It is suggested that the XeF_2 formed initially undergoes an exchange reaction with the halogen from the $SiCl_4$ (or CCl_4) with the formation of $XeCl_2$. It was shown later that an exchange reaction actually occurs in solutions of XeF_2 in CCl_4 under the action of ultraviolet radiation[301]; (b) by the action of a microwave discharge in a mixture of xenon and chlorine in the molar ratio 25:1 with subsequent rapid withdrawal of the reaction products into a zone cooled to 4°K;[302] (c) in the β-decay reaction[303]: $^{129}ICl_2^- \rightarrow {}^{129}XeCl_2$; (d) by the reaction of xenon with chlorine at high pressure and room temperature for several days[304] (Malm and Appelman think[3] that under the experimental conditions[304] unstable clathrates of xenon are formed, and not $XeCl_2$).

Xenon dichloride is a colourless crystalline substance which can be stored in sealed glass ampoules for long periods, which sublimes under reduced pressure at room temperature and decomposes in a high vacuum or when heated to 80°C.[300] The calculated standard enthalpy of formation ΔH°_{298} $XeCl_2$ (g) is 27 kcal mole^{-1},[286], which corresponds to a thermochemical bond energy of 15 to 16 kcal mole^{-1}.

In the infrared[302] and Raman[305] spectra of matrix-isolated $XeCl_2$ at 4°K bands with maxima at 319 and 253 cm^{-1} respectively are observed. These experimental wavenumbers agree with those calculated for a linear symmetric molecule (symmetry $D_{\infty h}$). The force constant of the Xe–Cl bond is 1.34 mdyn Å^{-1}.[304] The Mössbauer effect in solid $XeCl_2$ at 4.2°K was investigated[303]. The quadrupole splitting is 28.20 mm s^{-1}, the isomer shift 0.17 mm s^{-1} (relative to atomic xenon). The formal charge on each chlorine atom is 0.5.

Xenon tetrachloride $XeCl_4$ was identified by the Mössbauer spectrum as the product of the β-decomposition of ^{129}I introduced into $KICl_4$: $^{129}ICl_4^- \rightarrow {}^{129}XeCl_4$.[303] The quadrupole splitting in $XeCl_4$ is 25.62 mm s^{-1}, the isomer

shift 0.25 mm s^{-1}. The results of the investigation confirm the square planar configuration for $XeCl_4$. The charge on the central xenon atom in $XeCl_4$ is 1.9.

The negative ion $XeCl^-$ is formed as a result of the occurrence in the gas phase at a pressure of 10^{-4} mmHg of the ion-molecular reaction $Xe + CoCl^-$.[306] The energy of the dissociation of $XeCl^-$ into Xe and Cl^- is less than 10 kcal $mole^{-1}$.

Xenon dibromide $XeBr_2$, which is formed in the β-decay of ^{129}I in $KIBr_2$, was identified from the Mössbauer spectrum[307]. The outer ones of the three intense, sharply resolved lines are regarded as an $XeBr_2$ doublet with quadrupole splitting 22.2 mm s^{-1}. The formal charge on the bromine atoms in $XeBr_2$ is 0.41.[307]

Attempts to synthesise xenon chloride fluorides were unsuccessful[308,309]. The existence of $FXeBF_2$[310] has not yet been confirmed. The stable ion CH_3Xe^+ is formed in the interaction of xenon with CH_3FH^+ in the gas phase[311].

D. Radiochemistry of Xenon Compounds

The synthesis of xenon fluorides containing ^{133m}Xe or other radioactive isotopes can be effected from the elements by traditional methods, and also by the irradiation of xenon fluorides with neutral fluxes in a nuclear reactor[1,3]. The xenon fluorides are then used for obtaining oxygen compounds of xenon[274]. The retention of radioactive xenon in the initial XeF_2 and XeF_4 when they are irradiated in neutron fluxes (10^{12}–10^{13} n cm^{-2} s^{-1}) reaches 98% in XeF_4 and 93% in XeF_2,[312] that of radioactive fluorine is 100% in XeF_2 and 90% in XeF_4.[313] In the isomeric transformation of ^{135m}Xe in XeF_2 in organic solvents, ^{133}Xe is released in the elemental state to the extent of 95%.[314] The effectiveness of such processes for XeF_4 in aqueous solutions of XeO_3 is 50%.[315]

The distribution of iodine among the chemical species in the process of capture of an electron $^{125}Xe \rightarrow {}^{125}I$ in H_2O, XeF_2, and XeF_4 has been studied. It has been found that 95% of the ^{125}I is found in the form IO_4^- and 5% in the form IO_3^-. These investigations[316] allowed a method to be developed for obtaining ^{125}I without a carrier, which enabled preparations in the form of NaI with a specific activity exceeding 100 mC ml^{-1} to be obtained. The irradiation with an integral neutron flux of 2.5×10^{19}–5.1×10^{19} of a matrix target, for which XeF_2 was used, leads to the formation of a final product with a yield of 26–43 mC per g XeF_2.[317]

The chemical changes in the β-decay of iodine isotopes in the composition in iodates and periodates are regarded as an effective method of investigating the processes of formation of the xenon fluorides[318]. For example, the yield of chemically bound xenon in the decay of the isotopes ^{131}I, ^{133}I, ^{135}I in periodates reaches 45–85% in crystals and 70% in H_2O, 0.001 M H_2SO_4, and 1 M HNO_3.[319,320] The yield of combined xenon in the decay of isotopes in the alkali metal iodates varies from 10% (Cs, Rb, K) to 43.8% (Na) and 62.2% (Li) in 0.001 M H_2SO_4 and amounts to only 0.3% (K, Na) in 2 M NaOH.[321] An analysis of the results obtained allowed a complex relation to be found between the yield of chemically bound xenon and the valence of the iodine in the compounds, the state of these compounds (solution or crystal), the nature of the cation, the conditions of storage, the presence or absence of carriers, etc.[319–321] XeO_3 is formed in these processes. Xenon trioxide is also the only form of combined xenon in the β-decay of ^{131}I in I_2O_5 (yield 27%) and HIO_4 (yield 44%).[322] The processes for the formation of oxygen compounds of xenon in the β-decay of iodine and some of their properties have been discussed[323,324]. It has also been shown that XeO_3 is formed in aqueous solutions in the β-decay of ^{131}Xe in the composition of $C_6H_5IO_2$.[325] Several methods have been proposed for the separation of radioactive XeO_3 from the parent compounds by use of ion-exchange and thin-layer chromatography[326–329].

The possibility of the formation of xenon compounds under natural conditions as a result of the occurrence of nuclear processes has been examined[330]. The Szillard–Chalmers effect in dissolved XeO_3 has been investigated[331]. The retention of radioactive xenon amounts to 3%. It was found that the factor of enrichment of the xenon radioactive isotopes in the gas phase varies with the period of irradiation. Investigations[332,333] of processes of β-decay of ^{131}I or ^{133}I in C_6H_5I, $(C_6H_5)_2ICIO_4$, and other iodonium salts showed the formation of chemically bound xenon in an involatile form and it was concluded that $C_6H_5Xe^+$ is formed. The yield of onium compounds depends on the nature of the anion present, and the stabilising ability in relation to $C_6H_5Xe^+$ decreases in the order:

$$ClO_4^- > BF_4^- > SO_4^{2-} > NO_3^- > Cl^-.$$

III. KRYPTON COMPOUNDS†

Krypton difluoride is formed by the action of an electric discharge (15–20 mA, 3000–4000 V) on a mixture of krypton and fluorine with the molar ratio 1.1 : 1 at a total pressure of 20 mmHg.[230] The variation of the yield of KrF_2 with the parameters of the electric discharge, the pressures of krypton and fluorine, and the geometry and the temperatures of the walls of the discharge tube was investigated[334]. The synthesis of KrF_2 in an electric discharge can also be brought about in a metallic reactor at a wall temperature of −196°C, pressure of the gas mixture 4–20 mmHg, molar ratio $F_2 : Kr = 5 : 1$, current 20–30 mA, potential 500–1000 V.[335]

Gaseous krypton and fluorine react readily, with the formation of KrF_2 under the action of protons with energies of 10 MeV or α-particles with energies of 40 MeV at −140°C.[39] The radiation-chemical yield is 1.0–1.5, depending upon the temperature. A photochemical reaction is effected in the $Kr–F_2$ and $Kr–OF_2$ systems at room temperature[336]: the yield of KrF_2 in these experiments is insignificant.

At room temperature krypton difluoride is a colourless crystalline substance; it sublimes below 0°C. The vapour pressure in the temperature range from −30° to +25°C is described by the equation[337]:

$$\lg P_{mmHg} = 8.814 - 2000/T.$$

The physical properties of KrF_2 are given in Table 5.

The kinetics of thermal decomposition of gaseous KrF_2 were studied in the temperature range 20–100°C and at KrF_2 pressures of 5–70 mmHg.[338] The variation of the homogeneous decomposition of KrF_2 with temperature (60–100°C) is expressed by the equation:

$$k_{(hom)} = 2 \cdot 10^{13} \exp(-23\,800/RT)\,s^{-1}.$$

In the general instance, the activation energy of the thermal decomposition of KrF_2 varies from 10.2 kcal $mole^{-1}$ (20°C) to 23.8 kcal $mole^{-1}$ (60–100°C).

†See Prusakov and Sokolov's review[10] for a more detailed account of the papers published up to 1971.

The ions KrF^+ and Kr^+ with appearance potentials of 13.21 ± 0.25 and 13.71 ± 0.20 eV respectively have been observed[335] in the mass spectrum of KrF_2. The emission spectrum of KrF_2 in the ultraviolet range has been investigated[65]. The infrared and Raman spectra of gaseous KrF_2 have been obtained and interpreted[339] and have confirmed that the symmetry of this molecule is $D_{\infty}h$. The force constants were found to be: f_r = 2.46, f_{rr} = −0.20, f_{α} = 0.21 mdyn Å^{-1}. The negative force constant for the interaction between the bonds f_{rr} = −0.20 mdyn Å^{-1} and also the absence of Fermi resonance between the frequencies ν_1 and $2\nu_2$ were discussed[339–342]. The asymmetric stretching vibration ν_3 in the infrared spectrum of $^{86}KrF_2$ was studied[343] further with a resolution of 0.08 cm^{-1}. Two alternative assignments were proposed and two corresponding sets of constants were obtained. The most probable, in the opinion of Murchison and coworkers[343], set gives ν_0 = 589.889, B_0 = 0.126 26, B' = 0.125 75, D_0 = D' = 7.8 × 10^{-8} cm. Hence r(Kr–F) = 1.875 ± 0.002 Å (or 1.876 ± 0.002 Å). The spectrum of solid KrF_2 (400 to 1000 cm^{-1})[170] at 77 °K is characterised by sharply expressed maxima at 520, 536, and 573 cm^{-1}. It has been suggested that KrF_2 is polymerised in the solid state. The band at 573 cm^{-1} is assigned to the Kr–F (ν_3) stretching vibration of the monomeric molecule, the remaining bands to the polymeric species of KrF_2. Electron diffraction investigations of gaseous KrF_2 confirmed the linear symmetry structure of the molecule[344]. The mean interatomic distances are r(Kr–F) = 1.889 and r(F...F) = 3.781 Å.

The ^{19}F NMR spectrum of KrF_2 in anhydrous HF was investigated[230]. The two fluorine atoms in KrF_2 were found to be equivalent. Exchange by the fluorine atoms between HF and KrF_2 was not noted even at 25 °C. From the Mössbauer spectrum of $^{83}KrF_2$ the quadrupole coupling constant was found to be 130 mm s^{-1} and the ratio of the quadrupole moments of the excited and ground states (1.70), and the isomeric shift (in relation to atomic krypton) (1.50 mm s^{-1}) were found[345]. The formal charge on the krypton atom in KrF_2 is 1.06. High-resolution photoelectronic spectra were obtained for KrF_2 in He–I and He–II radiation[346,347].

The BrF_5–KrF_2 system was studied by the DTA method[348]. The complexes $KrF_2.SbF_5$, $KrF_2.2SbF_5$, $KrF_2.TaF_5$, $KrF_2.2TaF_5$, $KrF_2.2NbF_5$, $2KrF_2.SnF_4$, and $2KrF_2.TiF_4$ have been isolated[10,337] from solutions of KrF_2 in anhydrous HF and BrF_5. The stability of the complexes of KrF_2 in non-aqueous solvents is much lower than that in the solid state, owing to the chemical reaction of these compounds with the solvents. Investigations of the infrared spectra[10] enabled ionic structures to be suggested for these compounds which were also confirmed by measurements of the Raman spectra of $KrF_2.2SbF_5$, $KrF_2.TaF_5$, $KrF_2.2TaF_5$, $KrF_2.2NbF_5$, and BrF_5 at −196 °C.[349] The stretching vibration Kr–F (KrF^+) in the Raman spectra[349] is characterised by doublet and even triplet absorption bands 620 and 623 cm^{-1} in $KrF^+Sb_2F_{11}^-$, 599 and 604 cm^{-1} in $KrF^+TaF_6^-$, 600 and 609 cm^{-1} in $KrF^+Nb_2F_{11}^-$, and 597, 605, and 613 cm^{-1} in $KrF^+Nb_2F_{11}^-$. The stretching vibration Kr–F in KrF^+ corresponds to the band at 622 cm^{-1} in the infrared spectrum[170] of $KrF^+SbF_6^-$.

$2KrF_2.SbF_5$ was synthesised in BrF_5 solutions at −40 °C; it is stable at the synthesis temperature[350] and decomposes in a dynamic vacuum at −30 °C with the formation of $KrF_2.SbF_5$, which is stable at room temperature. The Raman spectra of these compounds were investigated[349]. The bands at 627 and 619 cm^{-1} in $KrF_2.SbF_5$ were assigned to the KrF^+ vibration; the bands at 595 and 607 cm^{-1} in $2KrF_2.SbF_5$ to the principal stretching vibrations of the $Kr_2F_3^+$ cation. Gillespie and Schrobilgen[351] obtained $KrF_2.MF_5$ (M = As, Pt), $2KrF_2.AsF_5$, and $(KrF_3^+MF_6^-)_n KrF_2$ (M = As, Sb) and confirmed the existence of $KrF_2.SbF_5$ and $2KrF_2.SbF_5$. The compound $KrF_2.PtF_5$ was prepared by the reaction of KrF_2 and PtF_6 at 0 °C. The Raman spectra of these compounds were studied[351] and the ^{19}F NMR in $KrF_2.SbF_5$ at −40 °C and in $2KrF_2.SbF_5$ at −66 °C was measured in anhydrous HF and BrF_5. The results show the existence of the cations KrF^+ and $Kr_2F_3^+$ in the solutions. In the NMR spectrum of $KrF^+SbF_6^-$ a singlet line with a chemical shift of 22.6 p.p.m. relative to CCl_3F (−55.6 p.p.m. for KrF_2 in HF) is observed. The NMR spectrum of a solution of KrF_2 and SbF_5 with molar ratio 2:1 is assigned to the AX_2 type, which suggests a

Notes. (1) The reaction of N_2F_4 proceeds through the formation of NF_2 radicals, for which the addition of fluorine with formation of NF_3 is energetically more favourable.

(2) In the reactions of OF_2 the radicals OF and F participate, in those of O_2F_2, the radicals O_2F and F.

(3) The relatively low fluoro-oxidising ability of N_2F_2 (according to the experimental results) is due to kinetic restraints.

*Estimated values.

V-shaped structure for $Kr_2F_3^+$ with fluorine bridging atom[351]. The ^{19}F chemical shifts are −19.0 p.p.m. (A) and −73.6 p.p.m. (X_2). The coupling constant ($^{19}F_A-^{19}F_X$) is 351 Hz, close to that found for $Xe_2F_3^+$ (308 Hz).[351] In the Raman spectrum of $Kr_2F_3^+$, bands are observed at 603 and 594 cm^{-1}, 555 and 456 cm^{-1}; the results are interpreted[351] in terms of the asymmetric structure $FKr^+...FKrF$.

$XeF_6.SbF_5$ was isolated from a solution of KrF_2, SbF_5, and XeF_6 (1 : 1 : 1) in BrF_5 at 0°C, showing that the donor properties of XeF_6 are stronger than those of KrF_2; this is also confirmed by XeF_6 replacing KrF_2 in its complexes[170]. Xenon difluoride is also a better fluoride-ion donor than KrF_2. The molecular complex $KrF_2.XeF_6$ has also been obtained[170]; it is a colourless crystalline substance with m.p. 41°C and a vapour pressure of 11 mmHg at 20°C. The molecular nature of the complex was established by measurements of the infrared spectrum.

Taken together, the properties of KrF_2 suggest that KrF_2 as a fluoro-oxidant surpasses such strong fluorinating agents as F_2, oxygen fluorides, and halogen fluorides, and is only slightly worse than atomic fluorine (see Table 6). The complexes of KrF_2 are also strong oxidants. For example, in solutions of bromine pentafluoride KrF^+ ($KrF_2.nSbF_5$) readily oxidises IF_5 to IF_6^+, $XeOF_4$ to $XeOF_5^+$,[184] and BrF_5 to BrF_6^+.[351]

Previous papers (cf. Neiding[1]) have discussed the preparation and study of krypton tetrafluoride, and also the formation during its low-temperature hydrolysis of kryptic acid and its barium salt. These results were not confirmed subsequently. Furthermore, mass-spectrometric measurements and investigations of the vibrational spectra and ^{19}F NMR spectra of the products of the reaction of krypton with fluorine in a glow discharge showed that the identification of the reaction product as krypton tetrafluoride is erroneous.

Mössbauer spectroscopy was used to observe the chemically bound states of krypton[352] formed during electron capture in ^{83}Kr. The Mössbauer spectra of ^{83}Kr in solid matrices are characterised by broad lines, which suggests a different degree of chemical bonding[345,352,353]. In an investigation[353] of the products of the β-decay of ^{83m}Br in $KBrO_3$ a resonance line 2 mm s^{-1} broad is observed in the spectrum and is assigned to the bond of ^{83m}Kr with oxygen. These results were confirmed by measurements of the Mössbauer spectra of the products of the β-decay of ^{83}Se ($^{83}Se \rightarrow {}^{83}Br \rightarrow {}^{83}Kr$) in Se, SeO_2, and $(NH_4)_2SeO_4$.[354]

IV. RADON COMPOUNDS

The preparation and identification of radon compounds is extremely difficult owing to the high activity of the most stable radon isotope ^{222}Rn ($\tau_{1/2}$ = 3.8 d.) Therefore information about radon compounds is only qualitative.

It has been reported[355] that radon is oxidised in aqueous solutions by certain oxidants, in particular H_2O_2, $KMnO_4$, and $K_2S_2O_8$. Subsequent investigations[356] showed that under the conditions of the experiment[355] the radon is held mechanically in the solid phase. The formation of significant amounts of oxygen-containing compounds of radon is also not observed[357] in the α-decay of ^{226}Ra.

Vasilescu[358] estimated $\Delta H^\circ_{298}RnF_n$ (g). After some refining of these values, the following quantities are obtained: $\Delta H^\circ_{298}RnF_2$ (g) = −57.4 kcal $mole^{-1}$ (mean energy of the Rn–F bond 46.5 kcal $mole^{-1}$), $\Delta H^\circ_{298}RnF_4$ (g) = −81.1 kcal $mole^{-1}$ (39.1), $\Delta H^\circ_{298}RnF_6$ (g) = −98.5 kcal $mole^{-1}$ (35.2).

Radon fluorides are formed in the reaction of elemental radon with ClF_3, KrF_2, and XeF_n at room temperature[359], with O_2F_2 at −100°C, or under the action of α-radiation in liquid fluorine or solid ClF_3 at −196°.[359] The products of these reactions were not identified. Radon fluoride of a definite composition is isolated by distillation with XeF_6 from the reaction products of mixtures of xenon and radon with fluorine at 300°C and 100 atm.[359] The formation of RnF_2 and RnF_4 has also been reported[360].

The oxidation of gamma amounts of radon was effected in BrF_3, BrF_5, and ClF_3 solutions[361]. The formation of RnF_2 was suggested. Radon can also be oxidised by the action of ClF, ClF_5, BrF, IF_7, or NiF_6^{2-} (in HF) in the temperature range from −195° to +25°C.[362] Experiments on the electrolysis of solutions of oxidised radon in BrF_3 (potential difference 18–50 V, current 50 mA) showed that the Rn is concentrated only in the near-cathode region without reduction. On this basis the existence in the solutions of the cations RnF^+ or Rn^{2+} (products of the dissociation of RnF_2) was suggested. The coprecipitation of radon fluoride with the molecular compound of XeF_2 and IF_5 was studied[363] to find the chemical composition of the radon in BrF_3–IF_5 solutions. The results show that the most probable product of the reaction Rn + XeF_2 (XeF_4) is RnF_2. Involatile radon compounds are formed in the reaction of radon with ClF_2SbF_6, BrF_2SbF_6, $BrF_4Sb_2F_{11}$, $If_4(SbF_6)_3$, or BrF_2BiF_6 at 25°C.[364] $KBrF_4$, $CsBrF_6$, $KClF_4$, $RbClF_4$, and BrF_2TaF_6 are less effective. It is suggested that the reaction leads to the formation of complexes of the type $RnF^+MF_6^-$ or $RnF^+M_2F_{11}^-$ and radon difluoride[364].

Vasilescu[358] discussed the possibility of obtaining various compounds of radon and their expected stability. Stein[365] discussed problems of radon chemistry in detail.

V. ELECTRONIC STRUCTURE OF COMPOUNDS OF THE NOBLE GASES

In her extremely thorough critical review[2] Dyatkina examined the main theoretical studies in this field published in the period 1963–1968 and compared the theoretical with the experimental results. Dyatkina came to the general conclusion "that the main reason for the formation of these compounds is the establishment of delocalised molecular orbitals and the specific characteristics of the molecular orbitals—their energies and atomic orbital coefficients—determine the properties of the molecules".[2]

Without any pretension to the completeness and depth of exposition present in Dyatkina's review[2] we will examine the most recent theoretical publications on the compounds of the noble gases.

First let us briefly examine the attempt of Mitchell[366–369] to prove by use of the valence bond method the significant role of the atomic *d*-orbitals (5*d* for Xe, 4*d* for Kr) in the formation of bonds in the halides of these elements. Mitchell calculated the excitation energy of three valence states of the Xe atom in hybridisations with participation of the 5*s*-, 5*p*-, and 5*d*-orbitals and with the aid of the method of Hartley, Lennard-Jones, and Pople evaluated the energies of the valence structures Hal–Xe–Hal, $Hal-Xe^+Hal^-$, and $Hal^-Xe^{2+}Hal^-$ (the first structure is based on the assumption of the hybridisation of the 5*s*- and $5d_{z^2}$-orbitals of Xe) for XeF_2 and $XeCl_2$.[368] The first structure seemed the most stable and on this basis Mitchell concluded that the 5*d*-orbitals of Xe participate in the formation of XeF_2 and $XeCl_2$, assuming that the high excitation energy is compensated by the gain in the bond

energy. Somewhat later, Catton and Mitchell[368] made a refined calculation of XeF_2 by the valence bond method and found that the structures based on the participation of the Xe $5d_{z^2}$-orbitals contribute ~ 69% to the complete wave function, whereas the contribution of the resonance structures which include only the $5p_z$-orbital totals only ~ 16%. Developing these ideas, the same investigators[369] calculated the energies of various valence structures in KrF_2, XeF_2, $XeCl_2$, and also in the hypothetical molecules ArF_2, $ArCl_2$, and $KrCl_2$. The calculations showed that in every instance (except ArF_2) the minimal energies are exhibited by the structure Hal–X–Hal. On this basis Catton and Mitchell concluded that the greater part is played by a valence scheme based on the promotion of p-electrons to a d-AO and the hybridisation of pd-AO; here the high excitation energy in the free atoms is compensated by the influence of the ligands on the AO atoms, greater for the fluorides than for the chlorides. The role of the Hal–X–Hal structure increases, according to the calculation, in the order Ar < Kr < Xe. Finally, in the most recent paper in this series[367] Mitchell has suggested the participation of the Xe $4f$- and $6s$-orbitals in the formation of xenon hexafluoride and he related the participation of the $4f$-orbitals to Bartell and Gavin's views (discussed above) on the structure of XeF_6.

Table 7. Correlation of the calculated[373] and experimental[53,374] values of the ionisation potentials of XeF_n (in eV).

*Doublet structure, due to spin–orbital coupling.

Before turning to the consideration of non-empirical calculations, we note the method proposed by Andreev for the determination of the conformation of the molecules of XeF_2, KrF_2,[370] and XeF_4[371] by the combined use of the theory of the interaction of bonding and unshared electron pairs and the maximal overlap criterion. The same investigator[372] considered the electronic structure of XeF_3 and XeF_3^+, having used the Wolfsberg–Helmholz method with allowance only for $p\sigma$-AO. According to the calculation, the most stable configuration for XeF_3 has C_{2v} symmetry, but for XeF_3^+ there are alternatives in the choice of a stable geometry—D_{3h} or C_{2v} are the most probable.

Basch and coworkers[373] made non-empirical calculations for XeF_2, XeF_4, and XeF_6, using Roothaan's complete SCF MO method with a basis set of gaussian functions including the $1s$-, $2s$-, $3s$-, $4s$-, $5s$-, $2p$-, $3p$-, $4p$-, $5p$-, $3d$-, and $4d$-AO of xenon, and the $1s$-, $2s$-, and $2p$-AO of fluorine (all the AO were checked by calculation of the orbital and total bond energies). The total and orbital energies were calculated and the composition of the valence MO was found. An analysis of the populations after Mulliken was made for the individual AO and the overlap populations were also found.

The photoelectron spectra of XeF_2 were investigated almost simultaneously by Brundle and coworkers[374] and by Brehm and coworkers[52]. The ionisation potentials found in the two studies agree and differ little from those obtained by the photon collision method[54] and by photoionisation mass spectrometry[44]. The photoelectron spectra of XeF_4 and XeF_6, investigated by Brundle and coworkers[53], led to ionisation potentials close to those found by photoionisation mass-spectrometry[44]. The assignment, proposed on the basis of these results[53,373,374], of the vertical ionisation potentials to ionisation from MO_5 and a comparison of the experimental results with the calculated orbital energies multiplied by 0.92 (a factor introduced by Brundle and coworkers[53] to correct for the approximations of the Koopmans theorem) are given in Table 7. Fig. 13 gives the corresponding correlation diagram.

The effective charges on the xenon atoms were evaluated in the calculation[373] and are +1.304, +2.455, and +3.458 for XeF_2, XeF_4, and XeF_6 for a comparatively constant charge on the fluorine atoms (−0.652, −0.614, and −0.576). Between the calculated effective charges and the quantities estimated on the basis of EPR[58] and NMR[375,376] investigations, Mössbauer spectra[303], and X-ray electronic spectra[50,51] there are significant differences; the reasons for these have been discussed[58].

Basch and coworkers[373] used the results of their non-empirical calculation of the xenon fluorides for a detailed interpretation of the electronic spectra of XeF_2 and XeF_4 on the basis of the experimental results of Jortner and coworkers (cf. Dyatkina's review[2]). They also calculated and tabulated certain one-electron properties of the molecules of the xenon fluorides: the mean values of magnetic screening tensor of the xenon and fluorine nuclei, the quadrupole moments of XeF_2 and XeF_4, the components of the field gradient at the xenon and fluorine nuclei[373].

A regular octahedral structure was chosen for XeF_6 in the calculation[373]. Such an approximation must reflect on the accuracy of the results obtained since in reality the XeF_6 molecule does not maintain strictly O_h symmetry. Unfortunately, later investigations of the electronic structure of XeF_6 made by the wave scattering method with statistical allowance for the exchange interactions[377] was also based on the adoption of O_h symmetry for this molecule. In this work[377] the orbital energies were calculated within the framework of the ideas of half-occupied spin-orbitals, since Koopmans' theorem is inapplicable in a statistical calculation of exchange interactions. When the factor 0.92 is not used, the results of the calculations by scattered waves method[377] give better agreement with experiment.

Three non-empirical calculations were made[378–380] for the krypton fluorides (KrF_2, KrF, and KrF^+). The calculations for KrF and KrF^+ were made by the SCF MO method with a large basis set of functions of the Slater type[380]. The potential curve for KrF was calculated by assuming the ground state $^2\Sigma^+$ (in agreement with EPR results[381]), and that for KrF^+ the state $^1\Sigma^+$. The curve for KrF, like that for XeF, is repulsive, since these molecules can exist in the gas phase solely owing to van-der-Waals interaction. The dissociation energy found for the molecular ion KrF^+ was $D_0 = 1.90$ eV, which agrees with the experimental $D_0 \geq 1.58$ eV.[382] The calculated spectroscopic constants of KrF^+ are also in good agreement

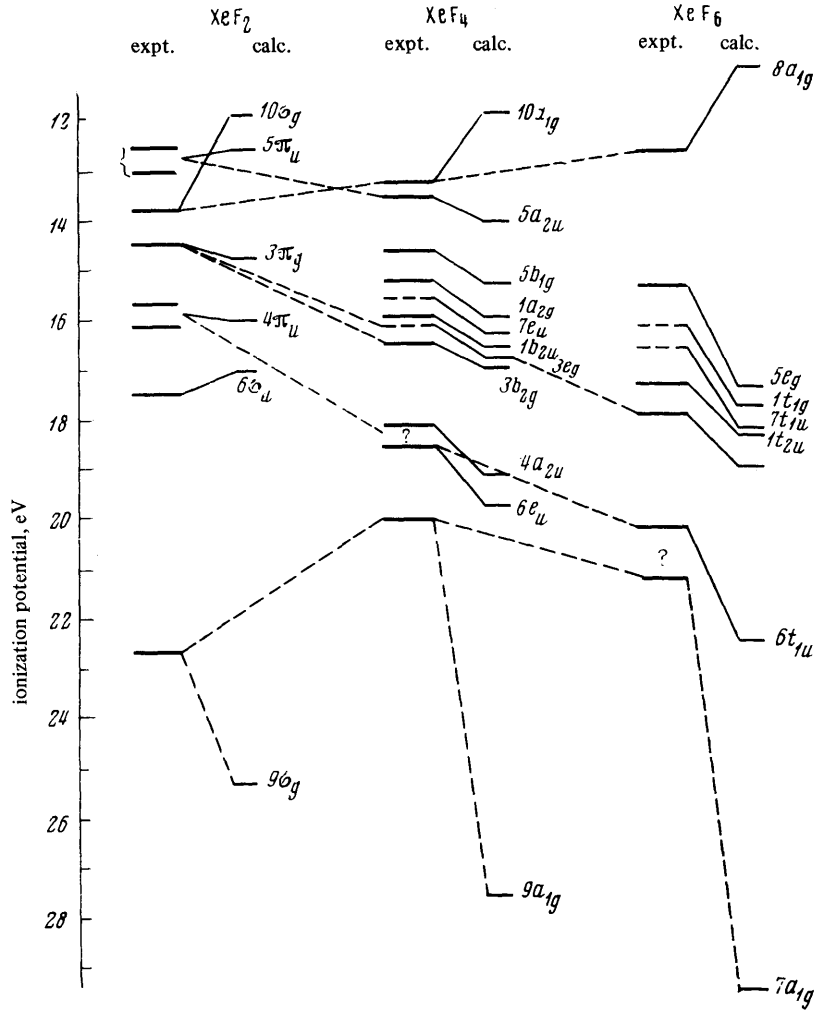

Figure 13. Diagram of the molecular orbitals of xenon fluorides.

with experiment, in particular the theoretical wavenumber of the stretching vibration (621 cm^{-1}) is close to that found from the Raman spectrum for $KrF^+Sb_2F_{11}^-$.[184]

Concerning the problem of the role of the "higher" AO's in the formation of bonds in noble gas compound (the role of the polarisation functions (4*d* and 4*f* for Kr and 3*d* and 4*f* for F) has been evaluated[380]. In KrF the inclusion of the polarisation functions decreases the total energy by only 0.0044 a.u., in KrF^+ by 0.0388 a.u. In the first non-empirical calculation for KrF_2, the main aim of which was the explanation of the role of the 4*d*-orbitals of Kr, the SCF MO method was used with a minimal set of Slater-type functions[378]. From the results of this work there follows the need for the inclusion in the basis of the Kr 4*d*-functions, but a calculation made with a broadened basis set[379] showed insufficient justification for this assertion.

