Catalysis of Symmetry-disallowed Reactions

V.I.Labunskaya, A.D.Shebaldova, and M.L.Khidekel'

Opportunities for applying the principle of the conservation of orbital symmetry to catalytic processes are surveyed. Current views on the role of a transition metal in the catalysis of symmetry-disallowed reactions are reported, and possible mechanisms are discussed. Close attention is paid to the correlation of the catalytic activity of metal-containing catalysts with the electron configuration of the transition metal, the structure of the complex, and the nature of the ligands. Examples of catalytic reactions disallowed by the Woodward-Hoffmann rules—valency isomerisation of hydrocarbons, hydrogenation and disproportionation of alkenes, cyclo-oligomerisation—are considered in the light of ideas on concerted and stepwise mechanisms. A list of 137 references is included.

I. INTRODUCTION

The study of catalysis as a method for conducting chemical processes has always made use of ideas developed in solid-state physics, organic, coordination, inorganic, and polymer chemistry, and enzymology. Many general theories of catalysis—physical, multiplet, semiconductor, supersaturation, etc. theories—were constructed in various historic periods on the foundation of advances in solid-state physics. From Sabatier to the present time the concept of intermediate compounds has been of the greatest assistance in the selection of new catalysts; such ideas were based on achievements in the preparation of various types of coordination and organometallic compounds. Generalisations such as the theory of "soft" and "hard" acids and bases, electronic theories developed in organic chemistry, etc. have proved extremely useful for catalysis. "Catalytic bionics"—whose aim is to create novel highly efficient and specific catalysts—has been constructed from data on the structure and the mechanism of the action of enzymes and the general principles of the action of biological catalysts.

One of the most important recent achievements of theoretical organic chemistry has been to elaborate rules for the conservation of orbital symmetry in concerted reactions (called the Woodward–Hoffmann rules). The directions of many chemical processes have been explained and predicted by means of these rules during recent years. It appeared useful to examine their application to the catalysis of reactions that are disallowed for

reasons of symmetry. Several possibilities of interpreting the mechanism of the process and describing (in isolated cases predicting) the nature of the action of a transition-metal catalyst are discussed for such important reactions as the valency isomerisation of hydrocarbons, the hydrogenation and disproportionation of alkenes, and cyclo-oligomerisation.

II. MAIN RULES FOR THE CONSERVATION OF ORBITAL SYMMETRY IN CONCERTED REACTIONS

The Woodward–Hoffmann rules[1-6] are based on the hypothesis that the direction of a synchronous reaction is determined by the symmetry of the highest occupied orbitals†. The view that these orbitals determine the reactivity of molecules had been expressed earlier by other workers. In this connection we must note the papers by Fukui and his collaborators on the theory of frontier electrons[13-15], which provide a basis for correlations between the position of the reaction centre and the maximum electron densities in the highest occupied orbitals and the lowest vacant orbitals of a molecule. Longuet-Higgins and Coulson[16,17] as well as Dewar[18] used the theory of perturbations to explain aromatic substitutions. The merits and defects of these methods have been analysed in detail in Salem's review[19].

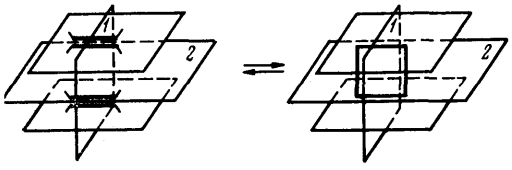

Figure 1. Symmetry elements for the coplanar combination of two ethylenic bonds to form cyclobutane.

The Woodward–Hoffmann method consists essentially in constructing correlation diagrams for the energy levels of products and reactants, and analysing them with respect to symmetry. If the symmetry of the highest occupied orbitals in the ground state of the products correlates with the symmetry of the ground state of the reactants, the reaction is thermally allowed. If the ground state of the products correlates with an excited state of the reactants, the reaction is thermally forbidden, but is allowed photochemically. The fundamental principle was formulated by Woodward and Hoffmann: "Orbital symmetry is conserved in synchronous reactions"[6].

Since we shall be interested mainly in synchronous cycloaddition and electrocyclic reactions, let us examine as example two correlation diagrams—of two ethylenic bonds for the cycloaddition, and of butadiene and cyclobutene for the cyclisation—for which purpose we make use of the arguments in Ref. 6. In the simultaneous combination of two ethylenic bonds to form a cyclobutane ring four π-levels of the two ethylene molecules, the latter lying in two parallel planes, and four σ-levels of cyclobutane are classified as symmetric S or antisymmetric A relative to the plane located midway between the carbon atoms of ethylene (plane *1* in Fig. 1) and the plane parallel to those of the molecules and located midway between them (plane *2*).

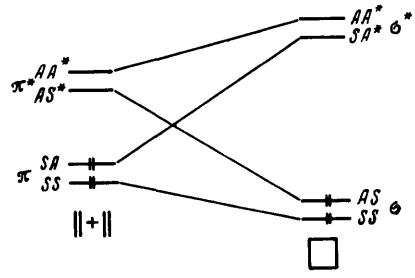

Figure 2. Correlation diagram of levels in the transition ethylene + ethylene → cyclobutane.

The correlation diagram for the transition ethylene + ethylene → cyclobutane shows (Fig. 2) that the reaction is thermally prohibited for reasons of symmetry, since the ground state of ethylene correlates with an excited state of cyclobutane. For reactions of this type the general rule of the conservation of symmetry can be written: reaction is thermally allowed provided that $m + n = 4q + 2$ (where m and n are the numbers of π-electrons in the reactants, and $q = 1, 2, 3, \ldots$); reaction is thermally forbidden for a system in which the number of electrons $m + n = 4q$.

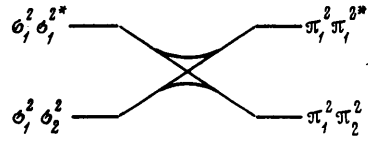

Figure 3. Diagram of states for cyclobutane and ethylene.

With forbidden reactions lines joining levels of similar symmetry intersect. Owing to electronic interaction, however, the system may cross from the adiabatic curve to the ground state of the product[20]. The diagram for the states of cyclobutane and two ethylene molecules shows that in this case symmetry prohibition is responsible for the high energy barrier opposing the transition ethylene + ethylene → cyclobutane (Fig. 3). No barrier due to symmetry is present with symmetry-allowed reactions (e.g. the Diels–Alder reaction).

A similar application of symmetry analysis to the cyclisation of butadiene (an electrocyclic reaction) shows[6]

†Numerous examples of concerted reactions obeying the rules of orbital symmetry (electrocyclic, sigmatropic reactions, cycloadditions, eliminations, etc.) are cited in Woodward and Hoffmann's monograph[6] as well as in reviews[7-12].

that conversion of a π-bond into a σ-bond may occur by either conrotatory or disrotatory motion of the ends of the molecule (Fig. 4). The corresponding symmetry elements are the axis of the molecule and a reflecting plane. The conrotatory path is thermally allowed with respect to symmetry, whereas the disrotatory path is forbidden (Fig. 5).

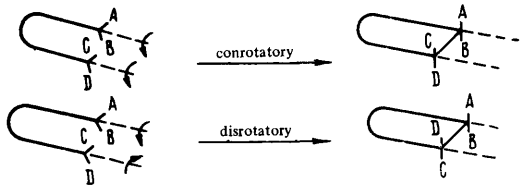

Figure 4. Conrotatory and disrotatory cyclisation of butadiene.

The general formulation of the prohibition rules for electrocyclic reactions is that the latter are thermally permitted with conrotatory motion if $k = 4q$ (where k is the number of π-electrons) and photochemically permitted when $k = 4q + 2$ (tne opposite relation applies with disrotatory motion).

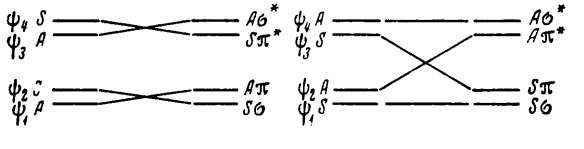

Figure 5. Correlation diagrams of levels for the transition butadiene → cyclobutane.

Correlation diagrams can be applied only to systems that possess symmetry. A different method of analysis was suggested for asymmetric systems [21]. A more general method (mapping) was proposed by Trindle [22] for a wide range of reactions, including those to which the Woodward–Hoffmann rules do not apply.

III. ROLE OF A TRANSITION METAL IN THE CATALYSIS OF SYMMETRY-DISALLOWED REACTIONS

Many symmetry-disallowed thermal reactions involving the cycloaddition of two ethylenic bonds with the formation of cyclobutane or the concerted opening of a cyclobutane ring (the valency isomerisation of strained σ-bonds, the disproportionation of alkenes, cyclo-oligomerisation) take place readily in the presence of complexes of transition metals. At the present time there is no generally accepted view on the role of the metal in catalysing such symmetry-disallowed reactions. The main problem consists in deciding whether such reactions are concerted or non-concerted (stepwise) in character.

A non-concerted mechanism involves essentially redox addition with formation of an intermediate complex, and can usefully be considered for specific examples of catalysed symmetry-disallowed reactions (Section IV). With a concerted mechanism the influence of the metal is apparent in a change in the symmetry of the highest occupied orbitals of the organic substrate.

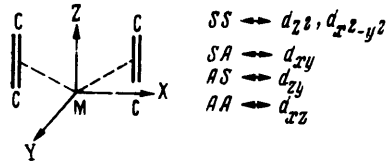

Figure 6. Metal–dialkene complex.

The correlation diagram (Fig. 2) shows that the orbitals of symmetry *SA* and *AS* play the main part in the concerted combination of two ethylenic bonds to form a cyclobutane ring. Occurrence of the thermal reaction requires conformity in symmetry between the ground states of cyclobutane and the two alkene molecules, which can be obtained by the mixing of metal and alkene orbitals in complexes of a transition metal with the alkene and with cyclobutane. Correlation diagrams for such complexes were first given by Mango and Schachtschneider [23] for the suprafacial $(2s + 2s)$‡ cycloaddition of two alkenes.

The concerted addition of two alkenes requires that their antibonding *AS* orbital should be populated (Fig. 2). Since the highest occupied ethylenic π-orbital is *SA*, formation of a metal–alkene complex involves transfer of an electron pair from this orbital to a metallic *d*-orbital of suitable symmetry, whereas an *AS** orbital obtains an electron pair from a *d*-orbital of the same symmetry (*AS*) [24,25].

Fig. 6 shows the symmetry relations between metal and alkene orbitals for a metal–dialkene complex in the given coordinate system. The interaction between metal and alkene orbitals results in their occupation in such a way that the symmetry-disallowed reaction ethylene + ethylene → cyclobutane becomes allowed in the presence of the metal, as follows from the correlation diagram (Fig. 7).

The ligand field of the non-reacting ligands has been disregarded in the construction of this correlation diagram: i.e. the diagram has been drawn for a metal–dialkene complex. In this case all the *d*-orbitals are degenerate. Nevertheless, the presence of non-reacting ligands creates a ligand field which splits the *d*-orbitals; this must be taken into account in studying the catalysis of symmetry-disallowed reactions [26]. Formation of an intermediate complex $ML_nAlkene_2$ in actual catalytic systems is accompanied by splitting of the *d*-levels, the degree of splitting and the distribution of the levels depending on the nature of the ligand and the structure of the complex. The symmetry of the highest occupied orbital of the complex is determined by its geometry. With strong ligand fields, where the splitting of the *d*-orbitals

‡Here and subsequently the symbols *s* and *a* denote suprafacial and antarafacial addition [7].

is large, the highest occupied orbital of the metal–cyclobutane complex may be of either *SA* or *AS* symmetry. Fig. 8 shows that the transition ethylene + ethylene → cyclobutane remains disallowed by symmetry: i.e. a ligand-field symmetry restriction operates in this case [26].

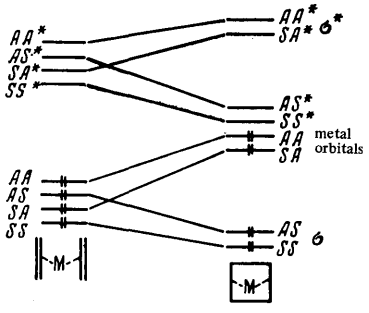

Figure 7. Correlation diagram for the conversion of the complexes metal–dialkene → metal–cyclobutane.

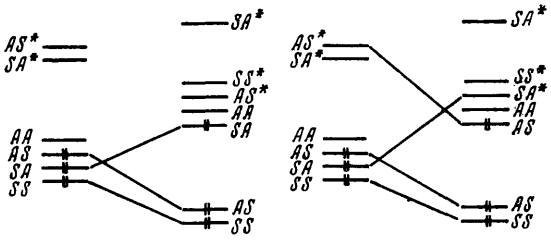

Figure 8. Correlation diagrams for the conversion of the complexes metal–dialkene → metal–cyclobutane for strong ligand fields.

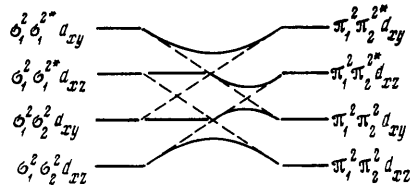

Figure 9. Diagram of states of metal–dialkene and metal–cyclobutane complexes.

The interaction between the orbitals of reactant and metal in electrocyclic reactions catalysed by transition metals produces the same effect as with cycloaddition of type 2 + 2.

A different view, that the metal acts by lowering the activation barrier to the disallowed reaction, not by changing the symmetry of the orbitals in the reactants, has been put forward by van der Lugt [27]. This view is supported by the correlation diagram of states for the concerted opening of the cyclobutane ring in the case of the square planar complex ML_2Cyclobutane and ML_2Alkene, where the metal has a d^8 shell. However, Mango has shown [28] that this example is a particular case of catalysis in which, owing to the effect of the ligand field, the splitting of the *d*-orbitals is such that the reaction remains disallowed by symmetry, but its activation barrier is greatly lowered by the mixing of the occupied orbitals with lower excited orbitals (Fig. 9).

IV. SYMMETRY-DISALLOWED REACTIONS CATALYSED BY TRANSITION-METAL COMPLEXES

Numerous examples of reactions, forbidden by the rules of the conservation of orbital symmetry but catalysed by transition metals, have become known since the publication of the Woodward–Hoffmann correlations [1–5]. They include the valency isomerisation of strained cyclic systems, the disproportionation and hydrogenation of alkenes, and also cyclo-oligomerisations. Examination of these catalytic reactions in the light of the conservation rules is extremely useful for determining the conditions under which such processes may be expected to occur.

Three views are currently held on the mechanism of symmetry-disallowed reactions catalysed by transition metals. Firstly, the reaction can be regarded as a concerted process of type 2 + 2, which becomes symmetry-allowed as a consequence of interaction between the electron levels of organic substrate and metal [26]. Another opinion [27] is that the introduction of orbitals of the metal intermediate in energy between the highest occupied and the lowest vacent orbital of the substrate lowers considerably the activation energy of the reaction, which remains symmetry-disallowed. Finally, a non-concerted process is possible, in which an organometallic intermediate is formed by oxidative addition of the metal to the substrate [29,30].

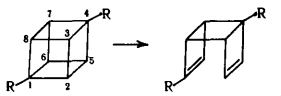
1. Valency Isomerisation of Strained Cyclic Systems

Valency isomerisations of cyclic systems having highly strained σ-bonds are of great interest among the symmetry-disallowed reactions known at the present time. While being in most cases "thermally forbidden" according the Woodward–Hoffmann rules, these reactions take place extraordinarily readily under mild conditions in the presence of compounds of transition metals; they are characterised also by high selectivity and by stereospecificity. Apart from the theoretical significance of valency isomerisations in developing the principle of the conservation of orbital symmetry, they are also useful for organic preparations, since they provide routes to the synthesis of several unique hydrocarbons (e.g. cuneane and semibullvalene).

Extraordinarily interesting examples of the catalytic valency isomerisation of strained σ-bonds are provided by cubane [31,32] and by homocubyl [33,34], 1,1′-bishomocubyl [33–38], and secocubane [39,40] systems, information on which has appeared quite recently. The very existence and the thermal stability of highly strained cubane compounds can probably be explained by the Woodward–Hoffmann rules, according to which thermal rearrangements of the type $\sigma 2a + \sigma 2a$ are not allowed for these molecules in the ground state.

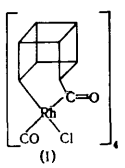
Ions and complexes of several transition and non-transition metals—rhodium, silver, palladium, copper, magnesium, zinc, iron, and mercury—have been examined as catalysts for the isomerisation of cubane and its derivatives. However, only silver(I), rhodium(I), and palladium(II) compounds were found to catalyse this

process, and their catalytic activity was varied and highly specific. In the presence of catalytic quantities of diene complexes of the type $(RhCl\,dien)_2$ (where diene represents norbornadiene, cyclo-octa-1,5-diene, or *syn*-tricyclo-octadiene) cubane undergoes rapid and quantitative isomerisation into *syn*-tricyclo-octadiene[31]:



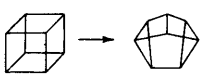
This process can be regarded as a concerted opening of the cyclobutane fragment of type $\sigma 2s + \sigma 2s$, i.e. as concerted rupture of the $C_{(1)}-C_{(2)}$ and $C_{(5)}-C_{(6)}$ bonds allowed by the participation of a transition metal of suitable electron configuration (d^8), which donates electrons to antibonding cubane orbitals of appropriate symmetry. However, no experimental evidence in support of a concerted mechanism was obtained.

Cassar et al.[31] quote certain results indicating a non-concerted mechanism for the isomerisation of cubane into tricyclo-octadiene. The rate-determining step in this mechanism is the rupture of one carbon–carbon bond by the oxidative addition of the metal to the cubane. Oxidative addition is well known with rhodium and other d^8 complexes[29,30]. A non-concerted route is supported by kinetic data, the distribution of isomeric products from a monosubstituted cubane, and above all the isolation of an intermediate rhodium complex in the stoichiometric reaction of cubane with the dimer of the dicarbonylrhodium chloride. The tetrameric structure of the intermediate complex



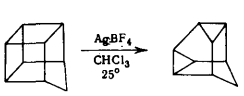
which corresponds to the tetragonal structure of the rhodium atom, is quite soundly based on its chemical reactions and infrared spectra[31].

The silver ion is an efficient catalyst for the isomerisation of cubane and its derivatives[32,34]. The valency rearrangement of cubane itself (catalysed by silver perchlorate in benzene) yields the saturated isomer cuneane (pentacyclo[3,3,0,$0^{2,4}$,$0^{3,7}$,$0^{6,8}$]octane), a representative of important natural ring systems (the cuneane molecule should be ~30–40 kcal mole^{-1} less strained than cubane):

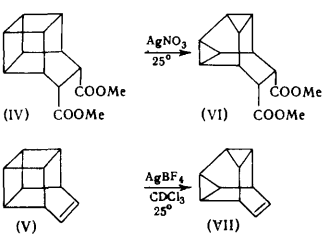


Cubane undergoes an analogous transformation under the influence of palladium(II) complexes (e.g. $[PdCl_2(C_6H_5CN)_2]$).[32]

The remarkable ability of the silver ion to promote symmetry-disallowed skeletal rearrangements is clearly apparent in the valency, isomerisation not only of cubane but also of its derivatives—homocubyl, 1,1′-bishomocubyl, and secocubane systems. In particular, homocubane (II) is converted in the presence of silver tetrafluoroborate into pentacyclo[4,3,0,$0^{2,4}$,$0^{3,8}$,$0^{5,7}$]nonane (III):[33]

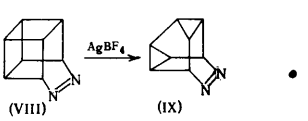


Although the homocubane structure is more strained than the pentacyclononane structure by about 45 kcal mole^{-1}, the purely thermal rearrangement ($\sigma 2a + \sigma 2a$) of (II) into (III) is not allowed by the Woodward–Hoffmann rules. The ease of the silver-catalysed process is probably due to mixing of the orbitals of the metal with the strained σ-orbitals of homocubane, resulting in the appearance of new occupied molecular orbitals, whose symmetry properties are compatible with the permitted isomerisation. Examples of the valency isomerisation of 1,1′-bishomocubyl derivatives are provided by the rearrangement of compounds (IV) and (V) into the corresponding pentacyclic isomers (VI) and (VII)[33–35]:



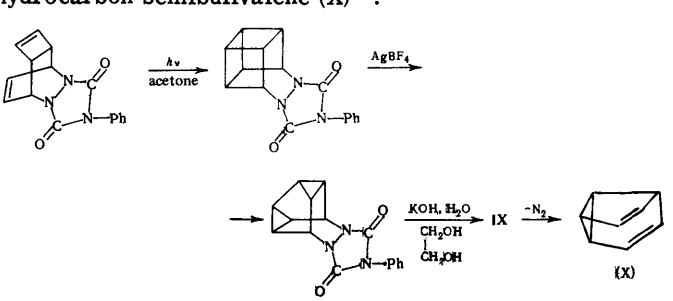
Formation of the pentacyclic diester (VI)has been observed also in thermal isomerisation. This suggests that here the effect of the transition metal is to lower the energy barrier to reaction, especially as four cyclobutane rings are converted into the thermodynamically more stable system comprising two cyclopropane and two cyclopentane rings. This reaction was not catalysed by compounds of mercury, copper, zinc, iron, and rhodium, nor by mineral acids.

It is noteworthy that a redistribution of σ-bonds occurs with compound (V), while the π-bond of the cyclobutene ring, having a greater tendency to coordinate with a metal, remains unchanged[33]. Nevertheless, the azo-derivative (VIII) does not isomerise into (IX)



under conditions of catalysis by the silver ion, probably owing to the presence of the lone pairs of electrons on the nitrogen atoms, which interact readily with the metal[36].

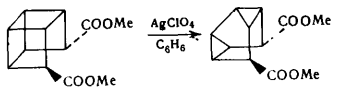
The silver-catalysed rearrangement of 1,1′-bishomocubyl systems has been used for preparative purposes, in particular to obtain the hitherto almost inaccessible hydrocarbon semibullvalene (X)[36]:



Although attempts to obtain this difficultly accessible hydrocarbon by the valency isomerisation directly of compound (VIII) were unsuccessful[36], use of its *NN*′-disubstituted derivatives (e.g. an *NN*′-diester) gave positive results[37].

The stereospecificity of catalytic valency isomerisations of cubane systems is excellently illustrated by the

silver-catalysed rearrangement of secocubane compounds[39,40]. Thus the *endo-endo*-diester (XI) gives a quantitative yield of the *endo-endo*-tetracyclo[3,3,0,$0^{2\ 8}$,$0^{4\ 6}$]-octane derivative (XII), and the *exo-exo*-diester is correspondingly converted into *exo-exo*-isomer[40]:



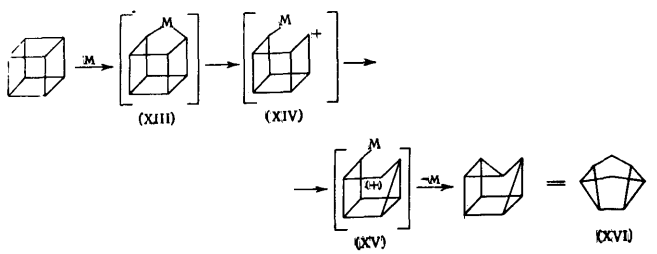
(XI) (XII)

Similar stereoselectivity has been observed also with tetra-substituted derivatives[39].

From the distribution of reaction products and a comparison of the rates of isomerisation of various *exo-endo*-isomers it is concluded[39] that substituted σ-bonds ($C_{(1)}$–$C_{(2)}$, $C_{(5)}$–$C_{(6)}$, $C_{(2)}$–$C_{(3)}$, and $C_{(4)}$–$C_{(5)}$) are not involved in the reaction. Furthermore, numerous examples of the isomerisation of homocubyl, 1,1′-bishomocubyl, and secocubane systems have shown convincingly that the presence of the $C_{(2)}$–$C_{(5)}$ bond is not necessary for the reaction.

The marked difference in catalytic properties shown by rhodium(I) compared with silver(I) and palladium(II) in the valency isomerisation of cubane and its derivatives cannot be explained in terms of electron configurations, since palladium(II) ($4d^8$) resembles silver(I) ($4d^{10}$) more closely than the isoelectronic rhodium(I) ($4d^8$). The reaction mechanism in this case is most probably determined by the oxidising properties of the metals or the effect of the ligand field.

The most general view of the valency isomerisation of cubane and related compounds catalysed by silver(I), palladium(II), and rhodium(I) has been given by Cassar et al.[41] on the basis of a non-concerted carbonium-ion mechanism involving a stage of oxidative addition:



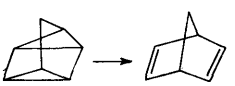
The oxidative addition of a metal ion (Ag^+, Pd^{2+}, or Rh^+) to the cubane molecule yields an organometallic adduct (XIII), which is obviously converted by the ions Ag^{2+} and Pd^{4+} into a cyclobutylcarbonium ion (XIV) (because of the strongly degenerate oxidative character of these metal ions). The ion (XIV) would in turn rearrange into the more stable cyclopropylcarbonium ion (XV). Subsequent reductive elimination of the metal ion should yield the final product, e.g. cuneane (XVI). In the case of catalysis by rhodium(I) further conversion of the organorhodium compound into a carbonium ion probably cannot occur owing to the lower oxidising power of rhodium(III)—compared with silver(II) and palladium(IV).

A stepwise mechanism is supported also by the influence of the positions and electronic effects of substituents on the rates of isomerisation of cubane systems[39,40,42]. Thus a linear free-energy correlation has been established[42] between the rate constants of the rearrangement of 1,4-disubstituted cubanes and the Taft polar δ* constants: rearrangement takes place more slowly the more negative is this constant (the greater the electron-repelling effect of the substituent). The closely similar rates of isomerisation of all stereoisomers of the secocubane ester (XI) and of reaction of the more strained dimethyl cubane-1,4-dicarboxylate probably indicate that electronic factors have a greater influence than geometric factors, which can be explained only in terms of a stepwise mechanism.

In spite of the above fairly convincing arguments in support of a non-concerted pathway for the valency isomerisation of cubane systems, interpretation of these reactions on the basis of a concerted mechanism cannot be finally rejected.

We can try to explain certain facts as due to the effect of the ligand field. The difference in catalytic activity between the isoelectronic palladium(II) and rhodium(I) is obviously associated, not with filling of the *d*-shells, but with the difference in the effects of the field due to the ligands (e.g. $[PdCl_2(C_6H_5CN)_2]$ and $[(RhCl\,dien)_2]$. Substitution of the ligands even in the rhodium complex may lead to a loss of activity towards the isomerisation of cubane (such an effect is produced in particular by replacing the diene ligands by triphenylphosphine ligands[31]). An intermediate complex of rhodium with cubane and its derivatives could be isolated only in the case of the dimer of carbonylrhodium chloride, which cannot be related to the specific properties of carbon monoxide as a ligand. Mango and Schachtschneider showed[26] that this ligand imposes a considerable ligand-field type of restriction on the concerted opening of the cyclobutane ring. They do not recommend the use of carbonyl-containing complexes as catalysts for valency isomerisations. The mechanism of the valency isomerisation of cubane and its derivatives catalysed by transition metals—silver(I), palladium(II), and rhodium(I)—has not yet been finally established. This problem may be solved when additional experimental results appear, and have been subjected to detailed analysis taking into account the orbital symmetry with the construction of correlation diagrams in each specific case.

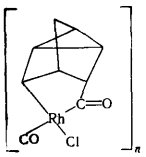
The conversion of quadricyclene into norbornadiene



is especially noteworthy among the valency isomerisations of strained cyclic systems disallowed by the Woodward–Hoffmann rules[43-45]. This skeletal rearrangement has been the object of the most thorough study of the dependence of the catalytic activity of transition-metal complexes on the filling of their *d*-shell and on the geometric configuration of the complexes[45]. The quantitative conversion of quadricyclene into norbornadiene has been effectively catalysed by mono- and di-alkene complexes of rhodium, palladium, and platinum—di-μ-chloro-dibicyclo-[2,2,1]hepta-2,5-dienedirhodium, di-μ-chloro-tetraethylenedirhodium, dichloro-cyclo-octa-1,5-dienepalladium, di-μ-chloro-bis-π-methylallyldipalladium, and dichloro-bicyclo[2,2,1]hepta-2,5-dieneplatinum—as well as by complexes of several transition metals with phthalocyanine and a tetraphenylporphyrin[45].

Two views are held on the mechanism of this reaction, as in the case of cubane: either the cyclobutane ring undergoes concerted opening, or a non-concerted process involves initial cleavage only of one carbon–carbon bond of the cyclobutane fragment by oxidative addition. A telling argument in support of a non-concerted mechanism is the formation of a rhodium complex of quadricyclene[43] by reaction of the dimer of dicarbonylrhodium chloride

with excess of quadricyclene. The structure of this complex



resembles that of the corresponding cubane complex (I).[31] However, a concerted mechanism is also quite likely, since the molecule could easily coordinate with the metal as a consequence of the π-character of the cyclopropane bonds common to the three- and four-membered rings[44].

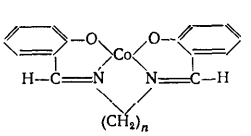
Table 1. Catalytic activity of square planar complexes of bivalent metals in the isomerisation of quadricyclene*.

Electronic structure	d^5	d^6	d^7	d^8				d^9		d^{10}
Metal ion	Mn^{2+}	Fe^{2+}	Co^{2+}	Ni^{2+}	Pt^{2+}	Rh^{1+}	Pd^{2+}	Cu^{2+}	Ag^{2+}	Zn^{2+}
	−	+	+	+	+	+	+	−	−	−

*+ = active; − = inactive.

Manassen has shown[45] that the ability of metals to catalyse the isomerisation of quadricyclene is primarily connected with the filling of the d-shell. Ions of metals with d^6, d^7, and d^8 electron shells are active in this process, whereas d^9 and d^{10} ions do not catalyse the reaction (Table 1). Such correlation is readily explained in terms of a concerted mechanism. In the d^8 complexes of rhodium, palladium, and platinum the d_{xy} orbital (i.e. the orbital of symmetry AS) should be vacant, or the highest unoccupied p-orbital should be quite close in energy to the occupied d-orbital. In the d^{10} complexes of copper(I) and silver(I) all the orbitals are occupied, and these ions are evidently incapable of catalysing the concerted opening of the cyclobutane ring.

The effect of ligands on the catalytic activity of the complexes (Section III) is due to splitting of the metal orbitals. In a study of complexes with quadridentate ligands (phthalocyanine, tetraphenylporphyrin, and certain Schiff bases) Manassen showed that a square planar configuration is the main condition for catalytic activity in the isomerisation of quadricyclene[45]. This configuration possesses vacant octahedral sites for the coordination of quadricyclene molecules with formation of an intermediate complex of symmetry such that concerted opening of the cyclobutane ring becomes permitted. As soon as the configuration of the catalytic complex ceases to be planar, the symmetry of the intermediate complex changes, and concerted opening of the ring remains symmetry-disallowed. For example, the most active catalyst for the rearrangement of quadricyclene was the square planar cobalt complex of a Schiff base



(XVII)

having $n = 2$. Complexes in which $n > 2$, whose configuration is non-planar, do not catalyse this isomerisation. Furthermore, the need for vacant octahedral sites in the square planar complexes is supported by the inhibition of their catalytic activity by pyridine bases, which are known to coordinate at octahedral sites in metal porphyrins[46].

Thus the important factor in the catalysis of symmetry-disallowed reactions is the field due to the ligands, together with the filling of the d-orbitals of the metal. On the whole the catalytic activity of each metal in concerted addition (or rupture of bonds) depends on its ability to form complexes of definite symmetry. That is why some metals possess catalytic activity, while others do not.

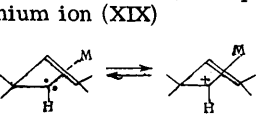
A detailed study has been made of the isomeric changes undergone by bicyclo[1,1,0]butane, which occurs as a structural unit in several polycyclic molecules. Available experimental results indicate that the direction of the valency isomerisation of bicyclobutanes catalysed by transition-metal complexes and ions is determined by the type of metal, the nature of the ligands, and also the positions of alkyl substituents in the bicyclobutane system.

Under the influence of the silver ion alkylated bicyclobutanes undergo almost quantitative and largely stereospecific conversion into dienes[47-50]. Thus *exo-exo*- and *endo-exo*-2,4-dimethylbicyclobutanes are converted mainly into *trans-trans*- and *cis-trans*-hexa-2,4-dienes respectively[47,48]. Under similar conditions 1,2,2-trimethylbicyclobutane yields not only hexa-2,4-dienes but also the corresponding vinylcyclopropane[49], whereas unsubstituted bicyclobutane is converted into butadiene[47].

Isomerisation proceeds differently in the presence of catalysts containing palladium[50,51]. Thus both 2,4- and 1,3-dimethylbicyclobutanes are converted under the influence of dichlorodibenzonitrilepalladium mainly into 2-methylpenta-1,3-diene[50]. Study of this complex together with bischloro-π-allylpalladium shows[51] that the nature of the ligand attached to the transition metal has a substantial influence on the direction of the isomerisation of bicyclobutanes. When small quantities (~ 0.2 mole %) of the catalyst are used, ligand exchange may occur during the reaction, which can lead to anomalous products[51].

In the presence of carbonyl complexes of rhodium, iridium, and ruthenium, alkylbicyclobutanes are converted into dienes and vinylcyclopropane. The structure and the proportions of the products are determined by the position of the alkyl substituents in the initial bicycle[50,52,53].

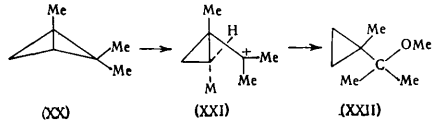
The mechanism of the valency isomerisations of the bicyclobutane system has been a matter of great debate. Several alternative mechanisms have been suggested. Paquette et al.[48,54] originally regarded the silver-catalysed rearrangement of bicyclobutanes into a 1,3-diene system as a concerted process of type $\sigma 2a + \sigma 2a$. However, later work[49,53,55,56] has led to rejection of a concerted mechanism for such processes. A silver–carbonium ion, resulting from rupture of the central $C_{(1)}$–$C_{(3)}$ bond of bicyclobutane followed by complex formation with the silver ion, was suggested[49] as intermediate. According to Gassman et al.[53] the intermediate compound is a transition-metal carbene complex (XVIII) in equilibrium with the hydride–carbonium ion (XIX)



(XVIII) (XIX)

These workers have since obtained[57,58] direct evidence that the interconversion (XVIII) ⟷ (XIX) is a stepwise

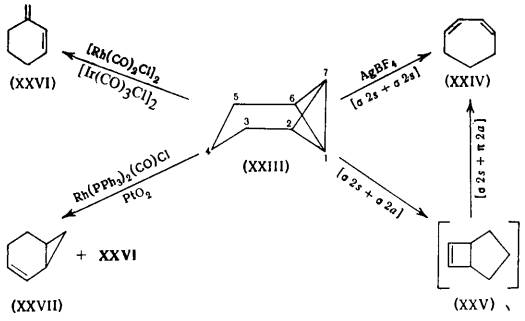
process involving successive rupture of the $C_{(1)}-C_{(2)}$ and $C_{(1)}-C_{(3)}$ bonds of bicyclobutane under the influence of the transition-metal complex. Formation of a cyclopropylmethyl cation (XXI) preceding appearance of the structures (XVIII) ⟷ (XIX) is supported by production of the corresponding methoxycyclopropane (XXII) from 1,2,2-trimethylbicyclobutane (XX) in the presence of bischlorodicarbonylrhodium in a strongly nucleophilic solvent (methanol):



(XX) (XXI) (XXII)

However, these workers [58] do not exclude the possibility of a different stepwise mechanism depending on the solvent.

The valency isomerisation of tricyclo[4,1,0,$0^{2,7}$]heptane (XXIII) is catalysed by a wide range of transition metals, the direction of the reaction being determined by the type of catalyst employed:

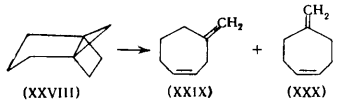


(XXVI) (XXIII) (XXIV) (XXVII) (XXV)

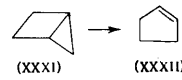
In the presence of silver tetrafluoroborate (XXIII) is converted rapidly and quantitatively into cyclohepta-1,3-diene (XXIV). [47,54] In view of the part played by the silver ion in several concerted processes, this reaction can be regarded as resulting from a symmetry-disallowed concerted ring opening of type $\sigma 2s + \sigma 2s$. With a non-concerted mechanism a two-step process can occur, involving as initial stage the thermally allowed rearrangement $\sigma 2s + \sigma 2a$ of (XXIII) to bicyclo[3,2,0]hept-6-ene (XXV) [59] followed by ring opening of type $\sigma 2s + \pi 2a$.

When (XXIII) isomerises in the presence of catalysts containing rhodium, iridium, platinum, ruthenium, palladium, and copper, the sole (or main) product is 3-methylenecyclohexene (XXVI), the yield of which is determined by the type of ligand [60,61]. Small quantities bicyclo[4,1,0]hept-2-ene (XXVII) are also formed. We must not overlook the fact that palladium(0), platinum(IV), and rhodium(I) were similar in their catalytic effects on this reaction, but the reason is still obscure. The ability of heterogeneous catalysts based on noble metals (PtO_2, Pd/C) to catalyse the isomerisation of tricycloheptane suggests that isomerisation is possible in their presence even during the hydrogenation of highly strained rings.

Examples of the valency isomerisation of polycyclic systems are the conversion of tricyclo[3,2,1,$0^{1,5}$]octane (XXVIII) into 4- and 5-methylenecycloheptenes (XXIX) and (XXX) [62] and the isomerisation of bicyclo[2,1,0]pentane (XXXI) into cyclopentene (XXXII) [63], which should take place in the presence of carbonyl complexes of rhodium, iridium, and ruthenium:



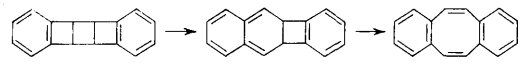
(XXVIII) (XXIX) (XXX)



(XXXI) (XXXII)

By analogy with the isomerisation of bicyclobutane and tricycloheptane the above changes are regarded [62] as stepwise processes with intermediate formation of a metal–carbene complex similar to structures (XVIII) ⟷ (XIX).

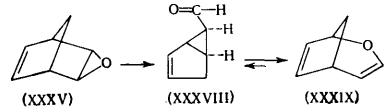
Several valency isomerisations involve the opening of a cyclobutene ring forming part of a bicyclic or tricyclic system. In the presence of silver ions at room temperature, for example, dibenzotricyclo-octadiene (XXXIII) isomerises to dibenzocyclo-octatetraene (XXXIV) [64–66]:



(XXXIII) (XXXIV)

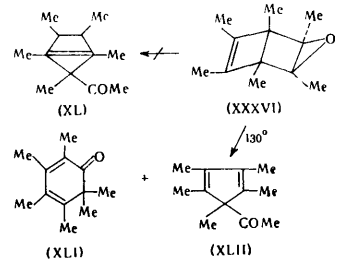
The forbidden disrotatory ring-opening (XXXIII) ⟷ (XXXIV) obviously becomes allowed thanks to the additional orbitals of the metal catalyst.

Papers have appeared recently [67,68] on the isomerisation of the epoxides of norbornadiene (XXXV), Dewar hexamethylbenzene (XXXVI), and cyclo-octatetraene (XXXVII). Under the influence of the dimer of dicarbonylrhodium chloride the first of these epoxides (XXXV) is converted quantitatively into the aldehyde (XXXVIII) and the cyclic ether (XXXIX):



(XXXV) (XXXVIII) (XXXIX)

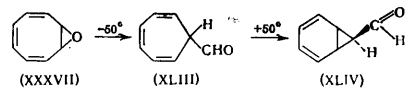
Thermal rearrangement of (XXXVI) is permitted and is a concerted process $\pi 2a + \sigma 2s + \sigma 2a$, which should yield the very strained cyclic system (XL). The actual products of thermal isomerisation, however, are the cyclohexadienone (XLI) and the cyclopentadienyl methyl ketone (XLII):



(XL) (XXXVI) (XLI) (XLII)

Catalytic isomerisation is more specific and gives mainly the latter product (XLII).

Cyclo-octatetraene epoxide (XXXVII) in the presence of the same rhodium complex is readily converted into the aldehyde (XLIII), which when heated to 50°C isomerises into the *exo*-aldehyde (XLIV) (probably as a result of disrotatory opening of the ring):



(XXXVII) (XLIII) (XLIV)

The rhodium-catalysed rearrangement of the epoxides (XXXV)–(XXXVII) is regarded [67,68] as a non-concerted process involving a step of oxidative addition to the metal with fission of a carbon–oxygen bond.

Despite the great attention paid to the valency isomerisation of strained cyclic systems catalysed by transition metals, it has not yet become generally accepted

whether the mechanism is concerted or stepwise. Sufficient experimental data are evidently not yet available to settle this question.

2. Disproportionation of Unsaturated Compounds

The disproportionation of a carbon–carbon double bond [69,70]

$$\begin{matrix} RCH{=}CHR' \\ RCH{=}CHR' \end{matrix} \rightleftarrows \begin{matrix} RCH \\ \| \\ RCH \end{matrix} + \begin{matrix} CHR' \\ \| \\ CHR' \end{matrix}$$

catalysed by transition-metal complexes, can be regarded as conforming to the Woodward–Hoffmann rules for the conservation of orbital symmetry [6]. The mechanism which is currently accepted involves intermediate formation of a "quasi-cyclobutane" four-membered ring (XLVI), which can break down in two ways with formation either of products or of the starting materials [71]:

$$\begin{matrix} RCH{=}CHR' \\ RCH{=}CHR' \\ \text{(XLV)} \end{matrix} \rightleftarrows \left[\begin{matrix} RHC\text{——}CHR' \\ | \quad\quad | \\ RHC\text{——}CHR' \end{matrix}\right] \rightleftarrows \underbrace{\begin{matrix} RCH \\ \| \\ RCH \end{matrix} + \begin{matrix} CHR' \\ \| \\ CHR' \end{matrix}}_{\text{(XLVII)}}$$
$$\text{(XLVI)}$$

Experiments with labelled alkenes confirmed [72–74] that redistribution of the double bonds took place via a four-centre state. Hence disproportionation can be regarded as a suprafacial cycloaddition (and cyclodecomposition) of type $\pi 2s + \sigma 2s$, disallowed by the Woodward–Hoffmann rules.

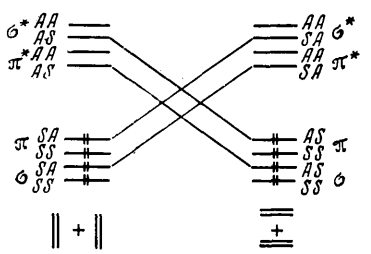


Figure 10. Correlation diagram for the disproportionation of alkenes.

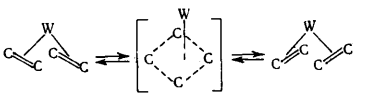
The correlation diagram (Fig. 10) shows that occurrence of the reaction (XLV) → (XLVII) [26] requires that either orbitals of symmetry *SA** in the reaction products (XLVII) or those of symmetry *AS** in the initial alkenes (XLV) should be filled. Only under these conditions can the intermediate cyclobutane structure be formed, and then two new alkene molecules (Fig. 11).

The disproportionation of unsaturated hydrocarbons can take place under conditions of either homogeneous or heterogeneous catalysis [69,70]. Inspection of the correlation diagram shows (Fig. 11) that interaction of alkenes with a metal may make disproportionation a symmetry-allowed process provided that the metal–dialkene complex has lower filled orbitals of symmetry *AS* and *SA*. Satisfaction of this condition depends on the geometry of the intermediate complex and on the relative effect of the fields due to the unchanged ligands.

In the early work on homogeneous disproportionation Calderon et al. [75] assumed that the intermediate complex was a tetragonal pyramid on a square base formed by two alkene molecules, with the metal atom (tungsten) located at the vertex:



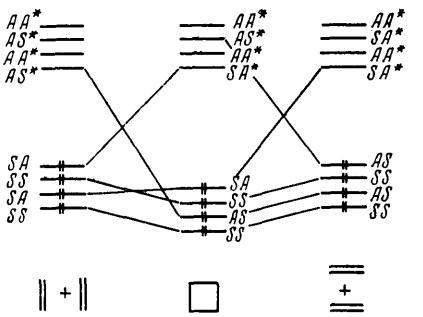


Figure 11. Correlation diagram for the transitions alkene → cyclobutane → alkene.

The position of the remaining ligands remained obscure. The double bonds were supposed to be weakened by coordination of the alkenes with the metal, so that exchange of the alkylidene groups became possible.

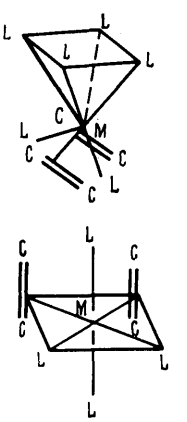

Figure 12. Possible structures of the intermediate metal–dialkene complex in disproportionation.

More precise geometries were suggested for the intermediate complex by Wang and Menapace [76] (for the catalytic system WCl_6 + n-C_4H_9Li) and also by Hughes [77] (for nitrosyl complexes of molybdenum). The intermediate complex can be regarded as an octahedron with the alkene ligands in the *cis*-position or as an Archimedean antiprism (Fig. 12).

Galdow and MacGregor [78] made calculations on the reactions alkenes → cyclobutane → alkenes [1] catalysed by d^6 and d^8 metals, and drew the corresponding correlation diagrams. They found that, in the presence of strong ligand fields and low-spin configurations, the most favourable geometry for the intermediate complex was (Fig. 13).

trigonal bipyramid (D_{3h}) ⇌ square pyramid (C_{4v}) ⇌ ⇌ trigonal bipyramid

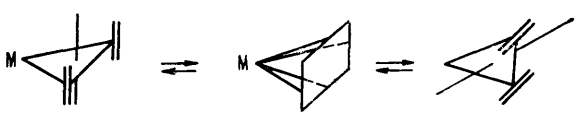

Figure 13. Geometry of the intermediate complex in the disproportionation of alkenes for low-spin d^6 and d^8 metal configurations.

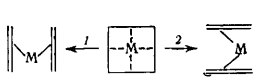
A tetrahedral or square planar configuration imposes strong field restrictions on the redistribution of double bonds in alkenes. Quantum-mechanical calculations for d^6 and d^8 metals show [26,78] that the transition alkenes ⇌ ⇌ cyclobutane is impossible in the presence of a strong ligand field. With weak ligand fields, when splitting of the d-levels is small, such conversion is made possible by mixing of the orbitals of the ground state with lower excited orbitals.

Mango and Schachtschneider [26] constructed correlation diagrams, based on calculations by the extended Hückel method, for carbonyl and chloride complexes of iron and nickel. They examined square planar and tetrahedral configurations for the complexes ML_2alkene$_2$ and ML_2cyclobutane. They found that the transition dialkene ⇌ cyclobutane with preservation of the square planar configuration of the whole complex was restricted with respect to symmetry, since the ground state of the reactants correlated with an excited state of the products. The tetrahedral configuration showed no symmetry disallowance, but the cyclobutane ring can open only in one direction (*1* or *2*):

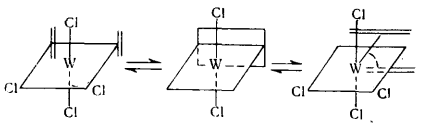


In particular, path *1* is symmetry-allowed for d^6 and d^8 metals, and path *2* for d^{10} metals.

When the complex contains a carbonyl ligand, the strong splitting of the d-orbitals results in the appearance of an energy barrier along the allowed path of the transition. Hence cycloaddition can be expected to occur—not disproportionation—when complexes with strong ligands are used as catalysts, since the latter process would require that the cyclobutane ring could break down in both directions. Such conditions can be achieved in weak ligand fields, where splitting of the d-orbitals is small.

Disproportionation of alkenes in the presence of the WCl_6 + RMgHal catalytic system [79] probably takes place by a four-centre mechanism, since a chloro-ligand does not produce strong fields. The reduction of tungsten hexachloride to the tetrachloride followed by coordination of two alkene molecules to the tungsten atom in the d^2 state suggests the transition

Alkenes ⇌ Cyclobutane ⇌ Alkenes



Attempts at the catalytic decomposition of cyclobutane into alkenes on disproportionation catalysts proved unsuccessful, which led Lewandos and Pettit [80,81] to suggest a four-centre mechanism of disproportionation but without cyclobutane as intermediate. They assumed the formation of a tetramethylene intermediate complex by interaction of the d-orbitals of the metal with four methylene orbitals of the alkene. This interaction is also severely restricted by symmetry: i.e. transitions are permitted only between orbitals of the same symmetry. Such interaction leads to formation of the four-centre system (XLVIII) (Fig. 14), which can break down to yield either (1) the initial substances or (2) disproportionation products.

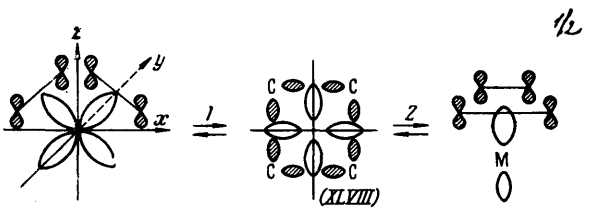


Figure 14. Possible mechanism of disproportionation.

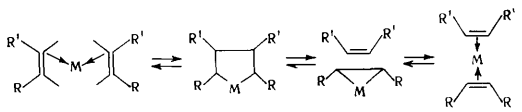
A significant difference between this mechanism and that involving formation of cyclobutane is that here the carbon σ-bonds of the initial alkenes are broken at the same time as the π-bonds. Coordination of the tetramethylene intermediate with the metal takes place at four sites: i.e. the metal must be in a low state of oxidation. Pettit [81] supports his hypothesis by results for the disproportionation of pent-2-ene and non-4-ene under the influence of an arene–$W(CO)_3$ complex. It is suggested that, when tricarbonyltungsten is used, the removal of one carbonyl group is the decisive factor in formation of the tetramethylene–$W(CO)_2$ complex, since only in this case does the tungsten have four vacant coordination sites. Disproportionation does not take place in the presence of excess of carbon monoxide, owing to an insufficient number of free sites for coordination of the tetramethylene complex.

In the Reviewers' opinion a configuration of the intermediate M–alkene complex that is unfavourable for the alkene ⇌ cyclobutane transition is obtained with excess of carbon monoxide, and furthermore carbonyl produces a strong ligand field. The existence of a tetramethylene complex as intermediate also seems improbable, since the proposed [81] symmetry analysis will not give satisfactory results for the simultaneous disproportionation of alkenes with an inner and a terminal double bond.

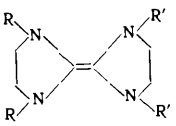
All the above mechanisms for the disproportionation of alkenes presuppose, independently of the structure of the intermediate complex, that the process is concerted.

Recently, however, data have appeared indicating that this reaction may have a non-concerted mechanism, as postulated earlier by Cassar et al.[31]

Formation of a metal ring as intermediate has been suggested[82]:



Carbene complexes have been isolated as intermediates (under the influence of rhodium(I) complexes)[83] in the disproportionation of "electron-rich" alkenes of the type



Thus the mechanism of the disproportionation of alkenes still remains a matter of controversy.

3. Hydrogenation of Alkenes

Special interest attaches to application of the conservation rules of orbital symmetry to a process of such theoretical and practical importance as the catalytic hydrogenation of unsaturated compounds in the presence of transition-metal complexes. Although many papers (including reviews[84-87]) have been published on homogeneous catalytic hydrogenation, many aspects of the reaction mechanism and of the action of the catalysts remain matters of debate. In particular, the sequence of the interrelated stages of activation of molecular hydrogen and activation of the substrate has not been established. Convincing explanations of the selective action of complex catalysts have not appeared.

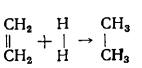
In the Reviewers' opinion, regarding catalytic hydrogenation as the concerted addition of molecular hydrogen to the double bond of an alkene allows us to postulate that the first stage of homogeneous hydrogenation is complex formation between alkene and metal. The selectivity of the action of complex catalysts should be related to the way in which the unsaturated substrate is coordinated with the metal.

Uncatalysed hydrogenation

The uncatalysed hydrogenation of a carbon–carbon double bond can occur in two ways. A free-radical mechanism involves dissociation of the hydrogen molecule followed by addition of the hydrogen atoms at the double bond:

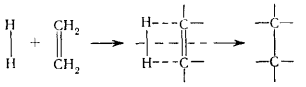
$$H_2 \rightarrow H + H$$
$$CH_2=CH_2 + H \rightarrow CH_3-CH_2^{\cdot}$$
$$CH_3-CH_2^{\cdot} + H \rightarrow CH_3-CH_3$$

The hydrogen molecule may undergo concerted addition to the alkene:

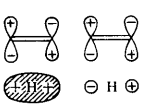


The first of these mechanisms is symmetry-allowed[88,89] according to the Woodward–Hoffmann rules[6], but the reaction has a high activation barrier owing to the large dissociation energy of the hydrogen molecule (104 kcal mole^{-1}). Extreme conditions—high temperatures and pressures—are therefore necessary for the uncatalysed hydrogenation of alkenes[90].

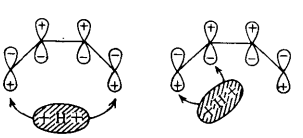
The second pathway—concerted addition—presupposes formation of an intermediate four-centre state followed by simultaneous cleavage of H–H and C=C bonds with formation of new C–H bonds:



Monoalkenes and alkenes having non-conjugated multiple bonds, like the hydrogen molecule, belong to the D_{nh} point group; the highest occupied orbitals in the ground state are the A_{1g} orbital of hydrogen and the B_{3u} orbital of the alkene. In the transition state for concerted addition (four-centre configuration, point group C_{2v}) the highest occupied orbitals have symmetry A_1 and B_2, while the B_{3u} orbital passes into B_1 and is an excited orbital. Thus the ground state of the reactants correlates in symmetry with an excited state of the intermediate configuration, so that the concerted addition of hydrogen to monoalkenes and alkenes having isolated double bonds is disallowed by symmetry[88,89]. According to the Woodward–Hoffmann rules[6] thermally forbidden reactions can be accomplished photochemically. Hence the photochemical hydrogenation of alkenes is fully able to occur by a four-centre mechanism:



The hydrogenation of conjugated dienes is symmetry-allowed when hydrogen adds at the 1,4 (or 2,3) positions, and disallowed in the case of 1, 2 (or 3, 4) addition[88,89]:

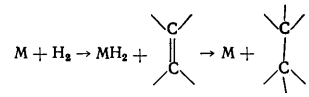


Catalytic homogeneous hydrogenation of alkenes

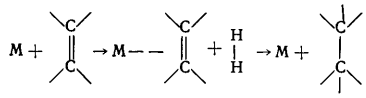
Homogeneous hydrogenation is currently regarded as being generally a stepwise process with successive addition of hydrogen atoms to the double bond of an alkene. The first stage is assumed to be activation of molecular hydrogen by its interaction with the metal (homolytic fission with formation of a mono- or a di-hydride or heterolytic fission with formation of a monohydrate). The H–H bond can be weakened both by transfer of electrons from a filled *d*-orbital of the metal to an antibonding orbital of the hydrogen molecule[91] and by redistribution of electron density between an occupied bonding orbital of the hydrogen molecule and a vacant orbital of the metal[87,92]. Aspects of the activation of molecular hydrogen by simple and complex ions of transition metals have been discussed in detail[84,85,87,91].

The possibility of the concerted addition of a hydrogen molecule to a carbon–carbon double bond was first pointed out by Pearson[88,89]. As already mentioned, a symmetry-forbidden reaction may become allowed by the participation of a transition metal[23]. If catalytic hydrogenation is regarded as a concerted process, three possible reaction paths can be distinguished—(1) formation

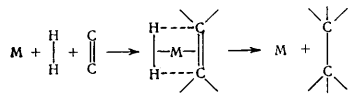
of a complex MH_2 and its subsequent interaction with the substrate



(2) formation of a metal–alkene complex followed by its interaction with hydrogen



and (3) simultaneous coordination of hydrogen and alkene molecules with the metal followed by interaction of hydrogen with the alkene in the complex



The formation of two new carbon–hydrogen bonds in the hydrogenation of a double bond requires the preliminary interaction of an unoccupied orbital of the hydrogen molecule A_{1u} with an occupied orbital of the alkene B_{3u} or of an occupied orbital of hydrogen A_{1g} with a free orbital of the alkene B_{2g}. In the absence of a transition metal such interaction between orbitals of the hydrogen molecule and of the substrate is symmetry-forbidden. When a hydrogen or an alkene molecule coordinates with a metal, interaction of a filled d-orbital of the metal with an unoccupied orbital of the molecule (Fig. 15) removes the symmetry restriction, independently of the geometry of the resulting complex. In both cases the given fragment of the complex has symmetry C_{2v}. With simultaneous coordination of hydrogen and alkene molecules with a metal concerted addition is impossible if the two molecules lie in the same plane (Fig. 15). Departure from a planar configuration may bring one hydrogen atom closer to the alkene molecule than the other, in which case there is no sense in considering a concerted process.

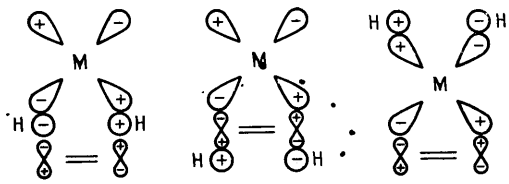


Figure 15. Possible intermediate configurations in the catalytic hydrogenation of alkenes.

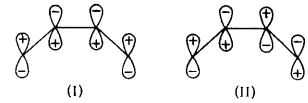
Thus, depending on the suggested mechanism for homogeneous hydrogenation, the metal either activates molecular hydrogen (in the stepwise scheme) or changes the symmetry of the highest occupied orbitals of the reactants by interaction with the substrate, so that the forbidden reaction becomes allowed (concerted addition).

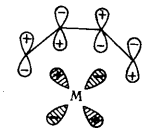
Regarding the hydrogenation of a double bond as a concerted process will explain the selective action of transition-metal complexes in the hydrogenation of conjugated dienes. As mentioned above, addition of a hydrogen molecule at the 1,4 (or 2,3) positions is a symmetry-allowed process. Such addition should result in monoalkenes having an internal double bond. The effect of the metal catalyst is then merely to lower the activation barrier without changing the symmetry of the system [27,93].

Conjugated dienes have two antibonding π-orbitals

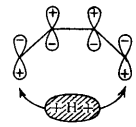


(I) (II)

Coordination of the diene with a metal and formation of a dative bond take place when the orbital (II) interacts with a filled d-orbital of the metal

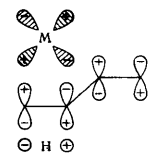


It has been shown in the formation of a metal–butadiene complex that the electron density is displaced from the periphery towards the centre of the diene molecule [93]. The antibonding π-orbital (I) remains vacant, but is allowed by its symmetry to interact with a filled σ-orbital of hydrogen: i.e. addition of hydrogen will occur at the 1,4 positions to form monoenes having an internal double bond



Thus interaction of a metal with a substrate does not change the symmetry of the highest occupied orbitals involved in the formation of carbon–hydrogen bonds, but merely removes the energy difference between them.

A different pattern is found in the hydrogenation of conjugated dienes at the 1,2 positions. As with monoalkenes, the concerted addition of a hydrogen molecule to this double bond is symmetry-forbidden. Interaction of the substrate with a metal may make the 1,2-addition symmetry-allowed, but only provided that coordination of the diene with the metal occurs only at the site of the hydrogenated bond. Thus the electron density of the metal–diene bond would be displaced towards the end of the diene molecule:



In this case the reaction products should be terminal alkenes.

The high selectivity exhibited by complexes of metals of the fourth period in the hydrogenation of conjugated dienes to monoalkenes (Table 2) is evidently connected with the mode of coordination of the diene molecule with the metal. When chromium and vanadium complexes are used as catalysts, for example, monoenes with a terminal double bond are almost completely absent from the products [98,99,101], which must definitely be related to the paucity of complexes of these metals with monoenes

and non-conjugated alkenes. The hex-2-ene and hex-3-ene obtained by the hydrogenation of hexadienes in the presence of tricarbonylchromium do not isomerise, which probably indicates the inability of these metals (especially of chromium) in a particular state of oxidation to coordinate alkenes at only one double bond.

Table 2. Hydrogenation of conjugated dienes in the presence of complex catalysts.

Catalyst	Substrate	Hydrogenation product	Yield, %	Ref.
$CoCl_2$—KCN(CN/Co>6)	butadiene	but-1-ene	80—85	95
$CoCl_2$—KCN(CN/Co<5,5)		*trans*-but-2-ene

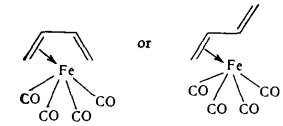
		3-methylbut-1-ene	15.4	
		2-methylbut-1-ene	40.7	
		2-methylbut-2-ene	35.4	

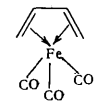
The possibility of the concerted addition of a hydrogen molecule to conjugated dienes at both the 1,4 and 1,2 positions can be illustrated by the hydrogenation of butadiene in the presence of pentacyanocobalt [94,95,104-115]. Kwiatek et al. [95] showed that the composition of the hydrogenation products depends on the CN/Co ratio. When the ratio is ≤ 5.5 the main product is *trans*-but-2-ene (70–86%), but dominant formation of but-1-ene (80–85%) takes place at ratios > 6. Such variation in the yields of the isomers was explained [95,107,115] by the possible formation of π-allyl and σ-allyl intermediate complexes at low and high ratios respectively.

An explanation of the above results in terms of concerted addition is that, at low ratios of the cyanide ion to cobalt, butadiene is probably coordinated on the complex ion $[Co(CN)_5]^{3-}$ (the activity of this ion has been demonstrated) [116-118], and a complex is formed in which the electron density of the metal–diene bond is localised in the region of the second and third carbon atoms of the diene: i.e. the diene acts as a bidentate ligand. In this case addition of hydrogen at the 1,4-positions will be symmetry-allowed, with the formation of but-2-ene. At high ratios an additional coordination site of the metal is occupied by a cyano-group ($[Co(CN)_6]^{4-}$ is probably formed), and the diene can be coordinated only through one double bond (the butadiene acts as a unidentate ligand). Addition of hydrogen at the 1,2-bond then becomes symmetry-allowed, with the predominant formation of but-1-ene.

Some support for the above arguments is provided by the existence of a butadiene complex of iron tetracarbonyl, in which the diene behaves as a unidentate ligand:



Nevertheless, butadiene occupies two coordination sites in the iron tricarbonyl complex:



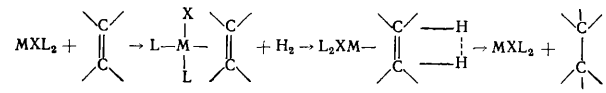
Considering the hydrogenation of a carbon–carbon double bond as a concerted process enables us to suggest complex formation between metal and alkene as the first stage in homogeneous hydrogenation. This view may be supported by several experimental results on the hydrogenation of monoalkenes and non-conjugated dienes in the presence of individual complexes of transition metals and complex organometallic compounds (catalysts of the Ziegler–Natta type).

The first stage in the hydrogenation of alkenes on phosphine complexes of rhodium and iridium is the detachment of one phosphine group, i.e. the freeing of one coordination site [119-121]:

$$MX(PPh_3)_3 \rightleftarrows MX(PPh_3)_2 + PPh_3$$

The second stage would be complex formation between the metal and one of the reactants, to give either the metal hydride or a metal–alkene complex.

The hypothesis that a dihydro-complex of the metal is an intermediate in this reaction was based on the isolation of iridium dihydride [122,123]. In a kinetic study of the hydrogenation of ethylene in the presence of hydrocarbonyltristriphenylphosphineiridium, however, Burnett and Morrison [124] found that the trihydrocarbonylbistriphenylphosphineiridium formed is an inhibitor of the reaction. Kinetic data on the hydrogenation of dimethyl maleate [125] indicate that the first stage is formation of an iridium complex of the substrate, which then reacts with hydrogen. Kinetic investigations of the hydrogenation of alkenes in the presence of chlorotristriphenylphosphinerhodium and hydrocarbonylbistriphenylphosphinerhodium also led Wilkinson et al. [126-128] to regard formation of a metal–alkene complex as the initial stage (the kinetic order with respect to the alkene varies from the first to zero). These results suggest concerted addition of hydrogen by the scheme



Complex organometallic catalysts of the Ziegler–Natta type are active in the hydrogenation of monoalkenes and non-conjugated dienes [84,85]. The decrease in reducing power of the organoaluminium component in the sequence

$$(AlEt_3 \geqslant Al(i\text{-}Pr)_3 > AlEt_2Cl > AlEtCl_2 > Al(OEt)Et_2)$$

leads to a fall in the catalytic activity of the system [129]. The sequence of transition metals with respect to their activity in catalysing the hydrogenation of alkenes is

$$Co \geqslant Ni > Fe > Mn \simeq Cr > V > Ti$$

i.e. their efficiency increases with increase in the number

of *d*-electrons. The calculated overlap integrals of the metal–alkene bond showed [130] that the energy of this bond diminishes in the same sequence

$$Ni<Co<Fe<Mn<Cr<V<Ti.$$

Hence the formation of a metal–alkene complex is an important stage in the hydrogenation of an isolated double bond, and permits the concerted addition of hydrogen.

No selectivity is observed when Ziegler–Natta catalysts are used in the hydrogenation of conjugated dienes [102,131]: monoenes having internal and terminal double bonds and also alkenes can be found among the reaction products. The whole process can be represented by the scheme

$$\text{Diene} + M \rightarrow (M\text{-Diene}) + H_2 \begin{cases} \nearrow M\text{-Monoene-1} \\ \searrow M\text{-Monoene-2} \end{cases} \xrightarrow{H_2} \text{Alkane} + M.$$

The absence of selectivity is probably due to the possibility of coordinating the resulting monoalkenes with Group IV metals in a low state of oxidation.

4. Cyclo-oligomerisations

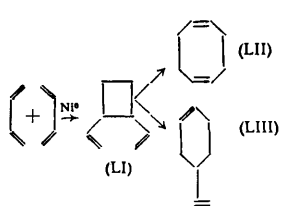
Among cyclo-oligomerisations of alkenes catalysed by transition-metal complexes that of butadiene is of the greatest scientific and practical interest. This reaction can be regarded as a concerted addition, in contrast to polymerisation, which involves closing the chain at the third unit. Concerted addition is supported by the fact that the larger and intermediate rings are formed by the polymerisation of butadiene only on strong dilution, whereas cyclo-oligomerisation takes place only at high concentrations of the monomer.

The formation of cyclododecatriene and cyclo-octatetraene from butadiene is symmetry-disallowed, 2 + 2 + 2 and 2 + 2. In the presence of a transition metal, e.g. nickel, this process becomes allowed, thanks to the coordination of butadiene on the metal and the formation of complexes of π-allyl type [132–135]

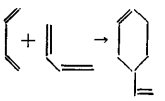
(XLIX) (L)

which have been isolated [134–136].

Heimbach and Brenner [133] studied the dimerisation of butadiene on nickel complexes, and found that, in the presence of zerovalent nickel, butadiene is converted via divinylcyclobutane (LI) mainly into cyclo-octa-1,5-diene (LII) together with some 4-vinylcyclohexene (LIII):



Up to 40% of (LI) appears among the reaction products at low concentrations of butadiene. Reaction of butadiene with isoprene in the presence of the same catalysts yields cyclododecatriene [134], which can also be explained by concerted addition. The formation of (LIII) can be regarded as resulting from the symmetry-allowed interaction of two π-bonds of one butadiene molecule with one π-bond of a second molecule:



The low yield of (LIII) is probably connected with the small probability of such relative orientation of the molecules. If the number of coordination sites is limited, the action of the metal may be to facilitate such orientation and form a complex of type

In particular, examples are known [132,135] in which the introduction of an additional ligand (e.g. triphenylphosphine or carbonyl) leads to the formation solely of (LIII). Vinylcyclohexene is also the sole product of the oligomerisation of butadiene in the presence of rhodium complexes in solvents of high complexing power (e.g. dimethylformamide) [137].

Equilibrium Acidity of Carbon - Hydrogen Bonds in Organic Compounds

O.A.Reutov, K.P.Butin, and I.P.Beletskaya

A survey is made of experimental results on the equilibrium acidity of CH acids in the gas phase and in aqueous solution, as well as in dimethyl sulphoxide, cyclohexylamine, benzene, ether, and other aprotic solvents. Reasons are discussed for the sharp difference between CH and OH acids that appears on passing from the gas phase to aqueous solutions. Various acidity scales for CH acids in aprotic solvents—the McEwen, Streitwieser, Cram, Breslow, and polarographic scales, and the acidity scale in dimethyl sulphoxide—are compared. A list of 114 references is included.

I. INTRODUCTION

Under the influence of a base (a proton acceptor) of suitable strength almost all organic compounds are capable of ionising with the formation of carbanions, i.e. negatively charged species in which the charge—or more often part of the charge—is concentrated on a carbon atom. This permits the occurrence of a multitude of organic reactions—e.g. carbonyl–methylene condensations, transmetallations, allyl rearrangements under the influence of bases, etc.—in which the limiting step is detachment of a proton. Even saturated hydrocarbons exhibit acidic properties, though fairly weak[1]. Several reviews have recently appeared on CH acids and carbanions[2-4], among which Cram's monograph[2] is of primary importance.

In the present paper we shall use the term *acidity* instead of the alternative "acid ionisation constant", in order to stress the connection

$$RH + B^- \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} R^- + HB;\ pK_a = -\lg K_a = -\lg \frac{k_1}{k_{-1}}$$

between the *equilibrium* (thermodynamic) acidity, i.e. the acid ionisation constant K_a, and the *kinetic* acidity, i.e. the rate of detachment of a proton from the molecule of the acid k_1. A linear relation is quite often observed between equilibrium and kinetic acidities, i.e. between pK_a and $\lg k_1$, when Brønsted's principle is valid. We shall consider only data on the equilibrium acidity of CH acids, which is independent of the mechanism of detachment of the proton and best represents the thermodynamic stability of carbanions in a given system. Since a correction for the energy of solvation should be made to the energy of every species involved in acid–base equilibrium in solution, we shall first examine the acid–base equilibrium in the gas phase, which best corresponds to the "intrinsic" acidity of the CH acid and is due solely to structural factors. Acid–base equilibrium in various solvents will be discussed subsequently.

II. ACID IONISATION IN THE GAS PHASE AND IN WATER

1. Acidity in the Gas Phase

The acidity of any acid in the gas phase can in principle be determined from the thermodynamic cycle[3,5]

$$\begin{array}{c} AH \rightarrow A^{\cdot} + H^{\cdot};\ DH \\ A^{\cdot} + e^- \rightarrow A^-;\ -EA \\ H^{\cdot} \rightarrow H^+ + e^-;\ IP \\ \hline AH \rightarrow A^- + H^+;\ \Delta H = DH - EA + IP \end{array}, \qquad (1)$$

where DH is the A—H dissociation energy, EA the electron affinity of the A· radical, IP the ionisation potential of the hydrogen atom, and ΔH the enthalpy of ionisation of the acid. Investigation of the dependence of acidity on the structure of the acid is of the greatest interest for organic chemistry. With such an approach the ionisation potential IP cancels out, and the variation in acidity in a series of CH acids can be predicted from a knowledge merely of DH and EA.

Brauman et al.[5], as well as several other workers[6], have used pulsed ion–cyclotron resonance to determine experimentally the electron affinities of several radicals, and have then employed the thermodynamic cycle (1) to calculate values of ΔH for the ionisation of the hydrides of several elements. The results (Table 1) indicate[5] that the acidity of hydrides in the gas phase increases from left to right in a period, and downwards in a group:

$$\begin{array}{ccccccccc} CH_4 & < & NH_3 & < & H_2O & < & HF \\ \wedge & & \wedge & & \wedge & & \wedge \\ SiH_4 & < & PH_3 & < & H_2S & < & HCl \\ & & \wedge & & \wedge & & \wedge \\ & & AsH_3 & < & HBr & & \\ & & & & \wedge & & \\ & & & & HI & & \end{array}.$$

The main factor determining the variation relative acidity is the electron affinity along a period, and the dissociation energy down a group (Table 1). A ready explanation of

this rule is that the A—H molecular orbital ψ is a combination of the atomic orbitals φ_A and φ_H, and will be the more stable relative to φ_A the closer the energies of φ_A and φ_H, i.e. the smaller the difference in electronegativity between the given element and hydrogen. With increase in the electronegativity of the element φ_H becomes more stable, the mixing coefficient of the orbitals decreases, and the energy of ψ approaches that of φ_A. Since Pauling's electronegativity shows a greater variation along a period than down a group and is a function of the electron affinity, the acidity of hydrides will be more strongly dependent on *EA* along a period than down a group in the Periodic System.

Table 1. Bond dissociation energies, electron affinities, and calculated enthalpies of ionisation for simple hydrides in the gas phase[5,6] (ionisation potential of hydrogen *IP* = 316 kcal mole^{-1}).

Hydride	*DH*	*EA*	ΔH	Hydride	*DH*	*EA*	ΔH
	kcal mole^{-1}				kcal mole^{-1}		
CH_4	104			H_2S	90	53	350
NH_3	110	17	407	HCl	103	83	333
H_2O	119	42	390	AsH_3		29.3	
HF	136	80	370	HBr	88	78	324
SiH_4	80			HI	71	71	314
PH_3	80	28.8	364				

The weakest acid among the above examples is methane; this in particular is a consequence of the low electron affinity of the methyl radical. However, replacing a hydrogen atom in methane by a group which increases the electron affinity of the corresponding radical, i.e. which stabilises the carbanion, leads to an increase in the acidity. Introduction of the inductively electronegative chlorine makes the enthalpy of ionisation for the carbon—hydrogen bond smaller than the value for ammonia: $CH_3Cl > NH_3 > CH_4$. Toluene, whose phenyl group stabilises the negative charge by a conjugation mechanism, is a stronger acid than is water[7].

Existing experimental results can be summarised by the sequence

$$n\text{-}C_4H_9SH > CH_3NO_2 > \text{cyclo-}C_6H_6 \geqslant CHCl_3 > CH_3COCH_3 > CH_3CN > CH_2Cl_2,\ CH_3SOCH_3 \geqslant C_2H_6,\ t\text{-}C_4H_9OH,\ i\text{-}C_4H_9OH > C_2H_5OH > CH_3OH > C_6H_4,\ C_6H_5CH(CH_3)_2 > C_6H_5CH_3 > C_3H_8 > H_2O > C_6H_6 > H_2 > NH_3 > C_2H_4,\ C_6H_{12} > (CH_3)_3,\ CH_4$$

in which various Brønsted acids are arranged in order of diminishing acidity (in the gas phase in a flowing afterglow at 300°K).[8] This sequence evidently destroys completely our usual ideas of the relative acidities of various compounds, based on the study of aqueous or alcoholic solutions.

It is interesting that in the gas phase alkyl substituents increase the acidity of a molecule: i.e. like halogens they possess a $-I$ effect. Thus the acidity of alcohols in the gas phase increases in the opposite sequence

propan-2-ol > ethanol > methanol > water

to the acidity of the same compounds in aqueous solution[9,10]. The reason is, of course, solvation. The ionisation of hydrogen chloride, for example, is endothermic in the gas phase (ΔH = +333 kcal mole^{-1}—Table 1), but in water ΔH = −16 kcal mole^{-1}.[11]

The energy parameters listed in Table 1, as well as the qualitative series given in the text, show that no sharp distinction exists between CH acids and other types of acids in the gas phase. This is indicated also by Ritchie and King's theoretical calculations[12] of potential-energy surfaces for a series of simple gas-phase proton transfers from the molecules—hydrogen, hydrogen fluoride, water, ammonia, and methane—to the hydride ion. As expected, the lowest energy corresponded in every case to that reaction path involving attack by the hydride ion along the axis of the X—H bond:

$$X{-}H \leftarrow\!-\!-H^- \ (X = H,\ F,\ OH,\ NH_2,\ CH_3)\ .$$

Water, ammonia, and methane were found to behave similarly, the only distinction between them consisting in a quantitative energy difference between reactants and products of proton transfer.

Thus hydrocarbons and their derivatives (i.e. CH acids) are inherently just as likely to exhibit acid properties as are hydrides of other elements and their substituted derivatives†. In hydroxylated solvents, however, the acidic properties of hydrides and substituted hydrides of electronegative elements (e.g. hydroxyl acids) are far more strongly developed than are those of CH acids. It has now been found that the ability of hydroxylated solvents to promote the acid ionisation of hydrides of electronegative elements is due to their specific property of forming hydrogen bonds with these elements. In the next subsection we shall compare the acidities of CH and OH acids in water.

2. Acidity of CH Acids in Water—Comparison with OH Acids

In the gas phase toluene possesses more strongly developed acidic properties than does water[7]. We shall examine what occurs in the acid ionisation of these two compounds in a hydroxylated solvent. Acid—base equilibria in the two systems can be written

$$H_2O\cdot solv. + B\cdot solv. \rightleftharpoons HB^+\cdot solv. + OH^-\cdot solv.$$
$$PhCH_3\cdot solv. + B\cdot solv. \rightleftharpoons HB^+\cdot solv. + PhCH_2^-\cdot solv.$$

The calculation of ionisation constants in solution must take into account the solvation of all species involved in the equilibrium, on both sides of the equations. If the proton acceptor B is the same in these two examples and reaction takes place in the same solvent, calculation of the relative acidity of water and toluene in solution will allow for the solvation energies only of water and toluene on the left-hand side of the equilibria, and of hydroxide and benzyl anions on the right-hand side.

The difference between the solvation of water and that of toluene in hydroxylated solvents is due to the fact that the latter solvate molecules and anions mainly by hydrogen bonding. Eigen gives the sequence

$$OH\cdots O > OH\cdots N,\ NH\cdots O > NH\cdots N > SH\cdots X,\ RH\cdots S > PH\cdots X,\ XH\cdots P > CH\cdots X,\ XH\cdots C$$

(where X is any element) of diminishing ability of elements to form hydrogen bonds[13], with OH and CH acids located at opposite ends: the former are the strongest, and the latter the weakest, hydrogen-bond donors. Hence on passing from the gas phase to a hydroxylated solvent,

† Acetic acid, for example, can be regarded as oxygen hydride substituted by an acetyl group.

e.g. water, the energy of the water molecule shows a greater decrease than that of the toluene molecule. Similarly, oxygen bases are the strongest, and carbon bases the weakest, hydrogen-bond acceptors. On passing from the gas phase to aqueous solutions, therefore, the energy of a hydroxide ion will also decrease far more strongly than that of a benzyl anion.

The principal factor determining the relative acidity of water and toluene in water is the difference between the solvation of the anions. According to results obtained by Parker[14] the most important energy contribution in reactions and equilibria involving anions is made by the difference in solvation of the anions on passing from an aprotic to a protic solvent (in the present case from the gas phase to water). The hydroxide ion, which is small and has a localised charge, is strongly solvated by water, whereas the benzyl anion, with a delocalised charge, is more poorly solvated‡. Hence it follows that the difference between the solvation energies of the hydroxide ion and of water considerably exceeds the difference between those of toluene and the benzyl anion: in other words, a hydroxylated solvent promotes strongly the process $H_2O \rightarrow OH^-$ and only weakly the process $C_6H_5CH_3 \rightarrow C_6H_5CH_2^-$. As a result, equilibrium involving water is far more strongly displaced to the right than the equilibrium involving toluene, in water compared with the gas phase, an effect illustrated by Table 2.

Table 2. Effect of solvation on change in relative acidity of water and toluene on passing from the gas phase to aqueous solution.

Molecule or ion solvated		Net change in acidity
H_2O	OH^-	
well	very well	strong increase
$PhCH_3$	($PhCH_2^-$)	
poorly	(poorly)	slight*

* The anion is therefore "instantly" protonated in water.

Thus solvation effects greatly enhance the acidity of water in aqueous medium, whereas toluene does not exhibit acid properties. This leads to the conclusion that the benzyl anion is "strongly basic", although it would be more correct to say "strongly basic in water", since in the gas phase all bases are strongly basic, as we have already seen.

The above example enables us to understand why, in water, CH acids are far weaker than OH acids. This is further illustrated in Table 3, which compares the acidities of acids of the two types of similar structure. It may be concluded that CH acids in water are on the average weaker than the corresponding OH acids by $\Delta pK_a = 20$.

However, some CH acids are quite strong even in water (pK_a values in Table 4). Appreciable dissociation in water is shown only by those CH acids which contain so called *acidifying* groups such as nitro, acyl, cyano, etc., capable of stabilising the carbanions formed by dissociation. The introduction of more than one such group adjacent to the ionised bond leads to a still greater increase in acidity. The ionisation constants of such CH acids in water can be determined by the usual methods--potentiometrically, spectrophotometrically, conductometrically, etc.

‡ This follows also from Pearson's principle of hard and soft acids and bases[15].

Table 3. Effect of substituents on acidity ($pK_a = -\lg K_a$) of related hydroxyl and methine acids (difference in acidity ΔpK_a) determined from the equilibria (other than methane):

$$H-OR + H_2O \rightleftarrows OR^- + H_3O^+$$
$$H-CH_2R + H_2O \rightleftarrows CH_2R^- + H_3O^+$$

Acid	pK_a	Ref.	ΔpK_a	Acid	pK_a	Ref.	ΔpK_a

The CH acids listed at the start of Table 4 are comparable in strength with mineral acids, e.g. hydrochloric and sulphuric acids. The weakest CH acid whose acidity could be measured in aqueous solution (cyclopentanone) has $pK_a = 16.7$. It is noteworthy that Table 4 contains barely a single "pure" hydrocarbon, i.e. a CH acid containing no acidifying group. The only exception is Kuhn's hydrocarbon (No. 15), but it occupies a special position, since the dibenzofluorenylidenemethyl group is a strongly acidifying substituent (other such groups and their effect on acidity have been discussed[33]).

Water is unsuitable as a solvent for determining the equilibrium acidity of alkanes, alkenes, arenes, cycloalkanes, and other hydrocarbons. It is not in general an ideal solvent for studying the ionisation equilibria of CH acids, since it has in water a fairly high acidity (for H_2O in water $pK_a = 15.7$). Methods have therefore been developed for determining the acidity of hydrocarbons in aprotic solvents, and will be considered below.

III. METHODS FOR DETERMINATION OF IONISATION EQUILIBRIUM OF CH ACIDS

The equilibrium acidity is determined by the position of equilibrium between acids and conjugate bases. Most of the data on the equilibrium acidity of hydrocarbons have been obtained from the study of *transmetallations*

$$R-H+R'-M \rightleftarrows R-M+R'-H$$
(M=Li, Na, K, Cs; R=Alk, Ar, Aralkyl, etc; R'=Alk, Ar, cyclo-$C_6H_{11}NH$, NH_2, etc.)

in solvents of low polarity and low proton-donating activity (ether, benzene, liquid ammonia, cyclohexylamine, dimethyl sulphoxide, etc.).

In 1908 Shorygin showed that ethylsodium metallates benzene, toluene, and diphenylmethane[45], which indicated that ethane was a weaker acid than the latter three hydrocarbons. Many similar qualitative results have since been obtained: it was shown[46], for example, that potassamide in liquid ammonia metallates diphenylmethane but not toluene, pentylsodium reacts with benzene, and phenylsodium in turn reacts with toluene[47]. These results enabled the sequence of increasing acidity to be constructed[48]:

pentane (or ethane) < benzene < toluene < ammonia < diphenylmethane.

Gilman et al. established that the yield of transmetallation product obtained with dibenzothiophen depends on the nature of the organolithium compound RLi with which it reacts (Table 5).[49] These results show that the acidity of the hydrocarbons RH should increase in the above sequence.

Table 5.

R	n-C_4H_9	C_6H_5	1-$C_{10}H_7$	p-$CH_3OC_6H_4$
Yield, %	55	12	7.6	0

By the end of the 1930s many data of this type had been obtained[50-54], enabling a qualitative assessment to be made of the relative strengths of CH acids. However, quantitative comparison of CH acidities began only with the work of Conant and Wheland[55,44,57] and of McEwen[56]. These papers are now regarded as classics.

1. Quantitative Assessment of Acidity of Weak CH Acids

Conant and Wheland[55] used a colorimetric method and the carboxylation of organosodium and organopotassium compounds to estimate the relative acidity of hydrocarbons; McEwen also used polarimetry[56]. This work involved study of the equilibrium of the sodium or potassium salts of the CH acids

$$R-M+R'H \underset{\text{ether or benzene}}{\overset{25^\circ}{\rightleftharpoons}} R-H+R'-M \qquad (2)$$

in ether by Conant and Wheland, in benzene by McEwen. The salts RM and R'M absorb at different wavelengths, so that their concentrations can be estimated colorimetrically. The change in colour usually occurs rapidly, but in some cases, especially when sodium salts are used, many days are required to reach equilibrium. The equation

$$pK_a(RH) - pK_a(R'H) = -\lg\frac{[RM]}{[RH]} + \lg\frac{[R'M]}{[R'H]} \qquad (3)$$

holds for the equilibrium (2). McEwen originally assumed that the salts RM and R'M were dissociated to the same extent, whereas the CH acids were not dissociated at all. With these postulates formula (3) becomes

$$pK_a(RH) - pK_a(R'H) = -\lg\frac{[R^-]}{[RH]} + \lg\frac{[R'^-]}{[R'H]}.$$

It was subsequently shown, however, that at 25°C the sodium and caesium salts of fluorene exist as internal ion-pairs, whereas the lithium salt occurs as separated ion-pairs, which have the same spectrum as intimate

ion-pairs in the visible region, but differ in the ultraviolet spectrum[58]. Electrical conductivity data show that these fluorene salts are only slightly dissociated. Thus the change in colour observed by McEwen is due to the formation not of dissociated compounds but of ion-pairs: i.e. Eqn. (3), proposed by Cram[2], is valid.

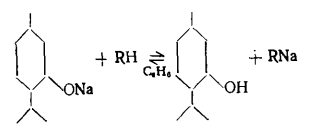
It follows from Eqn. (3) that, with equal initial concentrations of RM and R'H, visual observation of 91% (more precisely 90.9%) metallation will correspond to a difference between the acids RH and R'H of $\Delta pK_a = 2$. If such a degree of metallation is reached with a fivefold excess of R'H, the corresponding difference between the acids will be only 0.4.

McEwen compared various pairs of CH acids, which involved many cross experiments. An additional method of checking the correctness of the colorimetric results was provided by carbonation. The position of equilibrium between two acids and their salts was assessed from the relative yield of carboxylic acids obtained after carbonation of the equilibrium mixture

$$\begin{array}{ccc} RH + R'M & \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} & RM + R'H \\ \downarrow CO_2\ k_2 & & \downarrow CO_2\ k_3 \\ R'COOM & & RCOOM \end{array} \quad . \qquad (4)$$

Obviously, the method is applicable only when both $k_2 \gg k_1$ and $k_3 \gg k_1$ (Eqn. 4). The two methods gave mutually consistent values of ΔpK_a for various pairs of CH acids.

McEwen used a polarimetric method to determine the position of equilibrium between sodium mentholate and various CH and OH acids, as well as between menthol and the sodium salts of the CH and OH acids (in benzene):



$[\alpha]_D^{23} = -12.2°$ Na *laevo*-mentholate

$[\alpha]_D^{23} = -45.6°$ *laevo*-menthol

It thus proved possible to interrelate the acidities of OH, CH, and NH acids, and to construct a general scale covering acids from methanol to cumene. McEwen adopted the value $pK_a = 16$ [59] for methanol, and on this basis determined values for weaker acids. He noted that his values were minima, because of the postulates made in the colorimetric determinations. Table 6 gives McEwen's scale, which remained the only one for a long time.

In 1959 Streitwieser et al. began to elaborate another scale of equilibrium acidity[60,61], also based on transmetallations. He measured the equilibrium constant between lithium or caesium cyclohexylamide and the CH acids, or between the lithium and caesium salts of the CH acids and cyclohexylamine, with cyclohexylamine as solvent:

$$RH + \text{cyclo-}C_6H_{11}\overset{\delta-}{N}H\overset{\delta+}{M} \rightleftharpoons \overset{\delta-}{R}\overset{\delta+}{M} + \text{cyclo-}C_6H_{11}NH_2 \, . \qquad (5)$$

In order that equilibrium transmetallation data can be used without correction as a measure of relative acidities, the organometallic compounds should correspond as closely as possible to the free carbanion. Streitwieser et al.[61,62] adduce the following arguments indicating that this condition is satisfied for the lithium and caesium salts of polyarylmethanes in cyclohexylamine.

Firstly, the salts absorb at far longer wavelengths than do the corresponding hydrocarbons: i.e. conjugation increases on passing to the salt. Secondly, solutions of most of these salts obey the Lambert–Beer law over a wide concentration range. Thirdly, a diminution in the polarity of the solvent is accompanied by a hypsochromic shift in the spectra (by 30–70 nm), probably due to breakdown of the solvation of the cation in the ion-pair[62]. The most significant aspect, however, is that, despite the sharp difference between lithium and caesium cations in electronegativity and ionic radius, the spectra are almost independent of the nature of the cation. The electrical conductivity of fluorenyl-lithium in cyclohexylamine is very close to that of lithium perchlorate in this solvent[63].

Table 6. McEwen acidity scale.

Compound	pK_a	Compound	pK_a
Methanol (standard)	16	Diphenylamine	23
Pyrrole	16.5	Fluorene	25
Benzyl alcohol	18	Aniline	27
Ethanol	18	*p*-Toluidine	27
Diphenylmethanol	18	*p*-Anisidine	23
Propan-2-ol	18	Xanthen	29
Triphenylmethanol	19	9-Phenylxanthen	29
t-Butyl alcohol	19	Biphenylyldiphenylmethane	31
t-Pentyl alcohol	19	Triphenylmethane	33
Methol	19	1-Naphthyldiphenylmethane	34
Acetophenone	19	Diphenylmethane	35
9-Phenylfluorene	21	1,1-Diphenylethane	36
9-1'-Naphthylfluorene	21	Cumene	37
Phenylacetylene	21		
Indene	21		

The spectral data obtained by Streitwieser et al. will be found in Ref. 60. On the basis of these results they assumed that lithium and caesium salts exist as ion-pairs in cyclohexylamine, and that interaction leading to the formation of a covalent bond could be neglected. In such case equilibrium constants (Eqn. 5) determined spectroscopically are an absolute measure of the difference in acidity[60]. These constants were linked with the pK_a values by relating them to the arbitrary standard 9-phenylfluorene (in aqueous sulpholan $pK_a = 18.5 \pm 0.1$ [64])§. The values obtained by Streitwieser et al. are listed in Table 7.

Table 7. Streitwieser acidity scale.

Compound	pK_a	Compound	pK_a
9-Phenylfuorene	(18.5)	1,1,3-Triphenylpropene	26.4
3,4-Benzofluorene	19.4	Dihydro-9,9-dimethyl-10-phenylanthracene	28.0
1,2-Benzofluorene	20.0	*p*-Biphenylyldiphenylmethane	30.2
4,5-Methylenefluorene	22.6	Triphenylmethane	31.5
Fluorene	22.8	Diphenylmethane	33.1
2,3-Benzofluorene	23.2		

The Streitwieser scale is more precise than the McEwen scale by an order of magnitude, but it covers a narrower class of hydrocarbons, being restricted to polyarylmethanes and structurally similar compounds. Comparison of Tables 6 and 7 shows that polyarylmethanes have almost the same affinity in ether, benzene, and cyclohexylamine: i.e. solvation factors have only a slight effect

§ Choice of this compound as standard may not be altogether correct, since in dimethyl sulphoxide 9-phenylfluorene has $pK_a = 16.4$ (Table 12).

on the pK_a in these solvents. Both scales have the disadvantage of not extending to very weak CH acids, including monoarylmethanes, alkenes, arenes, and alkanes. The two scales can be used to assess the acidity of methine acids having $pK_a < 33$ (on the Streitwieser scale).

Filler and Wang used Streitwieser's system (cyclohexylamine + lithium cyclohexylamide) to determine the equilibrium acidity of polyfluorinated tri- and di-phenylmethanes and several other compounds[65]. The results are given in Table 8.

Table 8. Equilibrium acidity of polyfluorinated aromatic compounds on the Streitwieser scale[65].

Compound	pK_a
$(C_6F_5)_3CH$	15.8
$(C_6F_5)_2CH_2$	21.3
$(p\text{-}CH_3C_6F_4)_3CH$	17.9
$(p\text{-}CH_3OC_6H_4)_3CH$	19.3
$(C_6F_5)_2CHCH(C_6F_5)_2$	22.7

Shatenshtein et al.[66,67] used the Streitwieser and McEwen scales to assess the acidities of derivatives of *o*-, *m*-, and *p*-carboranes in various solvents (ether, dimethoxyethane, and cyclohexylamine). The pK_a values obtained for these methine acids varied little with the nature of the solvent. Table 9 gives the acidities of carboranes in dimethoxyethane on the Streitwieser scale.

Table 9. Equilibrium acidity of carboranes in dimethoxyethane with potassium fluorenylide[a] as base at 25°C.

Compound	pK_a	Compound	pK_a

1-Phenyl-1,2-carborane	22.6	1-Methyl-1,7-carborane	27.9[c]
1-Methyl-1,2-carborane	23.1	*m*-Carborane	27.9[c]
o-Carborane	23.3	*p*-Carborane	30.0[c,d]
1-Isopropyl-1,2-carborane	23.9		

[a] Use of lithium fluorenylide gives pK_a values 1–2 units smaller than those in the Table.

[b] Lithium fluorenylide as base.

[c] Potassium 9-phenylxanthylide as base.

[d] In cyclohexylamine $pK_a = 31.0$.

Transfer from dimethoxyethane to ether as solvent has hardly any effect on the acidity of carboranes[68]. A wider range of ethereal solvents has been studied for the acid ionisation of 9,10-dihydroanthracene ($pK_a = 30.4$ on the Streitwieser scale) and biphenylyldiphenylmethane[69]. Values of pK_a for these two hydrocarbons in diglyme, dimethoxyethane, diethoxyethane, ether, and cyclohexylamine vary within the range $\Delta pK_a = 0.5$. Shatenshtein et al. have also determined the acidity of potassium nido-(3)-1,2-dicarbaundecaborate[70]. Hydrogen attached to five atoms (three boron atoms and two carbon atoms) in the pentagonal plane of a truncated icosahedron probably possesses acidic mobility.

$$B_9C_2H_{13}^-K^+ + A^-K^+ \rightleftharpoons B_9C_2H_{11}^{2-}K_2^+ + HA$$

(where HA represents fluorene or indene). On the Streitwieser scale this compound has $pK_a = 21.3$: i.e. it is a fairly strong CH acid, in spite of the presence of an integral negative charge.

Although the McEwen and Streitwieser acidity scales have found wide practical application, they nevertheless have the above defect of not extending to such hydrocarbons as monoarylalkanes, arenes, alkenes, and alkanes. This is solely because of experimental difficulties in determining the ionisation equilibrium positions of these hydrocarbons. Indirect methods of estimating the acidities of very weak CH acids are therefore attracting attention. The first attempt to set up a universal acidity scale for CH acids, covering all classes of hydrocarbons, was made by Cram[2], who used McEwen's and Streitwieser's transmetallation equilibrium data, together with original investigations by Dessy et al. and by Applequist and O'Brien, which will be discussed below.

2. Cram's MSAD Scale

The direct determination of the ionisation equilibrium of alkanes, alkenes, and other weak CH acids encounters serious experimental difficulties. A method for solving this problem was suggested by Applequist and O'Brien[71], who measured the equilibrium constants between iodobenzene and various lithium alkyls, alkenyls, aryls, and aralkyls in ether and in ether–pentane mixtures at −70°C. Table 10 lists the negative logarithms of the constants K_{Ap} for the equilibrium

$$RLi + PhI \overset{K_{Ap}}{\rightleftharpoons} RI + PhLi\,.$$

Table 10. Logarithms of equilibrium constants between iodobenzene and RLi and between diphenylmercury and R_2Mg (K_{Ap} and K_{De} respectively—see text).

R	$\lg K_{Ap}$	$\lg K_{De}$	R	$\lg K_{Ap}$	$\lg K_{De}$
cyclo-C_5H_9	6.90	—	CH_3	—	2
cyclo-C_4H_7	6.14	—	cyclo-C_3H_5	0.98	0.9
neo-C_5H_{11}	5.46	—	C_6H_5	0	0
iso-C_4H_9	4.59	—	$CH{=}CH_2$	−2.41	0.5
iso-C_3H_7	—	6	$CH_2CH{=}CH_2$	—	−0.2
n-C_3H_7	3.88	—	$CH_2C_6H_5$	—	−0.4
C_2H_5	3.50	4			

Another method for assessing the equilibrium acidity of very weak CH acids was proposed by Dessy et al.[72,73], who estimated the constants K_{De} of the equilibrium

$$R{-}Hg{-} + Ph'{-}Mg{-} \overset{K_{De}}{\rightleftharpoons} R'{-}Hg{-} + R{-}Mg{-}$$

between various dialkyl-, dialkenyl-, and diaryl-magnesium compounds and diphenylmercury in oxolan at 25°C. Table 10 includes the relative logarithms of the equilibrium constants for this reaction.

The data obtained by Applequist and by Dessy were used by Cram[2] to determine the relative stability of anions formed from very weak CH acids. Cram felt, in his own words, "inner consistency" (Ref. 2, p. 29) between these

workers' results and certain data on the kinetic acidity of alkanes. Making a rational approach to these data, he set up the first universal acidity scale, covering such weak acids as saturated hydrocarbons. Cram's scale, which he termed the MSAD (McEwen–Streitwieser–Applequist–Dessy) scale, is given in Table 11. As already noted, the Applequist and Dessy data show good mutual agreement with the exception of the values for the vinyl group. According to Dessy ethylene is more acidic, but according to Applequist benzene (Table 10). Preference was given to the Dessy scale in setting up the MSAD scale.

Table 11. Cram's MSAD scale[2].

Methine acid	pK_a	Methine acid	pK_a
Fluoradene	11	Ethylene	36.5
Cyclopentadiene	15	Benzene	37
9-Phenylfluorene	18.5	Cumene (α)	37
Indene	18.5	Triptycene (α)	38
Phenylacetylene	18.5	Cyclopropane	39
Fluorene	22.9	Methane	40
Acetylene	25	Ethane	42
1,3,3-Triphenylpropene	26.5	Cyclobutane	43
Triphenylmethane	32.5	Neopentane	44
Propene (α)	35.5	Propane (s-)	44
Toluene (α)	35	Cyclopentane	44
Cycloheptatriene	36	Cyclohexane	45

Cram's MSAD scale undoubtedly requires refinement, especially in the region of the alkanes. It gives for methane $pK_a = 40$; the same value had been suggested in 1944 by Morton[48], and later by Pearson and Dillon[29]. However, the value for methane on Kosower's scale[74] is 47. Furthermore, calculation based on the equation[75,76]

$$pK_{CH_4} - pK_{NH_4^+} = pK_{NH_3} - pK_{OH_3^+}$$

with $pK_{NH_3} = 35$ [76] yields $pK_{CH_4} = 58$. On the polarographic scale the value for methane is 57 (see below). Maksič and Eckert-Maksič calculated pK_a values for several CH acids from the degree of *s*-character of the carbon–hydrogen bond undergoing ionisation; their scale has the value 50 for methane[77]. Streitwieser suggested that, in the case of planar unsaturated hydrocarbons, the equilibrium acidity is proportional to the difference between the energies of delocalisation of π-electrons in the carbanion and in the initial hydrocarbon $E_{\pi A^-}$ and $E_{\pi AH}$.[78] Assuming that the resonance integral β (in the molecular-orbital method) remains constant on passing from one system to another, and disregarding the difference in solvation and change in bond angles on passing from the hydrocarbon to the carbanion, we can use the equation

$$\Delta E_\pi = E_{\pi A^-} - E_{\pi AH} = 2\alpha + \Delta M\beta$$

(where α is the Coulombic integral in the molecular-orbital method) to calculate the parameter ΔM, and hence values of pK_a for planar hydrocarbons using the equation

$$pK_a = a + b\Delta M .$$

The dependence of ΔM on pK_a for toluene, fluorene, and indene is a straight line on the McEwen scale. The resulting graph gives $a = 48$ and $b = -15.5$. The former can be regarded as the pK_a of methane, since all these hydrocarbons are derivatives of methane, for which $\Delta M = 0$.

Thus the MSAD scale gives minimum pK_a values for the alkanes, and their true equilibrium acidities are probably smaller by factors of ~10^{10}. Ritchie[79] reached a similar conclusion by a different line of reasoning—from the difference in the solvation of anions having delocalised and non-delocalised charges.

3. Equilibrium Acidity of CH Acids in Dimethyl Sulphoxide

In contrast to many other dipolar aprotic solvents, dimethyl sulphoxide remains unchanged on treatment with its conjugate base (the dimsyl anion $CH_3SOCH_2^-$).[80] Kolthoff and Reddy showed that a glass electrode can be used for titration in pure dimethyl sulphoxide[81], and that acid ionisation constants up to $pK_a \simeq 30$ can be determined potentiometrically. For dimethyl sulphoxide itself the value is 33.1.[82,83]

Table 12. Acidity of CH acids in dimethyl sulphoxide, water, and cyclohexylamine[83].

No.	Acid	pK_{dmso}	pK_{cha}	pK_{H_2O}
1	9-Cyanofluorene	8.4	—	14.2 (methanol)

	Water	29	—	—

* Values of pK measured with respect to the acidity function and related to the standard state in aqueous solution.

** In dimethyl sulphoxide containing ~1% of water.

The first acidity scale in dimethyl sulphoxide, including CH and NH acids, whose acidity was determined by titration with potassium dimsylate in the presence of triphenylmethane as indicator (which gave a coloured anion), was proposed by Steiner and Gilbert[84]. This scale has since been modified by Ritchie[83] and by Ritchie and Uschold[82]. Table 12 gives the acidity scale in dimethyl sulphoxide.

It is interesting to compare the acidity of CH acids in dimethyl sulphoxide with their acidity in water (last column in Table 12). Benzoylacetone and tri-*p*-nitrophenylmethane have the same acidity in dimethyl sulphoxide, but in water these compounds exhibit a difference

ΔpK_a = 4.7: the acidity of benzoylacetone increases on passing from dimethyl sulphoxide to water, whereas that of tri-*p*-nitrophenylmethane decreases. Nitromethane and 9-phenylfluorene have similar pK_a values in dimethyl sulphoxide, but in water nitromethane is more acidic and 9-phenylfluorene less acidic. The acidity of malononitrile, fluorene, and indene remains almost unchanged on passing from aqueous solutions to solutions in dimethyl sulphoxide. The remaining CH acids in Table 12 can be divided into two groups: the first group comprises 9-cyano-, 9-methoxycarbonyl-, and 9-phenyl-fluorene derivatives, fluoradene, triphenylmethane, and trisnitrophenylmethane, which have lower pK_a values in dimethyl sulphoxide than in aqueous solution; the second group includes benzoylacetone, acetylacetone, hydrogen cyanide, and nitromethane, which are more acid in water than in dimethyl sulphoxide. The first group obviously contains CH acids that form anions with a delocalised charge, whereas CH acids of the second group yield anions having their negative charge localised on the heteroatom.

The above results are easily interpreted on the basis of Parker's theory[14], according to which the change in equilibrium constants and rate constants on passing from protic to dipolar aprotic solvents is attributable mainly to solvation of the anions. We have noted earlier that anions with a localised charge are well solvated by hydroxylated solvents. Dimethyl sulphoxide, in contrast, will well solvate strongly polarisable anions with a delocalised charge[14]. Thus the solvation of the latter anions will improve on passing from water to dimethyl sulphoxide, whereas that of anions having a localised charge will deteriorate. As a consequence, the acid ionisation equilibrium will shift to the right in the first case, and to the left in the second case. These arguments are valid, of course, provided that the difference in solvation of all other species involved in the ionisation equilibrium can be neglected.

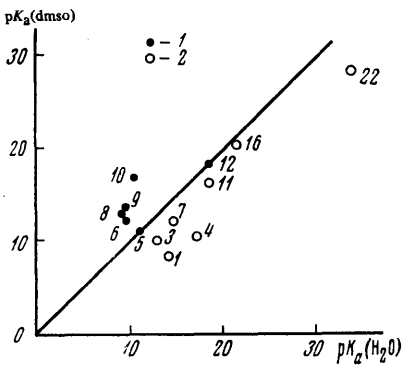

Figure 1. Dependence of acidity in dimethyl sulphoxide on acidity in water for carbanions: 1) well solvated by hydrogen bonds; 2) poorly solvated in water. Numbering as in Table 12. Straight line drawn at unit slope.

The relation between pK_a values in dimethyl sulphoxide and in water is plotted in Fig. 1 for several CH acids. The identity of pK_a values in water and in dimethyl sulphoxide for malononitrile and the other compounds located on the line of unit slope from the origin is fortuitous. With these compounds the energy of solvation of the anions of the conjugated bases changes little on passing from the solvent to water, although the actual nature of solvation becomes quite different. The fact that in water pentane-2, 4-dione is a stronger acid than malononitrile is due to stronger solvation of the conjugated base of the former by hydrogen bonds in water. In dimethyl sulphoxide the acidities of these two compounds have the "normal" sequence (Table 12). Thus the relative acidity in dimethyl sulphoxide corresponds more closely to the "true" acidity of the molecules (apparent in pure form in the gas phase—Section II)(than does the acidity in water.

The lower part of Table 12 gives pK_a values for water and simple alcohols determined in dimethyl sulphoxide. The acidity of alcohols in this solvent is evidently comparable with that of tri- and di-phenylmethane, which is consistent with qualitative results for ionisation in the gas phase (Section II) and diverges sharply from the "generally accepted" values of pK_a = 16—19 for alcohols[88]. This again is explained by a sharp decrease in basicity of oxygen-containing anions (increase in acidity of hydroxyl acids) in hydroxylated solvents due to hydrogen bonding. The high activity of metal alkoxides in dimethyl sulphoxide, first noted by Cram et al.[89], is now widely used in practical synthesis for accomplishing reactions in which the limiting or pre-equilibrium stage is detachment of a proton[2].

The penultimate column of Table 12 contains pK_a values for CH acids in cyclohexylamine. Here the value 16.4 has been chosen for 9-phenylfluorene[83], not 18.5 as in the Streitwieser scale. Hence the pK_a values for CH acids in cyclohexylamine given in Table 12 are smaller by 2.1 than the corresponding values on the Streitwieser scale. Transfer from dimethyl sulphoxide to cyclohexylamine is seen to have little effect on the relative acidities of the hydrocarbons.

4. Polarographic Acidity Scale

The polarographic method has the considerable merit of enabling acidities to be estimated over a very wide range of pK_a values in any polar solvent, even in one that is more "acidic" than the CH acid. It is based on the correlation between the cathodic reduction parameters of organomercury compounds having the general formula R_2Hg and the pK_a values of the corresponding acids RH

The first attempt to use polarography to assess the stability of carbanions was made by Streitwieser and Perrin[90], who measured the half-wave polarographic reduction potentials of substituted benzyl chlorides and polycyclic arylmethyl chlorides in dimethylformamide. If the transition state of this reduction

$$ArCH_2Cl + 2e^- \xrightarrow{E_{1/2}} ArCH_2^- + Cl^-$$

were structurally similar to the carbanion $ArCH_2^-$, a correlation could have been expected between the reduction potentials of the chlorides and the stabilities of the carbanions (i.e. the pK_a values of the methine acids). However, the slow stage in the reduction of halogenated organic derivatives in these systems proved to be transfer of the first electron, which is characterised by a radical-like transition state, so that the expected correlation was very poor. Dessy et al.[73] tried to use the half-wave potentials for the reduction of organomercury salts

$$RHgX \xrightarrow{\text{1st wave}} RHg \quad (\text{or } R_2Hg_2) \xrightarrow[\text{2nd wave}]{E_{1/2}} R^- + Hg$$

as a measure of the relative acidity of CH acids. However, this attempt also was unsuccessful.

The present Reviewers proposed determining the acidity of CH acids by measuring parameters of the cathodic reduction of symmetrical organomercury compounds

$$R_2Hg + 2e^- \xrightarrow{\alpha E_{1/2}} 2R^- + Hg\,.$$

This method takes into account not only the half-wave potential $E_{\frac{1}{2}}$ but also the change in the so called electrochemical transfer coefficient αn_a on passing from one organomercury compound to another[91,92]. On the assumption that the mechanism of cathodic reduction remains unchanged on passing from one mercury dialkyl to another over a quite large number of compounds, i.e. that only rupture of the carbon–mercury bond takes place in the transition state, with the group R acquiring a partial negative charge (which is probably true in most cases[93]), the tendency of the mercury dialkyl to undergo cathodic reduction can be related by simple reasoning with the acidity of the corresponding CH acid RH.

Three processes can probably be interrelated—(i) acid dissociation of the CH acid

$$RH \overset{K_a}{\rightleftharpoons} R^- + H^+\,, \qquad (6)$$

(ii) dissociation of the organomercury compound

$$R_2Hg \overset{1/K_m}{\rightleftharpoons} 2R^- + Hg^{2+}\,, \qquad (7)$$

and (iii) cathodic reduction of the organomercury compound

$$R_2Hg + 2e^- \rightarrow 2R^- + Hg\,.$$

The equilibrium constants (6) and (7) represent the stability of the carbanions in media containing a proton donor or a donor of the mercury cation respectively.

Deduction of a formula linking the acidity of CH acids with the cathodic reduction parameters of their mercury salts necessarily involved the assumption that the proton affinity of the carbanions was related linearly to their affinity for the mercury cation

$$\Delta \ln K_m = A \cdot \Delta pK_a \qquad (8)$$

(where A is a constant, $\Delta \ln K_m$ is the difference between the values of $\ln K_m$ for two organomercury compounds, and ΔpK_a is the difference between the pK_a values for the corresponding methine acids). The validity of this hypothesis has recently been proved[94] by analysing the nuclear magnetic resonance spectra of organomercury compounds. Scheffold has shown[95] that the spin–spin interaction constants between the magnetic isotope of mercury and the methyl protons $J_{^{199}Hg-CH_3}$ in complexes of the methyl mercury cation with various anions X^- (CH_3HgX) are proportional to the logarithm of the stability constants of these complexes:

$$CH_3Hg^+ + X^- \rightleftharpoons CH_3HgX;\ K'_m = \frac{[CH_3HgX]}{[CH_3Hg^+][X^-]}$$

Thus the (thermodynamic) stability of the bond between the cation CH_3Hg^+ and the anion of X^- can be assessed from the n.m.r. spectra. Scheffold's correlation embraces anions with various donor atoms—oxygen, sulphur, nitrogen, halogens, and, especially important, carbon (the cyanide anion)—and can be used to estimate the stability constants of complexes of the methylmercury cation with carbanions, in particular with alkyl anions.

Fig. 2 shows a plot of the constants $J_{^{199}Hg-CH_3}$ against $\lg K'_m$, representing the affinity of various anions X^- for the methylmercury cation. Values of $\lg K'_m$ for the anions—$CH{:}\,C^-$, CF_3^-, $H_2C{:}\,CH^-$, CH_3^-, and C_2H_5—can be estimated by marking off on this graph points corresponding to compounds having low values of J (the sign of the constant remains unchanged throughout the series[96]).

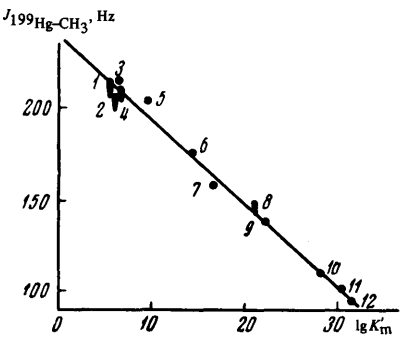

Figure 2. Linear relation between the constants $J_{^{199}Hg-CH_3}$ and $\lg K'_m$ for methylmercury compounds CH_3HgX, where X is: 1) Cl; 2) SCN; 3) $OCOCH_3$; 4) Br; 5) OH; 6) CN; 7) $SHgCH_3$; 8) $C{:}\,CH$; 9) CF_3; 10) $CH{:}\,CH_2$; 11) CH_3; 12) C_2H_5.

The values obtained for $\lg K'_m$ (Table 13) correlate well with the pK_a values for the corresponding hydrocarbons on the Cram scale (Fig. 3). This relation is described by the equation

$$\lg K'_m = 0{,}6 \cdot pK_a + \text{const}\,.$$

Table 13. Affinity of carbanions for methylmercury cation.

No.	Anion	$\lg K'_m$	No.	Anion	$\lg K'_m$
1	CN^-	14.2	4	$CH_2{=}CH^-$	28
2	$HC{\equiv}C^-$	21	5	CH_3^-	30
3	CF_3^-	22	6	$C_2H_5^-$	31.5

By analogy with the above we can assume a linear relation also between the proton affinity of the carbanions and their affinity for the Hg^{2+} cation (Eqn. 8). For the equilibrium reduction of R_2Hg we have

$$\Delta G^0 = -RT \ln K_m + \Delta G_{Hg^0/Hg^{2+}}\,,$$

where the second term on the right-hand side is the redox potential of the Hg^0/Hg^{2+} system. Hence comparison of two organomercuric compounds yields

$$-\Delta\Delta G^0 = RT \cdot \Delta \ln K_m\,. \qquad (9)$$

From Eqns. (8) and (9) it follows that

$$-\Delta\Delta G^0 = RT \cdot A \cdot \Delta pK_a\,. \qquad (10)$$

Rates of reduction of organomercury compounds must be compared at the same potential E, at which each compound will be reduced with a certain overpotential

$$\eta = E - E^0, \tag{11}$$

where E^0 is the equilibrium potential for the given mercury dialkyl. From Eqns. (10) and (11) we obtain for the difference between the overpotentials of two organomercury compounds the formulae

$$\Delta\eta = -\Delta E^0;\ \Delta\eta = \frac{\Delta\Delta G^0}{F},\ \Delta\eta = A^* \cdot \Delta pK_a, \tag{12}$$

where A^* is a constant.

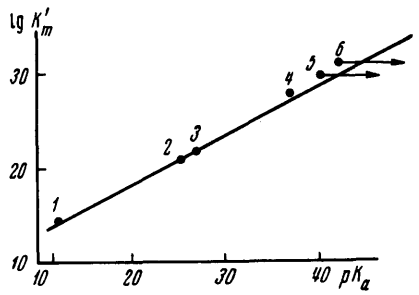

Figure 3. Relation between $\lg K'_m$ and pK_a on MSAD scale. Numbering of compounds as in Table 13.

The cathodic reduction rate constant depends on the overpotential[97]:

$$\ln k_e = \ln k_e^0 - \frac{\alpha n_a F}{RT}\eta, \tag{13}$$

where k_e^0 is the rate constant at the equilibrium potential, n_a the number of electrons involved in the slow stage, and α the electrochemical transfer coefficient¶. Equation (13) presupposes that the transfer coefficient α is independent of the overpotential. If α does depend on the overpotential[98,99], Eqn. (13) can be written, with $n_a = 1$,

$$\ln k_e = \ln k_e^0 - \frac{F}{RT}\int_0^{\eta} \alpha\, d\eta. \tag{14}$$

The difference between the rates for any pair of mercury dialkyls at the same potential, in particular at $E = 0$, is given by the formula

$$\Delta \ln k_e = \Delta \ln k_e^0 - \frac{F}{RT}\int_{\eta_1}^{\eta_2} \alpha\, d\eta.$$

whence

$$\Delta \ln k_e = \Delta \ln k_e^0 - \frac{\alpha_e F}{RT}\Delta\eta \tag{15}$$

in which α_e is the mean transfer coefficient over the range of overpotentials $\eta_1 - \eta_2$.

From Eqns. (12) and (15) we obtain

$$\Delta \ln k_e = \Delta \ln k_e^0 - \alpha_e \cdot A \cdot \Delta pK_a, \tag{16}$$

which shows that the relative rate of reduction of a mercury dialkyl at a given potential depends not only on the relative stability ΔpK_a of the corresponding carbanion R^- but also on the relative rate of reduction of the compound R_2Hg when $\Delta pK_a = 0$, i.e. on the difference between the rates of electron transfer at the equilibrium potentials $\Delta \ln k_e^0$. We may suppose by analogy that $\Delta\eta$ for electron transfer is equivalent to $\Delta pK_a = pK_a(HA) - pK_a(HB)$ for the proton transfer $HA + B^- \rightleftharpoons A^- + HB$, and $\Delta \ln k_e^0$ to the relative rate of proton transfer when $\Delta pK_a = 0$. The quantity $\Delta \ln k_e^0$ is evidently connected with the energy of structural reorganisation of the R_2Hg-R^- system involved in electron transfer. The change in rate of proton transfer when $\Delta pK_a = 0$ observed with change in the structure of the acid may be due to a change in the pK_a of the latter[13] Similarly, in the case of electron transfer we may suppose to a first approximation that $\Delta \ln k_e^0$ varies linearly with $\ln K_m(R_2Hg)$, i.e. with $pK_a(RH)$. If $\ln k_e$ is assumed to be constant over the given range of overpotentials, we find from Eqn. (16) that

$$\Delta \ln k_e = -\rho' \cdot \Delta pK_a \tag{17}$$

It thus remains to measure only the rate constants of cathodic reduction for a series of mercury dialkyls at the same potential, and the problem of determining the acidity of CH acids will be solved. However, since the organomercury compounds R_2Hg are reduced at potentials from 0 to −3 V depending on the nature of R, such measurements are impossible. We are therefore compelled to estimate the rate constants by means of the Koutecky–Delahay equation[100], which, provided that the drop period of the mercury electrode is constant and the diffusion coefficient of the mercury dialkyl varies little with the nature of the alkyl group, is written

$$\frac{\alpha n_a F}{RT} E_{1/2} = \ln k_{E=0} + \text{const}, \tag{18}$$

where $k_{E=0}$ is the rate constant of electron transfer at $E = 0$ relative to some reference electrode, and α is the polarographic transfer coefficient at the half-wave potential $E_{\frac{1}{2}}$. We find from Eqns. (17) and (18) that

$$\Delta(\alpha n_a E_{1/2}) = \rho \cdot \Delta pK_a, \tag{19}$$

where ρ is a constant depending on the experimental conditions. This constant cannot be calculated, and must therefore be determined experimentally each time.

Fig. 4 illustrates diagrammatically the dependence of $\ln k_e$ on the electrode potential[98,99]. The error in the determination of $\ln k_e$ obviously depends on the choice of potential E' at which the rates of reduction of the mercury dialkyls are compared. Thus the quantity $\alpha n_a E(E_{\frac{1}{2}} - E')/RT$, which is determined by linear extrapolation of the tangent at the point $E_{\frac{1}{2}}$ to the potential E' (Fig. 4), does not represent the true value k'_e, and the discrepancy will be larger when the compound is reduced at more negative potentials.

In spite of a number of theoretical limitations, Eqn. (19) was found to hold for a large number of organomercury

¶ This parameter has an analogous significance to the Brønsted coefficient for proton transfer. Change in potential corresponds to a change in equilibrium between oxidised and reduced forms of the substance, just as a change in pK_a corresponds to a change in the position of protolytic equilibrium. The quantity α shows the extent to which potential influences the rate of the forward reaction. The value of αn_a is readily determined from the slope of the polarograms.

compounds corresponding to a series of CH acids with a range of variation in pK_a exceeding 50.[101-107] In this way a polarographic acidity scale was set up, which included CH acids having pK_a values of 7–60 (Table 14).

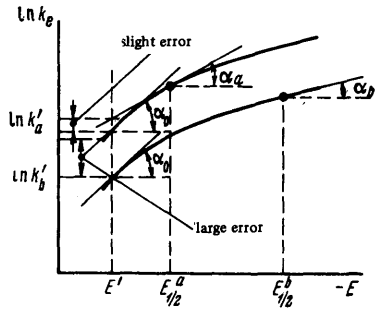

Figure 4. Scheme illustrating dependence of $\ln k_e$ on electrode potential for two different compounds R_2Hg.

Anhydrous dimethylformamide was used as solvent for the polarographic measurements. Half-wave potentials and αn_a were evaluated by means of Heyrovský graphs, and the dependence of the product $\alpha n_a E_{\frac{1}{2}}$ on the pK_a values of the corresponding CH acids was then plotted (Fig. 5).

Table 14. Polarographic acidity scale for CH acids.

Acid	Position of CH bond	pK_a	Acid	Position of CH bond	pK_a
Propane	2	60	Fluoroform		26
Methane		57	Methyl phenyl sulphone	α	25
1,3,5-Trimethylpyrazole	4	38	Ethyl difluoroacetate	α	25
Indole	3	38	Methyl acetate	α	24
	2	35	Pentafluorobenzene		23

The following CH acids were chosen for the experimental determination of the constant ρ (Eqn. 19)—(i) hydrogen cyanide, with pK_a = 12 determined by potentiometric titration in dimethylformamide, (ii) phenylacetylene, cyclopentadiene, toluene, and benzene, whose acidities were known on the MSAD scale, and (iii) methyl acetate, whose pK_a was taken to be 24 [104]—and a calibration graph was drawn through these points. Knowing the values of αn_a and $E_{\frac{1}{2}}$ for other organomercury compounds, we can hence determine the pK_a values for other CH acids. The graph in Fig. 5 shows that a correlation actually exists between values of $\alpha n_a E_{\frac{1}{2}}$ for R_2Hg and the pK_a of the corresponding acids RH.

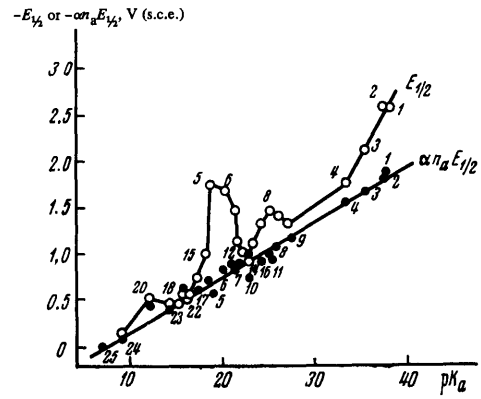

Figure 5. Correlation of parameters of polarographic reduction of organomercury compounds with acidity of corresponding CH acids. Numbering of points corresponds to that of compounds in Table 1 of Ref. 93.

It is important to note that the half-wave potentials do not correlate with the acidity. The reason is that they do not have the same physical significance in an irreversible electrochemical process as in reversible reduction: i.e. the value of $E_{\frac{1}{2}}$ does not directly represent the redox properties of the substance that is reduced irreversibly.

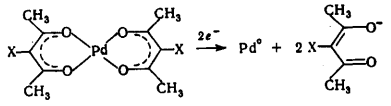
The polarographic method enabled a very wide range of variation in acidity to be investigated. It can be used to determine the acidity of compounds containing groups sensitive to the action of bases and, what is very important, the relative stability of isomeric carbanions differing in the position of their charge. The main experimental difficulty (usually easily overcome) is the need to prepare isomeric mercury derivatives of the CH acids.

The correlation of $\alpha n_a E_{\frac{1}{2}}$ with pK_a is valid only when the carbon–mercury bond alone is broken in the transition state, and no subsequent processes stabilising the resulting carbanion influence the potential. This requirement may not always be made for compounds towards the end of Table 14, since their reduction is in considerable measure reversible: e.g.

$$(CBr_3)_2Hg \overset{2e^-}{\rightleftharpoons} Hg + 2CBr_3^- \xrightarrow[\text{potential}]{\text{influences}} 2\,CBr_3 + 2Br^-.$$

If the proton affinity of carbanions is assumed to be linearly related to their affinity not only for the mercury cation but also for cations of other metals, similar correlations between cathodic reduction parameters and pK_a values should be observed for many other organometallic compounds. We have examined published data[108,109], and found that Eqn. (19) holds for acetylacetonate complexes of

palladium and acidopenta-amminecobalt complexes, which are reduced according to the schemes



$$[Co(NH_3)_5X]^{n+} \xrightarrow{e^-} [Co(NH_3)_5]^{n+} + X^-$$

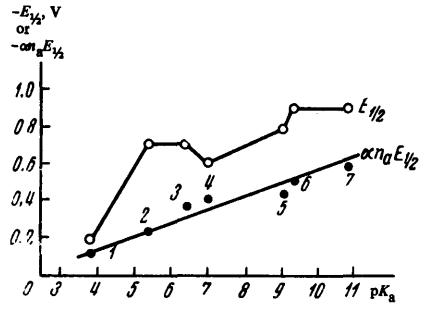


Figure 6. Dependence of $\alpha n_a E_{\frac{1}{2}}$ on pK_a of substituted acetylacetones for acetylacetonate complexes of palladium (substituent X): 1) CN; 2) $NHCOCH_3$; 3) $COOC_2H_5$; 4) Br; 5) H; 6) C_6H_5; 7) CH_3.

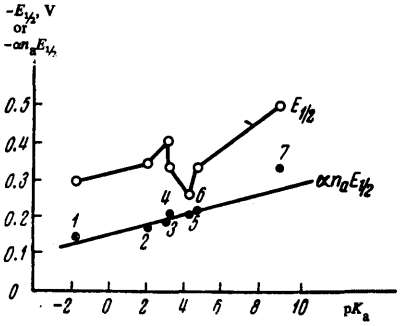

Figure 7. Dependence of $\alpha n_a E_{\frac{1}{2}}$ on pK_a of HX for reduction of $[CoX(NH_3)_5]$ where X is: 1) H_2O; 2) HSO_4^-; 3) F^-; 4) NO_2; 5) fumarate; 6) CH_3COO^-; 7) NH_3.

Figs. 6 and 7 show that the product $\alpha n_a E_{\frac{1}{2}}$ for the palladium complexes correlates well with the pK_a values of the corresponding pentane-2,4-diones, and that for the cobalt complexes with the pK_a values of the acids HX. As with the organomercury compounds, a linear relation is not observed between pK_a and $E_{\frac{1}{2}}$ (Figs. 6 and 7). With reversibly reducible cobalt complexes containing a cobalt–carbon σ-bond, however, good correlations are observed between the half-wave potential of the first polarographic wave and the pK_a values of the corresponding carbanions[110]. Graphs illustrating this relation are given in Figs. 8 and 9.

5. Breslow's Electrochemical Method

An interesting electrochemical method for determining the acidity of hydrocarbons for which direct measurement of pK_a is impossible was suggested by Breslow et al.[111-113]. It involved indirect determination of equilibrium acidity on the basis of the series of reversible reactions

$$R{-}H \overset{1}{\rightleftharpoons} R{-}OH \overset{2}{\rightleftharpoons} R^+ \overset{3}{\rightleftharpoons} R\cdot \overset{4}{\rightleftharpoons} R^-.$$

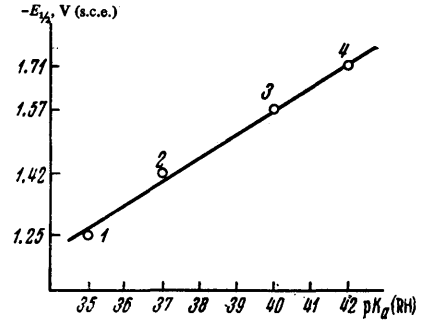

Figure 8. Dependence of half-wave potential for reduction of the complexes [CoR salen dmf] complexes[109] (first wave) on pK_a of RH on MSAD scale for R: 1) $C_6H_5CH_2$; 2) C_6H_5; 3) CH_3; 4) C_2H_5.

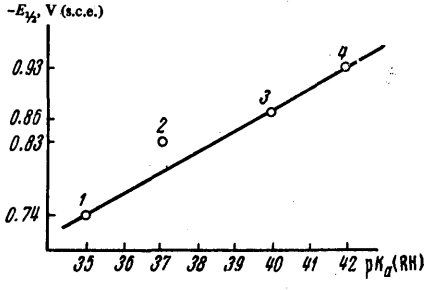

Figure 9. Dependence of half-wave potential for reduction of [CoR(DO)(DOH)pndmf] [109] on pK_a(RH). Numbering as in Fig. 8.

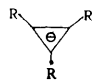
Breslow's method is applicable to hydrocarbons which yield relatively stable carbonium ions and relatively unstable carbanions. In this case it is easy to determine thermodynamic parameters for stages *3* and *4* by some electrochemical method, e.g. by measuring the redox potentials for the reduction in stages of the carbonium ion to the carbanion. The thermodynamic parameters for stage *2* are Deno's pK_{R^+} values[114], which characterise the equilibrium

$$R{-}OH + H^+ \overset{K_{R^+}}{\rightleftharpoons} R^+ + H_2O$$

between the alcohol and the carbonium ion. It is difficult to obtain thermodynamic parameters for stage *1*, but it was suggested that the difference between the heats of formation of hydrocarbon and alcohol was roughly constant for a series of related compounds.

Breslow et al. took $pK_a = 33$ on the McEwen scale for triphenylmethane as basis, and determined the thermodynamic acidity of several substituted triphenylmethanes,

as well as cycloheptatriene and substituted cyclopropenes (Table 15). The high pK_a values for substituted cyclopropenes are explained by the instability (anti-aromaticity) of the corresponding anion



unstable

Breslow's method is primarily valuable because such a low acidity is difficult to investigate by other methods.

Table 15. Breslow acidity scale for CH acids[111-114].

pp'p''-Trisubstituted triphenylmethane	pK_a ±2,0	Compound	pK_a
Trichloro	32.3	Cycloheptatriene	36±3
Monomethoxy	33.1	Triphenylcyclopropene	51±4
Trimethoxy	33.4	Trimethylcyclopropene	62±5
Trisdimethylamino	34.7	Tri-n-propylcyclopropene	64±5
Trimethyl	33.6	Tri-t-butylcyclopropene	65±5
Tri-isopropyl	36.2		
Tri-t-butyl	35,2		

---o0o---

In this Review we have been considering only papers reporting the determination of the equilibrium acidity of a *series* of CH acids by various methods, i.e. in which scales of relative acidity have been set up. There are also many isolated data on the acidity of individual CH acids, determined under various conditions (e.g. in an alkali-metal alkoxide—alcohol system) or estimated indirectly. These results, which undoubtedly merit attention, have been excluded from the present paper to avoid increasing its length.

It is now possible to determine the acidity of CH acids in aprotic solvents up to values of $pK_a \simeq 30$. The acidity of weaker acids (alkenes, arenes, alkanes, etc.) is assessed by indirect methods, since no direct methods are available. The acidity of these compounds is evidently less than that predicted by Cram's MSAD scale. The main problem of future research will be to compile a *quantitative* scale of acidities in the gas phase and to work out methods for calculating theoretically the empirical constants occurring in the equations relating pK_a values with other thermodynamic or kinetic parameters.

The Electronic Nature of Fluorine-containing Substituents

L.M.Yagupol'skii, A.Ya.Il'chenko, and N.V.Kondratenko

The available literature data up to 1973 on the electronic effects of fluorine-containing substituents are considered and discussed in the review.
The bibliography includes 143 references.