Bagus and coworkers[379] made a complete calculation of KrF_2 by the SCF MO method using an extended basis set of Slater-type functions with allowance for configuration interaction. The potential curve found with 993-configuration wave function corresponds to the bound state of KrF_2 in relation to three atoms infinitely removed from one another. The calculated Kr–F distance, found to be 1.907 Å, and the dissociation energy, 0.39 eV, are comparable with the experimental results (respectively 1.88 ± 0.01 Å and 1.013 eV). On the potential curve there is a barrier at r(Kr–F) = 2.42 Å of height 0.22 eV in relation to the total energy of the disconnected atoms. The electric field gradient at the Kr nucleus near to the minimum of the potential curve is close to the value calculated by the SCF method for the Kr^+ ion and falls rapidly to zero close to the maximum of the potential curve. These results show that the Kr–F bond is ionic at the equilibrium distance and covalent at greater distances, which agrees with Coulson's views[340].

To investigate the role of the polarisation functions (4*d* and 4*f* Kr, 3*d* and 4*f* F), a series of calculations was

made[379] with various basis sets and it was shown that the role of the Kr 4*d*-AO is significantly less than that found from the previous calculation[378]. A compilation of the theoretical results[378,379] with high-resolution photoelectron spectra of KrF_2,[346,383] are given in Table 8 and Fig. 14 (on which results for XeF_2 are given for comparison).

Table 8.

MO	-0.92ε (Ref.378)	-0.92ε (Ref.379)	Vertical IP (Refs.346, 383)	MO	-0.92ε (Ref.378)	-0.92ε (Ref.379)	Vertical IP (Refs.346, 383)

*Doublet due to spin–orbital coupling.

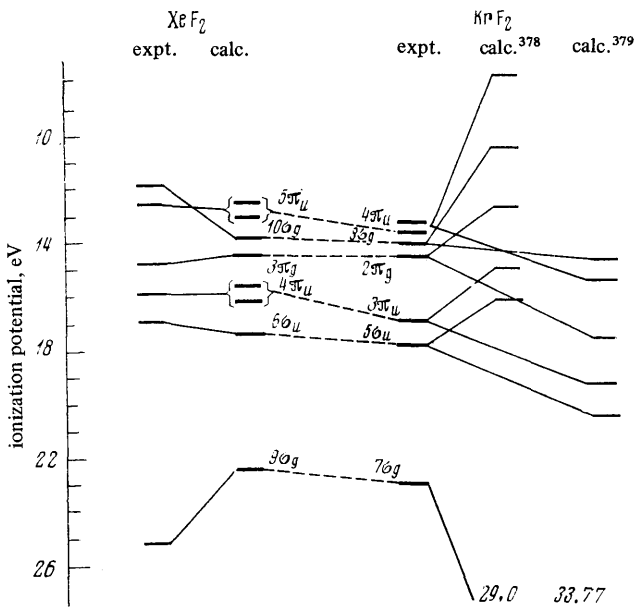

Figure 14. Diagram of the molecular orbitals of the lower fluorides of xenon and krypton.

The xenon oxide fluorides have been examined theoretically in only one paper, published comparatively recently[383]. The electronic structures of $XeOF_2$, XeO_2F_2, and $XeOF_4$ were calculated within the framework of the semiempirical modified Wolfsberg–Helmholz method. The results obtained by Gillespie using the method of localised electron pairs (see Dyatkina[2]) formed the basis of a comparison of the electronic and geometric structures of the oxide fluorides. The energies and populations of the MO were found on the basis of the nodal structure of the upper occupied MO and the geometric structure of the xenon oxide fluorides was predicted.

According to the prediction, the $XeOF_2$ molecule should have C_{2v} symmetry with an O–Xe–F angle less than 90°. For XeO_2F_2 the O–Xe–O angle should be less than 120°, and the F–Xe–F angle (at the side of both O atoms) less than 180°. For $XeOF_4$, C_{4v} symmetry was obtained with O–Xe–F angle greater than 90°. In all three molecules the Xe–O bond should be shorter than Xe–F.

When Hsu and coworkers' paper[383] appeared experimental results were known only for $XeOF_4$. They[383] cited only Martins and Wilson's study of the microwave spectrum[233] and did not consider a later electron diffraction investigation[234]. As for XeO_2F_2, a detailed electron diffraction investigation of this molecule appeared recently[241]. Theoretical calculations give qualitative agreement with experimental results for both XeO_2F_2 and $XeOF_4$. For the former the O–Xe–O angle is 105.7° and the Fe–X–F angle is 174.7°; the Xe–O and Xe–F distances are 1.714 and 1.889 Å respectively[241]; in the second instance the O–Xe–F angle is 91.9° and the Xe–O and Xe–F bonds are respectively 1.711 and 1.901 Å.[234]

VI. POSSIBILITY OF THE EXISTENCE OF COMPOUNDS OF THE NOBLE GASES LIGHTER THAN KRYPTON

An approximate evaluation of the possibility of obtaining some compounds of argon and their stability led Ferreria[384] to a conclusion about the similarity in stability of the Ar–F and Kr–F bonds and even of the greater stability of the Ar–O bond compared with Kr–O. However, an estimate of the enthalpy of formation of the hypothetical $ArF_2(g)$, made by extrapolation of the values of ΔH°_{298} along the series (RnF_2)–XeF_2–KrF_2–$[ArF_2]$ and on the basis of the ionisation potentials of the noble gases, leads to a negative bond energy in ArF_2. Some calculations show the possibility of the existence of HeF_2;[385] the results of other theoretical calculations[386,387], made by the SCF LCAO MO and valence bond methods show that for all forms of the geometry of HeF_2 an unstable repulsive state is characteristic. The potential curves for the processes of formation of HeF^+ and HeF, NeF, NeF_2, and NeO also do not have a minimum[388].

Liebman and Allen[389] undertook calculations for ArF^+ and ArO by the SCF LCAO MO method and showed that the $^1\Sigma\sigma^2\pi^4\pi^{*4}$ state should be rather stable and be characterised by the equilibrium distance r_e = 1.8 Å and dissociation energy $De \simeq 70$ kcal mole^{-1}. On the basis of these results they suggested the possibility of the synthesis of $ArF^+PtF_6^-$ by the reaction of argon with fluorine in the presence of platinum hexafluoride. Berkowitz and Chupka[390] reported that ArF^+ ($^1\Sigma\pi^4$) is formed in the ion-molecular reactions $F_2^+ + Ar$ and $Ar^+ + F_2$. On the basis of a simple analysis of the exothermic reaction

$$F_2^+ + Ar \rightarrow ArF^+ + F$$

they concluded that $D_0(ArF^+) \geqslant 38$ kcal mole^{-1}. Analogous reactions of F_2^+ with neon and helium were not observed even at high collison energies. Liebman and Allen[391] used the SCF LCAO MO method to calculate the potential curves for the lowest electronic states of HeF^+, NeF^+, HeN^+, and NeN^+ and made an analysis of the possibility of the synthesis and stability of these cations. Unlike earlier investigations[388], these calculations showed the rather high stability of the states $^1\Sigma\pi^4$ HeF^+ (r_e = 1.33 Å, $De \simeq$ 33 kcal mole^{-1}) and $^1\Sigma\pi^{*4}$ NaF^+ (re = 1.65 Å, $De \simeq$ 30 kcal mole^{-1}). It was suggested[391] that the stabilisation of these states can be effected by bonding in $HeF^+SbF_6^-$ and $NeF^+SbF_6^-$ by the reaction of He and Ne with fluorine (in the presence of SbF_5 or PtF_6) at high temperatures and pressures. Liebman and Allen[392] also showed that although

some of the states HeN^+, NeN^+, HeO^+, ArO^+, and NeO^+ are sufficiently stable and should be observed in ion-molecular reactions, the existence of the corresponding crystalline salts is improbable. On the basis of an SCF LCAO MO calculation of the potential surfaces of HeB^+, NeB^+, and ArB^+ the same investigators[393] concluded that the bound states of these ions were absent unlike the $^1\Sigma$ XeB^+ state, the bond energy of which is estimated to be 10–20 kcal $mole^{-1}$.

VII. POSSIBLE USES OF COMPOUNDS OF THE NOBLE GASES

The interest of the wide circle of investigators in the chemistry of the noble gases is not limited to the theoretical value of this problem. The considerable experimental and theoretical material on the compounds of the noble gases which has now accumulated allows the question of their practical use to be examined.

The investigation of the compounds of the noble gases is of prime importance in connection with the need for solving one of the most important problems of the protection of the environment—the collection of radioactive krypton and xenon—the gaseous products fission of uranium in nuclear reactors. The electrical power of atomic power stations now amounts to ~ 3% of the total power of all power stations. However, even in the next decade the position will change radically and the fraction of atomic power stations to the total production of electric energy will increase considerably. The development of atomic energy is responsible for the need for the reprocessing of large amounts of spent fuel elements of nuclear reactors. In the operation of nuclear reactors and the chemical reprocessing of irradiated nuclear fuel the removal of gaseous fission products is very complex, especially ^{85}Kr (half-life 10.76 years) and ^{133}Xe (9.27 days). This problem is still more complicated because of the future development of fast neutron reactors owing to the increased yield of fission products.

The successful development of noble gas chemistry opens new pathways for the utilisation of radioactive noble gases—in the form of their chemical compounds. The first success has already been achieved. This, it was shown recently[394] that when it reacts with O_2SbF_6 xenon is bonded in the solid involatile compound $XeF^+Sb_2F_{11}^-$. In five experiments with ^{133}Xe on a column of dia. 5.5 × length 65 mm. packed with O_2SbF_6 almost 100% bonding of the xenon from the air at 23–25°C was achieved (^{133}Xe from 2 to 10 mC $litre^{-1}$ mean flow rate 13 ml min^{-1}). It has been proposed to use the analogous reaction with radon for purifying the atmosphere in uranium mines[394]. The oxidation of radon and xenon can be effected also with the aid of K_3NiF_6, K_2NiF_6, Cs_2CoF_6, K_3CuF_6, $CsAgF_4$, Cs_2AgF_6, etc.[395–397] Radioactive xenon and radon are oxidised at 25°C by the action of N_2FSbF_6, but $N_2F_3Sb_2F_{11}$ oxidises only radon at 25–100°C.[398]

The most complex tasks in the problem of the removal of radioactive noble gases is the bonding of ^{85}Kr, since krypton forms only compounds that are comparatively unstable under ordinary conditions, their stability decreasing still further under the action of ionising radiations. In addition, the problems of the chemical bonding of krypton is further complicated by the high oxidising ability of krypton compounds, which is due to the need for obtaining inorganic fluoro-oxidants capable of oxidising krypton. Stein[394] notes that the replacement of the O_2^+ cations in O_2SbF_6 by a cation of greater oxidising ability can yield reagents capable of spontaneous reaction with krypton with the formation of $KrF^+Sb_2F_{11}^-$. On the basis of theoretical calculations[395] salts with the N_2F^+ cation can be regarded as potential oxidants for bonding ^{85}Kr.

Hence the problem of the chemical removal of radioactive xenon and krypton is closely connected with the fluoro-oxidising properties of the compounds of these elements. Naturally, use of the compounds of the noble gases as fluoro-oxidants is of independent interest. Table 6 gives the values of ΔG_{298} (ΔH_{298}) of the reactions of certain inorganic fluoro-oxidants with halogen fluorides, uranium tetrafluoride, nitrogen compounds, and radon. Comparison of the calculated and known experimental results suggests that the reactivity of the fluoro-oxidants correlates with their dissociation energies ($EF_n - EF_{n-} + 2F$) and on this basis the fluoro-oxidants can be arranged in the following series:

$$KrF_2 > O_2F_2 > RuF_6 > F_2 \approx N_2F_2 > XeF_6 > ClF_5 \approx XeF_4 > XeF_2.$$

Complexes of inorganic fluorides, the fluoro-oxidising ability of which is somewhat greater than that of the initial compounds, can also be regarded as potential fluoro-oxidants.

The noble gas fluorides and oxides of the noble gases are powerful oxidants in aqueous solutions of acids and bases. The redox potentials of the xenon compounds[3] are given below:

$$\begin{array}{ll} \text{acid} & Xe \xrightarrow{2{,}12\,V} XeO_{3(aq)} \xrightarrow{2.36\,V} H_4XeO_6 \\ & \quad \big\downarrow 2{,}36\,V\,(2{,}64) \\ & \quad XeF_{2(aq)} \\ \text{base} & Xe \xrightarrow{1.26\,V} HXeO_4^- \xrightarrow{0.95\,V} HXeO_6^{3-}. \end{array}$$

The oxidising ability of these compounds is not less than that of ozone. XeO_3 can also find a use as an effective oxidant in organic solvents[11].

The use of labelled xenon compounds is of importance for medical-biological investigations. Rapid methods for making periodates and perbromates labelled with short-lived isotopes[391–321] can be successfully developed on the basis of XeF_2. Methods of isolating ^{125}I without a carrier have been developed[316]. In view of their involatility, radon compounds can find a use in radiation therapy instead of gaseous radon[1].

The possibility of using XeF_2 and XeF_4 as photolytic sources of atomic fluorine for $F + H_2$ chemical lasers has been examined[399,400]. The use of xenon fluorides as initiators of polymerisations and in gas-filled incandescent lamps is known (cf. Jha[5]).

The study of the possibility of using noble gas compounds for practical purposes has only just begun, but already there is no doubt about the future possibilities of these compounds.

The Electronic Structure of Conjugated Systems in Terms of the Pariser-Parr-Pole Approximation

I.A.Misurkin and A.A.Ovchinnikov

The potentialities of the π-electron approximation for the description of the electronic structures of conjugated molecules are analysed and two modern schemes for the parametrisation of the model Pariser-Parr-Pople π-electron Hamiltonian are considered. The application of this theory in the calculation of the properties of the ground state (bond lengths and angles, heats of formation, and dipole moments) and excited states (the energies of singlet and triplet excitations, oscillator strengths, and ionisation potentials) is also discussed.
The bibliography includes 80 references.

I. INTRODUCTION

Molecules with Saturated and Unsaturated Bonds

The theory of the electronic structures of conjugated molecules constitutes the most extensively studied field in quantum chemistry. The reasons for this are in many respects related to the fact that the absorption spectra of such compounds occur in the optical and ultraviolet regions, which are very readily susceptible to experimental study, and also to the fact that the properties of such molecules are determined by a comparatively small proportion of their electrons. These electrons, called π-electrons, form a closed autonomous group, which impart to conjugated molecules all their specific properties.

The purely chemical definition of conjugated compounds is self-evident; they include molecules with multiple bonds and contain atoms with "unsaturated valences". They are characterised by enhanced reactivity, the transmission of influences through several atoms, and a marked influence of substituents on the geometrical structure (bond lengths and angles).

We shall attempt to specify more precisely from the standpoint of electronic structure the factors on which the differences between the properties of compounds with saturated and unsaturated bonds depend. For a qualitative interpretation of the cuases of these differences, one may confine the treatment to a one-electron computational scheme. Organic molecules are usually many-electron systems and therefore in the calculation it is necessary to take into account a large number of atomic orbitals (AO). As a result, in terms of the one-electron approximation there arise numerous energy levels, which are combined into groups (bands). The state of each band is characterised by some one property, for example symmetry and type of atomic orbitals, from which one-electron functions called molecular orbitals (MO) are made up.

In molecules with saturated bonds the bands are either completely filled with electrons (two electrons with opposite spins in each molecular orbital) or are vacant, while in molecules with unsaturated bonds there are bands partly filled with electrons. As a rule, each molecular orbital is a linear combination of the atomic orbitals of all the atoms in the molecule (the LCAO-MO approximation), i.e. there is delocalisation over the entire molecule. It is then found that the wave functions (MO) corresponding to the completely filled band can be subjected to a specific unitary transformation such that the new one-electron functions assume a distinct localised character. In particular, the new orbitals can be made largely localised at individual bonds in the molecule (with two electrons having opposite spins in each new orbital)[1].

In molecules with unsaturated bonds it is also possible to localise electrons at individual ("double") bonds when the so called π-electrons are considered. However, the interaction of two electrons of one such bond (proportional to the resonance bond integral) will be almost the same as the interaction between adjacent double bonds, because the resonance integrals for "single" and "double" bonds are almost the same. In molecules with saturated bonds the resonance integral is several times greater (in absolute magnitude) than the resonance integrals for electrons in adjacent bonds, so that in these compounds the steric localisation of electrons is accompanied by "energy" localisation: the interaction between bonds only slightly alters their energy. This implies that in molecules with saturated bonds the approximation of non-interacting bonds constitutes a satisfactory zeroth approximation, while in molecules with unsaturated bonds the introduction of functions localised at the bonds is as a rule ineffective and it is better to employ delocalised functions immediately.

In the language of the solid state theory systems with unfilled bands are metals. If the number of atoms in the saturated molecule is increased regularly, we obtain a system where the structure of the energy bands is analogous to the structure of the energy bands in a dielectric (for example, paraffins and diamond). On the other hand, an increase in the size of the π-electron system, for example on passing from condensed aromatic molecules

to graphite, leads to a system with an unfilled energy band, which is characteristic of metals. Admittedly one-dimensional π-electron systems (macro-molecules with conjugated bonds) are always semiconductors, but this is related to a specific phenomenon—the Mott "metal—dielectric" transition (described in detail in the review of Ovchinnikov et al.[2]).

Numerous studies on the theory of molecules with π-electrons have been published. This reflects the major role which compounds with conjugated bonds play in chemistry, biology, and chemical physics. Furthermore, the effectiveness of various methods for calculations on molecules of other classes is tested on conjugated systems. Molecules with conjugated bonds form a relatively small fraction of the total number of molecular systems and for this reason the theory of the structure of conjugated systems is of great heuristic value.

Significant advances have been made in the modern theory of conjugated systems in the qualitative and quantitative explanation of molecular properties.

Various characteristics of conjugated molecules are calculated with a relative error of about 10%, which reflects the comparatively high predictive power of the theory. Nevertheless, the errors, which in individual cases can exceed 10%, make it necessary to seek new ways for improving the theory. Owing to the enormous difficulties of the many-electron problem, the theory of conjugated systems is essentially semiempirical. Therefore various schemes and methods, differing in the procedures for the introduction of empirical parameters and in the degree of approximation of the methods of calculation are quite admissible in this theory and are indeed used. In all such studies a satisfactory agreement with experiment is as a rule achieved. Their analysis makes it possible to identify the most significant and general features of different computational schemes. It is found that the general and most important aspects of these schemes are very similar, which is an advantage of the theory as a whole.

Apart from studies where individual molecular properties are calculated, which is probably the main task of the theory, studies which justify the empirical and semi-empirical relations used to calculate specific molecular properties are very important for the development of the theory.

The aim of the present review is to outline the present state of the semiempirical theory of conjugated systems from the standpoint of general principles without going into the details of various computational methods. We are interested primarily in problems such as the internal logical self-consistency of the theory, the accuracy of the prediction of various experimental data and properties, and the possibility of improving the methods for the calculation of these data and properties.

II. THE π-ELECTRON APPROXIMATION FOR CONJUGATED SYSTEMS

Molecules with conjugated bonds are as a rule planar. The atoms supplying $2p_z$ electrons to the general π-electron systems have nuclei located in a single plane (the xy plane). The σ-bonds between the atoms of the molecule are also located in this plane and form the so-called σ-skeleton of the conjugated molecule. The electrons of the σ-skeleton occupy completely filled bands and therefore the corresponding one-electron functions may be localised at the interatomic bonds.

All the $2p_z$ orbitals are orthogonal with respect to all the one-electron functions of the σ-bonds. This orthogonality is the main reason why the electrons of the molecule can be divided into those of the σ-skeleton and π-electrons. Furthermore it is found that π-electrons are more weakly bound to the molecule than σ-electrons, so that almost all the observed properties of molecules with conjugated bonds are determined by π-electrons. These postulates form part of the basis of the theory of conjugated systems considered here, which explains molecular properties in terms of an explicit consideration of π-electrons alone. This is the so-called π-electron approximation.

We shall quote only one group of experimental data, which confirm directly the validity of the π-electron approximation. In the theory of conjugated hydrocarbons in the π-electron approximation there is a theorem that the optical spectra of the cation and anion derived from the same molecule are identical. This theorem is valid when full account is taken of the interaction between the electrons[3]. The experimental data presented in Fig. 1 demonstrate a striking similarity of the absorption spectra, which constitutes a direct confirmation of the theoretical conclusions.

Fig. 1 shows that certain absorption band maxima are displaced relative to one another by about 10% of the transition energies. We believe that these values demonstrate directly the limit of the accuracy with which it is possible to carry out calculations in terms of the modern theory employing the π-electron approximation. Examination of π-electrons alone when considering molecular properties greatly facilitates the theoretical analysis, since the number of π-electrons is several times smaller than the total number of electrons in the molecule. The presence of other electrons in the molecule (the electrons of the σ-skeleton) is taken into account implicitly. It alters the π-electron interaction, which is described by an effective model Hamiltonian. The parameters of this Hamiltonian depend on the properties of the σ-skeleton, i.e. on the σ-electrons.

For a quantum-mechanical description of a π-electron system, it is natural to employ the set of the atomic $2p_z$ functions as the basis functions. These $2p_z$ functions are non-orthogonal, which leads to considerable technical difficulties in calculations. Therefore it is natural to construct from the $2p_z$ functions an orthogonal basis set $\varphi_p(r)$ using the linear transformation

$$\varphi_p(r) = \sum_{i=1}^{M} U_{pi}\, 2p_{z_i}(r) \quad (p = 1, 2, \ldots M),$$

where M is the number of $2p_z$ functions or the dimension of the new basis set of the functions $\varphi_p(\bar{r})$. Löwdin[5] discovered the transformation U_{pi}, in which each of the functions $\varphi_p(r)$ consists largely of $2p_z$ functions of the atom p and contains only a slight admixture of the $2p_z$ functions of other atoms. Thus the functions $\varphi_p(r)$ are not only orthogonal (and normalised) but are also localised at the atoms. The slight delocalisation of these functions leads to effects associated with the mutual influence of the atoms.

We shall consider in greater detail the transition to an orthogonalised basis† set. This is done most naturally

† The idea of the treatment described below was communicated to the authors by M. V. Bazilevskii.

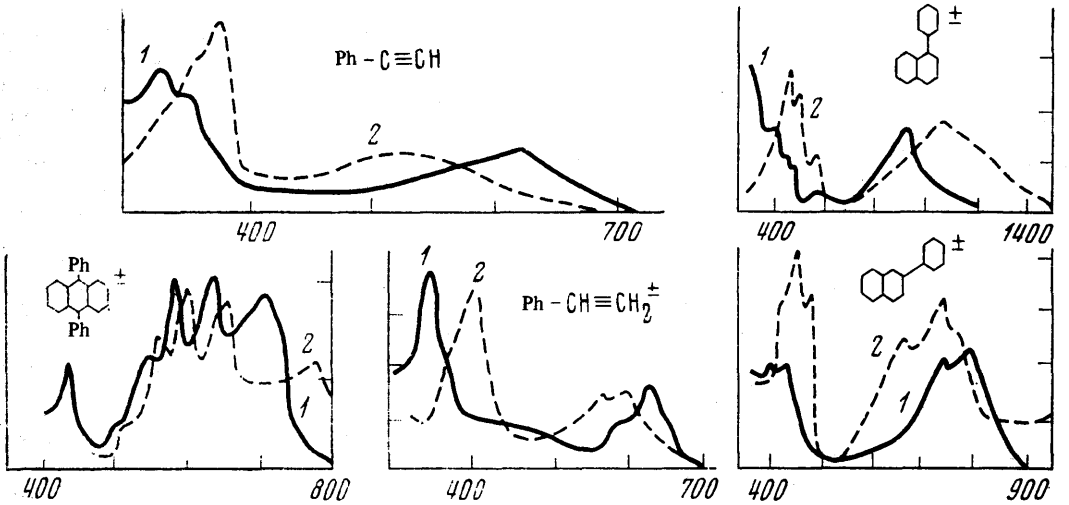

Figure 1. Experimental absorption spectra of the anions (curves *1*) and cations (curves *2*) of certain conjugated hydrocarbons[4].

by solving the standard quantum-chemical eigenvalue problem:

$$\hat{H}\psi = e\psi,$$

where $\hat{H}$ is a Hamiltonian or Fockian and ψ is the row-matrix of the molecular orbitals $\{\psi_1, \psi_2, \ldots\}$, which can be expressed in terms of the non-orthogonal atomic orbitals χ_i specified by the row-matrix $\{\chi_1, \chi_2, \ldots\}$ and the required coefficient matrix C (the LCAO-MO approximation):

$$\psi = \chi C, \quad \psi_l = \sum_{k=1}^{M} \chi_k c_{kl},$$

where c_{ki} are the elements of the matrix C.

We now introduce the overlap integral matrix

$$\chi^{+}\chi = \begin{bmatrix} \chi_1^* \\ \chi_2^* \\ \vdots \end{bmatrix} (\chi_1, \chi_2 \ldots) = S.$$

The row- and column-matrices are multiplied in accordance with the usual rules of matrix multiplication and integration with respect to coordinates is carried out; the asterisk (*) denotes a complex conjugate. The elements of the matrix S, for example, are of the form

$$S_{ij} = \int \chi_i^*(\mathbf{r})\chi_j(\mathbf{r})\,d\mathbf{r}.$$

We now reformulate our equation for eigenvalues as follows:

$$\hat{H}\chi C = \chi C e,$$

the left-hand side of the equation is multiplied by χ^{+}, and the matrix equation

$$HC = SCe$$

is obtained. Here $\chi^{+}\hat{H}\chi$ is the matrix $\hat{H}$ in the non-orthogonal basis set. The solution of the last matrix equation constitutes the familiar problem of double diagonalisation (of the matrices H and S). It would appear that, by multiplying the left-hand side of the equation by S^{-1} and obtaining thereby the equation

$$(S^{-1}H)C = Ce,$$

we reduce the problem to the diagonalisation of a single matrix $S^{-1}H$. However, this matrix is generally speaking asymmetric‡: its transposition (designated by the symbol ~)

$$\widetilde{(S^{-1}H)} = \tilde{H}\tilde{S}^{-1} = H\,S^{-1}$$

yields another matrix, namely

$$H\,S^{-1} \neq S^{-1}H.$$

At the same time it is known that the diagonalisation of an asymmetric matrix is difficult and requires special computer programs, which are difficult to devise.

Therefore the double diagonalisation problem will be solved in a different way. We reformulate our matrix equation as follows:

$$HS^{-1/2}S^{1/2}C = S^{1/2}S^{1/2}Ce,$$

multiply its left-hand side by $S^{-1/2}$, and obtain the equation

$$\bar{H}\cdot\bar{C} = \bar{C}e,$$

where $\bar{C} = S^{1/2}C$ and $\bar{H} = S^{-1/2}HS^{-1/2}$. The matrix $\bar{H}$ is symmetrical and therefore its diagonalisation is carried out with the aid of standard programs.

In order to obtain $\bar{H}$, it is necessary to calculate first the matrix $S^{-1/2}$. In qualitative studies one employs the method of expansion with respect to the non-diagonal part of S:

$$S = I + S',$$

where I is a unit matrix and S' the non-diagonal part of S.

---

‡ In all subsequent treatment it is assumed that all the atomic orbitals are real and therefore the matrices S and H are symmetrical and real.

Then

$$S^{-1/2} = (I + S')^{-1/2} = I - \frac{1}{2}S' + \frac{3}{8}S'S' - \ldots .$$

In computer calculations it is necessary to proceed in a different way. Initially S is diagonalised with the aid of a standard program, which yields S_{diag} and the transformation matrix $V(\tilde{V} = V^{-1})$:

$$S_{diag} = V^{-1}SV.$$

Suppose that S_{diag} is of the form

$$S_{diag} = \begin{pmatrix} a & & 0 \\ & b & \\ & & f \\ 0 & & & \ddots \end{pmatrix}.$$

Then it is easy to show that (a, b, f, ... are positive numbers)

$$S_{diag}^{1/2} = \begin{pmatrix} \sqrt{a} & & & 0 \\ & \sqrt{b} & & \\ & & \sqrt{f} & \\ 0 & & & \ddots \end{pmatrix}, \quad S_{diag}^{-1/2} = \begin{pmatrix} \frac{1}{\sqrt{a}} & & & 0 \\ & \frac{1}{\sqrt{b}} & & \\ & & \frac{1}{\sqrt{f}} & \\ 0 & & & \ddots \end{pmatrix}.$$

After calculating $S^{-1/2}$ in terms of the diagonal representation, we return to the non-diagonal representation with the aid of the matrix V and obtain the required expression for $S^{-1/2}$:

$$S^{-1/2} = VS_{diag}^{-1/2}V^{-1}.$$

In the diagonalisation of the matrix $\bar{H}$ we also find the coefficient matrix $\bar{C} = S^{1/2}C$. Hence we obtain $C = S^{-1/2}\bar{C}$.

We now express the wave function ψ in terms of $\bar{C}$:

$$\psi = \chi C = \chi S^{-1/2}S^{1/2}C = \lambda\bar{C},$$

where

$$\lambda = \chi S^{-1/2},$$

so that we arrive at a new orthogonalised basis set $\lambda = \{\lambda_1, \lambda_2, \ldots\}$. In fact

$$\lambda^+\lambda = S^{-1/2}\chi^+\chi S^{-1/2} = S^{-1/2}SS^{-1/2} = I.$$

We may also note that $\bar{H}$ is the matrix of the operator $\hat{H}$ in the basis set λ: $\bar{H} = \lambda^+H\lambda$. The functions λ_p are our required basis functions $\varphi_p(\mathbf{r})$ and the functions χ_i are the initial $2p_z$ functions.

1. The Effective Model Hamiltonian for π-electrons

The effective π-electron Hamiltonian can be formulated in terms of secondary quantisation:

$$H = \sum_{p,q,\eta} H_{pq}c_{p\eta}^+c_{q\eta} + \sum_{pqrt}\sum_{\rho\eta} \langle pq\,|\,rt\rangle c_{p\eta}^+c_{q\eta}c_{r\rho}^+c_{t\rho}. \qquad (1)$$

Any π-electron can be located in one of the basis states $\varphi_p(\mathbf{r})$ with projection of the spin η on the specified axis ($\eta = \pm 1/2$). The operators $c_{p\eta}^+(c_{p\eta})$ are called the operators of the generation (annihilation) of the π-electron in this state. These operators satisfy the transposition relations

$$c_{p\eta}^+c_{p'\eta'} + c_{p'\eta'}c_{p\eta}^+ = \delta_{pp'}\delta_{\eta\eta'},$$

$$c_{p\eta}c_{p'\eta'} + c_{p'\eta'}c_{p\eta} = c_{p\eta}^+c_{p'\eta'}^+ + c_{p'\eta'}^+c_{p\eta}^+ = 0.$$

The secondary quantisation representation makes it possible to avoid cumbersome steps involving Slater determinants made up of spin-orbitals. The Slater determinants, which ensure that the Pauli principle is observed for the wavefunction in terms of the coordinate representation are replaced by products of the operators $c_{p\eta}^+$, which operate in a special space. The Pauli principle (the antisymmetry of the wavefunction on transposition of two particles) holds automatically by virtue of the transposition relations for the operators $c_{p\eta}^+$ and $c_{p\eta}$.