I. INTRODUCTION

The chemistry of organofluorine compounds is developing very vigorously. Novel methods of synthesis are being devised, new reactions and new types of organofluorine compounds are being discovered, and relations are being established between their structures and properties[1,2]. The quantitative characteristics of the electronic effects of 80 fluorine-containing substituents were determined in recent years and the results of a gradual substitution of hydrogen atoms by fluorine in alkyl groups demonstrated, the positions of new fluorine-containing groups in the series of thoroughly investigated substituents were established, and substituents with unique properties (the most pronounced electron-accepting properties among all known compounds) were discovered. The results are of great interest for theoretical organic chemistry. Substituents such as the fluorine atom and the CF_3 group are introduced into organic molecules as frequently as other substituents which do not contain fluorine. Since convenient preparative methods have been developed recently for the synthesis of compounds containing various perfluoroalkyl [CF_3O, CF_3S, CF_3SO_2, and $N(CF_3)_2$] and other similar groups, there is no doubt that these substituents too will soon become commonplace.

Since organic compounds with fluorine-containing substituents are finding increasing application as medicinal preparations, pesticides, dyes, and monomers for thermostable polymers, a review of the available data on the electronic effects of fluorine-containing groups may be useful for the specific synthesis of substances with valuable properties.

The electronic nature of substituents was characterised quantitatively for the first time by Hammett[3,4] in terms of σ_m and σ_p constants. Subsequently the latter were resolved by Taft and Lewis[5-9] into components reflecting the inductive (σ_I) and resonance (σ_R) effects. In the presence of direct polar conjugation between the substituents and the reaction centre, anomalously high σ constants are observed. Therefore one distinguishes σ_p^0 and σ_R^0 constants without taking into account direct polar conjugation from σ constants when such conjugation is taken into account (σ_p^- and σ_R^- for electron-accepting substituents and σ_p^+ and σ_R^+ for electron-donating substituents).[10]

In order to determine the σ constants of fluorine-containing substituents, the following methods are most widely used: ^{19}F NMR on the basis of the chemical shifts δ^F of the fluorine atoms in *meta*- and *para*-substituted fluorobenzenes relative to fluorobenzene[11]; the determination of σ constants from the dissociation constants of *meta*- and *para*-substituted benzoic acids[3,6,12]; the measurement of pK_a for anilinium[6,13] or dimethylanilinium ions[14]; the determination of the dissociation constants of phenols[6,15].

Dewar and Grisdale[16,17] and Swain and Lupton[18] developed new methods for the resolution of σ constants into inductive and resonance components—F and M, and F and R respectively. The electronic nature of fluorine-containing substituents has been investigated also by other correlations between σ constants and absorption band shifts of azo-dyes or passing from a neutral to an acid medium[19], the pK_a of cyanine dyes[20,21], and the absorption intensity in the infrared spectra of monosubstituted benzenes[22,23]. Methods based on the measurement of molecular dipole moments are also used[24]. The determination of interaction dipole moments (μ_{int}), which reflect the direct polar conjugation between the substituent and the reaction centre and are correlated with the σ^- and σ^+ constants[10,24,25], is particularly valuable.

The electronic effects of fluorine-containing substituents can be estimated from their directing influence in electrophilic or nucleophilic substitution reactions involving the aromatic ring. Correlations have been discovered between the reaction rate constants and the σ^+ or σ^- constants[26,27].

The most detailed data on the applications of various σ constants are quoted in a series of monographs and reviews[3,4,10,28-30]. This review deals with published data on the electronic effects of fluorine-containing substituents and a comparison is made with the electronic influence of the analogous substituents without fluorine.

II. FLUORINE AND OTHER HALOGENS

Fluorine is the most electronegative element. The C–F bond is the most polar among bonds between carbon and halogens[31,32]. In aliphatic compounds the fluorine atom exhibits a powerful electron-accepting inductive effect. This can be inferred, for example, from the pK_a values for halogenoacetic acids[33] and the molecular diagram for methyl fluoride[34]:

$$\begin{matrix} 0.00 + 0.187 - 0.187. \\ H_3C - F \end{matrix}$$

Halogen atoms linked to an unsaturated carbon atom or an aromatic ring exhibit an electron-accepting inductive effect ($\sigma_I > 0$) and an electron-donating conjugation† effect ($\sigma_R < 0$), decreasing in the sequence F > Cl > Br > I (Table 1). Among the halogens, the fluorine atom has the smallest covalent radius[32], close to that of the carbon atom, which results in conditions for maximum overlapping of the *p* orbitals. Therefore despite its high electronegativity, the fluorine atom exhibits the most pronounced electron-donating conjugation effect among all the halogens.

Table 1. σ constants of the halogens*.

Substituent	σ_m^{12} B	σ_p^{12} B	$\sigma_p^{0\,35}$	$\sigma_p^{+\,36}$	σ_I B[11]	σ_I A[35]	σ_I F[10]	$\sigma_R^{0\,11}$ B	$\sigma_R^{0\,11}$ F	σ_R^{10} B
F	0.34	0.06	0.17	−0.07	0.52	0.55	0.52	−0.35	−0.32	−0.46
Cl	0.37	0.23	0.27	0.11	0.47	0.43	0.40	−0.20	−0.18	−0.24
Br	0.39	0.23	0.26	0.15	0.45	0.42	0.44	−0.19	−0.16	−0.22
I	0.35	0.28[4]	0.27	0.13	0.39	0.34	0.44	−0.12	−0.14	−0.13

*In this and subsequent tables the methods of determination of σ constants are indicated by letters: B—from the pK_a for benzoic acids; A—from the pK_a for anilinium ions; DA—from the pK_a for dimethylanilinium ions; F—from the δF chemical shifts (^{19}F NMR); P—from the pK_a of phenols; i.r.—from infrared spectra; Dy—from $\Delta\lambda$ for azo-dyes; C—from the pK_a for cyanine dyes.

The overall electronic effect of fluorine, characterised by the σ_p constant, is the smallest among all the halogens, since its large conjugation effect to a considerable extent neutralises the inductive effect. The σ_R^0 constant for fluorine in *p*-difluorobenzene, determined by ^{19}F NMR, is smaller than σ_R found from pK_a for *p*-fluorobenzoic acid in which the fluorine atom is involved in direct polar conjugation with the COOH group (−0.32 and −0.46 respectively). As a result the σ_p constant for fluorine is smaller than σ_p^0.

Since the σ_p constant for fluorine is close to zero, the acid-base properties of benzoic acid, phenol, and aniline hardly change when the fluorine atom is introduced into the *para*-position relative to the functional group. The remaining halogens increase the acid properties and reduce the basic properties to a much greater extent than fluorine[37].

† Usually referred to as the resonance effect in English (Ed. of Translation).

The σ_p^+ constants for halogen atoms are much smaller than σ_m, which is usually observed for *ortho*, *para*-directing substituents. Indeed in electrophilic substitution reactions the halogens behave as substituents of the first kind with predominantly *para*-directing properties, particularly in the case of fluorine. In nitration reactions fluorine deactivates the benzene ring but to a much smaller extent than chlorine and bromine[38].

The electrophilic constant σ_p^+ of the fluorine atom is negative, in contrast to the other halogens. Accordingly, fluorobenzene is chlorinated much faster than benzene. The relative rates of chlorination of halogenobenzenes and benzene increase in the sequence F > H > Cl > Br (6.3, 1.0, 0.4, and 0.25 respectively).[38]

The distribution of electrons in vinyl fluoride and fluorobenzene, calculated by the quantum-chemical method taking into account σ and π electrons, confirmed that the inductive effect of the fluorine atoms makes it a powerful electron acceptor and the conjugation effect makes it a powerful electron donor. The overall charge of the fluorine atom in fluorobenzene is negative[39]. Fluoro-, chloro-, bromo-, and iodo-benzenes have dipole moments of 1.47, 1.59, 1.57, and 1.40 D respectively with the negative pole at the halogen atom[24,40].

Many instances where the fluorine atom exhibits not only an inductive effect but also a conjugation effect have been observed in studies on the reactivities of fluoro-olefins and described in reviews[41–43]. An interesting case of the electron-donating effect of fluorine was observed in cyanine dyes with fluorine atoms in the polymethine chain[44]. It was found that, as a powerful electron-donating substituent, fluorine affects the colour of the dyes in a manner similar to that, for example, of the methoxy-group.

Thus, in considering the influence of fluorine atoms on the properties of organic compounds, one must take into account the unusual behaviour of fluorine, related to its dual electronic nature involving a powerful electron-accepting inductive effect and an electron-donating conjugation effect.

III. FLUOROALKYL GROUPS (R_F)

Among the fluoroalkyl groups, the CF_3 group is most frequently introduced as a substituent. The σ constants of this group have been determined by various methods. Their values together with the σ constants of other fluoroalkyl groups are listed in Table 2.

The trifluoromethyl group is a fairly powerful electron-accepting substituent both as regards the inductive and conjugation effects. A number of studies have been made on its unusual properties[14,45,55,56]. The inductive effect plays the main role in its electronic influence. It is somewhat smaller for the CF_3 group than for the fluorine atom. Thus the dissociation constant of trifluoromethylacetic acid is smaller by a factor of 2.2 than that of fluoroacetic acid[57].

The conjugation effects of the CF_3 group and the fluorine atom act in the opposite directions. The electrophilic constant $\sigma_m^+ = 0.52$ of the CF_3 group is smaller than $\sigma_p^+ = 0.61$.[36] In conformity with these data, trifluoromethylbenzene enters into electrophilic substitution reactions with greater difficulty than benzene and its *meta*-position is involved preferentially. Thus the nitration of trifluoromethylbenzene results in the formation of 100% of the *m*-nitro-isomer[58], while chlorination gives 80.2% of the *m*-isomer, 15.7% of the *o*-isomer, and 4.1% of the *p*-isomer[59].

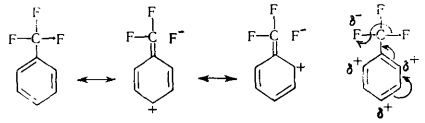
*$\sigma_p^+ = 0.61$.[36]

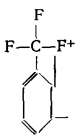
The following postulates have been used to account for the electronic nature of the trifluoromethyl group and in particular its electron-accepting conjugation effect.

1. The CF_3 group is conjugated with the aromatic ring—a negative hyperconjugation effect[45] (in contrast to the positive hyperconjugation effect of the methyl group, which acts in the opposite direction[60]). This effect can be represented by a series of limiting structures with an unbound fluoride anion or by curving arrows:



2. The trifluoromethyl group exhibits a π-inductive effect (I_π)—it withdraws electrons from the adjacent ring carbon atom at which a partial positive charge arises and withdraws electrons from the *ortho*- and *para*-positions via a resonance mechanism[14,60]:

3. The *p* electrons of the fluorine atoms of the CF_3 group interact with the π electrons of the benzene ring in such a way that the electron density in the *meta*-position is enhanced—*p*-π interaction[14]. Many experimental facts and also quantum-mechanical calculations[55,56], carried out taking into account all the valence electrons in the atom, have shown that not only σ electrons but also ring π electrons are transferred to the CF_3 group in the trifluoromethylbenzene molecule. This confirms the hypothesis of a significant role of the hyperconjugation of the CF_3 group with the aromatic ring.



$+0.0508\,\sigma - 0.0508\,\delta$
$+0.0134\,\pi - 0.0134\,\pi$
$C_6H_5 - CF_3$

Negative hyperconjugation is a consequence of the overlapping of the *p* orbital of the adjacent carbon atom of the aromatic ring and the CF_3 group orbital comprising the orbitals of the fluorine atoms forming σ bonds. As a result of the high electronegativity of the fluorine atom, the hyperconjugation effect leads to a decrease of the π electron density in the aromatic ring and its increase at the fluorine atoms of the CF_3 group. When electron-donating substituents are introduced in the *para*-position of trifluoromethylbenzene, the electron shift to the CF_3 group increases owing to direct polar conjugation. This is confirmed, for example, by calculated data[56] for the distribution of π electrons in *p*-fluoro(trifluoromethyl)benzene in relation to the analogous values for fluorobenzene and trifluoromethylbenzene:

$$\underset{F-\ C_6H_5}{+0.0489\,\pi - 0.0489\,\pi} \quad \underset{p\text{-}F-\!-\!C_6H_4-\!-\!CF_3}{+0.0522\pi - 0.0368\,\pi - 0.0154\,\pi} \quad \underset{C_6H_5-CF_3}{+0.0134\,\pi - 0.0134\,\pi}\ .$$

In the *p*-fluoro(trifluoromethyl)benzene molecule the π electron density at the CF_3 group is higher than in the trifluoromethylbenzene molecule, while at the fluorine atom it is lower than in fluorobenzene, i.e. direct polar conjugation results in a transfer of electrons from the fluorine atom to the trifluoromethyl group.

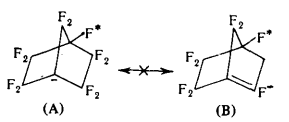
Direct polar conjugation of the CF_3 group with powerful electron-donating substituents (NH_2, NMe_2, O^-) was observed in a study of the dipole moments and chemical properties of *para*-substituted trifluoromethylbenzene. For example, *p*-amino(trifluoromethyl)benzene has μ_{int} = 0.49 D.[61] As a result of direct polar conjugation, *o*- and *p*-hydroxy- and *o*- and *p*-amino-(trifluoromethyl)benzenes readily undergo alkaline hydrolysis, in contrast to the *meta*-isomers[62,63]. For example, this has been used to synthesise 4-trifluoromethylanthranilic acid (a valuable intermediate) from 2,5-di(trifluoromethyl)aniline. In the alkaline hydrolysis of the latter the CF_3 group in the *ortho*-position relative to the amino-group is converted into a carboxy-group, while the substituents in the *meta*-position remain unchanged[64,65].

The high σ constants determined from the pK_a of substituted anilines (σ_p^-), compared with the values found by other methods, have been explained by direct polar conjugation (Table 2).

Andreades[66] investigated the base-catalysed exchange of hydrogen for deuterium in monohydrofluorocarbons: $R_FH + CH_3OD \rightleftharpoons R_FD + CH_3OH$. This reaction proceeds via a stage involving the formation of a carbanion and the

rate of exchange depends on its stability. Comparison of the deuteration rate constants showed that the relative reactivity increases in the series $R_F = CF_3 < CF_3(CF_2)_5CF_2 < (CF_3)_2CF < (CF_3)_3C$, the corresponding values being $1, 6, 2 \times 10^5$, and 10^9. The delocalisation of the charge in the corresponding anions can be described by 0, 2, 6, and 9 resonance structures, the stability of the carbanions and the rate of deuterium exchange increasing in the same sequence. This parallel variation is evidence in support of the hyperconjugation effect.

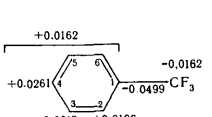
According to Streitwieser and Holtz [67,68] the following observation constitutes evidence against a significant role of negative hyperconjugation in the electronic effect of the CF_3 group. The rate of exchange of protons for the corresponding tritium species in 1*H*-undecafluorobicyclo[2,2,1]heptane is higher by a factor of five than for $(CF_3)_3CH$. Moreover the carbanion of the latter compound is stabilised by nine resonance structures, while the carbanion (A) is not stabilised by resonance in the authors' view, since, according to Bredt's rule, a double bond cannot be located at the bridgehead, i.e. structure (B) is impossible.



(A) (B)

However, these arguments are insufficient for the complete rejection of a contribution by hyperconjugation, since the involvement of the CF_3 group in conjugation does not require a change in the hybridisation of its carbon atom from sp^3 to sp^2 and its hyperconjugation effect is not described exactly by the resonance theory in terms of limiting structures with an unbound fluorine atom and a C=C double bond. As mentioned above, the hyperconjugation of the CF_3 group is due to the overlapping of the *p* orbitals of the adjacent carbon atom with the orbitals of the fluorine atoms of this group without a change in its steric configuration. Thus hyperconjugation in the carbanion (A) can be achieved also without the involvement of (B) type structures. Apart from this, the field effect of the fluorine atom (F*) at the bridgehead can have an influence on the stabilisation of the carbanion (A). [50]

The trifluoromethyl group exerts a powerful electron-accepting inductive effect on the aromatic ring, which is transmitted both via the nearest σ bonds and through space in the form of the field effect. This effect leads to the polarisation not only of σ electrons but also of π electrons, i.e. results in a I_π effect. The influence of the latter is indicated by the calculated π electron distribution in the trifluoromethylbenzene molecule [50]:



According to these data, a negative charge (−0.0499) is concentrated on carbon atom 1, exceeding the charge of the CF_3 group (−0.0162). Thus polarisation of the ring π electrons under the influence of the inductive effect of the CF_3 group is evidence for the presence of an I_π effect.

However, there are also objections to a significant role of the I_π effect [49,71]. They are based on the observation that groups such as $C(CN)_3$ and ICl_2, which have very high inductive effects ($\sigma_I = 0.98$ [49] and 1.3 [71]) do not exhibit a conjugation effect ($\sigma_R = 0.01$ [49] and 0.0 [71] respectively). The $C(CF_3)_3$ group behaves similarly (Table 2). The I_π effect should increase with the inductive effect of the substituents on the ring π electrons and should lead to an increase of the σ_R. However, this is not observed. The I_π effect probably does not play a significant role in the electronic influence of perfluoroalkyl groups.

In the study of the hyperconjugation effect of fluoroalkyl groups, it is interesting to compare the σ constants of the substituents CF_3, CF_2CF_3, $CF(CF_3)_2$, and $C(CF_3)_3$ in which the number of fluorine atoms capable of being involved in conjugation decreases steadily. All these groups are fairly powerful electron-accepting substituents with positive σ_m and σ_p constants.

Comparison of the σ_I and σ_R constants of the above perfluoroalkyl substituents obtained from ^{19}F NMR data (Table 2) shows that the replacement of fluorine atoms in the CF_3 group by trifluoromethyl substituents leads to a gradual increase of the σ_I constant and a decrease of the conjugation constant σ_R. The conjugation constant for the $C(CF_3)_3$ group is zero [51]. These findings confirm the hypothesis of an effect of the hyperconjugation of the fluorine atoms in the trifluoromethyl group with the aromatic ring, which decreases as CF_3 groups accumulate at a single carbon atom.

Despite the fact that the inductive effect of the fluorine atom is greater than that of the trifluoromethyl group, the σ_I constants increase on replacement of the fluorine atoms in the CF_3 group by trifluoromethyl substituents. This can probably be explained by the fact that the inductive effect is transmitted not only via σ bonds but also through space—the field effect *F*. The latter depends on the distance *r*, the dipole moments μ of the bonds in the substituent, the angles θ between the directions of the moments and the lines joining the centres of the dipoles to the reaction centre, and the dielectric constant *D* of the solvent [69,70]: $F = \mu \cos\theta / Dr^2$.

Sheppard explained a similar increase of the σ constant on passing from $CN(\sigma_I = 0.47)$ to the $C(CN)_3$ group ($\sigma_I = 0.98$) also by an increase of the field effect [49,71].

Since the inductive effect plays a dominant role in the electronic behaviour of perfluoroalkyl substituents, its increase according to ^{19}F NMR data in the series $CF_3 < CF_2CF_3 < CF(CF_3)_2 < C(CF_3)_3$ leads to an increase of the constants σ_m and σ_p in the same sequence despite the decrease of the σ_R. The constants σ_p obtained from the ^{19}F NMR data and the pK_a for the acids are virtually identical.

The σ_m and σ_I constants for the $CF(CF_3)_2$ and $C(CF_3)_3$ groups obtained from the same data differ markedly. The field effect of the $CF(CF_3)_2$ and $C(CF_3)_3$ substituents is greater than that of the CF_3 group and therefore their electronic influence depends to a greater extent on the possible operation of the field effect. In the *para*-position it is transmitted through space in the ring with its low dielectric constant and in the *meta*-position the effect is transmitted via the solvent and greatly depends on its polarity. It decreases with increase of the polarity. The acid dissociation constants were determined in a highly polar solvent—aqueous alcohol. This probably explains why the $CF(CF_3)_2$ and $C(CF_3)_3$ groups in the *meta*-position have a weaker electron-accepting influence than the CF_3 group.

In a series of *para*-substituted derivatives, the decrease of the field effect of the substituents under the influence of the solvent does not occur and therefore the strengths of the *p*-CF_3-, *p*-$CF(CF_3)_2$-, and *p*-$C(CF_3)_3$-benzoic acids are approximately the same [14,51]. The fact that *m*-(perfluoro-t-butyl)aniline is a stronger base and its *para*-isomer a

weaker base than the corresponding trifluoromethylanilines can be explained by a similar field effect[51]. For the same reason, the σ_p constants determined from the pK_a for the anilinium ions (σ_p^-) increase on gradual substitution of the fluorine atoms in the CF_3 group by trifluoromethyl groups.

Examination of the constants $\sigma_R^- = \sigma_p^- - \sigma_I$ shows that, when CF_3 groups accumulate at the same carbon atom, there is a tendency towards a decrease of direct polar conjugation. A similar phenomenon was observed in the study of the dipole moments of aromatic compounds with polyfluoroalkyl substituents. The dipole moments of the compounds C_6H_5X, where $X = CF_3$, C_2F_5, $CF(CF_3)_2$, and $C(CF_3)_3$, are very close (2.60[45], 2.73[14], 2.68[14], and 2.72 D[51]). The values of μ_{int} for *p*-amino(trifluoromethyl)benzene and *p*-amino(perfluoro-t-butyl)benzene (0.42[45] and 0.30 D[51]) show that the direct polar conjugation between the CF_3 and NH_2 groups is somewhat more pronounced than between $C(CF_3)_3$ and NH_2.

Like the CF_3 group, all the perfluoroalkyl groups are *meta*-directing in electrophilic substitution reactions (nitration, bromination)[14,51].

In order to account for the greater deactivation of the *para*-position compared with the *meta*-position by the CF_3, C_2F_5, and $CF(CF_3)_2$ substituents, for which $\sigma_m < \sigma_p$, Sheppard[14] put forward the hypothesis of p-π interaction of the p electrons of the fluorine atoms of the perfluoroalkyl groups with the π electrons of the aromatic ring. Such interaction results in an electron shift, which partially compensates the powerful inductive effect of the substituents in the *meta*-position, while the *para*-position is greatly deactivated.

A number of objections have been made to the hypothesis of p-π interaction. Dewar[72] noted that the p-π interaction has no chemical analogies and that a shift of π electrons to the *meta*-position as a result of a conjugation effect is unlikely. Stock and coworkers[73], Smith and Menger[74], and Holtz[68] failed to observe such p-π conjugation in model compounds.

We established[51] that the $C(CF_3)_3$ group does not exhibit a conjugation effect although in the presence of p-π interactions the nine fluorine atoms in the β-position should be equivalent to the three fluorine atoms of the CF_3 group, according to Sheppard's hypothesis, and should lead to similar values of the σ_R constants of these substituents. Theoretical calculations of the distribution of electrons and of bond orders in the trifluoromethylbenzene molecule also failed to confirm the hypothesis of $p - \pi$ interaction[50]. Thus the hypothesis has not been confirmed by theoretical and experimental studies[30,50,68].

The results of studies on the electronic nature of trifluoroalkyl groups discussed above lead to the conclusion that the electron-accepting inductive effect of these substituents, which is transmitted both via σ bonds and through space (field effect) is most important in their electronic influence. The conjugation effect of these groups is small and is mainly caused by hyperconjugation.

On gradual substitution of hydrogen atoms in the methyl group by fluorine, the electron-accepting properties of the substituents become more pronounced—the σ_m, σ_p, σ_I, and σ_R constants increase and their sign changes from negative to positive (Tables 2 and 3).

When fluorine atoms are introduced into the CH_3 group, the σ_I constant does not increase in proportion to their number. The "saturation effect" is particularly marked for chloro-, bromo-, and iodo-derivatives. As a result of this effect, the σ_I constants of the $CHCl_2$ and CCl_3 groups and of the $CHBr_2$ and CBr_3 groups hardly differ. Another anomaly is that the σ_I constants of the CH_2X and CHX_2 groups do not decrease in the sequence X = F, Cl, Br, and I, although the electronegativity of the halogens decreases on passing from fluorine to iodine. These anomalies may be related to the different field effects of the CH_2X, CHX_2, and CX_3 groups. When X = Cl, Br, and I, the CH_2X and CHX_2 groups cannot rotate freely about the bond with the aromatic ring owing to steric hindrance, in contrast to the analogous fluorine-containing substituents, and occupy fixed positions. The angle θ (see above) between the C–X bond and the line joining the centre of this bond to the fluorine atom in the *meta*-position (from the chemical shifts of which the σ_I constants are determined) will be smaller than the average statistical angle for freely rotating fluorine-containing groups.

Table 3. σ constants for halogenoalkyl groups[47,48].

The field effect of the CH_2X and CHX_2 substituents, where X = Cl, Br, and I, depends on $\cos\theta$, increases for this reason, and leads to an increase of the σ_I constants.

The accumulation of the large chlorine and bromine atoms at the same carbon atom in the CCl_3 and CBr_3 groups leads to an increase of the bond angles or and hence to an increase of the angle θ and a decrease of the field effect. This may be the reason for the appearance of the "saturation effect".

The angle θ in the $C(CF_3)_3$ substituent must be smaller than for CBr_3 and for the $C(CN)_3$ group θ should be smaller still, the steric hindrance to the rotation of this group is low and the valence angles apparently do not change, so that saturation is not observed for the $C(CN)_3$ group and the latter exhibits a very high inductive effect.

The conjugation constants for halogenoalkyl substituents are small. In terms of its conjugation effect, the CH_2F group is still not an electron donor and its σ_R constant is negative, while the CHF_2 and CF_3 substituents are electron acceptors on the basis of this effect.

On passing from fluorine to iodine in the series of substituents CH_2X, the electron-donating conjugation effect increases slightly, while the electron-accepting effect of the CHX_2 and CX_3 groups decreases.

The CH_2F and CH_2Cl groups are very similar as regards their electronic properties. Their directing effect in electrophilic substitution reactions is the same—they are

predominantly *ortho*, *para*-directing substituents. In the nitration of benzyl fluoride the ratios of the *p*-, *m*-, and *o*-isomers correspond to 54, 28, and 18%,[76] while the corresponding proportions for benzyl chloride are 52.5, 32, and 15%.[77] The directing effects of other partly fluorinated alkyl groups in electrophilic substitution reactions have not been investigated.

IV. PERFLUOROACYL GROUPS (COR_F)

The σ constants of the $C(=O)F$, $COCF_3$, and COC_3F_7[2] groups have been determined by ^{19}F NMR (Table 4). The $COCF_3$ and COC_3F_7 groups are much more powerful electron-accepting substituents, in terms of both their inductive and conjugation effects, than the analogous non-fluorinated acyl groups. In terms of the σ_p constants, they resemble the nitro-group ($\sigma_p = 0.78$)[10]. This is because, under the influence of the perfluoroalkyl substituents at the carbon atom of the carbonyl group, the positive charge increases appreciably and the inductive effect and capacity of the carbonyl group of the perfluoroacyl substituents become much more marked. The latter should also exhibit the effect of direct polar conjugation with electron-donating groups. It can be estimated from the σ_p^- constants. We calculated it from the correlation equation of Swain and Lupton[18]. σ_p^- for the $COCF_3$ group was found to be 1.22 (the corresponding values for the O_2 and $COCH_3$ groups are 1.27 and 0.8).[10]

Table 4. σ constants of perfluoroacyl groups.

Substituent	σ_m	σ_p	σ_I	σ_R
COF[2,11]	0.55	0,70	0,39	0,31
$COCF_3$[2,14]	0.63	0.80	0.47[a]	0.33
COC_3F_7[b]	0.63	0,79	0.46	0.33
COH[10,B]	0.43	0.52	0,25	0.27
COCl[10,B]	0.53	0.69	0,38	0.31
$COOC_2H_5$[10,C]	0,20	0.30	0.11	0.19
$COCH_3$[10,C]	0.28	0.38	0.18	0.20

Other data: [a]0.45;[11] [b]calculated from δ_m^F and δ_p^F (Sheppard[14]) data; [c](F).

In electrophilic substitution reactions, for example in nitration, the $COCF_3$ group exhibits predominantly a *meta*-directing effect[78].

The substitution of the hydrogen atom in the aldehyde group by fluorine leads to an increase of the electron-accepting inductive effect and of the conjugation effect. However, the fluoroformyl group has smaller σ constants than the $COCF_3$ group. This is because the fluorine atom exhibits, apart from a powerful electron-accepting inductive effect, an electron-donating conjugation effect. The latter is much smaller than for the ethoxy-group in the $COOC_2H_5$ substituent. For this reason, the COF group is a stronger electron-accepting substituent than $COOC_2H_5$. The constant σ_p^- for the COF group is also somewhat smaller than for $COOC_2H_5$, amounting to 1.09.

V. NITROGEN- AND PHOSPHORUS-CONTAINING SUBSTITUENTS (N – R_F, P – R_F)

The electronic properties of the substituents in which the CF_3, COF, $COCF_3$, and SO_2CF_3 groups are linked to the nitrogen atom have been investigated (Table 5). The replacement of the methyl by trifluoromethyl in the dimethylamino-group converts this powerful electron-donor into an electron-acceptor, whose σ_m and σ_p constants are close to those of the trifluoromethyl group. However, the inductive effect contributes most to the electronic influence of the $N(CF_3)_2$ group. Its conjugation effect is close to zero owing to the withdrawal of the free electron pairs of the nitrogen atom by the trifluoromethyl groups. For the same reason, di(trifluoromethyl)aniline and its derivatives do not exhibit basic properties and do not form salts with acids[79,82].

Table 5. σ constants for nitrogen-containing substituents (^{19}F NMR method).

Substituent	σ_m^a	σ_p^a	σ_I	σ_R

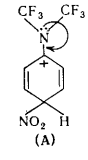
$N(CH_3)SO_2CH_3$[80]	0.29	0,24	0.34	−0.10
$N(CH_3)SO_2CF_3$[80]	0.46	0.44	0.48	−0.04
$N(COCH_3)_2$[80]	0.35	0.33	0.37	−0,04
$N(SO_2CH_3)_2$[80]	0,47	0.49	0,45	0.04
$N(SO_2CF_3)_2$[80]	0.75	0,80	0.70	0.10
$N(CF_3)COF$[79]	0.56	0,56	0,56	0.00
$N(COF)_2$[79]	0.58	0,57	0.58	−0.01
$N{=}C(CF_3)_2$[2]	0.29	0.23	0.35	−0.12
$N{=}N{-}CF_3$[80]	0.56	0.68[g]	0,44	0.24
$N{=}N{-}C_6H_5$[10]	0.23	0.27	0.19	0.08

Other data: [a]calculated from σ_I and σ_R; [b]$\sigma_m = 0.40$, $\sigma_p = 0.53$, $\sigma_I = 0.29$, $\sigma_R = 0.23$ (B),[14] $\sigma_m = 0.47$, $\sigma_p = 0.53$, $\sigma_I = 0.44$, and $\sigma_R = 0.06$ (A)[14]; [c]0.13 (i.r.)[23]; [d]$\sigma_m = 0.30$ and $\sigma_p = 0.12$ (B)[81]; [e]0.13 (C)[21]; [f]$\sigma_I = 0.38$ and $\sigma_R = -0.15$;[10] [g]0.74 (C)[21].

However, in electrophilic substitution reactions the $N(CF_3)_2$ group still behaves as an *ortho*, *para*-directing substituent. In the nitration of di(trifluoromethyl)aniline the proportions of the *para*-, *ortho*-, and *meta*-isomers are 92.4, 5.6, and 1.9%, while in the bromination reaction the corresponding proportions are 94.9, 0.3, and 1.7%.[79] Under the influence of electrophilic agents, the free electron pair at the nitrogen atom is probably nevertheless involved in conjugation and stabilises the transition state (A):



(A)

We estimated by two methods the constants σ_p^+ and σ_R^+, which determine the directing effect of the substituents

in electrophilic substitution reactions. The constants $\sigma_p^+ = 0.42$ and $\sigma_R^+ = 0.07$ were calculated for the $N(CF_3)_2$ group by the equation of Swain and Lupton[18].

The constant σ_R^+ was determined by another method, using the correlation equation $\mu_{int} = 1.10\ (\sigma_R - \sigma_R^+)$ derived by the present authors, for the compounds *p*-$XC_6H_4NO_2$, where X = NMe_2, NH_2, OH, Br, or SCH_3.[24] The dipole moments of *p*-$NO_2C_6H_4N(CF_3)_2$ and $C_6H_5N(CF_3)_2$ are 1.80 and 2.69 D,[79] $\mu_{int} = 0.40$ D, $\sigma_R^+ = 0.13$, and $\sigma_p^+ = 0.36$. The two methods yielded similar negative values of σ_R, and $\sigma_p^+ < \sigma_m$. Consequently the $N(CF_3)_2$ group should be *ortho*, *para*-directing, in agreement with experimental data.

The replacement of the hydrogen atom in the amino-group by $COCH_3$, SO_2CH_3, $COCF_3$, and SO_2CF_3 groups leads to an increase of the electron-accepting inductive effect and a decrease of the conjugation effect. However, the latter still retains its electron-donating character. Thus, even the $NHSO_2CF_3$ group is *ortho*, *para*-directing[83]. A change in the sign of the constant σ_R is observed only when two methane- or trifluoromethane-sulphonyl groups are introduced at the nitrogen atom. The σ_m and σ_p constants of the $N(SO_2CF_3)_2$ substituent resemble those of the nitro-group. Nitration of di(trifluoromethylsulphonyl)aniline yields a mixture of *meta*- and *para*-nitro-isomers in proportions of 8 : 1.[83] The $N(SO_2CH_2)_2$ group is predominantly *ortho*, *para*-directing[84].

The electrophilic constants σ_R^+ and σ_p^+ of the $N(SO_2CF_3)_2$ group, calculated by the method of Swain and Lupton[18], are 0.04 and 0.74. The positive value of the σ_R^+ constant indicates a *meta*-directing effect of this substituent. Thus the directing effect of the amino-group in electrophilic substitution reactions involving an aromatic ring was altered for the first time only by introducing at the nitrogen atom two powerful electron-accepting CF_3SO_2 groups[83].

There are linear relations[21,80] between the σ_p and σ_I constants of the NHR group on the one hand and the corresponding constants of the substituents R, where R = $COCF_3$, SO_2CF_3, and other acyl groups, on the other; they are expressed by the equations

$$\sigma_p(NHR) = 0.49\,\sigma_p(R) - 0.13 \text{ and } \sigma_I(NHR) = 0.38\,\sigma_I(R) - 0.23.$$

It is interesting to note that the $N(CH_3)R$ groups, where R = $COCH_3$, SO_2CH_3, or SO_2CF_3, are weaker electron donors in terms of their conjugation effects than the corresponding NHR groups, although the introduction of the electron-donating methyl group in place of a hydrogen atom should have resulted in the opposite effect[80]. The explanation is probably that the $N\begin{smallmatrix}CH_3\\R\end{smallmatrix}$ groups are displaced from the plane of the benzene ring owing to steric hindrance, which reduces the degree of conjugation between the free electron pair at the nitrogen atom and the ring π electrons.

The $N(CF_3)COF$ and $N(COF)_2$ substituents are somewhat stronger electron acceptors than $N(CF_3)_2$ due to the greater contribution of the inductive component. The trifluoromethylazo-group $-N{=}N{-}CF_3$ is a powerful electron-accepting substituent, approaching in this respect the nitro-group and greatly superior in its electron-accepting influence to the $-N{=}NC_6H_5$ group. In terms of its conjugation effect, the $-N{=}C(CF_3)_2$ substituent is an electron donor. This group is probably not located in the plane of the benzene ring and the free electron pair at the nitrogen atom is involved in conjugation with the aromatic ring.

The phosphorus-containing groups $P(CH_3)_2$ and $P(CF_3)_2$ are less effective electron-accepting substituents than their nitrogen-containing analogues. The inductive effects of the corresponding substituents are close and the conjugation effects of the phosphorus-containing groups indicate more pronounced electron-accepting properties than those of the nitrogen-containing groups (Tables 5 and 6). The σ_I and σ_R constants of the $P(CF_3)_2$ group virtually correspond to those of the nitro-group.

Table 6. σ constants for fluorine-containing substituents.

Substituent	σ_m^a	σ_p^a	σ_I	σ_R
$P(CH_3)_2$ [85]	0.05	0.03	0.08	−0.05
$P(CF_3)_2$ [85]	0.60	0.69	0.50	0.19
$P(CF_3)(C_6H_4F)$[b]	0.44	0.47	0.41	0.06

[a]calculated from σ_I and σ_R (F) data; [b]σ_I and σ_R calculated from δ_m^F and δ_p^F.[85]

The involvement of the free *d* orbitals of the phosphorus atom in conjugation with the π electrons of the aromatic ring is characteristic of phosphorus-containing substituents. The presence of electron-accepting groups at the phosphorus atom, such as CF_3, leads to a decrease of the size and diffuseness at the *d* orbitals, which makes their overlapping with the π electron cloud of the ring more effective and increases the electron-accepting character of the conjugation of the substituent. The replacement of one of the CF_3 groups by an aromatic ring with more marked electron-donating properties makes the conjugation effect of the $P(CF_3)(C_6H_4F)$ group much weaker than for $P(CF_3)_2$. Linear relations have been found for substituents of the type PX_3, where X = F, CF_3, CN, and other groups, whereby the constants of the substituents PX_2 can be calculated from the values of σ_I and σ_R for X:[85]

$$\sigma_I(PX_2) = 0.78\,\sigma_I(X) + 0.47\,\sigma_R(X) + 0.15;\quad \sigma_R(PX_2) = 0.44\,\sigma_I(X) + 0.08\,\sigma_R(X) - 0.03.$$

VI. OXYGEN-CONTAINING GROUPS (O–R_F)

The σ constants of fluorinated oxygen-containing groups are listed in Table 7. The replacement of three hydrogen atoms in the OCH_3 group by fluorine atoms greatly increases its electron-accepting inductive effect and decreases the electron-donating conjugation effect. However, the σ_R constant of the OCF_3 group is still negative, in contrast to all the known substituents of the type $X(CF_3)_n$. All the σ constants of the OCF_3 group resemble most closely those of the chlorine atom. Like the latter, the OCH_3 group is an *ortho*, *para*-directing substituent[97,98], but in the nitration and bromination of phenyl trifluoromethyl ether only the *para*-isomers are formed in yields of 91 and 82% respectively[99,100].

The *para*-directing influence of the trifluoromethoxy-group can be accounted for by the stabilisation of the transition state by the electron-donating conjugation effect of this group. The *ortho*-position relative to the OCF_3 group is deactivated, as in fluorobenzene, by the powerful electron-accepting inductive effect. The σ_I constant of the OCF_3 group is closer to that of fluorine than chlorine.

[52]				0.36[l]								

*Calculated from σ_I and σ_R data.

Other data: [a]approximate values, σ_R = −0.31 (i.r.)[87]; [b]−0.27;[87] [c]−0.23 (i.r.)[87]; [d]σ_m = 0.40, σ_p = 0.26, σ_I = 0.36, and σ_R = −0.15(P)[10]; [e]0.38;[2,14] [f]0.35;[2,14,19] [g]0.25;[88] [i]−0.04[2] and −0.17;[11] [j]−0.19[87] and −0.25 (i.r.)[22,23]; [k]σ_m = 0.43, σ_p = 0.21, σ_I = 0.42, and σ_R = −0.17(ρ);[90] [l]0.21(Dy).[96]

On gradual substitution of the hydrogen atoms in the OCH_3 group by fluorine, the σ_I constants increase regularly approximately by 0.1 and the absolute values of the σ_R constants decrease on average by 0.08 (according to ^{19}F NMR). The saturation effect is hardly observed. The inductive effects for analogous chlorinated groups also increase on accumulation of chlorine atoms, but a marked saturation effect is shown. Compounds containing the OCH_2F substituent have not so far been obtained but its σ constants have been calculated (Table 7).

Like OCF_3, the $OCHF_2$ group is an *ortho*, *para*-directing substituent[101]. However, since the inductive effect of the $OCHF_2$ group is smaller, the *ortho*-position in the difluoromethylphenyl ether molecule is less deactivated in relation to electrophilic substitution reactions than in phenyl trifluoromethyl ether, but is nevertheless more deactivated than in anisole. Thus nitration of anisole yields a mixture of *ortho*- and *para*-isomers in proportions of 1 : 2,[102] nitration of difluoromethylphenyl ether gives the corresponding proportion of 1 : 2.6,[101] while phenyl trifluoromethyl ether is nitrated only in the *para*-position.

Methoxy- and fluoromethoxy-groups are irregular substituents[24]. The methoxy-group has a group moment of 1.28 D[41] and an angle $\theta = 72°$,[41] the substituent constituting the positive end of the dipole. The fluorinated groups $OCHF_2$ and OCF_3 have group moments of 2.46[103] and 2.27 D[104] (2.36 D[90]) and angles θ of 137°30′[103] and 154°[104] (160°[24]). When the hydrogen atoms are replaced by fluorine in the methoxy-group, the angle gradually increases, the direction of the group moment approaches the direction of the C_{aryl}–O bond, and the substituent becomes the negative end of the dipole.

The conjugation effect of the OCH_3, OCH_2F, $OCHF_2$, and OCF_3 substituents depends on whether they are located in the plane of the aromatic ring or whether they are displaced from it under the influence of their steric interaction with the hydrogen atoms in the *ortho*-positions. It has been shown by quantum-mechanical calculations[87] that the π electron density in the *para*-position of the benzene ring depends on the angle between the planes of the benzene ring and C_{aryl}–OR. For the OCH_3, OCH_2F, $OCHF_2$, and OCF_3 substituents, these angles are 18°, 56°, 90°, and 90° respectively. With increase of the angle, the electron-donating properties of the substituents diminish, but still persist even when the angle is 90°.

The OCF_2CF_3, OCF_2CHF_2, and OCF_2CHFCl substituents have σ constants close to those of the OCF_3 group. The trifluoroacetoxy-group exhibits a more powerful electron-accepting inductive effect than the $OCOCH_3$ substituent and even OCF_3, while they all have virtually identical electron-donating conjugation effects.

As was to be expected, among all the known groups OR the OSO_2CF_3 group is the most powerful electron acceptor[84,93] and has the highest σ_I constant. Nevertheless in electrophilic substitution reactions the group is an *ortho*, *para*-directing substituent[93]. The OSF_5 group behaves similarly[95].

VII. SULPHUR- AND SELENIUM-CONTAINING GROUPS (S–R_F, Se–R_F)

According to ^{19}F NMR data, on passing from the methoxy- to the methylthio-group, the electron-accepting inductive effect diminishes by a factor of two, while the electron-donating conjugation effect decreases approximately by a factor of three (Tables 7 and 8). The methylthio-group exhibits inductive and conjugation effects which are almost of the same magnitude but have the opposite signs. The introduction of three fluorine atoms sharply enhances the electron-accepting properties of the methylthio-group. The inductive effect increases appreciably, being only slightly inferior to that of the ECF_3 group, while the conjugation effect of the trifluoromethylthio-group changes direction and becomes an electron-accepting effect, in contrast to that of the oxygen analogue. As a result, the σ_m constants of the OCF_3 and SCF_3 groups are very close and the σ_p constant of the SCF_3 group shows that it is a much more powerful electron-accepting substituent than OCF_3.

Successive substitution of the hydrogen atoms of the SCH_3 group by fluorine results in a gradual increase of the electron accepting inductive effect, while the conjugation effect changes from electron-donating for the SCH_3 and

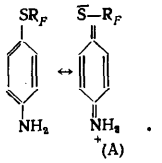
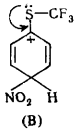
SCH_2F groups to electron-accepting for the $SCHF_2$ and SCF_3 substituents. The interaction of a sulphur atom with the aromatic ring is of a dual nature: it is an electron-donating $(3p - 2p)\pi$ interaction with charge transfer to the ring and an electron-accepting $(3d - 2p)\pi$ interaction with charge transfer from the ring to the vacant *d* orbitals of the sulphur atom. Electron-accepting substituents at the sulphur atom tend to increase the interaction involving the *d* orbitals of sulphur. The electron-accepting $(3d - 2p)\pi$ conjugation occurs when the *para*-position relative to the fluoroalkylthio-group contains electron-donating substituents, for example the amino-group.



As fluorine atoms accumulate in the methylthio-group, the $(3d - 2p)\pi$ conjugation becomes more marked and the contribution of the resonance structure (A) gradually increases, as can be seen from the increase of μ_{int} in the series of substituents $SCH_3 < SCHF_2 < SCF_3$ (0.27, 0.46, and 0.68 D)[103,104]. The group moments and the angles θ between the direction of the dipole moment and the Caryl–S bond of the above substituents also gradually increase (μ = 1.34[104], 2.48,[103] and 2.50 D[104]; θ = 77.5°,[24] 137°,[103] and 156°[24,104]). The change in the angle θ shows that the electrons in the SCH_3 group are displaced to the benzene ring ($\theta < 90°$), while in fluorinated groups the opposite shift obtains.

The electron-donating $(3p - 2p)\pi$ conjugation decreases on accumulation of fluorine atoms in the methylthio-group. This is evident from a comparison of the μ_{int} for the corresponding *p*-nitro-derivatives, which diminishes on passing from SCH_3 to $SCHF_2$ and SCF_3 (θ_{int} = 0.78, 0.48, and 0.21 D respectively).[103,104]

In electrophilic substitution of an aromatic ring, the SCF_3 group is *ortho*, *para*-directing. Thus nitration of phenyl trifluoromethyl sulphide results in the formation of 65% of the *p*-nitro-isomer and 35% of the *o*-nitro-isomer[112]. This is probably due to the stabilisation of the transition state (B) by $(3p - 2p)\pi$ conjugation with the electron pair of the sulphur atom:



(B)

An approximate estimate of the electrophilic conjugation constant σ_R^+ of the SCF_3 group from data for μ_{int} for the interaction with a nitro-group (see above) yields 0.09. The negative value of the constant is also consistent with the *ortho*, *para*-directing influence of the substituent. The electronic influence of the SCF_2CF_2H group hardly differs from that of the SCF_3 group.

When the SCF_3 group is converted into $SOCF_3$ and SO_2CF_3, there is a marked enhancement of the electron-accepting properties of the substituent. We have established[52,113] that the CF_3SO_2 group is one of the most powerful electron acceptors. The σ constants of this substituent greatly exceed those of the nitro-group. The strength of the $SOCF_3$ group is close to that of the nitro-group.

In contrast to SCF_3, the $SOCF_3$ and SO_2CF_3 groups are *meta*-directing. Nitration of phenyl trifluoromethyl sulphoxide yields 90% of the *m*-nitro-isomer and only 5% of the *p*-nitro-isomer[114] and nitration of phenyl trifluoromethyl sulphone results in the formation of the *m*-nitro-isomer alone[113].

When the hydrogen atoms in the $SOCH_3$ and SO_2CH_3 groups are replaced successively by fluorine, the inductive and conjugation effects gradually increase. The σ constants of the SO_2CH_2F group correspond to those of the nitro-group and the constants of the SO_2CHF_2 group are actually higher.

More marked electron-accepting properties of the SO_2CF_3 and SO_2CHF_2 substituents compared with those of the nitro-group are observed also in nucleophilic substitution reactions involving the aromatic ring. Thus the introduction of the SO_2CF_3 group in place of the nitro-group in the 4-position of 1-halogeno-2,4-dinitrobenzenes increases the rate of substitution of fluorine and chlorine in the reactions with aniline by a factor of 10 and 40 respectively[115].

When *p*-nitrophenyl trifluoromethyl and *p*-nitrophenyl difluoromethyl sulphones react with sodium alkoxides, the weaker electron-accepting substituent (the nitro-group) is preferentially substituted by the alkoxy-group[116-118]. In *p*-nitrophenyl trifluoromethyl sulphoxide the weaker electron-accepting $SOCF_3$ group is replaced.

The group moments of the SCF_3, $SOCF_3$, and SO_2CF_3 substituents gradually increase and are 2.50, 3.88, and 4.32 D, while the angles θ are 156°, 143°, and 167°.[104] The angles θ increase in the series of substituents SO_2CH_3, SO_2CH_2F, SO_2CHF_2, and SO_2CF_3: 117°,[24] 136°,[113] 152°,[103] and 167°,[104] while the group moment passes through a minimum: 4.73,[24] 4.04,[119] 4.08,[103] and 4.32 D.[104] The vibration frequencies (ν_{as}) of the SO bond[120] gradually increase in the above series of substituents: 1334, 1342, 1358, and 1380 cm^{-1}.

The σ_I constants for the SCF_3, $SOCF_3$, and SO_2CF_3 groups were also determined from the pK_a data for the corresponding substituted acetic acids and the σ_p constants were determined from the pK_a for the phenylacetic acid derivatives[108]. These results are close to the values of σ_I and σ_p constants obtained by ^{19}F NMR. It was found that trifluoromethylthioacetic acid is approximately 65 times, trifluoromethylsulphoxyacetic acid is 500 times, and trifluoromethylsulphonylacetic acid is 750 times stronger than acetic acid[108]. The last acid is the strongest of all known monosubstituted acetic acids.

The σ constants determined by different methods for powerful electron-accepting substituents, for example SO_2CHF_2 and SO_2CF_3, show differences. This is probably due to a contribution by the direct polar conjugation between these substituents and the reaction centre (the fluorine atom and the hydroxy- and amino-groups). The σ_R constants of the SCF_3, $SOCF_3$, and SO_2CF_3 groups determined by ^{19}F NMR include a definite contribution by polar conjugation as for other powerful electron-accepting substituents. Correlations whereby it is possible to determine the constants σ_R^0 free of the contribution by direct polar conjugation have been found by comparing the σH, $\sigma^{13}C$, and σF chemical shifts[121]. The σ_R^0 constants of the SCF_3, $SOCF_3$, and SO_2CF_3 groups are 0.01, 0.09, and 0.20; they are appreciably smaller than the σ_R = 0.06, 0.13, and 0.31 found by ^{19}F NMR.

The basicity of the anilines *p*-$NH_2C_6H_4SO_2R$ decreases markedly as fluorine atoms accumulate in the substituents. Thus pK_a = 1.48, 1.28, 0.51, and −0.02 for R = CH_3, CH_2F, CHF_2, and CF_3.[88] *p*-Trifluoromethylsulphonylaniline is the weakest base among all the known *p*-substituted anilines.

The enhancement of the electron-accepting influence of the substituents with increase of the number of fluorine atoms in the OCH_3, SCH_3, $SOCH_3$, and SO_2CH_3 groups is clearly shown in the ESR spectra of the radical-anions obtained by the reduction of the corresponding substituted nitrobenzenes. The splitting constants a_N for the nitrogen atoms of the nitro-groups and the reduction half-wave potentials $E_{1/2}$ decrease steadily as the electron-accepting properties of the substituent become more pronounced[122].

Transmission of the electronic effects of substituents in an aromatic ring to the OCF_3, SCF_3, and SO_2CF_3 groups was observed by ^{19}F NMR from the change in the chemical shifts of the fluorine atoms in these groups. It was found that the electronic influence is transmitted most effectively via the sulphur atom and with greater difficulty via the oxygen atom of the SO_2 group[123]. A similar behaviour was observed in a study of the shifts of the C–F stretching vibration frequencies in the infrared spectra of compounds of the type $XC_6H_4OCF_3$, $XC_6H_4SCF_3$, and $XC_6H_4SO_2CF_3$.[124,125]

When one hydrogen atom in the methyl group is replaced by the SCF_3, $SOCF_3$, or SO_2CF_3 groups, the inductive effect becomes of the electron-accepting type and the conjugation effect changes sign only for the $CH_2SO_2CF_3$ group. As the SCF_3 groups accumulate at the carbon atom, the inductive effect becomes increasingly of the electron-accepting type and a saturation effect is observed, as for chloro- or bromo-methyl groups. The conjugation effect becomes of the electron-accepting type only for the $C(SCF_3)_3$ group.

The SOF and SO_2F substituents have σ constants close to those for the SOCl and SO_2Cl groups. The SO_2F group is a much more effective electron-accepting substituent than SOF. The latter hardly differs in the values of the σ constants from the $SOCF_3$ group. The SO_2F substituent has a σ_I constant close to that of the SO_2CF_3 group, but its σ_R constant is somewhat smaller, probably owing to the electron-donating conjugation effect of the fluorine atom.

The electron-accepting inductive effect decreases in the series of substituents with Group VI elements $OCF_3 > SCF_3 > SeCF_3$, the values for the last two being very close, as for the corresponding methyl derivatives[109]. In contrast to the trifluoromethoxy-group, which exhibits an electron-donating conjugation effect, the SCF_3 and $SeCF_3$ groups have positive σ_R constants owing to the involvement in conjugation of the vacant *d* orbitals of the sulphur and selenium atoms. The more diffuse 4*d* orbitals of selenium show a smaller tendency towards $(p-d)\pi$ conjugation than the 3*d* orbitals of the sulphur atom and therefore the $SeCF_3$ groups exhibit a weaker electron-accepting conjugation effect than SCF_3. A similar phenomenon was observed on comparing the SCH_3 and $SeCH_3$ substituents[109]. The dipole moment of the interaction between $SeCF_3$ and the amino-group in the *para*-position (μ_{int} = 0.43 D)[126] is somewhat smaller for the same reason than that for the interaction between SCF_3 and NH_2 groups (μ_{int} = 0.68 D)[104].

Owing to the smaller tendency of the selenium atom towards $(4p-2p)\pi$ conjugation, the $SeCF_3$ substituent does not show electron-donating properties, in contrast to the

SCF_3 group, even when a nitro-group is present in the *para*-position (μ_{int} = 0.01 D)[126]. The group moment of the $SeCF_3$ substituent is 2.48 D (2.50 D for SCF_3) and its vector forms an angle $\theta = 140°$ with the C_{aryl}–Se bond[116] ($\theta = 156°$ for SCF_3).

Thus the SCF_3 and $SeCF_3$ substituents with bivalent sulphur and selenium have similar electronic properties; the substituents containing atoms of these elements in the quadrivalent ($SOCF_3$ and $SeOCF_3$) and hexavalent (SO_2CF_3 and SeO_2CF_3) states differ more markedly.

The $SeOCF_3$ and SeO_2CF_3 substituents have higher σ_I constants and somewhat lower σ_R constants than the corresponding sulphur-containing groups. This is probably due to the greater contribution of polar structures of the type $CF_3Se^+(=O)-O^-$, which results in a high positive charge on the selenium atom and a decrease of the multiplicity of the Se–O bond. The study of the dipole moments confirms this hypothesis. The group moments of the $SeOCF_3$ (4.13 D)[127] and SeO_2CF_3 (5.37 D)[127] substituents are higher than for the sulphur-containing groups (3.88 and 4.32 D respectively), while the μ_{int} for interaction with electron-donating substituents are lower. For example, μ_{int} is 0.97 D for *p*-$NH_2C_6H_4SeOCF_3$,[127] 1.11 D for the sulphur analogue[104], 0.18 D for *p*-$CH_3C_6H_4SeO_2CF_3$,[127] and 0.78 D for the analogous sulphone[104].

As for the SCF_3 and $SeCF_3$ groups, the angles θ in the $SeOCF_3$ and SeO_2CF_3 substituents (128° and 151°)[127] are smaller by approximately 15° than for the sulphur-containing groups. The electron-accepting influence of the $SeOCF_3$ and SeO_2CF_3 substituents, characterised by the σ_m and σ_p constants, is much greater than that of the analogous $SOCF_3$ and SO_2CF_3 groups. In terms of its inductive effect, SeO_2CF_3 is an even more powerful electron acceptor than the SO_2CN and $N^+(CH_3)_3$ groups (σ_I = 0.94[107] and 0.93[10] respectively).

VIII. UNSATURATED FLUORINATED GROUPS

The vinyl group has σ constants close to zero. On replacement of a hydrogen atom in such groups by CF_3 and SO_2CF_3, unsaturated groups are formed with electron-accepting properties, albeit considerably weakened by the introduction of the vinylene group (Table 9). The inductive effect decreases particularly markedly.

A correlation has been found between the σ_I constants of the CH=CHX and X substituents[10]: σ_I (*trans*-CH=CHX) = 0.01 + 0.41 σ_I(X). The decay of the inductive effect transmitted via the vinyl group is smaller by a factor of approximately two than via two methylene groups. This suggests that the inductive effect is transmitted not only via σ bonds but also via π bonds. In these unsaturated systems the I_π effect probably plays a certain role.

The σ_R constants of the CH=CHX and X groups are also linearly related: σ_R (*trans*-CH=CHX) = −0.03 − 0.96 σ_R(X). Comparison of the coefficients of σ_I(X) and σ_R(X) shows that the conjugation effect is more effectively transmitted via the vinyl unit than the inductive effect.

In the *cis*-isomer of the group $CH=CHCF_3$ the σ_I and σ_R constants are smaller than for the *trans*-isomer. This is probably because, owing to steric hindrance, the CH = $CHCF_3$ group in the *cis*-isomer is partly displaced from the plane of the benzene ring.

The σ_m and σ_p constants of the CH = $CHSO_2CF_3$ group resemble those of the CF_3 group. The ethynyl group is a more powerful electron acceptor than the vinyl group and the replacement of its hydrogen atom by a CF_3 group leads to the substituent $C{\equiv}CCF_3$ with more powerful electron-accepting properties than those of the $CH=CHCF_3$ group. The *trans*-$CF=CF-CF_3$ group has the same σ constants as the $C{\equiv}C-CF_3$ group. Thus the replacement of hydrogen atoms in the substituent $CH=CHCF_3$ by fluorine atoms is equivalent to the conversion of a double bond into a triple bond. The σ constants of the $CF=CFCF_3$ and $C{\equiv}CCF_3$ substituents are very close to those of the CF_3 group.

Table 9. σ constants for unsaturated fluorinated substituents.

C_6H_5 [10, 11]	0.06	0.04	−0.01	−0.01	0.10	0.08	−0.10	−0.09
C_6F_5 [129, i]	−0.12	0.26	−0.03	0.27		0.25		0.02
C_6Cl_5 [129]		0.25		0.24		0.25		−0.01

*Calculated from σ_I and σ_R.

Other data: [a] 0.20;[2,71] [b] 0.34;[2,71] 0.23 (C)[21], 0.23 (Dy)[19,128], and σ_p^- = 0.34 (A);[88] [c] 0.17;[2,71] [d] 0.20;[2,71] [e] 0.16;[2,71] [f] 0.07;[2,71] [g] σ_{p^-} = 0.83 (A)[88]; [h] 0.45 (C)[21]; σ_p^- = 0.65 (A)[88]; [i] σ_m = 0.34 and σ_p = 0.41 (DA).[129]

The group moments of the substituents increase in the series $CH=CHCF_3 < CF=CFCF_3 < C{\equiv}CCF_3 < CH=CHSO_3CF_3$, amounting to 2.79, 3.06, 3.38 and 4.93 D respectively[130,131]. As a result of the increase of the length of the dipole, these values exceed the group moments of CF_3 and SO_2CF_3 (2.51[132] and 4.32 D[104]). The dipole moments for the interaction with an amino-group in the *para*-position are 0.85, 0.94, and 2.71 D for the substituents $CH=CHCF_3$, $CH=CFCF_3$, and $CH=CHSO_2CF_3$ respectively and also exceed the μ_{int} for substituents without vinyl groups (μ_{int} = 0.49 and 1.46 D for CF_3 and SO_2CF_3).[130,131]

Despite the fact that the fluorine-containing unsaturated groups are electron-accepting in terms of their σ_m and σ_p constants, they are *ortho*, *para*-directing in electrophilic substitution reactions involving the aromatic ring[133], like other substituents of the type CH=CH–X, where X = NO_2, COOH, or $\overset{+}{N}(CH_3)_3$. Thus nitration of the compounds C_6H_5R results in a mixture of nitro-isomers having the following composition[133]:

R	*ortho*	*meta*	*para*
$CH=CH-CF_3$	46.5	3.5	50.0
$CF=CF-CF_3$	26.5	7.5	66.0
$CH=CH-SO_2CF_3$	27.0	15.0	58.0

Nitration of β-trifluoromethanesulphonylstyrene yields a considerable amount of the *meta*-isomer. This is because the SO_2CF_3 group, which has the highest σ_R constant, withdraws electrons from the *ortho*- and *para*-positions of the benzene ring and counteracts the formation

of the energetically favourable *ortho*- or *para*-quinonoid transition complex.

The pentafluorophenyl group, which we shall also consider in this section, should exhibit powerful electron-accepting properties. Indeed pentafluorophenol and pentafluorobenzoic acid exhibit much stronger acid properties (pK_a = 5.5 and 3.4)[129] than phenol and benzoic acid (pK_a = 9.98 and 4.2).[37] However, it has been found by ^{19}F NMR that the electron-accepting inductive effect of the C_6H_5 group is small and the conjugation effect is close to zero[129] The explanation is that the pentafluorobenzene ring in *m*- and *p*-$FC_6H_4C_6F_5$, which were used to determine the σ constants, is displaced from the plane by an appreciable angle. The electronic properties of the C_6Cl_5 group are very close to those of C_6F_5.

IX. SUBSTITUENTS WITH FLUORINE ATOMS LINKED TO HETEROATOMS (EF_n)

The σ constants for substituents of the type EF are listed in Table 10 in order of increasing Group number of the element. All groups of the type EF_n are powerful electron-accepting substituents in terms of both inductive and conjugation effects. The inductive effect of the EF_n group with the maximum number of fluorine atoms increases with the atomic number.

Table 10. σ constants for EF_n substituents (from ^{19}F NMR data).

Substituent		σ_m	σ_p	σ_I	σ_R
Group III	BF_2[2]	0.32	0.48	0.16	0.32
Group IV	CF_3[47,48]	0.44	0.49	0.39	0.10
	CCl_3[47,48]	0.30	0.31	0.29	0.02
	CBr_3[47,48]	0.26	0.27	0.25	0.02

Other data: [a]Calculated from δF;[134] [b]σ_m = 0.61(B), 0.63(A), and 0.61(P), σ_p = 0.68(B), 0.86(A), and 0.70(P), σ_I = 0.55(B), 0.56(A), and 0.53(P), and σ_R = 0.11(B), 0.27(A), and 0.12(P)[2,136].

Despite the fact that boron is less electronegative than carbon, under the influence of fluorine atoms the BF_2 group exhibits an electron-accepting inductive effect[2]. The higher σ_R constant of this substituent can be explained by the presence of a vacant *p* orbital in the boron atom to which the π electrons of the aromatic ring are displaced.

The σ_I constants gradually increase in the series of substituents with Group IV elements $CF_3 < SiF_3 < GeF_3$.[135] In the first two groups they are very close but on passing to GeF_3 the σ_I constant increases sharply. This is probably due to the increase of the polarity of the Ge–F bond with increase of the contribution of ionic structures of the type $ArGeF_2F^-$. The higher negative charges on the fluorine atoms in the SiF_3 and GeF_3 groups than in the CF_3 group are confirmed by the fact that the ^{19}F NMR signals for the first two groups are located in a higher field relative to trifluoromethylbenzene[135].

The σ constants of substituents with Group IV elements linked to chlorine and bromine atoms also increase on passing from carbon to silicon and germanium but their σ_I constants are lower than those of the fluorine analogues. This is because E–F bonds are the most polar[135]

The values of σ_R for the $SiHal_3$ and $GeHal_3$ groups greatly exceed the σ_R for the $CHal_3$ groups. This increase of the conjugation effect is accounted for by the involvement of the *d* orbitals of silicon and germanium in $(d-p)\pi$ conjugation. It is shown to the greatest extent in aryltrifluorosilanes and aryltrifluorogermanes where electron withdrawal by fluorine atoms promotes an increase of the $(d-p)\pi$ conjugation.

The dipole moment of phenyltrifluorosilane (2.77 D)[138] is higher than that of phenyltrichlorosilane (2.41 D)[138] and trifluoromethylbenzene (2.51 D)[132] which is consistent with the more marked electron-accepting properties of the SiF_3 group. It is also indicated by the increase of the dipole moment in the sequence $C_6H_5Si(CH_3)_2F <$ $C_6H_5Si(CH_3)F_2 < C_6H_5SiF_3$ (1.70, 2.55, and 2.72 D respectively)[139].

In electrophilic substitution reactions, for example in chlorination in the presence of $FeCl_3$, the $Si(CH_3)_3$ group is predominantly *ortho*, *para*-directing, activating the benzene ring. On gradual substitution of the methyl groups in $Si(CH_3)_3$ by fluorine atoms, the content of the *meta*-isomer in the reaction products increases, reaching 72% for the SiF_3 group, while the reactivity decreases by a factor of 1000 compared with the $Si(CH_3)_3$ group.[140,141]

The PF_2 group is a substituent with somewhat weaker electron-accepting properties than $P(CF_3)_2$.[85] The reason for this is the occurrence in the PF_2 group of an interaction between the *p* electrons of the fluorine atom and the *d* orbitals of the phosphorus, which acts in the opposite direction. In the PCl_2 substituent the $(p-d)\pi$ interaction between the chlorine and phosphorus atoms is weaker and therefore the electron-accepting inductive effect of the PCl_2 group is somewhat higher than that of the PF_2 group.

An increase of the number of fluorine atoms at the phosphorus atom leads to an increase of the constants σ_I and σ_R. The PF_4 group is one of the most powerful electron-accepting phosphorus-containing substituents. The pronounced electron-accepting effects of the PF_2 and PF_4 groups can be explained by the interaction of the π electrons of the aromatic ring with the vacant *d* orbitals of phosphorus, which become compact under the influence of the fluorine atoms and overlap fairly effectively with the *p* orbitals of the carbon atoms in the benzene ring[85]

Similar phenomena are observed in the SF_3 and SF_5 substituents. However, the conjugation effect of the SF_5 group proved to be smaller than that of SF_3 despite the higher number of fluorine atoms. Two *d* orbitals of the sulphur atom in the SF_5 group are involved in the formation of σ bonds and the remaining three vacant *d* orbitals, which have higher energies, are to a considerable degree saturated by the electrons of the five fluorine atoms and probably interact less effectively with the π electrons of the benzene ring. Only one *d* orbital of the SF_3 and PF_4 substituents is involved in the formation of σ bonds and

the remaining four vacant *d* orbitals interact fairly effectively both with fluorine atoms and with the π electrons of the aromatic ring[107].

Among all the substituents of the EF_n type investigated, only the SF_5 group is extremely resistant to hydrolysis. Nitration of phenylsulphur pentafluoride yields 80% of the *m*-nitro-isomer. The group moment of CF_5 is 3.44 D and μ_{int} for the interaction with an amino-group in the *para*-position is 0.6 D.[136]

Table 10 shows that groups with tervalent or quinquevalent iodine interact with an aromatic ring mainly via the inductive mechanism. The very high σ_I constants are probably due to the high polarity of the bonds between the iodine atom and halogen atoms or acyloxy groups. The ICl_2 and $I(OCOCF_3)_2$ groups, in which the contributions by the structures I^+Cl^- and $I^+(OCOCF_3)^-$ should be maximal, have the highest σ_I constants.

The accumulation of fluorine atoms at the iodine atom leads to an increase of the inductive effect and a considerable increase of the conjugation effect. The involvement of vacant *d* orbitals in substituents with a pentacovalent iodine atom in conjugation with the π electrons of the benzene ring is probably more effective than in the IF_2 and ICl_2 groups[137].

X. FLUORINE-CONTAINING SUBSTITUENTS WITH METAL ATOMS

Fluorine-containing substituents with a mercury atom have now been investigated (Table 11)[142]. The electronic properties of mercury-containing substituents are largely determined by their inductive effects. The constants σ_I of these substituents depend very markedly on the nature of the solvent. The lower the polarity of the solvent the higher the σ_I constant. The increase of the σ_I constants on passing from dichloroethane (DCE) to chloroform can probably be accounted for by the tendency of chloroform to form hydrogen bonds with electron-accepting groups linked to the mercury atom[143]. Mercury has vacant 6*p* orbitals and therefore solvents such as tetrahydrofuran (THF) may be coordinated to mercury atoms, which leads to a sharp decrease of the constants σ_I. For the same reason, the σ_R constants, determined by the interaction of the 6*p* orbitals of mercury with the ring π electrons, fall almost to zero in THF. The presence of electron-accepting substituents at the mercury atom (CN, CF_3, SCF_3) promotes the overlapping of the mercury 6*p* orbitals with the 2*p* electrons of the carbon atom in the benzene ring—$(6p - 2p)\pi$ interaction and an electron-accepting conjugation effect. The *p* electrons of the fluorine atom in the HgF substituent are displaced to the 6*p* orbitals of the mercury atom and probably further to the benzene ring, which leads to a weak electron-donating conjugation effect of this substituent.

Table 11. σ constants for substituents with a mercury atom (from ^{19}F NMR data).

Substituent	σ_I			σ_R		
	$CHCl_3$	DCE	THF	$CHCl_3$	DCE	THF
HgF[142]		0.34	0.18		−0.01	−0.01
HgCl[143]	0.31		0.17	0.04		0.01
$HgCF_3$[142]	0.27	0.16	0.06	0.05	0.03	0.01

$HgSCF_3$	0.37	0.32	0.18	0.05	0.04	0.02
$HgOCOCH_3$[143]	0.38		0.16	0.02		0.00
$HgOCOCF_3$[143]	0.48	0.37	0.22	0.04	0.03	0.00

XI. INDUCTIVE CONSTANTS σ^+ OF FLUORINE-CONTAINING SUBSTITUENTS IN ALIPHATIC COMPOUNDS

Taft's σ^+ constants[9], obtained mainly from the dissociation constants of aliphatic acids by means of the equation

$$\lg \frac{K}{K_0} = \rho^* \sigma^*$$

are used to characterise the inductive effect of substituents. Very exact correlations are achieved between the pK_a of R–COOH acids and the $\sigma^+(R)$ when two equations are employed[144]—for saturated acids [Eqn. (I)] and for unsaturated acids with an sp^2 hybridised carbon atom linked to the COOH group [Eqn. (II)]:

$$pK_a = -1.700\,\sigma^*(R) + 4.644\,, \qquad (I)$$

$$pK_a = -1.795\,\sigma^*(R) + 5.275\,. \qquad (II)$$

A similar equation [Eqn. (III)] has been found also for aliphatic alcohols of the type RCH_2OH:[144]

$$pK_a = -1.316\,\sigma^*(R) + 15.74\,. \qquad (III)$$

Table 12. Inductive constants σ^* for fluorine-containing substituents.

Substituent	σ^*	Substituent	σ^*
CH_3	0[9]	OCF_3	3.42[d]
F	3.10[10, 28]	SCF_3	2.74[d,e]
CH_2F	1.10[9, a]	$SOCF_3$	4.17[d,e]
CHF_2	2.05[9, b]	SO_2CF_3	4.55[d,e]
CF_3	2.60[10, 28, c]	NO_2	3.90[10]
CH_2CF_3	0.92[9]	$CH=CH_2$	0.57[144, f]
$CH_2CH_2CF_3$	0.32[9]	$CF=CH_2$	1.53[g]
$CH_2CH_2CH_2CF_3$	0.12[9]	$CH=CF_2$	1.17[g]
$CH(CF_3)_2$	1.34[51]	$CF=CF_2$	1.94[g,h]
$C(CF_3)_3$	1.48[51]	$CCl=CCl_2$	2.26[g]
CH_2SCF_3	0.99[108]	$CH=CHCF_3$	1.07[g]
CH_2SOCF_3	1.50[108]	$CH=CHCCl_3$	1.19[146]
$CH_2SO_2CF_3$	1.61[108]	C_6H_5	0.60[9]
$COCF_3$	3.70[145]	C_6F_5	1.10[147]
$N(CF_3)_2$	3.05[d]		

[a] 1.17;[144] [b] 2.00;[144] [c] 2.61;[147] [d] calculated from Eqn. (4); [e] calculated from Eqn. (V) for SCF_3, $SOCF_3$, and SO_2CF_3 groups (experimental values 2.77, 4.20, and 4.50); [f] 0.56[147] and 0.65;[148] [g] calculated from the pK_a for unsaturated acids[57] with the aid of Eqn. (II); [h] 1.73.[149]

The effects of substituents are additive in alcohols with the structure R′R″R‴COH, hydroxylamines R′R″R‴CNHOH, and oximes R′R″C=NOH.[145,146] However, on gradual substitution of the hydrogen atoms in the methyl group of acetic acid by fluorine or chlorine atoms or CF_3 groups, a "saturation effect" is observed instead of additivity[10,51].

The σ^* constants can also be calculated from Eqns. (IV) and (V):[10]

$$\sigma^* = 6.23\,\sigma_I \qquad \text{(IV)}$$

and

$$\sigma^*(R) = 2.8\,\sigma^*(CH_2R)\,. \qquad \text{(V)}$$

Table 12 lists the constants σ^* for fluorine-containing substituents found by the methods indicated. The σ^* for certain groups without fluorine are listed for comparison.

---o0o---

The data obtained for the σ constants made it possible to derive correlation equations whereby one can estimate the electronic properties of new substituents the σ constants of which are still unknown. For example, the σ constants of fluorine-containing substituents of the type XCF_3 and $XCHF_2$ may be determined from the σ constants of XCH_3 substituents[10,53,54,89]:

$$\sigma_I(XCF_3) = \sigma_I(XCH_3) + \begin{cases} 0.20 & (n=2) \\ 0.10 & (n=3) \\ 0.06 & (n=4) \end{cases};$$

$$\sigma_c(XCF_3) = \begin{cases} 0.88\,\sigma_R(XCH_3) + 0.19 & (n=2) \\ 1.05\,\sigma_R(XCH_3) + 0.08 & (n=3) \end{cases};$$

$$\sigma_R(XCHF_2) = 0.71\,\sigma_I(XCH_3) + 0.28$$

where X are various elements or groups of atoms and n is the number of bonds between the benzene ring and the CF_3 or CH_3 group.

The electronic properties of fluorine-containing substituents incorporating only 12 of the elements in the Periodic System have now been investigated. Nevertheless many relations useful to chemists have been discovered; these are already being used and will undoubtedly find wider applications in various branches of organic chemistry.

Oligomerisation of Acetylenes in the Presence of Transition Metal Compounds

L.P.Yur'eva

The literature data on acetylene cyclo-oligomerisation and polymerisation reactions in the presence of transition metal compounds are reviewed. Both catalytic reactions leading to the synthesis of benzene and cyclo-octatetraene derivatives and linear polymers and cyclo-oligomerisation reactions leading to the formation of organometallic compounds are considered. Modern ideas on the mechanism of acetylene cyclo-oligomerisation and polymerisation reactions are discussed in detail.
The bibliography includes 362 references.

CONTENTS

III. Synthesis of organometallic complexes by the cyclo-oligomerisation of acetylenes 50
IV. The mechanisms of acetylene cyclo-oligomerisation and polymerisation reactions in the presence of transition metal compounds 58

I. INTRODUCTION

A wide variety of inorganic and organometallic compounds (OMC) of transition metals give rise to the cyclo-oligomerisation and polymerisation of acetylenes. Catalytic reactions result in the formation of benzene and cyclo-octatetraene derivatives and also linear polymers. In many cases the cyclo-oligomerisation products are formed as π-complexes with the transition metal. Arene and cyclobutadiene complexes are produced in this way. The reaction of acetylenes with metal carbonyls is frequently accompanied by the insertion of the carbonyl group, which leads to the formation of cyclopentadienones, tropones, quinones, and their π-complexes. When acetylenes react with σ-derivatives of transition metals, the formation of simple cyclotrimerisation products may be accompanied by the formation of products involving the σ-group. The metal atom can also participate in the formation of a heterocycle with M–C bonds.

II. CATALYTIC OLIGOMERISATION REACTIONS OF ACETYLENES

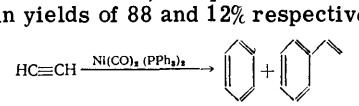
Since the discovery of the cyclo-oligomerisation of acetylenes in the presence of nickel compounds by Reppe in 1940, this reaction has become a convenient method for the synthesis of organic compounds which are otherwise difficult to obtain, such as cyclo-octatetraene, trivinylbenzene, and other benzene derivatives. An enormous number of original studies have been made on the cyclo-oligomerisation and polymerisation of acetylenes under the influence of transition metal compounds and many reviews have been written of which several may be recommended[1-6]. In the present review most attention has been devoted to studies in recent years.

The cyclotrimerisation of acetylenes is catalysed by transition metal compounds of various types, among which homogeneous and mixed metal carbonyls and catalysts of the Ziegler–Natta type are most frequently used. Certain organometallic compounds, salts, etc. also exhibit catalytic activity. The cyclotrimerisation of acetylenes is accompanied by linear polymerisation which becomes the main reaction under certain conditions.

The cyclotetramerisation of acetylenes takes place almost exclusively in the presence of nickel catalysts. Copper(I) salts catalyse the linear oligomerisation of acetylenes.

1. Catalysis by Metal Carbonyls

The first catalysts used in the cyclotrimerisation of acetylenes were carbonylphosphinenickel complexes[7-9]. When acetylene reacts with dicarbonyldi(triphenylphosphine)nickel in acetonitrile, the products are benzene and styrene (in yields of 88 and 12% respectively):



Detailed studies showed that monosubstituted acetylenes form a mixture of 1,2,4- and 1,3,5-trisubstituted benzenes[10-15]. The majority of disubstituted acetylenes (with the exception of but-2-yne-1,4-diol and its ethers[16] as well as monosubstituted acetylenes containing substituents such as t-butyl, COOH, CN, and halogens do not react.

Linear polymerisation of acetylenes occurs together with cyclotrimerisation. The preferential formation of benzene derivatives or linear polymers depends mainly on the nature of the substituent at the triple bond. More reactive monomers give rise mainly to aromatic products, while the yield of linear polymer increases for less reactive acetylenes.

The catalytic activity of the nickel atom and the nature of the product also depend on the nature of the ligand linked to the metal. For example, $Ni(CO)_3PPh_3$ is an effective catalyst of the polymerisation and cyclotrimerisation of acetylenes, while $Ni(CO)(PPh_3)_3$ and $Ni(PPh_3)_4$ are inactive in these reactions[7,17,18]. Reports have been published on catalysis by nickel tetracarbonyl[19-21]. $Ni(CO)_2[P(OPh)_3]_2$ promotes the aromatisation of acetylenes, while linear polymerisation takes place preferentially[17] in the presence of $Ni(CO)_2[P(CH_2CH_2CN)_3]_2$.

The cyclotrimerisation of tolane under the influence of iron, cobalt, manganese, nickel, molybdenum, and tungsten carbonyls has been investigated[20]. As shown below (see Section III), these metal carbonyls react with acetylenes, forming organometallic compounds of various types. Organic products are formed under more severe conditions. For example, tolane reacts with $Fe_3(CO)_{12}$ at 260–280°C with formation of hexaphenylbenzene (yield up to 75%); [20] at lower temperatures a number of organoiron compounds have been isolated[22,23]. Cyclo-octyne cyclotrimerises in the presence of $Fe(CO)_5$ even at room temperature[24].

Carbonyl derivatives of cobalt—$Co_2(CO)_8$, $MgCo_2(CO)_8$, $Hg[Co(CO)_4]_2$, and $RC_2R'Co_2(CO)_6$—exhibit a very high catalytic activity in the aromatisation of acetylenes. Both mono- and di-substituted acetylenes react. Acetylenes with various substituents give rise preferentially or exclusively to asymmetrically substituted benzenes[20,25]. When acted upon by $Hg[Co(CO)_4]_2$, substituted butadiynes are converted into a mixture of 1,2,4- and 1,3,5-trialkylnylbenzenes[26]. Non-conjugated terminal diacetylenes form, together with polymers, also dimers containing one aromatic ring and one triple bond[27]. The cyclotrimerisation of ferrocenylacetylenes in the presence of $Co_2(CO)_8$ has been described[28–30]. $[Co(CO)_3NO]$ has also been suggested as a catalyst[18,31].

Cobalt carbonyl and $RhM_4(CO)_{12}$ have been compared in the cyclotrimerisation of phenyl acetylene[32]. In catalysis by cobalt carbonyl 1,2,4-triphenylbenzene is formed 7–9 times faster than the symmetrical isomer; in catalysis by the rhodium compound the isomer ratio is 2:1.

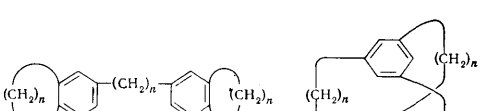
$[RhCl(CO)_2]_2$ has been used for the cyclotrimerisation of tolane[33].

Cyclotrimerisation also takes place in the presence of molybdenum and tungsten hexacarbonyls[20] and triacetonitriletricarbonyl[34] and arenetricarbonyl complexes of chromium and molybdenum[35].

2. Ziegler–Natta Catalysts

Acetylenes undergo linear polymerisation[36–38] and cyclotrimerisation[39–47] in the presence of a catalytic system comprising titanium halides or alkoxides and alkylaluminium derivatives. The R_3Al–$TiCl_4$ systems (R = ethyl or t-butyl) are usually employed to synthesise benzenes. The yields of the corresponding benzene derivatives and linear polymers depends markedly on the Ti:Al ratio[48,49]. Monosubstituted acetylenes do not decompose the catalyst but cyclotrimerise with formation of a mixture of 1,2,4- and 1,3,5-trisubstituted benzenes[28,50].

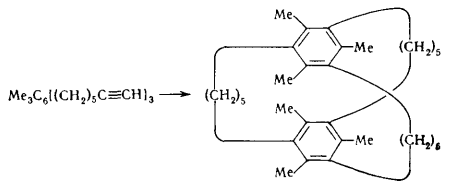
The reactions of conjugated and non-conjugated diacetylenes and triacetylenes have been investigated[27,51–55]. Hexa-2,4-diyne forms trimethyltripropynylbenzene (5%) together with polymers. Non-conjugated alkadiynes $HC{\equiv}C(CH_2)_nC{\equiv}CH$ produce, together with polymers, two types of trimers: (I) (in yields up to 13% for $n = 2$) and traces (less than 1%) of compound (II) containing two benzene rings linked by three polymethylene chains:



(I)

(II)

Cage compounds have been obtained in yields up to 50% from aromatic triynes[51]:



Acetylenes trimerise and polymerise in the presence of trialkylaluminium and vanadium[39,56–60] or cobalt[61,62] derivatives. The $i\text{-}Bu_3Al$–NiX_2 [63–65] and $i\text{-}Bu_3Al$–iron(III) naphthenate[66] systems polymerise acetylene. Et_2Zn–$Cr(OBu\text{-}t)_3$ induces the dimerisation of monosubstituted acetylenes to vinylacetylene derivatives[67]. The replacement of diethylzinc by triethylaluminium leads to the formation of alkylbenzenes.

It has been shown for the R_3Al–$VOCl_3$ and $i\text{-}Bu_3Al$–$TiCl_4$ catalytic systems that the activity of the catalyst is related to the formation of a reduced form of the metal[56,68].

3. Catalysis by Organometallic Compounds

Dicyclopentadienyl derivatives of titanium[69] and vanadium[70] polymerise acetylene. Many monosubstituted acetylenes give rise to the corresponding benzene derivatives in the presence of vanadocene and phenylacetylene produces a linear oligomer. A catalytic effect of tricyclopentadienyllanthanides in the cyclotrimerisation of certain acetylenes has been mentioned[71].

Acetylenes cyclotrimerise and copolymerise with olefins in the presence of di(cyclo-octatetraene)iron[72,73]. The linear polymerisation and cyclotrimerisation of acetylenes is catalysed by cyclo-octa-1,5-dienenickel halides[75] and π-allyl complexes of palladium and nickel[76–79].

Both catalytic and stoichiometric cyclisation and polymerisation reactions of acetylenes take place in the presence of diacrylonitrilenickel. Thus acetylene produces cyanoheptatriene, benzene, and cyclo-octatetraene (COT)[80,81]. Triphenylphosphine suppresses the formation of COT and the synthesis of benzene becomes a catalytic process. In the presence of an excess of acrylonitrile, the main reaction product is cyanoheptatriene (see also Cairns et al.[82]). Disubstituted acetylenes give rise to tetrasubstituted benzonitriles together with hexasubstituted benzenes[80,83]. Similarly hexaphenylbenzene and tetraphenylbenzaldehyde have been obtained from tolane and diacroleinnickel.

When acted upon by diacrylonitrilenickel, but-2-yne[20] and hexafluorobut-2-yne (HFB)[84] undergo linear polymerisation together with cyclotrimerisation. Propargyl alcohol, phenylpropiolaldehyde, propiolic and acetylenedicarboxylic acid esters, and phenylacetylene form polymers[80].

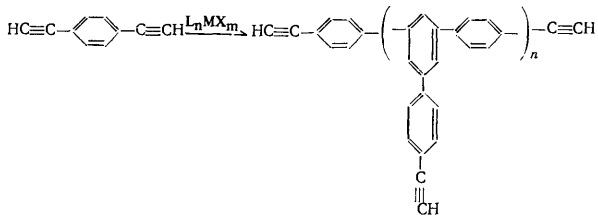
Dimesitylcobalt catalyses the trimerisation of but-2-yne[85]. The cyclisation of acetylenes in the presence of σ-aryl and σ-alkyl derivatives of other metals is a stoichiometric reaction and will be considered below (see Section III). Platinum and nickel σ-acetylides $(Ph_3P)_2M(C{\equiv}CPh)_2$ polymerise phenylacetylene[86,87].

2. Catalysis by Phosphine and Phosphite Complexes of Cobalt Subgroup Metals

Certain rhodium and iridium complexes catalyse the cyclotrimerisation and polymerisation of acetylenes[88].

Thus $RhCl(PPh_3)_3$ causes the polymerisation of HFB [89]. Dimers have been obtained from dialkylethynylmethanols [90]. Phenylacetylene produces a polymer together with the dimer [90-92]. Certain disubstituted acetylenes give rise to the corresponding benzene derivatives [93]. Rhodium and iridium complexes $RhH(CO)(PPh_3)_3$, $IrH(CO)_2(PPh_3)_2$, [94] and certain others [89,90] catalyse the cyclotrimerisation of alk-1-ynes.

Cobalt complexes, for example $CoBr[P(OEt)_3]_4$, have been used for the polycyclotrimerisation of aromatic diacetylenes [95-98]:



Complexes of zerovalent nickel with phosphines and certain other ligands of a similar type are active in the copolymerisation of acetylenes with butadiene [99].

5. Catalysis by Salts of Transition Metals and Their Complexes

Palladium(II) chloride and its benzonitrile complex $(PhCN)_2PdCl_2$ (BNP) [100-103], nickel compounds $(R_3P)_2NiX_2$ [60, 87,104], and $K_4Ni_2(CN)_6$ [105], and rhenium, niobium, and tantalum pentahalides and their adducts with NaX, KX, $POCl_3$, and amines [106-108] catalyse the cyclotrimerisation of disubstituted acetylenes.

Copper(I) salts catalyse the linear polymerisation of acetylenes. When acetylene is passed into an acid solution of CuCl in the presence of NH_4Cl, vinylacetylene, divinylacetylene, and polymers are formed [109,110]. These reactions have been reviewed in detail in monographs [111-113].

6. Other Catalysts

A number of catalytic systems comprising Group VIII transition metal salts and a hydride reducing agent, for example $(Ph_3P)_2NiCl_2$–$NaBH_4$), have been suggested for acetylene cyclotrimerisation and linear polymerisation reactions [18,92,114-118]. Acetylenes cyclotrimerise in the presence of metal oxide catalysts (chromoaluminosilicate, alumina–nickel oxide–molybdenum oxide, and others [119]). Various acetylenes are converted into dimers, benzene derivatives, and higher polymers in the presence of palladium on charcoal [120].

7. Cyclotetramerisation of Acetylenes

The cyclotetramerisation of acetylenes is catalysed almost exclusively by nickel compounds. Among compounds with other metals, $Zn[Co(CO)_4]_2$ is known; acetylene gives rise to about 3% of COT together with benzene [121].

The interaction of acetylene with bivalent nickel compounds (cyanide, acetylacetonate) takes place at temperatures in the range 80–120°C and pressures between 15 and 25 atm. [8,122] The yields of COT amount to 70 to 90%, in addition up to 15% of benzene is obtained as well as polymers and a nickel-containing product resembling cuprene. Insignificant amounts of styrene, 1-phenylbuta-1,3-diene, and vinylcyclo-octatetraene as well as traces of azulene and naphthalene are produced [123-128]. Under analogous conditions, substituted acetylenes form linear polymers and benzene derivatives [129]. In the mixed cyclotetramerisation of acetylene with mono- and di-substituted acetylenes, a number of mono- and di-substituted cyclo-octatetraenes were obtained [130-134].

Acetylenic alcohols, for examples 2-methylbut-2-yn-3-ol, form the corresponding isomeric tetrasubstituted cyclo-octatetraenes in the presence of the following catalytic systems: nickel tetracarbonyl and di(cyclo-octa-diene) nickel; nickel cyanide, acetylacetonate, and ethoxide; $NiCl_2$ – $NaBH_4$. [135] When acted upon by di-(π-allyl)- nickel propargyl alcohol and 2-methylbut-3-yn-2-ol are converted into linear dimers and cyclo-octatetraene derivatives [136]. The addition of phosphine suppresses the formation of the latter. The formation of small amounts of tetrasubstituted cyclo-octatetranes was observed also when $Ni(PX_3)_4$(X = = Cl or F) were allowed to act on propiolic acid esters [137]; in this case the main reaction products are benzene derivatives.

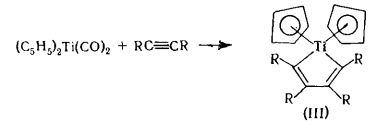
III. SYNTHESIS OF ORGANOMETALLIC COMPLEXES BY THE CYCLO-OLIGOMERISATION OF ACETYLENES

When acetylenes were allowed to react with various transition metal compounds, cyclo-oligomerisation resulted in the formation of all types of π-complexes known at present as well as compounds with an M–C σ-bond. The synthesis of organometallic compounds from acetylenes has been described in a number of reviews (see, for example, Refs. 2, 4, 5, and 138–142).

1. Reactions of Acetylenes with Metal Carbonyls

The reactions of acetylenes with the carbonyls of certain metals (iron, nickel) were investigated for the first time by Reppe [8,143], who isolated a number of organometallic compounds and organic cyclo-oligomerisation and carbonylation products.

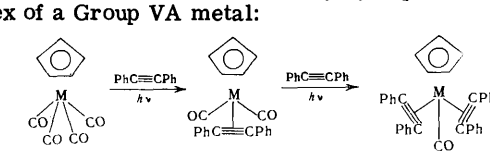
Acetylenes cyclo-oligomerise in the presence of carbonyl-cyclopentadienyl complexes of Group IVA and VA metals. The two carbonyl groups of dicarbonyldicyclopentadienyltitanium are displaced by phenylacetylene and tolane with dimerisation of acetylene and the inclusion of the metal atom in the ring [144]:



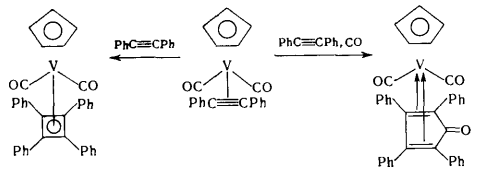
(III)

Acetylenic π-complexes and also π-complexes with other organic ligands and benzene and cyclopentadienone derivatives have been obtained from tolane and tetracarbonylcyclopentadienyl complexes of vanadium [145], niobium [146], and tantalum [147]. It was possible to trace the formation of cyclobutadiene, cyclopentadienone, and benzene structures in these reactions.

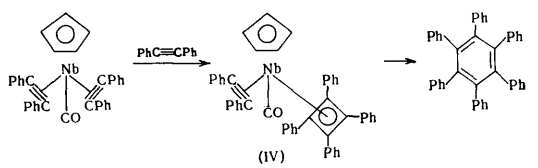
Two acetylene molecules can be introduced successfully into the molecule of the tetracarbonylcyclopentadienyl complex of a Group VA metal:



The ditolane complex of vanadium decomposes fairly readily with formation of tetracyclone. On heating, the monotolane complex combines with another tolane molecule with formation of a cyclobutadiene complex. In the presence of carbon monoxide, a tetracyclone complex is formed together with the cyclobutadiene complex[148]:



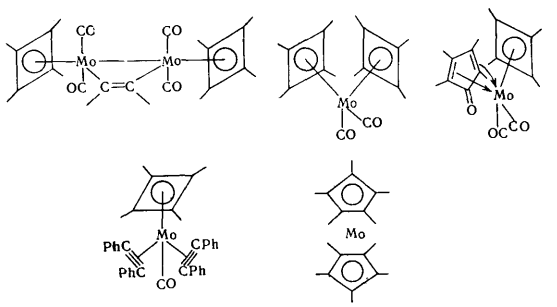
The ditolane complex of niobium combines with a third tolane molecule to form a mixed diphenylacetylene–tetraphenylcyclobutadiene complex (IV).[149] On heating, the complex decomposes with formation of hexaphenylbenzene:



The ditolane complex of tantalum undergoes similar reactions[147]. The structures of the niobium[149–153] and vanadium[154] complexes have been confirmed by X-ray diffraction.

Thus the formation of cyclic structures is preceded by the incorporation in the acetylene complex of a second and third acetylene molecule. The formation of the cyclopentadienone fragment is due to the insertion of a carbonyl group linked to the metal or of the carbon monoxide introduced into the system, which probably is also first coordinated to the metal. Hexaphenylbenzene is presumably formed as a result of an intramolecular interaction of the coordinated acetylene and cyclobutadiene. The parallel orientation of the triple bond of the acetylene ligand in relation to one of the sides of the cyclobutadiene ligand in complex (IV), which was established by X-ray diffraction analysis, suggested that the formation of hexaphenylbenzene proceeds via an intermediate complex with Dewar benzene.

The following complexes have been obtained from tolane and molybdenum carbonyls [$Mo(CO)_6$ and (diglyme)$Mo(CO)_3$]:

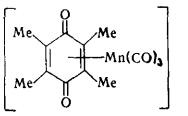


as well as tetracyclone and hexaphenylbenzene[155].

The reaction of triacetonitriletricarbonylchromium with tolane gives rise to a cyclopentadienone complex of chromium, which rapidly decomposes with formation of tetracyclone[34].

Carbonyl derivatives of manganese, $Mn_2(CO)_{10}$ or $CH_3Mn(CO)_5$, react with acetylene at an elevated pressure and temperature to form[156–158]

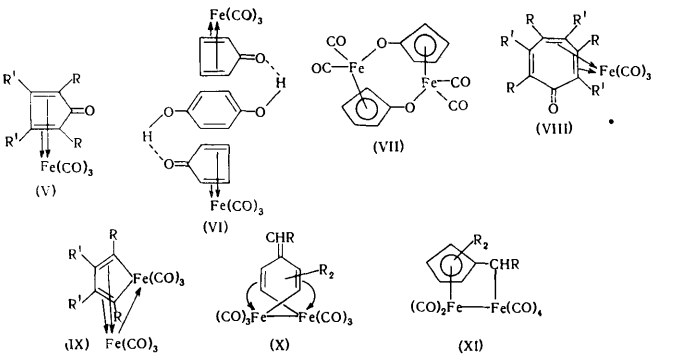
The reaction of but-2-yne with $[Mn(CO)_5]^-$ in sunlight leads to the formation of a mixture of products, one of which is duroquinone[159]. It is presumably formed from the intermediate duroquinone complex



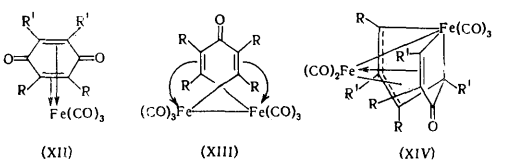
The most typical products of the reactions of acetylenes with iron carbonyls are organometallic complexes with new ligands formed as a result of the cyclo-oligomerisation of acetylenes with participation of the carbonyl group and/or the iron atom. Complexes of certain types are produced only from acetylene or its monosubstituted derivatives, while others are formed from disubstituted acetylenes.

The reaction of acetylene with $Fe(CO)_5$[8,143] or $Fe_3(CO)_{12}$ and $Fe_2(CO)_9$[138,160–164] yielded complexes (see Scheme 1) with cyclopentadienone [(V)–(VII)] and tropone (VIII) as ligands as well as metal-containing cyclic products [(IX)–XI) (R and R′ = H)].

Scheme 1



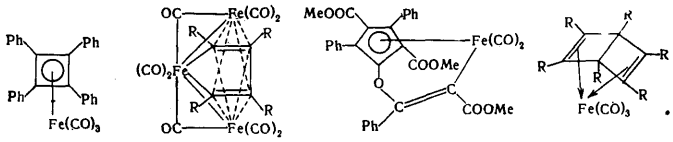
The formation of quinone complexes (XII)[24,165] and also complexes of types (XIII)[22,166] and (XIV)[138] is characteristic of dialkylacetylenes:



Cyclobutadiene (XV) and cyclopentadienone (V) complexes as well as di- and tri-nuclear metal-containing cyclic complexes (IX), (XIII), and (XVI) have been obtained from diarylacetylenes[22,23,167–173]. Complexes of types (V), (IX), (XIII), and (XVI) have been synthesised from diferrocenylacetylene[30].

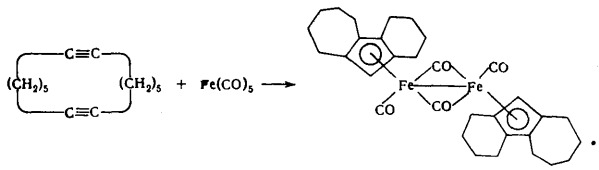
The complex (XVII) has been synthesised from ethyl phenylpropiolate and iron nonacarbonyl[174]. The structure of a complex (XVIII) with a hexasubstituted Dewar benzene as the ligand has been attributed to the product of the

reaction of the dimethyl ester of acetylenedicarboxylic acid with $Fe_2(CO)_9$ (Avram et al.[175]):

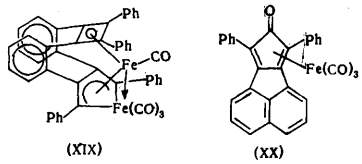


(XV) (XVI) (XVII) (XVIII)

Fluoroacetylenes form complexes analogous to (V) and (IX).[84,176-178] Only one of the two triple bonds is involved in the reaction of diphenylbutadiyne with iron carbonyls and the products are isomeric complexes of types (V), (IX), etc. with phenyl- and phenylethynyl-substituted ligands[26]. Both triple bonds of non-conjugated diacetylenes are involved in the reaction, for example[179]:



The reaction of *o*-di(phenylethynyl)benzene with $Fe(CO)_5$ and $Fe_3(CO)_{12}$ gives rise to a number of complexes[180], one of which has the structure (XIX)[181]. Acecycloneiron tricarbonyl (XX) has been obtained from 1,8-di(phenylethynyl)naphthalene and $Fe(CO)_5$ (Bossenbrock and Shechter[182]):



(XIX) (XX)

Many of the organoiron products described can be obtained by the reaction of acetylenic π-complexes of iron $RC_2RFe(CO)_4$ and $RC_2RFe_2(CO)_7$ with acetylenes[138].

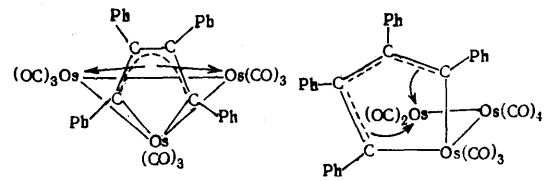
The structures of iron complexes were established on the basis of infrared and NMR spectroscopic data and chemical properties and in many cases also by specific synthesis. X-Ray diffraction structural studies have been made on the following complexes: (V),[183] (VIII),[184,185] (IX),[186] (X),[187,188] (XI),[188,189] (XIII),[190,191] (XIV),[192] (XV),[193] (XVI),[194] (XVII),[174], and (XIX).[181]

The formation of the ferracyclopentadiene structure was traced in the reaction of tolane with tri-iron dodecacarbonyl. Low yields of polynuclear complexes containing one[195] and two[22,194] acetylenic ligands were isolated from the reaction products under mild conditions. Determination of the structures of these intermediates by X-ray diffraction made it possible to deduce the mode of the gradual transformation of the acetylenic ligand into a metal-containing ring (see Scheme 2). In the first reaction stage carbonyl groups in $Fe_3(CO)_{12}$ are replaced by an acetylene molecule as in compound (XXI). Further substitution of CO results in the formation of a violet complex (XXII) which contains two independently coordinated acetylenic ligands. The violet complex then rearranges to the black isomer (XVI) containing the ferracyclopentadiene fragment. In the last stage one of the iron atoms is eliminated with formation of the stable dinuclear complex (XIX) with a metal-containing ring.

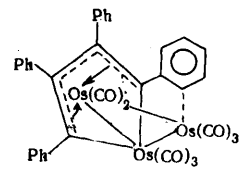
When phenylacetylene reacts with iron carbonyls, the complexes (V), (VIII), (IX), (XI), and (XIV) are formed, while the product of the reaction of *p*-bromophenylacetylene and $Fe_3(CO)_{12}$ is the complex (X).[23,138,196]

A characteristic feature of the behaviour of ruthenium and osmium dodecacarbonyls is a higher stability of the metal-containing cluster in the reaction with acetylenes compared with the corresponding iron carbonyl. After refluxing tolane with $Ru_3(CO)_{12}$ in petroleum ether, complexes analogous to the corresponding iron complexes (V), (IX), and (XVI) were isolated[197-202]. Under the reaction conditions, the dimethyl ester of acetylenedicarboxylic acid trimerises quantitatively to $C_6(COOCH_3)_6$.

The reaction of $Os_3(CO)_{12}$ with but-2-yne involves the formation of the osmium analogues (V) and (IX)[203]. Tolane gives rise to $(Ph_2C_2)_2Os_3(CO)_9$ (XXIII) which may be represented by the alternative structures (XIIIa) and (XIIIb)[204] and the complex $(Ph_2C_2)_2Os_3(CO)_8$,[204,205] which has the structure (XXIV) according to X-ray diffraction analysis[206]:



(XXIIIa) (XXIIIb)

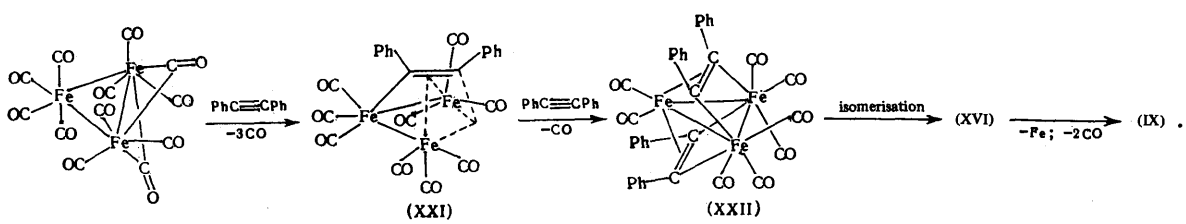


(XXXIV)

When carbon monoxide is allowed to act on (XXIII), the product is an analogue of the complex (IX).

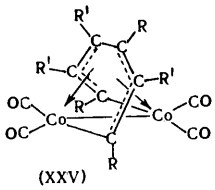
The cobalt carbonyls $Co_2(CO)_8$ and $Co_4(CO)_{12}$ react with acetylenes to form acetylenic π-complexes $RC_2R'CO_2(CO)_6$ and $RC_2R'CO_4(CO)_{10}$ and their cyclo-oligomerisation products—the complexes (XXV) and (XXVI), as well as

Scheme 2

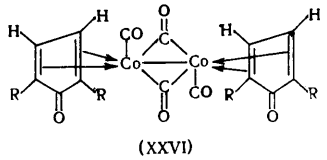


(XXI) (XXII)

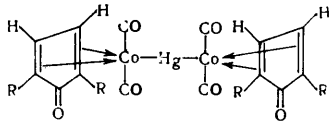
the corresponding cyclopentadienones and benzenes [25,176,207-211]. The structure (XXV) was established by X-ray diffraction [212]:



(XXV)



(XXVI)

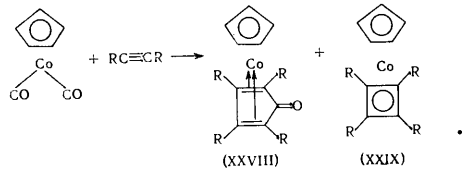


(XXVII)

Mercury tetracarbonylcobaltate reacts with disubstituted acetylenes to form acetylenic complexes, while the reaction involving monosubstituted acetylenes proceeds without the elimination of mercury and with formation of the cyclopentadienone complexes (XXVII) [25,138,213]. The complexes $R_2C_4H_2Co_4Hg_2(CO)_{12}$, which probably contain a cyclobutadiene ligand, have been obtained from certain monosubstituted acetylenes.

When acetylenehexacarbonyldicobalt reacts with acetylenes different from that coordinated to the metal atom, isomers of substituted benzenes and cyclopentadienones, with partial incorporation of the initial acetylene bound in the complex, are produced [25,214-217].

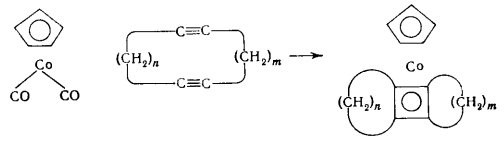
Disubstituted acetylenes dimerise in the presence of π-cyclopentadienylcobalt dicarbonyl with formation of cyclopentadienone (XXVIII) and cyclobutadiene (XXIX) complexes as well as hexa-substituted benzenes and tetrasubstituted cyclopentadienones [218,219]:



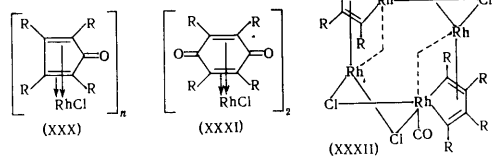
(XXVIII) (XXIX)

X-Ray diffraction structural analysis of compound (XXVIII) has been carried out [220,221].

Depending on R, the reaction involves the formation of complexes (XXVIII) [84,159,222,223] or (XXIX) [224] only. Macrocyclic alkadiynes undergo transannular cyclisation [225,226]:

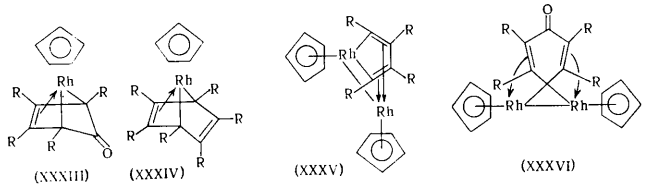


The reaction of disubstituted acetylenes with chlorodicarbonylrhodium leads to the formation, depending on the acetylene, of cyclopentadienones and quinones and their π-complexes (XXX) and (XXXI), as well as complexes with a metal-containing cyclic fragment (XXXII) [33,222,227-229] [the structure (XXXII) was established by X-ray diffraction [230]] and hexasubstituted benzenes:



(XXX) (XXXI) (XXXII)

The reaction of π-cyclopentadienylrhodium carbonyl with HFB leads to the complexes (XXXIII) and (XXXIV) [222] as well as metal-containing cyclic complexes (XXXV) and (XXXVI) [231]. The structure (XXXIV) was established by X-ray diffraction [232]:



(XXXIII) (XXXIV) (XXXV) (XXXVI)

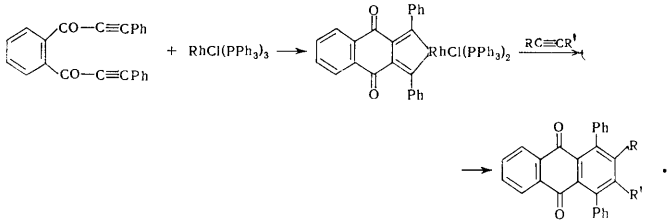
The complexes (XXXIII), (XXXIV), and (XXXVI) were obtained by treating the acetylene complex $[C_5H_5Rh(CO)]_2.(CF_3C_2CF_3)$ with HFB.

Di(pentafluorophenyl)acetylene yielded the pentafluorophenyl analogues of compounds (XXXIII) and (XXXV) and also hexa(pentafluorophenyl)benzene [223,233,234]. The complexes (XXXIV) have also been obtained from $(CH_3)_5C_5M(OAc)_2H_2O$ (M = Rh or Ir) and the dimethyl ester of acetylenedicarboxylic acid in the presence of hydrogen [235].

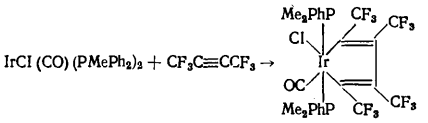
The reaction of $Ni(CO)_4$ with tolane [19] or cyclo-octyne [129] yields the corresponding cyclopentadienones and their nickel complexes.

2. Reactions of Acetylenes with Phosphine, Arsine, and Stibine Metal Complexes

As for the carbonyls, the substitution of phosphine and other similar ligands in the reaction with acetylene is frequently accompanied by the formation of cyclo-oligomerisation products. Rhodium and iridium form metal-containing cyclic products under these conditions. For example, the reactions of $RhCl(MPh_3)_3$ (M = Sb or As) with HFB [236-238] and of $RhCl(PPh_3)_3$ with *o*-di(arylpropionyl)benzene and 2,3-di(phenylpropionyl)naphthalene [239-243] yielded rhodiacyclopentadiene complexes, which can subsequently react with acetylenes whereby they are converted into benzene derivatives:



Similar reactions have been achieved for iridium complexes[244]:



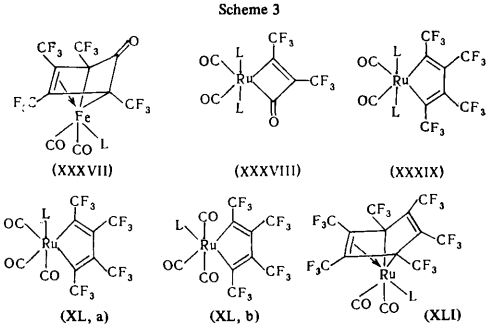
The reactions proceed via intermediate acetylene π-complexes, which were isolated when the reaction was carried out under milder conditions.

The cyclotrimerisation of HFB in the presence of tetra-(dimethylphenylarsine)nickel with formation of $(PhMe_2As)_2NiC_6(CF_3)_6$ has been described[245].

3. Reactions of Acetylenes with Carbonylphosphine and Phosphitocarbonyl Complexes of Group (VIII) Metals

The photochemical reaction of HFB with complexes of metals in the iron triad of the type *trans*-$M(CO)_3L_2$, where L = tertiary phosphine or phosphite, has been investigated[246]. The nature of the reaction product depends primarily on the metal and to a lesser extent on the reaction conditions. The reaction of iron with an excess of HFB yielded the complexes (XXXVII). The ruthenium complexes react differently depending on the reaction conditions. The complex (XXXVIII) was obtained from equimolar amounts of $Ru(CO)_3[P(OMe)_3]_2$ and HFB. The complexes (XXXIX) and (XL, a and b) are formed in the presence of HFB. When the reaction is carried out with more prolonged irradiation, the product is the complex (XLI) (see Scheme 3).

Scheme 3



The osmium complexes do not catalyse the cyclo-oligomerisation of HFB.

4. The Reactions of Acetylenes with Certain Transition Metal π-Complexes

At the instant of its formation dicyclopentadienyltitanium reacts with tolane[247] or propyne[248], forming compound (III). Together with a small amount of hexaphenylbenzene, the same complex is formed on thermal decomposition of di-(π-cyclopentadienyl)-σ-diphenyltitanium in the presence of tolane[249].

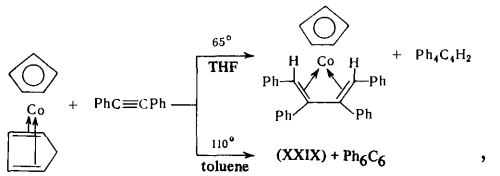
The rhodium complex of norbornadiene (NBD) reacts with an excess of but-2-yne to form an arene complex[250]:

$$[Rh(NBD)]^+ + MeC{\equiv}CMe \rightarrow [Rh(C_6Me_6)(NBD)]^+ .$$

In many instances acetylene substitutes an organic π-ligand, two or three acetylene molecules forming a new ligand.

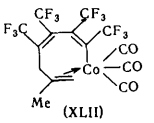
Thus the complexes (XXIX) have been obtained from cobaltocene and disubstituted acetylenes[84,251] including macrocyclic alkadiynes[225]. The complexes (XXIX) are formed also from cyclopentadienylcyclo-octatetraenecobalt[252,253] or cyclopentadienylcyclo-octa-1,5-dienecobalt[251,252].

Tolane reacts with π-cyclopentadienyl-π-cyclopentadienecobalt via the mechanism[253]

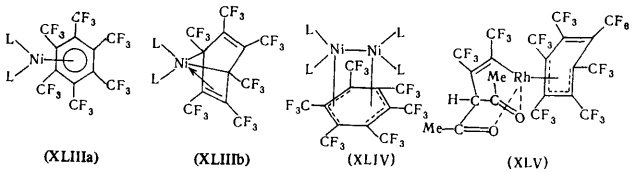


while its reaction with cyclo-octatraeneiron tricarbonyl results in the formation of the complexes (IX) and (XV)[253-255].

Together with polymerisation the reaction of π-2-methylallylcobalt tricarbonyl with HFB leads to the formation of the compound (XLII) produced by the insertion of two acetylene molecules in the cobalt-allyl bond[256]:

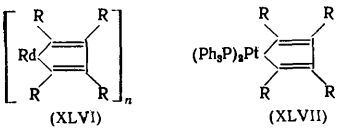


Di(cyclo-octa-1,5-diene)nickel reacts with HFB to form a mononuclear complex (XLIIIa) or (XLIIIb) and a dinuclear complex (XLIV) (L_2 = 1,5-C_8H_{12})[245]:



The displacement of cyclo-octa-1,5-diene by hexafluorobut-2-yne from acetylacetonatocyclo-octadienerhodium has been described[257]. According to X-ray diffraction data, the product has the structure (XLV)[258].

The action of certain acetylenes on dibenzylideneacetone complexes M(DBA)$_2$ (M = Pd or Pt) and Pt(DBA)$_3$ has been investigated[259,260]†. The product of the reaction of the palladium complex with the dimethyl ester of acetylenedicarboxylic acid is palladiacyclopentadiene (XLVI), which gives rise to hexasubstituted benzenes on heating with acetylenes R'S≡CR'. The reaction is catalytic for R' = COOMe:



The structure (XLVI) was established on the basis of the chemical behaviour and also spectroscopic data. The association of individual molecules is due to the involvement of the ester group in coordination to the metal of the type  Pd. Platinum complexes react more slowly with the dimethyl ester of acetylenedicarboxylic acid than the palladium analogue. The metal-containing

†In complexes of this type the metal–ligand bond is formed by the π-electron system of the carbonyl group.

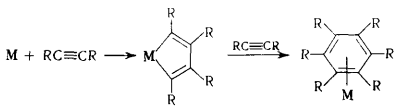
cyclic product was isolated in the form of a triphenylphosphine derivative (XLVII). Hexamethyl mellitate was also isolated from the reaction products, which is evidence of the greater ease of conversion of the metallocyclopentadiene into benzene in the case of platinum.

5. Cyclo-oligomerisation Reactions of Acetylenes Involving σ-Derivatives of Transition Metals

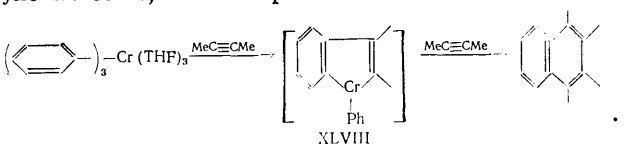
When triphenylchromium tristetrahydrofuranate reacts with but-2-yne, a number of organic and organochromium products are formed[261-264]. The reaction mode depends on the proportions of the reactants. Thus when less than 4 moles of the butyne per mole of Ph_3Cr are employed, the products are 1,2,3,4-tetramethylnaphthalene and its π-complex. An excess of the acetylene promotes the formation of hexamethylbenzene. When the reactant ratio is $Ph_3Cr : C_4H_6 = 1 : 6$, 40% of tetramethylnaphthalene 55% of hexamethylbenzene, and small amounts of the corresponding π-complexes are produced.

The authors believe that the reaction mechanism consists in the stepwise substitution of THF molecules in $Ph_3Cr(THF)_3$ by acetylene. The coordinated acetylene molecules cyclise with formation of aromatic systems and the corresponding π-complexes. The effect of the reactant ratio on the composition of the reaction products is evidence that the displacement of THF by acetylene takes place in steps. The phenyl group linked by a σ bond to chromium can also participate in the intramolecular reaction, which results in the formation of tetramethylnaphthalene.

The possible formation of a five-membered metal-containing ring, which then combines with a third acetylene molecule and is converted into a π-bonded benzene ring, has been suggested[265]:



In order to account for the formation of tetraphenylnaphthalene, a mechanism involving stages in which the butyne is inserted in the phenyl–chromium bond with formation of styrylchromium, its cyclisation to "benzochromole" (XLVIII), and the reaction of benzochromol with a second butyne molecule, has been put forward[266]:



XLVIII

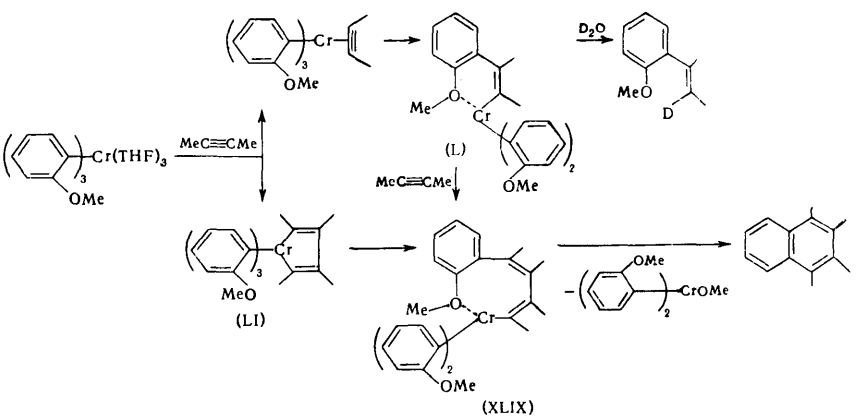
However, objections have been raised to the formation of (XLVIII) as a precursor of tetramethylnaphthalene[267]. When but-2-yne reacts with tri-(2-methoxyphenyl)chromium, 1,2,3,4-tetramethylnaphthalene is formed together with *cis*-2-(2-methoxyphenyl)but-2-yne and 2,3-di-(2-methoxyphenyl)but-2-ene. Since the elimination of the methoxy-group from the *o*-anisyl substituent is observed only in the formation of tetramethylnaphthalene, the authors believe that the *o*-anisylbutadienechromium compound (XLIX) is more likely to be its precursor. The chromium complex can be formed in its turn as a result of the reaction of the σ-vinyl derivative of chromium (L) with a second but-2-yne molecule or as a result of the transfer of the aryl group within the metal-containing ring (LI) formed from two acetylene molecules (see Scheme 4).

Tolane does not form arene complexes with triphenylchromium, the only products being hexaphenylbenzene, tetraphenylnaphthalene, 9,10-diphenylphenanthrene, terphenyl, and tetraphenylethylene[262,268]. Acetylene and monosubstituted acetylenes polymerise. *trans*-Isomers of 1,6-diphenylbuta-1,3-diene and also biphenyl and the conjugated *trans*-polyene $Ph-(-CH=CH-)_n-Ph$ were obtained from acetylene at −70°C.[269] HFB forms a linear polymer[84].

Various aryl derivatives of chromium can be used as cyclising agents[262,270,271]. If the *ortho*-positions are blocked, for example in trimesitylchromium, the only reaction product is a hexa-substituted benzene.

Like the phenyl group, an alkyl group linked by a σ bond to chromium can also participate in the formation of a new ring[263,265,272]. Thus the reaction of tolane with triethylchromium tetrahydrofuranate leads to the formation of 1,2,3,4-tetraphenylbenzene in addition to hexaphenylbenzene, the role of the chromium atom consisting not only in the elimination of the hydrogen atom from the

Scheme 4

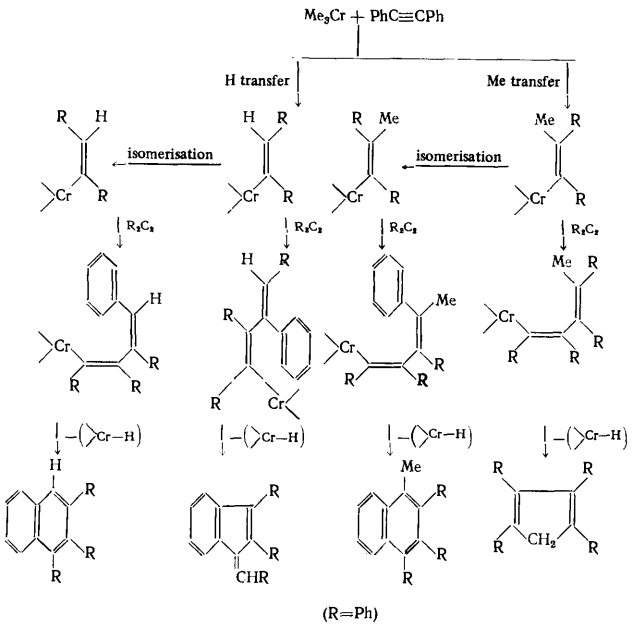


(XLIX)

CH_3 group of the ethyl substituent but also in the dehydrogenation of the resulting dihydrotetraphenylbenzene to an aromatic product. Trimethylchromium gives rise to phenyl derivatives of cyclopentadiene, benzene, and naphthalene [265 269 272-275].

The formation of certain reaction products may be interpreted in terms of metal hydride elimination from isomeric σ-butadienyl derivatives of chromium in accordance with Scheme 5 (Sneeden and Zeiss [276]):

Scheme 5



Tri-n-butylchromium forms with oct-4-yne and but-2-yne a complex mixture of products, from which the corresponding hexa-alkylbenzenes were isolated [270]. Trivinyl chromium [277] and triallylchromium [278] react with but-2-yne to give, together with hexamethylbenzene, condensation products involving σ-groups. Tri-β-styrylchromium forms only hexasubstituted benzenes [279].

The cyclisation of butyne to di(hexamethylbenzene)-chromium on reaction with a mixture of chromyl chloride and triethylaluminium has been described [280, 281]. The methyl derivative of chromium Li_3CrMe_6 does not react with phenylacetylene [273]. The cyclotrimerisation of disubstituted acetylenes in the presence of σ-derivatives of bivalent chromium has been described [273,278,282].

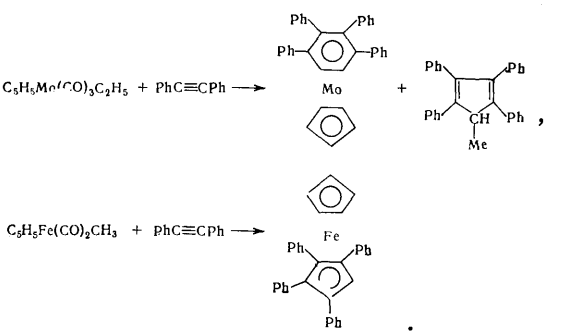
σ-Derivatives of bivalent manganese and cobalt (diphenylmanganese and dimesitylcobalt) cyclotrimerise but-2-yne with formation of hexamethylbenzene and arene π-complexes [283,284]. Naphthalene derivatives are not formed in this case. The π-complex obtained from Ph_2Mn and but-2-yne has the structure of benzene(hexamethylbenzene)manganese(I) [285]. Hexamethylbenzene is formed on cyclotrimerisation of butyne, while the second σ-linked ligand (benzene) is formed from the σ-phenyl group as a result of a σ–π rearrangement.

As a rule acetylene cyclisation reactions in the presence of the organometallic compounds considered are stoichiometric. Dimesitylcobalt, which acts as a catalyst in the reaction with butyne, is an exception. A constant amount (up to 20%) of the corresponding π-complex is always formed in this process. Dimesitylcobalt reacts also with acetylene: the stoichiometric trimerisation to benzene is accompanied by a catalytic reaction involving the formation of a solid polymer. The reaction also yields a certain amount of dibenzenecobalt [286].

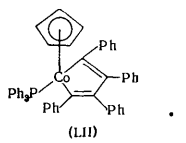
The reaction of tolane with dimesitylnickel(II) results in the formation of hexaphenylbenzene and the complex $[(Ph_2C_2)_4Ni]_n$. [263,282,287] Diethylnickel also induces the cyclisation of tolane to hexaphenylbenzene and provides the ethyl group for mixed cyclisation. However, nickel, being a weaker hydrogen acceptor than chromium, is incapable of abstracting hydrogen from the dihydrobenzene compound (1,2,3,4-tetraphenylcyclohexa-1,3-diene), which is in fact the final product of this reaction [272]. HFB polymerises under the influence of diethylnickel [84] and tolane cyclises also in the presence of dimesityliron [263,282].

The methyl derivatives of many metals $M(Me)_n$ (M = Ti, Zr, V, Nb, Mo, Mn, Fe, Ru, Co, Rh, or Pd) react with tolane to form hexaphenylbenzene, tetraphenylcyclopentadiene, and 1,2,3-triphenylnaphthalene [265,273]. The reaction of tolane with $(Ph_3P)_3RhMe$ yielded the following products: triphenylnaphthalene, tetraphenylbutadiene and a cyclisation product incorporating the σ-methyl group–tetraphenylcyclopentadiene [288].

On reaction with σ-alkyl-π-cyclopentadienyl complexes of molybdenum and iron carbonyls, tolane cyclo-oligomerises with insertion of the alkyl group σ-linked to the metal [254,289]:



The reaction of tolane with π-cyclopentadienyltriphenylphosphinecobalt(III) iodide in the presence of isopropylmagnesium bromide leads to the formation of the metal-containing cyclic complex (LII) [290,291]:



(LII)

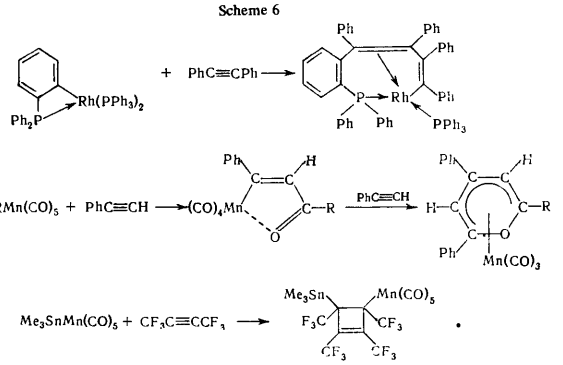
Acetylene and phenylacetylene undergo linear oligomerisation in the presence of σ-methyltris(triphenylphosphine)cobalt(I) [292]. For example:

$$(Ph_3P)_3CoMe + HC{\equiv}CH \rightarrow (Ph_3P)_2Co(CH{=}CH)_nMe .$$

The insertion of two molecules of acetylene derivatives in the σ-bonds Rh–C (Keim [293]) (the structure of the product was confirmed by X-ray diffraction [294]), Mn–C (Booth and

Hargreaves[295]), and Mn–Sn (Bichler et al.[296]) has been described (see Scheme 6).

Scheme 6



The reaction of but-2-yne with a σ-trifluoromethyl derivative of platinum yielded a cyclobutadiene complex[297].

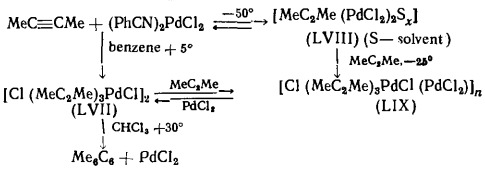
6. Reactions of Acetylenes with Transition Metal Salts

The reaction of acetylenes with bivalent platinum compounds has been investigated in greatest detail. The reaction proceeds in different ways depending on the nature of the substituents, conditions, etc. On treatment with palladium(II) chloride or its benzonitrile complex $(PhCN)_2PdCl_2$ (BNP) in benzene, diarylacetylenes yield π-cyclobutadiene complexes (LIII) together with hexasubstituted benzenes[100–103]. When the reaction is carried out in alcohol[100,103,298–303], the products are the *endo*-ethoxycyclobutenyl complexes (LIV)[103] [the structure of (LIV) has been established by X-ray diffraction[304]], which are converted under the influence of hydrogen halides into cyclobutadiene complexes (LV).

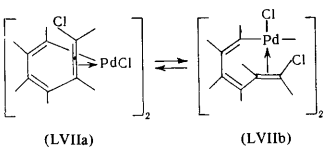
The cyclobutadiene complexes are not intermediates in the synthesis of benzenes[100,260,305]. For example, the reaction of (LIII) with tributylphosphine in the presence of tolane leads to the formation of the corresponding cyclooctatetraene in 92% yield; not even traces of hexaphenylbenzene are formed in this reaction.

The complexes (LV) were obtained from t-butylphenylacetylene and BNP; the formation of cyclotrimerisation products was not observed[173,306]. The structure of the cyclobutadiene complex (LVI) has also been attributed to the complex obtained from *o*-di(phenylethynyl)benzene and $PdCl_2$:[307,308]

Acetylenes containing less bulky substituents behave differently from those discussed above. But-2-yne reacts with $PdCl_2$ in benzene to form the complex (LVII)[260,309,310]. When the reaction was carried out in chloroform, two intermediates—the acetylenic π-complex (LVIII) and the complex (LIX)—differing from (LVII) by including $PdCl_2$ in their composition, were detected:

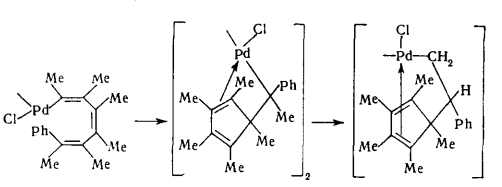


On heating, (LVII) decomposes with formation of hexamethylbenzene; treatment with triphenylphosphine, triphenylarsine, or triphenylstibine in the cold results in the formation of 5-vinylpentamethylcyclopentadiene with a small amounts of hexamethylbenzene. The structure of the product produced by the insertion of three acetylene molecules in the Pd–Cl bond was attributed to the complex on the basis of physicochemical data and the nature of its chemical reactions[260,310,311]. In this complex the ligand can exist as two conformers (LVIIa) and (LVIIb):



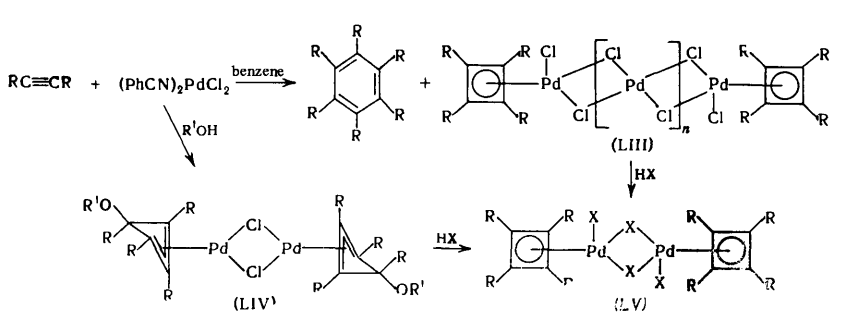
(LVIIa) (LVIIb)

The reaction of but-2-yne with "phenylpalladium chloride" yields a complex having the structure (LX), probably as a result of the cyclisation of (LXI) with a subsequent 1,2-hydride shift[312]:

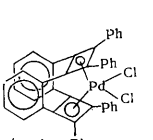


(LXI) (LX)

Together with the expected 1,2,4- and 1,3,5-isomers of trimethyltriphenylbenzene (yields 58 and 39%), the reaction of methylphenylacetylene with BNP in benzene gives rise to a small amount (3%) of the 1,2,3-isomer[102,260,310].