We shall now consider briefly the essential feature of secondary quantisation in order to lift the "veil of incomprehensibility" from this concept, which is increasingly used in the literature on quantum chemistry. Secondary quantisation is introduced in quantum chemistry essentially when a one-electron wavefunction (molecular orbital) is expanded in terms of a basis set made up of atomic functions (the LCAO-MO approximation):

$$\psi(\mathbf{r}) = \sum_p c_p\varphi_p(\mathbf{r}).$$

One may say that the quantum-mechanical state $\psi(\mathbf{r})$ is yet again ("secondarily") "quantised" with respect to the states $\varphi_p(\mathbf{r})$. It is then possible to employ a matrix representation [all the operators are matrices with respect to the basis set $\varphi_p(\mathbf{r})$ with the wave functions expressed in the form of Slater determinants made up of the spin-orbitals $\varphi_p(\mathbf{r})\eta$] ($\eta$ is a spin function) or one can employ the secondary quantisation "representation" introduced by V. A. Fok (W. A. Fock), in which one again employs matrices made up of operators with respect to the basis set $\varphi_p(\mathbf{r})$ in which the expansion coefficients c_p are now regarded as operators, This makes it possible to employ simpler computational procedures without Slater determinants.

In the present review the secondary quantisation representation will be rarely used, mainly for the formulation of the Hamiltonian and other operators. Attention will be concentrated on the analysis of the matrix elements which are usually parametrised in semiempirical theories and which should be calculated, in accordance with general rules, in terms of the orthogonalised basis set $\varphi_p(\mathbf{r})$.

The parameters of Hamiltonian (1)

$$H_{pq} \text{ and } \langle pq\,|\,rt\rangle \qquad (2)$$

correspond to the one-particle and two-particle terms in the π-electron Hamiltonian in the coordinate representation

$$H_\pi = \sum_i \hat{H}(\mathbf{r}_i) + \sum_{i<j}\frac{1}{|\mathbf{r}_i - \mathbf{r}_j|}. \qquad (3)$$

Here $\hat{H}(\mathbf{r}_i)$ is the one-particle operator of the ith λ-electron, describing its kinetic energy and attraction to the σ-skeleton. The second term in Eqn. (3) is the two-particle operator of the Coulombic repulsion of π-electrons. The hamiltonians (1) and (3) are formally linked by relations of the type

$$H_{pq} = \int \varphi_p^*(\mathbf{r}_i)\,\hat{H}(\mathbf{r}_i)\,\varphi_q(\mathbf{r}_i)\,d\mathbf{r}_i,$$

$$\langle pq\,|\,rt\rangle = \iint \frac{\varphi_p^*(\mathbf{r}_1)\,\varphi_q(\mathbf{r}_1)\,\varphi_r^*(\mathbf{r}_2)\,\varphi_t(\mathbf{r}_2)}{|\mathbf{r}_1 - \mathbf{r}_2|}\,d\mathbf{r}_1\,d\mathbf{r}_2. \qquad (4)$$

These relations usually serve as a basis for the determination of the parameters (2).

As a result of the slight delocalisation of the functions $\varphi_p(\mathbf{r})$, the parameters (2) or (4) depend not only on the atomic indices indicated in formulae (2) or (4) but also on the indices for other atoms. Analysis of Eqns. (4) carried out by Fischer-Hjalmars[6] made it possible to

localise in the parameters (2) and (4) the contributions due to atoms with other indices, for example indices differing from p, q, r, and t. Such separation makes it possible to develop ideas on the mechanism of the mutual influence of atoms and to understand the changes in parameters on passing from one molecule to another. These ideas are important because the correct values of the parameters (2) cannot as yet be calculated theoretically. These parameters are determined from a comparison with experimental data and Eqns. (4) make it possible to reduce to a minimum the elements of arbitrary choice in the selection of the empirical values of the parameters.

The fundamental formulae relating the matrix elements in the orthogonal (φ_p) and non-orthogonal, atomic (χ_p) basis sets are obtained with the aid of the relation

$$\varphi = \chi S^{-1/2},$$

with which we are already familiar, and the series expansion of the matrix $S^{-1/2}$, which was also discussed above. Namely it was found that

$$H_{pq}^{(\varphi)} = H_{pq}^{(\chi)} + O(S^3) \ (p \text{ and } q \text{ are adjacent}),$$

$$H_{pq}^{(\varphi)} = O(S^3) \ (p \text{ and } q \text{ are not adjacent}),$$

$$H_{pp}^{(\varphi)} = H_{pp}^{(\chi)} - \sum_q S_{pq} H_{pq}^{(\chi)} + O(S^3),$$

(q are adjacent to p),

$$\langle pq \mid rs \rangle^{(\varphi)} = \delta_{pq}\delta_{rs} \langle pp \mid rr \rangle^{(\chi)} + O(S^3) .$$

In these formulae the left-hand side represents the matrix element in the basis set φ_p and the right-hand side represents the element in the basis set χ_p; the symbol $O(S^3)$ denotes terms of the order of S_{ij}^3 or a higher power of S_{ij}—the overlap integral for neighbouring atoms. These formulae are used below in a discussion of the difference between spectroscopic and thermochemical parameters (Section III, 2) and partly in devising one of the parametrisation schemes (Section IV, 1). The diagonal matrix elements $H_{pp}^{(\varphi)}$ and $H_{pp}^{(\chi)}$ differ by terms of the order of S_{pq}^2 (q are neighbours of p). These differences have been shown by M. V. Bazilevskii (see Section III, 2) to be important in the calculation of heats of formation and in the construction of potential energy surfaces.

2. The Pariser–Parr–Pople (PPP) Approximation and Method

Goeppert-Mayer and Sklar[7] calculated all the parameters (4) for benzene with the aid of Slater $2p_z$ functions and refined the concept of the σ-skeleton, having proposed special formulae for the parameters H_{pq}. As a result, a qualitatively correct description of the absorption spectrum of benzene was obtained in terms of the self-consistent field (SCF) approximation[7]. This was a major success of the theory and indicated the validity of the π-electron approximation.

Subsequently Pariser, Parr, and Pople[8] proposed other rules for the determination of the parameters (2) using partly the approximation of Geoppert-Mayer and Sklar for the σ-skeleton. The most significant feature in the new rules was the rejection of formulae of type (4) for the calculation of the parameters (2), which were now determined empirically. Next the approximation of zero differential overlapping (ZDO) was introduced which greatly reduced the number of non-zero parameters in the Hamiltonian. In the ZDO approximation $H_{pq} \neq 0$ only for neighbouring p and q or for $p = q$; $H_{pq} = 0$ for the other p and q and $\langle pq \mid rt \rangle = \langle pp \mid tt \rangle \delta_{pq}\delta_{rt}$. For the orthogonal functions $\varphi_p(r)$ the ZDO approximation is reasonable, since all the rejected integrals are indeed small.

In calculations on the ground state, the LCAO-MO SCF approximation was used[9]. For example, the ground state of benzene was described by a single Slater determinant of molecular spin-orbitals or by a single configuration. Pariser et al.[8] showed that in the description of excited states of conjugated molecules it is necessary to employ a superposition of all singly excited configurations and not just one excited configuration, as in the method of Goeppert-Mayer and Sklar. Because of the high symmetry of benzene (D_{6h}), it was possible to obtain simple formulae for the energies of the first electronic transitions in terms of combinations of the parameters $H_{p,\,p+1} = \beta$§ and $\langle pp \mid qq \rangle = \gamma_{pq}$. These energies are given by formulae of the type[8]

$$\begin{aligned}
\Delta E(^1B_{2u}) &= -2\beta + \tfrac{1}{6}(\gamma_{12} - 3\gamma_{13} + 2\gamma_{14}),\\
\Delta E(^1B_{1u}) &= -2\beta + \tfrac{1}{6}(2\gamma_{11} - 5\gamma_{12} + 7\gamma_{13} - 4\gamma_{14}),\\
\Delta E(^1E_{1u}) &= -2\beta + \tfrac{1}{6}(\gamma_{11} + 4\gamma_{12} - 4\gamma_{13} - \gamma_{14}),\\
\Delta E(^3B_{1u}) &= -2\beta + \tfrac{1}{6}(-2\gamma_{11} + 3\gamma_{12} - \gamma_{13}) \text{ etc.}
\end{aligned} \qquad (5)$$

Simple formulae were also obtained for the energies of ethylene. Comparison of these energies with experimental data (absorption spectra) led to numerical values of the parameters for these molecules and to the formulation of a system of rules for the determination of the parameters of other molecules, including molecules with heteroatoms[8]. The entire system of concepts concerning the parametrisation of the π-electron Hamiltonian and the degree of approximation in calculations on the states of the system (one configuration for the ground state and superposition of singly excited configurations for the excited state) has been called the "Pariser–Parr–Pople approximation" (the PPP approximation or method).

In most cases the theory of the electronic structure of conjugated systems in terms of the π-electron approximation uses the PPP Hamiltonian

$$H = \sum_{p,q,\eta} h_{pq} c_{p\eta}^{+} c_{q\eta} + \sum_{p,q} \sum_{\eta,\rho} \gamma_{pq} c_{p\eta}^{+} c_{p\eta} c_{q\rho}^{+} c_{q\rho} . \qquad (6)$$

The methods for the calculation of molecular properties using Hamiltonian (6) can differ from the PPP method by the procedures employed in the estimation of the parameters. In calculations on conjugated systems one uses nowadays methods which differ in the extent to which account is taken of the π-electron interaction, from the Hückel approximation in which all the parameters $\gamma_{pq} = 0$ up to different versions of the many-configuration approximation using several or all possible configurations.

3. The Information Contained in the Effective Parameters of the Model π-electron Hamiltonian

The PPP Hamiltonian (6) is a model or effective π-electron Hamiltonian. Having postulated that all the properties of a conjugated molecule are described by π-electrons alone, we have greatly simplified the problem of the calculation of molecular properties. If all the electrons in the molecule were considered, we would have found that σ-electrons and atomic orbitals other than those of the $2p_z$ type have a relatively small influence on the

§ The $2p_z$ atomic orbitals are numbered consecutively around the ring formed by carbon atoms.

properties of the π-electron system. Nevertheless these electrons and orbitals make a finite contribution to the observed properties. Therefore the semiempirical theory can yield the observed values when π-electrons alone are considered explicitly only in the case where the parameters of Hamiltonian (6) take into account the neglected electrons and states.

As a result the parameters of the Hamiltonian differ somewhat from the values calculated by Eqns. (4). These differences can be reduced to a minimum by a special choice of the functions $\varphi_p(\mathbf{r})$. However, some differences always remain. This is a consequence (or manifestation) of many-electron correlations.

The contribution of σ-electrons to the π-electron Hamiltonian has been examined by Fischer[10] for a simple model of a conjugated molecule. The effect of the neglected electrons and atomic orbitals on the effective Hamiltonian has been considered by Freed[11]. The problem of the calculation of the parameters of the effective π-electron Hamiltonian by more accurate formulae than Eqns. (4) (taking into account the effects of electronic correlation and the influence of the σ-skeleton), which was raised in these investigations[10,11], remains very complex and has still not been solved. However, it is known that equations of type (4), based on physical intuition, yield in the main the correct idea about the parameters of the effective Hamiltonian [when a successful choice of the functions $\varphi_p(\mathbf{r})$] is made. Since these parameters can be determined from a comparison with experiment, it is always possible to estimate the accuracy of formulae of type (4). Analyses of this kind have been carried out[12,13].

The unreal nature of the π-electron Hamiltonian is enhanced by the fact that, in terms of the ZDO approximation, a number of parameters are neglected. There are simplified versions of the PPP method with short-range action of π-electrons[14,15], in which only the parameters γ_{pp} and $\gamma_{pp\pm1}$ remain (for electrons at the same atom and at adjacent atoms) (see also Ovchinnikov[16]). In this case it is hardly possible to calculate these parameters, which are determined only by an empirical procedure.

Yet another aspect of the unreal nature of the Hamiltonian is associated with the degree of its approximation used in the calculation of the observed properties. If the electronic transition energies are calculated in terms of the PPP approximation, then one set of the Hamiltonian parameters must be used to recover the experimental values. If a calculation involving a larger number of configurations than in the PPP method is carried out, then the parameters which reproduce the experimental values differ from those of the first set. Clearly it is impossible to take into account these differences and to estimate the changes in the parameters. Nevertheless this is difficult to tolerate and for this reason several schemes have been proposed for the calculation of the parameters (mainly for the PPP method), which are partly based on equations of type (4); to some extent simple formulae for the interpolation of empirical values of the parameters are also employed. Parameters which correctly reproduce the experimental electronic transition energies, ionisation potentials, etc. are obtained as a result. This approach is characteristic of a semiempirical theory, in contrast to *ab initio* calculations based solely on formulae of type (4).

Yet another aspect of the problem of the separation of σ- and π-electrons and the derivation of the model Hamiltonian has been examined from the standpoint of summetry in terms of the SCF approximation for σ- and π-electrons[17]. It was found that the solutions (molecular orbitals) can be divided into symmetrical and antisymmetrical with respect to the reflection operation in the molecular plane. The SCF equations in terms of the LCAO-MO approximation (the Roothaan equations[9]) are divided into two systems of equations: for σ-electrons (symmetric solutions) and for π-electrons (antisymmetric solutions). These systems of equations are related (by the Coulombic interaction of σ- and π-electrons) and must be solved together. If only π-electrons are considered, the effect of σ-electrons may be taken into account by choosing effective parameters[17].

Calculations of this kind are made at present for specific molecules (the LCAO-MO SCF approximation for all valence σ-electrons and π-electrons). In calculations of this kind the effect of the σ-skeleton on the π-electron system and the nature of different degrees of the σ-electron approximation are elucidated[18,19]. So far such calculations are fairly crude because a parametrisation scheme has not been developed. This applies also to *ab initio* calculations. The latter are at present performed using equations of type (4) and specified functions $\varphi_p(\mathbf{r})$. In this sense such calculations resemble semiempirical calculations, since the functions $\varphi_p(\mathbf{r})$ are specified with the aid of certain constants. So far the *ab initio* calculations are crude and have a low predictive power. One may hope that, by varying the initial functions $\varphi_p(\mathbf{r})$, it will be possible to improve their accuracy. Moreover, we believe that in the distant future the *ab initio* calculations will reach the accuracy of the semiempirical theory.

The conclusions drawn from studies where σ- and π-electrons are considered jointly in terms of the SCF approximation are so far only qualitative. An improvement of the accuracy of such calculations will make it possible, in principle, to correct the π-electron approximation from the outside, from the standpoint of a more complete calculation.

In the present review we shall not consider the qualitative conclusions of modern *ab initio* calculations, since this would significantly increase its size. Moreover, we believe that the results of these calculations merit a separate and more detailed discussion. Much attention will be devoted to problems of the interaction of π-electrons with the σ-skeleton in the authors' next review "Adjustment of the Methods of Calculation and Semiempirical Parameters for Consistency in the Theory of Molecules with Conjugated Bonds", where an attempt will be made to keep the treatment within the framework of the π-electron approximation. Such tactics in relation to *ab initio* calculations are also dictated by the fact that so far we can only indicate the causes of a number of difficulties in the semiempirical theory, but complete recipes for overcoming the difficulties of the π-electron theory cannot as yet be proposed on the basis of modern *ab initio* calculations. The point is that such calculations for molecules are carried out in terms of a limited atomic orbital basis set (filled atomic orbitals are as a rule employed as the basis set). Correlation contributions, which, for example, have been found to be fairly significant in atoms (this was demonstrated in atomic calculations with a greatly extended basis set) are thereby neglected. On the other hand, in semiempirical calculations using a limited atomic orbital basis set these correlation contributions are largely included in the parameters. Therefore the role of modern *ab initio* calculations, carried out in terms of a restricted atomic orbital basis set, in proving the validity of the semiempirical molecular theory is so far limited.

III. THE PROPERTIES OF THE GROUND STATE OF CONJUGATED MOLECULES

1. The Geometrical Structure of Molecules (Bond Lengths and Angles)

An important characteristic of a conjugated molecule is its geometrical structure, bond lengths, and bond angles. The "bond length–bond order formula"[20]

$$R_{\mu\nu} = R_0 - bP_{\mu\nu} \qquad (7)$$

is usually employed to calculate bond lengths. Here $R_{\mu\nu}$ is the length of the $\mu\nu$ bond, $P_{\mu\nu}$ the π-electron order of the $\mu\nu$ bond, and R_0 and b are constants determined from a comparison with experiment. It has been found that Eqn. (7) is not an independent empirical relation, since its constants are expressed in terms of parameters describing the electronic structure of the molecule[21].

The presence of π-electrons leads to a slight change in bond lengths (by $\delta R_{\mu\nu}$) and angles (by $\delta\varphi_l$) compared with the lengths $R^0_{\mu\nu}$ and angles φ^0_l which would be observed in a hypothetical molecule without π-electrons. If the molecule does not contain heteroatoms, then usually all the $\varphi^0_l = 120°$ and all the $R^0_{\mu\nu} = R_0$ (for example, in benzene). We thus begin with the hypothesis of an ideal structure of the σ-skeleton and assume that all the distortions of this ideal structure are due to π-electrons. The σ-skeleton is regarded as elastic (characterised by force constants) and the total energy E is equal to the sum of the energies of the σ-skeleton (E_σ) and of the π-electrons (E_π): $E = E_\sigma + E_\pi$.

In terms of the Hückel approximation in the molecular orbital method, the molecular energy of alternant hydrocarbons is[21]

$$E = E^0_\sigma + \underset{(\text{w.r.t.atoms})}{\sum_n \alpha_n} + 2\underset{(\text{w.r.t.bonds})}{\sum_l \beta_l P_l} + \underset{(\text{w.r.t.bonds})}{\sum_l \frac{k_{1l}\delta R_l^2}{2}} + \underset{(\text{w.r.t.angles})}{\sum_l \frac{k_{2l}R_0^2\delta\varphi_l^2}{2}}, \qquad (8)$$

where P_l is the bond order between adjacent atoms and β_l is the corresponding resonance integral; the last two terms in Eqn. (8) are due to the distortion of the initial σ-skeleton having the energy E^0_σ, k_{1l} and k_{2l} being the force constants for the lengths R_l and angles φ_l respectively.

The resonance integral β_l can be conveniently represented by an expansion in terms of the deviation δR_l from the equilibrium length R_0 in the ideal σ-skeleton:

$$\beta_l = \beta^0_l + \beta'_l\delta R_l + \beta''_l\frac{\delta R_l^2}{2}, \qquad (9)$$

where β'_l and β''_l are the first and second derivatives of $\beta_l(R)$ with respect to the distance R calculated at the point $R = R_0$.

By varying the total energy E with respect to independent δR_l and $\delta\varphi_l$, we obtain the values of δR_l and $\delta\varphi_l$ for which this energy is a minimum. The number of independent δR_l and $\delta\varphi_l$ for a planar molecule with N conjugated atoms is $2N - 3$. The observed values of δR_l and $\delta\varphi_l$ depend in a complex manner on the bond orders. On substituting these expressions in the formula for E [(Eqn. 8)], we obtain the total energy E as a function of the coefficients of the molecular orbitals c^k_n. By varying E with respect to c^{k*}_n, we obtain non-linear equations for c^k_n (the bond orders P_l are quadratic functions of c^k_n and E is a non-linear function of P_l). These non-linear equations are solved for c^k_n with the aid of a procedure whereby adjustment for self-consistency is made.

If the molecule does not contain rings, all the $\delta\varphi_l$ are independent and variation with respect to them yields $\delta\varphi_l = 0$ (the angles are not distorted). By varying with respect to δR_l, we obtain:

$$\delta R_l = -\frac{2\beta'_l}{k_{1l} + 2\beta''_l P_l}P_l. \qquad (10)$$

The equation for c^k_n is

$$0 = 2(\alpha_n - E^k)c^k_n + 2\frac{\partial}{\partial c^{k*}_n}\left(\sum_l \beta_l P_l\right) + \frac{\partial}{\partial c^{k*}_n}\left(\sum_l \frac{k_{1l}\delta R_l^2}{2}\right).$$

If $\beta'^2_l/k_{1l}|\beta_l| \ll 1$, the terms non-linear in c^k_n in this equation may be neglected and the bond orders P_l can be determined from the equation with undistorted bond lengths. As a result, we arrive at a "bond length–bond order" formula[21]:

$$R_l = R_0 - \frac{2\beta'_l}{k_{1l} + 2\beta''_l P_l}P_l. \qquad (11)$$

If the distortions of the angles and terms of the order of P^2_l are neglected, the formula is found to apply also to molecules containing rings.

To determine the angles, terms corresponding to the interaction of π-electrons at non-adjacent atoms must be included in the formula for the energy. We may note that a successful albeit unique example of the calculation of angles by the above general method has been achieved for the naphthalene molecule[21]. It was found that approximately half the contribution to the angular distortion $\delta\varphi_l$ comes from the bond length distortion δR_l.

In the calculation of the π-electron energy of the molecule one can employ methods which include the interaction of the electrons. In terms of the PPP approximation, it is easy to show that the "bond length–bond order" formula is

$$R_{\mu\nu} = R_0 - \frac{2\beta'_{\mu\nu}P_{\mu\nu} + \gamma'_{\mu\nu}\left[(P_{\mu\mu} - N_\mu)(P_{\nu\nu} - N_\nu) - \frac{P^2_{\mu\nu}}{2}\right]}{\kappa_{1\mu\nu} + 2\beta''_{\mu\nu}P_{\mu\nu} + (\text{terms with } \gamma''_{\mu\nu})}, \qquad (12)$$

where N_μ and N_ν are the numbers of electrons introduced by the atoms μ and ν to the overall π-electron system and $\gamma'_{\mu\nu}$ and $\gamma''_{\mu\nu}$ are derivatives of $\gamma_{\mu\nu}(R)$ with respect to R at the point $R = R_0$. In alternant hydrocarbons $N_\mu = N_\nu = P_{\mu\mu} = P_{\nu\nu} = 1$. $P_{\mu\mu} - N_\mu$ is equal to the charge of the atom μ. Comparison of Eqn. (12) with Eqn. (11) of the Hückel method for alternant hydrocarbons shows that the entire difference has been reduced to the following change of parameters:

$$\beta_{\mu\nu}(\text{Hückel MO method}) \to \beta_{\mu\nu}(\text{PPP method}) - \tfrac{1}{4}\gamma_{\mu\nu}P_{\mu\nu}.$$

Thus the parameters in the formula for the bond length depend significantly on the parametrisation scheme for $\beta_{\mu\nu}$ and $\gamma_{\mu\nu}$.

The linear "bond length–bond order" relation [Eqn. (7)] usually describes satisfactorily the experimental bond lengths in conjugated molecules not only of hydrocarbons but also of compounds with the heteroatoms N, O, F, and S.[22,23] The average accuracy of the determination of bond lengths by Eqn. (7) is of the order of 0.01–0.02 Å (see, for example, Table 1). The causes of the individual discrepancies are the approximate nature of equations of type (7), the hypothesis that σ-bonds are additive, etc.

2. Heats of Formation of Conjugated Molecules

Another important characteristic of conjugated molecules is the heat of formation $-\Delta H$. The modern scheme for the calculation of this quantity was proposed by Dewar[22,23]. The formula

$$-\Delta H = n_H E_{CH} + \sum E^{\sigma}_{CC}(R) - E_{\pi} \qquad (13)$$

is used to calculate the heat of formation of a conjugated hydrocarbon. Its first term is the dissociation energy of all the C—H bonds (there are n_H such bonds in the molecule), the second term represents the dissociation energy of all the C—C σ-bonds, and the third term represents the π-electron energy with a minus sign. The usual hypothesis of the additivity of the energies of the σ-bonds and of σ- and π-energies was used here, as in Eqn. (8). The dissociation energy E_{CH} of C—H bonds is an empirical term. The C—C σ-bond energy $E^{\sigma}_{CC}(R)$ is described by a Morse function with empirical parameters. The π-electron energy E_{π} was calculated in terms of the LCAO-MO SCF approximation using the PPP Hamiltonian and $R_{\mu\nu}$, necessary for the calculation of $E^{\sigma}_{CC}(R_{\mu\nu})$, was evaluated with the aid of the empirical relation (7).

Table 1. The bond lengths in certain conjugated molecules[23].

Molecule	Bond	Bond length, Å	
		calc.	expt.
	12	1.333	1.334
	23	1.348	1.388
	12	1.338	1.340
	23	1.396	1.395
	34	1.397	1.395
	12	1.381	1.371
	23	1.347	1.354
	34	1.459	1.440

The parameters of the PPP Hamiltonian used by Dewar to calculate heats of formation[22,23] were approximately the same as in the calculation of absorption spectra. The resonance integral $\beta_{\mu\nu}$ was an exception. The values of $\beta_{\mu\nu}$ were determined by Dewar from the thermochemical conditions and exceeded by a factor of 1.3—1.4 the values used in the calculation of absorption spectra¶. This inconsistency of the parameters indicated a defect of the theory, although the agreement with experiments was very good[23] (Table 2).

In Bazilevsky's studies[24,25] this theoretical difficulty was overcome. On the basis of the study by Fischer-Hjalmars[6], it was shown that it is possible to retain the spectroscopic values of $\beta_{\mu\nu}$, provided that in derivation of the model Hamiltonian all the terms which arise naturally on transformation from $2p_z$ functions to the orthogonal functions $\varphi_p(r)$ are retained. These additional terms, which are usually neglected†, make a new contribution to the total energy, which is[25]

$$\widetilde{\Delta E} = \sum K_{\mu\nu} S^2_{\mu\nu} + O(S^3),$$

where $K_{\mu\nu}$ are coefficients which depend on the molecule and $S_{\mu\nu}$ is the overlap integral of the $2p_z$ functions of the atoms μ and ν. The addition of $\widetilde{\Delta E}$ leads to the so called exchange repulsion of atoms and molecules. This exchange repulsion is well known, for example, in studies on the interaction of two helium atoms, non-bonded hydrogen atoms, etc., which was examined for the first time for non-polar conjugated systems by Bazilevsky, who proposed a simple formula for $\widetilde{\Delta E}$ containing a single empirical parameter[24], retaining $S_{\mu\nu}$ only for adjacent atoms μ and ν:

$$\widetilde{\Delta E} = \gamma \sum_{\substack{\mu\nu \\ \text{(adjacent)}}} S^2_{\mu\nu} \quad (\gamma > 0).$$

Table 2. The energies of formation of certain conjugated molecules[23].

Molecule	Energy of formation $-\Delta H$, eV	
	calc.	expt.
pyridine	51.87	51.79
 quinoline	85.322	85.18
pyrazine	46.272	46.44
pyridazine	45.741	45.59
 indole	78.438	78.06

The validity of this approximation for $\widetilde{\Delta E}$ was confirmed by the satisfactory agreement of the heats of formation with experiment (Table 3). This computational scheme can be improved by employing a more accurate formula for $\widetilde{\Delta E}$.[25]

As a result, the π-electron energy of the conjugated molecule becomes[24]

$$E_{\pi} = E_{\pi}\{\beta^{\text{spectr.}}\} + \gamma \sum_{\substack{\mu\nu \\ \text{(adjacent)}}} S^2_{\mu\nu}.$$

Here the first term is the π-electron energy calculated using spectroscopic values of the resonance integral $\beta^{\text{spectr.}}$. If $S_{\mu\nu}$ is calculated using Slater $2p_z$ functions,

$$\varphi_{2p_z}(r) = \frac{Z^{5/2}}{4\sqrt{2\pi}} r\cos\theta\, e^{-\frac{Zr}{2}} \quad (Z = 3.18), \qquad (14)$$

then γ = 8.7 eV.[24] This value of γ was determined by comparing $-\Delta H$ calculated by Eqn. (13) with the experimental value and depends both on the parameters of the σ-bond and on Z.

We may note that in calculations of absorption spectra there was no need for the additional exchange term $\widetilde{\Delta E}$, since it is the same for the ground and excited states (the changes in molecular geometry on excitation are usually small and are as a rule disregarded). However, this

¶ For the C—C bond length R = 1.4 Å, the spectroscopic value of the resonance integral is $\beta \simeq -2.4$ eV.

†These additional terms arise on passing to an orthogonal basis set using the formulae derived towards the end of Section II, 1.

additional term ΔE is significant in calculations on chemical reactions of conjugated systems, since terms proportional to $S^2_{\mu\nu}$ are significant in the energy of molecular interaction. Specifically exchange repulsion leads to a potential barrier and a positive activation energy for such reactions[25].

Table 3. The energies of formation of certain conjugated hydrocarbons calculated using a modified PPP method[24].

Molecule	Heat of formation $-\Delta H$, eV		Molecule	Heat of formation $-\Delta H$, eV	
	calc.	expt.		calc.	expt.

3. Dipole Moments

One of the difficult problems in quantum mechanics of molecules is the calculation of dipole moments, since such calculations require the knowledge of the wavefunction of all the electrons in the molecule. Brown and Coller[26] made a preliminary assessment of the many years of efforts to calculate the dipole moments of conjugated hydrocarbons containing N and O heteroatoms. It is suggested that σ- and π-electrons contribute to the overall dipole moment $\vec{\mu}$:

$$\vec{\mu} = \vec{\mu}_\sigma + \vec{\mu}_\pi.$$

Table 4. The dipole moments of certain conjugated hydrocarbon molecules with the N and O heteroatoms[26].

Molecule	Magnitude and directions of the σ- and π-contributions (μ_σ and μ_π) to the dipole moment	Overall dipole moment, D	
		calc.	expt.
Pyridine-*N*-oxide		3.8	4.24
Pyrimidine		2.32	2.0
Benzaldehyde		2.87	2.80

The component $\vec{\mu}_\pi$ is calculated from the distribution of π-electrons among the atoms in the molecule and the contribution to $\vec{\mu}_\sigma$ comes (by hypothesis) only from the lone electron pair localised in the sp^2 hybrid orbitals (belonging to the σ-skeleton) of the N and O atoms. These contributions of the lone electron pairs of the N and O atoms are respectively

$$\mu_N = 1.77\ D, \quad \mu_O = 1.52\ D.$$

The wavefunction χ_n of the sp^2 hybrid orbital of the lone pair is

$$\chi_n = \chi_{2s} + \theta\chi_{2p_\sigma}.$$

The contribution to $\vec{\mu}_\sigma$ is proportional to θ and in its calculation using Slater functions is given by[26]

$$\mu_n = 14.68\,\theta/Z\,(1+\theta^2)\,(D),$$

where Z is the effective Slater charge. Generally speaking, μ_n depends on the angles in the molecules (θ also depends strongly on these angles), but Brown and Coller[26] used for simplicity an estimate of μ_n from the sp^2 hybrid orbitals of neutral N and O atoms. This led to the values of μ_N and μ_O indicated above.

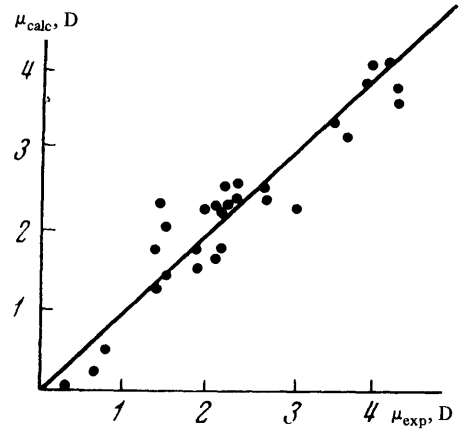

Figure 2. Correlation between the calculated (μ_{calc}) and experimental (μ_{exp}) dipole moments according to Brown and Coller[26].

To calculate $\vec{\mu}_\pi$, Brown and Coller[26] used a self-consistent method with a variable π-electronegativity. This method resembles that in Section IV, 2, but, in contrast to the latter, it does not take into account the redistribution of σ-charges in the molecule. This redistribution has an appreciable influence on the electronic excitation energies in molecules with heteroatoms (see Section IV, 2 below). However, Brown and Coller[26] neglected the contribution of σ-charges to the dipole moment.

The results of the calculation of $\vec{\mu}$ for certain molecules are presented in Table 4 together with experimental data. Fig. 2 illustrates the correlation between the experimental and calculated dipole moments. The overall accuracy of the prediction of the dipole moments of compounds with N and O heteroatoms proved to be to within about 0.4 D. This is probably all that can be expected of a theory with such rough allowance for the contribution by the σ-skeleton to $\vec{\mu}$. Table 4 shows that this contribution is very significant.