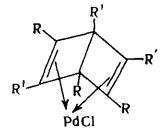
(LIII) (LIV) (LV)



(LVI)

The formation from methyl- and ethyl-phenylacetylenes in the presence of $PdCl_2$, together with hexasubstituted benzenes, of complexes containing acetylene tetramers and having the compositions $(PhC_2R)_4PdCl$ and $(PhC_2R)_4Pd_2Cl_2$ [299,313] has been reported.

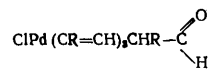
The structure of a complex of Dewar benzene (LXII, R = R' = COOMe) has been attributed to the product of the reaction of the dimethyl ester of acetylenedicarboxylic BNP:[175]



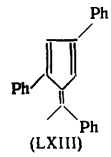
(LXII)

Acetylene and its monosubstituted derivatives undergo linear oligomerisation under the influence of palladium salts. Thus treatment of acetylene with $PdCl_2$ results in the formation of *trans*-alka-1,3,5,7,...polyene as the main product[314]. Stable σ-organometallic polyene products with the general formula $PdCl(CR{=}CR')_nX$ were isolated in the reactions of acetylene, vinylacetylene, and phenylacetylene[315-321]. Acetylene compounds undergo similar reactions in rhodium(III) chloride solutions[321].

The reaction of dialkylethynylmethanols with $PdCl_2$ in aqueous solutions has been investigated[322-325]. The following structure has been proposed for the complexes on the basis of infrared spectra[326-329]:

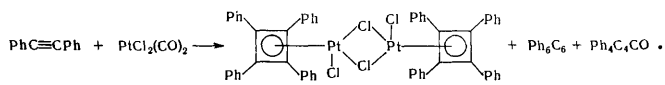


The reaction of phenylacetylene with BNP yielded fulvene (LXIII) and tetramers of unknown structure, tentatively dihydropentalenes[260]. The interaction of BNP with other monosubstituted acetylenes has also been described[310,330-332].

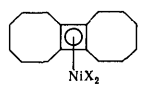


(LXIII)

In contrast to palladium salts, derivatives of bivalent platinum form mainly acetylenic π-complexes with acetylene. The cyclo-oligomerisation reaction has been described in only one instance[333]:



Nickel salts react with cyclo-octyne with formation of a complex to which the cyclobutadiene structure (LXIV) was attributed[129]. Another reaction product is the corresponding benzene derivative:

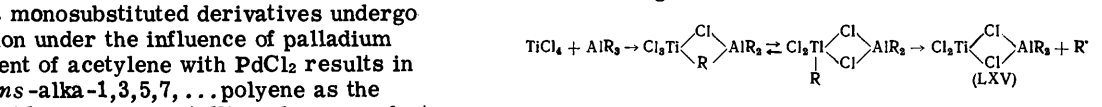


(LXIV)

The possible formation of the cyclobutadienegold complex[334] $[(C_4H_4)AuCl_2]^+$ when acetylene is passed into $AuCl_3$ solutions has been suggested[335].

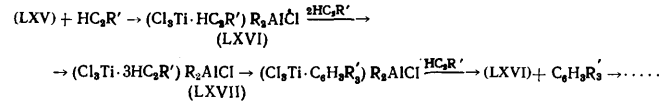
IV. THE MECHANISMS OF ACETYLENE CYCLO-OLIGOMERISATION AND POLYMERISATION REACTIONS IN THE PRESENCE OF TRANSITION METAL COMPOUNDS

The problem of the mechanisms of acetylene cyclo-oligomerisation and polymerisation reactions is now the subject of persistent attention of many chemists. Kinetic investigations involve considerable difficulties in view of the high rate and high heats of these reactions[17]. Such studies have been made on the cyclotrimerisation of hex-1-yne in the presence of the $i\text{-}Bu_3Al\text{-}VOCl_3$ catalytic system, which proceeds at a comparatively low rate. The reaction is described by a second-order equation with respect to the alkyne[57]. It has been shown that a tervalent form of titanium is catalytically active in the presence of $i\text{-}Bu_3Al\text{-}TiCl_4$.[68] The catalytic complex (LXV) is formed via the following mechanism:



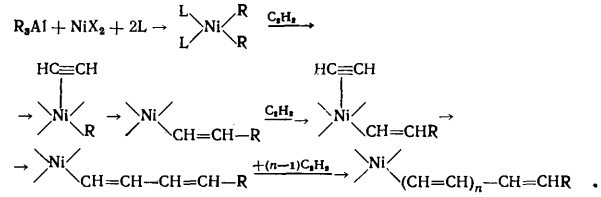
(LXV)

An acetylene molecule reacts with the titanium atom entering into the composition of the catalytic complex with formation of the monoacetylene complex (LXVI), which subsequently combines with two acetylene molecules in the rate-determining stage. In the octahedral complex (LXVII) three acetylene molecules cyclise with formation of a benzene derivative, which is displaced from the complex by a new acetylene molecule, etc.:



It has been shown that the polymerisation of phenylacetylene in the presence of the $Et_3Al\text{-}TiCl_3$ catalytic system is a first-order reaction with respect to the monomer[336]. The authors suggest that the mechanism of the formation of cyclic products is not determined by the simultaneous reaction of three monomeric units in a single step, the rate-determining step involving the abstraction of the linear trimer from the catalytic centre with ring closure.

The kinetics of the polymerisation of acetylene in the presence of $i\text{-}Bu_3Al\text{-}Ni(acac)_2$ have been investigated[337]. The initiation reaction is of first order with respect to the monomer and the order of the propagation reaction is close to zero. The following reaction mechanism including the stage involving the formation of an acetylene π-complex with subsequent insertion of the coordinated acetylene in the Ni–C σ-bond has been proposed:



It proved possible to isolate intermediate complexes incorporating the monomer and having the compositions $i\text{-}Bu_2Ni.C_2H_2.Bipy$ and $i\text{-}Bu_2Ni.C_2H_2.(PPh_3)_2$ in the reaction of acetylene with $i\text{-}Bu_3Al\text{-}Ni(acac)_2$ in heptane in the presence of stabilising ligands (triphenylphosphine or bipyridyl). The complexes polymerise acetylene at −10°C.

The study of the kinetics of the dimerisation of acetylene to vinylacetylene in the presence of copper(I) complexes led to the following mechanism for this reaction involving stages with formation of an acetylene π-complex and its conversion into a σ-acetylide with subsequent insertion of a second acetylene molecule in the Cu–C σ-bond [338–340]:

$$C_2H_2 + [Cu_nCl_{n+1}]^- \rightleftarrows \underset{\pi\text{-complex}}{[C_2H_2Cu_nCl_{n+1}]^-} \xrightleftharpoons[-H_3O^+,\,-Cl^-]{+H_2O} \rightleftarrows \underset{\sigma\text{-acetylide}}{[Cu_nCl_nC{\equiv}CH]^-} \xrightleftharpoons{C_2H_2} \underset{\pi\text{-complex}}{[Cu_nCl_nC{\equiv}CH\,(C_2H_2)]^-} \xrightarrow{\text{slow}}$$

$$\rightarrow [Cu_nCl_nC_4H_3]^- \xrightarrow[\text{fast}]{+H_3O^+ + Cl^-} [Cu_nCl_{n+1}]^- + C_4H_4 \ .$$

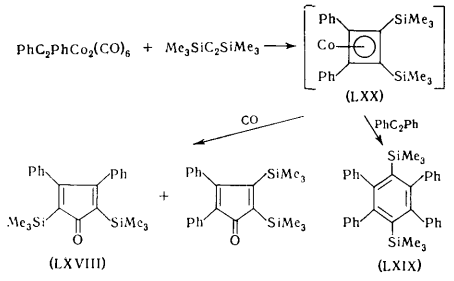
A number of studies have been made on the effect of the polarity of the solvent and various additives on the cyclo-oligomerisation reaction. It was found that the cyclotrimerisation of acetylenes catalysed by metal carbonyls and catalysts of the Ziegler–Natta type is insensitive to a change in solvent polarity. This enabled a number of workers [20,44,83] to put forward the hypothesis that a ionic mechanism of these reactions is unlikely. However, the hypothesis of an ionic mechanism has received increasing recognition recently. These ideas will be considered below.

In most studies ideas concerning the mechanism of the interaction of acetylenes with transition metal compounds were based on the nature of the final reaction products and the structure of intermediates. It is now generally accepted that the first stage of the reaction is a π-complex type of coordination of the acetylene to the metal. The formation of acetylene π-complexes under certain conditions and the possibility of obtaining from them acetylene cyclo-oligomerisation products were frequently pointed out above.

There are two main points of view on the problem of the ways in which coordinated acetylene is subsequently transformed into the final reaction product. The first is that the coordinated acetylene molecules react with one another, the process being accompanied by the formation of new C–C bonds and carbon ring closure. A six- or eight-membered ring can be formed either by the simultaneous formation of three (or four) C–C bonds or via the intermediate formation of the cyclobutadiene ring. The second view presupposes the conversion of the acetylene π-complex into a σ-compound (a metal-containing ring, a σ-ethynyl or a σ-vinyl derivative) with subsequent insertion of acetylene in the metal–carbon bond.

The hypothesis of the intermediate formation of cyclobutadiene complexes has been frequently put forward by a number of workers [142,334,341]. Evidence in support of this hypothesis comes from the conversion of an acetylene complex of niobium into a diacetylene complex and further into a mixed cyclobutadiene–acetylene complex, which splits off hexaphenylbenzene on heating [146,149] (see above).

Heating of diphenylacetylenedicobalt hexacarbonyl with di(trimethylsilyl)acetylene unexpectedly results in the formation, together with other products, of 3,4-diphenyl-2,5-di(trimethylsilyl)cyclopentadienone (LXVIII) and 2,3,5,6-tetraphenyl-1,4-di(trimethylsilyl)benzene (LXIX) [25,138,168]. According to the authors, the most probable mechanism of the synthesis of these products consists in the intermediate formation of the cyclobutadiene complex (LXX), which can then undergo ring expansion in any conceivable manner:



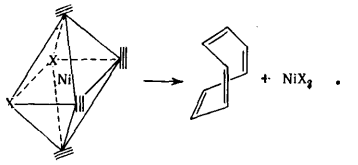
The problem of the possible intermediate formation of cyclobutadiene complexes on cyclotrimerisation of acetylenes was studied in relation to 1,1,1-trideuteriobut-2-yne [266,342,343]. If the reaction proceeds via a cyclobutadiene complex, all three possible isomeric benzenes should presumably be formed. The 1,2,3-$(CD_3)_3$-4,5,6-Me_3C_6 isomer is absent from the products of the reaction involving triphenylchromium, dimesitylcobalt, dicobalt octacarbonyl, di(acrylonitrile)nickel, and i-Bu_3Al–$TiCl_4$. In the presence of $AlCl_3$, the 1,2,3-isomer is formed quantitatively (on the assumption of the intermediate formation of a cyclobutadiene structure‡), while on treatment with BNP its yield is intermediate between the two extreme values. As already mentioned, similar results were obtained in the cyclisation of phenylmethylacetylene in the presence of BNP [102,310], which is consistent with the cyclobutadiene hypothesis. However, it has been shown [100,305] that cyclobutadiene complexes of palladium are not intermediates in the synthesis of benzenes. It has been suggested that dynamic processes involving the intermediate complex (LVII), accompanied by the migration of the substituents, are responsible for the "unexpected isomers" [260].

The hypothesis of the simultaneous coordination of several acetylene molecules around the metal atom was put forward for the first time by Reppe [122] and was developed further in subsequent investigations [80,83,345–348] (see also Refs. 349 and 350). The acetylene cyclo-oligomerisation reaction is a many-centre process with simultaneous formation of C–C bonds. These ideas have been developed in detail in relation to the cyclotetramerisation of acetylene under the influence of nickel compounds.

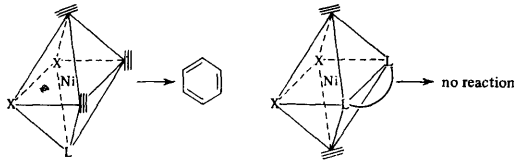
Paramagnetic (at least in solution) nickel(II) complexes with low-field ligands–di(salicylaldehydo), di(acetylacetonato)-, and di-(*N*-alkylsalicylaldimino)-nickel and nickel cyanide are catalytically active in the synthesis of COT. These complexes have an octahedral structure or can readily acquire it. Planar nickel(II) complexes with high-field ligands—phthalocyanine or dimethylglyoxime complexes—are inactive. The yield of COT is proportional to the rate of ligand exchange in the complex. Under the influence of acetylene, the coordinate bonds

‡But-2-yne reacts with $AlCl_3$ under milder conditions with formation of Dewar hexamethylbenzene [344]. This result is also consistent with the hypothesis of the intermediate formation of a cyclobutadiene structure with subsequent addition of an acetylene molecule as in the Diels–Alder reaction.

are ruptured and in the resulting intermediate complexes the four acetylene molecules are arranged favourably for closure of the eight-membered ring:



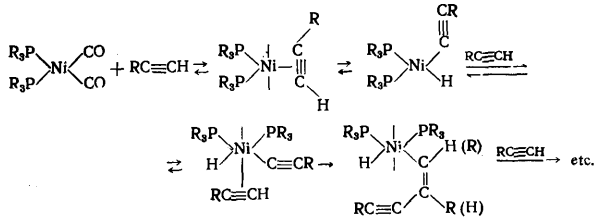
On addition of triphenylphosphine, which blocks one coordination site in the complex, COT is not formed and the reaction product is exclusively benzene. The addition of substances capable of blocking two coordination sites at once [$\alpha\alpha'$-bipyridyl, *o*-phenanthroline, and 1,2-bis-(diphenylphosphino)ethane] fully deactivates the catalyst in the cyclo-oligomerisation reaction:



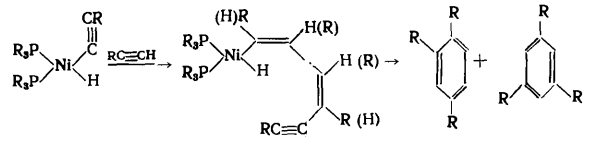
The formation of COT in the presence of $Zn[Co(CO)_4]_2$ can be accounted for by dinuclear catalysis. Two acetylene molecules are coordinated around each of the two cobalt atoms with simultaneous formation of new C–C bonds [121,351]. This hypothesis is open to many objections. In particular it cannot explain the preferential formation of 1,2,4-isomeric substituted benzenes in the cyclotrimerisation of asymmetric acetylenes.

The essential feature of the hypotheses concerning the mechanism of the cyclisation and polymerisation of acetylenes discussed reduces to the postulate of the intermediate formation from the acetylenic π-complex of an organometallic compound with metal–carbon σ-bonds; chain growth takes place as a result of the insertion of π-coordinated acetylene in the M–C bond.

The mechanism proposed [17] explains satisfactorily the formation of linear polymers in the reactions of terminal acetylenes with metal carbonyls. On the basis of the finding that deuteriated hept-1-yne reacts much more slowly with dicarbonyldi(triphenylphosphine)nickel than its non-deuteriated analogue, the authors proposed a mechanism based on the oxidative addition of acetylene to the metal with formation of an acetylide–hydride complex. The insertion of acetylene in the M–C bond leads to the formation of a σ-vinyl derivative:

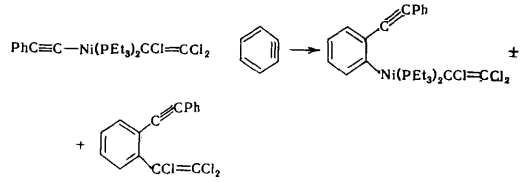


In the presence of a favourable conformation, ring closure may take place with formation of benzene derivatives:

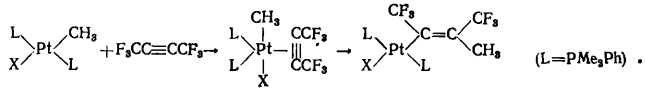


A similar mechanism has been proposed for the polymerisation of alk-1-ynes in the presence of rhodium(I) and iridium(I). [90,91,94]

The occurrence of certain reaction stages has been confirmed experimentally. Thus the formation of hydride-acetylide compounds is observed when certain terminal acetylenes add to the coordination-unsaturated iridium complex $IrCl(CO)(PPh_3)_2$. [352] The insertion of acetylene in the metal-alkynyl group has been described for the interaction of nickel acetylide with dehydrobenzene [353]:



In platinum complexes coordinated acetylene has been inserted in the Pt–CH_3 bond [354–356]:

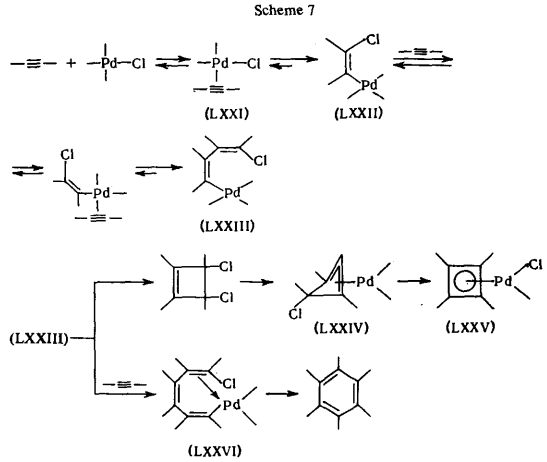


The formation of iridium complexes containing both a σ-vinyl group and a π-acetylenic ligand, $(Ph_3P)_2Ir(CR=CHR)(RC_2R)(CO)$ (R = CF_3 or $COOCH_3$), can also serve as evidence in support of the mechanism proposed [357].

Finally linear polymerisation of phenylacetylene with participation of nickel and platinum acetylide complexes has been achieved [86,87,358].

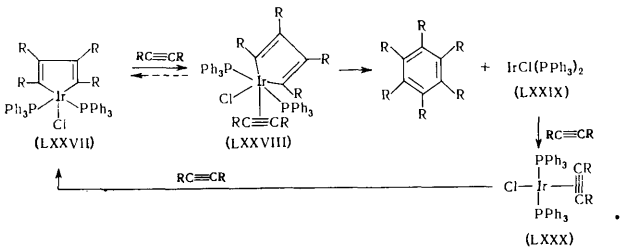
In the polymerisation of alkynes in the presence of transition metal halides of the type $(R_3P)_2NiX_2$, [104] BNP, [100,309] $PdCl_2$, and $RhCl_3$ [321] a σ-vinyl derivative may be formed as a result of the insertion of acetylene in the M–Hal bond. Thus Scheme 7 has been proposed for the cyclo-oligomerisation of acetylene in the presence of BNP. [260,309,310,312] The acetylene π-complex $(RC_2R)\cdot(PdCl_2)_2S_X$ (LXXI) formed initially is converted in the rate-determining stage into the σ-vinyl intermediate (LXXII), which subsequently coordinates a second acetylene molecule and is converted into (LXXIII). The reaction pathways of the latter depend on the size of the substituents in acetylene. For bulky substituents (Ph, t-Bu), cyclisation into inactive cyclobutene or cyclobutadiene complexes (LXXIV) or (LXXV) is observed. For small substituents (Me), a third acetylene molecule is inserted with formation of (LXXVI), which cyclises to hexamethylbenzene.

Scheme 7

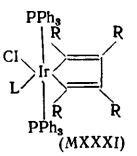


The polymerisation of acetylene in the presence of Ziegler–Natta catalysts can be explained similarly by the insertion of acetylene in an M–R bond[359].

In order to account for the formation of benzene derivatives from disubstituted acetylenes in the presence of nickel catalysts, the hypothesis of the intermediate formation of a metal-containing cyclic complex was put forward[17]. It was developed further in subsequent investigations[5,32,100,290,352,360]. The reaction mechanism for iridium as an example is as follows[361]:



The reversible addition of acetylene to the coordination-unsaturated cyclic iridium compound (LXXVII) leads to the formation of the intermediate complex (LXXVIII), which then decomposes with liberation of hexasubstituted benzene and the moiety (LXXIX). The latter combines with an acetylene molecule to form the acetylene complex (LXXX), which is in turn converted into the cylic iridium complex (LXXVII), etc. The changes involving the conversion of (LXXX) into (LXXVII) and of (LXXVII) into a benzene derivative have been achieved experimentally. The capacity of the coordination-unsaturated complex (LXXVII) to react with CO and tertiary phosphines with formation of the hexacoordinate complex (LXXXI),



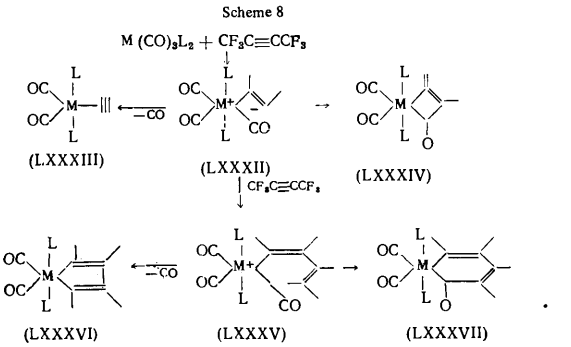
suggests that the stage involving the formation of (LXXVIII) is also likely. A similar series of transformations has been achieved for rhodium complexes[236,239–243].

The employment of the metal-containing cyclic compound hypothesis in relation to non-stoichiometric cyclisation reactions of acetylenes in the presence of σ-alkyl and σ-aryl metal derivatives was described above (Section III).

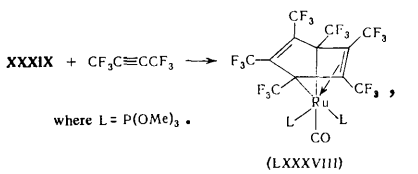
The attempts to apply the metal-containing cyclic compound hypothesis in the version described in order to account for the reaction of HFB with carbonylphosphine (phosphitocarbonyl) complexes of iron, ruthenium and osmium of the type $M(CO)_3L_2$ [L = PMe_2Ph or $P(OMe)_3$] have encountered many objections. In particular the formation of, for example, the complex (LXXXIV) cannot be accounted for in terms of the "insertion reaction" of carbon monoxide (more correctly the migration of the alkyl group), since electronegative substituents in σ-linked alkyl groups are known to hinder strongly the insertion of CO in the M–C bond.

Scheme 8, postulating the formation of an intermediate ionic product (LXXXII), has been proposed as an alternative to the "insertion reaction". This product is either converted into an acetylene π-complex (LXXXIII) with elimination of CO or the metallocyclobutenone (LXXXIV) is formed as a result of the intramolecular attack of the carbanion on the coordinated carbonyl group. Compound (LXXXII) can also react with a second acetylene molecule, forming the ionic intermediate (LXXXV), which yields as a result of similar reactions either the metallocyclopentadiene (LXXXVI) or the complex (LXXXVII) as a precursor of cyclopentadienone.

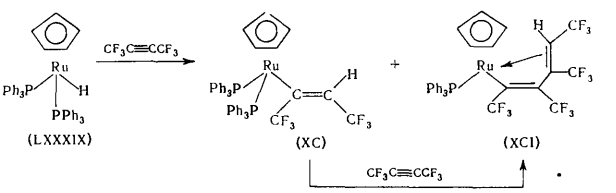
Scheme 8



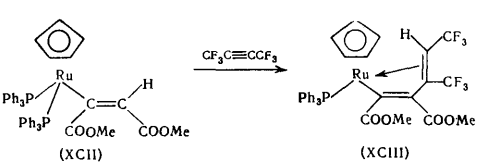
The formation of the complex (LXXXVIII) from (XXXIX) on irradiation is consistent with the hypothesis that the benzene ring is formed from the metallocyclopentadiene:



The mechanism in which the formation of ionic intermediates is postulated has been confirmed in studies by other investigators. When π-cyclopentadienyldi(triphenylphosphine)ruthenium hydride (LXXXIX) reacts with HFB, the complexes (XC) and (XCI) are formed[362]:



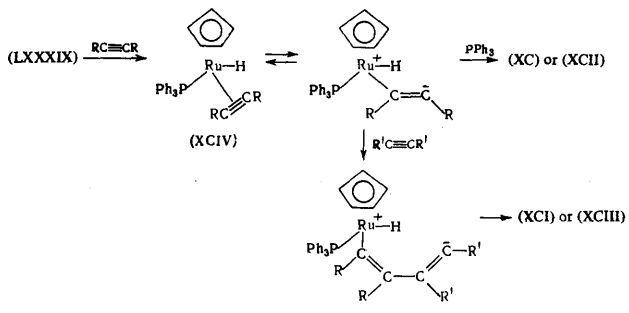
Compound (XCII) was similarly obtained from (LXXXIX) and the dimethyl ester of acetylenedicarboxylic acid. The reaction of (XCII) with HFB yields a complex which has the structure (XCIII) according to X-ray diffraction data:



The formation of (XCIII) cannot be accounted for from the standpoint of the insertion of acetylene in the M–C bond, since one would expect in this case the formation of the isomeric product $C_5H_5Ru(PPh_3)[C(CF_3)=C(CF_3)-C(COOMe)=CH(COOMe)]$. Evidently (XCIII) is formed as a result of the insertion of HFB in the C–H bond in (XCII). Scheme 9, in which the formation of ionic

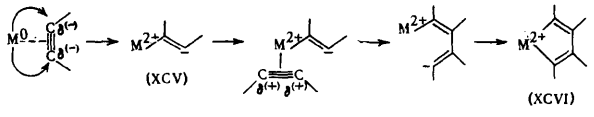
intermediates is postulated as in Scheme 8 discussed above, has been put forward on the basis of the data obtained for the reaction:

Scheme 9

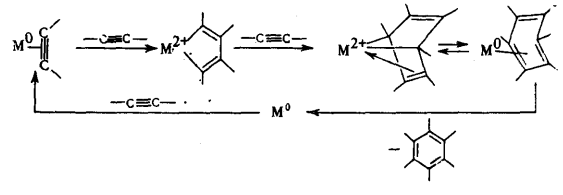


A similar mechanism has been proposed for the cyclo-oligomerisation of acetylenes with participation of zero-valent palladium and platinum complexes (Scheme 10).[260] The hypothesis of the formation of dipolar intermediates (XCV) is based on the observed acceleration of the reactions in polar solvents. A second acetylene molecule is coordinated to the metal which is already in a +2 state of oxidation as a result of which the acetylene is activated in relation to the nucleophilic agent and undergoes intramolecular attack by the vinyl anion:

Scheme 10



It has been suggested that the subsequent conversion of the metal-containing cyclic product (XCVI) into a benzene derivative involves the formation of a π-tetrahaptobenzene complex:



Thus an obligatory stage in all the cyclo-oligomerisation and polymerisation reactions of acetylenes in the presence of transition metal compounds is the formation of acetylene π-complexes. The pathways followed in the subsequent conversion of the π-complexes into the final products can apparently be different depending on the nature of the metal and the acetylene.

Polymeric Chemotherapeutic Agents with Carcinolytic Activity

I.Iliev, M.Georgieva and V.Kabaivanov

The review deals with advances in research on the applications of polymeric compounds in active cancer chemotherapy and prospects for its development. The principal aims to which efforts are at present directed are indicated and arguments are adduced in support of the necessity for a further and comprehensive development of this problem. Attention is concentrated on the employment of synthetic polyelectrolytes as transporting agents for active chemotherapeutic preparations. The bibliography includes 52 references.

The treatment of different types of cancer is one of the most important problems being solved at present in medicine. The widespread occurrence of these affections in all parts of the world, their wide pathological variety, and the absence in certain cases of means for a complete cure — all these necessitate an active search for chemotherapeutic antitumour agents.

There exist several hypotheses at present concerning the nature of cancer and the mechanism of its occurrence and development. One can now state with complete certainty that cancer constitutes the formation of new tissue (tumour), which arises in different parts of the human organism as a result of continuous uncontrolled division of cancer cells. Usually this is a result of the response of the organism to the action of various external and internal irritants, toxic substances, physical (ionising radiation and others) and biological agents (certain types of viruses and hormones), etc.[1].

The concept of "cancer" is collective[2] (carcinomas, sarcomas, lymphomas, etc.). The wide variety of forms of cancer and their morphological, aetiological, and clinical differences make it necessary to select specific agents to treat the disease. The principal modern methods for the treatment of a cancer are surgery, radiotherapy, hormonotherapy, chemotherapy, and combined procedures[3]. When chemotherapy is used in the fight against cancer, it is necessary to overcome a specific difficulty — the identical response of normal and cancer cells to chemotherapeutic agents.

Many authors believe[3-5] that chemotherapeutic preparations used in modern practice can be divided into four principal groups: alkylating agents, antimetabolites, antibiotics, and preparations of plant origin. Larionov[4] includes hormonal preparations among them. Boesen and Davies[5] distinguish yet another group, combining all preparations with anticancer activity which cannot be included in any of the four groups stated above in terms of the principle of their action.

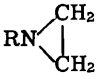
Antimetabolites are largely structural analogues of compounds important to the organism, such as vitamins, hormones, and aminoacids.

Antibiotics are not as effective against cancer cells as against bacterial infections. However, their capacity to influence the metabolism of tumours and also the virus theory of certain forms of cancer[6] resulted in the use of many antibiotics in the fight against cancer. Actinomycins have been most widely used.

Among preparations of plant origin, the alkaloids colchamine and vinblastine show the highest antitumour activity.

The main group of preparations includes alkylating compounds with anticancer activity. It has been most thoroughly investigated and a large number of carcinolytic preparations employed in clinical practice belong to it. The different types of biological alkylating agents, the mechanism of their action, the kinds of tumours which they effectively inhibit, the methods for the enhancement of their selectivity, and the prospects of finding new preparations have been considered in detail in reviews[4, 7-9].

A common property of biological alkylating agents is their capacity to alkylate the nucleophilic centres of biological systems under very mild conditions (aqueous solution at pH 7 – 7.5, temperature 37°C). The following nucleophilic centres are encountered in biological systems: anions of organic and inorganic acids and ionised sulphydryl groups and thioethers. The main alkylating compounds employed are β-chloroethylamines $R_2NCH_2CH_2Cl$, epoxy-compounds $R_2CH-CH-CH_2$ (O), aziridine derivatives



and alkanesulphonic acid esters.

It has been established that many alkylating agents react *in vitro* directly with the functional groups of proteins and nucleic acids. They attack the carboxy- or hydroxy-groups of aminoacids and phosphoric acids.

In order to account for the biological activity of alkylating substances, two hypotheses have been put forward[7]: (1) the formation of cross-links between two points in the same biomacromolecule or between two different biomicromolecules; (2) local polymerisation. In the latter case compounds capable of being alkylated and containing reactive groups are polymerised in the organism with formation of macromolecules. The majority of investigators tend to give preference to the first hypothesis. On the other hand, the second hypothesis makes it possible to detect the carcinolytic activity of certain alkylating polymers[10].

The principal requirement which must be met by alkylating agents (as well as all other anticancer chemotherapeutic agents) is selectivity of their action. The selectivity is measured by the so called chemotherapeutic index, which is defined as the ratio of the therapeutic and toxic doses of the given preparation[9].

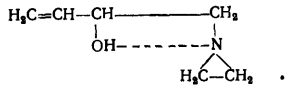
The high reactivity and low specificity of alkylating compounds introduced into the organism frequently preclude their employment as chemotherapeutic agents. Thus the idea arose that an inert carrier, which as a rule exhibits a specific affinity for the particular system toward which the therapeutic activity is directed, be employed.

An important principle of the preparation of chemotherapeutic compounds with high selectivity and low toxicity involves the employment of latent activity[8]. The principle is based on the possibility of introducing into the organism inactive preparations which are gradually converted into their active form under the influence of enzymes. Such preparations may be high-molecular-weight compounds.

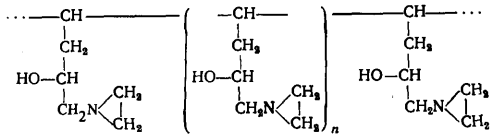
The successful application of polymers in all branches of medicine stimulated the synthesis of polymeric medicinal preparations with carcinolytic activity. Krentsel'et al.[11]

state that interest in polymeric materials increased particularly after the development of methods for stereospecific polymerisation whereby it is possible to synthesise rigorously ordered macromolecules, which were previously known only among natural compounds. The same workers believe that there are three promising trends in the synthesis of polymeric antitumour preparations.

The first important trend involves the synthesis of physiologically active polymers from physiologically active monomers. Alkylating aromatic preparations derived from di-(2-chloroethyl)amines, derivatives of aziridine, and ethylene derivatives in which the double bond is activated by groups such as NO_2, SO_2R, COR, etc. are believed to be the most promising in this respect. In the synthesis of such preparations the main factor is the endeavour to increase the selectivity by controlling the length of the macromolecule and the content of functional groups. In most cases polymerisation of monomeric anticancer alkylating substances of such types is difficult and advances in this field are so far insignificant. The first positive result was achieved by Lidaks and Hillers[12], who polymerised the familiar antitumour preparation ethoxen (1-azirindino-2-hydroxybutene):

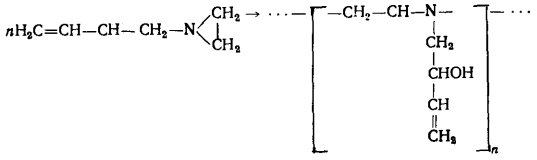


The main task in the synthesis was to achieve polymerisation via the double bonds and to prevent the opening of the aziridine ring. This was done by employing hydrogen peroxide at 100°C as the initiator. According to the authors, the resulting physiologically active polymer has the following structure:



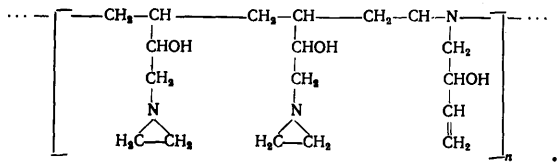
This structure presupposes the complete retention of the aziridine ring, which is unlikely. The polymeric preparation obtained was used in the treatment of the carcinoma of the alimentary canal and the stomach and was administered *per os*, which ensured good contact with the surface of the tumour and prevented a premature reaction of the reactive alkylating aziridino-group. The polymer exhibits almost the same anticancer activity against sarcoma S-45 in mice as the initial monomer, but is less toxic.

Subsequently it was established[11] that the polymerisation of ethoxen proceeds not only via the double bonds but also via the opening of the aziridine ring:



When synthesised by thermal polymerisation, the polymer includes up to 37% of units containing the aziridine ring, 58.8% of such units are retained on radical polymerisation under the influence of benzoyl peroxide and 67 to 68% on radiation-induced polymerisation (using γ-rays from a cobalt source). Thus the maximal antitumour effect is to be expected for the polymer obtained by γ-irradiation.

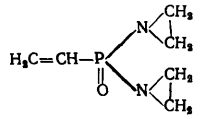
This polymer probably has a structure of the type[11]



i.e. of each three monomeric molecules two enter the growing chain as a result of the dissociation of the C = C double bond and one as a result of the opening of the ring.

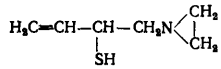
Shimanskaya[13] has listed the following other promising monomeric aziridine derivatives which are of interest for the synthesis of anticancer polymeric preparations:

bis(1-aziridinyl)vinylphosphine oxide:



(the presence of the phosphoryl group might have increased the latent activity of the polymer);

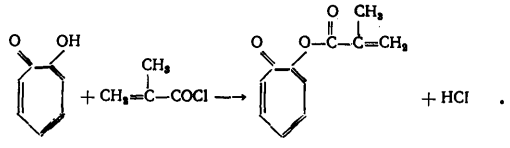
1-aziridino-2-mercaptobut-3-ene (mercapto-analogue of ethoxen):



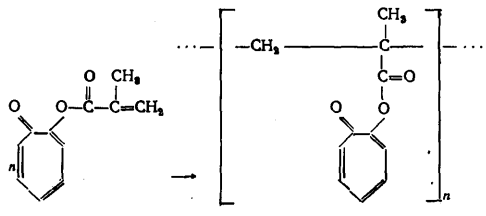
1,4-diaziridinobut-2-ene (product of the addition of aziridine to butadiene):

Cornell and Donaruma[14, 15] used 2-methacryloxytropone as the monomer. They assumed that the corresponding polymer would exhibit a moderate physiological activity, since at the biological pH it should be insoluble and resistant to biological decomposition. Indeed, the polymer obtained from 2-methacryloxynitrile[11, 12] does show a weak physiological effect. On the other hand, the homopolymer of methacryloxytropone exhibits a higher carcinolytic activity in relation to experimental strains.

Methacryloyloxytropone is a product of the reaction between tropolone and methacryloyl chloride:



The polymerisation can be represented by the following scheme:



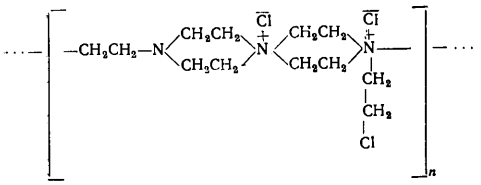
The authors do not explain the mechanism of the anticancer activity of the polymer which they synthesised. The carcinolytic activity of the monomer is probably due to the structural similarity between tropolone, colchicine, and other troponoids of this kind, the physiological activity of

which is known. Colchamine is an analogue of this group substances among preparations of plant origin.

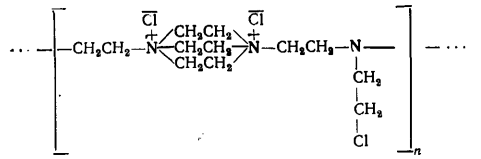
Galstyan[16] reported studies on the anticancer activities of the polymeric preparation Kh-1. This chloroalkylating preparation, obtained by Avetyan and Matsoyan[17], has been investigated clinically and introduced into chemotherapeutic practice under the name "polychlorimine". 2-Chloroethylaziridine, which constitutes a combination of two groups with a high cytostatic activity,

was used as the monomer for its synthesis.

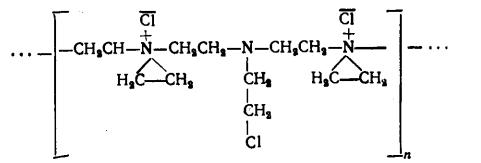
The monomer is unstable and polymerises readily in the presence of water. Controlled polymerisation was achieved in aqueous dimethylformamide solution at 30 – 40°C for monomer : water : dimethylformamide ratios of 1 : 5 : 1. The analytical data lead to the conclusion that the fundamental unit of the resulting linear polymers contains two ammonium ions formed by cyclisation. Three probable versions (A – C) of the structure of the polymer chain have been put forward:



(A)

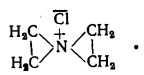


(B)



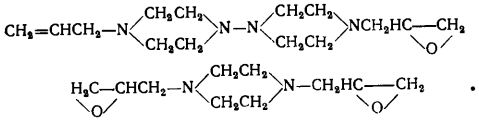
(C)

The authors believe that polymerisation proceeds via a cationic mechanism involving self-initiation with participation of a quaternary ammonium salt produced from the monomer:



The mechanism of the anticancer activity of the preparation has not been established. Its effectiveness can hardly be accounted for solely by the presence in the chain of a large number of active alkylating groups. This could lead to an extremely high toxicity and would reduce the selectivity of the polymeric chloroalkylating agent. The preparation is probably a polyelectrolyte. Thus, bearing in mind certain characteristics of cancer cells, which will be discussed below, one can assume that the effectiveness of the preparation is based on its combined action as a polyelectrolyte and as an active alkylating agent.

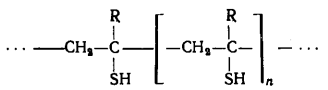
It would probably be interesting to obtain and test polymeric analogous of a number of compounds containing the epoxy-group, for example:



The copolymerisation of methacrylic acid with alkylating derivatives based on it is also interesting.

According to Krentsel' et al.[11], a second important trend in the synthesis of polymers with carcinolytic activity involves the formation of simple macromolecules containing physiologically active groups. Such studies are also important because they make it possible to explain the influence which a given polymer structure can exert on the reactivity of physiologically active functional groups. Polymers containing sulphydryl and imidazole groups are particularly interesting in this respect[18]. These polymers can inhibit the influence of ionising radiation, which is responsible for the carcinogenic degeneracy of cells.

Polyvinylmercaptans with various substituents in a side chain may be quoted as a possible example:



The presence of phenolic rings increases the resistance of polyvinylmercaptans to oxidation.

Certain reports concerning the use of polymeric molecules as carriers of active anticancer low-molecular-weight substances can also be referred to studies of this kind. The inclusion of an active sarcolysine preparation in the molecules of a number of polymers and copolymers (the copolymers are conventionally designated by K_2, K_7, K_{10}, K_{12}, etc.) led to the synthesis of effective agents with a comparatively low toxicity and high selectivity[19].

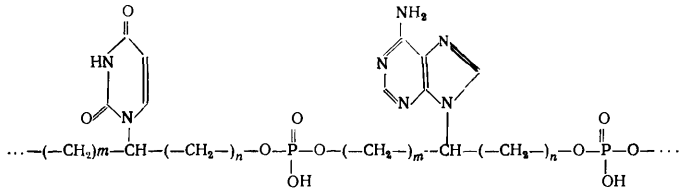
Vernick and Hoppe[20] discovered that the polyvinylpyrrolidine – iodine complex has an inhibiting effect on Walker carcinosarcoma 256. The possibility of using polyvinylpyrrolidine as a polymer forming complexes with various cytostatic substances and increasing their selectivity has also been reported by other workers[21].

A third, exceptionally promising but unfortunately as yet uninvestigated type of synthesis of polymeric carcinolytic substances is asymmetric synthesis[22]. The synthesis may be based on the relation demonstrated by many investigators between the stereoisomerism of chemical substances, in particular sarcolysin derivatives[23, 24], and their carcinolytic activity. The method of polymerisation on polymeric matrices might find an application here[25].

The study of the use of polymeric analogous of natural macromolecules to suppress the selective action of the enzyme RNA-polymerase[26] showed that polymers with a specific configuration may inhibit the synthesis of protein and arrest the growth of malignant tumours. It has been suggested[26] that it might be possible to synthesise polymers whose structure would resemble various enzymes with a rigorous alternation of a large number of aminoacids in the monomeric unit with an appropriate chain length and appropriate distances between individual units. Such "depressant polymers" can "recognise", via one of their units much more readily than low-molecular-weight chemotherapeutic substances, the appropriate enzyme centre susceptible to

attack and block its activity. Merrifield's method — solid-phase polymerisation — is most suitable for the synthesis of such polymers[27].

The synthesis of a polymer of this kind was achieved by Hillers[28], who obtained oligomeric polynucleotides complementary to natural aminoacids and having the following structure:

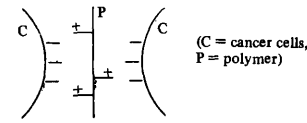


In all the instances mentioned, the activity was explained on the basis of the already established mechanisms of the action of alkylating substances on biological centres or the mechanisms of the suppression of the activity of enzymes responsible for cell division. Polymeric preparations exhibit almost identical activities in relation to both cancer and normal cells. Therefore, even a slight qualitative difference between such cells has been the subject of numerous wide-scale investigations in order to find new ways for the inhibition of the growth of tumours.

Another interesting type of study, which gives rise to the possibility of creating various combinations and modifications of polymeric substances, involves the use of polyelectrolytes. Both polycations and polyanions, i.e. polybases and polyacids, can probably be used with equal success.

The majority of natural and biological polymers are polyelectrolytes. They include, for example, peptides and enzymes[29, 30]. The surface of normal and cancer cells has a definite electrical charge. The possibility of the formation of electrostatic bonds between natural or synthetic polyelectrolytes and a biopolymer of a living organism constitutes yet another basis for the inhibition of tumour growth. For example, by binding a suitable polyelectrolyte to enzymes e.g. deoxyribonuclease responsible for cell division, one might retard or arrest such division. It is then necessary to protect the organism from the toxic action of the polyelectrolytes, since they act with equal force on both cancer and normal cells[29]. Cationic polyelectroyltes proved to be the most selective. This may be attributed to the negative surface charge of the cells, arising mainly from ionised phosphate or carboxy-groups.

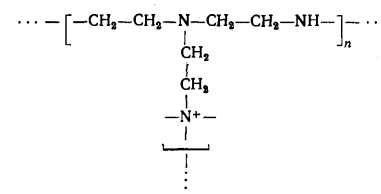
On the basis of studies by a number of investigators, Ambrose et al.[31] showed by electrophoresis that the negative charges arising on the surfaces of normal and cancer cells are of different magnitudes. Subsequently these workers[32] confirmed this by experiments with cancer cells from mouse kidneys and lungs. They tested synthetic polycations as antitumour preparations *in vitro*. Polyethyleneimine ... $-[-CH_2CH_2NH-]_n$ ..., polyvinyl-4-butylpyridine, and polyhexamethylenediguanidine ... $-[-(-CH_2-)_6-\underset{\underset{NH}{\|}}{C}-NH-\underset{\underset{NH}{\|}}{C}-NH-]_n-$... were tested. It was found that only polyethyleneimine exhibits a fairly marked antitumour activity. The highest efficiency is obtained at a low concentration of the test polymers. The agglutination of tumour cells in such experiments confirms the hypothesis that the cancer cell has a higher negative charge than the normal cell. According to these investigators, this can be explained by a decrease on the surface of cancer cells of the number of Ca^{2+} ions, which play the role of an intercellular adhesive. A decrease of the number of these ions on the surface of cancer cells impairs the intercellular linkages. Polycations which combine with the negatively charged surface neutralise the surface charge. This increases the adhesion between the cells and causes the agglutination of the tumour cells[33].



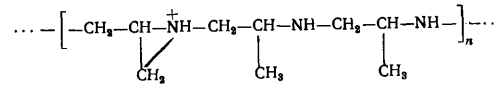
It has been shown that the units of sialic acids are responsible to a greater extent than phosphate residues for the formation of the negative surface charge of cancer cells[33, 34].

In accordance with the latest research, Moroson[34] believes that, apart from the Coulombic cytostatic binding of cancer cells described above, polycations in general enhance the immune response of the organisms to cells transplanted from the outside. Polycations of the following types were investigated *in vivo* and *in vitro*:

Polyethyleneimines with molecular weights of 600, 1800, 60 000, and 100 000:

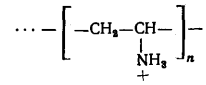


Polypropyleneimine with a molecular weight of 10 000 to 15 000:

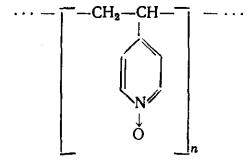


A polyamine with a molecular weight of 30 000 – 50 000:

Polyvinylamine with a molecular weight of 10 000 to 300 000:



Poly(vinylpyridien *N*-oxide) with a molecular weight of 100 000:



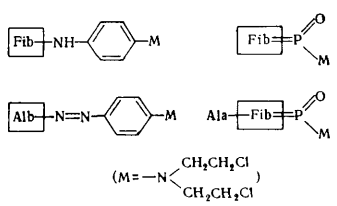
These polymers have basic properties and in the neutral form each of the four nitrogen atoms carries a positive charge. The mechanism of the polymerisation of the ethyleneimine [aziridine] monomer includes a stage involving the formation of a quaternary immonium ion and then interaction with yet another ethyleneimine molecule. Polyethyleneimine molecules with a higher molecular weight (in excess of 100 000) has been obtained by treatment with ethylene chloride.

Apart from inhibiting the growth of tumours by direct electrostatic addition, some investigators believe that polycations are capable of transporting powerful cytostatic substance to the cancer cells. In his experiments, Woodman[35]

employed for this purpose chitosan (a copolymer of hexosamine and *N*-acetylhexosamine), polyethyleneimine, polypropyleneimine, diethylaminodextran, "polybrene" [poly-1, 5-dimethyl-1, 5(diaza-undecamethylene dimethobromide)], and other polymers. These high-molecular-weight compounds are capable of forming complexes with iododeoxycytidylic acid and thus transporting iododeoxyuridine — an active metabolite. The presence of polycations probably facilitates the passage of the active metabolite through the membrane of the cell after its enzymatic decomposition (cell dephosphorylation[8]) or even the entire polycation–metabolite complex may pass into the cell. As a result, the activity of nuclear deoxyribonuclease is inhibited.

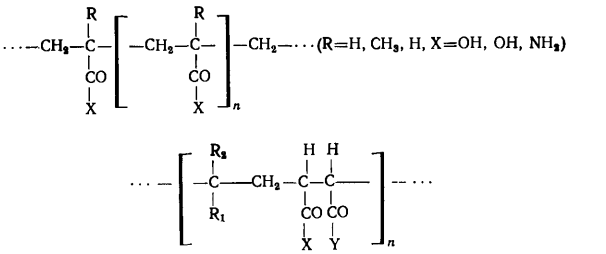
Ryser[36] and Larsen[37] observed an increase of the transmitting capacity of a cell membrane model (thiolated gelatin) in the presence of polycations. Larsen and Thörling[38] therefore explained their observation of the anticancer inhibiting effect of diethylaminodextran and the sodium salt of sulphonated dextran by the facilitation of the passage of the macromolecule through the cell membrane.

The possibility of the transport of cytostatic agents of another type with the aid of polycations is also of great interest. Experiments with complexes of methotrexate, chlorambucil, etc. and polyethyleneimine proved unsuccessful, since these complexes dissociate in 0.015 M NaCl. Nitrogen mustard gas, linked covalently to albumin (a natural polyelectrolyte) as well as a phenylalanine–mustard gas polymer did not exhibit the expected antitumour activity[39]. However, the diphenylamine analogue of mustard gas and some of its derivatives exhibited a high chemotherapeutic selectivity. These preparations proved to be effective in relation to certain mouse tumours[40]. Some derivatives of nitrogen mustard gas linked to biopolycations of the type of albumin, globulin, and fibrinogen showed a high latent activity[40]



Regelson and coworkers[41] discovered that many synthetic heparinoid polyanions exhibit a comprehensive antitumour activity. Regelson attributes this activity to the anticancer activity of heparin itself, which is an inhibitor of cell division. Heparin is a sulphomucopolysaccharide—a natural anionic hydrophilic polymer, which acts as a coagulator. While the causes of the anticancer activity of polycations are known comparatively accurately, for polyanions there are numerous likely mechanisms and hypotheses. It has been suggested that polyanions bind Ca^{2+} and Mg^{2+} ions, keeping them on the surface of the cell, which promotes cohesion among the cells. As mentioned above, cancer cells are distinguished by impaired intermolecular adhesion owing to a lower coverage of the surface by Ca^{2+} or Mg^{2+} ions. Polyanions can also combine with various biopolycations (enzymes), which results in a decrease or complete disappearance of the activity of enzymes, promoting uncontrolled cell division. Polyanions also inhibit the activity of nuclear deoxyribonuclease of cancer cells.

Regelson investigated the sodium salt of polyethylenesulphonic acid (molecular weight 15 000 – 35 000)[42] as the first analogue of heparin and demonstrated its anticancer activity on various types of tissue culture. Later, in order to confirm this hypothesis, he investigated the anticancer activity of other polyanions — polyacrylic acid and ethylenemaleic acid anhydride[43], both pure and hydrolysed. Polyanions in the amidoacid form have also been examined. They differ by the density of electrical charges:



(R_1=H; H; H: H; H; H; CH_3; CH_3
R_2=H; H; H; H; CH_3; CH_3; CH_3; CH_3
X=OH; NH_2; NH_2; NH_2; ONH_4; NH_2; ONa; NH_2
Y=OH; ONH_4; OH; NH_2; ONH_4; ONH_4; ONa; NH_2)

It was found that the amidoacid form of the copolymer of ethylene and maleic anhydride exhibits a broad spectrum of antitumour activity, while the hydrolysed form inhibits most effectively the growth of sarcoma 180 (equally toxic doses were compared). The highest effectiveness is, however, achieved when the carboxamide groups are distributed along the main copolymer chain. The enhanced anticancer activity of the cobalt, copper, and nickel salts of the copolymer of ethylene and maleic anhydride against Walker sarcoma in mice was also discovered by Hodnett et al.[44]

Another polyanion, a pyran copolymer, investigated by Merigan, Regelson and coworkers[45–48], exhibits an interesting antitumour activity. To facilitate its elimination from the organism (with urine), it is convenient to employ a polymer with a molecular weight of 17 000. It was established that the pyran copolymer induces the formation in the organism of an active interferon, giving rise thereby to a broad spectrum of carcinolytic activity[49]. Interferon, which is a low-molecular-weight protein, exhibits a universal antiviral activity. It appears in the cells of many animals and man as a result of the action of virusus and viral nucleic acids. Its activity against carcinogenic viruses has been demonstrated[49].

The monomeric pyran ring is formed in the polymer chain after the copolymerisation of divinyl ether with maleic anhydride (in a pure form and with a 50% admixture of the amidoacid form) or by the interaction of methyl vinyl ether with maleic anhydride (also in a pure form and with a 50% admixture of the amide). Other methods of synthesising this ring are also known, for example, by the reaction of maleic anhydride and styrene. It has been established that methylation of 50% of the carboxy-groups does not block the formation of interferon, while amidation sometimes does have a blocking effect. The capacity of these copolymers to induce the formation of interferon depends on the steric accessibility of the carboxy-groups at the instant of their addition to cancer cells. Copolymers without free carboxy-groups are inactive[45].

Finally, special mention should also be made of the search for carcinolytic substances directly related to Szent-Gyorgyi's interesting hypothesis concerning the essential nature of the cancer cell[50]. According to his view, the cells of a living organism are in a state of equilibrium in the presence of free methylglyoxal. By virtue of its high activity, only traces of methylglyoxal are required for normal cell reproduction. The division of normal cells begins as a result of the liberation of the enzyme glyoxalase,

which inactivates methylglyoxal. When the cell is capable of binding glyoxalase, division ceases at the required instant. If the cell loses this capacity, it changes, according to Szent-Gyorgyi's idea, from a normal to a cancer cell. Possibly special administration of glyoxalase-inactivated methylglyoxal from the outside might have a definite therapeutic effect. Polymeric carriers have the ability to maintain a constant therapeutic concentration of methylglyoxal liberated on gradual decomposition of the polymer chain. Experimental evidence for the anticancer activity of methylglyoxal and its derivatives has been published in a number of studies[51, 52].

Despite the vigorous development of the applications of polymers in all branches of medicine and particularly their recent use in chemotherapy, carcinolytic activity has been demonstrated or even investigated for only a small number of polymeric preparations. The reason for this is probably lack of an exhaustive explanation of the mechanism of carcinogenesis and of the control of cell division as well as the mechanism of the antitumour activity of various polymeric substances. This hinders the search for new preparations and forces investigators to study mainly the available commercial polymers with suggested carcinolytic activity.

There is no doubt that polymers constitute an exceptionally promising field for the search for antitumour agents. They are particularly suitable for the application of the principle of latent activity (by employing carrier polymers with marked carcinolytic properties). Complexes with an ionic linkage or polymers modified by a covalently linked agent might transport the active form in a combined state to the cancer cell, where, as a result of a chemical change (decomposition, reduction, oxidation), the cytostatic activity against malignant formations may be liberated. Vast possibilities are also inherent in the use of synthetic polycations as covalent or ionic carriers of alkylating agents. Thus, there are many possibilities in polymer cancer chemotherapy which have not yet been utilised.

Editorial Note

The translated reviews by V. Herout and H. Z. Levinson published in this issue describe the trends in studies designed to elucidate the role of low-molecular-weight products as regulators in biological systems. Until recently the problem of chemical control was developed mainly in relation to the control of functions at the level of the organism. This problem was investigated in greatest detail for the hormonal system of mammals. During the last 15–20 years, the range of these studies has expanded significantly—new data have been obtained on hormonal control in lower animals too, particularly in arthropods, as well as in higher and lower plants.

The problem of the possible role of metabolites excreted by the organism to the surrounding medium has remained much less thoroughly investigated. Numerous facts long known to biologists have shown that these substances can function as regulators in specific interrelations between organisms. Thus it has been shown at the level of a phenomenological description that many biological phenomena, such as, for example, the mutual influence of plants (allelopathy), the interrelation between plants and insects, and the wide variety and complexity of control in communities of social insects and certain behavioural responses of fish can be accounted for only if it is assumed that chemical substances excreted by individuals into the medium play the role of regulators acting on the behaviour and vital activity of other individuals. However, owing to the inadequacy of analytical methods, the apparent analogy between hormonal control within the organism and control in social groups involving metabolites entering the medium (in "hormonal" amounts) for a long time remained largely a speculative hypothesis, which has been reflected in the appearance of terms such as "ectocrines","exohormones", and "environmental hormones".

Quite recently (at the end of the 1950s and at the beginning of the 1960s) the idea of the regulatory importance of the metabolites excreted into the medium received rigorous experimental support as a result of the employment of new physical chemical methods (chromatography, NMR, and mass spectrometry). The studies by Butenandt and Karlson, who isolated the sexual attractant (pheromone) of the silkworm and established its structure, can probably be regarded as the beginning of this new period in research on exohormones. Further studies showed that the system of chemical communication employing signalling substances (pheromones) is present not only in insects but also in higher animals, up to primates.

Even more complicated and varied chemical control mechanisms have been observed in studies on non-trophic relations in biocenoses—stable communities of various species of living organisms populating a given region. Owing to the external and dense network of trophic relations (food chains—"who eats whom") subtler relations of a purely regulatory signalling type have been discovered in communities. In other words, it has been found that ecology cannot be restricted to the study of the energy flux and metabolism in communities but must also take into account the no less important flux of signalling substances carrying information about the presence, behaviour, and physiological state of various species constituting the given biological system. This aspect of ecological studies is in fact reflected in the term "chemical ecology" which appeared recently. Some idea about the subject and scope of this concept is provided by the titles of the articles in the collected volume "Chemical Ecology" published in the USA in 1970: "Plants and Chemical Environment", "Chemical Interactions between Plants and Insects", "Hormonal Interactions between Plants and Insects", "Intraspecies Chemical Communication in Animals", "Chemical Protection Against Arthropods", etc.

For chemists the most significant aspect of this problem is the question of the nature of the substances whereby chemical control processes are achieved. It appears evident (apparently G. Frenkel' was the first to draw attention to this) that metabolites involved in basal metabolism, providing the organism with energy and constructional material, cannot behave as chemical regulators of this kind (because such metabolism is of the same type for all living beings) and that these must consist of substances the metabolism of which is fairly specific to various species. The set of such natural products, sometimes referred to as "secondary metabolites", is extremely large, particularly in plants. Isoprenoids, alkaloids, certain aliphatic and aromatic compounds, and antibiotics are usually included among them. Some of these substances (for example steroids) are known to be involved in the control of the most important biological functions at the level of the organism. However, it remained obscure for a long time whether the majority of the others fulfil any kind of function in nature or whether they are simply the metabolic "waste" of the organisms producing them. Chemical ecological data have now demonstrated convincingly that at least some of the "secondary metabolites" do in fact play the role of regulators in the interrelations between organisms at the level of populations and communities.

Thus both at the level of the organism and at the level of communities of organisms, there is a characteristic chemical communication channel between individual components of the biological system, certain types of low-molecular-weight natural products being widely used as signals.

The problem of the way in which this chemoregulating system functions is still obscure, but in one of its main aspects the problem is essentially one of chemoreception. One must emphasise that the latter hardly reduces to the problem of the mechanism of signal reception by specialised organs of taste and smell in animals but embraces the entire range of interactions of the signal molecule with the receptor in a particular biological system.

Another important aspect of the problem of chemical control is related to the study of the question of the organisation of the system governing the chemical communication channel. Interesting data on this question were obtained by Sutherland, who found that in many cases the hormonal control system in the animal organism is constructed as a system of primary messengers (hormones), which induce in the target cells the formation of a secondary messenger (cyclic adenosine 3,5'-monophosphate, cyclic AMP). Possibly the principle of this type of hierarchy of signal systems is as common as the principle of the hierarchy of the control systems in biological organisation.

The entire range of problems associated with chemical control is of undoubted interest to chemists. The literature on this general problem is extremely large and could not be covered by the two reviews published here. Therefore we felt it necessary to include an additional list of references, which provides more complete information about the principal trends in studies on chemical control phenomena.

This list of references, divided into several fairly arbitrary sections, is quoted at the end of the list of references in Levinson's review.

Effect of Impurities on Radiation-chemical Processes in Crystals of Inorganic Salts

V.V.Gromov

Research results obtained on radiation-chemical processes in crystals of inorganic salts having composite anions (nitrates, sulphates, oxyhalides, etc.) containing various chemical impurities are analysed. The effect of water of crystallisation on the mechanism of the radiolysis and on the radiation-chemical resistance of inorganic compounds is examined. The role of heterophase additives (of a mixture of inorganic substances), the conditions of exposure, and the mechanism of transfer of energy in irradiated systems are discussed. The contributions of various factors (ionisation potentials of lattice ions, electron affinity of radiolysis products, lattice parameters, electrophysical properties of impurities, etc.) to the radiolysis of inorganic salts are estimated. Possible ways of controlling the radiation resistance of exposed materials are discussed.
The bibliography includes 121 references.

I. INTRODUCTION

Research on the effect of ionising radiations on crystalline compounds has been especially widely developed during the past 15–20 years, largely because of the need to ascertain how corpuscular radiation and γ-rays affect the diverse structural materials employed in reactor engineering and also to establish the general features of radiation and radiation-chemical processes in various substances. Close attention has been paid in particular to the physical and chemical phenomena produced by ionising radiations in ionic compounds. This is associated e.g. with problems of trace techniques and the monitoring of radiations, study of the radiation stability of materials, and also attempts at a scientific approach to the change in properties of irradiated compounds. All these aspects require in some way a knowledge of the general mechanism (or mechanisms) of radiation-chemical processes in various classes of compounds.

Radiation and radiation-chemical processes have hitherto been most fully studied in crystals of alkali-metal halides, in nitrates, and in oxyhalides. Efforts have been directed mainly at identifying the products of radiolysis, studying the kinetics of their accumulation and annealing, establishing qualitative and quantitative relations between the yield of radiolysis products and the lattice energy,

linear energy transfer, pressure, and temperature, and recently at establishing the effect of various impurities on radiation-chemical processes. Impurities can sometimes have a decisive effect on the radiation-chemical resistance† of irradiated compounds, which can be utilised for controlling radiation-chemical processes in crystalline substances.

Although contributions increase annually, no systematic review and analysis has yet been made of the results scattered in many papers and journals, which may even in some degree hinder research in this field. The present Review attempts to fill the existing gap.

No claim is made to complete coverage of all the material. For example, the large section concerned with the radiation-thermal decomposition of solids is omitted, nor are many aspects of the action of radiation on alkali-metal halides considered. Attention is paid mainly to salts having composite anions. Deliberate restriction in the selection of material is due to the desire to adhere more closely to the essence of the question, without encumbering the paper with a mass of additional factual data. Nevertheless, references to the appropriate papers can always be found in the text.

II. GENERAL ASPECTS OF THE RADIOLYSIS OF INORGANIC SALTS

The experimental information that has accumulated on the radiolysis of salts of various acids shows that many features of radiation-chemical processes depend on the chemical composition of the test materials. Despite this, however, it is always possible to distinguish a large group (or groups) of typical primary and secondary reactions taking place whatever the compound irradiated. It is also noteworthy that the general processes do not exclude the presence of individual specific elementary reactions in the radiolysis of certain salts.

The primary processes of radiolysis comprise mainly the ionisation and excitation of anions A and cations C or the excitation of groups of ions according to fundamental schemes[1,2] of the type

$$h\nu \rightsquigarrow (K^{z_K}, A^{z_A}) \rightarrow (K^{z_K}, A^{z_A})^* \text{ or } (K^{z_K})^*, (A^{z_A})^* \quad (1)$$

$$h\nu \rightsquigarrow (K^{z_K}, A^{z_A}) \rightarrow K^{z_K-n}, A^{z_A-m}, (m+n)e^-, R_A^* , \quad (2)$$

where z is the ionic charge and R_A* are the excited radicals formed from the anions. Repeated ionisation is improbable, so that m and n are usually unity.

Because there are two main types of primary interaction of radiation with matter, the radiolysis of salts occurs in two ways—through secondary reactions of excited molecules and secondary interconversions of ionisation products—but it is often very difficult to determine the contributions of ionisation and excitation in the primary and subsequent stages of radiolysis. The reason is that present-day techniques (conductivity measurements, electron spin resonance) enable only ionised products to be reliably and fairly simply identified in a solid. The role of excited species in radiation-chemical processes must usually be assessed from indirect results. However, many analyses have recently been made of the formation of excited states and their role in various radiation processes.

† The radiation-chemical resistance of a salt is usually characterised by the extent of decomposition of the compound (Section II).

According to Lushchik, for example, a cascade of secondary electrons produces a series of electronic excitations of the ions of the main substance (of energy ~ 100 eV). These electronic states are unstable, and pass rapidly into stable electronic states of low energy—excitons and electron–hole pairs of energy ~ 10 eV—which determine the final radiation effects—luminescence, formation of colour centres, dislodged atoms, and subsequent radiation-chemical reactions—in ionic crystals[3,4]. Analogous phenomena can be observed as a result of the self-trapping of holes formed at low and even room temperature[5,6].

Elango et al.[7-10] showed in a series of experiments that colour centres are formed in alkali-metal halide crystals on exposure to light and soft X-rays. They consider that the main role is played by excitons, whose decay is able to initiate the formation of ionised species. In several papers the formation of excited species has been regarded as the primary stage of radiolysis[10-12].

Excited and superexcited electronic states evidently play an important part in radiation-chemical reactions[13,14]. However, analysis of numerous papers shows (without going into the mechanism of the primary act of absorption of the radiated energy and the intermediate stages of its transfer) that the conventional separation of all radiation-chemical reactions into two groups (reactions 1 and 2) is probably legitimate. It must be borne in mind that under certain conditions reaction (1) may precede the ionisation of cations and anions.

Certain workers usually distinguish two temperature regions when considering typical secondary reactions in the most thoroughly studied ionisation branch of radiolysis, in each of which a characteristic group of reactions takes place[1,14,15]. At low temperature (up to ~ 200°K) processes involving the recombination of radicals R with an electron are most often observed:

$$R + e \rightarrow (R^-)^* \rightarrow R^- + h\nu , \quad (3)$$

or

$$R + e \rightarrow (R^-)^* \rightarrow \text{product} . \quad (4)$$

In sulphates of alkali and alkaline-earth metals, for example, the reaction

$$SO_4^- + e \rightarrow (SO_4^{2-})^* \begin{cases} \nearrow SO_4^{2-} + h\nu \\ \searrow SO_3^- + O^-,\ (SO_3^- + O + e) \end{cases} \quad (5)$$

takes place[16], with formation of the initial sulphate ion and its radical dissociation products. At low temperatures dimerisation of the primary radicals

$$R + R \rightarrow R_2 \quad (6)$$

or

$$R_1 + R_2 \rightarrow R_2' \quad (7)$$

is also possible. The above reactions are typical of organic compounds and certain composite inorganic salts[17]:

$$ClO_3 + ClO_3 \rightarrow Cl_2O_6 . \quad (8)$$

In the region of ~ 200°K the most probable processes involve the decay of composite radicals into simple radicals and stable products:

$$R \rightarrow R_1, R_2, R_3 \ldots \text{(stable products)} . \quad (9)$$

For example[1,17]

$$ClO_3 + e \begin{cases} \nearrow ClO_2^- + {}^1/_2 O_2 \\ \searrow Cl^- + {}^3/_2 O_2 \end{cases} . \quad (10)$$

The above classification of primary reactions is, of course, extremely arbitrary, and individual deviations from the suggested scheme are possible in particular cases. Thus the dimerisation of radicals or processes resembling (8) are often observed at temperatures above 200°K.[1,15-19]

It is not only difficult but also dubious to introduce exact limits to these temperature regions without specifying the compounds. Even with a definite substance the temperature ranges within which particular radiation-chemical reactions occur may shift with the nature and the quantity of various impurities, the "biography" of the crystal, etc. It is therefore advisable to refine this concept (classification) in subsequent investigations.

Besides the above reactions there are still quite a large number of intermediate reactions of primary and secondary radicals, molecules, and fragments of composite anions or cations. Such processes fall into the main types[1]—(i) reactions between R and its breakdown products with the formation of composite radicals, e.g. $ClO-ClO_3^-$ and $N_2O_3^-$ in chlorates and nitrates respectively; (ii) interaction of thermalysed electrons with radicals and anions (processes 3–6); (iii) reactions of atomic oxygen with anions and radicals, e.g. the interaction of O and NO_2^- in the nitrates, and of ClO_3^- and O in chlorates and perchlorates; and (iv) reactions among excited molecules, ions (breakdown), and atoms with the formation of O_2 and O_3^- in oxy-salts, etc.

The formation of various products in irradiated salts may depend in larger or smaller degree on many factors. Substances that are less subject to the action of radiation possess several specific features responsible for their radiation.resistance[20]. *Radiation resistance* (or stability) is taken to be the ability of substances to withstand the action of radiation without change in their structure-sensitive properties, and could be measured by the stored energy[21-23]. This concept is close to the *radiation-chemical resistance*, which determines the extent of radiation chemical changes in an irradiated specimen, and is characterised by the yield G of the corresponding product (or decomposition of the whole compound).

The radiation-chemical yield of a particular product depends on a large number of properties of the solid, the radiation, and the conditions of irradiation. No unequivocal general quantitative relations have yet been established between G and the various parameters of the test systems. Only in isolated cases have the first steps in this direction been taken.

These two criteria, representing in different ways the interaction of radiation with a given compound, are almost identical. With alkali-metal halides, for example, a sharp distinction cannot be made between them, the differences being purely terminological. It is therefore more expedient (and even essentially more correct) to replace them by a concept such as *radiation resistance* defined by the totality of changes in the irradiated specimen due to the action of radiation. The *radiation yield* (G)—the quantity of various products (F-centres, localised holes, dislodged atoms, radicals, ions, new molecules, etc.) formed in the specimen by the absorption of 100 eV of radiant energy—must obviously be adopted as an [inverse] measure of radiation resistance. This preserves all the previously established relations for the variation in properties of exposed substances, determined by the stored energy or the radiation-chemical yield: it unites the purely "physical" and purely "chemical" approaches to the phenomenon.

The type of bond is usually very important. When various oxides are exposed in a reactor, for example, their radiation stability diminishes in the sequence

$$Al_2O_3 > BeO > ZrO_2 > SrO\ .$$

The covalent character of the bonds increases in a similar sequence[20]. Furthermore, radiation stability decreases from metallic to ionic, covalent, and molecular bonds[20,24]. These rules hold in series of compounds of the same type. However, the correlations are purely qualitative and extremely tentative.

The stability towards radiation usually increases with increase in the *lattice energy*[21-25], which is evidently one of the main characteristics determining the radiation resistance of solids. Thus the properties of ionic crystals of low lattice energy change considerably more strongly in the exposed zone than those of substances of high lattice energy. However, the resulting reversible radiation disturbances disappear far more slowly in compounds of the latter type[21,26].

The sensitivity of inorganic ionic compounds to radiation is largely dependent on the composition and on the nature of the bond. Thus in ionic crystals containing composite anions, in contrast to binary ionic salts such as alkali-metal halides, the bonds between elements in the lattice may be strong, with a small volume of free interstices‡, and hence little probability that atoms (ions) will be displaced from their normal positions. In many cases, therefore, a correlation is observed between the yields of radiolysis products from ionic salts and the free volume V_{fr} of the unit cell, defined as the difference between the volume of the cell and that of the ions occupying it[27-29]. The relation between radiolysis yields and free volume, noted by almost all authors, probably represents a cage effect. For a first-order or pseudounimolecular radiolytic process G and V_{fr} are related by the formula[29]

$$G = f[\exp(-k/V_{fr})]\ . \qquad (11)$$

The free volume—a phenomenological characteristic of the properties of crystals—is a parameter representing the cooperative character of the bonds in a solid that are responsible for solid-phase reactions. The disintegrating ion is usually more weakly bound in crystals with large free volumes (loose lattices): i.e. the probability of dissociation and of escape of radiolysis products from the cell is increased, while reverse processes of recombination diminish. Hence the initial yields of radiolysis products should increase, in series of compounds of the same type in which the cation or the anion is replaced (presumably also with bonds of the same character and the same lattice structure), as the free volume increases[27,28]. But macroscopic diffusion is also increased in loose crystals, which may tend to diminish the yields G.[30]

The nature of the cation has an appreciable effect on the yield G, which e.g. with nitrates increases in the sequence[28,30-33]

$$Li < Na < Rb < Cs < K$$

$$Cd,\ Ag < Pb < La < Ba\ .$$

In this case the properties of the cation must evidently also be taken into account, especially in series of salts having the same anion, besides the above role of the free volume.

‡ It makes sense to compare the volume of free interstices with the size of the lattice ions in series of salts of the same type.

Thus with silver and cadmium halides rise in the ionisation potential of the cation intensifies the irreversibility of radiolysis and increases the yield of decomposition products[34,35].

The effect of the free volume is usually decisive where the variation of ionisation potential in a series of salts of the same type is small. In salts with like anions and the same or almost the same free volumes the radiation resistance is higher in the compound whose cation has the lower ionisation potential. This is probably due to the polarising effect of the cation on the anion. Such interaction was reflected in the empirical dependence of the efficiency of decomposition of salts of the same type on the ratio of the ionisation potentials of the cations[1,36]:

$$G = G_A E_A + G_c E_c \frac{I_{M_1^+}}{I_{M_2^+}} \quad , \qquad (12)$$

where G_A and G_C are the efficiencies of decomposition of the salts calculated per 100 eV of energy absorbed solely by anions and by cations respectively, E_A and E_C their ionicities, and the I the ionisation potentials. This formula describes well the radiolysis of several halogenates at not very high temperatures (Fig. 1).

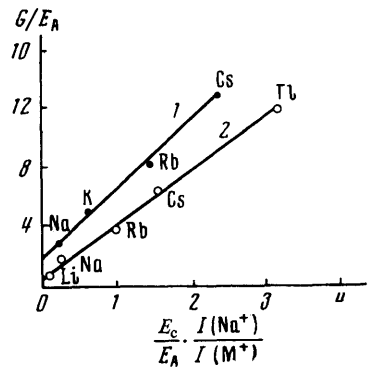

Figure 1. Dependence of radiolysis of salts on ionicity of anion and cation allowing for ionisation potential of cation[1]: 1) chlorates; 2) bromates.

Where ionisation processes predominate in the formation of the primary products, increase in their *electron affinity* involves a decrease in the radiolytic decomposition of the salts. This rule is illustrated by the selenates, sulphates, and carbonates of alkaline-earth metals (barium, calcium). In these compounds the primary products of radiolysis are the radical-ions SO_4^-, SeO_4^-, and CO_3^-, whose relative electron affinities are approximately 1 : 1.3 : 2§. The total yield of paramagnetic species from the salts follows the same sequence.

Where the formation of the primary radiolysis products involves rupture of bonds in the anion, the subsequent radiation processes depend on the electron affinity of these products. Alkali-metal nitrates, chlorates, bromates, and iodates can be included in this group of salts (with a readily broken bond in the anion). In this case increase in the electron affinity of the primary products is accompanied by an increase in the overall efficiency of decomposition of the salt. Thus because ClO_2 in chlorates possesses a greater electron affinity than does NO_2 in nitrates, the reaction

$$ClO_2 + e^- \rightarrow (ClO_2^-)^* \rightarrow ClO^- + O \qquad (13)$$

goes more strongly than does

$$NO_2 + e^- \rightarrow (NO_2^-)^* \rightarrow NO^- + O \; . \qquad (14)$$

Therefore the total yield of radiolysis products should be higher (under the same conditions) e.g. in potassium chlorate than in potassium nitrate, as is observed experimentally. The electron affinity of ClO_2 actually governs reaction (13) to some extent. However, the final yield of radiolysis products from reaction (14) largely depends on competition between deactivation of the excited state and dissociation of $(NO_2^-)^*$ into NO^- and O. Salts of this type conform to the relation

$$A_1/A_2 = K \frac{G_1(O_2)}{G_2(O_2)} \; , \qquad (15)$$

where A_1 and A_2 are the electron affinities of the primary products of radiolysis in the salts, and K is a constant representing all the factors other than electron affinity that influence the radiolysis (type of cation, free volume of lattice, energy of bond, etc.). In the above salts, for example, $A_{NO_2} = 1.62$ and $A_{ClO_2} = 3.43$, while $G(O_2)_{KClO_3} = 2.0$ and $G(O_2)_{KNO_3} = 0.8$.[31] Formula (15) is probably general in character, and can be used for the approximate comparison of radiation resistance in series of analogous salts of the second group.

The above examples show that radiation-chemical processes in salts, and hence the yield of individual products, depend on many factors governing the individual and collective interactions in the undisturbed and irradiated crystal lattice.

The linear energy transfer and the dosage rate are also very important in radiolysis[37-45]. Several investigations have recently been made on these aspects, including experiments on the exposure of various salts to heavy accelerated particles. For example, the bombardment of nitrates with protons changes substantially the rate of formation of nitrite, the initial yields of which are 0.50, 0.92, 1.65, and 2.00 for sodium, rubidium, caesium, and potassium nitrates respectively[38-41]. The γ-irradiation of these salts results in lower initial yields—approximately 0.3, 0.6, and the range 1.0–1.2 for the potassium and caesium salts[27,31].

Exposure of compressed pellets of sodium nitrate to protons produces a maximum yield of nitrite if the specimens are at +180°C.[40,42] At the same time a monotonic decrease in $G(NO_2^-)$ from 1.6 to 0.6 is observed with increase in the linear energy transfer from 2 to 6 eV $Å^{-1}$. At lower temperatures the yield of nitrite first increases and then falls with increase in the linear energy transfer (Fig. 2). These effects are well explained by the enhanced probability of reverse processes with large linear energy transfers (too high density of primary defects in the track), which ultimately lowers $G(NO_2^-)$. It is assumed further that local heating in the track tends to accelerate the radiation-chemical processes. Two regions of radiolysis are therefore distinguished: in the low-temperature range (the track is at a higher temperature than the matrix) local heating in the tracks is of decisive importance; in the high-temperature region the

§ The electron affinities were taken for the species in the gas phase (from standard tables).

yield of radiolysis products is affected mainly by processes of recombination in regions having a high content of primary products (the yield $G(NO_2^-)$ decreases).

It has been concluded[43] from a study of the radiolysis of alkali-metal azides, perchlorates, and nitrates by cobalt-60 γ-quanta and by protons that the variation in yield of products cannot be explained by thermal effects in the track even with large linear energy transfers. It was also shown that the bombardment of azides, nitrates, and especially perchlorates by protons diminishes the dependence of the yield on the free volume of the unit cell.

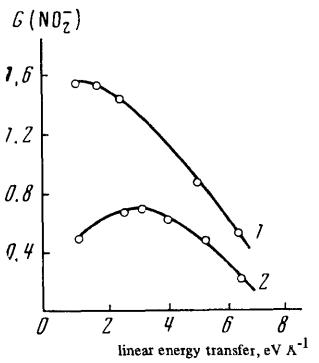

Figure 2. Variation in yield of nitrite in proton-irradiated compressed sodium nitrate pellets for radiolysis at: 1) 180°C; 2) 25°C[40].

Several investigators prefer to explain the variation of yield with linear energy transfer solely by thermal effects in the tracks[37,38]. It was also suggested that charges may be displaced in the region of the tracks, with intensified dissociation of lattice ions[39].

The effects of dosage rate on radiation-chemical processes in various salts involve problems closely similar to the influence of linear energy transfer on yield, but have not yet been studied in adequate depth. Most of the relevant publications reveal no variation in yield at different dosage rates[39,44-50]. For example, variation in the rate of electron irradiation from 10^{17} to 10^{20} eV g^{-1} s^{-1} produces hardly any change in $G(NO_2^-)$ in potassium, sodium, caesium, and lead nitrates[48], a conclusion supported by other work[46,47] for a wider range of dosage rates (10^{15}–10^{20} eV g^{-1} s^{-1}) and other forms of radiation. Similar conclusions can be reached also for chlorates and bromates[49,50].

The above examples still do not give complete clarification of this field. Thus there are indications that yields of primary radicals vary with different intensities of self-irradiation in radioactive alkaline-earth metal sulphates[51-53]. Experiments with strontium sulphate crystals exposed to cobalt-60 γ-quanta have also shown that at room temperature the radical concentration ratio $C_{SO_4^-}/C_{SO_3^-}$ decreases from 2.9 to 2.1 with increase in the dosage rate from 6.2×10^{13} to 6.2×10^{16} eV g^{-1} s^{-1} (in both cases the absorbed dose was $\sim 10^{20}$ eV g^{-1}). At low dosage rates the total concentration of paramagnetic centres increases at the same time by almost 30%. The observed effects are probably caused by accelerated recombination of radicals in "hot zones" (or points), whose concentration is higher at high dosage rates[54].

The nature of the cation can exert a great influence on primary radiation-chemical processes (in series of salts of the same type, e.g. alkali-metal nitrates). Several workers consider that the yield of radiolytic decomposition products from the anion depends not only on its ionicity but also on interaction of the cation with the radiation[30,31,33,55]. Ionisation of the cation and the transfer of excitation energy (charge) from cation to anion play an important part here[1,33,56].

In concluding this Section we note that such factors as degree of dispersion, pressure, and temperature also affect the occurrence of radiation-chemical processes in crystals of inorganic salts. Increase in the dispersity of crystalline nitrates is accompanied by increase in $G(NO_2^-)$, an effect attributed to oxygen trapped in the crystal surface[55], which usually promotes the reverse reactions. Furthermore, gaseous products may migrate to the surface of fine particles, where they may react chemically among themselves and with the surrounding medium, as has been observed in the radiolysis of powdered succinic acid[57].

The effect of temperature is largely dependent on the mechanism of radiolysis and the reverse reactions, which are accelerated by heating. In sodium, potassium, and rubidium nitrates, for example, the yield of NO_2^- increases with rise in temperature above $\sim$ 130°C[41,57-61]. With sodium nitrate this is attributed[59,60] to an increased probability that excited $*NO_3^-$ ions will break down into NO_2^- and O. In the case of rubidium[41] and potassium[59] nitrates the observed increase in $G(NO_2^-)$ is ascribed to polymorphic transitions in crystals. The irradiation of potassium[16], barium, calcium, and strontium sulphates at high temperatures stimulates the breakdown of excited sulphate ions resulting from the recombination of primary SO_4^- radical-ions with electrons:

$$SO_4^- + e \rightarrow \overset{*}{SO_4^{2-}} \rightarrow SO_3^- + O^-(O + e)\,. \qquad (16)$$

A reaction of type (4) without destruction of $*SO_4^{2-}$ occurs between −196° and −50°C. There are examples in which temperature has hardly any effect on radiolysis. Thus the yields of Cl, ClO^-, Cl_2^-, O_2^-, and ClO_2 in potassium chlorate remain almost unchanged between 77° and 300°K[58].

Changes in the crystal lattice caused by pressure have an appreciable influence on the yields of radiolysis products, owing to the slowing down or acceleration of radiation-chemical reactions. Increase in pressure (preliminary compression) usually lowers $G(NO_2^-)$ in nitrates[41]. Analogous effects occur if the irradiated crystals and the surrounding medium (air, an inert gas) are under pressure[61]. The dependence of the yield of radiolysis products on pressure and temperature (both these parameters usually vary in experiments) is quite complex, and largely determined by the mechanism of primary and secondary reactions[61].

All the above features of the radiolysis of inorganic compounds depend in considerable measure on the presence of impurities, which are directly or indirectly involved in radiation-chemical processes.

III. EFFECT OF WATER OF CRYSTALLISATION ON RADIATION-CHEMICAL PROCESSES IN CRYSTALS

The effect of water of crystallisation (which can also be regarded as an impurity in the matrix of the main material) on radiolysis was first noted in 1952 during an

investigation of the photochemical decomposition of lanthanum nitrate[62]: the crystal hydrate was found to decompose more rapidly than the anhydrous salt. Somewhat later a similar effect was observed in the same salt on exposure to γ-quanta[46]. Baberkin and Proskurin then undertook a detailed study of the radiolysis of a series of hydrated nitrates of bivalent cations[63,64]. On exposure to cobalt-60 γ-rays at room temperature the tetrahydrate of calcium nitrate decomposed several times more rapidly than the anhydrous salt (Table 1).

Table 1. Effect of water of crystallisation on the radiolysis of calcium nitrate[63].

Compound	$G(NO_2^-)_{part}$	$G(O_2)_{part}$*
Cryst. $Ca(NO_3)_2$	0.25	—
Cryst. $Ca(NO_3)_2.4H_2O$	1.50	0.37±0.02
Molten $Ca(NO_3)_2.4H_2O$	0.13	0.02±0.01

* G_{part} represents the yield of radiolysis products taking into account the ionicity and the weight of the component of the hydrate from which they have been formed.

The yield of nitrite in aqueous calcium, cadmium, zinc, and magnesium nitrates varies with the dosage rate of γ-rays[64], passing through a minimum at 0.8×10^{16} eV g^{-1} s^{-1} (dose 7×10^{19} eV g^{-1}) in the case of the calcium and cadmium salts. The other two nitrates show a similar variation in $G(NO_2^-)$, but at an exposed dosage rate of 1.2×10^{16} eV g^{-1} s^{-1}. This is evidently connected with a change in the rate of certain radiation-chemical processes depending on the density of ionisation of the crystals with increase in the linear energy transfer. Furthermore, the increased yield of nitrite was attributed to reactions such as

$$H_2O + e^- \rightarrow H_2O^- \rightarrow H + OH^- \text{ aq.} \quad (17)$$

$$2H + NO_3^- \rightarrow NO_2^- + H_2O\,. \quad (18)$$

On present-day views it is legitimate to introduce these reactions, since the nitrate ion is considerably more efficient than water in capturing electrons.

Study of the radiolysis of sodium nitrate containing various quantities of adsorbed water (this salt is hygroscopic) shows[65] that the yield of the nitrite ion increases smoothly with increase in the content of water molecules in the crystal lattice of the nitrate (Fig. 3). A possible explanation of this increase in yield was the involvement of H and OH radicals of water in the decomposition of the nitrate ion, e.g.

$$NO_3^- + H^\cdot \rightarrow NO_2^\cdot + OH^-\,. \quad (19)$$

More probably increase in the water content of sodium nitrate is accompanied by a diminution of the cage effect, and the reverse reactions involving recombination of NO_2 are inhibited. It must be noted that the investigation was in effect made on the heterogeneous system $NaNO_3$–H_2O; nevertheless the yield of NO_2^- was determined by the energy absorbed not by the salt but by the whole "mixture". When the ionicity of the components is taken into account, therefore, the dependence of $G(NO_2^-)$ on the water content of sodium nitrate may be different.

Formation of H·, OH·, $HO_2^\cdot$, and O_2^-—radicals whose concentration increases with increase in the number of molecules of water of crystallisation—is usually observed in irradiated crystalline hydrates of various salts[66–75].

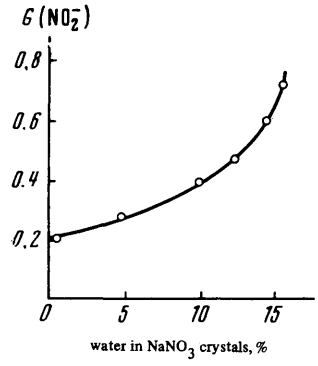

Figure 3. Variation of yield of nitrite in γ-irradiated sodium nitrate with water content of crystals[65].

Furthermore, electron spin resonance has revealed in certain salts (e.g. $BeSO_4.4H_2O$, $BeSO_4.2H_2O$, $CaSO_4.2H_2O$, $ZnSO_4.6H_2O$, $ZnSO_4.H_2O$) a paramagnetic centre (g = 2.000 ± 0.001, H = 4 ± 1 oersteds), probably due to a stabilised electron[69]. Water of crystallisation impedes[68,75] the radiation decomposition of certain salts. Thus Table 2 shows that the total yield diminishes by a factor of ten on passing from the anhydrous salt to the tetrahydrate.

Table 2. Yields of radiolysis products from beryllium sulphate and its crystalline hydrates*[69].

Compound	Temperature	G_{total}	$G_{part}(SO_3^-)$	$G_{part}(H, OH, HO_2)$
$BeSO_4$	room	0.12	0.12	—
	−196°	0.43	—	—
$BeSO_4.2H_2O$	room	0.02	0.045	—
	−196°	0.22	—	3.3
$BeSO_4.4H_2O$	room	0.005	0.016	—
	−196°	0.13	—	0.8

* Irradiation with γ-quanta (^{60}Co); dosage rate 1000 r s^{-1}.

However, radiolysis products accumulate in the same way in beryllium sulphate and in its hydrates: the concentration of paramagnetic centres increases initially, and then decreases slightly from absorbed doses of ~ 3×10^{20} eV g^{-1} (Fig. 4). Similar relations are obtained even at low temperatures, and also if the distribution of absorbed energy in the crystal according to the ionicities of the main substance and of water is taken into account[68,69].

The above results suggest that water of crystallisation exerts some "protective" action on the crystalline matrix. In the radiolysis of sulphates the water molecules may donate electrons to the primary SO_4^- radicals formed on exposure, tending to transform them to the initial state SO_4^{2-}. It is also possible that the water of crystallisation

"takes to itself" part of the radiant energy and disseminates it through the lattice, which ultimately leads to heating of the whole specimen. The hypothesis that products of the radiolysis of water take part in radiation-chemical processes with radicals of the main substance is not considered[68,69], since the yield of radiolysis products in specimens having a high content of water of crystallisation remains depressed as the temperature of the experiments is lowered to −196°C (Table 2), when reactions between radicals can be neglected.

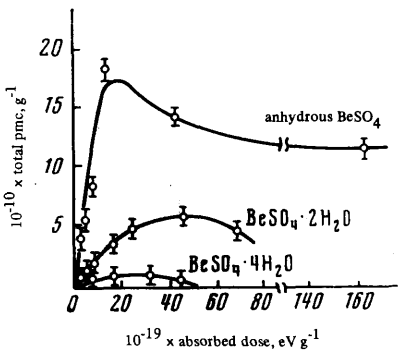

Figure 4. Accumulation of sum of paramagnetic centres (pmc) in γ-irradiated beryllium sulphate and its hydrates at room temperature[69].

Interaction between products of the radiolysis of water molecules probably occurs in the crystalline hydrates of transition metals ($MnSO_4.H_2O$, $NiSO_4.6H_2O$, $CoSO_4.7H_2O$).[73] Thus the suggested mechanism of the radiolysis of manganese sulphate hydrate by γ-irradiation may involve a reaction such as

$$MnO(SO_4) + H_2 \rightarrow MnO_2 + 2H^+ + SO_3^{2-} . \qquad (20)$$

The hydrogen and the intermediate compound of quadrivalent manganese are formed by radiolysis of the initial compound. The crystalline hexahydrate of ammonium iron(II) sulphate undergoes extensive decomposition after treatment with hard X-rays, to give products such as Fe^{3+}, SO_3^{2-}, and H_2 in maximum yields of 1.8, 0.43, and 0.35 respectively[74]. Chemical interaction between products of the radiolysis of water and the main compound is assumed also here.

Aqueous sulphates of copper, magnesium, zinc, and chromium remain almost undecomposed by cobalt-60 γ-rays. The radiant energy is mainly adsorbed by the water of crystallisation, which decomposes into oxygen and hydrogen. In $Li_2SO_4.H_2O$ exposed at the temperature of liquid nitrogen to accelerated electrons (1 MeV), for example, appreciable decomposition of the sulphate ion could not be detected even by such a sensitive method as electron spin resonance[72,75,76].

Although the effect of water of crystallisation on the radiolysis of salts has not yet been finally settled, existing experimental results indicate that the water is able to protect the matrix of the main substance from destruction when the radiolysis products do not undergo chemical reactions with ions or radicals of the compound[68,69]. If, however, water or its radiolysis products are involved in radiation-chemical processes, decomposition of the salts is promoted.

Further investigations on these lines will help to provide a deeper understanding of radiation-chemical processes in crystalline hydrates.

IV. RADIATION-CHEMICAL PROCESSES IN CRYSTALS OF INORGANIC SALTS CONTAINING IMPURITIES

Experimental workers encountered the effect of impurities on the radiolysis of solid compounds literally in the first investigations of radiation-chemical processes in inorganic compounds. However, systematic research on this aspect has been undertaken only recently.

In 1958 Cunningham and Heal expressed the view that impurities and lattice defects have no significant influence on the radiolysis of potassium nitrate[47]. This largely unfounded statement was very soon refuted. For example, not only the yield of nitrite but also the kinetics of the accumulation (annealing) of the radiolysis products are changed in potassium nitrate contaminated with strontium, lead, thallium, and sulphate ions[77]. The strongest effect is exerted by strontium and lead(II) ions, which produce cationic vacancies in potassium nitrate (the impurities were introduced into the crystals by fusing the nitrates and potassium sulphate with potassium nitrate at 340°C). It was also noted that thallium(I) ions, which are electron donors, increase the yield of nitrite, whereas strontium and lead(II) ions lower the yield. This is due to competition between impurities and radiolysis products for the electrons involved in the radiation-chemical processes. It is significant also that sulphate ions, which give anionic vacancies, hardly affect the rate of annealing of defects, whereas lead and strontium impurity ions accelerate the annealing.

Tervalent rare-earth metal ions inhibit the radiolysis of crystalline nitrates; those which are able to pass into the quadrivalent state (primarily Ce^{3+} and Pr^{3+}) are less effective[78]. Donor–acceptor interaction between impurity and radiolysis products probably occurs here also. The authors assume, as in their early papers[77,79], that the inhibition of radiolysis by impurity rare-earth metal ions is due to the resulting cationic vacancies, which facilitate recombination processes in the irradiated system.

A similar view was developed[80] in an investigation of the radiolysis of sodium nitrate contaminated with calcium ions replacing sodium isomorphously in the crystal lattice. However, decomposition of the nitrate is intensified in this case, although the proportions of the radiolysis products remain unchanged.

Impurities in potassium nitrate crystals which should produce neither cationic nor anionic vacancies (potassium hydroxide was introduced by fusion) nevertheless do affect radiolysis[81,82]. The yield of nitrite in potassium nitrate contaminated with the hydroxide is higher than in pure specimens. Furthermore, the yield at a dosage of $\sim 2.5 \times 10^{18}$ eV g^{-1} first increases with the alkali concentration, and then decreases, approaching the value of $G(NO_2^-)$ for the pure salt. These results are explained by the effect of hydroxide ions on the localisation and the decay of excited states of nitrate ions. It is also possible that hydroxide ions may take part in radiation-chemical reactions with radiolysis products of potassium nitrate.

The radiolysis of potassium nitrate is inhibited by contamination with nitrite and perchlorate ions[83]. The yield of nitrite in the impure crystals is 1.15, which compares

with the 1.7 obtained[81] for the pure crystals. A mechanism of acceptor–donor interaction[71-80] probably operates here.

According to the views developed earlier, univalent anionic impurities, included isomorphously in the lattice of potassium nitrate, compete with radiolysis products in reactions involving electrons, which may either accelerate or retard (depending on the mechanism of radiolysis) breakdown of the crystalline matrix.

It has also been shown[83] that the yields of radiolysis products from potassium nitrate (NO_2^- and O_2) increase sharply at temperatures above 128°C, when potassium nitrate undergoes a transition from a rhombic to a trigonal structure.

Lykhin and Boldyrev made a detailed investigation of the radiolysis of sodium nitrate contaminated with silver, thallium(I), strontium, and lead(II) ions, introduced into the crystals by fusing the nitrates with sodium nitrate[84]. The products were exposed to X-rays in air. The experiments support the main concept of the authors that bivalent ions facilitate breakdown of an excited nitrate ion by generating cationic vacancies in the potassium nitrate lattice. This occurs because the cage effect diminishes in the vicinity of a cationic vacancy. Therefore the yield of the nitrite ion is increased in sodium nitrate contaminated with bivalent cations. On the other hand, vacancies promote annealing reactions (the yield falls), which occur at an appreciable rate at high temperatures. As a result of competition between these processes the yield of nitrite becomes even smaller in the impurity crystals, relative to that in the pure crystals, as the temperature of irradiation is raised (Fig. 5).

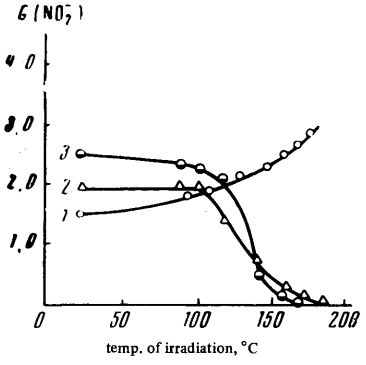

Figure 5. Dependence of yield of nitrite on temperature of irradiation[84] for: 1) pure KNO_3; 2) KNO_3 + 2.5 mole % Sr^{2+}; 3) KNO_3 + 2.5 mole % Pb^{2+}.

Several workers have observed that annealing processes are accelerated in crystals in which impurities have created cationic vacancies (and thereby facilitated the movement of products of radiolysis)[15,59,77,85-87]. Thus Mohanty has demonstrated that aluminium ions present in lead nitrate increase appreciably the rate and the degree of annealing of radiation disturbances in exposed crystals[87]. Contamination with bivalent cations (strontium, lead) accelerates considerably annealing processes in potassium nitrate[59,77]. The effect of impurities is especially noticeable during the initial periods of annealing (Fig. 6). It is significant that the sulphate ion, which should form anionic vacancies, has no effect on annealing (curves *1* and *2*).

An investigation of annealing in proton-irradiated crystals of sodium, potassium, and rubidium nitrates (contaminated with calcium, cadmium, and strontium) has led to the conclusion[15] that annealing is decisively affected by impurities producing cationic vacancies, on which intermediate products of radiolysis may even "accumulate". The donor–acceptor properties of the impurities are regarded as of no significance. This view cannot be fully accepted, since the acceleration of annealing observed in crystals of alkali-metal nitrates is not entirely unambiguous.

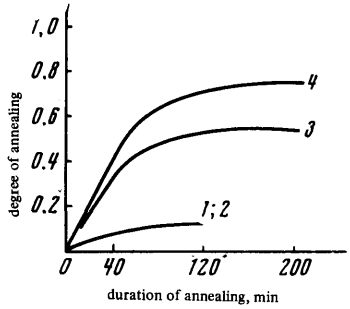

Figure 6. Effect of impurities on the post-radiation (absorbed dose 20.8 Mrad) annealing of potassium nitrate crystals at 130°C[85]: 1) pure specimen; 2) KNO_3 + 1.5 mole % K_2SO_4; 3) KNO_3 + 2.5 mole % $Sr(NO_3)_2$; 4) KNO_3 + 2.5 mole % $Pb(NO_3)_2$.

The slowing down of annealing processes in rubidium and caesium nitrates contaminated with carbonate ions (0.6–3 mole %) is attributed to an increase in the yield of nitrite when the crystals are irradiated with protons[88]. The carbonate ions are assumed to be balanced in the nitrate lattice by an increase in the number of interstitial ions and a decrease in the number of cationic vacancies. The increased yield is therefore due to a slowing down of radiation annealing on cationic vacancies. In addition to this mechanism, colour centres formed on anionic vacancies (some result from the incorporation of carbonate ions) may prevent the recombination of electrons with radicals by promoting the breakdown of radical products to nitrite.

The decrease in rate of radiolysis of sodium nitrate containing isomorphous silver nitrate as impurity is explained by Cunningham solely by the acceptor properties of silver ions[89,90].

Similar conclusions have been reached for the radiolysis (by X-rays) of lead azide containing a homophase impurity (silver or copper ions)[91,92]. The radiation decomposition of the azide is accelerated quite considerably by silver ions, the effect tending to saturation at an impurity content of ~ 10 mole %. The introduction of copper ions into the azide produces a sharp decrease in rate of radiolysis proportional to their content. Experiment shows that radiolysis is accelerated by impurities that increase the concentration of electrons in the material,

and slowed down by impurities that diminish the number of free electrons. This rule holds, of course, only if electrons are involved in reactions tending to increase the yield of radiolysis products[29,79,93].

We cannot in general confine our attention to the donor–acceptor action of impurities when considering the effect of foreign ions on radiolysis. Indeed, change in the nature and concentration of various defects in the preparation of crystalline compounds may affect also the fate of excited states. This indicates the complicated and multistage character of the influence of homophase additives on the radiolysis of solid compounds. When the impurity enters the lattice isomorphously, replacing ions of the main substance at lattice points and producing no vacancies, the impurity may act mainly by taking part in radiation-chemical reactions. For example, the increase in the yield of radicals observed in experiments with irradiated crystals of potassium perchlorate is due to the diminished probability of the recombination of electrons with radicals caused by the impurity silver ions, which act as acceptor centres for electrons[94]. But the effect of impurity copper ions in accepting electrons is probably balanced by a diminished concentration of anionic vacancies, and the copper ions act only as centres of recombination:

$$ClO_4^- + Cu^{2+} + e \rightarrow ClO_4 + Cu \rightarrow ClO_4^- + Cu^+ . \qquad (21)$$

As a consequence of these reactions the degree of decomposition of potassium perchlorate decreases[94].

The results of experiments with impure crystals can sometimes be explained by redistribution of the radiant energy and the localisation of electrons (holes) in specimens with defects. Thus powdered crystalline barium sulphate contaminated with nitrite and nitrate ions exhibited inhibited radiolysis of the main substance with intense decomposition of the impurity. This is explained by a hole–exciton mechanism of transfer to the impurities of the energy absorbed by the whole crystal lattice. Defects such as vacancies formed in the vicinity of an impurity may serve as sites for the localisation of holes and the destruction of excitons, which will lead to decomposition of the impurity[95–98].

Preferential radiolysis of impurities has been observed in crystals of sodium sulphate, lithium sulphate monohydrate[99], and strontium phosphate[100]. Various impurities of both donor and acceptor types—nitrite, sulphite, nitrate, and formate ions, hydrogen peroxide, methanol, benzene—were studied in the latter work. In all cases the impurity ions underwent considerable radiolysis. Their effect on the course of radiolysis of the carrier material largely depended on their donor–acceptor properties and on the transfer to the impurities of the energy absorbed by the crystal.

One consequence of the work on the radiolysis of contaminated barium sulphate is to establish that energy absorbed in an irradiated crystal can be transmitted to considerable distances[97]. Such a process is evidently quite possible, since energy transfer has already been observed between spatially separated rare-earth metal ions in crystals of the chlorides and bromides of various elements[101,102].

A purely electron–hole mechanism of the effect of impurities on the concentration of radiation defects has been postulated[103]. The number of localised holes in γ-irradiated α-alumina at 77°K increases proportionally to the content of the impurity ion Ti^{4+}. The latter, being located at an Al^{3+} lattice point, captures an electron, thus presenting its recombination with a hole.

There are indications that radicals formed from impurities may interact chemically. In fused potassium chloride crystals containing hydroxide and cyanide or nitrite impurity ions, for example, photolysis was followed by formation of a radical type of impurity HNO_2^-. Such reactions as

$$\rightsquigarrow HO^- \rightarrow H^\cdot + O^-$$

and

$$H^\cdot + NO_2^- \rightarrow HNO_2^- \qquad (22)$$

probably occur in this system[104].

At the conclusion of this Section it must be noted that the concept of the donor–acceptor effect of impurities on radiolysis, the vacancy mechanism, the transfer of the radiated energy from the matrix to impurity ions, and the mutual stabilisation of defects have long been successfully used in investigating the radiolysis (or coloration) of alkali-metal halide crystals. The literature on this problem is vast, so that it is sufficient to give merely a few examples. Thus transition-metal impurities (nickel, copper) in sodium chloride accelerate the decay of F-centres[105]. Traces (0.01 wt.%) of chromium, manganese, iron, cobalt, and nickel are electron traps and sources of vacancies (potassium chloride and bromide crystals)[106]. Contamination with sulphate, nitrate, and hydroxide ions diminishes the probability of the formation of F-centres, since radiolysis products of the impurities (O_2^-, O, etc.), being centres for the capture of electrons, compete with anionic vacancies for electrons[107]. A detailed analysis has been made[108,109] of the effect of bivalent cations (Pb^{2+}, Sr^{2+}, Ca^{2+}) and anions (S^{2-}) on the kinetics of accumulation and the stability of colour centres in potassium chloride and other alkali-metal halide crystals. Fairly complete reviews of the effect of impurities on the accumulation of various colour centres in alkali-metal halide crystals can be found[20–24,110–112].

In all cases the results have been explained (independently of the test material) in terms of the effect of vacancies created in the crystal lattice by the introduction of impurities. The donor–acceptor properties of impurities and ions of the main substance have also frequently been considered. Mechanisms involving the transfer of excitation energy from the lattice to impurities have been far more rarely analysed, although the role of such processes in a solid is quite large[3–9,20,113].

Little study has been made of the participation of impurities in intermediate reactions with radicals produced by irradiation of the crystalline matrix, the effect of the mode of inclusion of the impurity in the lattice (isomorphous or non-isomorphous), and other questions.

V. RADIOLYSIS OF MIXTURES OF INORGANIC SUBSTANCES

Although the effect of foreign impurities on radiation-chemical processes has now been studied fairly thoroughly, little work has yet been done on the radiolysis of salts with heterophase additions[90,114–118]. The first paper on the effect of impurities forming an independent phase on the radiolysis of inorganic compounds appeared only in 1967[114]. This showed that powdered thorium dioxide and nickel and zinc monoxides (particle size 90–140 μm) added in amounts of 1.5–7 mole % accelerate the radiolysis of ammonium nitrate by X-rays (the degree of radiolysis was assessed

from the total gas evolution). The efficiency of catalysis by the additives varied in the sequence

$$ThO_2 > ZnO > NiO > \text{pure } NH_4NO_3 .$$

The electronic work function φ in these oxides increases from nickel to thorium. Impurities of low work function were regarded as donors of electrons in the irradiated system. Therefore the above additives, by raising the concentration of electrons, accelerate the intermediate stages of radiolysis, which leads to the more intense gas evolution observed experimentally.

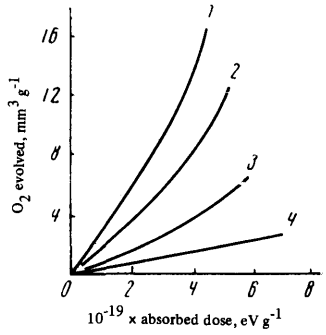

Figure 7. Radiolysis of sodium nitrate by X-rays at room temperature: 1) $NaNO_3$ (+3.5 mole % ZnO); 2) $NaNO_3$ (+3.5 mole % ThO_2); 3) pure $NaNO_3$; 4) $NaNO_3$ (+3.5 mole % CoO).[115]

This conclusion was confirmed by these workers on several new systems[92,115]. Thus Fig. 7 illustrates the radiation-chemical decomposition of potassium and sodium nitrates containing mechanically admixed powdered oxides of thorium, nickel, cobalt, and zinc. In these experiments, too, impurities of low work function accelerated radiolysis, and those with high values of φ slowed it down. By analogy with homophase additives, the impurities probably affected reactions such as[115]

$$\rightsquigarrow NO_3^- \rightarrow NO_3 + e , \quad (23)$$

$$NO_3 + e \rightarrow NO_3^- + O , \quad (24)$$

$$NO_3^- + e \rightarrow \overset{*}{N}O_3^{2-} \rightarrow NO_2^- + O^- . \quad (25)$$

A comprehensive investigation has been made of the effect of heterophase additions on the radiation-chemical stability of lead azide[116,117]. The additives used were the oxides of zinc, cadmium, cobalt, and nickel. The first two accelerate considerably the evolution of nitrogen from the azide when the mixtures are exposed to X-rays. Nickel and cobalt oxides retard the radiolysis of the azide under the same conditions. It was also found that these additives have no effect on the activation energy of radiolysis. From the results of numerous experiments the fully justified suggestion was made[116] that donor–acceptor interactions between the compounds in the mixture undergoing irradiation were of decisive importance. Introduction of a heterophase impurity of donor type increases the steady-state concentration of electrons in the irradiated system, whereas acceptor impurities have the opposite effect. As a result, radiation-chemical reactions involving electrons in silver azide are either slowed down or accelerated, e.g.

$$\rightsquigarrow N_3^- \rightarrow N_3^0 + e , \quad (26)$$

$$N_3^0 + e \rightarrow N_3^- . \quad (27)$$

Analogous effects have been observed in perchlorates[117]. It should also be noted that the donor or acceptor character of impurities is greatly dependent on the type of systems in contact during exposure, and may not coincide with assessments based on the measured work functions of the pure oxides in the absence of irradiation.

Processes entailing the redistribution (and primary distribution) of energy in heterogeneous systems under irradiation (transfer of charges, migration of excitons) should also be very important in these cases. These phenomena accompanying radiolysis can be represented by the proposed[117] empirical relation

$$v_d/v_0 = 1 + f\left(\alpha \frac{I_d}{I_0} - 1\right), \quad (28)$$

where v_0 and v_d are the rates of radiolysis of the pure salt and of the salt with the additive, I_0 and I_d are the corresponding absorbed dosage rates, α is a constant defining the transfer (redistribution) of energy between the components, and f is the fraction by weight of the heterophase additive. Experiments show that the radiant energy may actually undergo redistribution even when particles of the mixtures are in poor contact. The mechanism of such transfer is not yet clear. However, there is direct evidence that radiant energy absorbed in crystalline mixtures is able to migrate at least to distances up to 60 Å.[118]

Heterophase impurities would probably have a weaker effect than similar homophase impurities on the radiolysis of the main substance. For example, the yield of NO_2^- radicals falls with increasing contamination of barium sulphate with the nitrate ion, to reach a minimum when the latter forms a separate phase[97,98]. Hence transfer of the radiant energy, absorbed in the matrix of the main substance, to the heterophase nitrate impurity is difficult. Although heterophase additives are less effective, study of the effect of foreign mechanical inclusions on the radiolysis of various salts is a promising line of research on the radiation chemistry and the physics of solids. Heterophase additives are very easy to "introduce", a factor which may be decisive in work with impurities, limiting the experimental possibilities. Investigations in this field will probably enable new methods to be developed for systematically varying the radiation resistance of various compounds.

---o0o---

Experiment shows that external actions on a crystal, varying the mobility and the steady-state concentrations of charged species and excited states, change the rate of radiation-chemical processes. The direction of these changes can be predetermined and even controlled if the mechanism of radiolysis is known. The introduction of impurities into a crystal may be an effective method for monitoring and controlling processes of radiolysis.

Analysis of the experimental results shows that several mechanisms have been suggested for the effect of impurities on radiolysis, corresponding to the actual processes occurring in the crystal lattice.

1. Donor–acceptor interaction of impurity and products of radiolysis. The specific effect of an impurity is

largely dependent in this case on radiation-chemical processes in the exposed crystals. For example, stages of radiolysis having a radical mechanism or involving excited states will be relatively insensitive to donor or acceptor impurities.

2. Generation of vacancies by impurity ions. Vacancies may provide a site for the localisation of electrons or holes capable of increasing the mobility of the products of radiolysis, which will accelerate recombination processes. The same defects can often have opposite effects on the rate of radiolysis. For example, the addition of cadmium ions, which create cationic vacancies in the lattice of silver salts, enhances the radiation resistance of silver oxalate[119] but promotes decomposition of silver carbonate[119-121]. In this case the mechanism of the radiolysis of the specific compound is also decisive.

3. Transfer of the energy of the radiation absorbed by the lattice to the impurity, as occurs in organic systems[113]. The impurity itself decomposes, protecting, as it were, the main compound.

4. Acceleration and extension of the radiolytic decomposition of salts by interaction of radiolysis products of "impurity" molecules and matrix components. This mechanism is typical of crystalline hydrates or compounds with considerable inclusions of water molecules.

Research workers have so far paid less attention to the role of impurities in the intermediate stages of radiation-chemical reactions. The mechanism of the introduction of foreign atoms into the lattice, and hence the specific mode of participation of the impurity in radiation and radiation-chemical processes, have not always been studied in detail.

The preparation of specimens—quenching, thermal and radiation conditioning—is very important in radiation-chemical investigations. Due attention will probably also be paid to this factor in future work.

In conclusion it must be noted that the action of an impurity is usually a complicated multistage process: only in very rare cases is its role determined by a single one of the above mechanisms. And the first advances in this direction support the hope that reliable methods (and a theoretical basis) will be developed for controlling the radiolysis of inorganic compounds.

Structure and Behaviour of Aluminate Ions in Solution

N.I.Eremin, Yu.A.Volokhov, and V.E.Mironov

The most important published data on the composition and structure of aluminate ions in solutions of different concentrations and pH values are systematised and analysed. The views of various workers on the types of interaction present in aluminate solutions are discussed. The significance of different hypotheses and models of mononuclear and polynuclear aluminate ions is examined in the light of the results of recent physicochemical investigations.
The bibliography includes 154 references.

I. INTRODUCTION

The structure of aluminate ions in solution is among the most important problems in the chemistry of aluminium and also in the production of alumina by alkali methods [1,2]. Even the fundamental nature of these solutions (colloidal [3-14], or true solutions [15-25]) remained controversial until quite recently. The lack of general agreement on the nature and structure of aluminate ions in solution is due to the complexity of their behaviour and to the inconsistency of many of the experimental results which have been reported. Nevertheless, the most reliable experimental results appear to be consistent with the ionic model of aluminate solutions [1,2,19-25].

However, the problem of the composition and structure of the aluminate ion in solutions of different concentrations and pH values is still not finally settled. Hence, the structural differences between unsaturated and supersaturated solutions, and the decomposition mechanism of aluminate solutions, are also still unclear [1,2,19-23,26-28].

It is generally agreed that the predominant species in aluminate solutions (at least, in unsaturated solutions at high pH) is the mononuclear aluminate ion [22-26,29-32], although divergent views are held on the structure of this ion. The following compositions have been proposed: AlO_2^-, [22,29-31,33-41] $AlO(OH)_2^-$, [22,29-30,33] $Al(OH)_4^-$, [22,24-26,29-31,33,42-65] and $Al(OH)_4.2H_2O^-$. [19,51,66] Several workers [22,29,30,33] believe that the first three types of mono-aluminate ion can coexist in aluminate solutions as singly-charged anions with different degrees of hydration:

$$Al(OH)_4^- \rightleftharpoons AlO(OH)_2^- + H_2O \rightleftharpoons AlO_2^- + 2H_2O, \qquad (1)$$

the equilibrium being shifted towards the right by increase of temperature and concentration.

The formation of measurable amounts of ions of the $Al(OH)_5^{2-}$ and $Al(OH)_6^{3-}$ type, reported in most of the textbooks and monographs on the chemistry of aluminium, is not confirmed by experimental results [23,24].

Published information on the presence and on the existence region of poly-nuclear hydroxo aluminium complex anions in alkaline solutions is scarce, and contradictory [22,25,28,31,32]. However, this type of information is highly relevant both to the behaviour of metastable aluminate solutions and to the more general problem of poly-nuclear complex formation in solutions [67,68]. Furthermore, the control of industrial processes for the production of alumina requires a full understanding of the structure of the aluminate ions and of the phenomena which occur in supersaturated solutions.

The aim of this review is to survey and discuss critically the most important recent work which can serve as a basis for the further development of our views on the structure and behaviour of aluminate solutions.

II. RESULTS OF SPECTROSCOPIC INVESTIGATIONS

A wide range of spectroscopic methods has been applied to the study of the composition and structure of aluminate ions: Raman spectroscopy (RS), [31,39-41,52,62,63] infrared spectroscopy (IRS), [39,63,69,70] ultraviolet spectroscopy (UVS), [28,32,53,57,58,66] nuclear magnetic resonance (NMR), [30,51,60,61,63,71,72] and also X-ray [73,74] and acoustic (ultrasonic) spectroscopy [71,75].

The earliest reported (1952) RS spectra of dilute aluminate solutions [52] contained two lines (310 cm^{-1} and 615 cm^{-1} respectively) with relative intensities in the ratio of 1 : 5. The authors did not comment on the polarisation of these lines. From these results, they concluded that the $Al(OH)_4^-$ ion corresponds to the T_d model, although they were unable to observe the $\nu_3(F_2)$ line at 720 cm^{-1} which that model predicts. They merely state that the line is too weak to be observed experimentally. Further evidence in favour of the tetrahedral configuration was obtained from the values of the force constants calculated [76] by Hertzberg's method from the T_d model, which agreed satisfactorily with the values calculated from Gordy's equation [77] relating force constants and electronegativities in tetrahedral molecules. It should be noted, however, that neither the T_d nor the O_h symmetry is fully consistent with the observed [52] spectra of the aluminate ion, since the former symmetry should give four Raman-active (normal) vibrations (including two at similar energies), and the latter symmetry should give three active vibrations [52,78]. In any case, conclusions made from Raman spectra should be confirmed by IR spectroscopy whenever possible.

Lanaspeze and Eyraud[62] agreed with these conclusions[52], although they observed only one ν_1 line (at 615 cm^{-1}) in the Raman spectra of their aluminate solutions. They, also, did not comment on the polarisation of this line.

More recent work[31,39-41,63] on the Raman spectra of aluminate solutions covers a range of pH values and concentrations, as well as exploiting the helium–neon laser as a source of radiation. Only one of these investigations[63] is in partial agreement with the previous work[52,62]. Carreira and coworkers[39] found that at pH $\geqslant$ 13 the Raman spectra contain only one line, at 628 cm^{-1}, with a depolarisation ratio close to zero. At lower pH values they observed three lines (540, 625, and 830 cm^{-1}) and they found that the 830 cm^{-1} line is polarised. All these findings were confirmed (within measurement error) by other workers[40,41], who reported lines at 530, 620, 630, and 825 cm^{-1}. Some experimental data, together with the vibrations expected for the most likely symmetries with allowance for the selection rules and for line polarisation, are shown in Tables 1–4 and in Fig. 1.

Table 1. Raman and i.r. spectra of 4 M aluminate solutions (after Carreira and coworkers[39]).

pH	ν, cm^{-1} exper.	ν, cm^{-1} calc.	Depolarisation ratio	Line width $\Delta\nu$, cm^{-1}	Symmetry and activity of vibrations in Raman or i.r. spectra	
10.2	830	910	0	25	ν_1 (A_{1g} Raman)	O_h
	625	—	6/7	40	ν_2 (Eg Raman)	
	1240	1209	—	35	ν_3 (F_{1u} i.r.)	
	—	606	—	—	ν_4 (F_{1u} i.r.)	
	540	—	6/7	30	ν_5 (F_{2g} Raman)	
	—	—	—	—	ν_6 (F_{2u} i.r. inactive)	
13	628	—	0	35	ν_1 (A_1 Raman)	

The results given in Table 2 show a spontaneous change in the intensity of the Raman spectra, accompanied by a change in pH, if the pH of the solution is below 12.5–13.0. According to Tables 2 and 3, and Fig. 1, the bands at 530 and 825 cm^{-1} become weaker, and the band at 620 cm^{-1} becomes stronger, as the solution becomes progressively more alkaline. It is evident from Table 4 that in the pH region 8.3–13 the presence of three Raman lines cannot be reconciled with the $D_{\infty h}$ symmetry of the AlO_2^- ion for any of the models considered. Since none of the RS lines is found in the IRS (Table 1), we may assume that the aluminate ion is centrosymmetric[76,79]. Hence, the presence of $AlO_2^-(C_{2v})$ and $Al(OH)_4^-(Td)$ anions in solutions of pH $\leqslant$ 13 is not experimentally confirmed. The existence of aluminate ions having the O_h symmetry in weakly alkaline solutions is not eliminated by the spectra, but it is not confirmed by the vast majority of experimental results[23,24].

Thus, by comparing experimental results[31,39-41] with the calculated results of Table 4 we are led to the conclusion that solutions of pH $\leqslant$ 13 contain either $Al(OH)_4^-$ ions with the D_{4h} symmetry or polymeric associations, for which the linear group factor is isomorphous with the $D_{2h}(XY_4Z_2)$ or $D_{4h}(XY_4Z_2)$ point group. In the latter case the vibrations should be the same as in the octahedral $Al(OH)_6^{3-}(O_h)$ molecule if the transition from the octahedron to the polymer does not produce splitting of the degenerate vibrations or if the splitting is masked by solvent effects.

The presence of a planar $D_{4h}(XY_4Z_2)$ polymer in aluminate solutions seems unlikely. Therefore, the experimental results indicate an $Al(OH)_4^-$ structure, with D_{4h} symmetry, or an octahedral polymeric structure, $[Al(OH)_4]_n(OH)_2^{(n+2)-}$, with D_{2h} symmetry. However, the observed ageing of aluminate solutions accompanied by slow changes in pH,[30,31,48,49] and also the electrochemical measurements reported by Plumb and Swaine[78], convincingly point to the presence of polymeric aluminate ions in weakly alkaline solutions (pH $\leqslant$ 13).

Table 2. Raman spectra of 3 M aluminate solutions as a function of ageing time[40].

In the region of pH $\geqslant$ 13, the requirement of a single, polarised line at 630 cm^{-1} is satisfied only by the AlO_2^- structure with $D_{\infty h}$ symmetry (Tables 1 and 4, Fig. 1). This conclusion is confirmed by the absence of isotopic shifts in the spectra of deuteriated aluminate solutions at pH $\geqslant$ 13 (Fig. 1), which shows that in these solutions practically none of the protons are combined with aluminium through oxygen. On the other hand, the shift of the Raman bands towards lower frequencies following deuteriation at pH $\leqslant$ 13 (Fig. 1) justifies the conclusion[31,39-41] that under these conditions the Al ligands are hydroxyl ions.

The Raman spectra of potassium aluminate solutions [41] are practically indistinguishable from those of sodium aluminate. This suggests that the AlO_2^- and $[Al(OH)_4]_n(OH)_2^{(n+2)-}$ ions undergo only outer-spher interactions [80] with the alkali metal cations. Outer-sphere complex formation in aluminate solutions can be represented by the reactions

$$x\,M(H_2O)_y^+ + (OH)_2[Al(OH)_4]_n^{(n+2)-} \rightleftharpoons \{[M(H_2O)_y]_x(OH)_2[Al(OH)_4]_n^{x-n-2}\}, \quad (2)$$

$$M(H_2O)_y^+ + AlO_2^- \rightleftharpoons [M(H_2O)_y]AlO_2, \quad (3)$$

where M is an alkali metal cation.

Table 4. Symmetry and spectroscopic data according to the selection rules for structures similar to the aluminate ion [31,39].

Chemical formula	Точечная группа	I.r. active vibrations	Raman active vibrations	Inactive vibrations
AlO_2^-	C_{2v}	$\nu_1(A_1)$ $\nu_2(A_1)$ $\nu_3(B_2)$	$\nu_1(A_1)$ $\nu_2(A_1)$ $\nu_3(B_2)$	
	$D_{\infty h}$	$\nu_1(E1u)$ $\nu_3(A1u)$	$\nu_1(A1g)$

	D_{2h}	$\nu_3(B1u)$ $\nu_3'(B2u)$ $\nu_3''(B3u)$ $\nu_4(B1u)$ $\nu_4'(B2u)$ $\nu_4''(B3u)$	$\nu_1(Ag)$ $\nu_2(Ag)$ $\nu_2'(B1g)$ $\nu_5(Ag)$ $\nu_5'(B2g)$ $\nu_5''(B3g)$	$\nu_6(Au)$ $\nu_6'(B2u)$ $\nu_6''(B3u)$

*These lines were predicted by Lippincott and coworkers [52].

The large charge of the $[Al(OH)_4]_n(OH)_2^{(n+2)-}$ ion could lead to association of this anionic ligand with several cations. Hence, we could discuss these systems from the standpoint of polynuclear outer-sphere complex formation [81], possibly complicated by inner-sphere interactions in concentrated solutions, which may become significant when the system passes through the full solvation boundary [82].

Moolenaar and coworkers [63] also studied the state of aluminium in alkaline aqueous and deuteriated solutions by RS and IRS methods. They also examined the NMR spectra of ^{23}Na and ^{27}Al, covering the concentration range 0.5–6.0 g-ion litre^{-1} of Al. They were unable to prepare solutions containing appreciable quantities of aluminium at pH $\leqslant$ 13, such as had been prepared by earlier workers [39–41], and, therefore no comparison is possible outside the strongly

The RS and IRS results obtained [63] in aqueous and in deuteriated aluminate solutions at pH > 13 are summarised in Table 5. At aluminium concentrations below 1.5 g-ion litre^{-1} we find four vibrational bands, two of which correspond to infrared-active vibrations (950 and 725 cm^{-1}) and three to Raman-active vibrations (725, 625, 325 cm^{-1}). However, on raising the concentration of aluminate ions beyond 1.5 g-ion litre^{-1} new spectral bands are observed (900 cm^{-1} in the IRS and 705 and 540 cm^{-1} in the RS). The additional, weak Raman lines, which had not been observed by earlier workers [39–41,52], are ascribed [63] to the use of a more powerful source of radiation. None of the strongly alkaline aluminate solutions studied in this work [63] showed any significant ageing effects.

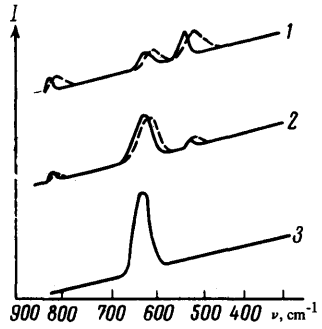

Figure 1. Raman spectra of 3 M aqueous solutions of sodium aluminate [41]: *1*) pH 10.5, *2*) pH 12.7, *3*) pH 12.9. The broken lines correspond to 80% deuteriated samples.

The Raman spectra of strongly alkaline aluminate solutions containing less than 1.5 g-ion litre^{-1} of aluminium are claimed [63] to be consistent with the tetrahedral model of the $Al(OH)_4^-$ ion predicted by Lippincott [52] (see Table 4). The IRS results only partly confirm this claim. According to Table 4, aluminate ions with T_d symmetry should give rise to two lines, both IRS and RS active. One line at 725 cm^{-1} (Table 5) satisfies this condition, but the second broad and weak IR line at 950 cm^{-1} is absent in the RS. This band cannot be seen in the deuteriated solutions because its new position (close to 700 cm^{-1}) is obscured by the strong line at 745 cm^{-1}. The R line at 950 cm^{-1} is assigned [63] to Al–O–H bending vibrations. The solvent isotope effect on the position of the spectral lines (Table 5) suggests that linear AlO_2^-, non-linear AlO_2^-, or indeed any solvated form of AlO_2^- containing the O–Al–O structural element cannot be present in significant amounts in aluminate solutions. NMR studies of ^{27}Al confirm that the aluminate ion has a tetrahedral configuration.

Additional evidence in favour of the T_d symmetry of the $Al(OH)_4^-$ anion in dilute solutions is obtained [63] by interpreting the spectra of concentrated aluminate solutions. Increasing the concentration of aluminate and of sodium hydroxide should favour the formation of ion pairs between $Al(OH)_4^-$ and hydrated sodium ions, with very little effect on the shape of the spectra [80]. However, this interaction could assist the formation in solution of mononuclear $AlO(OH)_2^-$ ions [29,30] or dinuclear dehydrated $Al_2O(OH)_6^{2-}$ ions. The latter were discovered and studied by Johansson [74] in crystalline potasium aluminate using X-ray diffraction spectroscopy. The $AlO(OH)_2^-$ and $Al_2O(OH)_6^{2-}$ ions have a lower symmetry than the T_d $Al(OH)_4^-$ ion, and therefore they could be responsible for the appearance of additional spectral lines in concentrated solutions (Table 5).

The monomeric, singly charged $AlO(OH)_2^-$ ion is probably the most convenient species for interpreting the vapour pressure, osmotic, and other properties of aluminate solutions [23]. However, Moolenaar and coworkers [63] prefer to discuss their results in terms of the dimeric, doubly charged $[(HO)_3Al-O-Al(OH)_3]^{2-}$ ion.

Table 5. Raman and i.r. spectra of aluminate solutions [63]*.

Composition of solution	Raman ν, cm^{-1}		I.r. ν, cm^{-1}	
	in H_2O	in D_2O	in H_2O	in D_2O
1 g-ion Al $litre^{-1}$	–	–	~950	–

6 g-ion Al $litre^{-1}$	–	–	900 ± 5 s	895 ± 5 s
2.3 mole $litre^{-1}$ NaOH (excess)	705 ± 10 p –	725 ± 10 p –	– 725 ± 5 s	– 745 ± 5 s
	625 ± 2 s, p 540 ± 5 p 330 ± 10 w, dp	605 ± 2 s, p 534 ± 5 p 316 ± 10 w, dp	625 ± 3 v.w.	–

*s = strong, w = weak, vw = very weak, p = polarised line, dp = depolarised line.

Their only evidence for this choice is the similarity between the spectra of the solutions (Table 5) and the IR and Raman spectra of the dimeric ion in the solid state. A comparison of the spectra for the solid and the liquid phase, allowing for the spectral effects of the phase itself, has shown that all the bands found in concentrated solutions (Table 5) appear also in the spectra of the solid material. However, the latter contain additional bands at wavelengths which are obscured in aluminate solutions by strong bands from the solvent and from the $Al(OH)_4^-$ monomer. Hence, the conclusion [63] is that two types of ion coexist in concentrated aluminate solutions: $Al(OH)_4^-$ and $Al_2O(OH)_6^{2-}$, having T_d and C_s symmetry respectively.

Moolenaar and coworkers [63] also made another interesting observation: the IR, Raman, and NMR spectra of 2 M aluminate solutions containing ions of both types remain unchanged at temperatures up to 150°. Obviously, the equilibrium is relatively independent of temperature, or the concentration of dimeric ions is not large enough to influence the spectra significantly. If the first explanation is correct, the effect of temperature on the stability of metastable aluminate solutions cannot be ascribed to a structural rearrangement of the aluminate ion.

It should be noted that most of the concentrated aluminate solutions examined by Moolenaar and coworkers [63] were supersaturated with respect to aluminate ions, and therefore some caution is needed in extending their results and conclusions to the structure of unsaturated aluminate solutions. So far, the only (indirect) confirmation of the existence of polymeric ions with a single Al–O–Al oxygen bridge in supersaturated solutions of hydrated sodium aluminate comes from the work of Ni and coworkers [69,70], who also observed lines at 900, 740, 635, and 540 cm^{-1} in the IR spectra of their aqueous solutions. By comparing these spectra with those of the solid salt $K_2O.Al_2O_3.3H_2O$, whose lattice is known to consist of double $Al(OH)_4^-$ tetrahedra [83] joined by a single oxygen bridge, those workers concluded that a similar structure must be present in solution. Their Raman spectra [70] were not fully consistent with those of Moolenaar [63].

Thus, a search of the literature on the vibrational spectra of aluminate solutions suggests that monomeric aluminate ions with T_d symmetry are present in moderately concentrated solutions at pH > 13. The problem of polynuclear aluminium complexes, and of their existence regions, requires further study.

Studies of the NMR spectra of aluminate solutions also led a number of workers [51,60,61,63,71,72,84] to the conclusion that the aluminate ion has tetrahedral symmetry. The large negative chemical shift of ^{27}Al in alkaline solutions [51,60,61,63,71] as compared with the octahedrally hydrated Al ion in acid solutions [85–88] suggests that the coordination number of aluminium in the aluminate ion is less than six.