IV. CALCULATIONS ON EXCITED STATES OF CONJUGATED MOLECULES AND TWO MAIN SCHEMES FOR THE DETERMINATION OF THE EFFECTIVE PARAMETERS OF THE MODEL π-ELECTRON HAMILTONIAN

The theory of conjugated systems was developed initially and was improved by studying the properties of conjugated hydrocarbons. One of the greatest achievements in recent years has been the inclusion of calculations on systems with heteroatoms in the general scheme. This was done after a careful study of the entire parametrisation technique. As a result, several computational schemes were devised, differing in the methods used to introduce empirical information into the model Hamiltonian.

We shall consider in detail two modern parametrisation schemes for the model π-electron Hamiltonian. In one of these the parameters are introduced approximately as in the initial version of Pariser and Parr, i.e. they are calibrated against a series of simple molecules by comparing the calculated and experimental excitation and ionisation energies. This scheme is being developed by Scandinavian workers[6,27-36]. We shall call it "Scheme 1". In the second scheme ("Scheme 2") $2p_z$ functions [these are usually Slater functions defined in Eqn. (14) with different effective charges] and certain other quantities are parametrised. All the parameters are specified as before, which makes Scheme 2 less empirical than Scheme 1. Nevertheless all the parameters of Scheme 2 have been chosen empirically in the course of prolonged studies on molecular spectra using intermediate hypothesis and assumptions. Calculations on excited states by Scheme 2 have been carried out, for example, by Hammond[37], who also quotes all the references relevant to Scheme 2.

1. Scheme 1

Scheme 1 [27-36] is devised as follows. In the first place the ZDO approximation, which is natural for orthogonalised basis functions $\varphi_p(r)$ is used: the overlap integrals

$$S_{\mu\nu} = \delta_{\mu\nu},$$

the non-zero integrals of the skeleton

$$H_{\mu\mu} \equiv \alpha_\mu \text{ (definition) and } H_{\mu\nu} = \beta_{\mu\nu} \text{ for adjacent } \mu \text{ and } \nu;$$

and finally

$$\langle \mu\tau \mid \rho\nu \rangle = \gamma_{\mu\nu}\delta_{\mu\tau}\delta_{\nu\rho}, \quad \gamma_{\mu\nu} = \langle \mu\mu \mid \nu\nu \rangle.$$

Thus the PPP Hamiltonian [Eqn. (6)] is used.

The parameters of the skeleton are specified as follows.

$$\alpha_\mu = W_\mu - \sum_{\nu(\neq\mu)} \gamma_{\mu\nu}, \tag{15}$$

where the first term is the energy of the attraction of a π-electron of the atom μ to its positively charged ionic residue (W_μ is approximately equal to the ionisation potential of the atom μ with a minus sign) and the second term represents the energy of the attraction of a π-electron of the atom μ to the ionic residues of other atoms; the approximation for the integral $U(\nu:\mu\mu)$ for the attraction of a π-electron of the atom μ to the positively charged ionic residue of the atom ν, which is usual in the PPP method, was employed here:

$$U(\nu:\mu\mu) \simeq \gamma_{\mu\nu}.$$

Furthermore,

$$W_\mu = W_0 + \sum_{\substack{\nu \\ \text{(adjacent } \mu\text{)}}} \Delta W_\mu(R_{\mu\nu}). \tag{16}$$

Eqn. (16) takes into account the influence of neighbouring carbon atoms on the ionisation potential of the atom μ. The contributions to $H_{\mu\mu}$ by other atoms are a consequence of the orthogonalisation of the $2p_z$ functions, as shown by Fischer-Hjalmars[6]. Under these conditions, the main contribution comes from neighbouring atoms, which is reflected in Eqn. (16). If there are no neighbouring atoms, the sum in Eqn. (16) is missing and $W_\mu = W_0$. Therefore the ionisation potential of the CH_3 radical with a minus sign is chosen as the value of W_0 ($W_0 = -9.84$ eV).

The contributions to W_μ by adjacent atoms depend on distance according to the formula

$$\Delta W_\mu(R_{\mu\nu}) = \Delta W_0 + \delta(R_{\mu\nu} - R_0). \tag{17}$$

Here (and subsequently) it is assumed that the functions of $R_{\mu\nu}$ can be represented by expansions in terms of the deviations $(R_{\mu\nu} - R_0)$ from the standard line $R_0 = 1.397$ Å (the C–C bond length in benzene‡). In view of the smallness of these deviations (usually $|R_{\mu\nu} - R_0| \leqslant 0.2$ Å), one need retain only two terms of the expansion. It was found that $\Delta W_0 = 0.09$ eV and $\delta = 8.63$ eV Å^{-1}. The values of these and the remaining parameters were determined by a least squares fit of the ionisation potentials and electronic transition energies in the CH_3 radical and in the C_2H_4 (ethylene), C_6H_6 (benzene), and C_4H_8 (butadiene) molecules.

A formula of type (17) was proposed also for the resonance integral:

$$\beta_{\mu\nu} = \beta_0 + \delta_\beta \cdot (R_{\mu\nu} - R_0) \text{ (adjacent } \mu \text{ and } \nu\text{)} \tag{18}$$

$\beta_0 = -2.43$ eV and $\delta\beta = 3.1$ eV Å^{-1}.

The following formulae have been proposed for the parameters of the Coulombic repulsion of π-electrons:

$$\begin{aligned} \gamma_{\mu\mu} &= 11.97 \text{ eV} \\ \gamma_{\mu\nu} &= \gamma_0 + \delta_\gamma(R_{\mu\nu} - R_0) \text{ (adjacent } \mu \text{ and } \nu\text{)} \end{aligned} \tag{19}$$

$\gamma_0 = 6.95$ eV and $\delta_\gamma = -4.65$ eV Å^{-1}; for non-adjacent μ and ν, we have

$$\gamma_{\mu\nu} = \gamma_{\mu\mu}[\gamma_{\mu\mu} R_{\mu\nu} + \exp(-\gamma_{\mu\mu} \cdot R_{\mu\nu})]^{-1}. \tag{20}$$

In terms of the ZDO approximation, the electronic transition energies depend only on differences between type I Coulombic integrals [see Eqn. (6) and Refs. 8 and 14–16]:

$$\gamma_{11} - \gamma_{1p}, \quad \gamma_{12} - \gamma_{1p}, \quad \gamma_{13} - \gamma_{1p}, \quad \ldots$$

or between type II integrals

$$\gamma_{11} - \gamma_{12}, \quad \gamma_{12} - \gamma_{13}, \quad \gamma_{13} - \gamma_{14}, \quad \ldots$$

(Here γ_{1p} denotes the Coulombic integral for the most remote atoms in the molecule). As a result, for small molecules it is important to know how $\gamma_{\mu\nu}$ depends on the distance between adjacent atoms, while the variation for larger distances $R_{\mu\nu}$ is less important. This is reflected in Eqns. (19) and (20) and explains certain arbitrary features in the selection of the formula for $\gamma_{\mu\nu}$ with non-adjacent μ and ν.

If the variation of the theoretical parameters with interatomic distances is known, it is possible to obtain formulae for bond lengths and angles, as noted above, and also to

‡ A similar method for the introduction of parameters of functions, which depend on the bond length, was used in our earlier studies[21,38].

calculate the vibration frequencies of conjugated molecules. Thus semiempirical parameters must be calibrated so as to reproduce satisfactorily both the electronic spectra and the geometrical characteristics of the conjugated molecules. We approached the choice of the parameters in the Hückel method from these general standpoints: the force constants of the σ-skeleton and the variation of the resonance integral with bond length were determined, which led to six very satisfactory frequencies of the in-plane vibrations of benzene[38] and to the correct coefficient in the "bond length–bond order" formula[21].

The problem of a similar adjustment for consistency between empirical parameters and experimental data, based on optical and infrared spectra and geometrical structures of conjugated molecules, has not so far been solved for the PPP Hamiltonian. Although the problem of the in-plane vibrations of benzene has been solved in terms of the PPP approximation[39-42], only three frequencies were considered, which hinders the calibration of the parameters. A similar situation arises in the adjustment of the parameters for consistency with the geometrical structure. When the parameters of Scheme 1 for $\beta(R)$ and $\gamma(R)$ [Eqns. (18) and (19)] and the elastic constant of the σ-skeleton k_1 = 47.6 eV Å^{-2} are used[39], we find that in the formula for conjugated hydrocarbons

$$R_{\mu\nu} = R_0 - bP_{\mu\nu} \qquad (7)$$

the parameter b = 0.162 (for $P_{\mu\nu}$ = 2/3 in the case of benzene) according to Eqn. (12), instead of the value b = 0.18 used in Scheme 1.[20]

As in Dewar's studies[22,23], empirical formulae of type (7) with the parameters R_0 and b, which depended on the type of adjacent atoms, were used to calculate the bond lengths in conjugated molecules with heteroatoms[29-36]. The results obtained for these bond lengths agreed with experiment to within the same limit (about 0.01–0.02 Å) as in Dewar's work[23].

In the calculation of electronic excitation energies for molecules with heteroatoms (N, O, S, etc.) the same parametrisation method was used as for hydrocarbons: equations of type (16)–(20), in which the corresponding constants were fitted by least squares to experimental ionisation potentials and electronic transition energies in a number of simple molecules containing one of the heteroatoms, were employed for the parameters of the Hamiltonian. Thus the computational scheme was extended to the large classes of molecules with heteroatoms[29-36].

Recently the authors of Scheme 1 have tended to reduce the total number of empirical parameters, because each heteroatom introduces several parameters into the calculation. It was noted[43] that the dependence of the resonance integral on the distance between the atoms C and X (X = C, N, O, or F) may be described satisfactorily by two types of relations, which are usually employed in different parametrisation schemes:

$$\beta = \beta_0 + \delta\,(R - R_0) \qquad (21)$$

and

$$\beta = k\,S, \qquad (22)$$

where S is the overlap integral calculated using the Slater functions (14) for the $2p_z$ functions of the atoms C and X with the corresponding values of $Z_{\text{eff}} = 2\zeta$. For all the CX bonds, δ = 3.05 eV Å^{-1}, R_0 = 1.397 Å, β_0 = −2.42 eV, and k = −8.98 eV were adopted. The values of ζ for different atoms together with the values of β for R = 1.34 Å, calculated by Eqns. (21) and (22), are presented in Table 5, which shows a close similarity between the parameters of Scheme 1 and Scheme 2, where, as will be shown below, the resonance integral is calculated by a formula of type (22) and the ζ values are close to those in Table 5.

Table 5. Resonance integrals calculated in different ways[43].

X	βCX, eV		$\zeta = Z_{\text{eff}}/2$	X	βCX, eV, ∞		$\zeta = Z_{\text{eff}}/2$
	Eqn.(21)	Eqn.(22)			Eqn.(21)	Eqn.(22)	
C	−2.59	−2.65	1.56	O	−1.80	−1.61	2.22
N	−2.25	−2.06	1.92	F	−1.30	−1.29	2.55

The general scheme for calculations on molecules is of the usual type for the PPP method. Initially calculations are made on the ground state by the LCAO-MO SCF method, the molecular orbital coefficients and bond orders are found, and the bond lengths are calculated. Next linear combinations of singly excited molecular configurations are set up on the basis of molecular orbitals of the ground state. The coefficients of the configurations, which define the wavefunction of the excited state, are found together with the excitation energies from the minimum in the average molecular energy calculated using the PPP Hamiltonian for the nuclear configuration of the ground state. According to Koopmans' theorem, the ionisation potential is assumed equal to the energy of the highest occupied molecular orbital with the sign reversed[9].

The results of calculations in accordance with Scheme 1[29-36] will be discussed below after examining a further parametrisation scheme.

2. Scheme 2

Hammond[37] carried out calculations on a large number of conjugated molecules within the framework of a single approach (Fig. 3). We shall now consider the parametrisation scheme adopted (Scheme 2).

The Fock equation is

$$F\chi = \varepsilon\chi, \qquad (23)$$

where ϵ are the orbital energies of the molecular orbitals, χ is the column–vector of atomic function coefficients, and F is the Fock matrix with the following elements:

$$F_{pp} = H_{pp} + N_p\gamma_{pp} - \frac{1}{2}P_{pp}\gamma_{pp} + \sum_q (P_{qq} - N_q)\,\gamma_{pq},$$
$$F_{pq} = H_{pq} - \frac{1}{2}P_{pq}\gamma_{pq}\ . \qquad (24)$$

Here $H_{pp} = -I_p$ when the atom p contributes one electron to the π-electron system and N_p = 1 and $H_{pp} = -I_p - \gamma_{pp}$ when N_p = 2; the non-diagonal elements H_{pq} are non-zero for all p and q:

$$H_{pq} = \text{const} \cdot \frac{H_{pp} + H_{qq}}{1 + S_{pq}} \cdot S_{pq}\ , \qquad (25)$$

where const. = 0.56 [from the condition H_{pp+1}(benzene) = −2.45 eV]. The overlap integrals S_{pq} are calculated from the Slater functions (14). The values of ζ_p, I_p, and γ_{pp} are listed in Table 6.

As already mentioned, formula (25) is similar in form to formula (22) and the Slater exponents $\zeta_p = Z_p/2$ listed in Tables 5 and 6 are also similar. This similarity is not fortuitous, since both parametrisation schemes (Schemes 1 and 2) are based on the same experimental data.

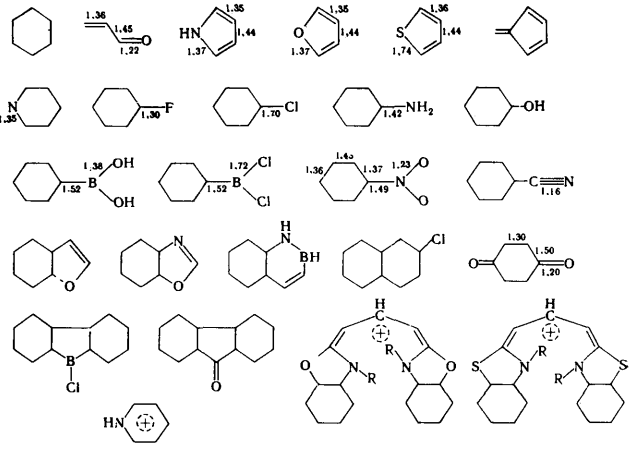

Figure 3. The molecules and ions for which calculations were made by Hammond[37] with parametrisation according to Scheme 2. The bond lengths (in Å) used in the calculation are indicated.

The following formulae were adopted for the parameters of the Coulombic repulsion of electrons in Scheme 2:

$$\gamma_{pq} = \frac{14.397}{a_{pq} + R_{pq}}, \quad a_{pq} = \frac{28.794}{\gamma_{pp} + \gamma_{qq}} \quad . \tag{26}$$

It is found that γ_{pq} for adjacent hydrogen atoms is smaller by 1.6 eV according to this scheme than according to Scheme 1. These differences are probably compensated when a special procedure is used to take into account the polarisation of the σ-skeleton and the mutual influence of σ- and π-electrons as well as the changes in other parameters.

In calculations on systems with heteroatoms an important factor is the correct allowance for effects associated with the mutual influence of atoms. This influence via the σ-skeleton has been taken into account in Scheme 2 with the aid of the concept of the atomic electronegativities ω_p of the σ-bond orbitals. The fraction of σ-electron n_p in the atom p due to the presence of the σ-bond with the atom q can be expressed in terms of ω_p and ω_q:

$$n_p = \frac{2\omega_p}{\omega_p + \omega_q}. \tag{27}$$

In each σ-bond pq there are two σ-electrons:

$$n_p + n_q = 2.$$

As a result of the influence of neighbouring atoms, the effective Slater charge Z^0_p of an isolated atom p is replaced by Z'_p according to the formula

$$Z'_p = Z^0_p + 0.35 \sum_{\substack{q \\ \text{(adjacent } p\text{)}}} \left(\frac{2\omega_q}{\omega_p + \omega_q} - 1\right)\left(\frac{1.41}{R_{pq}}\right)^2. \tag{28}$$

where 0.35 is the Slater screening constant and the multiplier $(1.41/R_{pq})^2$ characterises the rate of decrease of the inductive effect with distance, becoming unity when R_{pq} = 1.41 Å. If all the atoms are the same (all $\omega_p = \omega_q$), then the Slater functions (14) have the same $Z'_p = Z^0_p$ and the mutual influence of atoms is taken account only via the π-electron system in the usual way.

Table 6. The atomic parameters used in calculations on conjugated molecules by Scheme 2.[37]

Atom p	N_p	$Z^0_p = 2\zeta_p$	I^0_p, eV	γ^0_{pp}, eV	ω_p
B	0; 1	2.25; 2.60	8.33	6.91	1.96
C	1	3.25	11.16	11.13	2.75
N	1; 2	3.90; 4.25	14.12	12.34	4.13
O	1; 2	4.55 4.90	17.7	15.23	5.54
F	2	5.55	20.86	17.36	3.90
S	2	5.80	12.7	9.94	3.46
Cl	2	6.45	15.03	11.30	2.95

As a result of the σ-inductive effect, I^0_p and γ^0_{pp} of isolated atoms are replaced by I'_p and γ'_{pp} according to the following formulae:

$$I'_p = I^0_p - 0.324\,[(Z^0_p)^2 - (Z'_p)^2] - 6.03\,(Z^0_p - Z'_p),$$
$$\gamma'_{pp} = \gamma^0_{pp}\,(Z'_p/Z^0_p). \tag{29}$$

Z'_p, I'_p, and γ'_{pp} are the initial values for the first π-electron calculation: Eqn. (23) is solved with the above parameters. After determining the bond order matrix P_{pq}, allowance is made for the π-inductive effect, according to which the effective charge becomes

$$Z'_p = Z_p - 0.35\,(P_{pp} - 1). \tag{30}$$

The quantities I''_p and γ''_{pp} for the next π-electron calculation (using Z''_p) are evaluated by Eqn. (29), etc. Several iterations are performed until the successive P_{pq} agree to within the required accuracy.

This scheme for taking into account inductive effects involves a logical inconsistency, which, however, may be concealed by the special selection of parameters. This inconsistency was noted earlier[44,45] in relation to the Hückel method with parameters which depend on P_{pq}. As noted by Bagatur'yants[46], the point is that, by minimising the total average energy and by deriving the Fock equation, we should take into account the dependence of the parameters γ_{pp} and I_p on bond orders already at this stage. Otherwise the iterative procedure does not lead to a minimum in the total energy. The complete scheme for taking into account the changes in parameters when P_{pq} is altered, developed by Karlsson[47] for the PPP approximation, is free from this disadvantage but is very cumbersome and has not so far been used.

The excitation energies for each molecule were calculated taking into account 10 singly excited configurations for the given configuration of the nuclei: the experimental bond lengths and angles or their values for fragments of known molecules were used. The variation of several bond lengths in a series of molecules had little effect on the calculated excitation or ionisation energies, which were also determined using Koopmans' theorem. The results of the calculations of the excitation energies and

ionisation potentials are compared with experiment in Fig. 4. The average deviation of the calculated excitation energies and ionisation potentials from the experimental values proved to be 0.1—0.2 eV and about 0.4 eV respectively. The satisfactory overall agreement between the theory and experiment can be accounted for by the logic of the fundamental postulates of the theory and the exact choice of parameters. Since the same conclusions and estimates are valid for the results of calculations with the parameters of Scheme 1, these results will not be quoted. We shall only note that in calculations with the parameters of Scheme 1 the excitation energies agree better with experiment than the ionisation potentials.

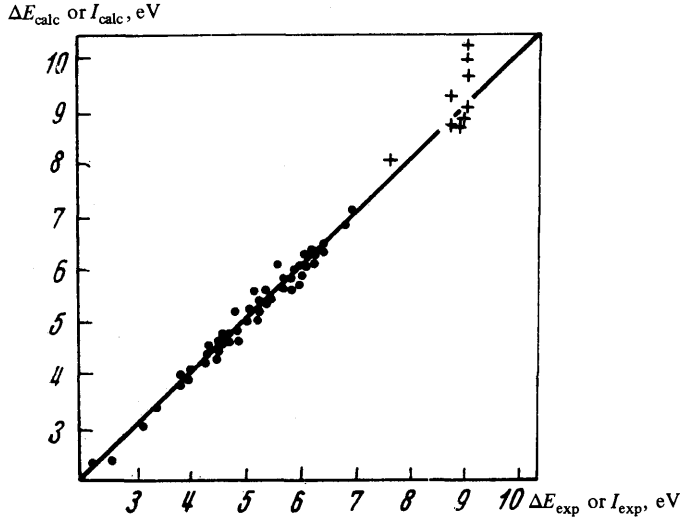

Figure 4. Correlation between the calculated and experimental excitation energies (ΔE) and ionisation potentials (I) for the molecules shown in Fig. 3. The calculated values are plotted against the experimental values[37]: ●—ΔE; +—I.

V. THE DIFFICULTIES OF THE THEORY IN THE CALCULATION OF THE INDIVIDUAL PROPERTIES OF EXCITED STATES

1. Ionisation Potentials

Large discrepancies between theory and experiment for ionisation potentials, reaching 1 eV, are characteristic of the π-electron approximation and are related to the approximate nature of Koopmans' relation:

$$I = -\varepsilon^{\pi}_{h.occ} \qquad (31)$$

where I is the ionisation potential and $\epsilon^{\pi}_{h.occ}$ the energy of the highest occupied molecular orbital. Roothaan[9] showed that Koopmans' theorem [Eqn. (31)] is valid in the LCAO-MO SCF approximation. The reasons for the large discrepancies with experiment are as follows: (1) the change in the molecular orbital energies ϵ_i on passing from the molecule to the ion is neglected; (2) the correlation contributions to the energies of the ground states of the molecule and the ion are neglected. Thus in the derivation of Eqn. (31) it was assumed that all the molecular orbital energies $\epsilon_i^{(o)} = \epsilon_i^{(+)}$, where the superscripts o and + refer to the neutral molecule and the cation respectively. Moreover, the approximate nature of the method of calculation itself (LCAO-MO SCF) has an effect. In it the ground state energy is calculated in terms of the single-configuration approximation, which implies neglect of the π-electron correlation energies, the latter being taken into account to some extent by the choice of the parameters of the effective Hamiltonian.

The calculation of the ionisation potentials of a number of conjugated molecules showed[48] that, as a rule, the calculated I_{calc} exceed the experimental values I_{exp} and the differences between them depend on the choice of parameters. Furthermore, it has been shown[48] that the agreement with experiment can actually be impaired if doubly excited configurations are included in the calculation for the same values of the parameters. This is because the parameters of the effective Hamiltonian must depend on the method of calculation: in the parameters of the SCF method correlation effects are to some extent taken into account and when these effects are taken into account explicitly other parameters must be used.

Table 7. The calculated (I_{calc}) and experimental [I^{el}_{expt} (electron impact) and I^{ph}_{expt} (photoionisation)] ionisation potentials[50].

Molecule	I_{calc}	I^{el}_{exp}	I^{ph*}_{exp}	Molecule	I_{calc}	I^{el}_{exp}	I^{ph*}_{exp}
Benzene	(9.56)	9.56	9.25	Benzaldehyde	9.87	9.82	9.50
Ethylene	10.39	10.62	—	Pyridine	9.65	9.70	9.30
trans-Butadiene	9.3	9.3	—	Quinoline	8.69	—	8.62
Aniline	8.78	8.32	7.7	*p*-Benzoquinone	9.76	—	9.96
Phenol	9.21	9.16	8.7				

*According to Potapov[51].

It has been shown[49,50] that the agreement between I_{calc} and I_{exp} is improved (Table 7) when Koopmans' relation with the correction

$$I_{calc} = -\varepsilon^{\pi}_{h.occ} - \Delta \qquad (\Delta \simeq 1\,eV) \qquad (32)$$

is employed.

In order to understand the reasons for this correction, we shall consider the results of the calculations on urazole and pyrrole and their anions and cations in terms of the SCF approximation with all the σ- and π-electrons[18]. It was found that a change in the number of π-electrons in the system alters the effective potential of the σ-skeleton for the π-electrons. This leads to a decrease of all the molecular orbital energies when the number of π-electrons is reduced:

$$\varepsilon_i^{(-)} > \varepsilon_i^{(*)} > \varepsilon_i^{(+)}. \qquad (33)$$

In order to make some allowance for this change in molecular orbital energies, it is necessary to introduce a positive correction Δ. We may note that a similar formula has been proposed[52] for the electron affinity E_A:

$$E_A = -\varepsilon^{\pi}_{1.free} - \Sigma \qquad (\Sigma \simeq 2-3\ эв) \qquad (34)$$

where $\epsilon^{\pi}_{l.free}$ is the energy of the lowest unoccupied molecular orbital of the conjugated molecule and a positive sign of Σ follows from Eqn. (33). The corrections Δ and Σ can eliminate only the average systematic error, leaving an inaccuracy of about 0.5 eV. This inaccuracy is characteristic of calculations of ionisation potentials using Koopmans' relations (31) and (32).

2. Energies of Triplet States

As stated above, the energies of electronic singlet excited states can be calculated with a high accuracy (to within 0.1—0.2 eV). The same satisfactory accuracy is characteristic of calculations using other parametrisation schemes[15,49,53-61]. The situation is less satisfactory for calculations of the energies of triplet levels. This is probably why the authors of Schemes 1 and 2 did not calculate the energies of triplet states and it has actually been suggested[62] that the parameters be altered in calculations on such states.

Table 8. The energies of the triplet states of benzene (eV) (relative to the ground state)[63].

Symmetry of level	Calc.	Expt.
$^3B_{1u}$	3.37	3.66
$^3E_{1u}$	4.85	4.65
$^3B_{2u}$	5.33	5.76
$^3E_{2g}$	6.31	6.56
$^3E_{2g}$	8.70	8.55

In fact the best agreement between theory and experiment for the energies of the triplet states of benzene has been achieved[63] with parameters which are not optimal for the calculation of the singlet energy levels (Table 8). Furthermore, the discrepancies between the calculated and experimental energies of triplet states can reach 1 eV.[56-58] Finally in the calculation of the energies of the $T-T$ transitions for a large number of aromatic molecules[64,65] it was found that a satisfactory agreement between theory and experiment (to within about 0.1—0.2 eV on average) is achieved only when all the calculated transition energies are reduced by 0.4 eV. This adjusting constant was determined from the $T-T$ transition in naphthalene.

The decrease of accuracy in the calculation of the energies of triplet states is associated with the different effects of the σ-skeleton on the singlet and triplet energy levels. In order to understand the reason for this, we shall consider the wavefunctions $\Psi_{S=0}$ and $\Psi_{S=1}$ for the singlet and triplet molecular states. These functions will be expressed as sums of products of the wavefunctions of π-electrons ($\Psi^{\pi}_{S_\pi}$) and σ-electrons ($\Psi^{\sigma}_{S_\sigma}$) with different spin multiplicities:

$$\Psi_{S=0} = N_0(\Psi^{\sigma}_{S_\sigma=0}\Psi^{\pi}_{S_\pi=0} + C_0\,\Psi^{\sigma}_{S_\sigma=1}\Psi^{\pi}_{S_\pi=1} + \ldots),$$

$$\Psi_{S=1} = N_1(\Psi^{\sigma}_{S_\sigma=0}\Psi^{\pi}_{S_\pi=1} + C_1\Psi^{\sigma}_{S_\pi=1}\Psi^{\pi}_{S_\pi=0} + \ldots),$$

where the coefficients C_0 and C_1 characterise the contributions of the excited states of the σ-skeleton to the singlet and triplet states of all the electrons in the molecule and N_0 and N_1 are normalising factors. In terms of the π-electron approximation, $C_0 = C_1 = \ldots = 0$ and $\Psi_{S=0} \rightarrow \Psi^{\pi}_{S_\pi=0}$ and $\Psi_{S=1} \rightarrow \Psi^{\pi}_{S_\pi=1}$. The coefficients C_0 and C_1 are inversely proportional to the differences between the energies corresponding to the first two terms in the singlet and triplet functions $\Psi_{S=0}$ and $\Psi_{S=1}$. This difference is greater for the singlet function than for the triplet function, namely

$$(E^{\sigma}_{S=1} + E^{\pi}_{S=1}) - (E^{\sigma}_{S=0} + E^{\pi}_{S=1}) > (E^{\sigma}_{S=1} + E^{\pi}_{S=0}) - (E^{\sigma}_{S=0} + E^{\pi}_{S=1})$$

owing to the self-evident inequality $E^{\pi}_{S=1} > E^{\pi}_{S=0}$. Therefore the admixture of the second term is smaller for the singlet than for the triplet,

$$|C_0|^2 < |C_1|^2,$$

which indicates a greater influence of the σ-skeleton on triplet states.

As already mentioned, the effect of the σ-skeleton is taken into account in principle by an empirical choice of the parameters of the effective Hamiltonian. Owing to the different contributions of the σ-skeleton to the singlet and triplet states, the optimal values of the parameters for the calculation of the energies of the singlet and triplet levels should differ, as has actually been observed in a number of calculations[62,63].

We may also note that, in the calculation of excitation energies (singlet and triplet), it is generally speaking necessary to take into account fully the electron interactions. If the treatment is limited to singly excited configurations, it is found that different energy levels are calculated with different accuracies, because the contributions of the neglected configurations (doubly excited, etc.) will be different for different excited states. In this connection there has been a notable failure in the calculation of transition energies between excited singlet and triplet levels of a number of molecules[66]. Another reason for this failure is associated with the increase of error in the calculation of the transition energies between excited states: when the average accuracy in the determination of the energies of excited singlet states is 0.1—0.2 eV, larger deviations are possible, being on average doubled for energy differences, i.e. for transition energies.

3. Transition Probabilities (Oscillator Strengths)

Yet another weak point in the theory is the calculation of transition probabilities (oscillator strengths) for electronic excitations of conjugated molecules. We have analysed the results of studies by a Scandinavian group of investigators[27-36], who employed the parameters of Scheme 1 and failed to find any correlation between the calculated (f_{calc}) and experimental (f_{exp}) oscillator strengths for a large number of electronic transitions. In the plot of f_{calc} against f_{exp} (Fig. 5) most of the points are distributed between two straight lines: $f_{calc} = 3f_{exp}$ and $f_{calc} = \frac{1}{3}f_{exp}$. Thus values of f_{exp} differing by a factor of 10 can correspond to the same f_{calc}. For this reason, in the majority of later studies the f_{calc} are not compared with f_{exp} but with $\lg\epsilon$, ϵ being the extinction coefficient at the corresponding maximum in the experimental absorption spectrum. The parallel variation of f_{calc} and $\lg\epsilon$ for the spectral maxima is regarded as constituting satisfactory agreement.

In the calculation of oscillator strengths one usually employs an approximation without a specific atomic orbital basis set. Suppose that ψ_0 and ψ_a are the wavefunctions

of the ground and excited states respectively and suppose that ψ_a represents a superposition of the singly excited configurations $\Phi_{i\to k}$:

$$\psi_a = \sum_{i,k} A^a_{i\to k}\Phi_{i\to k},$$

where $\Phi_{i\to k}$ is the wave function of the configuration formed from the configuration of the ground state by the transfer of an electron from the ith to the kth molecular orbital and $A^a_{i\to k}$ is a coefficient defining the contribution of this configuration to the excited state. Then the oscillator strength for the transition to the singlet state can be calculated from the formula:

$$f_{0a} = \frac{2m}{3\hbar^2 e^2}\Delta E_{0a}\vec{\mu}^2_{0a},$$

(e is the charge of the electron, m its mass, h the Planck constant, and ΔE_{0a} the excitation energy), where

$$\vec{\mu}_{0a} = \langle\psi_0|\vec{\mu}|\psi_a\rangle = e\sqrt{2}\sum_{i,k} A^a_{i\to k}\sum_\nu c^*_{\nu i}c_{\nu k}\mathbf{R}_\nu.$$

In this equation $\mathbf{R}_\nu$ is the coordinate of the atom ν, and $c_{\nu i}$ and $c_{\nu k}$ are the coefficients of the basis function $\varphi_\nu(\mathbf{r})$ in the LCAO—the expansions of the ith and kth molecular orbitals respectively.