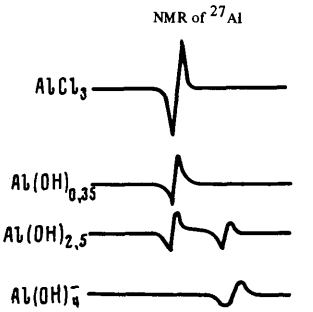

Figure 2. NMR spectra of ^{27}Al for solutions with different OH : Al ratios [51].

Fig. 2 shows the NMR spectrum of ^{27}Al in solutions with different OH : Al ratios [51]. In the acid solutions the resonance peaks are assigned to ^{27}Al in the AlO_6 group, whereas in alkaline solutions (OH/Al > 4) they are assigned to AlO_4. However, it appears from the spectra that both six- and four-coordinated aluminium ions can exist in solutions with an OH/Al ratio close to 3. This conclusion has been confirmed [89].

According to O'Reilly [60], the small width of the quadrupole line in aluminate solutions indicates a high degree of symmetry of the field surrounding the aluminium nuclei. The $Al(OH)_4^-$ ion has the required symmetry, whereas the AlO_2^- ion should give a broader line.

Mal'tsev and coworkers [30,90] used the NMR method (with ^1H and ^{23}Na) to study aluminate solutions containing up to 24% of Na_2O, and they observed a correlation between the chemical proton shift and the vapour pressure [29,30]. This work confirmed Dibrov's suggestion [29] that the tetrahydroxoaluminate ion becomes dehydrated at high concentrations according to reaction (1).

More recent work [63] also confirmed the dehydration of the $Al(OH)_4^-$ ion with increasing concentration of Na_2O and Al_2O_3, but to give the dimeric complex $Al_2O(OH)_6^{2-}$ rather than ions of the $AlO(OH)_2^-$ or AlO_2^- type. It is pointed out that the chemical shift of the ^{27}Al NMR line of the $[(HO)_3Al-O-Al(OH)_3]^{2-}$ ion should not differ significantly from that of $Al(OH)_4^-$, as is found in practice. If, on the other hand, a dehydrated ion of $AlO(OH)_2^-$ type had been

formed, no resonance would have been observed because of the line broadening caused by the asymmetric electric field gradient surrounding the nucleus of the aluminate ion. The insensitive dependence of the chemical shift of ^{27}Al on the concentration of alkali and of aluminate ions in solution can be ascribed[71] to the strong screening effect of the OH ions on the aluminium ion. Hence, the various interactions between the components of the solution and the $Al(OH)_4^-$ ion have only a minor effect on the electron density around the ^{27}Al ion.

The formation of ionic associations between sodium and aluminate ions has been convincingly demonstrated[30,63,71,90]. The increasing concentration of these associations with concentration of Na^+ ions in solution is revealed by a broadening of the ^{27}Al and ^{23}Na lines. This observation is consistent with analogous studies of the ^{23}Na line width in aqueous solutions of NaOH and certain salts[30,91,92]. Ion-pair formation significantly affects the time of half-exchange between free and associated ions in solution[30], and therefore the concentration dependence of the ^1H relaxation time observed in NMR cannot be ascribed wholly to polymerisation of the aluminate ions, as suggested by Romanov and Ni[72].

There is a single report[71], not supported by other published work[30,90,91], that the ^{23}Na resonance signal is shifted towards weaker fields in alkali as well as in aluminate solutions. The large changes in the chemical shift of ^{23}Na with Al concentration suggest that the interaction of the aluminate ions is stronger with sodium cations than with OH ions. It is important to take account of this interaction in any discussion of the bulk properties of the solution (electrical conductivity, viscosity[1,2]), and also when considering the dissociation mechanism of aluminate solutions.

The line widths and nuclear relaxation times of ^{23}Na and ^{27}Al, and also the results of ultrasonic and refractometric investigations[71], are consistent with the conclusions reached by analysing the chemical shifts of ^{23}Na and ^{27}Al. The NMR spectra indicate[71] the formation of dimeric complexes of the $Al_2O(OH)_6^{2-}$ type[63] at concentrations of aluminium above 1.5–2.0 g-ion litre^{-1}.

U.v. spectral studies of aluminate solutions over a wide range of concentrations[23,28,53,57,58,66] have identified two absorption bands at wave lengths 230 and 265 nm[32,66]. The overall absorption band[93] of aluminate solutions[32] is shown in Fig. 3 together with its expansion into two Gaussian components.

According to Taichi[66], the absorption bands at 230 and 265 nm are due to the presence of the ions $Al(H_2O)_6^{3+}$ and $Al(OH)_4.2H_2O^-$ in aluminate solutions. This assignment of the first absorption band to the hexa-aquo Al ion is not convincing, since optical studies of acid solutions of Al have shown that this ion does not absorb at wave lengths greater than 200 nm.[32,94] Equally, the presence of the $Al(OH)_4.2H_2O^-$ ion in aluminate solutions has not been confirmed experimentally[23]. Hence, we cannot accept Taichi's explanation of the anomalously high viscosity of aluminate solutions in terms of hydrogen-bond formation between these two non-existent species.

It can be seen from Fig. 3 that the relationship between optical density and concentration of the aluminate ion in solution follows the Lambert–Beer law[93]. The law is obeyed in solutions both undersaturated and supersaturated with respect to hydrargillite. This behaviour suggests that one particular type of aluminate ion (which could not be identified from u.v. spectra alone) is predominantly present in the solutions examined. Because of the low values of the extinction coefficients, structural rearrangements of the aluminate ion as between undersaturated and supersaturated solutions cannot be detected.

However, in supersaturated solutions a decrease in the concentration of alkali and aluminium (at a constant $Na_2O : Al_2O_3$ ratio of 2.0) produces a bathochromic shift of both u.v. bands by 3–5 nm. This effect is absent in undersaturated aluminate solutions. The bathochromic shift observed in supersaturated solutions could be due to the formation of small amounts of polymeric aluminate ions.

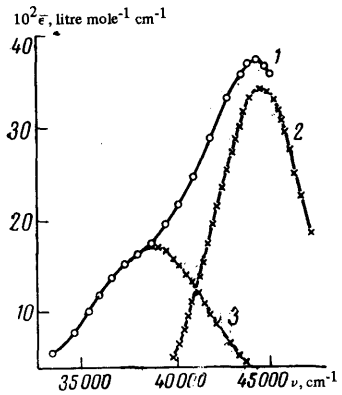

Figure 3. Absorption spectrum of aluminate solutions (*1*) resolved (*2*, *3*) according to Volokhov[32]: Na_2O concentration 0.5–2.51, alkalinity modulus α (Na_2O/Al_2O_3) 2–10.

Thus, some published work[31,39–41,78] suggests that polynuclear anions may be present in aluminate solutions of pH < 12–13, but when the pH is greater than 13 spectroscopic methods indicate that monomeric aluminate ions are predominant in concentrated solutions. Very accurate measurements of electrical conductivity and of diffusion coefficients[57,58], and also by the anion exchange method[84], have confirmed this conclusion, but unfortunately these measurements have been confined to aluminate solutions with a total electrolyte concentration not greater than 2 M.

III. ELECTROCHEMICAL INVESTIGATIONS

Studies of the chemistry of aluminium in aqueous solutions are complicated by the lack of simple and reliable methods for determining equilibrium concentrations of aluminium ions[78,95,96]. For this reason the Al–OH system has been studied by the very convenient pH method[97], which allows the composition of the aluminate ions to be determined from the measured concentration of hydroxyl ions[98]. However, the study of concentrated aluminate solutions in which the concentration of alkali is greater than 1 M is precluded by the large errors attending the use of glass or hydrogen electrodes in strongly alkaline solutions[97]. Not surprisingly, therefore, the solutions studied by the pH method have been more dilute, on the whole, than those studied by spectroscopic methods.

Brosset[48] reported, in 1952, one of the most important investigations of the chemistry of hydroxo-complexes of aluminium. He studied the hydrolysis of aluminium ions at concentrations between 2.21×10^{-3} and 1.11×10^{-2} g-ion litre^{-1} by a potentiometric method, using hydrogen electrodes. The measurements were made at a constant ionic strength of 2, maintained by sodium perchlorate[99,100]. Brosset concluded, from his results, that the main products of the hydrolysis of aluminium ions in alkaline solutions are polynuclear hydroxo complexes of $[Al(OH)_3]_n(OH)^-$ type.

However, a recalculation of these results by the method developed by Sillén to establish the mechanism of polynuclear hydrolysis[101-103] led to the conclusion[49] that the main hydrolysis product is the mononuclear $Al(OH)_4^-$ complex. The following reactions were suggested for the formation of these ions:

$$Al(OH)_{3(s)} + H_2O \overset{K'}{\rightleftharpoons} Al(OH)_4^- + H^+ , \quad (5)$$

or

$$Al(OH)_{3(s)} + OH^- \overset{K}{\rightleftharpoons} Al(OH)_4^- . \quad (6)$$

The logarithms of the constants for these equilibria are 12.5 ± 0.2 and 1.0 ± 0.2 respectively. Ageing of an $Al_2O_3 . xH_2O$ precipitate may result in the transformation of amorphous aluminium hydroxide into a more stable form, for which [according to Eqn. (6)] $\lg K = 0.5 \pm 0.2$.

It is stressed[49] that the precision of the measurements is relatively low, and there is no really convincing evidence of the absence of polynuclear anions in the solution.

After a more detailed analysis[51] of the data for these hydrolytic equilibria Sillèn concluded that alkaline aluminate solutions contain predominantly mononuclear anions with a tetrahedral $[Al(OH)_4^-]$ or octahedral $[Al(OH)_4 . 2H_2O^-]$ configuration.

Most of the published potentiometric investigations[24,26,55,65,104] confirm Sillèn's conclusion that the most abundant species in dilute aluminate solutions are mononuclear tetrahydroxo or dioxo complexes of aluminium.

Table 6 lists the published data for the equilibrium constant of reaction (5), assuming different modifications of aluminium hydroxide. It is evident that the equilibrium in the heterogeneous aluminate system depends very significantly on the structure of the solid aluminium hydroxide. The differences (Table 6) between the constants for a given modification of aluminium hydroxide suggest that in some of the work the crystalline form of the solid phase was not identified with sufficient care. In some cases the solid aluminium hydroxide was prepared under conditions different from those chosen for the equilibrium study. The criterion adopted as an indication of the establishment of equilibrium, and possibly also the presence of aluminate ions of composition other than $Al(OH)_4^-$, may have influenced the results.

Berecz and Szita[26] used as their equilibrium criterion for the dissolution of hydrargillite in alkali an electrochemical cell containing two mercury–oxide electrodes:

$$-Hg\,|\,HgO\,|\,OH^-,\ Na^+,\ Al(OH)_4^-\,|\,Al(OH)_3(s)\,HgO\,|\,Hg^+. \quad (7)$$

The electromotive force of this cell decreases with time as the $Al(OH)_3$ dissolves, and vanishes when equilibrium between the solution and the solid phase is established. This method has the advantage that the cell e.m.f. does not include a diffusion potential, and it gives reliable results with concentrated as well as with dilute NaOH solutions. Hence, the equilibrium constants can readily be extrapolated to zero ionic strength (Table 6).

These workers[26] did not observe a break in their plots of e.m.f. against time, and they showed that the rate of change of potential is practically independent of alkalinity, and hence of the concentration of aluminate ions. By combining this observation with other published data they concluded that the dissolution of hydrargillite in NaOH produces only $Al(OH)_4^-$ anions. However this conclusion[26] applies only to solutions with pH > 12.5.

Table 6. Thermodynamic equilibrium constants of reaction (5) for different modifications of aluminium hydroxide.

*This value was obtained at a constant ionic strength of 2.

Except for the paper by Stefanowicz and Kiziak[65], there are no data on the stability of tetrahydroxoaluminate ions in aqueous solutions. These workers studied the state of the aluminate ions by potentiometric titration with a glass electrode, using an ionic strength of 0.1 and varying the pH from 1 to 10–11. They interpreted their results in terms of monomer hydrolysis only, to give complexes of the $Al(OH)_n^{3-n}$ type with $n = 1$, 3, and 4 and stability constant logarithms of 12.30 ± 0.3, 31.98 ± 0.3, and 36.58 ± 0.3 respectively.

The complex $Al(OH)_2^+$ does not appear to be formed in the solutions examined[65]. This fact is contrary to the principle of stepwise complex formation[105] and needs to be confirmed. Furthermore, the large difference between the stability constant of the $AlOH^{2+}$ ions and the values reported by other workers[25,32], and also the convincing evidence for the presence of polymeric associations in weakly acid solutions of aluminium salts[24,25,89,106,107], raise some doubts on the reliability of the stability constant obtained for the $Al(OH)_4^-$ ion.

Plum and Swaine[78] obtained some interesting results on the composition and structure of aluminate ions in their study of dilute aluminate solutions with a special electrode[108] reversible towards aluminium ions. They found[78] a definite relationship between the electrode potential and the concentration and pH of the aluminate solution. At pH > 12.4 the potential of the aluminium electrode against the saturated calomel electrode becomes independent of the concentration of aluminate ions and varies less steeply with pH. Under these conditions only four protons take part in the electrode reaction, and the experimental results are described by the empirical equation

$$E_{SCE} = 0.962 + {}^4/_3(0.059)\,pH . \quad (8)$$

However, in solutions of pH < 12.4 the potential depends on the concentration of aluminate ions, and is described by the equation

$$E_{SCE} = 0.5099 + \frac{0.059}{3} \lg [\text{aluminate}] + 2(0.059)\text{pH}. \quad (9)$$

The authors assumed the electrode reaction

$$Al + 4H_2O \rightleftharpoons Al(OH)_4^- + 4H^+ , \quad (10)$$

whose potential should be given by

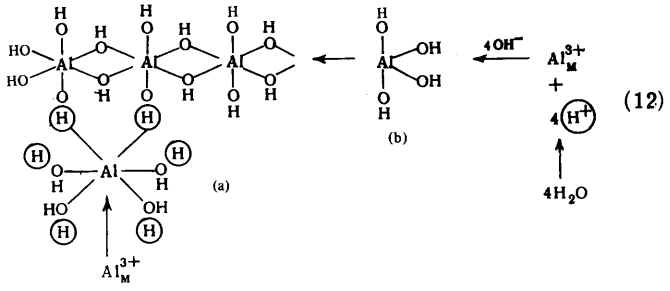
$$E = E^0 - \frac{0.059}{3} \lg [Al(OH)_4^-] + \frac{4}{3}(0.059)\,\text{pH} . \quad (11)$$

However, Eqn.(11) is inconsistent with the empirical equations (8) and (9). Hence, the hypothetical electrode reaction (10) cannot be correct. But if we assume that the formation of the products of the electrode reaction is independent of the total concentration of aluminate ions in solutions of pH > 12.4, and is determined only by the concentration of OH^- ions, Eqns.(8) and (11) become identical. Under these conditions, as can be seen from Eqn.(8), we have a direct reaction between four hydroxyl ions and one aluminium ion from the metal electrode.

In order to explain the dependence of the potential on the concentration of aluminate ions in solution of pH < 12.4 the authors assume that the aluminate ion takes part in the electrode reaction. In other words, the aluminium ion transferred to the solution from the metal electrode must react with aluminate ions to give some form of polynuclear association. It would appear from the experimental results [Eqn.(9)] that six protons are set free when an aluminium ion goes into solution.

Plumb and Swaine [78] considered the most probable structures of aluminate ions in which the Al can have a coordination number of four or six. By combining their own results with those of others [49,52] they concluded that the anion has a polymeric structure of the type $[Al(OH)_4]_n.(OH)_2^{(n+2)-}$. They assume, with little justification, that the same polymer must exist also in solutions of high pH, in which the monomeric ions are thought to be in equilibrium with the ends of polymer chains. If the chains are sufficiently long, the electrode potential will be independent of the total concentration of aluminate ions in solution.

According to Plumb and Swaine [78], the two reactions in solutions of low and high pH respectively can be described by the following scheme:



(12)

where the circles denote replaceable protons.

The reaction between active centres on the side of the polymer chain and an aluminium ion hydrated by four water molecules gives a branched structure in which bonding is by two adjacent oxygen bridges [Eqn.(12a)]. A linear polymer with n aluminium ions will have $(n-1)$ such positions, and therefore the electrode reaction leading to the formation of the branched polymer will depend on the concentration of aluminate ions in solution [see Eqn.(9)].

However, at high pH the concentration of OH ions exceeds the number of active centres in the polymer, and $Al(OH)_4^-$ ions are formed (probably in equilibrium with the ends of polymer chains). In this case, according to mechanism (12b), the coordination number of the aluminium should change from four to six. We can expect the branched polymer to be metastable with respect to the linear polymer, since the former should have a greater density of negative charges than the latter. A thermodynamic analysis of experimentally observed standard electrode potentials [78] has confirmed this expectation.

The polymeric model of the aluminate ions, $[Al(OH)_4]_n(OH)_2^{(n+2)-}$, is formally consistent with the observation [49] that the mean Bjerrum number $\bar{n}$ [105] in dilute aluminate solutions is slightly greater than four. Using published [49] values of $\bar{n}$ for different Al concentrations, Plumb and Swaine calculated that the number of monomer units (n) in the polymer chain increases with concentration and can reach a value of 100 at an Al concentration of 1.1×10^{-2} g-ion litre^{-1}. However, this calculation is possible only for the unlikely case of a solution containing only polymeric anions of uniform composition.

The reaction of the $Al(OH)_4^-$ ion with a polymer (mechanism 12b) does not explain the well known increase of pH with time in freshly prepared aluminate solutions [49]. The effect could be due to the migration of branches in a metastable (highly branched) polynuclear structure towards the ends of the chain, the oxygen bridges taking up a proton from the solution, or to mutual interaction of the polymer chains according to the equation

$$[Al(OH)_4]_n(OH)_2^{(n+2)-} + [Al(OH)_4]_m(OH)_2^{(m+2)-} \rightleftharpoons [Al(OH)_4]_{m+n}(OH)_2^{(n+m+2)-} + 2OH^- . \quad (13)$$

If the increase of pH with time is due to polymerisation of the aluminate anions, and each elementary step is accompanied by the generation of two free OH ions, it can easily be shown from Brosset's results [49] that in solutions with $\bar{n} > 4$ the amount of polymer does not exceed 2%. If this is so, the disagreement between the results of pH measurements [24,48,49] and those of electrochemical measurements [78] is not surprising.

Plumb and coworkers [39] have recently confirmed by spectroscopic methods that polymeric species are present also in concentrated aluminate solutions of pH < 13.

IV. MONONUCLEAR AND POLYNUCLEAR ALUMINATE IONS IN STRONGLY ALKALINE SOLUTIONS

The existence of polymeric aluminate ions in solutions of different concentrations but pH $\leqslant$ 12–13 has been proposed in a number of publications [31,39–41,78] discussed in the previous sections of this review. However, information on the presence of polynuclear structures in strongly alkaline solutions is controversial, and erroneous in parts.

The first report of the polymerisation of aluminate ions in alkaline solutions is due to Brintzinger [109], who concluded from dialysis results that the two polymeric structures $[Al_2(OH)_{10}]^{4-}$ and $[Al_2O_2(OH)_8]^{8-}$ were present in his solutions. Because of the difficulty of interpreting dialysis data correctly, the equivalent weights of the ions cannot be established with confidence [110]. In our system the problem is further complicated by the fact that the equivalent weights of the dimeric anions are almost identical. Brintzinger's results [109] are also inconsistent with more recent work which suggests that the formal

charge on the aluminate ion, at least in equilibrium solutions at high pH, is unity [22-26,29-31,33,66]. However, the former of the above ions, $[Al_2(OH)_{10}]^{4-}$, agree in composition with the general polymer formula $[Al(OH)_4]_n \cdot (OH)_2^{(n+2)-}$, with $n = 2$, proposed for solutions of pH < 12.5. [31,39-41,78]

Calvet and coworkers [12] have shown, by diffusion measurements, that the calculated apparent radius of the aluminate ions decreases by about a factor of two on raising the temperature of the solution from 20° to 50°. This effect could be due to dissociation of ion pairs and polymeric ions, or to the dehydration of aluminate ions, but the diffusion method lacks the power to distinguish between these processes.

Jahr and Plaetschke [53] also used the diffusion method to study aluminate solutions. By referring to some earlier and unconfirmed diffusion measurements they concluded that the size of the aluminate ion is determined mainly by the alkalinity of the solution. Weakly alkaline solutions contain polymeric aluminate ions whose size decreases with increasing concentration of OH^- ions according to the reaction

$$[(H_2O)_2(OH)_3Al{-}OH{-}Al(OH)_3(H_2O)_2]^- + OH^- \rightleftharpoons 2[Al(OH)_4 \cdot 2H_2O]^- , \quad (14)$$

The resulting mononuclear aquohydroxoaluminate ions are dehydrated if the concentration of OH^- ions is increased from 6.5 to 20 (expressed as OH : Al ratio), giving rise to water-free polymers of general formula $[Al_n(OH)_{3n+1}]^-$, for example by the reaction

$$2[Al(OH)_4^-] \rightleftharpoons [(HO)_3Al{-}OH{-}Al(OH)_3]^- + OH^- , \quad (15)$$

with an average degree of polymerisation not greater than four. Further increase in alkalinity leads to decomposition of the $[Al_n(OH)_{3n+1}]^-$ complexes, and $Al(OH)_4^-$ ions become the predominant species in solution.

The polymerisation scheme proposed by Jahr and Plaetschke [53] is in general agreement with other experimental results obtained at about the same time, and is not incompatible with the growing belief that the aluminate ion carries a unit charge. However, later work has not produced any convincing evidence in favour of the formation of polymers by reactions of the type of (14) and (15).

Indeed, Jahr and Pernoll [57,58] made a series of high-precision measurements in 1965 but they were unable to confirm the earlier conclusions [53]. Their measurements of OH^- ion activity [57] indicated that only monomeric $Al(OH)_4^-$ complexes are present in alkaline solutions of pH $\geqslant$ 11.5. Their measurements of diffusion coefficient and electrical conductivity [58] also suggested that the composition of the aluminate ions is independent of the OH : Al ratio, and that polymeric anions cannot exist in strongly alkaline solutions.

An improved anion exchange method [64] has been used to show that aluminate ions in 1 M NaOH solution are always present as the monomer $Al(OH)_4^-$. The composition of the ions is independent of the ageing time of the solution, and remains unchanged up to the onset of visible decomposition of the aluminate solutions. It should be noted that these conclusions [57,58,64] apply to solutions in which the overall concentration of the components is less than 2 M, i.e. to dilute and moderately concentrated solutions.

The work of Kuznetsov [2,20-22,111] has had a profound effect on the development of our views on the structure of alkaline solutions of aluminium. According to Kuznetsov, aluminate solutions with a high alkalinity modulus ($\alpha = \frac{Na_2O}{Al_2O_3}$) contain $Al(OH)_4^-$ ions, which can form polymeric groupings in low-modulus solutions containing less than 150–180 g litre^{-1} of Na_2O according to the scheme

$$Al(OH)_4^- \rightarrow Al_n(OH)_{4n}^{n-} \rightarrow Al_6(OH)_{24}^{6-} \rightarrow \underset{\text{(Gibbsite)}}{\text{hydrargillite}} . \quad (16)$$

The formation of hydrargillite from ring structures of the $Al_6(OH)_{24}^{6-}$ type is explained by assuming that aluminate ions in solution have the same structure as the elements of the crystal lattice of hydrargillite, and also from electrical conductivity and viscosity data [20-22,111].

At Na_2O concentrations greater than 150–180 g litre^{-1} Kuznetsov assumes [2,20-22,111] that dehydrated polymers of the $[AlO(OH)_2]_n^{n-}$ type are present in solution. He suggests that changes in size of the polymer are due to fluctuations in the solutions, leading to changes in local concentration, temperature, density, etc. Hence, "conditions favourable to polymerisation are created in some microscopic regions, giving rise to hetero-phase fluctuations" [22]. Kuznetsov has not attempted to confirm his hypothesis experimentally, particularly since the problem of homogeneity or microheterogeneity in supersaturated solutions in general is still highly controversial [112].

Measurements of the electrical conductivity and viscosity of aluminate solutions [20-22,111] indicate a strong dependence of structure on concentration. Thus, the specific conductance of the alkali decreases very markedly when aluminate ions are introduced into the solution, but the electrical conductivities of aluminate solutions and of NaOH have very similar concentration dependences, going through a maximum as the concentration increases. The decrease in conductivity with increase in concentration occurs when the system has crossed the full solvation boundary [82,113], and can be explained by the formation of ion pairs [30] or by polymerisation of the aluminate ions [111].

In dilute aluminate solutions the activation energies for viscous flow ($E\eta$) and for electrical conduction ($E\lambda$) are small (less than 1 kcal mole^{-1}), and approximately equal. This suggests the presence of mobile ions, small in size, in dilute solutions. In aluminate solutions containing more than 150 g litre^{-1} of Na_2O the quantity $E\eta$ increases much faster than $E\lambda$. According to Kuznetsov [21,111], this behaviour could be associated with the appearance of large aluminate ions in solution, since viscosity is more sensitive than electrical conductivity to the presence of low-mobility ions.

Kuznetsov has also pointed out [22] that at some particular concentrations the solution develops a quasi-crystalline structure due to the formation of hydrogen bonds between aluminate ions. This effect is favoured by low temperature and low alkalinity.

Starting from the hydrated model of the aluminate ion, $Al(OH)_4.2H_2O^-$ (O_h), Pearson [19] also finds a correlation between the hydrogen bonding of aluminate ions and the viscosity of the solution. However, other work [26,30,57-59,63,64] has failed to confirm the presence of these ions, in which the aluminium should have a coordination number of six.

Kuznetsov and coworkers [114] found additional evidence in favour of hydrogen bond formation between hydroxo complexes in aluminium solutions in their study of the rheological properties of these solutions [115]. The deviations from Newtonian behaviour in aluminate solutions suggest that these liquids are structured, becoming quasi-crystalline beyond the full solvation boundary. It is pointed out [114] that structural ordering is more marked in solutions with a high content of aluminate ions and at low OH : Al ratios. Hence, plots of the stability of the structure (said [114] to be related to the degree of polymerisation)

against the alkalinity modulus at constant Al_2O_3 concentration go through a maximum at a $Na_2O : Al_2O_3$ ratio of 1.6.

Unfortunately, the authors [114] do not comment on the similarity between the concentration dependences of electrical conductivity [111] and structural stability in aluminate solutions, and they offer no explanation for the appearance of a stability maximum at that particular value (1.6) of the alkalinity modulus. Furthermore, the interpretation of the rheological properties of aluminate solutions is complicated by the lack of data on the rheological properties of concentrated solutions of pure alkalies, which are also known [116,117] to have a quasi-crystalline structure.

Thus, Kuznetsov's views on the presence of polymeric aluminate ions formed by hydrogen bonding in alkaline solutions of aluminium salts are based essentially on measurements of electrical conductivity, viscosity, and rheological properties, although the concentration dependence of these parameters could equally well be explained by postulating the formation of ion pairs or associated ionic species with a more complex structure.

Firstly, the electrical conductivity of aluminate solutions varies with concentration in the same way as in pure alkali solutions [1,2,30,111]. The conductivity of NaOH solutions begins to decrease beyond the full solvation boundary as a result of a decrease in the concentration of Na^+ and OH^- ions, due to ion pair formation [29,30,117]. The analogous trend of the conductivity changes in aluminate solutions could also be due to the formation of ionic associations between aluminate and hydroxyl anions, on the one hand, and sodium cations [30,71]. Of course, hydrogen bonding between the water molecules of the hydration shell surrounding the Na^+ cations and the hydroxyl groups of the aluminate ions could assist the formation of ionic associations of the $[Na(H_2O)_x^*]_yAl(OH)_4$ type, where y cannot be greater than 4. But in this case the formation of significant amounts of large polynuclear aluminate ions is unlikely, because ion pairs held by strong hydrogen bonds do not readily polymerise [118]. The increase in the viscosity of alkali solutions following the addition of aluminate ions can be ascribed to the same interactions. Furthermore, electrostatic considerations suggest that aluminate anions in alkali solutions should more easily form bonds with the oppositely charged Na^+ cations than interact with each other. Only when the concentration of aluminate ions is not very different from the concentration of Na^+ ions are conditions favourable to the formation of polynuclear aluminate structures, particularly in supersaturated solutions.

Secondly, reactions leading to the formation of complicated polymeric structures are kinetically slower than simple hydrolysis reactions [32,68], because they involve a number of separate steps. However, equilibrium is established very rapidly both in the dissolution of metallic aluminium in NaOH solutions and in the dilution of aluminate solutions with solutions of alkali, and the properties of supersaturated aluminate solutions (electrical conductivity, density, viscosity, pH,[119] optical density [32,63], velocity of ultrasonic waves [71,120]) remain constant up to the onset of visible decomposition. If, on the other hand, mononuclear and polynuclear anions of different degree of condensation were present in aluminate solutions of high pH, and if their composition were changing with time during the ageing period of the solution, none of the above properties would remain constant during the period preceding the precipitation of aluminium hydroxide.

Thirdly, the stability of supersaturated and undersaturated aluminate solutions as a function of temperature, concentration, and alkalinity modulus [2,121] can be explained not only in terms of polynuclear complex formation but also by considering the formation of ionic associations between aluminate anions and sodium cations [28], particularly since these associations are fairly stable [71] and they appear to be of the outer-sphere complex type [122], whose formation in concentrated salt solutions is known to be endothermic. Hence, increase of temperature may produce not only a rearrangement of the structure of the aluminate ions but also a blocking of those ions by sodium cations, thus increasing the stability of the solutions. Differences in behaviour between potassium and sodium aluminate solutions [41,123] lend some support to these views.

Many other published results [26,29,30,39-41,57-61,63] are also inconsistent with the presence of significant amounts of highly complex polymeric aluminate ions in strongly alkaline and concentrated solutions. An analysis of data on polynuclear hydroxo complexes of various metal ions [25] suggests that the stability of these complexes is, in general, low, and therefore their concentration must be small. Evidently, aluminate solutions are not exceptional in this respect. To some extent, this is confirmed by the low intensities of the i.r. and Raman lines obtained [63] with supersaturated solutions. It seems likely that the formation of aluminium hydroxide from alkaline solutions does not require large numbers of large polynuclear aluminate ions to be formed during the induction period.

V. THERMODYNAMIC PROPERTIES

The fullest and most reliable thermodynamic data on alkaline and aluminate solutions of composition $NaOH-H_2O$, $KOH-H_2O$, $Na_2O-Al_2O_3-H_2O$, $K_2O-Al_2O_3-H_2O$, and also $Na_2O-K_2O-Al_2O_3-H_2O$, were obtained in the Physical Chemistry Department of the Lensovet Leningrad Technical Institute. Measurements of density, equilibrium water vapour pressure, and specific heat were made over a wide range of concentrations and at temperatures between 25° and 300°. Details of the apparatus, procedures, and results obtained have already been given [29,30,33,90,117,124-140]. Most of the results relate to stable aluminate solutions. Only one publication [141] deals with the saturated vapour pressure and relative partial molar enthalpy of water in a small range of metastability. Some workers have calculated the thermodynamic characteristics of aluminate solutions by taking the aqueous solutions of pure alkali (NaOH or KOH) as the solvent [142], since their thermodynamic properties are known with sufficient precision [143-145]. The validity of this approach has been demonstrated by Karapet'yants [146].

Mal'tsev and Mashovets [30,128] obtained a large amount of valuable experimental data on the specific heat of alkali and aluminate solutions in the temperature range 25-90°. They showed that the specific heat is fairly high at low temperatures, and decreases with increasing temperature. This effect is more marked in aluminate solutions than in pure alkali solutions. The decrease in heat capacity observed on adding aluminium to a solution of sodium hydroxide is ascribed [128] to the formation of polymers or complex ions.

The theoretical interpretation of the results is extremely difficult, because of the complexity of the processes which can take place in aluminate solutions. Negative deviations from additivity of the specific heat may arise through changes in the structure of water under the influence of the dissolved ions and their hydration processes, since water is known to have a lower specific heat when in

a bound state. Positive deviations from additivity indicate predominantly interionic interactions (formation of ion pairs or polymeric associations). Using this type of argument, Mal'tsev and Mashovets [128] ascribed the small changes in specific heat at 75–90° to decomposition or dehydration of polymeric aluminate ions. Increase in concentration is also thought [128] to assist the degradation of polymeric structures at all temperatures.

More recently, Mal'tsev and coworkers [30,90] have tried to explain the measured specific heats of aluminate solutions by postulating monomeric aluminate ions of different degree of hydration. Positive deviations of the measured specific heats from the linearly interpolated values are ascribed to the formation of ionic association or ion pairs by the reactions

$$Na^+ + Al(OH)_4^- \rightleftharpoons Na^+[Al(OH)_4^-] \rightleftharpoons Na^+\left[O{-}Al\begin{matrix}OH\\OH\end{matrix}\right]^- + H_2O \rightleftharpoons Na^+AlO_2^- + 2H_2O \quad (17)$$

This equilibrium should be shifted towards the right by increasing the concentration. In addition to the heat capacity measurement, data on the electrical conductivity of aluminate solutions [30,90] and the NMR spectra of ^{23}Na [30,90] provide indirect support for the suggested interionic interactions [Eqn.(17)]. Direct proof of the very strong interaction of aluminate ions with sodium cations is given in Ref. 71. Other workers [130,139–141] have critically assessed the experimental vapour pressure data, and have proposed new formulae and graphical methods for determining the vapour pressure of sodium and potassium aluminate solutions over a wide range of concentrations and temperatures. Mal'tsev [30] concludes from the dependence of vapour pressure on Al content that the total number of ions in a sodium aluminate solution is almost the same as in the corresponding solution of pure alkali, and that the two solutions have very similar structures. The dehydration mechanism of aluminate ions is consistent with the observed increase in water vapour pressure with concentration of aluminate ions [29,30]. Eqn.(17) predicts a sharp decrease in the symmetry of the aluminate ion after dehydration: the prediction is not borne out by the NMR spectra of ^{27}Al [51,60,61,63,71] or by other spectroscopic observations [52,62,63,71]. This discrepancy between the vapour pressure data and the NMR spectra of ^{27}Al can be resolved [63] by postulating the presence of partly dehydrated anions (e.g. $[Al_2O(OH)_6]^{2-}$) in concentrated solutions, since in these anions the tetrahedral configuration of the aluminate point group is distorted to a negligibly small extent.

Chakhal'yan [141] has carried out a thermodynamic assessment of the structure of aluminate solutions and of various models of the aluminate ion by combining thermochemical data with vapour pressure data for the stable and the metastable regions of these solutions. Using specially designed apparatus, he obtained some important experimental results:

1. The relative partial molar and specific enthalpies of water and of the defined solvent [aqueous alkali with a constant $(Na_2O)/(Na_2O + H_2O)$ ratio] were measured in sodium and potassium aluminate solutions at 25°, and also the heats of dilution of these solutions with solutions of pure alkali.

2. The differential heats of dissolution of hydrargillite in $R_2O–Al_2O_3–H_2O$ systems (where $R = Na^+$ or K^+) and in pure alkali solutions with a ratio $(R_2O)/(R_2O + H_2O) = 0.23243$ by weight were measured at 85°.

3. The saturated water vapour pressure was measured only over sodium aluminate solutions, for nine values of the alkalinity modulus [$\alpha = (Na_2O)/(Al_2O_3)$] in the Na_2O concentration range 5–25 wt.% and at two temperatures (25° and 75°).

From his experimental results he calculated the integral heats of dissolution of hydrargillite at three constant $(Na_2O)/(Na_2O + H_2O)$ ratios, the relative partial molar entropic terms of water in sodium and potassium aluminate solutions at 25°, and some other parameters, and he compiled an enthalpy–concentration diagram for the $Na_2O–Al_2O_3–H_2O$ ternary system.

Because of the profound influence of water on the behaviour of aluminate solutions, Chakhal'yan [141] calculated the activity of water as a function of $1/\alpha$ at various concentrations of R_2O, using vapour pressure data for solutions of sodium and potassium aluminates, and of pure alkalies. The data for 300° and for the $K_2O–Al_2O_3–H_2O$ system, were taken from the work of Mashovets and coworkers [126,130,140]. As an example, the activity of water in the $Na_2O–Al_2O_3–H_2O$ system (a_{AR}) is compared in Fig.4 with the same parameter for a pure alkali solution (a_R) as a function of the alkalinity modulus and of the Na_2O content at 25°.

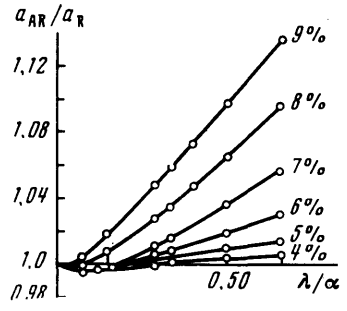


Figure 4. Ratio of the activities of water in sodium aluminate solutions (a_{AR}) and in alkali solutions (a_R) against $1/\alpha$ at 25°.[141] The numbers against each curve denote mol.% of Na_2O.

It is evident from the Figure that the activity of water in aluminate solutions with a high alkalinity modulus drops below the value for solutions of pure alkali at first, but it then crosses the horizontal axis and begins to increase at a rate depending on the Na_2O content. This type of curve is believed [141] to indicate the existence of two regions in which the structure of the aluminate ion is different, and therefore the degree of hydration is also different: for example, $Al(OH)_4^-$ and $AlO(OH)_2^-$. However, no allowance was made for the possible formation of hydrates such as $[Al(OH)_4^-](H_2O)_X$.

In order to investigate further the structure of the aluminate ion, the $a_{AR}/a_R = f(1/\alpha)$ curves (Fig.4) were compared with $n_{AR}/n_R = f(1/\alpha)$ curves (where n_{AR} and n_R are the mole fractions of water in the aluminate and the pure alkali solutions respectively) calculated for

various proposed models of the aluminate ion. The calculations showed that the mole fraction of water decreases with increase in $1/\alpha$ in the following sequence:

$$[AlO(OH)_2]_n^{n-} > [AlO(OH)_2]_6^{6-} > Al(OH)_4^{3-} > [Al(OH)_4]_6(OH)_2^{8-} >$$
$$> AlO_2^- = [Al(OH)_4]_n^{n-} = [Al(OH)_4]_n(OH)_2^{(n+2)-} > [Al(OH)_4]_6^{6-} =$$
$$= [Al_6(OH)_{24}]^{6-} > AlO(OH)_2^- > [Al_6(OH)_{18}](OH)_6^{6-} >$$
$$> Al(OH)_4^- = [Al_6(OH)_{18}]_n(OH)_6^{6-} \quad (\text{for } n \gg 6).$$

The mole fractions of water in aluminate and in pure alkali solutions become the same if the aluminate solution is assumed to contain only monomeric AlO_2^- ions or polymeric $[Al(OH)_4]_n^{n-}$ and $[Al(OH)_4]_n(OH)_2^{(n+2)-}$ ions. In other words, these calculations[141] suggest that the hydration properties of Al_2O^- and OH^- ions are identical. This surprising result can be explained by the failure to take account, in the calculation of n_{AR} and n_R, of the water molecules in the hydration shells of the components of the solution, and also of the trans-solvation effects accompanying the formation of various ion pairs or ionic associations between sodium cations and hydroxyl or aluminate anions[30,71,90,117]. Furthermore, it is not easy to distinguish "physical" from "chemical" phenomena in these solutions without *a priori* knowledge of the final result[147], though some allowance for the "chemical" contribution to the phenomenon can be made by choosing the correct model for the aluminate ion.

Evidently, still greater complications can be expected in the calculation of the mole fraction of water in concentrated solutions, where the composition of the aluminate ions can be even more complex. In particular, the increase in the activity of water with concentration (Fig. 4) could be due not only to dehydration and polymerisation of the aluminate ion[141], but also to interactions between aluminate anions and sodium cations stronger than the corresponding interactions between Na^+ and OH^-.[71] Hence, the real composition of the aluminate ion cannot readily be inferred from integral properties of the system such as the activity of water.

From his comparison of the $a_{AR}/a_R = f(1/\alpha)$ plots (Fig. 4) with calculated plots of $n_{AR}/n_R = f(1/\alpha)$ Chakhal'yan concludes[141] that $Al(OH)_4^-$ ions are present in solutions with a high concentration of Na_2O (>8 mol.%) but a low concentration of aluminium. Increasing concentration apparently leads to dehydration of these anions and formation of polymers of the $[AlO(OH)_2]_n^{n-}$ type, or even $[AlO_2]_n^{n-}$. The existence of these polymers is not inconsistent with the thermodynamic measurements carried out by the author, or with his calculations[141] of the equilibrium constants of aluminate solutions saturated with hydrargillite at 25°. But his analysis of the equilibrium constants involve the doubtful assumption that ions of the same charge have the same activity coefficient in a given solution, although quite different numerical values have been reported for concentrated electrolytes of the same type[148].

Chakhal'yan's model[141] resembles Kuznetsov's theory[2,21,22] most closely. However, the presence of polymers of composition $[AlO(OH)_2]_n^{n-}$ and $[AlO_2]_n^{n-}$ is not confirmed by the spectroscopic results[5,52,60-63,71], or by the very low heats of dilution of aluminate solutions by solutions of alkali[141], since the degradation of these polymers should require a fairly large expenditure of energy.

A comparison of the relative partial molar entropies of water in solutions of aluminates and of pure alkalies respectively has shown[141] that water is more strongly bound in aluminate solutions (containing not more than 8 mol.% of Na_2O) than in solutions of sodium hydroxide. This finding agrees with conclusions reached by other methods[19,71], but it is given a different interpretation: some assume[19,141] that the water is built into the "intrinsic" structure of the aluminate ion ($[Al(OH)_4^-]$ (T_d)[141] or $[Al(OH)_4 \cdot 2H_2O]^-$ (O_h)[19]), whereas others[71] believe that the aluminate ion itself can form hydrates of the $[Al(OH)_4^-](H_2O)_X$ type, in which the tetrahedral (T_d) configuration is retained.

VI. KINETIC DATA ON THE BEHAVIOUR OF THE $Na_2O-Al_2O_3-H_2O$ SYSTEM

In contrast to the hydrolysis of Al ions in acid solutions, the hydrolysis of this metal in the alkaline region usually produces an increase of pH with time[48]. The decomposition of aluminate solutions is an autocatalytic process in which the resulting aluminium hydroxide (and various salt additives[1,2]) can act as catalysts[22].

Brosset[48] studied the rate of hydrolysis of aluminium ions in alkaline solutions, but he was unable to obtain reproducible results. He ascribed the varying rates to the slow establishment of equilibrium potentials on the hydrogen electrode. The errors in the measured pH were particularly serious during the first hour after mixing of the Al and alkali solutions.

This problem was avoided[32,149] by using glass electrodes, whose equilibrium potentials are developed almost instantaneously[97]. Mironov[81] monitored the hydrolysis of Al in alkaline solutions by pH measurements at a constant ionic strength of 3, maintained by adding sodium perchlorate, at 40°. The total concentration of aluminium was varied between 10^{-3} and 10^{-1} g-ion litre^{-1}, but most of the measurements were made at an aluminium concentration of 1×10^{-2} g-ion litre^{-1}.

Measurements of pH, combined with Raman spectral studies, have shown[149] that the ratio of the total concentrations of alkali and aluminium (OH : Al) has a profound effect on the hydrolytic reactions. We can distinguish three regions of OH : Al values, corresponding to different hydrolysis rates and mechanisms.

Region No. 1 (OH : Al $\simeq$ 4.4, pH $\geqslant$ 13.0) is a region of stable solutions, where equilibrium is established very rapidly.

Region No. 2 (OH : Al $\simeq$ 3.3–4.4, pH $\simeq$ 9.3–12.8) gives pH–time curves of the type shown as curve *a* in Fig. 5).

Region No. 3 (OH : Al $\simeq$ 3.01–3.3, pH $\simeq$ 8.2–9.3, curves *b* and *c* of Fig. 5). There seems to be general agreement[24-26,29-31,33-65] that monomeric aluminate ions are the predominant species in solutions within region No. 1.

In region No. 2, polymers of composition $[Al(OH)_4]_n \cdot (OH)_2^{(n+2)-}$ are formed as soon as sodium hydroxide is added to the solutions[31,39-41,78]. Migration of the polymer chains leads to gradual chain breaking and formation of hydroxyl ions, so that the pH of the solution increases with time.

Solutions prepared within region No. 3 show a rapid formation of a mixture of aluminium hydroxide and polymers of the $[Al(OH)_3]_n(OH)^-$ and $[Al(OH)_4]_n(OH)_2^{(n+2)-}$ type (sections *1* and *2* of the curves in Fig. 5*b* and 5*c*), the former consisting of fine colloidal particles. The transformation of these polymers into aluminium hydroxide (sections *2–3–4–5* in Fig. 5*b* and 5*c*) causes a gradual release of OH^- ions into the solution.

The apparent first-order rate constants for the generation or disappearance (region No. 3) of OH^- ions, calculated for sections *1* and *2*, are $(5.5 \pm 0.7) \times 10^{-2}$, $(3.0 \pm 0.5) \times 10^{-2}$, and $(3.6 \pm 0.4) \times 10^{-2}$ min^{-1} respectively. The rate constants calculated from Figs. 5*b* and 5*c* are the same within experimental error: this is not surprising, since the two curves refer to systems within the same region.

Scotford and Glastonbury [150] studied the effect of temperature on the rate of dissolution of gibbsite and boehmite in NaOH solutions at temperatures between 25° and 100°. They assumed the following reactions

$$\underset{\text{(gibbsite)}}{Al(OH)_3} + OH^- \rightleftarrows Al(OH)_4^- \qquad (18)$$

$$\underset{\text{(boehmite)}}{AlOOH} + OH + H_2O \rightleftarrows Al(OH)_4^- \ . \qquad (19)$$

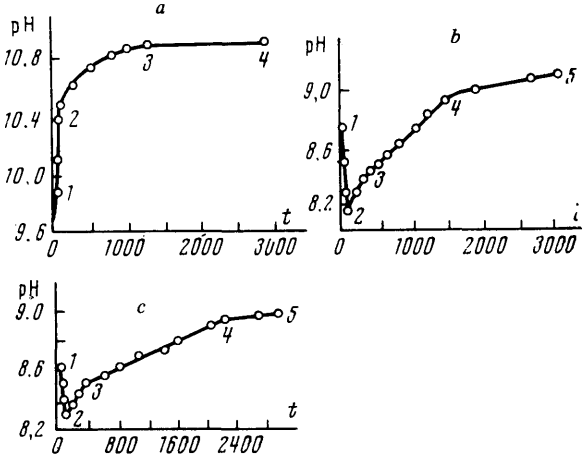

Figure 5. Changes of pH with time [149] t, min, for different OH : Al ratios: *a*) 3.5, *b*) 3.1, *c*) 3.01.

The activation energies, calculated from the initial rates of dissolution, were found to be (30.6 ± 0.9) and (29.4 ± 1.3) kcal $mole^{-1}$ respectively.

The heat of reaction (18), according to Sato [151], lies between 5.88 and 7.34 kcal $mole^{-1}$. However, most workers prefer to use the higher value (approximately 7.3 kcal $mole^{-1}$) obtained by Russell and coworkers [37], who also estimated the heat of dissolution of boehmite as ~4.8 kcal $mole^{-1}$. By combining these values with the activation energies obtained for the forward reaction (18) and (19), Scotford and Glastonbury [150] calculated the activation energies for the reverse reactions (23 and 25 kcal $mole^{-1}$ for gibbsite and boehmite respectively).

The high activation energies obtained for both the forward and the reverse reactions suggest that the lixiviation of alumina and the decomposition of aluminate solutions are both activation controlled. Herrmann [13] on the other hand concludes that these reactions are diffusion controlled, but his views on the nature of aluminate solutions have been severely criticised, in particular by Kuznetsov [22].

The calculation [150] of the activation energy from the initial rates of dissolution of alumina avoids the difficulties arising from the reversibility of reactions (18) and (19) and from the need to find the true rate constants, particularly since the latter cannot be determined unless the correct kinetic equations and the complex mechanisms of the dissolution and precipitation of alumina are known. Furthermore, activation energies obtained from the temperature dependence of rate constants are valid only on the assumption of constant composition of the components of the solution, and of the solid phase, at different temperatures. This condition, of course, is not fulfilled in the present system, since both the composition and the structure of the aluminate ions may vary with temperature [23,30]. An incorrect value of the activation energy will be obtained from the temperature dependence of the rate of reaction also if the surface area of the precipitate after a given time is different at different temperatures.

The latter effect is probably responsible for the low activation energy attending the dissolution of gibbsite in alkali, previously reported [152,153] as 23.8 kcal $mole^{-1}$, determined from the temperature dependence of the reaction rate measured over long time intervals (and therefore possibly affected by changes in the specific surface area of the alumina).

Elson and coworkers [154] reported an even lower value of the activation energy (19.6 kcal $mole^{-1}$). This value was calculated from the following empirical kinetic equations, which relate the reaction rate to the surface area of the solid phase and the composition of the aluminate solution:

$$\frac{dx}{dt} = k_2 A_t \left(\frac{x_\infty - x_t}{a_\infty + x_\infty} \right)^2 \qquad (20)$$

$$\frac{dx}{dt} = k_1 A_t (x_\infty - x_t)^2 \ , \qquad (21)$$

where $k_2 = k_1(a_\infty + x_\infty)^2$; x_t and x_∞ are the molar concentrations of aluminium at time t and at equilibrium; a_∞ is the molar concentration of sodium expressed as NaOH at equilibrium; A_t is the surface area of the solid phase at time t; k_1 and k_2 are the rate constants.

These workers [154] did not attempt to justify theoretically their choice of Eqns. (20) and (21): some of the arguments against the use of these equations are discussed briefly above, and in greater detail by Scotford and Glastonbury [150]. The latter recalculated previous results [152–154] by the initial dissolution rate method, and they showed that the resulting value of the activation energy for the dissolution of gibbsite in alkali is close to their value of (30.6 ± 0.9) kcal $mole^{-1}$. Hence the activation energy is essentially independent of the initial particle size of the solid phase (20–120 μm) and of the concentration of alkali (30–210 g $litre^{-1}$ of Na_2O).

In spite of the fairly large effort devoted to the study of the kinetics of the lixiviation of alumina and of the decomposition of aluminate solutions [1,2], the mechanism of these processes is still far from clear. A full understanding of the processes taking place in metastable aluminate solutions must await the final resolution of the structural problem presented by aluminate ions under different conditions.

Conformational Analysis of Sulphur-containing Six-membered Heterocycles

N.S.Zefirov and I.V.Kazimirchik

The review deals with one of the problems of dynamic stereochemistry—the conformational analysis of six-membered heterocycles containing bivalent sulphur. The general conformation characteristics of the above class of compounds are reviewed.
The bibliography includes 115 references.

I. INTRODUCTION

The extensive use of conformational concepts in the interpretation of various transformations of organic compounds is due to the relative simplicity and largely universal applicability of the main postulates of conformational analysis. On the one hand, it involves (at least in its commonest form) taking into account the steric interaction of non-bonded groups of atoms (usually repulsion), from which the most stable conformation is deduced, and, on the other, the steric hindrance in various conformations to the approach of the attacking agent. However, it is quite evident that the presence of a powerful additional non-steric interaction between two or more groups in the molecule could allow the relative stability to be determined precisely by this factor. Such additional interactions (usually regarded as "effects" specific to the given group) are associated mainly with the introduction of polar functional groups and heteroatoms. Hence the unusual conformational behaviour of heterocyclic compounds in relation to their alicyclic analogues becomes understandable.

The replacement of a carbon atom in an alicyclic system by a heteroatom can lead to a change both of molecular geometry and of electronic structure. Although the influence of a change in geometry is to a rough approximation often insignificant, particularly in a purely qualitative treatment, nevertheless on passing to a quantitative treatment this inevitably leads to the conformational non-equivalence of the individual positions in the molecule and hence to a wide variety of conformational behaviour of these systems. Sometimes such geometrical changes are shown also on a qualitative level. The change in electronic structure leads to a change in the electric moments, polarity, and degree of solvation, etc. of heterocyclic systems compared with their alicyclic analogues, which is also bound to have an effect on their conformational properties.

The aim of the present review is to examine the conformational behaviour of six-membered systems containing a bivalent sulphur atom. Fairly extensive experimental data have now accumulated, demonstrating the fundamental difference between the conformational behaviour of sulphur-containing heterocycles and not only the corresponding alicyclic compounds but also the analogous oxygen-containing heterocycles. This is why we thought it useful to review the available literature data on the conformational behaviour of six-membered heterocycles containing a bivalent sulphur atom and to formulate its characteristic.

II. GENERAL PROBLEMS IN THE CONFORMATIONAL ANALYSIS OF SULPHUR-CONTAINING COMPOUNDS

The chair conformation of cyclohexane is the most stable and the difference between the energies of the boat and chair forms is estimated as 5–7 kcal mole^{-1} (Table 1) [1-3]. On passing to heterocyclic compounds, the fundamental problem is the change in the energy difference between the chair and flexible conformations (twist-boat). This difference may be related to a change in the barrier to rotation about the C-heteroatom bond compared with the C–C bond. The barrier to rotation about the C–S bond (2.1 kcal mole^{-1} in dimethyl sulphide [4]) is smaller than that to rotation about the C–C bond (3.4 kcal mole^{-1} in propane [5]). Thus, since the eclipsed conformations of sulphur-containing heterocycles are energetically less favourable than those of carbocyclic compounds, presumably compounds of the first kind will show a greater tendency towards existence in the boat conformations. We may note also that the flagstaff–flagstaff interaction, which destabilises the boat conformation, is likewise weakened by virtue of the greater length of the C–S bond. For example, in 1,3-dithiane this distance is 2.4 Å, while in 1,3-dioxane it is 1.46 Å. [6]

Numerous experimental data on the geometry of sulphur-containing heterocycles (derivatives of oxathiane [7,8] and dithianes [9-12]) show that they exist in the chair conformation, which is the main, most stable conformation. However, there are reliable experimental data showing a decrease of the energy difference between the chair and flexible forms. For example, the study of the epimerisation of 2,5-di-t-butyl-1,3-dithiane showed that the difference between the enthalpies of these conformations,

is 3.4 kcal mole^{-1} (Table 1). [13,14]

Table 1. Thermodynamic parameters of the conformational equilibria of the chair/twist type.

System	$\Delta G_{25°}$, kcal mole^{-1}	ΔH, kcal mole^{-1}	ΔS, cal mole^{-1} deg^{-1}	References
Cyclohexane	4.9	5.9	3.5	2
1,3-Dioxane	5.7	7.1	4.8	14,27,28
1,3-Dithiane	1.8	3.4	5.3	13,14

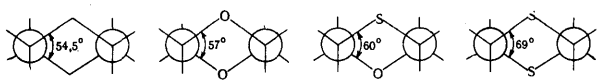
Cyclohexene exists in the stable half-chair conformation [15-17] and the "sofa" conformation is in many instances more stable only for polycyclic compounds [18]. There is also evidence that this conformation predominates for certain sulphur-containing heterocycles [19] (see Section III, 6).

Here special emphasis must be laid on the fundamental difference between sulphur-containing heterocycles and their oxygen analogues. Bearing in mind that the barrier to rotation about the C–O bond is greater than for the C–S bond [20] (2.7 kcal mole^{-1} in methyl ether [21]), the energy difference between the chair and boat conformations of oxygen-containing systems is presumably the same as for cyclohexane. There has been a fairly lively discussion of this problem in the literature; however, the evidence in support of the dominance of boat conformations is frequently based on incorrect theoretical postulates or an incorrect interpretation of experimental data. (See, for example, the discussion concerning 1,4-dioxane derivatives [22-24].) The theoretical estimates of the enthalpy differences between the two conformations of tetrahydropyran [25] (3.9 kcal mole^{-1}) and 1,3-dioxane [26] (2.2 kcal mole^{-1}) evidently cannot be regarded as satisfactory because they were derived taking into account the barrier in methanol, whereas it would be more logical to employ the barriers to rotation in ethers†. Reliable experimental data on the thermodynamics of epimerisation and the heats of formation of 1,3-dioxane derivatives yield 7.1 kcal mole^{-1} for the difference between the enthalpies of the chair and boat forms [14,27-29]. The thermodynamic parameters of the conformational equilibrium of the chair–twist type for the cyclic compounds under consideration are compiled in Table 1.

Thus the specific features of sulphur-containing heterocycles should be revealed in a tendency towards an increased fraction of boat conformations in conformational equilibrium; this should be particularly true of heterocycles with several heteroatoms.

Next, the replacement of a carbon atom by a sulphur atom in a six-membered alicyclic compound should lead to an appreciable distortion of the geometry of the ring, since the length of the C–S bond (1.81 Å) [30] is much greater than that of the C–C bond (1.52 Å) and the C–S–C angle (about 100°) [7-12] differs appreciably from the tetrahedral value. This should lead to an increase of the degree of puckering of the ring and a change in the magnitude of the 1,3-diaxial repulsion.

We shall consider the effect of these factors on the conformational characteristics. An increase in the degree of puckering should lead to an increase of the dihedral angles in the ring.



(I) (II) (III) (IV)

The dihedral angles for cyclohexane [31] (see Buys and Geise [32] for a compilation of data on cyclohexane), dioxane [31], oxathiane [33,34], and dithiane [34,35] are shown in diagrams (I)–(IV). The "average dihedral angle" has been introduced [34] as a parameter characterising the puckering or flattening of the ring. For the above compounds, the values of this parameter are 54.5°, 57.9° (Romers et al. [34]), 58.3° (Schultz et al. [33]), and 65° (Schultz et al. [33]) respectively, which also confirms the above view. Thus, whereas the cyclohexane ring is flattened, the introduction of a sulphur atom leads to an appreciable increase of the dihedral angles.

Table 2. The parameters R for certain six-membered compounds of type X⬡Y.

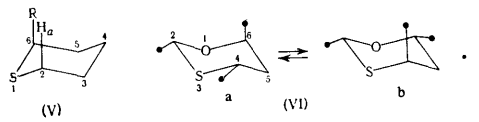
X	Y	I_{trans}, Hz	I_{cis}, Hz	R	Refs.	X	Y	I_{trans}, Hz	I_{cis}, Hz	R	Refs.
CD_2	CD_2	8.04	3.65	2.20	40	S	S	8.11	2.40	3.38	36
O	O	6.11	2.78	2.20	36	O	CD_2	7.41	3.87	1.9	37
O	S	7.35	2.65	2.77	36	S	CD_2	8.54	3.26	2.61	37

Analogous data were obtained in a study of the conformations in solution by ^{1}H NMR. The protons of adjacent methylene groups of 1,4-heterocyclic systems give rise to the AA'BB' signal in the spectrum, from which one can obtain experimental values of I_{cis} and I_{trans}. The first is equal to I_{ae} and the second to $\frac{1}{2}(I_{aa} + I_{ee})$. Their ratio $R = I_{trans}/I_{cis}$ is a parameter characterising the distortion of the chair conformation [36-39]. For a normal chair, $R \simeq 2.2$, while for a puckered chair the parameter should be greater [36-40]. Table 2 lists the values of I_{trans}, I_{cis}, and R for a series of six-membered rings. Evidently all the sulphur-containing compounds have significantly higher values of the parameter R, reaching 3.38, which is evidence of a very marked increase of the dihedral angle in the ring.

We shall examine the variation of the 1,3-*syn*-axial interaction in sulphur-containing rings. The $C_{(2)}$–$C_{(6)}$ distance in tetrahydrothiopyran (V) is greater than in

†The conclusion that the energy difference between the above conformations of 1,3-dioxane is reduced [6] is likewise unsatisfactory owing to the neglect of the eclipsed butane conformations.

cyclohexane, because the smaller C–S–C valence angle compared with C–C–C does not compensate the increased C–S bond length. For example, the $C_{(2)}$–$C_{(6)}$ distance in dithiane is 2.8 Å,[9-12,34] while in cyclohexane the distance is 2.5 Å.[31,32,41] Consequently this should lead to an increase of the distance between R and H_a in tetrahydrothiopyran and hence to decreased 1,3-*syn*-axial repulsion. Consequently the quantity ΔGR, characterising the difference between the free energies of the equatorial and axial conformers[42], will have a smaller absolute magnitude in a series of sulphur-containing heterocycles than in the cyclohexane series, as has been confirmed experimentally[43-47]. In this connection it is important to emphasise also that the reverse situation obtains with oxygen-containing compounds: since the $C_{(2)}$–$C_{(6)}$ distance in this case is 2.3 Å, the steric interaction between R and H_a is much more pronounced[14,29]. This can be clearly illustrated for the isomerisation of trimethyloxathianes (VI, a and b):



(V) a (VI) b

It has been found that for this equilibrium $-\Delta H = 1.15$ kcal mole^{-1}, $-\Delta S = 0.04$ e.u., and $-\Delta G_{25^\circ} = 1.16$ kcal mole^{-1}.[44] Thus the methyl group in the axial position is located "preferentially" next to the sulphur atom at $C_{(4)}$. Pihlaja and Pasanen[44-46] calculated by an additive procedure the contributions of the individual interactions in 1,3-heterocyclic six-membered systems, the relevant data being presented in Table 3.

Table 3. The contributions of the 1,3-interactions for heterocycles with heteroatoms in the 1,3-positions[44].

Heteroatom		Interaction energy, kcal mole^{-1}				
1	3	$H_{(2)}$-$Me_{(6)}$ or $H_{(6)}$-$Me_{(2)}$	$H_{(2)}$-$Me_{(4)}$ or $H_{(4)}$-$Me_{(2)}$	$H_{(4)}$-$Me_{(6)}$ or $H_{(6)}$-$Me_{(4)}$	$Me_{(5)}$-1	($Me_{(5)}$-3
O	O	2.035	2.035	0.885	0.46	0.46
S	S	0.885	0.885	0.805	0.52	0.52
O	S	2.20	1.05	0.73	0.74*	

*The sum $Me_{(5)} - 1 + Me_{(5)} - 3$.

Table 3 shows that the energies of the *syn*-axial interaction of the methyl group and the hydrogen atom in the 2- and 6-positions in dioxane and dithiane are 2.035 and 0.885 kcal mole^{-1}, i.e. differ by a factor of 2.3. We may mention for comparison that ΔG for methylcyclohexane is 1.7 kcal mole^{-1}.[42]

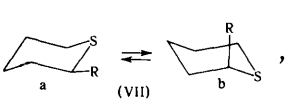
The introduction into the ring of a heteroatom with a lone pair of electrons gives rise to the problem of their interaction with the axial substituent. The problem of the existence of the "steric volume" of the electron pair of the heteroatom as an effective conformational parameter is controversial[13,48-55]. Table 3 shows that the repulsion of the axial methyl group in the 5-position from the oxygen atom (0.46 kcal mole^{-1}) is weaker than its repulsion from the sulphur atom (0.52 kcal mole^{-1}), which may be attributed to the increase of the van der Waals radius. However, both these values are fairly low, which is the reason for the possible existence of axial conformers.

The most striking example is provided by 2,5-*cis*-disubstituted derivatives of 1,3-dioxane and 1,3-dithiane[52-55] in which even the t-butyl group can assume the axial conformation[52]. However, in the presence of a polar substituent the situation becomes more complicated. Dipole–dipole repulsion or attraction between the substituent and the heteroatom[44] as well as interaction between the orbitals of the lone electron pairs of the ring heteroatom and the substituent become possible ("the hockey-stick effect")[29,56,57]; see Section III, 4). However, *a priori* estimates for dipole interactions in sulphur-containing compounds are difficult. On the other hand, the overlapping of the orbitals should become more marked on passing from oxygen to sulphur by virtue of the greater spread of the 3*p* orbital of sulphur compared with the 2*p* orbital of the oxygen atom. Possibly one should also consider the difference between the degrees of hybridisation of oxygen and sulphur atoms (the C–O–C and C–S–C valence angles should be compared) and consequently the difference between the steric directions of the orbital axes of the lone electron pairs[13]. We may also note that the most striking effect of the conformational characteristics of heterocyclic compounds is probably the anomeric effect[58-60]. Bearing in mind the polar nature of this effect, it should be expected also for sulphur-containing compounds[59]. Finally the sulphur atom can be formally quadrivalent and sexivalent and hence tricoordinate and tetracoordinate respectively. Such compounds have many interesting conformational characteristics (see, for example, Refs. 61–63); but their discussion is outside the scope of the present review.