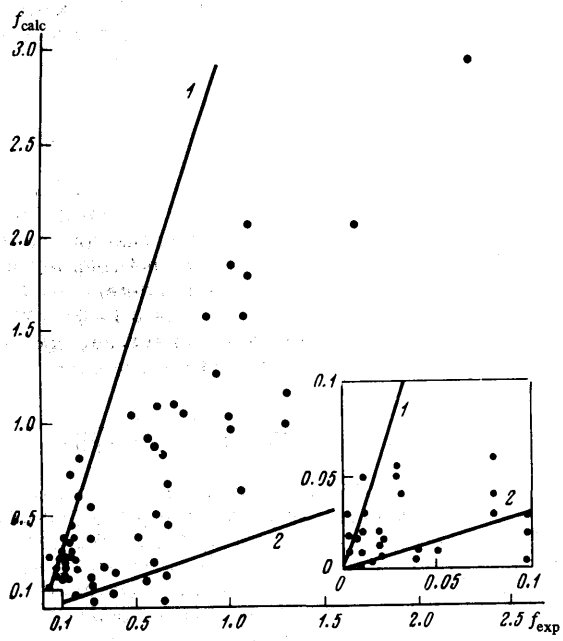

Figure 5. Correlation between the calculated (f_{calc}) and experimental (f_{exp}) oscillator strengths for 86 allowed electronic transitions in conjugated molecules according to the literature[27-36]. The section with $f < 0.1$ is shown separately on an enlarged scale: 1) $f_{calc} = 3f_{exp}$ line; 2) $f_{calc} = \frac{1}{3}f_{exp}$ line.

In the calculation of $\vec{\mu}_{0a}$ the dipole length operator

$$\vec{\mu} = e\sum_i \mathbf{r}_i$$

(summation with respect to all the electrons) was used, and in the matrix element μ_{0a} only the terms diagonal with respect to the atomic orbital indices were retained:

$$\int \varphi_p(\mathbf{r})\,\mathbf{r}\,\varphi_\nu(\mathbf{r})\,d\mathbf{r} \simeq \delta_{p\nu}\,\mathbf{R}_\nu.$$

In this formula the approximate equality $\varphi_p(\mathbf{r}) \simeq \chi_p(\mathbf{r})$, where $\chi_p(\mathbf{r})$ is the atomic orbital of the pth atom, was used. In fact (see Section II above) the orthogonal basis functions $\varphi_p(\mathbf{r})$ represent superpositions of the atomic functions $\chi_i(\mathbf{r})$, so that this approximation neglects all terms with the overlap integrals of the atomic function $\chi_i(\mathbf{r})$. As a result, the dependence of the oscillator strengths on the type of atomic functions is lost.

The development of experimental methods for the investigation of excited singlet and triplet molecular states and the important role of these states in the elementary steps of chemical and photochemical reactions should stimulate the development and improvement of theories of electronic transitions. In the calculation of transition probabilities (oscillator strengths) it is apparently necessary to describe very accurately the real (ground and excited) states of the system: account must be taken of changes in the geometry (bond length) of the molecules in the excited state and of the vibrations of the nuclei.

We shall now consider a series of studies[67-69] in which the effect of temperature on the probability of the electronic excitation and ionisation of complex molecules was investigated. As a result, a criterion was obtained for the determination of the true ionisation potential from the ionisation curve (the variation of the ion current with the energies of the photons which dislodge an electron from the molecule). This criterion is suitable for the determination of the position of the line of 0—0 transitions in the absorption spectra of complex conjugated molecules with unresolved vibrational structure and has in fact been used for this purpose[70].

The extent to which the interelectron interaction is taken into account is also of definite importance in the calculation of oscillator strengths. Thus the inclusion of doubly excited configurations in the calculation altered f_{calc} severalfold[56-58]. However, whereas in some studies[56,57] these changes improved the agreement with experiment, in one investigation[58], for other types of molecules, the agreement with experiment was impaired to such an extent that the results of the calculation were not even quoted.

Certain possible ways of improving the theory of oscillator strength have been analysed in a series of studies[71-73]. In the first of these[71] it was suggested that the gradient operator instead of the dipole length operator should be used in the calculation of f. The oscillator stengths calculated by the two procedures are

$$f_1 = \frac{2}{3}|M|^2\Delta,\quad f_2 = \frac{2}{3\Delta}|G|^2,$$

where

$$M = \left\langle\psi_0\left|\sum_i \mathbf{r}_i\right|\psi_A\right\rangle a_0^{-1},\quad \Delta = (E_A - E_0)\cdot\frac{a_0}{e^2},$$

(a_0 is the Bohr radius and e the electronic charge) and

$$G = \left\langle\psi_0\left|\sum_i \nabla_i\right|\psi_A\right\rangle a_0.$$

For the exact wavefunctions of the initial (ψ_0) and final (ψ_A) states with the energies E_0 and E_A, the equality $f_1 = f_2$ should hold. This equality does not hold for approximate variational functions involved in the theory of conjugated systems. It has been found[71-73] that, for benzene, ethylene, polyenes, and polyacenes, we always have

$f_1 > f_2$ and $f_1 > f_{exp}$. As a result, the use of f_2 instead of f_1 improved the agreement with experiment (Table 9). This agreement is fortuitous, since as a rule $f_2 < f_{exp}$ and the differences between f_2 and f_{exp} are also not small.

The reasons for the unsatisfactory situation in the theory as regards the calculation of oscillator strengths have been discussed[74,75]. It was suggested that the failures are caused by the employment of a finite basis set of atomic functions and the neglect of correlation effects in the wavefunctions (this disagrees with the results of studies[56-58] where an effect of doubly excited configurations on f_{calc} was noted). In this connection it is suggested that the approximation of random phases, which combines the simplicity of molecular orbital methods with allowance for correlation effects, be used. The random phase approximation has already been employed in the calculation of oscillator strengths[76-79]. However, in one study[76] a satisfactory parallel variation of f_{calc} with $\lg \epsilon$ was merely noted and in others[77-79] no comparison with experiment was made.

Table 9. The calculated (f_1 and f_2) and experimental (f_{exp}) oscillator strengths for certain allowed transitions in a number of molecules[71-73].

Molecule	f_1	f_2	f_{exp}	Molecule	f_1	f_2	f_{exp}
ylene	0.597	0.272	0.29	Hexatriene	2.312	0.446	~0.7
Benzene	2.369	0.945	0.88	Naphthalene	0.53	0.18	0.11
Butadiene	1.423	0.35	0.55		2.10	0.87	1.2
				Anthracene	2.77	1.21	1.6

Analysis of the solutions of certain model problems[74,75] has shown that in most cases $f_1 > f_{exact}$ and $f_2 < f_{exact}$. However, for different types of transitions, a wide variety (as regards sign and magnitude) of deviations of f_1 and f_2 from f_{exact} may be encountered. As mentioned by Dancz and Harris[75], there exists an infinite set of operators, apart from the dipole length and velocity operators, which yield the same oscillator strength f_{exact} in calculations using exact functions. In calculation with variational functions, which are not solutions of the Schrödinger equation, all these operators yield different f_{calc}: $f_1 \neq f_2 \neq \ldots \neq f_{exact}$. We believe that, in order to overcome this difficulty in a theory in which the matrix elements of operators and not wavefunctions are used, it is necessary to make sure that the matrix elements are chosen in accordance with commutative relations for the operators. For example, operators for the momentum $\hat{p} = i\hbar(\partial/\partial \bar{r})$ and the coordinate $\bar{r}$ satisfy definite commutative relations and therefore the choice of the parameters p_{mn} and r_{mn} must not conflict with these relations. With this choice of parameters, it is possible to minimise the inaccuracies associated with the employment of variational functions on a limited atomic orbital basis set. Interesting possibilities for a correct choice of parameters p_{mn} and r_{mn}, which are used in calculation of f_2 and f_1, were demonstrated by Linderberg[80]. We believe that the approach to the problem of oscillator strengths from such general standpoints will make it possible to develop a scheme (which is not at present available) for the determination of parameters, including consistently calculated oscillator strengths and other characteristics of molecular systems.

New Reactions of *N*-Methylated Oxopurines

E.S.Golovchinskaya

The reactions of *N*-methylated oxopurines with phosphorus chlorides, resulting in the formation of highly reactive amidochloride compounds (amidochlorides or adducts), are described. Two isomeric series of $C_{(2)}$- or $C_{(6)}$-substituted oxopurine derivatives as well as $C_{(6)}$- or $C_{(2)}$-iminopurines can be obtained from such compounds.
The properties and characteristics of the compounds, their structures, and the demethylation reactions of the amidochlorides and the adducts, accompanied by the elimination of methyl chloride, are discussed.

I. INTRODUCTION

The synthesis of various derivatives of *N*-methylated xanthines (2,6-dioxopurines) from natural purine alkaloids (theobromine, theophylline, and caffeine) has been for a long time one of the popular ways of seeking new medicinal preparations, mainly with cardiovascular activity, in the purine series.

Hitherto, the protons at the $N_{(1)}$ or $N_{(7)}$ atoms in 3,7-dimethyl-or 1,3-dimethyl-xanthines (theobromine or theophylline)[1] as well as the hydrogen linked to the $C_{(8)}$ carbon atom of the imidazole ring in all three purine alkaloids[2] were usually substituted by various groups for this purpose.

The substitution at ring nitrogen and carbon atoms does not entail a change in the xanthine structure. Therefore new sometimes extremely valuable properties, appearing as a result of the introduction of additional substituents, are always manifested against the background of the manifold pharmacological activity characteristic of the initial purine alkaloids, although individual aspects of this activity may vary within fairly wide limits.

Such studies were begun as early as 60—70 years ago. Nevertheless, they cannot be regarded as exhausted: the literature of the last decade contains numerous examples of the synthesis of previously unknown theobromine, theophylline, and caffeine derivatives as well as certain monomethylxanthines, which, although not fundamentally different from those described earlier, contain substituents with a more complex structure, frequently simultaneously in the 1-, 7-, and 8-positions.

Reactions of *N*-methylated xanthines which lead to the loss of the xanthine structure and hence of the set of pharmacological properties characteristic of this structure have also been known for a long time. One of the clearest examples of this is provided by the interaction of theobromine with phosphoryl chloride in a closed system at a high temperature, described for the first time by Fischer as early as the end of the last century, which leads to the elimination of the methyl in the 3-position and to the formation of 2,6-dichloro-7-methylpurine, from which it is subsequently easy to obtain various derivatives of 7-methylpoxanthine and oxygen-free purine, as well as paraxanthine, its derivatives, and many other compounds[1,3,4].

Although the mechanism of this reaction has been little investigated and has remained obscure until recently, the principles underlying it subsequently acquired considerable preparative value, since the synthetic possibilities in the purine series were greatly extended with the aid of similar reactions[5].

Studies dealing with the reactions of theobromine with phosphorus chlorides under milder conditions than those described by Fischer have been published since 1962. Such reactions lead to the formation of various derivatives of 6- or 2-oxodihydropurines retaining both methyl groups in the 3- and 7-positions—compounds which differ significantly in their structure and in their chemical and physical properties not only from methylated xanthines but also from all other purine derivatives described previously. These extremely reactive compounds can be of considerable interest as a new potential source of biologically active compounds.

The present review deals with problems of their synthesis and structure and also with certain aspects of the mechanism of their formation.

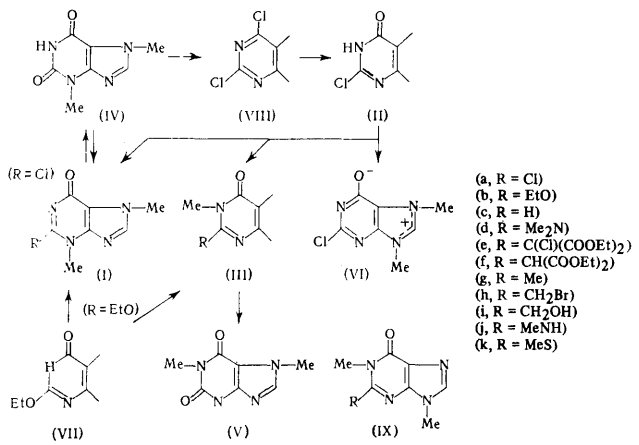
II. DERIVATIVES OF DIHYDRO-3,7-DIMETHYLMONOXOPURINES

1. Synthesis of $C_{(2)}$-Substituted Derivatives of 3,7-Dimethylhypoxanthine (3,6-Dihydro-3,7-dimethyl-6-oxopurine)

The first representative of the 3,7-dimethylhypoxanthine (I) series, namely 2-chloro-3,7-dimethylhypoxanthine (Ia), was recently isolated[6] as one of the side products in the methylation of 2-chloro-7-methylhypoxanthine (II) to form 2-chloro-1,7-dimethylhypoxanthine (IIIa), which, like (II), is an intermediate in the conversion of theobromine (IV) into paraxanthine (1,7-dimethylxanthine) (V).[3,4] This reaction has been known for a long time. 2-Chloro-6-oxo-7,9-dimethylpurinium betaine (VI), which is stable on heating with inorganic acids, is yet another side product in the methylation of (II) by dimethyl sulphate (DMS) in an aqueous alkaline medium[7]. It is formed as the main product when the reaction is carried out in dimethylformamide (DMF).[8]

2-Chloro-3,7-dimethylhypoxanthine (Ia), which is readily hydrolysed to theobromine, is converted on treatment with sodium ethoxide into the 2-ethoxy-derivative (Ib), identical with the side product isolated in a small amount in the analogous methylation of 2-ethoxy-7-methylhypoxanthine (VII).[9]

A single-stage preparative method for the synthesis of the key chloride (Ia) directly from theobromine was discovered somewhat later. A 1:10 mixture of theobromine and $POCl_3$ is heated until the former dissolves, the excess $POCl_3$ is distilled off, and the residue is treated with ice in the presence of $NaHCO_3$. Apart from the chloro-derivative (Ia), about 10% of 2,6-dichloro-7-methylpurine (VIII) can be isolated in this reaction[5]. If the treatment with ice is carried out in the absence of $NaHCO_3$, i.e. at a low pH, the entire chloro-derivative formed hydrolyses and the initial theobromine (IV) is regenerated (see below).

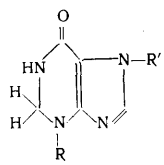


The above easy method of synthesising the chloro-derivative (Ia) and the high mobility of its chlorine atoms made it possible to synthesise many derivatives of 3,7-dimethylhypoxanthine substituted in the 2-positions by various groups [for example compounds (Ib)—(Ik) and many others][10,11], in which the presence of the methyl group in the 3-position fixes one of the double bonds of the pyrimidine ring in the 1,2-positions. Owing to the *p*-quinonoid structure of the ring due to the distribution of the substituents, the entire series of compounds (I), probably differs fairly significantly in its properties from compounds of the 2-R-1,9-dimethylhypoxanthine series (IX) and (III) with the same substituents R,[12-14] i.e. from the isomeric 2-substituted derivatives of *NN*-dimethylhypoxanthines with a "normal" bond distribution.

The characteristics of compounds (I), due to the high electrophilicity of the second ring carbon atom, have been noted in many reactions. They are shown by the enhanced reactivity of the substituents at this carbon atom, which is particularly evident in certain reactions of the chloro-derivative (Ia): it is not only exceptionally readily hydrolysed with elimination of chlorine at low pH, but it also undergoes nucleophilic substitution reactions when treated with alkoxides, ammonia, primary and secondary amines, and other nucleophilic agents, much more vigorously than the isomeric 2-chloro-1,9- and 2-chloro-1,7-dimethylhypoxanthines (IXa) and (IIIa). Such reactions of compound (Ia) usually do not require heating and actually occur with evolution of heat.

The system of compounds (I) as a whole exhibits an enhanced reactivity. This is shown, in particular, by the fact that the catalytic dehalogenation of (Ia) in the presence of Pd/C or Raney nickel results in the formation of a mixture of the expected compound (Ic) and its dihydro-derivative—1,2,3,6-tetrahydro-3,7-dimethyl-6-oxopurine (X).[10]

The catalytic debenzylation of 3-benzyl-7-β-D-ribofuranosylhypoxanthine, i.e. a compound which does not differ from (Ic) in the distribution of the double bonds in the pyrimidine ring, resulted in a mixture of 7-β-D-ribofuranosylhypoxanthine and a dihydro-derivative of the initial compound, which should be regarded as 3-benzyl-1,2,3,6-tetrahydro-6-oxo-β-D-ribofuranosylpurine (XI) on the basis of the results of a study of the ^1H NMR spectra[15].



(X, R+R′=Me)

(XI, R = $PhCH_2$, R′ = β-D-ribofuranosyl

Comparison of the abilities of 2-ethoxy-derivatives of three *NN*-dimethylhypoxanthines (the 3,7-, 1,7-, and 1,9-dimethyl derivatives) to function as ethylating agents with respect to malonic ester by splitting off their ethoxy-group (which is described in greater detail in another review[2]) demonstrates yet again that the isomer (Ib), containing *N*-methyl groups in the 3- and 7-positions, is the most reactive and forms ethylmalonic ester in a high yield. Data obtained by quantum-chemical calculations for the electronic structures of (Ib), the isomeric compounds (IIIb) and (IXb), their 8-chloro-derivatives, and three dimethylmonoxopurines unsubstituted at $C_{(2)}$ and $C_{(8)}$ [compounds (Ic), (IIIc), and (IXc)] confirmed that the electron density and the free valence index at $C_{(2)}$ in 3,7-dimethyl-6-oxopurines are appreciably reduced and therefore compound (Ib) and its 8-chloro-derivative should indeed exhibit the maximum alkylating capacity[16]. It has also been noted that the dialkylamino-group in the 2-position in compounds of type (Id) is readily hydrolysed in the presence of inorganic acids with regeneration of theobromine[2,17].

The replacement of chlorine in compound (Ia) by a dialkylamino-group and its subsequent hydrolytic elimination in the last stage can be used in the synthesis of $C_{(8)}$—C derivatives of theobromine as a method of protecting the proton at the first nitrogen atom[18].

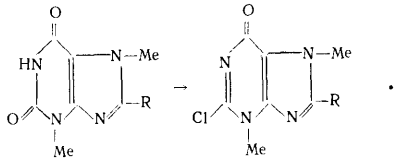
Not only the Cl—$C_{(2)}$ and N—$C_{(2)}$ bonds but also the C—$C_{(2)}$ bond can readily undergo hydrolytic cleavage in compounds (I). An example of this reaction is provided by the formation of theobromine as a result of heating 2-chloromalonate (Ia) with inorganic acids[19].

It is interesting that the $C_{(2)}$—C bond in 1,7- and 1,9-dimethylhypoxanthines with chloromalonic acid groups [compounds (IIIe) and (IXe)] does not undergo cleavage and the main reaction products are the corresponding 2-hydroxymethyldimethylhypoxanthine (IIIi) or 2-chloromethyldimethylhypoxanthine (IXi).[13,14]

In derivatives of compounds (I) the $C_{(2)}$—C bond is not cleaved when the malonic acid residue does not contain chlorine: in compound (If) only the ester groups are hydrolysed with decarboxylation. 2,3,7-Trimethylhypoxanthine (Ig) was obtained in this way and was subsequently converted by treatment with dibromodioxan into the monobromo-derivative (Ih). A wide variety of compounds can be obtained from the latter on replacing the bromine by various substituents (including groups with a complex structure). When the purinylmalonate (If) is treated with ethanol in the presence of catalytic amounts of hydrogen

chloride, only one ethoxycarbonyl group is split off. The resulting ethyl ester of 3,7-dimethylhypoxanthine-2-acetic acid was converted into its amides by treatment with ammonia and amines[19].

The series of compounds with structure (I), whose synthesis is based on the reaction of theobromine with $POCl_3$, can be greatly extended by introducing a second substituent at the $C_{(8)}$ atom of the imidazole ring. For this purpose, instead of theobromine one may treat with $POCl_3$ its 8-substituted derivatives—8-chlorotheobromine (XII) or 8-methyltheobromine (XIII)—which are thereby converted into the dichloro-derivative (XIV) or into 2-chloro-3,7,8-trimethylhypoxanthine (XV).[20-22] The use of the former leads to the greatest possibilities: by successive substitution of the chlorine atoms, initially at $C_{(2)}$ and then at $C_{(8)}$, it is possible to vary the nature of the substituents at the ring carbon atoms in both rings of the purine molecule.



(XII, R=Cl) (XIV, R=Cl)
(XIII, R=Me) (XV, R=Me)

The above reactions of 8-chlorotheobromine and the synthesis from it of 2,8-disubstituted derivatives of 3,7-dimethylhypoxanthine result in relative freedom from restrictions on the structure of the substituents at $C_{(8)}$, while that of the substituents at $C_{(2)}$ may sometimes be subject to limitations due to the characteristics of the system, mentioned above, probably due to its *p*-quinonoid structure.

On the other hand, syntheses from 8-methyltheobromine provide a considerable scope for the preparation of 3,7,8-trimethylhypoxanthines with a wide variety of substituents in the 2-position. However, the attempts to modify subsequently the substituent at $C_{(8)}$ by replacing one of the hydrogen atoms of the methyl group by a halogen[2] were unsuccessful. Nor is it always possible to employ as starting materials 8-substituted theobromine derivatives with a specified structure of the substituent at $C_{(8)}$ joined to the ring via a C—C bond; such compounds char appreciably on heating with $POCl_3$.[17,22]

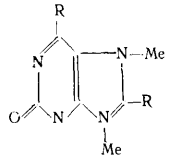
Derivatives of 3,7-dimethylhypoxanthine differ from the isomeric 1,7- and 1,9-dimethylhypoxanthines not only in their chemical properties but also in their physical properties[10]. For example, the ultraviolet spectrum of (Ia) exhibits an 8 nm bathochromic shift of the long-wavelength maximum accompanied by an increase of ϵ relative to the ultraviolet spectrum of the chloro-derivative (IIIa); a similar shift is characteristic of the majority of compounds (I) obtained from the chloro-derivative (Ia) as a result of the replacement of its chlorine atom by other substituents. Comparison of the infrared spectra of the isomeric 3,7- and 1,7-dimethylhypoxanthines shows clearly in the latter a shift of the characteristic bands of the amide carbonyl towards longer wavelengths, in full agreement with data[23] indicating a decrease of the C—O vibration frequency in purines having the *p*-quinonoid structure relative to other purine derivatives.

Certain characteristics of compounds of type (I) arising from their structure are not typical for this series alone (cf. Refs. 24—26). They are typical to some extent for many purines, including those substituted at the nitrogen atoms of the pyrimidine ring, but not for 6- or 2-aminopurines unsubstituted in the imidazole ring. Such aminopurines have been obtained in different ways, for example by direct alkylation or glucosidation of adenine[27-31], *N*-benzoyladenine, or 6-dimethylaminopurine[32], by synthesis from the corresponding 4,5-diaminopyrimidines[33-35], or from 3-methylguanine by the reaction of the latter with P_2S_5 and subsequent alkylation of the resulting 2-amino-6-mercapto-3-methyl-3,6-dihydropurine and substitution of the alkylthio-group in the 6-position by various groups[26,32].

It has been shown convincingly by ultraviolet spectroscopy and ^1H NMR that these compounds exist in the amino- and not in the imino-form and that consequently substitution at $N_{(1)}$ or $N_{(3)}$ should be accompanied by the transfer of a proton from the imidazole ring of the aminopurines to the pyrimidine ring and migration of double bonds, which results in an *o*- or *p*-quinonoid structure of the purine stabilised by the substituent at the ring nitrogen atom. These and many other purine compounds with an unusual fixed distribution of double bonds differ from purine derivatives having the "classical" structure by their chemical behaviour and spectroscopic characteristics. These differences are shown particularly clearly when there is a substituent at the $N_{(3)}$ atom and in most cases they are very similar to the differences characteristic of compounds of series (I), which were mentioned above. It is self-evident that substitution at the nitrogen atom of the imidazole ring of aminopurines is not reflected in the state of the system, since it involves merely a simple replacement of the proton and does not entail changes in the distribution of double bonds[36].

2. Synthesis of $C_{(6)}$-Substituted Derivatives of 2,3-Dihydro-3,7-dimethyl-2-oxopurine

The applications of the reaction of theobromine with phosphoryl chloride are not limited to the synthesis of compounds of series (I). This reaction is also used to synthesise certain isomeric derivatives of the 6-R-2,3-dihydro-3,7-dimethyl-2-oxopurine series (XVI). 8-Chloro- and 8-methyl-derivatives of (XVI) [compounds (XVII) and (XVIII)] can be obtained similarly from the 8-chloro- and 8-methyl derivatives of theobromine [(XII) and (XIII)].



(a, R = MeO)

(h, R = Me_2N)
(i, R = Cl)

(XVI; R=H); (XVII; R=Cl);
(XVIII; R=Me)

6-Alkoxypurines (XVI, a—d) have been obtained by treating with the corresponding alcohols the product of the reaction of theobromine with $POCl_3$ and subsequent hydrolysis with $NaHCO_3$ solution[37].

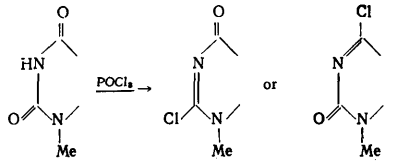
The structures of these compounds have been confirmed by many reactions and that of compound (XVIb) has been demonstrated unambiguously by its identification with the compound obtained by allowing sodium ethoxide to react with 1,2-dihydro-3,7-dimethyl-6-methylthio-2-oxopurine (XVIe) known previously under the trivial name "6-methylthiotheobromine"[38,39]. When compound (XVIb) was heated with ammonia, methylamine, and dimethylamine, the corresponding 6-amino-derivatives (XVIf), (XVIg), and

(XVIh) were obtained, the last two being identical with the compounds synthesised by allowing the same amine to react with compound (XVIe).[40]

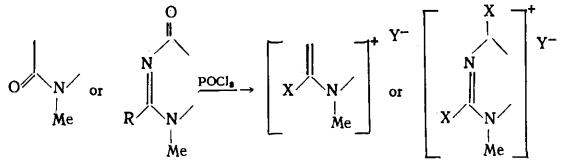
It is noteworthy that the properties of compound (XVIa) agree fully with those described for dihydromethoxy-3,7-dimethyloxopurine obtained by the methanolysis of the tetra-acetate of theobromine β-D-glucoside[41].

The above syntheses are not merely of preparative value. They throw light on the essential features of the reactions, occurring when *N*-methyloxopurines are heated with $POCl_3$ and also on certain problems concerning the structures of the primary products of these reactions (this is discussed in greater detail in Section III).

Depending on the method of treatment of the residue obtained after distilling off the excess $POCl_3$ from the reaction mass (treatment with $NaHCO_3$ solution or with alcohol first and only then with aqueous $NaHCO_3$), it is possible to obtain from compound (IV) either the chloro-derivative (Ia) [10] or one of the compounds of type (XVI, a–d),[40] each in a yield exceeding 50%. This undoubtedly shows that the members of both isomeric series, (I) and (XVI), have a common precursor, which is formed by the reaction of both carbonyl groups with $POCl_3$. One of them (probably either one) should react with $POCl_3$, by virtue of the presence of a proton at the neighbouring ring nitrogen atom, via the general mechanism of the conversion into the corresponding chloro-derivative of 2- and 4-oxo-(hydroxy)pyrimidines[42], α-oxo(hydroxy)purines[1], and also oxo(hydroxy)-derivatives of other nitrogen heterocycles:

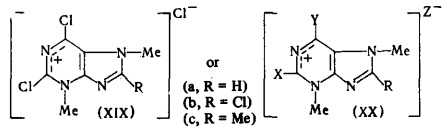


The second carbonyl probably reacts with $POCl_3$ as an *N*-substituted cyclic amide, which may result in the formation of a fairly stable compound containing the amidochloride group[43]:



(where X and Y are both Cl or Cl and $OPOCl_2$)

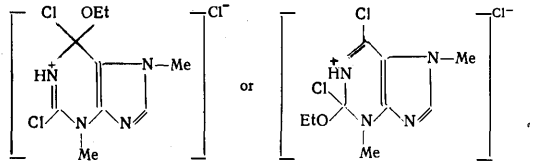
Since each carbonyl group of theobromine or its derivatives (XII) and (XIII) is probably capable of reacting in either way, the primary products of their interaction with $POCl_3$ are compounds (XIX) or (XX):



(X, Y and Z = Cl or Cl and $OPOCl_2$)

The presence of amidochloride groups in these compounds has been confirmed by numerous reactions[43], primarily by their ability to combine with an alcohol molecule to form the hydrochlorides of amidoester chlorides.

In the present instance the crystalline substances formed when alcohols are allowed to react with the products of the reaction of (IV), (XII), or (XIII) with $POCl_3$ are of this kind. The overall formula $C_9H_{13}N_4Cl_3O$ of the crystalline compound obtained from (IV) after treatment with ethanol makes it possible to attribute to it the structure of the hydrochloride of 2,6-dichloro-6(or 2)ethoxy-3,6(or 2,3)-dihydropurine [(XXI) or (XXII)]:



Many reactions of this compound—hydrolytic cleavage at low pH, aminolysis, interaction with thiourea, etc.—are consistent with both structure (XXI) and (XXII) and there are no grounds for making a choice between them, since in either case the same products should be obtained: theobromine, the hydrochloride of 6(2)-amino-3,6(3,2)-dihydro-2(6)-imino-3,7-dimethylpurine and 2,6-dithiotheobromine[44]. On the other hand, the formation from it of 6-ethoxy-2,3-dihydro-3,7-dimethyl-2-oxopurine (XVIb) on hydrolysis in a neutral medium undoubtedly indicates that the ethoxy-group is at $C_{(6)}$, i.e. there is evidence that the compound has the structure (XXI). This is also shown by another reaction characteristic of amidoester chlorides, namely the thermal cleavage of the ester chloride group accompanied by the evolution of an alkyl chloride and the regeneration of the initial amide[43].

When the above amidoester chloride is heated, ethyl chloride is liberated and the chloro-derivative (Ia) is formed in a high yield. Since the fragment C(Cl)(OEt) must be the precursor of the carbonyl group, the formation of the chloro-derivative (Ia) as a result of the thermal cleavage constitutes yet another confirmation of the presence of the ethoxy-group in the amidoester chloride at $C_{(6)}$ and not at $C_{(2)}$, i.e. of structure (XXI) rather than (XXII).

On the other hand, the formation of the amidoester chloride (XXI) from the amidochloride compound (XIXa) or (XXa) suggests that the ring carbon atom $C_{(6)}$ in the latter is more electrophilic than $C_{(2)}$ and that consequently the substituents in the 6-position in (XIX) and (XX) should undergo hydrolytic cleavage first, with regeneration of the carbonyl group. Therefore it is quite reasonable that hydrolysis at pH 7 of the intermediates obtained from theobromine on heating the latter with $POCl_3$ results in the formation of the monochloromonoxopurine (Ia) as the main product, both substituents (at $C_{(6)}$ and $C_{(2)}$ atoms) undergoing hydrolytic cleavage only under more severe conditions (pH 2–3).

This sequence in the hydrolytic cleavage of the intermediate does not, however, rule out the probability of the simultaneous formation in the hydrolysis also of a certain amount of another monoxopurine, namely the isomeric 6-chloro-2,3-dihydro-3,7-dimethyl-2-oxopurine (XVIi). In practice it proved impossible to isolate this compound from the reaction mass (see below), but the study of similar reactions with 8-substituted theobromine derivatives, (XII) and (XIII), showed that 2-chloro-6-oxopurines (XIV) and (XV) are not the only products of hydrolytic cleavage at pH ~7 of the intermediates (XIX, b and c) or (XX, b and c) and that the formation of small amounts of the isomeric 6-chloro-2-oxo-derivatives (XVIIi) and (XVIIIi) does indeed occur[20,22].

It was also impossible to isolate 6,8-dichloro-2-oxopurine (XVIIi) in a pure state after hydrolysis, but its presence in the unpurified dichloro-derivatives (XIV) was demonstrated chromatographically and confirmed by the

formation of the 6-ethoxy-derivatives (XVIIb) in the reaction with sodium ethoxide. It was identified with specimens of the compound (XVIIb) obtained in two ways: by treating (XVIb) with sulphuryl chloride[45] and by the hydrolysis of the 8-chloro-derivative of the amidoester chloride (XXI).[20] Both isomeric monochloro-oxo-3,7-dimethylpurines ($C_8H_8ClN_4O$) were comparatively readily isolated in 43 and 9% yields only in the reaction of 8-methyltheobromine (XIII) with $POCl_3$. The former was characterised as the 2-chloro-6-oxo-derivative (XV) and the latter proved to be 6-chloro-2-oxopurine (XVIIIk). As a result of the substitution of chlorine by other groups, they gave rise to two series of compounds—8-methyl derivatives of (I) and (XVIII).

The ultraviolet spectra of compounds (I) and their 8-methyl derivatives with the same substituent R proved to be very similar, just as the ultraviolet spectra of (XVI) and (XVIII) are similar, differing from the former pair by the bathochromic shift of the long-wavelength maximum. Possibly this can be accounted for by the presence in these compounds of the straight conjugation chain $O{=}C_{(2)}{-}N{=}C_{(6)}R{-}C_{(5)}{=}C_{(4)}{-}N{=}C_{(8)}$.[20] The study of the ultraviolet spectrum of unpurified (Ia), isolated directly in the hydrolytic reaction at pH 7 of the product of the interaction of theobromine with $POCl_3$, suggests that in this case a small amount of a second isomer, i.e. (XVIi), can nevertheless be formed in the course of the hydrolysis. The isomer (XVIi) probably cannot be isolated from the reaction mixture because it is formed in comparatively small amounts and, by virtue of its high reactivity, is completely hydrolysed to theobromine[46].

III. AMIDOCHLORIDE DERIVATIVES OF THE PURINE SERIES

1. Phosphorodichloridates and Their Structure

The ability of theobromine and its 8-substituted derivatives to be converted on heating with $POCl_3$ into compounds of the amidochloride type† is not a distinctive feature of 3,7-dimethyldioxopurines. It is characteristic also of other oxopurines methylated at $N_{(1)}$ or $N_{(3)}$, which react with phosphorus chlorides in the form of cyclic *N*-methylamides[47-49].

The properties of amidochlorides and adducts of the amidochloride type have been investigated in comparative detail only recently. The initial objects of these investigations were DMF and other aliphatic acid amides[50,51] and then cyclic *N*-substituted lactams—1-methylpyridone, 1-methylquinolone, etc.[52] In 1966 an adduct obtained from 4-dimethylamino-1,3-dimethyluracil was described[53]. The hypothesis of the formation of cyclic amidochlorides or adducts as a result of the reaction of $POCl_3$ with *N*-methyloxopurines was put forward somewhat earlier[47] and the first experimental data confirming it were published.

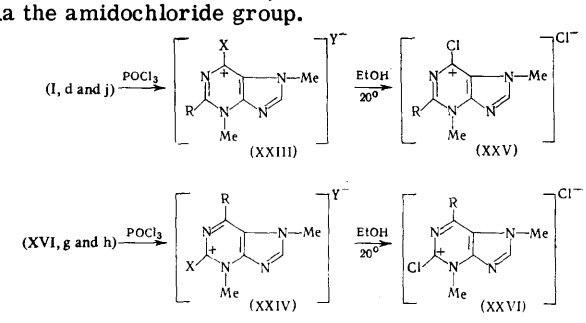
† In this review the name amidochlorides is given only to the true amidochlorides having the general structure [N—C(Cl)—]$^+$Cl$^-$, for example compound (XIX), while all the amidochloride products obtained by the addition of acid chlorides to *N*-methyloxopurines will be referred to by the general term adducts. These therefore include the phosphorodichloridates [N—C(X)—]$^+$Y$^-$ (X and L = Cl and $OPOCl_2$) formed as a result of the addition of $POCl_3$ to *N*-methyloxopurines for example (XX).[43]

Depending on the nature of the initial *N*-methylated oxopurine, the products of the reactions with $POCl_3$, isolated from the reaction mass on cooling the latter or after partial distillation of $POCl_3$, may be amidochlorides or, as happens in most cases, the phosphorodichloridates [—N(Me)—C(X)—]$^+$Y$^-$ or [—N(Me)—CR=N—C(X)—]$^+$Y$^-$ (X and Y = Cl and $OPOCl_2$). The reaction product is sometimes a mixture of the amidochloride and the phosphorodichloridate[48,49,54].

The conversion of 1,9- and 3,7-dimethylxanthines (2,6-dioxopurines), their 8-substituted derivatives, and 2-chloro-derivatives of 1,9- and 3,7-dimethylhypoxanthines (IX, R = Cl) and (Ia) into phosphorodichloridates requires fairly prolonged refluxing with $POCl_3$. For other monooxopurines, for example, 6-R-2,3-dihydro-3,7-dimethyl-2-oxopurines (XVI), heating at 50—60°C for 5—30 min is sufficient, while the majority of the isomeric 2-R-3,7-dimethylhypoxanthines (I), with the exception of the chloro-derivative (Ia), react vigorously with $POCl_3$ at 20°C, the reactions in many instances occurring with spontaneous evolution of heat[54].

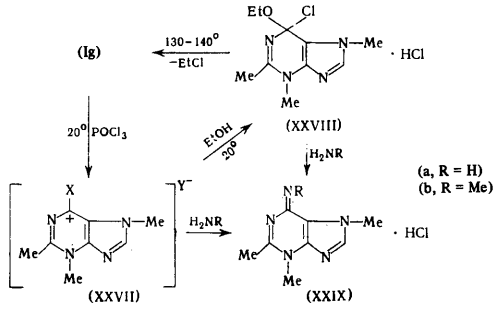
Purine phosphorodichloridates and amidochlorides are crystalline substances, almost insoluble in non-polar solvents and usually fairly and sometimes very soluble in $POCl_3$. Therefore the isolation of the phosphorodichloridates from the reaction solutions obtained as a result of the reflexing of *N*-methyloxopurines with $POCl_3$ sometimes involves appreciable difficulties. In particular, the phosphorodichloridate (XXa), formed when theobromine is refluxed with $POCl_3$, cannot be isolated from the reaction solution. It has to be converted, by being passed through a solution of hydrogen chloride, into the less soluble amidochloride (XIXc), which crystallises from the solution. To obtain the phosphorodichloridate (XXa) in a pure state and to characterise it, the purified chloro-derivative (Ia) was made to react briefly with a small amount of $POCl_3$ at a moderate temperature (60—80°C).[46] The crystalline adduct (XXa) formed is hydrolysed at pH ~7 to the initial chloro-derivative (Ia), exactly like the overall product of the reaction of compound (IV) with $POCl_3$, obtained after the distillation of the latter from the reaction solution.

Like other adducts of the purine series, the phosphorodichloridates have the properties of the amidochlorides. One of these, the ability to combine with an alcohol molecule and be converted thereby into the hydrochlorides of amidoester chlorides, does not, however, extend to all purine phosphorodichloridates. For example, those which have been obtained from the isomeric 2- and 6-methylamino-derivatives of 3,7-dimethyloxopurines [I, d and j) or (XVI, g and h)], i.e. the phosphorodichloridates (XXIII) and (XXIV), react slowly with alcohols at room temperature and are converted into the corresponding amidochloride (XXV) or (XXVI), but do not combine with alcohol via the amidochloride group.

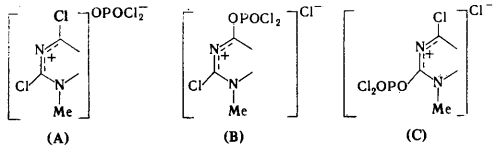


(R = MeNH or Me_2N; X and Y = Cl or $OPOCl_2$

In contrast to these, the phosphorodichloridate (XXVII), obtained from the 2-methyl derivative (Ig) is readily converted on treatment with alcohol into the hydrochloride of the amidoester chloride (XXVIII), which was found to undergo all the reactions characteristic of compounds belonging to this class. Thus, on treatment with ammonia or monoalkylamines, it is converted into the hydrochlorides of 6-amino(or alkylimino)-2,6-dihydro-2,3,7-trimethylpurine (XXIX, a and b) and its ester chloride group is cleaved on heating with evolution of ethyl chloride and the formation of the hydrochloride of the initial oxopurine (Ig).[54]



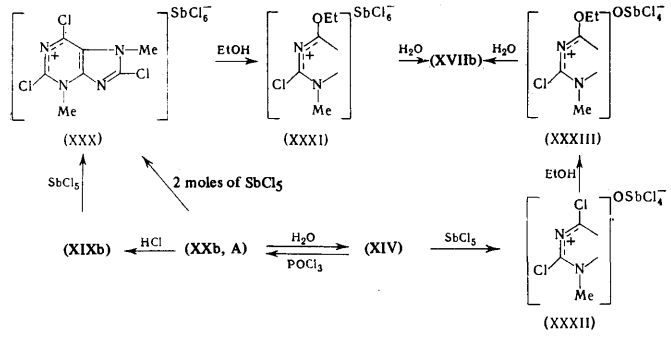
In order to make a choice between the three possible structures of the phosphorodichloridates (XX)—(A), (B), and (C)—a study was made of the interaction of (XXb) with antimony pentachloride[55].



The reaction with two moles of antimony pentachloride led to an almost quantitative yield of the hexachloroantimonate (XXX), i.e. to the replacement of the $\overset{\oplus}{O}POCl_2$ residue by the $SbCl_6$ residue. When the adduct (XXX) was treated with alcohol, one of the chlorine atoms was exchanged for the ethoxy-group and the resulting hexachloroantimonate of the ethoxy-derivative, i.e. the adduct (XXXI), was converted as a result of hydrolysis in a neutral medium into the known compound (XVIIb). These last two reactions also take place with high yields.

Analysis of the quantitative aspects of the above reactions—the theoretical yield of the hexachloroantimonate (XXX) and the high yields of compounds (XXXI) and (XVIIb) obtained from it—permitted the conclusion that the initial phosphorodichloridate (XXb) is a pure compound and not a mixture of the isomers (A), (B), and (C) and that the $SbCl_6$ residue in compound (XXX) and hence the $OPOCl_2$ residue in the initial phosphorodichloridate (XXb) constitute the anionic part of the molecules of these adducts and not a fragment of their cationic component. On the basis of these findings, it is suggested that the phosphorodichloridate (XXb) most probably has the structure (A), which is in full agreement with current ideas about the structure of the adduct obtained when $POCl_3$ is allowed to react with DMF: $[-HC(Cl)NMe_2]_2OPOCl_2^-$.[56]

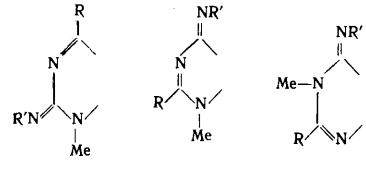
The adduct (XXX) is also formed as a result of the addition of one mole of antimony pentachloride to the amidochloride (XIXb), which in turn is obtained by the reaction of hydrogen chloride with a solution of the phosphorodichloridate (XXb) in $POCl_3$.[55] Yet another antimony-containing purine adduct (XXXII) with the $OSbCl_4$ residue is formed when 2,8-dichloromonoxopurine (XIV) reacts with antimony pentachloride, by analogy with the method of the synthesis from it of the phosphorodichloridate (XXb) by reaction with $POCl_3$.[46] Like the adduct (XXX), it reacts with alcohol, whereby it is converted into the ethoxy-derivative (XXXIII), in which the position of the ethoxy-group at $C_{(6)}$ was confirmed by the formation of (XVIIb) from it. The entire series of the above reactions fits the scheme illustrated below[55,57]:



Phosphorodichloridates, other purine adducts, amidochlorides, and also amidoester chlorides are comparatively stable in the absence of moisture, but are rapidly hydrolysed by water with regeneration of the initial oxopurines. They are particularly reactive in reactions with nucleophilic agents—ammonia, amines, alkoxides, etc.[2]

2. *C*-Iminopurines

Amidochloride compounds of different classes—aliphatic, aromatic, and heteroaromatic—are known to react with ammonia and primary amines to form amidines[50,52,58,59]. In the amidines obtained from purine amidochlorides, adducts, and amidoester chlorides[54] one of the nitrogen atoms forms part of the pyrimidine ring in the purine system.

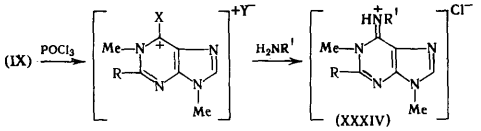


Consequently these amidines are $C_{(2)}$ or $C_{(6)}$-iminopurines, which differ from *C*-aminopurines by their high basicity (pK_a = 10—12, instead of 3—4).

The first iminopurines alkylated at the nitrogen atoms of both rings of the purine system, namely $N_{(1)}$-alkyl-6-iminopurines, were described about 30 years ago. They were obtained from 4-amino-5-cyano-1-methylimidazole[60] or by the alkylation of adenosine, adenylic acid, and other adenine derivatives substituted at the nitrogen atom of the imidazole ring[61–66].

The method of preparation of *C*-iminopurines from *NN*-dimethyloxopurines, based on the intermediate formation of amidochloride compounds and treatment of the latter with ammonia or monoalkylamines[67], has led to new possibilities in the synthesis of this unusual group of purine derivatives. It permits the variation of the structure of the substituents at the exocyclic nitrogen atom by employing a wide variety of primary amines and also the introduction of additional groups at the second ring carbon atom of the pyrimidine part of the molecule.

The first series of iminopurines obtained in this way—the hydrochlorides of 2-R-1,6-dihydro-6-imino-1,9-dimethylpurines (XXXIV)—were synthesised from compounds (IX) in accordance with the following scheme[48,49]:



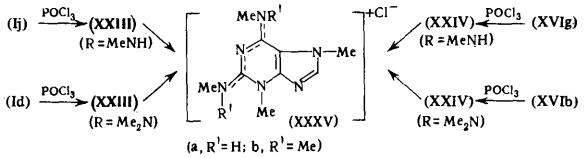
(X and Y = Cl or $OPOCl_2$; R' = H or Me)

The hydrochlorides of $C_{(6)}$- and $C_{(2)}$-imino(or alkylimino)-3,6(or 2,3)-dihydro-3,7-dimethylpurines, including 6-imino-2,3,7-trimethylpurines (XXIX, a and b) mentioned above, were synthesised similarly from 2-R(or 6-R)-3,7-dimethyloxopurines (I) and (XVI).[54]

If the substituent R in (XXIII) and (XXIV) is an amino- or monoalkylamino-group, it is possible to obtain the same aminoiminopurine from the corresponding representatives of two different series—(I) and (XVI). For example, the hydrochloride of 2,6-di(methylamino)-3,7-dimethylpurine (XXXVa) was obtained from (Ij) and (XVIg) by treatment with methylamine[67].

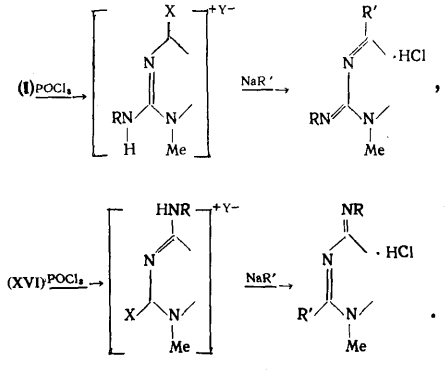
The problem of which exocylic nitrogen atom (at $C_{(2)}$ or at $C_{(6)}$) undergoes protonation in this case remains open.

Under similar conditions, the two isomeric phosphorodichloridates obtained from (Id) and (XVIh) react with dimethylamine to form 2,6-bis(dimethylamino)-3,7-dimethylpurinium chloride (XXXVb).



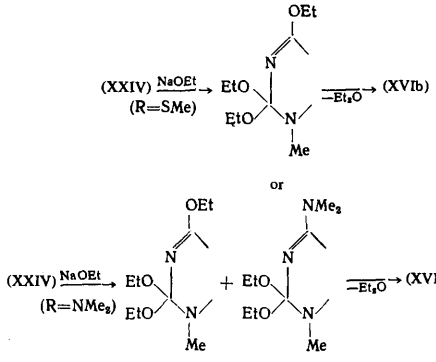
(a, R'=H; b, R'=Me)

This method of synthesis of *C*-iminopurines can be usefully employed to obtain compounds substituted at the second ring carbon atom ($C_{(2)}$ or $C_{(6)}$) by alkoxy-groups or other substituents capable of reacting with $POCl_3$ or of being substituted by amines. The *C*-methyl group also interferes with the reaction, since its presence entails charring of the reaction mass on heating with $POCl_3$. In such cases the synthesis can be carried out in accordance with another, more universal scheme based on the use of *C*-amino- or monoalkylamino-oxopurines as starting materials. The amino-group in the phosphorodichloridates or amidochlorides formed from them plays the role of a potential imino-group, while the labile substituent is introduced into the latter by treatment with nucleophilic agents such as alkoxides, sodiomalonic ester, sulphides, etc.

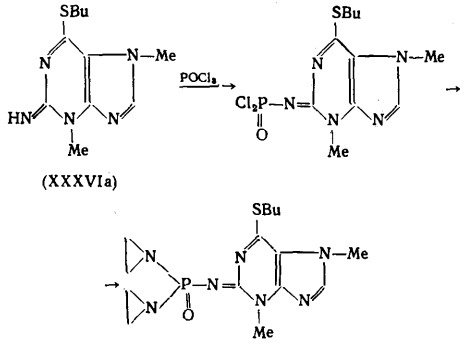


(X, Y=Cl, $OPOCl_2$)

When purine amidochloride or phosphorodichloridate, in which the substituent R is an alkylthio-, dialkylamino-, or other group without a hydrogen atom capable of migrating to form a tautomer, is acted upon by an alkoxide, the final reaction product is the initial oxopurine. Its formation from the amidochloride compound is accompanied by the formation of a dialkyl ether, probably as the result of the cleavage of an unstable intermediate acetal[68]. In such reactions there is a possibility also of a simultaneous replacement of the residue R, linked to $C_{(6)}$, by an alkoxy-group, for example:

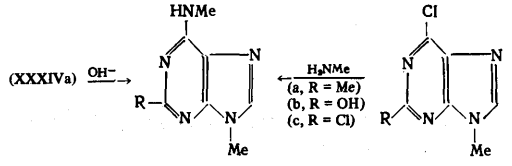


As was to be expected, the *C*-iminopurines, whose basicity is close to that of aliphatic amines, are much more vigorously acylated and, in particular, react much more vigorously with $POCl_3$ than *C*-aminopurine, which are much less basic. Whereas the formation of acid dichlorides of 7(or 9)-methyl-6-phosphoramidopurines requires prolonged heating of the initial $C_{(6)}$-aminopurines with an excess of $POCl_3$,[69] the iminopurine bases, for example (XXIX), (XXXIVa, R = Me), the two isomeric $C_{(6)}$- and $C_{(2)}$-butylthio-2-imino-3,7-dimethylpurines (XXXVIa), and the corresponding 6-imino-derivatives (XXXVIb) react with a calculated amount of $POCl_3$ in methylene chloride at a temperature as low as 15—20°C. A number of diaziridides of *NN*-dimethylpurinylphosphoramidic acids were synthesised in this way for biological tests from the acid dichlorides of *NN*-dimethylpurinylphosphoramidic acids by reaction of the latter with aziridine in the presence of hydrogen chloride acceptors[70]. These reactions are illustrated schematically below using compound (XXXVIa) as an example:



When 6-imino-1,9-dimethylpurines (XXXIV) are heated with a solution of alkali, various reactions take place, which are greatly influenced by the substituent R in the 2-position. Compound (XXXIVa) undergoes the Dimroth rearrangement in an alkaline medium, i.e. is converted into 2,9-dimethyl-6-methylaminopurine (XXXVIIa), which

is identical with the compound obtained from 6-chloro-2,9-dimethylpurine (XXXVIII) and monomethylamine:



(R'=Me) (XXXVII) (XXXVIII)

When monoalkylamino-derivatives (XXXIV, R = NHMe) are acted upon by alkali, there is partial hydrolytic cleavage of the 6-imino-group and the final reaction product consists of a mixture of the initial iminopurines and 2-monoalkylamino-1,9-dimethylhypoxanthines.

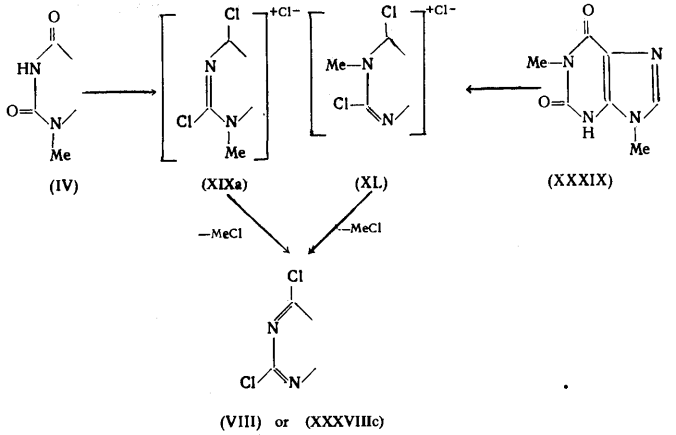
On the other hand, when the dimethylamino-group is present in the 2-position, the reaction product is 2-hydroxy-6-monomethylamino-9-methylpurine (XXXVIIb), since in this case two processes probably take place: the Dimroth rearrangement and hydrolytic elimination of the dimethylamino-group[49].

3. The Cleavage of Purine Adducts and Amidochlorides

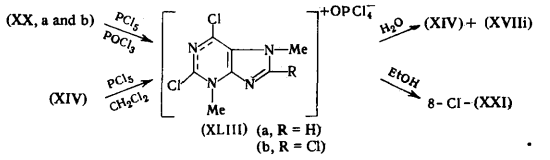
Another feature of *NN*-dialkylamidochlorides, which is of considerable preparative importance together with nucleophilic substitution reactions, is their capacity to undergo cleavage with liberation of an alkyl chloride and to be converted thereby into imidochlorides:

$$Alk_2N{-}CO{-}\rightarrow [Alk_2N{-}C(Cl){-}]^+Cl^- \xrightarrow{-AlkCl} AlkN{=}C(Cl){-},$$

i.e. to undergo the reaction on which a method of dealkylation of dialkylamines, known for a long time, is based[71]. Accordingly, the conversion of theobromine into 2,6-dichloro-7-methylpurine (VIII) and also the analogous conversion of the isomeric 1,9-dimethylxanthine (XXXIX) into 2,6-dichloro-9-methylpurine (XXXVIIIc) [11] can be represented as the demethylation of cyclic *N*-methylamides, which leads to the formation of cyclic iminodchlorides and proceeds with formation of the intermediate amidochlorides (XIXa) and (XL).



The amidochlorides (XIX, a and b) are readily cleaved on heating with $POCl_3$, liberating methyl chloride[57], and are converted at the same time into 2,6-dichloro-7-methylpurines (VIII) and its 8-chloro-derivative (XLI) in high yields. In contrast to these, the phosphorodichloridates (XX, a and b) undergo such cleavage only to a slight extent even on prolonged refluxing with $POCl_3$.

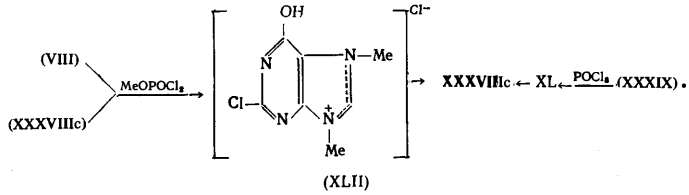


The reason for this difference may be that, on being cleaved, the phosphorodichloridates split off not only the volatile methyl chloride but also the high-boiling methyl phosphorodichloridate ($MeOPOCl_2$), which remains in the reaction sphere and alkylates the imidochlorides formed as a result of the cleavage.

The hypothesis that this ester can alkylate (cf. Lugovkin and Arbuzov[72]) 2,6-dichloropurines was confirmed by the preparation of 8-chlorotheobromine (XII) by heating the trichloride (XLI) with $MeOPOCl_2$ in $POCl_3$ and by the hydrolysis of the product:

$$(XLI) + MeOPOCl_2 \rightarrow (XXb) \xrightarrow{H_2O} (XII).$$

The ring nitrogen of not only the pyrimidine component but also of the imidazole component of the molecule can be methylated under these conditions: when $MeOPOCl_2$ was allowed to react with the two isomeric $N_{(7)}$- and $N_{(9)}$-methyl derivatives of 2,6-dichloropurine [(VIII) and (XXXVIIIc)], the same compound was isolated after treating the products with water—2-chloro-7,9-dimethylhypoxanthinium chloride (XLII):



The same chloro-derivative (XLII) was detected in the reaction product after heating 1,9-dimethylxanthine (XXXIX) with $POCl_3$ (cf. Pfleiderer[73] and Gutorov[74]).

The formation of 2,6-dichloro-7-methylpurines from the phosphorodichloridates (XX) can also be facilitated by agents other than hydrogen chloride, the purines being converted into the readily cleaved amidochlorides (XIX). Tertiary amines have also come to be used in reactions of this kind. For example, on heating with $POCl_3$ in the presence of *NN*-dimethylaniline[75], theobromine is known to be converted into the dichloro-derivative (VIII) in 25% yield instead of 10—15%.[3] It has been suggested that in this reaction tertiary amines can partly promote the processes occurring because they prevent the elimination from the reaction sphere of the hydrogen chloride which promotes the conversion of the phosphorodichloridate (XXa) into the readily cleaved amidochloride (XIXa). Indeed, the use of dimethylanilinium hydrochloride instead of the base increased the yield of (VIII) to 35—40%. Nevertheless the yields in this reaction or in the analogous syntheses of (XLI) or (XXXVIIIc) continued to be fairly low, evidently due to side processes involving the *para*-condensation of the intermediate amidochloride and the adduct with dimethylaniline[2,76].

In order to rule out the possibility of the *para*-condensation side reaction, dimethylanilinium hydrochloride was replaced by triethylammonium hydrochloride (the hydrochloride of a tertiary amine), which cannot block the

intermediate phosphorodichloridates. This replacement immediately led to an appreciable enhancement of the yields: 2,6-dichloro-7-methylpurine (VIII) and its 8-chloro-derivative (XLIII) were obtained in 90—95% yield and the yield of 2,6-dichloro-9-methylpurine from 1,9-dimethylxanthine (XXXIX) was 75%.[76]

The most effective method for synthesising 2,6-dichloro-7-methyl- or 2,6-dichloro-9-methyl-purines [(VIII), (XLI) and (XXXVIIIc)] from the corresponding $N_{(3)}$- or $N_{(1)}$-methyloxopurines involves the conversion of the intermediate phosphorodichloridates into more readily cleaved phosphorus-containing adducts, which differ from the phosphorodichloridates by the fact that their anion is $OPCl_4^-$ instead of $OPOCl_2^-$.[57]

The formation of these new adducts, which for brevity may be called phosphorotetrachloridates, is achieved by treating solutions of phosphorodichloridates in $POCl_3$ with phosphorus pentachloride. Being much less soluble in this solvent than the initial phosphorodichloridates, the phosphorotetrachloridates can be crystallised comparatively rapidly. The phosphorotetrachloridates (XLIII, a and b)‡ were obtained in this way from the phosphorodichloridates (XX, a and b) and the phosphorotetrachloridate (XLIIIb) was obtained in addition by treating 2,8-dichloro-6-oxopurine (XIV) in methylene chloride with phosphorus pentachloride.

The ability to be readily cleaved with formation of 2,6-dichloropurines constitutes the most significant difference between phosphorotetrachloridates and phosphorodichloridichloridates. Their cleavage is accompanied by the liberation of $POCl_3$ and methyl chloride. It takes place comparatively rapidly on heating not only in $POCl_3$ but also in chlorobenzene, as well as in the absence of a solvent at the melting point and leads to the formation of 2,6-dichloropurines in high yields[57]. An example of the employment of the principle of the conversion of phosphorodichloridates into phosphorotetrachloridates is provided by the preparative syntheses of 2,6-dichloro-7-methylpurines (VIII) and (XLI) from theobromine[5,20,21].

The remaining properties of the phosphorotetrachloridates are very similar to those of the phosphorodichloridates and they exhibit all the features typical for purine adducts and amidochlorides. For example, the hydrolysis of the phosphorotetrachloridate (XLIIIb) in a neutral medium leads to the formation of a mixture of 2,8- and 6,8-dichloro-3,7-dimethylmonoxopurines (XIV) and (XVIIj), while in the reaction with ethyl alcohol it is converted into the amidoester chloride [the 8-chloro-derivative of (XXI)][57].

Presumably the phosphorotetrachloridates are not the last link in the long chain of reactions undergone by dimethylxanthines on treatment with $POCl_3$ compounds which are completed by the elimination of $N_{(3)}$- or $N_{(1)}$-methyl groups and the formation of 2,6-dichloropurines (VIII), (XLI), or (XXXVIIIc). It appears most likely that the cleavage of the phosphorotetrachloridates is a two-stage consecutive process and that the true precursors of 2,6-dichloro-7-methyl- or 2,6-dichloro-9-methyl-purines are the thermally unstable amidochlorides formed as a result of the elimination of $POCl_3$ from the phosphorotetrachloridates.

The principal stages of the process, illustrated by the schemes quoted in this review, can be followed experimentally for 3,7-dimethylxanthines. Nevertheless one cannot claim that this represents all the features of the complex conversion of *NN*-dimethylxanthines into the corresponding 2,6-dichloromonomethylpurines. It is quite probable that this process includes also additional hitherto undetected stages, which should be investigated further.

‡ The conversion of phosphorodichloridates into phosphorotetrachloridates is probably a result of the chlorination of the $OPOCl_2^-$ anion by phosphorus pentachloride and not of the exchange of its phosphorus-containing component $POCl_2$ for the PCl_4 residue. This hypothesis followed from the experimental preparation of the phosphorotetrachloridate (XLIIIb) by treating the phosphorodichloridate (XXb) with $^{32}PCl_5$ at 20°C in $POCl_3$: the yield of the resulting phosphorotetrachloridate was 92—94% and its molar radioactivity hardly reached 5% of the value for the initial $^{32}PCl_5$.

Stereochemical Results of Electron Transfer

Z.V.Todres

Data characterising the contribution of electron transfer processes to the stereochemistry of reactions of organic compounds are discussed and the stereochemical changes accompanying electron transfer are analysed. It is shown that the decrease of the barrier to rotation in electron transfer facilitates the *cis–trans* isomerisation of ethylenes and an increase of the difference between the energies of the rotational isomers of certain radical-ions relative to neutral molecules decreases the rate of mutual rotation. The influence of the formation of ion pairs by the anionic and cationic components of the radical-ion salts on the stabilisation of unusual geometrical forms of the molecule is discussed. The conversion of cyclopolyenes into ionic forms with a ring current of delocalised electrons, which fixes the ring atom in a single plane, is considered as a special case of electron transfer. The chemical and physical properties of cyclo-octatetraene, azocine, and their ionic forms are compared. The bibliography includes 143 references.

I. INTRODUCTION

Electron transfer processes occupy an increasingly important position in modern ideas about reaction mechanisms[1,2]. It is assumed that the migration of atoms or atomic groups in a chemical reaction is preceded by electron transfer from one of the reacting molecules to the other[3]. Thus, by taking into account the role of electron transfer processes, it is possible to extend significantly the available information about the mechanism of the given reaction and facilitate thereby the selection of the optimal conditions for its occurrence. Naturally, the study of electron transfer processes has become possible only when new instrumental research techniques, particularly ESR, NMR, and microwave spectroscopy of chemically polarised nuclei, have been introduced into chemical practice.

Electron transfer results in products with new interesting properties. We may note that one-electron transfer gives rise to products corresponding to the transfer of a unit charge from the donor (D) to the acceptor (A). Products of incomplete transfer (donor–acceptor complexes) have been adequately investigated. Since the studies of Izmail'skii[4,5] and then Brackman[6] and Mulliken[7], considerable advances have been made in the elucidation of the structure of charge-transfer complexes and their thermodynamic and spectroscopic characteristics[8,9]. Much attention is devoted at present to the determination of the role of these complexes in reaction mechanisms[10,11]. Molecular complexes are formed when the interaction between D and A is insufficient for complete charge transfer; in complete charge transfer the products are radical-ion salts or even free radical-ions:

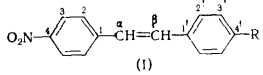
$$D + A \rightarrow [D^{\delta+}, A^{\delta-}] \rightarrow [D^{\cdot}, A^{\cdot-}] \rightarrow D^{+} + A^{-}.$$

Naturally, molecules involved in charge transfer undergo changes in their electronic structure to a greater extent the stronger the donor–acceptor interaction. There is also then a possibility of a qualitatively new result when the change in electronic structure leads to a change in molecular geometry. However, due attention has not so far been paid to the geometrical consequences of electron transfer. In considering the properties of charge-transfer complexes it has usually been assumed that on formation of the complex neither the donor nor the acceptor undergoes a change in its geometry (see, for example, Hanstein et al.[12]). This was based on the conclusion reached by Orgel and Mulliken[13] that the geometry of charge-transfer complexes (or the steric effect) does not in general influence the position of the spectral charge-transfer bands.

On the other hand, X-ray diffraction studies have shown that the formation of the radical-ion salt $[D^{+}, A^{-}]$ entails a serious distortion of the geometry of the initial molecule. For example, the conversion of the neutral molecule of 7,7,8,8-tetracyanoquinodimethane into the radical-anion is accompanied by an increase in the length of the multiple bonds and a shortening of the single bonds. This effect has been observed for the rubidium[14], morpholinium[15], and *N*-ethyl-1-methylbenzimidazolium[16] salts.

II. GEOMETRICAL ISOMERISATION AS A RESULT OF ELECTRON TRANSFER

The addition of a further electron to the 7,7,8,8-tetracyanoquinodimethane molecule leads to a change in its electronic structure: the multiple bond orders are reduced and those of single bonds are increased[14]. A similar change in bond orders is revealed also by quantum-mechanical calculations by the Hückel molecular orbital method for electron transfer to *p*-nitrostilbene and its substituted derivatives with the general formula (I).[17] In the radical-ion the order of the $\alpha-\beta$ bond is reduced and those of the $1-\alpha$ and $\beta-1'$ bonds are increased. The orders of the $2-3$ and $2'-3'$ bonds in the ring are also increased, while those of the $1-2$ ($1'-2'$) and $3-4$ ($3'-4'$) are diminished.



(I)

Similar results were obtained in calculations on the radical-ions of *p*-nitrobiphenyls [18]. Thus calculations have shown that electron transfer to nitrostilbenes (I) can lead to changes in the electronic structure which verge on the formation of a quinonoid structure or the ethylenic $\alpha-\beta$ bond approaches a single bond. In the ground state of the stilbene molecule the rotation of the benzene rings around the ethylenic bond is forbidden. However, the partial decrease of the double-bond character of the link between the atoms α and β as a result of electron transfer should probably lead to some decrease of the energy barrier to rotation. The presence of the nitro-group in stilbenes naturally promotes this conversion into the quinonoid form. Therefore, recent calculations on the ionic forms of unsubstituted stilbene, carried out by a combination of the Coulson–Hay and LCAO-MO methods [19] are extremely interesting. These calculations have shown that the conversion of stilbene into a radical-cation or a radical-anion lowers the barrier to *cis–trans* isomerisation almost by a factor of 2. The results of the calculations are presented in Fig. 1. In order to assess their validity, it is important to note that the calculated energy of the *cis–trans* isomerisation of the neutral stilbene molecule agrees well with thermochemical measurements [19]. The calculated geometrical parameters of stilbene and the results of X-ray diffraction analysis are also satisfactorily consistent [19]. The calculated barrier to the *cis–trans* isomerisation of stilbene (35.4 kcal mole^{-1}) agrees well with the experimental value (36.7 kcal mole^{-1}) and the predicted value for the first excited state is extremely low, as has in fact been assumed in the familiar models for the photoisomerisation of stilbene [19].

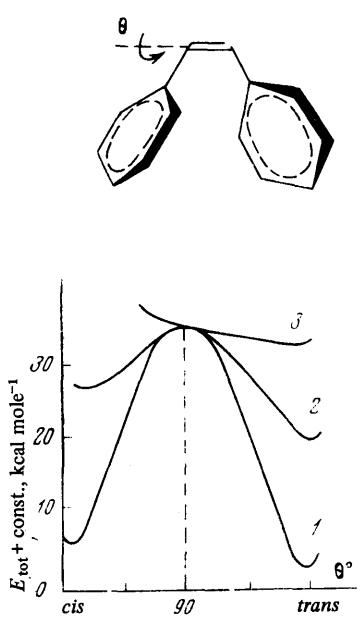


Figure 1. Changes in the energy E_{tot} of the stilbene molecule and radical-ion as a function of the angle of rotation of the ring θ about the central ethylenic bond ($\theta = 0°$ for the *cis*-configuration): 1) neutral molecule; 2) radical-anion or radical-cation; 3) molecule in the first excited state.

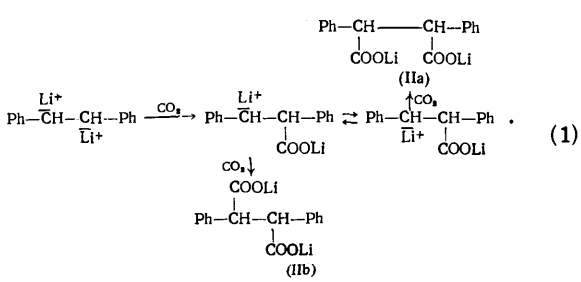
From the standpoint of the results of these calculations, it is interesting to consider the experimental data concerning the behaviour of olefins in reactions where electron transfer may be an intermediate stage. Schlenk and Bergmann [20,21] established that, when ethylenic compounds are treated with alkali metals in ethers, the products are adducts which react with carbon dioxide to from dicarboxylic acids. The steric structures of these acids were found to be determined by the nature of the metal employed and not by the configuration of the initial ethylene. It was discovered that the reaction of vicinal and organodimetallic derivatives with methyl iodide gives rise to the initial ethylenes and not to methylation products. Under these conditions, only the *trans*-isomer is obtained from both *trans*- and *cis*-stilbenes after treatment with metals and then with methyl iodide. An admixture of *trans*-stilbene appeared in certain experiments on the carboxylation of the products obtained by the treatment of *cis*-stilbene with alkali metals.

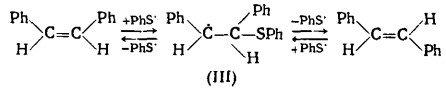
The results of Schlenk and Bergmann were tested by Wright and coworkers [22,23] and by Doran and Waack [24]. It was found that olefins give rise very readily to products resulting from the addition of two alkali metal atoms (dianions) with a change in colour. The electronic spectra of the stilbene dianion and radical-anion differ little [24] and the ESR spectra have not been recorded. On treatment with dimethyl sulphate, the stilbene metallation product gives rise to 2,3-diphenylbutane, while the reaction with methyl iodide, methyl alcohol and benzoyl chloride regenerates the stilbene, which always has the *trans*-structure. Since alkali metals, which can cause exhaustive reduction of the ethylenic double bond, were used in the reaction, it may be that these observations are due to the characteristics of the structure of the stilbene dianion. Szwarc and coworkers [25] believe that the *cis*-stilbene radical-anion is stable and that the product of the two-electron transfer (the dianion) actually undergoes isomerisation. According to Suzuki et al. [26], the stilbene dianion is almost planar and its alkali metal salts in ethereal solvents are ionic aggregates in which cations are located close to the carbon atoms of the central ethylenic bond above and below the plane of the molecule. The substitution of one of the ethylenic carbon atoms results in mutual rotation [27]. This is why the same mixture of the dilithium salts of *meso*- and (±)-diphenylsuccinic acids, (IIa) and (IIb), in proportions of 2 : 1 [reaction (1)] was obtained by Wright [22] in the carboxylation of the dilithium adducts of both *cis*- and *trans*-stilbenes.



(1)

cis-Stilbene is converted similarly into the *trans*-form on heating in the presence of traces of thiophenol. It was established that [28] the isomerisation is due to the addition

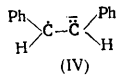
(and subsequent elimination) of the phenylthiyl radical to stilbene [reaction (2)]:



(2)

(III)

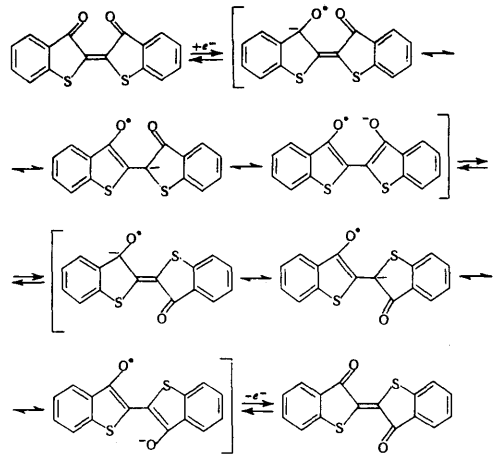
In contrast to the transfer of two electrons, the capture of one electron does not by itself convert stilbene into the almost "hydrogenated" product. However, the state of the central ethylenic bond in this radical-anion (IV) approaches that of the radical (III).



(IV)

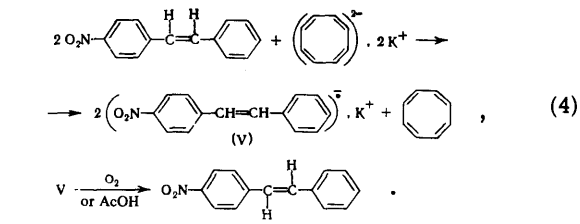
Johnson and Chang [29,30] attempted to compare the ESR spectra of the radical-anions of *cis*- and *trans*-stilbenes and to compare the rates of electron transfer from these radical-anions to the corresponding neutral molecules. They assumed that the ESR spectra should differ at least slightly and that the rate of electron transfer to *cis*-stilbene should differ from the rate of simple electron exchange between *trans*-stilbene and its radical-anion if the process is associated with a change in configuration. Electron exchange between species with similar configurations should be faster [31]. It was found that the ESR spectra of the potassium or tetra-alkylammonium salts of the radical-anions of *cis*- or *trans*-stilbene do not differ significantly. However, Johnson and Chang emphasise that the absence of differences between the ESR spectra does not alone indicate that *cis*- and *trans*-stilbenes give rise to radical-anions with the same structure. It was not possible to discover differences between the rates of electron transfer from the radical-anion to the neutral molecule either. In the formation of the stilbene radical-anion in the presence of a large amount of the *cis*-isomer, it was impossible to measure the broadening of the ESR line during the exchange and hence calculate the electron transfer rate constant. Having modified the method for the formation of the radical-anions, Chang and Markgraf [32] were able to detect by ESR a difference between the kinetics of electron transfer reactions involving *cis*- and *trans*-stilbenes. For this purpose, it was necessary to employ ultraviolet irradiation. However, irradiation sharply reduces the activation barrier to isomerisation (cf. Fig. 1). Clearly, under such conditions one observes only the rates of complex processes and the values obtained cannot be attributed to electron transfer alone. The reaction rate constants for *trans*- and *cis*-stilbenes are 10^9 and 10^3 litre mole^{-1} s^{-1} respectively. If the electron transfer rate constants differed by this amount, the implication would be that the stilbene radical-anions have the *trans*-configuration. However, it has been noted in a number of studies that irradiation of the radical-anions with ultraviolet light entails their *cis*–*trans* isomerisation and not *trans*–*cis* isomerisation, as for the corresponding neutral compounds [33,34].

Chang et al. [35] used a combination of the ESR and ultraviolet irradiation methods also in the investigation of the radical-anions formed in the reduction of thioindigo with metallic potassium. No difference was observed in the rates of electron exchange between the thioindigo radical-anion and the *cis*- and *trans*-isomers of thioindigo. However, the authors nevertheless suggest that the paramagnetic species formed from thioindigo has the *trans*-structure. They believe that the mutual repulsion of the carbonyl groups, which is sharply enhanced after electron transfer [reaction (3)], is the driving force of the isomerisation.



(3)

Direct evidence for *cis*–*trans* isomerisation as a result of electron transfer was obtained [36] in a study of the reaction of the dipotassium derivative of cyclo-octatetraene with nitro-derivatives of stilbene of type (I, R = H or NO_2) in tetrahydrofuran (THF). The reaction is homogeneous in THF. Dipotassiocyclo-octatetraene is a fairly weak reducing agent. After giving up its electrons, it is converted into neutral cyclo-octatetraene, whose yield can be readily determined. All these factors make it possible to specify exactly the amount of donor, to estimate the extent of electron transfer, to determine the nature of the products, and to elucidate their reactivities. It was established that under these conditions 4-nitro-*cis*-stilbene (I, R = H) gives rise to the potassium salt of a radical-anion, whose ESR spectrum was obtained and analysed. After treatment of the products of reaction (4) with oxygen, 4-nitrostilbene was isolated as a mixture of the *cis*- and *trans*-isomers in proportions of 1.5 : 1 in an overall yield of 80%. The electron transfer reaction went to completion under these conditions (there was a quantitative formation of cyclo-octatetraene). When equimolar amounts of the donor and acceptor were used, i.e. under the conditions of two-electron reduction of 4-nitro-*cis*-stilbene, only partial *cis*–*trans* isomerisation was again observed. Oxygen abstracts an electron from the radical-anion, for example the reaction of the potassium salt of nitrobenzene with oxygen in THF results in the formation of nitrobenzene in 80% yield. The neutral compound is formed also on treatment of the potassium salt of nitrobenzene in THF with water [37]. When the products of the electron transfer to 4-nitro-*cis*-stilbene are treated with water or acetic acid, the same mixture of the *cis*- and *trans*-isomers of 4-nitrostilbene is formed in an overall yield of 90%. [36] Since neither oxygen nor the resulting potassium acetate gives rise to any chemical changes in the 4-nitro-*cis*-stilbene solution in THF, it was concluded that the reaction proceeds in accordance with reaction (4).



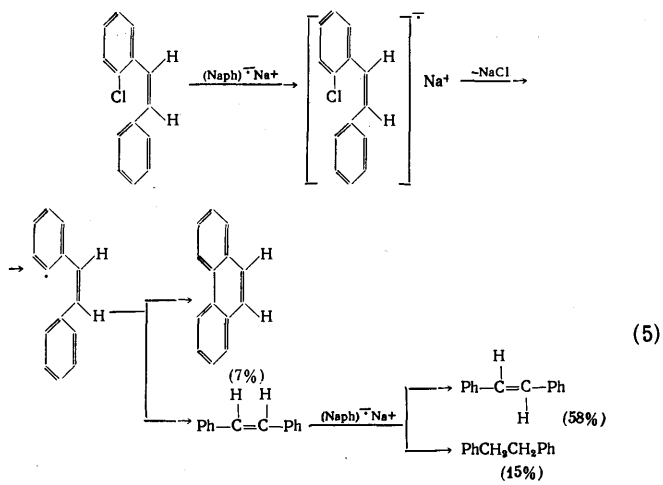
(4)

(V)

The one-electron transfer to 4-nitro-*trans*-stilbene under these conditions leads to the recovery of the initial

trans-isomer and the quantitative formation of cyclo-octatetraene. The absence of the isomerisation of 4-nitro-*trans*-stilbene is probably due to the fact that, under the reaction conditions, the energy barrier to the rearrangements of the radical-anion of this compound to the *cis*-isomer is much higher than for the *trans*-trans-formation of the radical-anion of 4-nitro-*cis*-stilbene. Thus, according to Golebiewski and Parczewski [19], the conversion of the *cis*-stilbene radical-anion into the *trans*-isomer requires approximately 10 kcal mole^{-1}, while the conversion of the *trans*-form into the *cis*-form of the radical-anion requires about 18 kcal mole^{-1} (Fig. 1). The symmetrical 4,4'-dinitro-*cis*-stilbene is completely converted into the *trans*-isomer on treatment with dipotassio-cyclo-octatetraene and then with oxygen or acetic acid [38]. It is interesting that protonation of the radical-anions or dianions of *p*-nitrostilbenes does not lead to the formation of *p*-nitrobibenzyls, i.e. the ethylenic bond is not hydrogenated. This finding is unexpected, since electron-transfer from sodionaphthalene to stilbene in THF leads to bibenzyl after protonation [see reaction (5)]. [39] The introduction of the nitro-group into stilbene should, of course, promote reduction. In nitrostilbene the additional electron is probably effectively held by the nitro-group, which prevents the addition of protons to the carbon atoms of the ethylenic bond. In other words, the degree of electron saturation of the central ethylenic bond in the products under consideration is sufficient for isomerisation but not for the addition of protons.

The conclusions reached in the study of the stereochemical results of electron transfer are consistent with the literature data concerning the behaviour of the corresponding neutral compounds under conditions where electron exchange is possible. Thus selective reduction of 4,4'-dinitrostilbene with tin in hydrochloric acid leads to 4,4'-diamino-*trans*-stilbene regardless of whether the initial dinitro-compound has the *cis*- or *trans*-configuration [40]. On treatment with potassium methoxide, 4-nitro-*cis*-stilbene is converted into a mixture of the *cis*- and *trans*-isomers [41]. On treatment with lithium in ether and then with carbon dioxide, 4-chloro-*cis*-stilbene gives rise to a mixture of products consisting of 4-chloro-*trans*-stilbene, 4-chloro-*cis*-stilbene, and *trans*-stilbene-4-carboxylic acid [42]. The reaction of 2-chloro-*cis*-stilbene with an excess of sodionaphthalene [(Naph)$^-$Na$^+$] in THF leads to phenanthrene, bibenzyl, and *trans*-stilbene. Singh and Kumar [39] explain the observed reactions in terms of reaction (5).



(5)

The addition of an electron to the double bond evidently lowers the barrier to rotation about the bond. The one-electron reduction of ethylenic compounds can be regarded in a certain sense as a stage in the conversion into ethane derivatives. From this point of view, it is important, in principle, to know the stereochemical results of the abstraction of an electron from the double bond. Calculations have shown [19] that the enhanced stability of the *trans*-form is also characteristic of the stilbene radical-cation, i.e. the one-electron oxidation product. The experimental confirmation of this finding is still inadequate. It is known [43] that fuming nitric acid induces the *trans*-isomerisation of *cis*-stilbene. The conversion of *cis*-stilbene into *trans*-stilbene under the influence of iodine [43] may proceed via the formation of the stilbene radical-cation and the iodide anion, which then give rise to neutral stilbene (*trans*-form) and iodine. In this case complete charge transfer may not, of course, necessarily occur. The isomerisation takes place in a complex where the donor and acceptor orbitals strongly overlap. Indeed, *cis*- and *trans*-stilbenes form in hexane solution different complexes with iodine, which give rise to charge-transfer bands at 354 and 365 nm respectively [44]. It is not clear from the literature whether the bands merge after a time and microwave spectroscopic studies have not been made on the system. Furthermore, it would be interesting to show whether the interaction leads to the appearance of paramagnetic species, i.e. whether the ^{1}H NMR signal of the olefinic protons of *cis*-stilbene shifts as a result of the mixing of the reactants. For example, in the presence of the stable 2,2,6,6-tetramethylpiperidin-1-oxy-radical the signal of the $\overset{|}{=}C-H$ protons in dimethyl maleate shifts towards a high field [45]. The signals of the methyl protons of dimethyl maleate remain in the same position. Hence it follows that a complex is formed in which the orbitals of the unpaired electron of the radical overlap with the π orbitals of the dimethyl maleate double bond. In the presence of nitroxy-radicals there is a sharp increase in the rate of isomerisation of dimethyl maleate to dimethyl fumarate and the radicals are not consumed. The probability of the isomerisation of maleate in a complex with the radical exceeds by seven orders of magnitude the probability of the isomerisation of its free molecule [45].

According to Il'ina [46], the oxidation of *cis*-stilbene by the salts $Mn(OAc)_3$ and $Co(OAc)_3$ in acetic acid or by the salt $Tl(OCOCF_3)_3$ in trifluoroacetic acid leads to a mixture of acetates (or trifluoroacetates) of hydrobenzoin (*meso*-type) and isohydrobenzoin [(±)-type]. As in the synthesis of diphenylsuccinic acids according to Scheme 1, the amount of *meso*-derivatives obtained is approximately twice as large as that of the (±)-derivatives. This ratio of stereoisomers holds for *trans*-stilbene, but the oxidation is faster. When $Mn(OAc)_3$ in acetic acid is used, *trans*-stilbene is oxidised seven times faster than *cis*-stilbene. Part of the olefin remains unchanged at the end of the process and an appreciable amount of the *trans*-isomer is produced from *cis*-stilbene. Bivalent metal salts, for example $Mn(OAc)_2$, formed as a result of the reaction cannot induce the *trans*-isomerisation of *cis*-stilbene. Such isomerisation is not caused by trifluoroacetic acid either. When $Tl(OCOCF_3)_3$ in CF_3COOH was used as the oxidant, stilbene radical-cations were detected, their amount decreasing in the course of the reaction. Il'ina [46] proposed reactions (6) and (7), according to which one-electron oxidation of stilbene involves the intermediate formation of the radical-cation, possibly in the form of the complex (VI). This stage is reversible. If the

starting compound in reaction (6) is *cis*-stilbene, then the organic part of the complex (VI) is capable of at least partial *cis–trans* isomerisation. The conversion of (VI) into an acetoxy-derivative and oxidation of the resulting radical (VII) lead to the complex (VIII), which decomposes with formation of the final products (IXa) (*meso*-type) and (IXb) [(±)-type], as in reaction (7).

$$\underset{(cis\text{- or }trans\text{-})}{PhCH{=}CHPh} + Tl(OCOCF_3)_3 \overset{CF_3COOH}{\rightleftharpoons} \underset{(VI)}{[PhCH\dot{C}HPh][Tl(OCOCF_3)_3]^-} \xrightarrow{CF_3COOH}$$

$$\rightarrow \underset{(VII)}{[PhCH(OCOCF_3)CHPh]} + Tl(OCOCF_3)_2;$$

$$2Tl(OCOCF_3)_2 \xrightarrow{fast} Tl(OCOCF_3)_3 + TlOCOCF_3\ , \qquad (6)$$

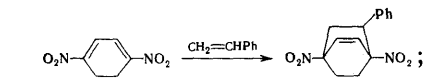
$$VII + Tl(OCOCF_3)_3 \xrightarrow{CF_3COOH} \underset{(VIII)}{[PhCH(OCOCF_3)\dot{C}HPh][Tl(OCOCF_3)_3]^-} \xrightarrow{CF_3COOH}$$

$$\rightarrow \underset{(IX)\ [a)meso\text{-};\ b)\ (\pm)\text{-}]}{PhCH(OCOCF_3)CH(OCOCF_3)Ph} + Tl(OCOCF_3)_2;$$

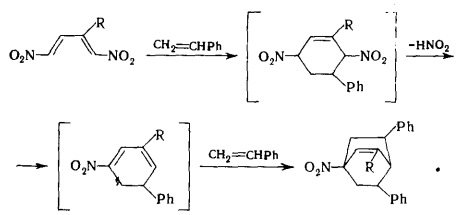
$$2Tl(OCOCF_3)_2 \xrightarrow{fast} Tl(OCOCF_3)_3 + TlOCOCF_3\ . \qquad (7)$$

The salt $Tl(OCOCF_3)_2$, which should be paramagnetic disproportionates very rapidly[47] [see reactions (6) and (7)]. This leads to the formation of the diamagnetic thallium(III) and thallium(I) trifluoroacetates and the ESR spectrum reveals the presence of the stilbene radical-cations only. Owing to its high acidity, in trifluoroacetic acid the addition of the acetoxy-group to the double bond proceeds via the one-electron oxidation to the radical-cation and not via the addition of Tl^{3+} to one of the olefinic atoms (as in acetic acid[48]).

From the standpoint of the changes in geometry induced by electron transfer, it is interesting to consider again the mechanism of the 1,4-addition of dienes to the ethylenic bond (the Diels–Alder reaction). An early charge transfer stage[49], associated with a change in the geometry of the initial reactants, is also possible in this process. Naturally, this effect can appear most clearly when there is a difference between the polarities of the diene and dienophile. The reaction of styrene with 1,4-dinitrobuta-1,3-diene constitutes an example with a very large difference of this kind. Clearly the dinitro-derivative must be regarded as an electron acceptor in relation to styrene. Dienes of this type are inactive in the classical diene synthesis reaction[50], but they do react with nucleophilic dienophiles of the styrene type[51]. The reaction is therefore of "inverse" electronic type. 1,4-Dinitrocyclohexa-1,3-diene reacts with styrene under comparatively mild conditions (100°C, 10 h, in xylene) with formation of a 1 : 1 adduct [reaction (8)].[51] The fixed *S-cis*-configuration of this diene remains unchanged also in the intermediate stages, which ensures that the familiar rules of Alder and Stein[49] hold. Since the configuration of the open-chain 1,4-dinitro-1,3-dienes may change in the initial stage of the reaction, more severe conditions are required for the formation of adducts. The reaction proceeds only on heating at 140°C for 40 h in the absence of solvent and is accompanied by the elimination of the nitro-group and a second interaction with the dienophile [reaction (9)].[51] Presumably, more severe conditions are needed to impart to the diene component of the transition complex the configuration required for the formation of the ring†.



(8)



(9)

The occurrence of *cis–trans* isomerisation in the chemical reaction involving an electron transfer stage was confirmed by Fraser and Taube[53], who investigated the reaction of Cr^{2+} or V^{2+} ions with complex salts containing the (methyl maleato)pentamminecobalt(III) cation. In an acid medium an oxidation–reduction reaction takes place, as a result of which there is not only a decrease of the charge of the complex cation by unity but the cation also exchanges the methyl maleate ligand for water [reaction (10)]:

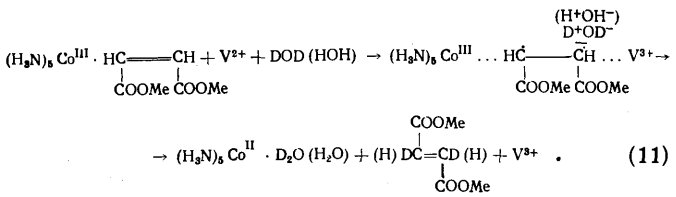
$$[Co(NH_3)_5 \cdot (CHCOOMe)_2]^{3+} + Cr^{2+}\ (or\ V^{2+}) + H_2O \xrightarrow{HClO_4}$$

$$\rightarrow [Co(NH_3)_5 \cdot H_2O]^{2+} + Cr^{3+}\ (or\ V^{3+}) + (CHCOOMe)_2\ . \qquad (10)$$

The liberated ligand is hydrolysed in an acid medium to ethylene-1,2-dicarboxylic acid. Under these conditions, not all the acid formed has the *cis*-configuration corresponding to the ligand in the initial complex. Fumaric acid (*trans*) is formed together with maleic acid (*cis*); the amount of the latter is greater the higher the concentration of perchloric acid in the reaction mixture. A mixture of isomeric acids is formed in the presence of D_2O and the C–D bond is present only in fumaric acid but not in maleic acid. When the (methylfumarato) pentamminecobalt(III) cation is reduced in D_2O [reaction (10)], only fumaric acid without an admixture of maleic acid is formed and which does not contain C–D bonds. Probably electron transfer from Cr^{2+} or V^{2+} to the complex ion proceeds via the mechanism of the socalled "double exchange"[54]. The reducing agent (Cr^{2+} or V^{2+}) transfers an electron to the bridging group (maleate) and the latter transfers it further to the oxidising agent [cobalt(III)]. Thus the bridging $(CHCOOMe)_2$ group is alternately reduced and oxidised with isomerisation of maleic acid to fumaric acid. When the electron is localised at the ethylenic bond, the addition of a proton (deuteron) takes place. After the abstraction of an electron from the ethylenic bond, the H^+ ion (in H_2O) or H^+ and D^+ ions in (D_2O) are split off. Hydrogen isotope exchange involving the –C=C– bond is observed. The conversion of cobalt(III) into the bivalent form proceeds simultaneously with the substitution of the ethylenedicarboxylic acid diester in

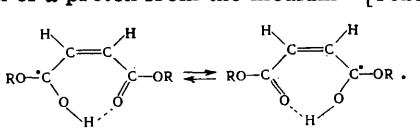
† A somewhat similar situation arises in the dehydration of fumaric acid to maleic anhydride on heating. Eliel believes[52] that at a high temperature the dehydration is preceded by the migration of the double bond. Thermal isomerisation has been observed for many olefins; in all such compounds there is a barrier to rotation about the double bond of about 40 kcal $mole^{-1}$.[52]

the inner sphere of the complex by a water molecule [reaction (11)].



(11)

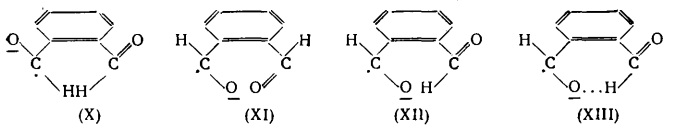
The absence of hydrogen isotope exchange involving the ethylenic bond in the dimethyl fumarate ligand can be explained by the fact that in this case the bridge is not directly involved in the electron transfer. The role of this ligand is more likely to be to bring closer together the two positively charged ions for "direct electron exchange" [54] between their overlapping orbitals. Fraser and Taube's study [53] contributed much to the elucidation of the mechanism of the inner-sphere electron transfer. At the same time an explicit relation between electron transfer and geometrical transformations was first noted. A few more studies were then made in which the properties of the products resulting from electron transfer to dialkyl fumarates or dialkyl maleates were compared [55-59]. It was shown that in pyridine, dimethyl sulphoxide (DMSO), and dimethylformamide (DMF) these compounds are reduced in stages [55-57]. Radical-anions capable of undergoing one-electron oxidation are formed in the first stage. The half-wave potentials for the reduction of maleate and fumarate differ but the one-electron oxidation of the resulting radical-anions is characterised by the same half-wave potentials. The above relations between the $E_{1/2}$ for the cathodic and anodic waves hold also at a very high alternating frequency, up to 500 Hz. [57] This implies that the radical-anions formed from maleate and fumarate have similar energies. The ESR spectra of the products of the electrochemical reduction of dimethyl fumarate and maleate are identical at the potential of the limiting currents of the first waves regardless of the temperature at which they are recorded [58]. According to the authors, it is unlikely that the ESR spectra of the *cis*- and *trans*-radical-anions are completely identical. Thus, if it is assumed that the ESR spectra of the *cis*- and *trans*-radical-anions should differ, the above observation indicates a rapid and almost complete *trans*-isomerisation of the *cis*-radical-anions. At the same time, if the radical-anions are obtained in a proton-donating medium, the *cis*- and *trans*-isomers give rise to different ESR [60] and electronic [59] spectra. Under these conditions, maleates evidently give rise to unusually stable radical-anions, whose structure is fixed by the formation of a ring with participation of a proton from the medium [59] [reaction (12)].



(12)

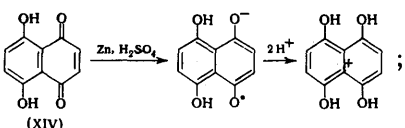
III. INFLUENCE OF COORDINATION INTERACTIONS ON THE STEREOCHEMISTRY OF ELECTRON TRANSFER PRODUCTS

Carbonyl compounds capture an electron and are converted into ketyls, which contain a negatively charged oxygen atom. This atom is a particularly powerful proton acceptor. Reaction (12) shows how the formation of a hydrogen bond prevents the *cis*–*trans* isomerisation of the maleate ester, which can occur on electron transfer. The enhancement of the affinity of the negatively charged carbonyl oxygen for a proton ensures the formation of stable hydrogen bonds with molecular fragments which are otherwise incapable of it. An example is provided by the C–H fragment of the aldehyde group. The radical-anion of phthalaldehyde is planar [61] and therefore might exist in three forms: *exo*- (X), *enao*- (XI), and *meso*- (XII):

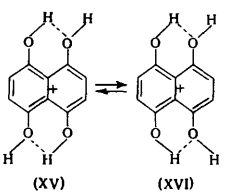


(X) (XI) (XII) (XIII)

Only the *meso*-conformer, in which the mutual orientation of the functional groups ensures the formation of a hydrogen bond involving the proton of one aldehyde group and the negatively charged oxygen atom of the other [structure (XIII)], can be detected by ESR. The influence of hydrogen bonds of this type on the conformation of electron transfer products is shown also when the negative charge of the oxygen atom is neutralised by protons from the medium. Thus the reduction of naphthazarin (XIV) with zinc dust in sulphuric acid leads to the radical-cation of naphthazarin semiquinone [reaction (13)], whose ESR spectrum changes with temperature [62]. This variation has been attributed to mutual interconversions of the *cis*- and *trans*-forms (XV) and (XVI) respectively. The equilibrium position (and hence the form of the ESR spectrum) can be represented at a specified temperature with satisfactory accuracy if it is assumed that the isomerisation mechanism includes the dissociation of the intramolecular hydrogen bond via mechanism (14). The exchange of the hydroxyl protons of the radical-cation with the medium is then much slower than isomerisation. The height of the potential barrier to isomerisation is 3–5 kcal and is comparable to the energy of the hydrogen bond in systems of type (XV) (3–7 kcal). [62]

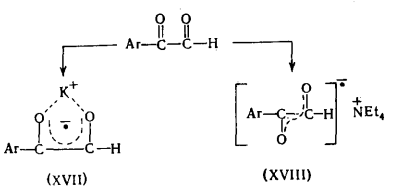


(XIV) (13)



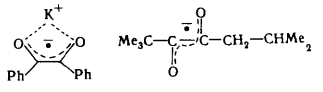
(XV) (XVI) (14)

The conformation of the semidione is fixed even more rigidly when an alkali metal cation is coordinated to the two carbonyl groups. Thus the one-electron reduction of 3,4,5-trimethoxyphenylglyoxal with potassium t-butoxide in DMSO gives rise mainly to the *cis*-semidiones (XVII), while in the electrolysis in DMF, in the presence of tetraethylammonium perchlorate as the carrier electrolyte, the main product is the *trans*-isomer (XVIII) [63] [reaction (15)].



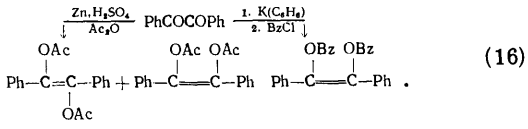
(XVII) (XVIII) (15)

The ESR spectrum of the sodium salt of the benzil ketyl in THF shows splitting due to Na^+ (0.6 G), while in the ESR spectrum of the sodium salt of the ketyl of 2,2,6,6-tetramethylhexane-3,4-dione in THF there is no splitting whatever due to Na^+.[64] While the benzil ketyl can give rise to the contact ion pair (XIX), the formation of a species of type (XX) from the 3,4-dione is difficult owing to steric hindrance. This semidione exists in the form of a free ion or an ion pair separated by solvent molecules.



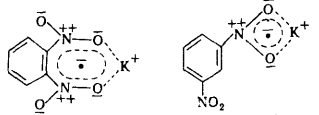
(XIX) (XX)

If the benzil ketyl ion does not form part of an ion pair, it exists in the *trans*-form, but in the case of the potassium salts the *cis*-form, in which both charged oxygen atoms are in the vicinity of the metal cation, [as in compound (XIX)] is more stable[65]. On benzoylation, such a radical-ion pair gives rise mainly to *cis*-dibenzoylethylene[65], while the reduction of benzil under conditions which do not stabilise the contact ion pair is not stereospecific[65,66] [reaction (16)].



(16)

The coordination of the potassium cation to two oxygen atoms in the radical-anion of *o*-dinitrobenzene leads to the stabilisation of the unusual configuration in which the nitro-groups are spread out in a single plane. In neutral *o*-dinitrobenzene the coplanarity of the two nitro-groups is ruled out both by calculation[67] and experiment[68,69]. In the potassio-derivative of *o*-dinitrobenzene (XXI) the coordination of the metal cation to both nitro-groups leads to the formation of a condensed "ring" in which there is a possibility of additional delocalisation of the unpaired electron. Indeed, the ESR spectra in dimethoxyethane (DME) or in THF show that the unpaired electron in (XXI) is equally delocalised over the two nitro-groups (the constants for the splitting by the nitrogen atoms $a_N^1 = a_N^2 = 3.2$ G),[70] while in the potassium salt of the radical-anion of *m*-dinitrobenzene (XXII) the delocalisation is essentially over only one of the two groups ($a_N^1 = 9.3$ G, $a_N^2 \leq 0.2$ G).[71,72] This contrasts sharply with ESR spectroscopic data for the radical-anions obtained by electrolysis in acetonitrile in the presence of tetra-n-propylammonium perchlorate as the supporting electrolyte: $a_N^1 = a_N^2 = 3.16$ G for *o*-dinitrobenzene and $a_N^1 = a_N^2 = 4.68$ G for *m*-dinitrobenzene[73]. The difference can be understood if account is taken of the nature of the counterion. When the counterion is a small cation (potassium), the formation of a closely knit ion pair is possible. The K^+ ion can than make its vacant *d* and *p* orbitals available for the π electrons of the radical-anion system[54]. When a tetraalkylammonium cation is used as the counterion, the mutual approach of species with different charges is hindered by the alkyl groups. Ion pairs with the potassium cation are stable, i.e. exist longer than is required for the detection of the ESR signal. This follows from a comparison of the polarographic behaviour of the three isomeric dinitrobenzenes in the same solvent (DMF) using tetraethylammonium or potassium perchlorate as the carrier electrolyte[74]. The half-wave potentials corresponding to the conversion of *p*- and *m*-dinitrobenzenes into radical-anions are independent of whether tetraethylammonium or potassium counterions are employed. The radical-anion is formed from *o*-dinitrobenzene at a potential more positive almost by 100 mV when tetraethylammonium perchlorate is replaced by potassium or sodium perchlorate. Changes in the composition and structure of the electrical double layer do not influence under these conditions the reduction mechanism, which has been shown by a special study[75] to consist of the reversible transfer of one electron. Since the transfer of one electron to *o*-dinitrobenzene in the presence of potassium perchlorate as the carrier electrolyte proceeds at a less negative potential than in the presence of tetraethylammonium perchlorate, it is clear that the potassium salt does indeed have the minimum energy, i.e. is characterised by the highest degree of delocalisation of spin density.

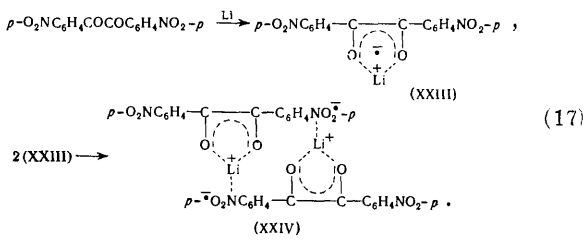


(XXI) (XXII)

The structure (XXI) favours greater delocalisation of the unpaired electron, but the anionic component of the salt is then forced to assume an unusual conformation. These properties of *o*-dinitrobenzene should be manifested also in chemical reactions, where, as can be seen from reaction (12), the role of the ring-closing species may be played by the proton. Indeed, the reduction of both nitro-groups at once is observed in the electrolysis of *o*-dinitrobenzene in the presence of water[76], while in the *para*-[76] or *meta*-isomer[77] only one nitro-group is reduced.

The relation between the distribution of spin density in the products of electron transfer to organic molecules and the behaviour of these products in reactions is important but has so far been little investigated. It would be especially useful to know the reason for the particular sequence of chemical changes in the groups present simultaneously in the molecule.

From this standpoint, it is interesting to examine electron transfer to 4,4'-dinitrobenzil [reaction (17)]. Paramagnetic species whose ESR spectra depend on temperature and concentration, are then formed. It has been shown[78] that such electron transfer products can exist in the monomeric or dimeric forms [(XXIII) or (XXIV) respectively]. The former is present at high dilution and the latter at an increased concentration or at a low temperature.



(XXIII) (XXIV) (17)

In form (XXIII) the unpaired electron is delocalised mainly over the dicarbonyl group and in form (XXIV) over the nitro-groups. Under these conditions, 4,4'-dinitrobenzophenone gives rise to radical-anions in which the nitro-group and not the carbonyl group carries the maximum electron density[78]. These results of the analysis of the ESR spectra are consistent with chemical data; on

reduction with tin in hydrochloric acid, 4,4′-dinitrobenzophenone is converted into 4,4′-diaminobenzophenone[79] and 4,4′-dinitrobenzil is converted into 4,4′-diaminodeoxybenzoin (p-$H_2NC_6H_4CH_2COC_6H_4NH_2$-$p$).[80]

IV. CONFORMATIONAL INHOMOGENEITY OF THE ELECTRON TRANSFER PRODUCTS

The radical-anions obtained from aromatic nitro-compounds retain a twofold symmetry axis. It follows from the analysis of the hyperfine structure of the ESR spectrum of the nitrobenzene radical-anion that this species contains protons of three kinds only; *ortho*-, *meta*-, and *para*-[81,82] [structure (XXV)].

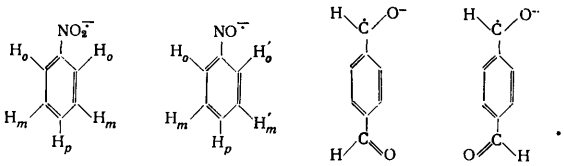
The situation is quite different in the conversion of nitrosobenzene into the corresponding radical-anion. According to ESR data[82,83], the nitroso-group is to some extent fixed in the plane of the ring after electron transfer. This leads to the appearance of five kinds of protons, since the two *meta*-positions (as well as the *ortho*-positions) become non-equivalent [structure (XXVI)].

The one-electron reduction of acetophenone leads to an ESR spectrum comprising 128 lines, corresponding to the three equivalent protons of the methyl group and the five non-equivalent ring protons[84].

The ESR spectrum of the products of the reversible one-electron reduction of benzaldehyde in DMF in the presence of tetra-alkylammonium supporting electrolytes contains 64 lines[84]. This form of the spectrum shows that the absence of a symmetry plane is characteristic of the benzaldehyde radical-anion. It was noted[85] that this unexpected result cannot be attributed solely to the interaction of the negatively charged carbonyl group with the nearest ring atoms. A more interesting phenomenon is probably involved—an unusual polarisation of the π-electron system of the radical-anion by the electric dipole of the charged carbonyl group.

The ESR spectra of the radical-anions of nitrobenzonitriles, obtained electrochemically in DMF,[86] show that the equivalence of the positions with respect to the nitrile group is maintained. This can be due either to the free rotation of the nitrile groups or to their linear disposition with respect to the symmetry axis of the molecule. The ESR spectra of the potassium salts of the radical-anions of terephthalonitrile in DME[87] demonstrate the equivalence of both the cyano-groups in the *para*-positions with respect to one another and of the benzene ring protons. It follows from the analysis of the hyperfine structure of the spectra that the constants for the splitting by the two nitrogen atoms are equal; also equal are the constants for the splitting by all the hydrogen atoms.

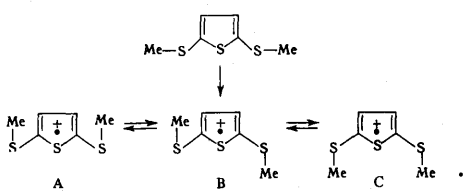
At the limiting current potential of the first reduction wave in DMSO in the presence of tetra-n-propylammonium perchlorate as the carrier electrolyte terephthalaldehyde gives rise to radical-anions, which exhibit two ESR spectra superimposed on one another. These spectra are characterised by the same g-factor, but have significantly different splitting constants[61,85]. If the rate (frequency) of rotation of the aldehyde groups were much higher than the frequency differences between the splitting constants of the rotational *cis*- and *trans*-isomers, the ESR spectrum of the radical-anions of terephthaldehyde would be averaged out. On the other hand, if the rate of mutual rotation of the groups were comparable to the frequency difference corresponding to the splitting in the spectra of the rotational *cis*- and *trans*-isomers, the ESR spectral lines would be broadened. Since a superposition of the spectra is observed, the implication is that the frequency of rotation is much smaller than the frequency difference corresponding to the splitting. It is unlikely that the observed superposition of the spectra could arise due to the presence of ion pairs with the same radical-anion but with different separations of the latter from the cation: a tetra-alkylammonium cation, which hardly forms ions pairs, was used in the above experiment[61,85]. Thus electron transfer to terephthalaldehyde leads to the formation of the two conformers (XXVIIa) and (XXVIIb).



(XXV) (XXVI) (XXVIIa) (XXVIIb)

The conformers (XXVIIa) and (XXVIIb) are physically distinguishable and the duration of their existence at any rate exceeds the ESR time constant, i.e. is greater than 1 ms. It follows from the analysis of the intensities of the corresponding signals that the rotational *cis*- and *trans*-isomers are formed in proportions of 1 : 1.4.[61,85] Conformationally inhomogeneous products were obtained also in electron transfer to 1,4-diacetylbenzene[88] and thianthrene-5,10-dioxide[89]. Durosemiquinone[90] and naphthazarin[62] are known to give rise to rotational *cis*- and *trans*-isomers of the radical-cations.

The oxidation of oximes leads to iminoxy-radicals having the general formula $R_2C{=}N{-}O^{\cdot}$. Under these conditions, *syn*-benzaldoxime yields both *syn*- and *anti*-isomers[91] and a similar result was obtained in the oxidation of benzophenone and fluorenone oximes[92]. Thiophen substituted in the 2- and 5-positions by methylthio-groups exists as one conformer only. One-electron oxidation with aluminium chloride in nitromethane results in the formation of conformationally inhomogeneous products, which may have structures A, B, or C. ESR showed the presence of the asymmetric conformer B and of one symmetrical conformer (A or B).[93]



A B C

The hindered rotation of the dimethylamino-groups about the bonds between the nitrogen atoms and the ethylenic carbon atoms is responsible for the presence of two types of methyl protons in the radical-cation of tetrakis(dimethylamino)ethylene[94]. Another instance of the restriction of the freedom of the mutual rotation of the groups was observed in Coppinger's cation, which is formed on oxidation of 3,3′,5,5′-tetra-t-butylbis-(4-hydroxyphenyl)methane[95].

The examples enumerated above are sufficient to illustrate the fact that the conjugation conditions in neutral molecules and in the corresponding one-electron transfer products are different. This entails a significant change in the mobility of the groups and ultimately a change in the energy relations of the rotational isomers. Thus calculations have shown[96] that the energies of the rotational *cis*- and *trans*-isomers of terephthalaldehyde differ by not more than 0.012 eV. On the other hand, in the series of

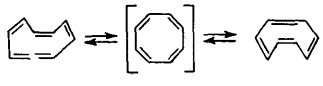
the corresponding radical-anions the *trans*-isomer (XXVIIb) is more stable than the *cis*-isomer (XXVIIa) by 0.083 eV, i.e. almost by 2 kcal. These calculations describe fairly completely the electronic structures of the molecules considered (the extended Hückel method with allowance for valence electrons by the Wolfsberg–Helmholtz method was used[97]). At the same time solvation and intermolecular electrostatic interaction effects would not of course be reflected when this approach is used. Therefore the observed quantitative difference between (XXVIIa) and (XXVIIb) can be far from the true values. Nevertheless, all the results show that electron transfer can significantly enhance the difference between the energy relations of the conformers.

Detailed study of the causes responsible for the conformational inhomogeneity of electron transfer products is one of the most attractive aspects of the present state of the investigations. There is a possibility of discovering general relations which are important and not self-evident.

V. ELECTRON TRANSFER AND CONFORMATIONS OF CYCLOPOLYENES

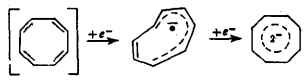
While in the instances discussed above electron transfer alters the conjugation conditions and hence the conformational mobility of the molecule, in cyclopolyenes electron transfer can lead to the formation of π-electron ring systems embracing all the ring atoms as a result of which the ring is maintained in one plane. We shall consider this phenomenon using cyclo-octatetraene and azocine as examples.

It is generally accepted that the structure of cyclo-octatetraene is best represented by the bent boat form (XXVIII) with L_{2d} molecular symmetry[98,99]. Single (1.462 Å) and double (1.334 Å) bonds, whose lengths do not differ significantly from the normal values for bonds of the C–C (sp^2–sp^2) (1.479 Å) and C=C (sp^2–sp^2) (1.338 Å) types respectively, alternate in the molecule[100]. The p_z orbitals located at the end of each single bond cannot overlap. This implies that there is no cyclic conjugation in cyclo-octatetraene and the bonds are localised. Cyclo-octatetraene, which is a vinylogue of benzene, behaves as a typical olefin. Some authors state[101,102] that it exhibits "blatant and unquestionable non-aromaticity". According to NMR data[102,103], there is a rapid and reversible migration of the double and single bonds in the cyclo-octatetraene molecule, leading to the conversion of the form (XXVIIIa) into (XXVIIIb) [reaction (18)].



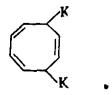
(XXVIIIa) (XXIX) (XXVIIIb) (18)

It follows from the spectra that the activation energy for this transition is 14 kcal mole^{-1}, which is close to the 17 kcal mole^{-1} calculated by the LCAO-MO SCF method[104]. The planar conformation of cyclo-octatetraene (XXIX) is an intermediate form in equilibrium (18). It is believed[104] that the above inequality of bond lengths should persist in form (XXIX). The planar or almost planar form (XXIX) is involved in electron transfer. The unpaired electron in the resulting radical-anion (XXX) can probably be delocalised to some extent over the perimeter of the molecule[105]. In other words, one can imagine this radical-anion as a fairly planar cyclic system with nine π-electrons. This system should tend to capture yet another electron and become converted into the completely planar dianion (XXXI) with ten delocalised electrons, satisfying the familiar Hückel aromaticity rule ($4n + 2$; $n = 2$). Electron transfer thus prevents the bending of the planar form [see reactions (18) and (19)].



(XXIX) (XXX) (XXXI) (19)

The transfer of a second electron is of course associated with the expenditure of appreciable additional energy, since it requires the final flattening of the molecule and the overcoming of the mutual repulsion of the free electrons[106]. However, this results in the formation of the stable aromatic cyclo-octatetraene dianion. In THF solutions cyclo-octatetraene reacts fairly rapidly with two equivalents of metallic potassium and on extensive cooling well formed crystals of the dipotassium salt of the dianion (XXXI) may be precipitated. These crystals have not so far been investigated by X-ray diffraction. On drying or on contact with air, they explode. However, the solutions are stable. The vibrational spectrum of the dipotassium salt of the cyclo-octatetraene dianion resembles those of other planar aromatic systems[107]. The transition energy in the short-wavelength region of the electronic spectra of this dianion and benzene, calculated by the free electron method, are close[108]. The method of calculation used is said[109] to represent fairly well the qualitative features of the electronic spectra, including the transition energies. The protons of the dianion (XXXI) are represented in the NMR spectrum by a sharp singlet. The ^{1}H NMR spectrum of cyclo-octatetraene also consists of a singlet with a very similar chemical shift[110]. These characteristics of the spectrum can be in no way related to the previously proposed[111] structure of the dipotassio-compound (XXXII).



(XXXII)

The fact that the compound with a double negative charge does not exhibit a shift of the ^{1}H NMR signal to a high field is evidence for a ring current. The hypothesis of a π-electron ring current is described, for example, by London[112] and the problem is discussed by Peacock[109] and Musher[113]. The ^{7}Li NMR spectrum was used to demonstrate the presence of a π-electron ring current in the dilithium salt of the cyclo-octatetraene dianion (see Table and Fig. 2).

^{1}H NMR data[110,116] show that the dipotassium salt of the cyclo-octatetraene dianion exists preferentially in the form of a close ion pair. If a π-electron ring current is possible in the organic component of the dilithium salt (XXXI), the chemical shift of the ^{7}Li signal should differ from the usual value, for example, from the ^{7}Li shift in lithium alkyls. The ^{7}Li signal for the salt (XXXI) should be displaced towards both lower and higher fields, depending on whether the metal atom is in the deshielding or shielding zone (Fig. 2, zones A or B). The data in the Table show that, compared with n-butyl-lithium, dilithiocyclo-octatetraene resonates in a much higher field. The ^{7}Li shift for the salt (XXXI) is close in magnitude to the shift for cyclopentadienyl-lithium and the aromaticity of the cyclopentadienyl anion has already been reliably demonstrated (see, for example Rafiel'[101]). Since the ^{7}Li signal in the (XXXI) spectrum is significantly displaced towards a high

field, the following conclusions may be reached: (1) Li^+ is associated with the π-electron system of the dianion; (2) the π-electron system of the dianion can indeed induce a local magnetic field, i.e. ring currents; (3) the Li^+ cations are in the regions of increased shielding, i.e. below and above the plane of the dianion (Fig. 2).

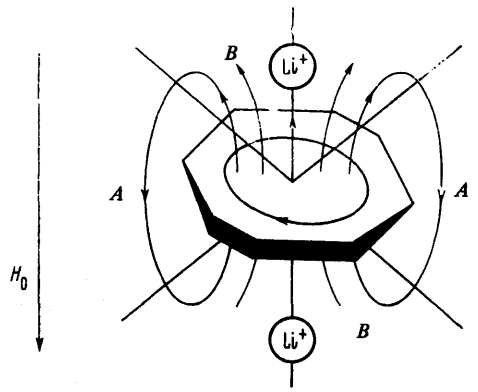


Figure 2. Graphical representation of the effect of the π-electron ring current in the dilithium salt of the cyclo-octatetraene dianion; A—deshielding zones; B—shielding zones.

It would be interesting to test these conclusions experimentally, particularly since, according to the results of recent studies [117,118], the possibility of the electrochemical synthesis of the ten-π-electron cyclo-octatetraene dianion is in fact ruled out. It was found that, after the formation of the radical-anions in THF, DMF, acetonitrile or pyridine ($E_{1/2} = -1.746$ V relative to the saturated calomel electrode), the addition of a second electron does not occur. The radical-anion is protonated by the hydrogen atom of the tetra-alkylammonium salt present in solution as the carrier electrolyte and this is followed by the one-electron reduction of the resulting radical $C_8H_9^{\cdot}$ [reaction (20)]. The anion $C_8H_9^-$ formed shows a smaller tendency than the radical-anion $[C_8H_8]^{\cdot-}$ to react with the supporting electrolyte cation and to be converted into cyclo-octatriene in the interaction with submillimolar (10^{-5} M) admixtures of water, which remain even in absolute solvents. Thus the electrochemical reduction of C_8H_8 consists of stages involving electron transfer and chemical reduction of the products; the process as a whole is irreversible:

$$C_8H_8 \xrightarrow{+\bar{e}} [C_8H_8]^{\cdot-} \xrightarrow{Bu_4N^+} C_8H_9^{\cdot} + Bu_3N + CH_3CH_2CH{=}CH_2;$$
$$C_8H_9^{\cdot} \xrightarrow{+\bar{e}} C_8H_9^- \xrightarrow{H_2O} C_8H_{10} \xrightarrow{+ne^-} \text{products.} \qquad (20)$$

It has been noted [117] that, when no account is taken of the interactions between the dianion $C_8H_8^{2-}$ and the medium, leading to a specific organisation of the solvation shell, it is possible to estimate the difference between the potentials of the reduction of C_8H_8 to $[C_8H_8]^{\cdot-}$ and of the latter to $C_8H_8^{2-}$ as 3 V. Therefore, under the conditions of the electrochemical process, it is difficult to create potential differences such that the dianion $C_8H_8^{2-}$ can be formed.

On the other hand, earlier investigators, for example Allendoerfer and Rieger [106], concluded on the basis of both classical and a.c. polarographic data that electrochemical electron transfer to the radical-anion $[C_8H_8]^{\cdot-}$ in DMF, DMSO, and acetonitrile is rapid, reversible, and takes place at a moderately negative potential. It is now necessary to either regard this conclusion as erroneous or to undertake a detailed test of the behaviour of cyclo-octatetraene in these systems. At the same time it would be necessary to compare the structures and properties of the two-electron reduction products obtained at the electrode and with the aid of alkali metals. A fairly high stability of alkali metal salts of the cyclo-octatetraene radical-anion and dianion in THF, DME, and even in liquid ammonia has been noted [119]; the dipotassium salt (XXXI) is capable of undergoing one-electron oxidation in THF solution with formation of $C_8H_8^{\cdot-}$, K^+. [120] The conversion of cyclo-octatetraene into an aromatic dianion is probably significantly facilitated by the formation of contact aggregates with the alkali metal cation. The latter increases the stability of the electron transfer products and at the same time itself interacts with the delocalised electron cloud.

The ^7Li chemical shifts for certain organolithium derivatives (relative to LiCl).

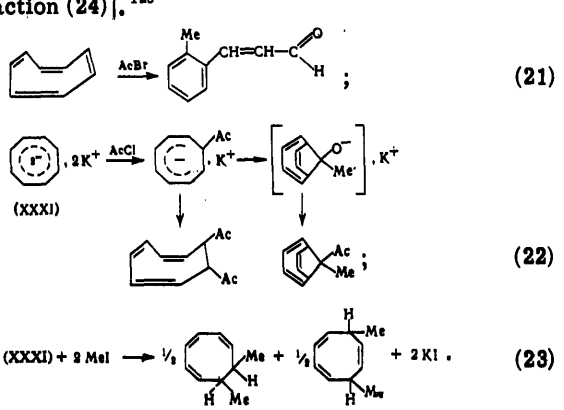
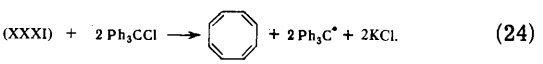
$Me(CH_2)_3CH_2Li$	1.5	114
	−8.55	114
	−8.37	115

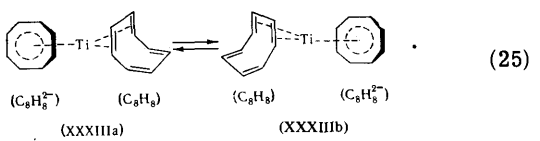
It is noteworthy that the chemical properties of the salts (XXXI) are determined primarily by the presence of the double negative charge. The chemical reactions cannot by themselves demonstrate whether this dianion has a planar or a non-planar structure. The results of the acylation of cyclo-octatetraene [121] and its dipotassio-derivatives [122] are presented in formulae (21) and (22). The alkylation of the salt (XXXI) by methyl iodide [reaction (23)] proceeds in the same way as reaction (22). [123] However, when triphenylmethyl chloride is used as the halide, disubstituted derivatives are not formed (cf. Azatyan [124]) and the reaction stops at the electron transfer stage [reaction (24)]. [125]





(24)

Electron transfer from (XXXI) to titanium tetrachloride leads to the reduction of the cation Ti^{4+} with simultaneous binding of two C_8H_8 rings into the complex $(C_8H_8)_2Ti$.[126] It follows from X-ray diffraction studies[127] that one eight-membered ring in this complex is bent, while the other is planar and that the rings are linked in different ways to the central metal atom. According to NMR data[128], at about 60°C there is intramolecular electron transfer via the metal, from one ligand to the other, so that form (XXXIIIa) is converted into (XXXIIIb) [reaction (25)].



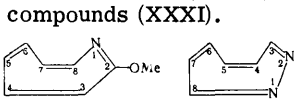
(25)

(XXXIIIa) (XXXIIIb)

Here one ring, which was previously planar, is bent, while the previously bent ring is converted into the planar form. The activation energy for this transition is 16–17 kcal mole^{-1}. It is extremely significant that the observed value is comparable to the one stated above for the inversion of cyclo-octatetraene[102,104] via reaction (18).

The abstraction of an electron from cyclo-octatetraene leads to a radical-cation whose ESR spectrum indicates a non-planar structure[129]. Calculations[106] also predict a non-planar form of this radical. The cyclo-octatetraene dication contains six π-electrons. If this dication had a planar structure, then, according to the Hückel rule, it would be aromatic and would exhibit an enhanced stability. So far such a dication has not been obtained, but it has been shown[130] that the ion $C_8H_8^{2+}$, formed under the influence of electron impact in a mass-spectrometer, is stable.

Azacyclo-octatetraene[102] has C=C vibration frequencies[131] and ultra-violet spectra[132] surprisingly similar to those of the nitrogen-free analogue (XXVIII). Hence one may conclude, according to Paquette and Kakihana[102], that the nitrogen-containing ring has, like cyclo-octatetraene, a strain-free boat form of type (XXXIV). According to the conditions of synthesis[102], all the azacyclo-octatetraene derivatives investigated contained a methoxy-group in the 2-position; in THF, DME, or liquid ammonia these compounds combine with two equivalents of potassium, forming dianions[133]. The NMR spectra show that the dianions are planar and contain delocalised ten-electron systems, i.e. have the structure (XXXV).[134] These are aza-analogues of compounds (XXXI).

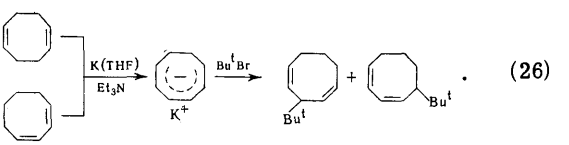


(XXXIV) (XXXVI)

The equalisation of the charge is also indicated by the formation of 3,4-, 3,6-, and 7,8-dihydro-derivatives on reaction of (XXXV) with proton donors and the interconversions of the dihydro-derivatives are impossible under the reaction conditions[133,134]. The electrochemical reduction of (XXXIV) at mercury or platinum electrodes in DMF or THF in the presence of tetra-n-butylammonium salts as carrier electrolytes[135–137] also leads to the dianion (XXXV). We may note that, according to data from the same laboratory[117], the electrochemical reduction of cyclo-octatetraene in an aprotic medium is arrested at the stage involving the formation of the radical-anion (XXX). This difference between (XXVIII) and (XXXIV) also follows from the calculation of the corresponding π-electron energy levels[138]. According to the authors, the transfer of the first electron to azacyclo-octatetraene is coupled with a change in its configuration (XXXIV) to an almost planar form, actually more planar than in the case of compound (XXX). This process requires such a high energy expenditure that the capture of a second electron, required to complete the decet ($4n + 2$; $n = 2$), proceeds without additional activation. This implies that the reduction of the radical-anion in a polarographic experiment should proceed more readily than that of the initial azacyclo-octatetraene and that, after the attainment of the potential corresponding to the transfer of the first electron, the second electron should also be transferred. It follows from the analysis of polarographic data[136] that the two-electron reduction of (XXXIV) to (XXXV) does indeed consists of two simultaneous one-electron stages.

Recently it proved possible to obtain also the diaza-analogue of cyclo-octatetraene for which the authors suggest the structure (XXXVI).[139] It would be interesting to show whether this compound is capable of undergoing a change in geometry in electron transfer reactions.

Electron transfer might also induce the isomerisation of non-conjugated cyclo-olefins to conjugated forms. Thus metallation of cyclo-octa-1,3-diene and cyclo-octa-1,5-diene leads [see reaction (26)] to the same anion, which on treatment with t-butyl iodide gives rise to a mixture of equal amounts of 3-t-butylcyclo-octa-1,4-diene and 5-t-butylcyclo-octa-1,3-diene[140].



(26)

---o0o---

The data discussed in this review permit the conclusion that the geometry of organic compounds can change on electron transfer. The cause of such changes have been discussed. They may determine the stereochemical structure of the products obtained as a result of reactions involving an electron transfer stage. Consequently the detection of the stereochemical changes induced by electron transfer is important for the investigation of the mechanisms of many organic reactions. In particular, it is important to study the relation between the geometry of the repeat units in high-molecular-weight compounds and the method used to initiate polymerisation. On the other hand, it would be useful to take into account more fully the role of electron exchange processes in biochemical reactions. Indeed, many biomolecules with unsaturated bonds are involved in reactions associated with electron transfer. Here one may include the chemical changes arising, for example, in the processes involved in vision[141] or in the isomerisation of unsaturated aliphatic acids under the influence of enzymes[142,143]. The capacity to undergo a change in configuration on electron transfer might be used to select new biologically active substances; no doubt other no less important applications are also possible. The aim of the present review is to attract attention to the stereochemical results of electron transfer.