III. CONFORMATIONS OF SIX-MEMBERED SULPHUR-CONTAINING HETEROCYCLES

1. Derivatives of Tetrahydrothiopyran

There are no data on the geometry of tetrahydrothiopyran (thiane), but ^{1}H NMR spectroscopic data[36-38] (Table 2) show that the compound exists in the puckered chair form. The experimental barrier to the inversion of tetrahydrothiopyran is 11.7 kcal mole^{-1} [37] (cf. 10.7 kcal mole^{-1} for tetrahydropyran[37]) and is therefore close to the value for cyclohexane derivatives[64]. Systematic conformational studies on functional derivatives of tetrahydrothiopyran have not been made either. In stereochemical studies on compounds of this series attention was concentrated on the problem of the anomeric effect. The equilibrium (VII) has been investigated[43,47,65] for a wide range of 2-substituted tetrahydrothiopyrans and the presence of a distinct anomeric effect was demonstrated [the predominance of conformer (VIIb) in the conformational equilibrium]:

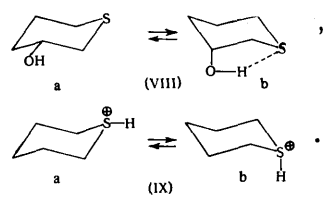


a (VII) b

where R = Cl,[47] OH,[66] OR,[43,47] SAlk,[43,47] SAr,[43] or $SP(S)(OR)_2$.[43]

The effect of the solvent on the position of conformational equilibrium is consistent with the polar nature of the anomeric effect: on passing from CCl_4 to CH_3CN, the contribution of conformer (VIIb) diminishes. The anomeric effect is shown to a greater extent with the

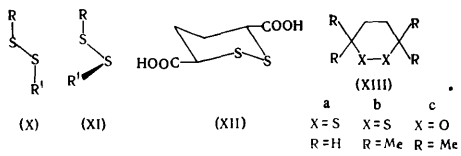
C–S–C–OR fragment than with C–O–C–SR.[59] This behaviour was explained by the weakening of the 1,3-*syn*-axial repulsion in tetrahydrothiopyran (see Section II). It must be emphasised that the anomeric effect has been found for the C–S–C–SR fragment and therefore the repulsion between the two sulphur atoms is fairly strong and must be taken into account as one of the factors in conformational equilibrium (0.7 kcal mole^{-1} in carbon tetrachloride[43]). As expected, the anomeric effect for 2-chlorotetrahydrothiopyran is fairly pronounced (1.75 kcal mole^{-1}).[47] We may also note that an appreciable "benzene effect" has been found for 2-alkoxytetrahydrothiopyrans[34,47]. An interesting conformational features has been noted for 3-hydroxytetrahydrothiopyrans[67]. Infrared spectroscopy revealed the presence of an intramolecular hydrogen bond in this compound, but the existence of the latter is possible only for the axial conformation (VIIIb). We may also note that the axial conformer (IXb) predominates in the conformational equilibrium of the protonated form (IX)[37]:



^{1}H NMR data have shown that the geometries of the rings of tetrahydrothiopyran and its *S*-methylsulphonium salt are almost identical and *R* is in the range 2.3–2.6.[68]

2. Derivatives of 1,2-Dithiane

For aliphatic disulphides, the transoid conformation (X) is not the most stable, as might have been expected on the basis of elementary stereochemical considerations. The disulphide molecule has the zig-zag shape (XI),[69–72] as shown by quantum-mechanical calculations of the potential curves for barriers to rotation about the S–S bond, and is consistent with the concept of the so called "*gauche*-effect"[73,74]. It is important to emphasise in this connection that such geometry of the disulphide bridge makes it possible to incorporate it without much strain in the chair conformation of the six-membered ring.



There are few experimental data for 1,2-dithianes. X-Ray diffraction analysis of *trans*-1,2-dithiane-3,6-dicarboxylic acid (XII) showed that the compound exists in the chair conformation with the carboxy-groups in the equatorial positions[75,76].

A study of the temperature variation of the ^{1}H NMR spectra of 1,2-dithiane (XIIIa) showed that the free energy of the inversion of the chair form is 11.6 kcal mole^{-1}.[77] Similarly $\Delta G^{\neq}_{-20^\circ C}$ for the tetramethyl derivative (XIIIb) is 13.8 kcal mole^{-1} ($\Delta S^{\neq}$ = 6.7 e.u.)[77]. This value is smaller than for the corresponding oxygen-containing analogue (XIIIc), where $\Delta G^{\neq}_{12^\circ} = 14.6$ kcal mole^{-1} ($\Delta S^{\neq} = 14.4$ e.u.).

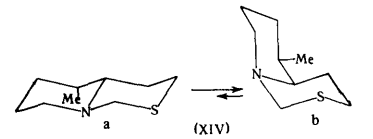
It is particularly interesting that the curves giving the energy as a function of the coordinate for the conformational transition of the last two compounds differ appreciably from one another[77]. The authors attribute this to different transition states in the inversion of these compounds. Compound (XIIIc) undergoes inversion via an asymmetric boat form (minimum) with two maxima corresponding to conformations with planar five-atom fragments. The maximum for the sulphur-containing compound (XIIIb) corresponds to the symmetrical boat conformation. This conformation is impossible for compound (XIIIc) owing to the powerful repulsion of the methyl group in the "flagstaff" position; such repulsion for the sulphur-containing compound (XIIIb) is much weaker owing to the increase of the C–S distance.

3. Derivatives of 1,3-Oxathiane and 1,3-Dithiane

Six-membered systems with heteroatoms in the 1,3-positions have recently been studied extremely vigorously. The results of these investigations have been described in several reviews[6,13,14,29,44]. Therefore we shall confine ourselves to an examination of the general relations formulated in Section II. The preferential conformation of 1,3-dithiane is the chair form with an inversion barrier of 10.4 kcal mole^{-1}.[78]

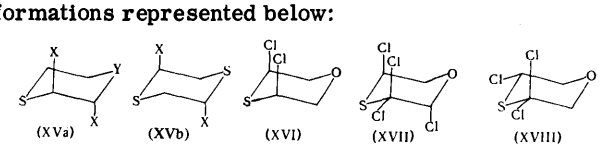
The powerful influence of hydrogen bonds on the relative stabilities of the conformations may also be noted. Thus the axial isomer of 5-hydroxy-1,3-dithiane is more stable than the equatorial isomer [ΔG = 0.5 kcal mole^{-1} (Luttringhaus et al.[79]) and 0.8 kcal mole^{-1} (Abraham and Thomas[80])].

Derivatives of 1-aza-3-thiabicyclo[4,4,0]decane exist in the chair conformation, like *trans*-decalin[81]. However, in the presence of the axial methyl group in the 7-position of compound (XIV) the conformation with the *trans*-junction becomes less stable and conformer (XIVb) with the *cis*-junction of the rings predominates in the conformational equilibrium[81]:

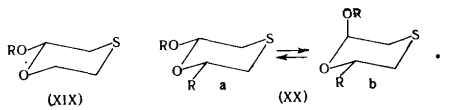


4. Derivatives of 1,4-Oxathiane and 1,4-Dithiane

Numerous studies on the geometries of oxathiane[7,8,34,82,83] and dithiane[9–12,34,35,84,85] showed that these compounds exist in the chair conformation. The inversion barrier for 1,4-dithiane itself is unknown; however it amounts to 10.05 kcal mole^{-1} for the perfluoro-derivative[86]. A distinct anomeric effect has been found for the *trans*-2,3- and *trans*-2,5-dihalogeno-derivatives (XV, a and b), since the halogen atoms occupy the axial positions[7,9,10]. Judging from the infrared spectra and the dipole moments, the same conformation exists also in solution. It has been found[82] that *trans*-3,5-dichloro-oxathiane (XVI) and also polychloro-oxathianes (XVII) and (XVIII) have the conformations represented below:



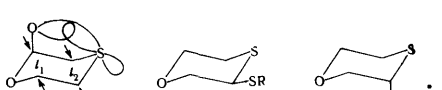
However, we may note that these assignments are based on the spin–spin interaction constants which sometimes had an "intermediate" value of the order of 6 Hz. Possibly this indicates the occurrence of conformational equilibria. Although the anomeric effect has been found for the majority of the compounds, for example (XV) and (XVI), certain questions remain obscure. For example, it is not clear why the diaxial repulsion between two chlorine atoms leads to the predominance of conformation (XVIII) but is not found in compound (XVII). The anomeric effect has been found also for a series of polyfluoro-derivatives of oxathianes and dithianes [87,88].



(XIX) (XX)

Unusual results were obtained in a study of the alkoxy-derivatives of oxathiane. Detailed studies of various 2-alkoxyoxathianes by ^{1}H NMR showed that the equatorial conformer (XIX) predominates in the conformational equilibrium [56], in sharp contrast to 2-alkoxy-derivatives of tetrahydropyran, tetrahydrothiopyran, and 1,4-dioxane [59]. For example, at least 50% of the equatorial form is present in conformation equilibrium for 2-methoxy- and 2-butoxy-1,4-oxathianes, These data were confirmed by a study of the epimerisation of 2-alkoxy-6-methyl-, 2-alkoxy-6-hydroxymethyl-, and 6-acetoxymethyl-2-alkoxy-1,4-oxathianes (XX) [89–92]. Epimerisation leads to an equilibrium in which the diequatorial isomer (XXa) (67%) predominates, in sharp contrast to the behaviour of tetrahydropyrans[59].

A possible explanation of this phenomenon was based on the "hockey-stick" effect [56,57]. The overlapping of the orbitals of the substituent and the sulphur atom leads to repulsion, because the two orbitals are populated by four electrons. Such repulsion probably depends on the nature of the heteroatoms (S > O) and fine geometrical details [for example, the relative distances l_1 and l_2 in compound (XXI)]:

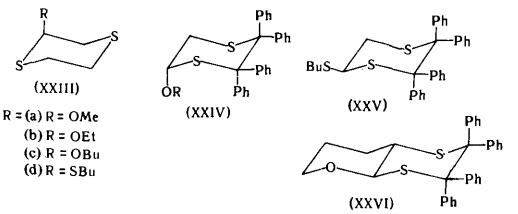


(XXI) (XXIIa) (XXIIb)

The position of conformational equilibrium for 3-propylthio- and 3-butylthio-1,3-oxathianes [93,94] depends on the solvent. In acetonitrile these compounds exist almost entirely in the equatorial conformation (XXIIa). An increased content of the axial conformer (XXIIb) (25–40%) is observed in carbon tetrachloride.

The data on the conformational behaviour of dithiane derivatives are non-systematic. The anomeric effect has been discovered for a series of 2-alkoxy- and 2-alkylthio-1,4-dithianes by ^{1}H NMR, [94] i.e. the axial conformation (XXIII) predominates. However, as noted by the authors themselves, these data are based on arbitrarily selected standard values of Iaa, Iae, and Iee and in the absence of a large set of data for model compounds this conclusion must be treated with caution. A distinct predominance of the axial conformer was found for the tetraphenyl derivative (XXIV). [95] However, the corresponding butylthio-derivative (XXV) exists in the equatorial conformation [95]. Possibly as a result of the large bulk of the sulphur atom, the 1,3-repulsion between the butylthio-substituent and the axial phenyl group predominates in this case over the anomeric effect. The axial conformation (XXIV) is possible owing to the weakening of the 1,3-repulsion (see Section II).

The reaction of thiobenzophenone with dihydropyran leads to the bicyclic compound (XXVI) having the *trans*-configuration [95,96]. In this connection it is interesting to investigate its epimerisation and to compare its stability with that of the *cis*-isomer.



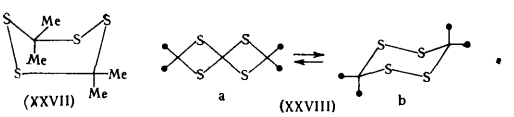
(XXIII) (XXIV) (XXV)

R = (a) R = OMe
(b) R = OEt
(c) R = OBu
(d) R = SBu

(XXVI)

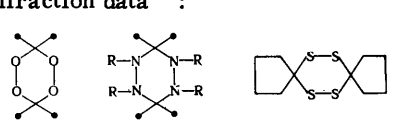
5. Heterocycles with Several Sulphur Atoms

As early as 1937, it was shown by X-ray diffraction that 1,3,5-trithiane exists in the chair conformation [97,98]. The inversion barrier is 11.0 kcal mole^{-1}. [99] However, X-ray diffraction analysis of 3,3,6,6-tetramethyl-1,2,4,5-tetrathiane (XXVII) showed that in the crystal lattice this compound has the true boat conformation (XXVII), the sulphur atoms being displaced from the plane [100]:



(XXVII) a (XXVIII) b

The study of the conformations of this compound in solution by ^{1}H NMR demonstrated the presence in the equilibrium mixture of two conformers: the more stable twist-form (XXVIIIa) and the less stable chair conformation (XXVIIIb). [101] At −15°C the (XXVIIIa)/(XXVIIIb) ratio in carbon disulphide is 2.6 and $\Delta G^{\neq}_{50}{}^{\circ} = 16$ kcal mole^{-1}. It must be emphasised that the oxygen analogue (XXIX) [102] and the nitrogen analogue (XXX) [103] of compound (XXVII) exist in the chair conformations. We may also note that the inversion barrier for the thia-derivative (XXVIII) is higher than for compounds (XXIX) ($\Delta G^{\neq}_{30}{}^{\circ} = 15.4$ kcal mole^{-1}) and (XXX) ($\Delta G^{\neq} = 11.7$ kcal mole^{-1}). An equilibrium between the chair and twist conformations, with the former predominating (80%) was observed also for the bistetramethylene derivative (XXXI). [101] The stability of the chair conformation of (XXXI) was also demonstrated by X-ray diffraction data [101]:



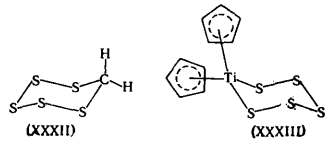
(XXIX) (XXX) (XXXI)

It is interesting that, when crystals of tetrathiane (XXVIII) are cooled to −80°C and dissolved at this temperature in carbon disulphide, a solution of the pure twist form is formed. Bearing in mind the above X-ray diffraction data, this finding implies that the boat/twist transition (XXVII) → (XXVIIIa) has an extremely low potential barrier [101].

Thus a minimal difference between the energies of the twist and chair conformations (0.49–0.6 kcale mole^{-1}) is characteristic of tetrathiane (XXVIII). This finding can be explained both by the factors discussed in section (II) and

by additional factors among which mention may be made of the *syn*-axial interaction of the electron pairs ("the rabbit ear effect"[104]) and the influence of the *gem*-dialkyl groups (the Thorpe–Ingold hypothesis concerning the deviation of the valence angles[105,106]).

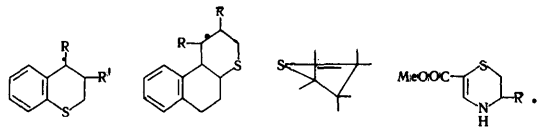
Pentathiane exists in an exceptionally stable chair conformation (XXXII).[107] The ^{1}H NMR spectrum at room temperature shows the signal of the AB-system of the equatorial and axial protons. The authors point out the possibility of inversion at elevated temperatures but do not quote experimental details. The separate signals of the two cyclopentadienyl rings are also shown for the analogous cyclic pentathia-compound (XXXIII) at +30°C. However, coalescence is observed at 90°C and at 120°C the spectrum consists of a sharp singlet, which indicates rapid (on the NMR time scale) inversion of the six-membered ring of compound (XXXIII)[108].



(XXXII) (XXXIII)

6. Sulphur-containing Heterocycles with a Multiple Bond in the Ring

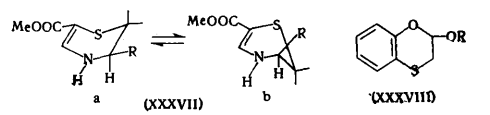
As stated above (section II), the half-chair conformation is the most stable for cyclohexene[15–17]. The "sofa" conformation is encountered in isolated cases[18]. The data concerning the most stable conformations of unsaturated sulphur-containing systems are unfortunately limited. The "sofa" conformation (XXXVI) has been adopted for a series of thiachromans (XXXIV) and dihydronaphthothiapyrans (XXXV):[19]



(XXXIV) (XXXV) (XXXVI) (XXXVII)

However, this conclusion was based only on the spin–spin interaction constants using the Karplus equation and cannot be regarded as very reliable. The "sofa" conformation was also postulated for derivatives of 2,3-dihydro-6-methoxycarbonyl-1,4-thiazine (XXXVII)[109–111], but the evidence supporting this is doubtful too.

A number of studies have been made on the conformations of functional derivatives. A distinct anomeric effect was found for 2-alkoxybenzoxathianes (XXXVIII):[112]



a (XXXVII) b (XXXVIII)

The content of the axial conformer is in excess of 80% and is almost independent of the nature of the alkoxy-group. Interesting data were obtained for compounds of type (XXXVII)[109–111]. The methyl derivative (XXXVII) (R = CH_3) contains equal amounts of the equatorial and axial forms, (XXXVIIa) and (XXXVIIc), in conformational equilibrium. The axial conformers (XXXVIIb) of compounds (XXXVII, R = OH, OAc, CH_2Cl, and CH_2I) predominate in the conformational equilibrium. The equilibrium position for the methoxycarbonyl derivative (XXXVII, R = $COOCH_3$) depends on the solvent: the conformer (XXXVIIa) predominates in non-polar solvents, while in polar solvents the equilibrium is displaced towards the axial form (XXXVIIb). Evidently a detailed interpretation of these results is fairly difficult.

The numerous "exceptions" found in conformational studies on heterocyclic compounds clearly show that the introduction of heteroatoms with lone electron pairs, which cause an appreciable change in the geometrical relations in the molecule, leads to the appearance of a new set of properties, the understanding of which requires a development of the principles of conformational analysis. Although experimental studies have clearly demonstrated the inadequacy of the theoretical concepts in the field of conformational analysis, nevertheless it is already possible to discover in broad outline the principal characteristics of the conformational behaviour of heterocycles. As shown by the present review, sulphur-containing compounds exhibit interesting and even unique conformational features, the further study of which will undoubtedly promote a general progress in this branch of stereochemistry.

---o0o---

Further reports were published[113–115] during the period when the review was considered by the editors.

The Mode of Cyclisation of the Arylhydrazones and *O*-Phenyl Ethers of the Oximes of Asymmetric Ketones Under the Conditions of the Fischer Reaction

I.I.Grandberg and V.I.Sorokin

Both the Fischer synthesis of indoles and the recently discovered rearrangement of *O*-phenyl ethers of oximes, which takes place under similar conditions and leads to the formation of benzofurans, are assessed in the review from the same standpoint. A number of studies published recently altered the ideas held for a long time concerning the mode of cyclisation of the arylhydrazones of asymmetric ketones into indoles. It was believed previously that CH_3, CH_2, and CH groups in the α-position in the carbonyl fragment constitute a series in which the capacity for cyclisation increases. However, it has been found that the acidity of the medium plays a very significant role in determining the mode of cyclisation and can actually reverse it. The concepts put forward to account for this finding are examined critically and general ideas are developed which, in the author's view, explain satisfactorily the influence of the pH of the medium and of certain other factors on the mode of cyclisation of both arylhydrazones and *O*-aryloximes.
The bibliography includes 109 references.

1. GENERAL POSTULATES OF THE MECHANISM OF THE FISCHER REACTION

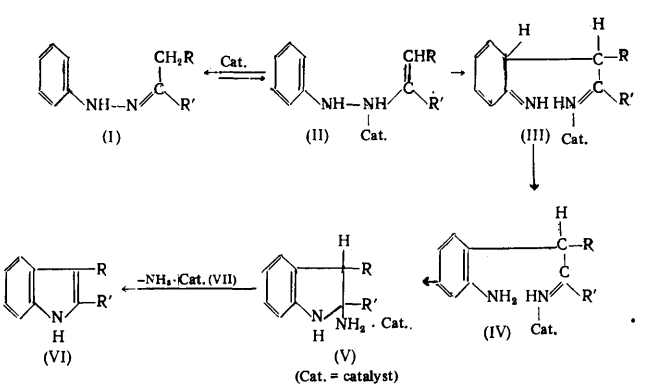
The cyclisation of arylhydrazones into indole derivatives in acid media, discovered by Fischer in 1883,[1] still continues to attract attention. This reaction has become the basis for a general, convenient, and easy preparative method for synthesising a wide variety of indole derivatives. Several mechanisms have been proposed at different times for this reaction, but those put forward by Reddelin[2] and Wieland[3], Bamberger and Landau[4], Neber et al.,[5] and Pausacker and Schubert[6] failed to pass experimental tests.

The generally accepted mechanism of the Fischer indole synthesis, to which a number of reviews have been devoted[7-12], is now that proposed by G. M. and R. Robinson[13,14] supplemented and additionally elucidated by Allen and Wilson[15], Carlin and Fischer[16], Arbuzov and Kitaev[17], and Suvorov et al.[18]

The elucidation of the mechanism of the synthesis of tryptamines from arylhydrazones and γ-chloroketones in a number of studies by Grandberg and coworkers[19-22] also made a definite contribution to the Robinson mechanism.

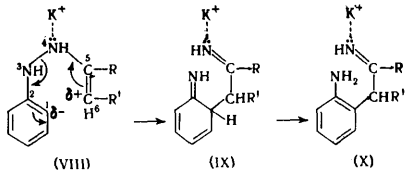
According to the Robinson mechanism, the reaction proceeds via the following main stages: (1) tautomeric conversion of the hydrazone (I) into the enehydrazine (II); (2) formation of a new C–C bond [(II) → (III)]; (3) cyclisation with subsequent elimination of an ammonia molecule and the formation of the indole structure [(III) → (IV) → (V) → (VI)].

The first and second stages of the reaction [(I) → (II) and (II) → (III)] are of greatest theoretical interest, while the last stage [(III) → (IV)] permits different ways of indole ring closure, depending on the conditions under which the indole is formed.



The most important stage of the process—the formation of a new C–C bond [(II) → (III)]—was regarded until recently as involving intramolecular electrophilic attack by the ene fragment on the aromatic ring[9-12]. On the basis of the concepts of the general theory of conjugation[23,24], Arbuzov and Kitaev[17] suggested that this stage be regarded as an intramolecular rearrangement of the activated 1,6-conjugated system. In an acid medium or on formation of a complex with the catalyst, this conjugated system is activated: bond polarisation is enhanced as a result of which the atoms in the 1- and 6-positions receive excess charges which are of opposite sign. When these atoms are in significantly close proximity, the formation of a bond between them, leading to a redistribution of

electron density in the system and the rearrangement (VIII) → (X) with dissociation of the 3–4 linkage, becomes quite probable.

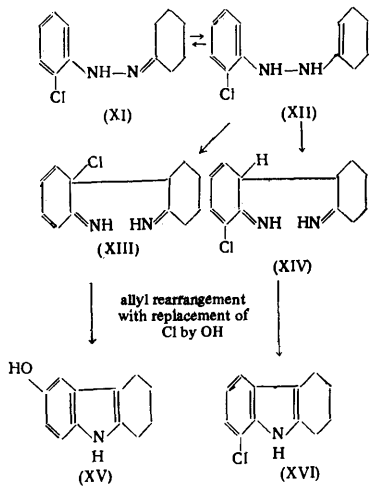


(VIII) (IX) (X)

However, it is noteworthy that there is virtually no direct experimental evidence for the electrophilic attack.

The evidence supporting the electrophilic attack, which explains the influence of substituents in the aromatic ring of arylhydrazones on the reaction, quoted by a number of workers[25–28] is based on two unproved hypotheses, namely that the stage involving the formation of a new C–C bond [(II) → (III)] determines the rate of the entire reaction and that the yield of the indole derivative is directly proportional to the rate of the stage. Moreover, the ideas according to which the formation of the C–C bond involves a carbon atom in the aromatic ring already occupied by a substituent are inconsistent with the general theory of electrophilic substitution. It is well known that as a rule an electrophilic species is directed to the position without a substituent even in those cases where the substituent is an electron-donating group. This is because the abstraction of a proton from the resulting σ-complex is more favourable on energy grounds than the abstraction of another positively charged group. Exceptions are observed only in the case of non-concerted orientation, severe process conditions, and marked electrophilicity of the attacking species (NO_2^+, SO_3H^+).[29]

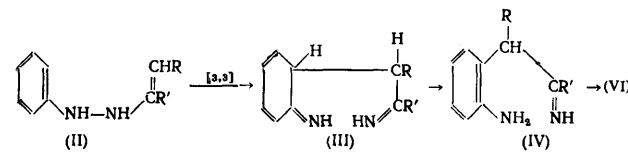
As an example one may quote the data of Barnes et al.,[30] who observed the formation of a mixture of two products [(XV) and (XVI)] on conversion of the *o*-chlorophenylhydrazone of cyclohexanone (XI) into an indole derivative. It was found that, together with the normal product 8-hydroxytetrahydrocarbazole (XVII), the reaction involves also the formation of 6-hydroxytetrahydrocarbazole (XVI), the structure of which was subsequently proved[31], i.e. the formation of the C–C bond involves also a position occupied by a substituent even though a free position is present in the aromatic ring.



(XI) (XII) (XIII) (XIV) (XV) (XVI)

Indole structure syntheses of this kind, in which the C–C bond is formed with a carbon atom of the aromatic ring occupied by a substituent with subsequent migration or elimination of the substituent, are fairly numerous[16,32–42]. These results led to doubts being cast in one of the recent studies on the electrophilic mechanism of the formation of the C–C bond in the second reaction stage[43] and it was suggested that the formation of the C–C bond in the Fischer reaction occurs as a result of a sigmatropic [3,3] rearrangement.

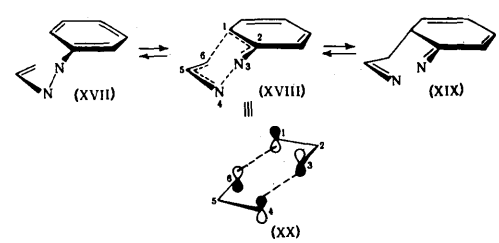
A similar approach was previously justified in the discussion of the mechanism of the Claisen rearrangement[44,45]. Other reactions related to the Fischer indole synthesis (for example the benzidine rearrangements) were also regarded in the above study as sigmatropic rearrangements[43].



(II) (III) (IV) →(VI)

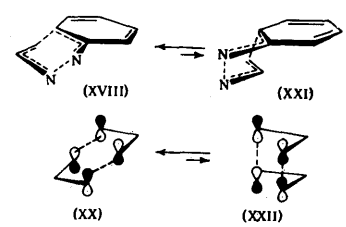
Cautious attempts to regard the Fischer reaction as a sigmatropic rearrangement were described in the literature even earlier. Thus Schmid and coworkers[46] suggested that the acid-catalysed Fischer reaction may be a sigmatropic process and Robinson suggested, using a more cautious form of words[10], that a process of this kind is possible only in the thermal indole-formation reaction.

In the study quoted above[43] an attempt was made to explain the available experimental literature data for the Fischer reaction and similar processes from the standpoint of the principle of the conservation of orbital symmetry. In this treatment the formation of a new C–C bond in the reaction proceeds via a four-centre transition state [the chair conformation (XVIII)], which consists of two highest occupied molecular orbitals of allyl radicals in which the 3–4 linkage has still not been finally ruptured and the 1–6 linkage has not been finally formed [formula (XX)].



(XVII) (XVIII) (XIX) (XX)

The interaction of the central parts of the non-bonding molecular orbitals does in fact occur in the chair conformation[47], which is the reason for its advantage over the boat conformation of the transition state (XXII).

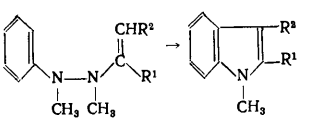


(XVIII) (XXI) (XX) (XXII)

In this approach to the process the nitrogen atoms in the 3- and 4-positions, in the system of atoms in the positions ranging from 1 to 6 which are directly involved in the rearrangement, are formally treated as carbon atoms; hence it is assumed that their n electrons are not involved in the process[43]. The recently described syntheses of 1-acylindoles can probably be regarded as experimental confirmation of this postulate[48-50].

Sigmatropic rearrangements are known to be non-catalysed intramolecular thermal processes. Therefore the question of the validity of the extension of the theory of sigmatropic reactions to the Fischer cyclisation of phenylhydrazones, which are classified as acid-catalysed processes[7-12], may seem to arise at first sight. However, it has recently been suggested in a number of studies that the involvement of acid catalysts in the Fischer reaction is not obligatory[51,52]. Moreover it has been shown that, when the enehydrazine formed is reduced in the synthesis of the arylhydrazone, it is readily converted into an indole derivative on heating both with and without a catalyst[43].

Chiess and Grieder[53] investigated the behaviour of enehydrazines on heating in the absence of a catalyst and established that the enehydrazines (XXIII) give rise in this case to a 25–74% yield of the corresponding indoles (XXIV) in decalin at 110°C. This cyclisation was also achieved in absolute acetonitrile in the presence of 0.5 N dichloroacetic acid:



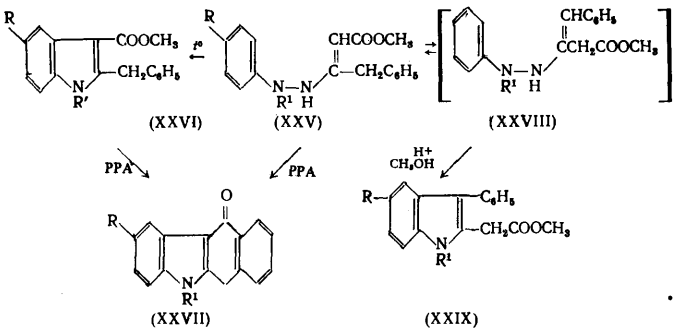
(XXIII) (XXIV)

In most cases the use of an acid catalyst accelerates the process and lowers the reaction temperature.

Kelly et al. investigated the thermal conversion of phenylhydrazones into indoles without using acid catalysts, which proved to be successful[54] (this study is described in detail below).

In a study of the behaviour of methyl γ-phenylacetoacetate in the Fischer indole synthesis, Grinev and coworkers[55,56] established that compound (XXV) is converted in a thermal process into 2-benzylindole derivatives (XXVI). When compound (XXV) was treated with polyphosphoric acid, derivatives of 6,11-dihydro-11-hydroxybenzo[b]carbazole (XXVII) were isolated. The reaction probably proceeded via a stage involving the formation of methyl esters of 2-benzylindole-3-carboxylic acids (XXVI) with subsequent intramolecular cyclisation, since on heating with polyphosphoric acid compound (XXVI) yielded compound (XXVII). When compound (XXV) was treated with sulphuric acid in methanol at room temperature, methyl esters of 3-phenylindole-2-acetic acid (XXIX) were isolated.

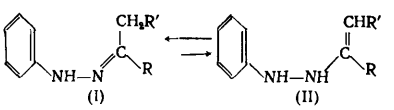
Thus experimental data show that, contrary to the generally accepted view, the Fischer reaction can occur also in the absence of acid catalysts. It is well known that, for compounds containing atoms with different electronegativities in the tautomeric triad (for example, in the keto–enol, lactim–lactam, and thione–thiol tautomerism), the tautomeric equilibrium is usually displaced towards the form in which the proton is linked to the less electronegative atom.



(XXVI) (XXV) (XXVIII)

(XXVII) (XXIX)

For arylhydrazones of the usual carbonyl compounds (I), the shift of the equilibrium towards the hydrazone should be enhanced also in consequence of the electronegative influence of the C_6H_5NH residue on the main tautomeric fragment, since electron-accepting substituents at the nitrogen atom in potentially tautomeric systems are known to shift the tautomeric equilibrium in this particular direction[57]:



(I) (II)

Calculations by the LCAO-MO method in terms of the Hückel approximation of the molecular energies of the tautomeric forms of acetophenone phenylhydrazone confirmed that arylhydrazones exist in the hydrazone and not the enehydrazine form—the latter is less favourable to the extent of approximately 4 kcal mole^{-1} even for acetophenone hydrazone, where it is stabilised by conjugation[58].

This can explain the finding that the existence of the enehydrazine form (II) in solutions of arylhydrazones of aliphatic aldehydes and ketones has not so far been observed by physicochemical methods[10]. The 23 kcal mole^{-1} energy gain for the protonated hydrazine molecule in relation to the enamine is evidence that acid agents displace the equilibrium towards the hydrazone form but at the same time they should increase also the rate of the tautomeric transformation by taking part in proton transfer[43].

However, insufficient attention has been devoted to the mechanism of the tautomeric transformation, particularly bearing in mind that, according to kinetic studies[59-62], this is in fact the rate-determining stage in the Fischer reaction. Pausacker and Schubert[59] made the first attempt to investigate the kinetics of the Fischer reaction. They established that in glacial acetic acid the reaction is of first order. Subsequently this was confirmed by other investigators[60,61], although the cyclisation conditions were different. The reaction was performed in glacial acetic acid[60] and in alcoholic solutions of hydrochloric acid[62], while Grandberg and Przheval'skii[61] studied the kinetics of the conversion of cyclohexanone phenylhydrazone into an indole derivative on treatment with allyl bromide.

Scheltus determined the rate constants for the cyclisation of cyclohexanone phenylhydrazone in an aqueous alcoholic solution of hydrochloric acid[62]. Measurements were

also made of the rate constants for the conversion of the phenylhydrazones of various cyclic ketones into indole derivatives, which were compared with the pK_a values for these compounds[62]. Moreover it has been noted[59-62] that, following the addition of water to the solvent, the rate of reaction increases. Thus Pausacker and Schubert[59] established that, on diluting glacial acetic acid by the addition of 6.3 and 16.0 mole % of water, the rate constant increases from 6.18×10^{-5} to 7.68×10^{-5} and 9.37×10^{-5} respectively.

In a study of the effect of the acidity of the medium on the rate of the Fischer reaction it was established[62] that the values of $\lg k$ are satisfactorily correlated with the acidity functions H_0 (Fig. 1).

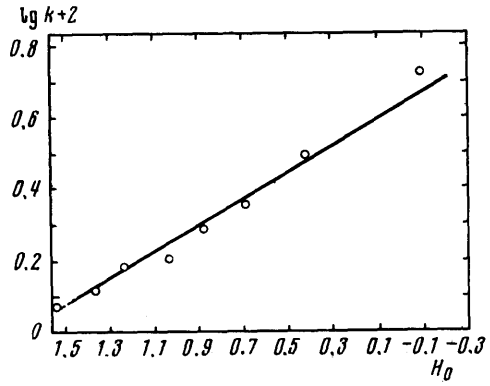


Figure 1. Variation of the logarithm of the rate constant for the reaction of cyclohexanone phenylhydrazone with the acidity function H_0 in 60% methanol as the solvent.

The problem arises of which stage of the conversion of the arylhydrazone into an indole should be regarded as the slowest. If one assumes that this stage is the formation of a new C–C bond as a result of electrophilic attack on the aromatic ring, it is difficult to explain from this standpoint the marked acceleration of the reaction by the p-CH_3O group in relation to the m-CH_3O group (from the standpoint of electrophilic substitution, the opposite effect should have been observed). Moreover, it is well known that electrophilic substitution in the aromatic series is accelerated by the introduction of electron-donating substituents into the ring, but it has been observed that the introduction of the m-CH_3O group leads to a decrease of the rate of reaction compared with the unsubstituted product.

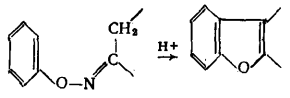
Thus experimental facts suggest that the stage involving the formation of a new C–C bond is hardly rate-limiting in the Fischer reaction and throw doubt on its electrophilic nature.

These kinetic data can be satisfactorily accounted for from another standpoint, namely that the slowest stage is the tautomeric conversion of the hydrazone into the enehydrazine [(I) ⇌ (II)].

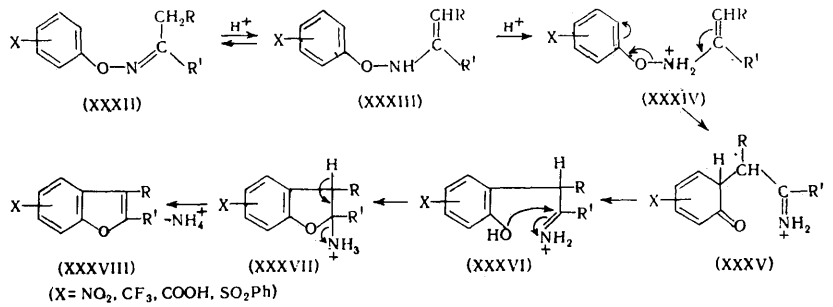
The following facts confirm this view: (1) on cyclisation of the phenylhydrazone of α-deuterated cyclohexanone, a kinetic isotope effect was observed ($K_D/K_H = 1.8$)[62]: (2) in the D_2O–CH_3OH–HCl solution cyclohexanone phenylhydrazone reacts twice as fast as in the H_2O–CH_3OH–HCl system[62]; (3) the rate constants for the phenylhydrazones of cyclic ketones are satisfactorily correlated with the basicities of these compounds[62]; (4) a methyl group introduced into the 2-position of the cyclohexane ring of cyclohexanone phenylhydrazone accelerates the reaction approximately by a factor of eight compared with the unsubstituted hydrazone[60]; an increase of the acidity of the medium leads to an increase of the rate of reaction[62].

In addition it is possible to explain from this standpoint the effect of substituents in the aromatic ring on the rate of reaction. Electron-donating substituents in the p- and o-positions in the aromatic ring of arylhydrazones increase the basicity of the β-N atom (protonation is probably the initial stage of the tautomeric transformation), in contrast to the substituents in the m-position. This is also indicated by the finding[63,64] that the basicity of the three isomeric methoxyphenylhydrazones decreases in the sequence 4 > 2 > 3.

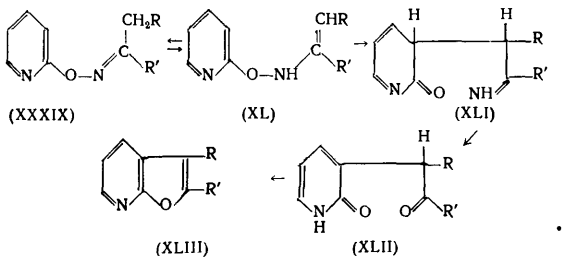
Thus, on the basis of data for the kinetics of the Fischer reaction, one can probably assume that the rate-limiting stage is the tautomeric conversion of the hydrazone into the enehydrazine [(I) ⇌ (II)]. In 1966 Sheradsky reported the acid-catalysed rearrangement of phenyl ethers of oximes (XXX) into benzofuran derivatives (XXXI), which he discovered[65]:



This report was followed by several communications in which it was suggested that the mechanism of this reaction is analogous to that of the Fischer indole synthesis[66-76]:



It is interesting to note that the introduction of two powerful electron-accepting groups, such as two NO_2 groups or a CF_3 and an NO_2 group, into the *o*- and *p*-positions in the aromatic ring does not prevent the closure of the benzofuran ring (39% yield for derivatives with *o*-CF_3 and *p*-NO_2 groups and 20% yield for derivatives with NO_2 groups in *o*- and *p*-positions)[68,72]. The initial attempt to carry out this rearrangement under thermal conditions did not lead to the required result, since on heating the product charred markedly[67]. However, subsequently the thermal rearrangement (XXXIX) → (XLII) was achieved using *O*-(2-pyridyl) oximes of carbonyl compounds[74]:



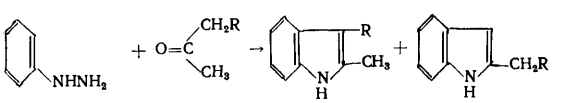
(XXXIX) (XL) (XLI) (XLIII) (XLII)

It has been suggested[43,52] that, in the stage involving the formation of a new C–C bond, this rearrangement should also be regarded as a sigmatropic [3,3] shift and not electrophilic substitution.

2. THE MODE OF CYCLISATION OF ARYLHYDRAZONES OF ASYMMETRIC KETONES

a. The Mode of Conversion of the Arylhydrazones of Alkyl Methyl Ketones into Indoles

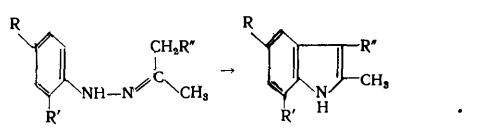
In 1886 Fischer stated that two isomeric indoles, the products of cyclisation involving both alkyl groups, can be formed in the reaction of phenylhydrazine and asymmetric ketones[77]:



(XLIV) (XLV) (XLVI) (XLVII)

However, until recently the entire vast experimental data on the Fischer reaction indicated that only one compound (XLVI) is formed in this process.

Thus Buu-Hoi and Reyer[79] showed that, when a methyl and a methylene group adjoin the carbonyl group, indoles are formed only via the methylene group. Schofield and Theobald[80] demonstrated chromatographically that there is no second substance in the product isolated after the cyclisation of the *o*- and *p*-nitrophenylhydrazones of 2-pentanone (XLVIII, a and b) and *o*- and *p*-nitrophenylhydrazones of phenylacetone (XLVIII, c and d).

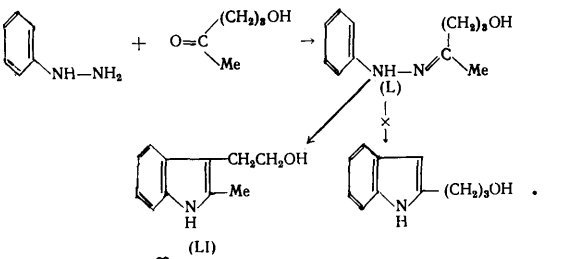


(XLVIII) XLIX

(a) R=NO_2 R′=H R″=Et
(b) R=H R′=NO_2 R″=Et
(c) R=NO_2 R′=H R″=Ph
(d) R=H R′=NO_2 R″=Ph

Later a very small amount of a dark tarry product, the structure of which was not established, was isolated in the chromatographic separation on alumina of the cyclisation products of the phenylhydrazone of phenylacetone (XLVIII, R = R′ = H, R″ = Ph). However, it was suggested that this consisted of traces of 2-benzylindole.

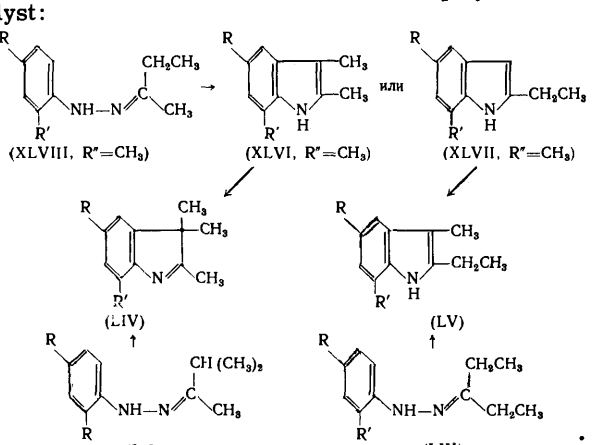
Grandberg et al.[82] established that the reaction of phenylhydrazine (XLIV) and 1-hydroxypentan-4-one yields the hydrazone (L); they cyclised it under the conditions of the Fischer reaction using zinc chloride and copper(I) chloride as catalysts. In both cases 3-(β-hydroxyethyl)-2-methylindole (LI) was isolated in a pure form and 2-(γ-hydroxypropyl)indole, the possible second product, was not detected:



(L) (LI)

Deorha and Joshi[83] confirmed that the methylene group is exclusively involved in the Fischer conversion of the phenylhydrazones of asymmetric ketones into indoles. The structures of the compounds isolated were established by methylation. Thus the methylation product of the indole obtained from the arylhydrazone of 2-butanone (XLVIII) is either compound (LIV) or (LV), since the indole has either the structure (XLVI) or (XLVII). It was established that compound (LIV) is identical with the compound obtained in the cyclisation of the arylhydrazone of 3-methylbutan-2-one (LII) and compound (LV) is identical with the product of the cyclisation of the arylhydrazone of 3-pentanone (LIII). Thus the indole obtained from compound (XLVIII) is 2,3-dimethylindole formed as a result of the cyclisation involving the methylene group [compound (XLVI)].

The formation of two isomers was noted only in a study by Korczynski et al.[78]; having discovered that *p*-diazonitrobenzene reacts with 2-monosubstituted indoles but not with 2,3-disubstituted derivatives, the authors established that the phenylhydrazone of ethyl methyl ketone yields a mixture of products as a result of the Fischer reaction, containing 20% of ethylindole and 80% of 2,3-dimethylindole, when an excess of zinc chloride is employed as the catalyst:



(XLVIII, R″=CH_3) (XLVI, R″=CH_3) (XLVII, R″=CH_3)
(LIV) (LV)
(LII) (LIII)

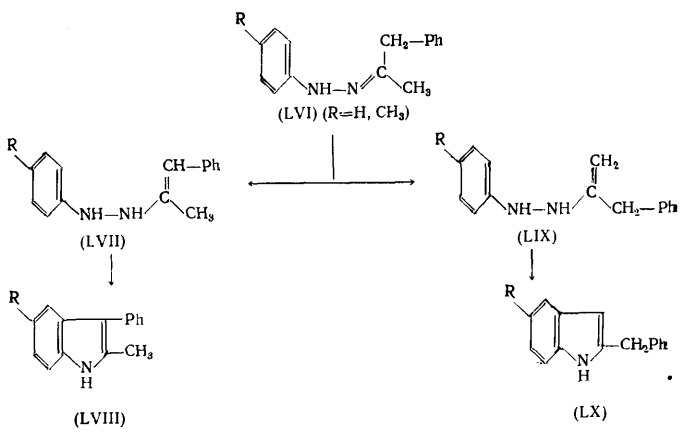
(a) R=NO_2, R′=H; (b) R=H, R′=NO_2; (c) R=Cl, R′=NO_2; (d) R=NO_2, R′=Cl; (e) R=I, R′=NO_2; (f) R=NO_2, R′=I

Thus numerous examples of the synthesis of 3-substituted 2-methylindoles by the Fischer reaction using various catalysts, which have been described in the literature[7-12], suggest that the arylhydrazones of asymmetric ketones yield exclusively 3-substituted 2-methylindoles as a result of the Fischer reaction.

Against the background of the numerous investigations published in 1965, the study by Buu-Hoi et al.[84] appeared to be an exception to this rule. When polyphosphoric acid (PPA) was used as the catalyst in the cyclisation of the arylhydrazone of phenylacetone (LVI), it was found that the product of the cyclisation involving the methyl group (LX) is formed together with the usual product (LVIII) in proportions of 1 : 5.

Earlier they showed that the Fischer reaction of this compound under the influence of gaseous hydrogen chloride in glacial acetic acid leads to cyclisation involving the methylene group, yielding indoles which do not contain any traces of 2-substituted isomers[85].

It was suggested that the action of the catalyst in the Fischer reaction involves the tautomeric conversion of the phenylhydrazone (LVI) into two intermediate enehydrazines (LVII) and (LIX), (LVII) being formed when zinc chloride, boron trifluoride, and hydrogen chloride in acetic acid are employed as catalysts and compound (LIX) is formed in the presence of polyphosphoric acid[84].



Yamamoto's data[49] confirm these results: for example, it was shown that, when R = Ph, the ratio of the two isomeric indoles (XLVII)/(XLVI) increases with increase of the concentration of phosphorus pentoxide in the orthophosphoric acid employed as the catalyst.

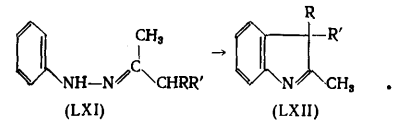
The selective action of the catalysts was investigated in greater detail by Palmer and McIntyre[86]. It was established by ^{1}H NMR that the reaction yields a mixture of isomeric indoles in which the (XLVI) : (XLVII) ratio depends on the catalyst employed. The following catalysts were investigated: boron trifluoride-ether in acetic acid, sulphuric acid at different concentrations in 1 : 1 aqueous ethanol, 90% orthophosphoric acid, and various polyphosphoric acids.

When boron trifluoride-ether in acetic acid was employed as the cyclising agent, only one product (XLVI, R = CH_3, C_6H_5, or p-$NO_2C_6H_4$), formed as a result of the cyclisation involving the methylene group, was isolated. The use of other catalysts led to the formation of a mixture of indoles, the ratio of the isomers depending on the concentration of phosphorus pentoxide in orthophosphoric acid. In all the reactions the fraction of the 2-substituted indole (XLVII, R = CH_3, C_6H_5, or p-$NO_2C_6H_4$), the product of the cyclisation involving the methyl group, increases from O when 90% H_3PO_4 or 40% H_2SO_4 is employed to a level which makes it the main component in 70% sulphuric acid or 83% solution of phosphorus pentoxide in 90% orthophosphoric acid.

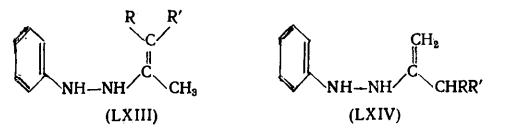
It was shown[86] that the formation of two isomeric indoles is not a consequence of an intramolecular rearrangement, which might have been postulated by analogy with the familiar migrations of substituents in indole systems[87], since the indoles isolated remain unchanged on heating under conditions where mixtures of two isomeric compounds are formed.

b. The Mode of Conversion of Arylhydrazones of 3-Substituted Alkyl Methyl Ketones into Indoles

For arylhydrazones of ketones with an α-branched alkyl chain, there is a rule[88] according to which these compounds cyclise exclusively via the third carbon atom, yielding 2-methylindolenines:

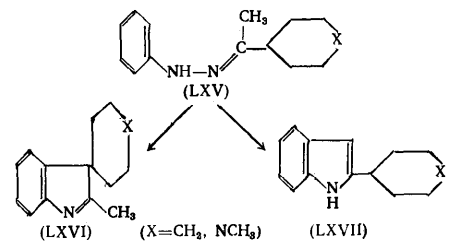


This mode of cyclisation was explained by the fact that the enehydrazine (LXIII), which has the greatest number of substituents at the double bond, is more stable than compound (LXIV).



Numerous examples of this type of cyclisation have been compiled[7-12].

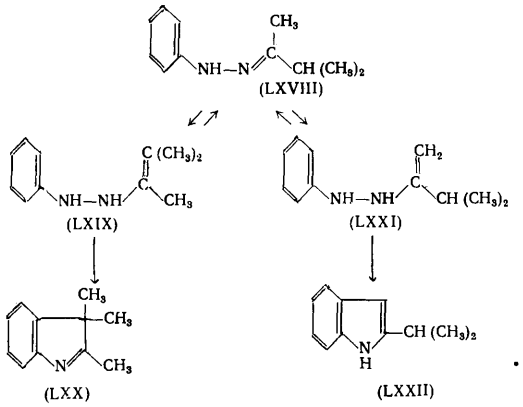
However, it is striking that the cyclisation of the phenylhydrazone of cyclohexyl methyl ketone (LXV, X = CH_2) resulted in an 18% yield of 2-cyclohexylindole (LXVII)[89], an excess of zinc chloride being used as the catalyst. Spiro-3*H*-indole (LXVI), expected as the product of the main reaction pathway, was not isolated, although it had been shown previously that the reaction does in fact follow this pathway[90]:



Later Lyle and Skarlos reinvestigated this reaction[91]. They converted into indoles the phenylhydrazones of cyclohexyl methyl and methyl 1-methyl-4-piperidyl ketones (LXV, X = CH_2 or NCH_3) and established that the Fischer indole synthesis catalysed by polyphosphoric acid yields mainly the products of the cyclisation via the methyl group (LXVII), while the use of an excess of zinc chloride or acetic acid as the catalyst makes it possible to obtain the corresponding spiro-3*H*-indoles (LXVI) alone.

The authors suggested[91] that the mode of cyclisation leading to two products is associated with the stability of the transition states for two different cyclisation pathways. (The cyclisation mechanism is discussed in greater detail below.)

In a study of the cyclisation of the phenylhydrazone of isopropyl methyl ketone (LXVIII), Illy and Funderburk concluded that the pathway followed in the indole formation reaction depends on the acidity of the medium[92]:



Zinc chloride, acetic acid, the hydrogen sulphate ion, and aqueous phosphoric acid always give rise to 2,3,3-trimethyl-3*H*-indole (LXX), the product of the cyclisation involving the more branched chain of the ketone. Polyphosphoric acid and concentrated sulphuric and hydrochloric acids give rise to a mixture of products, the yield of 2-isopropylindole, the product of the cyclisation involving the methyl group, increasing with the acidity of the medium (Fig. 2).

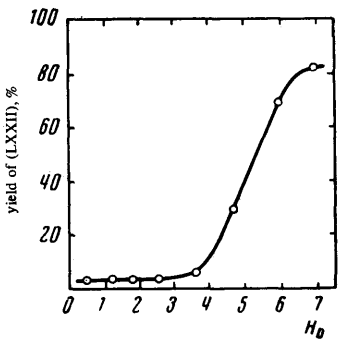


Figure 2. Variation of the yield of 2-isopropylindol (LXXII) with the acidity function H_0 in the cyclisation of compound (LXVIII) for the molar ratio catalyst : hydrazone = 5 : 1.

Palmer and McIntyre[86] also investigated the cyclisation of the phenylhydrazone of isopropyl methyl ketone (LXVIII) as a function of the concentration of the acids employed as catalysts. Their results agree satisfactorily with those of Illy and Funderburk[92]. At relatively low catalyst concentrations the cyclisation involves the more branched chain of the ketone, but, on increasing the concentration, the cyclisation involves the less branched chain[86].

c. The Mode of Conversion of the Phenylhydrazones of 2-Substituted Cyclohexanones into Indoles

The cyclisation of the phenylhydrazones of 2-substituted cyclohexanones (LXXIII) leads to two products: 1,2,3,4-tetrahydrocarbazole (LXXIV) and 1,2,3,4-tetrahydro-4a*H*-carbazole(LXXV)[9,10,12]:

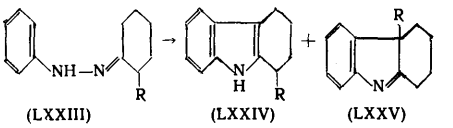

Table 1.

R in phenylhydrazone (LXXIII)	(LXXIV):(LXXV)		
	catalyst		thermal cyclisation
	20% H_2SO_4	CH_3COOH	
CH_3	45:21	6:61	49:51
C_2H_5	44:28	13:76	—
n-C_3H_7	—	—	72:28
i-C_3H_7	44:18	16:70	—
cyclo-C_6H_{11}	29:17	9:79	94: 4
C_6H_5	54:19	27:69	87:13

Hughes and Lions[90] and subsequently Pausacker and Schubert[93,94], established that the ratio of the isomers formed depends on the catalyst employed and the substituent R (Table 1).

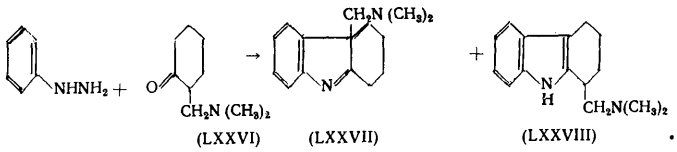
Table 2.

Catalyst	Solvent	Yield of (LXXIV), %	Yield of (LXXV), %
CH_3COOH	CH_3COOH	6	61
CH_3COOH	H_2O	—	56—40*
CCF_3COOH	H_2O	—	53
HCL(gas)	C_6H_6	4	65
HCL(gas)	C_2H_5OH	19	44
HCl(conc.)	H_2O	40	38
H_2SO_4(conc.)	C_2H_5OH	33	36
H_2SO_4(conc.)	H_2O	45	21

*The yields varied with the concentration of acetic acid in water.

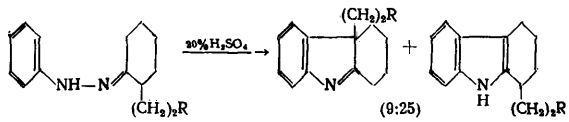
Pausacker showed[94] for 2-methylcyclohexanone phenylhydrazone that the ratio of the products formed is influenced by the nature of the acid catalyst and the solvent employed (Table 2). However, in a later study[95] on the behaviour of compounds (LXXIII) (R = CH_3, C_2H_5, C_3H_7, C_4H_9, C_6H_{11}, and C_8H_{17}) products other than (LXXV) were not detected. Concentrated hydrochloric acid in glacial acetic acid was used as the catalyst. The absence of the second isomer (LXXIV) when the reaction was carried out under these conditions appears strange, since subsequent studies on these lines demonstrated the formation of two products.

Thus Grandberg et al.[96] established that the reaction of phenylhydrazine and the ketone (LXXVI) yields two products (LXXVII) and (LXXVIII):



(LXXVI) (LXXVII) (LXXVIII)

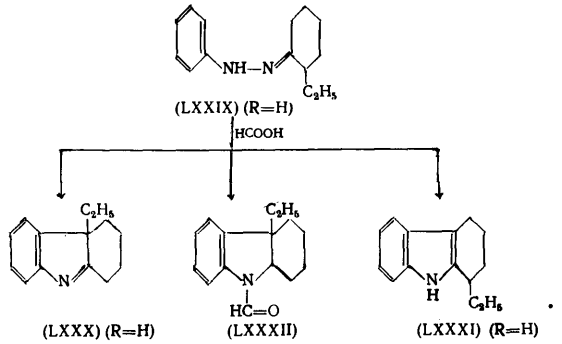
Two products are formed also on cyclisation of the phenylhydrazone of 2-(2-cyanoethyl)cyclohexanone (LXXIX)[97]:



(LXXIX) (LXXX) (9:25) (LXXXI) (R=CN)

A tetrahydrocarbazole was obtained together with compound (LXXXI) on heating compound (LXXIX) with a catalytic amount of zinc chloride at 170–190°C. The appearance of the tetrahydrocarbazole among the reaction products was explained by the elimination of the cyanoethyl group from compound (LXXXI). However, one cannot rule out the possibility that the cyanoethyl group can be eliminated not only from compound (LXXXI) but also from compound (LXXX) and reaction intermediates. On the basis of these findings, the authors concluded[96,97] that, when there is competition between the methylene and methyl groups, the Fischer reaction proceeds via both pathways.

However, when 98–100% formic acid is used as the catalyst, the cyclisation of (LXXIX) leads mainly to 4a-ethyl-1,2,3,4-tetrahydro-4a*H*-carbazole (LXXX), although it was isolated in only a low yield, since it reacts with formic acid under the process conditions, yielding 4a-ethyl-9-formyl-1,2,4,4a,9a-hexahydrocarbazole (LXXXII). The ultraviolet spectra of the product also indicate the formation of a small amount of 1-ethyl-1,2,3,4-tetrahydrocarbazole (LXXXI)[98]:

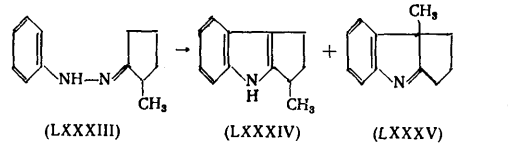


(LXXIX) (R=H)

(LXXX) (R=H) (LXXXII) (LXXXI) (R=H)

Kelly et al.[54] carried out the thermal conversion of compound (LXXIII) into an indole. They found that here too a mixture of indoles (LXXIV) and (LXXV) is formed. The ratio of the isomers is given in Table 1, where it is compared with the results of other studies[93,94].

In addition the phenylhydrazone of 2-methylcyclopentanone (LXXXIII) was converted into indoles by the thermal reaction[54], since the previous attempt to carry out this reaction with the aid of acid catalysis failed[95]. The authors report that in this case two products are also formed, but do not quote their proportions:

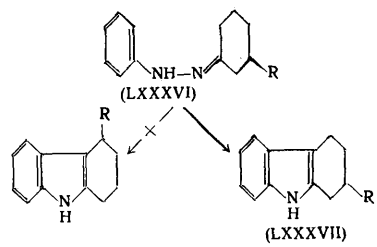


(LXXXIII) (LXXXIV) (LXXXV)

According to the results of Berlin et al.,[99] when equimolar amounts of phenylhydrazine and 2-cyclohexylcyclohexanone are refluxed in glacial acetic acid, 1-cyclohexyl-1,2,3,4-tetrahydrocarbazole (LXXIV, R = C_6H_{11}) is formed in 28.5% yield.

d. The Mode of Conversion of Phenylhydrazones of 3-Substituted Cyclanones

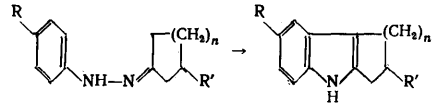
It has been reported[100] that 3-methylcyclohexanone phenylhydrazone (LXXXVI, R = CH_3) gives rise to one product, the structure of which was not established. Later, it was shown[101] that it is a tetrahydrocarbazole (LXXXVII, R = CH_3), since its dehydrogenation yields 2-methylcarbazole. An admixture of 4-methylcarbazole was not detected.



(LXXXVI) (LXXXVII)

In one of the earlier studies it was stated[102] that the cyclisation of the phenylhydrazones of 3-oxocyclohexanecarboxylic acid (LXXXVI, R = COOH) yields one isomer of unknown structure. Later Allen[103] took up the study of this problem and established that the product is 1,2,3,4-tetrahydrocarbazole-2-carboxylic acid (LXXXVII, R = COOH).

A similar study was made recently on the phenylhydrazones of cyclopentanone and cycloheptanone[104]. The structures of the compounds formed under the conditions of the Fischer reaction were established on the basis of their ^{1}H NMR spectra using Eu(DPM)$_3$. In both cases the formation of only one isomer was demonstrated.

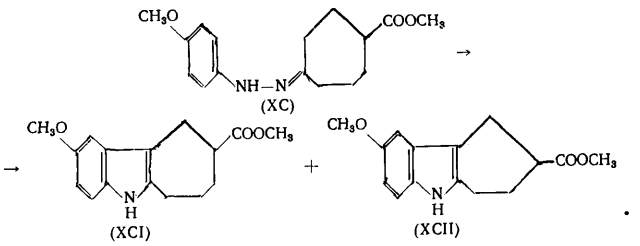


(LXXXVIII) (LXXXIX)

n=1, R=H, OCH_3 R′=COOH, $COOCH_3$

n=3, R=H, OCH_3 R′=CN, COOH, $COOCH_3$

As expected, the cyclisation of the phenylhydrazone of a 4-substituted cycloheptanone yields a mixture of two isomeric compounds (XCI) and (XCII):



(XC) → (XCI) + (XCII)

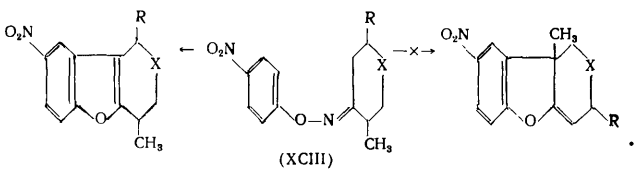
Calculations by the LCAO-MO method in terms of the Hückel approximation for model compounds showed that the equatorial 4-methylcyclohexene is more stable than the pseudoequatorial 3-methylhexene to the extent of 0.8 kcal mole^{-1}. [104] The authors used this fact in an attempt to explain the high selectivity of the Fischer reaction for the phenylhydrazones of 3-substituted cyclanones, although such a small difference can hardly exert a large influence under fairly severe reaction conditions. It is much more likely that steric factors operate in the transition state in the formation of the carbon–carbon bond.

3. THE MODE OF REARRANGEMENT OF *O*-PHENYL ETHERS OF THE OXIMES AND ASYMMETRIC KETONES

Mainly the aryl ethers of the oximes of symmetrical carbonyl compounds or compounds capable of rearranging in one specific position were investigated in rearrangements of the type (XXX) → (XXXI). However, the rearrangement of the oximes of asymmetric ketones was studied in several investigations.

Mooradian noted initially that a mixture of two benzofurans may be formed in the rearrangement of the *p*-nitrophenyl ether of the oxime of 2-butanone, as shown by the ^{1}H NMR spectrum of the unpurified reaction product [68]. However, the product of the rearrangement involving the methyl group could not be isolated.

On cyclisation of aryl ethers of the oximes of 2-methylcyclohexanone (XCIIIa) [69] and 1,2,5-trimethylpiperidin-4-one (XCIIIb) [76] in dilute acid solutions, compounds were formed as a result of a rearrangement involving exclusively the methylene group [compound (XCIVb)] and not the methine group [compound (XCV)]:

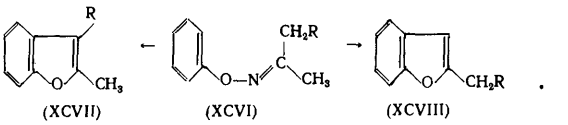


(XCIV) ← (XCIII) → (XCV)

(a) X=CH$_2$, R=H
(b) X=NCH$_3$, R=CH$_3$

The authors noted that, under analogous steric conditions, the closure of the indole ring in the Fischer reaction of the arylhydrazones of the same ketones involves exclusively the α-methine group. However, no explanation of this phenomenon has been put forward [68,76].

The mode of rearrangement of compounds of this kind was investigated in greater detail in other studies [52,105]. It was established that the cyclisation of compound (XCVI) (for R = alkyl) involves both the α-methylene and the α-methyl groups with formation of a mixture of isomeric benzofurans. The reaction was carried out in a dilute alcoholic solution of hydrochloric acid. However, when the substituent was a powerful electron-accepting group, only one compound (XCVII) was formed. The ratio of the isomers formed was determined by ^{1}H NMR and by gas-liquid chromatography (Table 3).



(XCVII) ← (XCVI) → (XCVIII)

It has also been shown [52] that the ratio of the products [(XCVIII) : (XCVII), R = CH$_3$] is determined by the reaction conditions (Table 4).

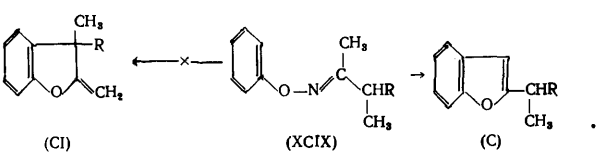
Table 3.

R in compound (XCVI)	Isomer ratio (XCVIII): (XCVII)	R in compound (XCVI)	Isomer ratio (XCVIII): (XCVII)	R in compound (XCVI)	Isomer ratio (XCVIII): (XCVII)
CH_3	55:45	C_6H_5	40:60	$COCH_3$	0:100
C_2H_5	65:35	$CH_2C_6H_5$	60:40	$COOC_2H_5$	0:100
n-C_3H_7	70:30	C_2H_4OH	70:30	CN	0:100
i-C_3H_7	85:15				

Table 4.

Reaction conditions (t = 100°C)		Isomer ratio (XCVIII): (XCVII)
acid catalyst [acid : (XCVI) = 1 : 1]	solvent	
HCl	methanol	78:22
—	2-propanol	55:45
—	t-butyl alcohol	37:63
—	nitromethane	33:67
—	DMSO	30:70
—	DMF	25:75
—	dioxane	12:88
—	THF	8:92
—	benzene	22:78
H_2SO_4	methanol	82:18
—	2-propanol	75:15
—	dioxane	58:42
$CH_3C_6H_4SO_3H$	2-propanol	65:35
$HClO_4$		81:19

^{1}H NMR and gas-liquid chromatography [52] have shown that the products of the rearrangement of the *O*-phenyl ethers of the oximes of branched alkyl methyl ketones are benzofurans (C). This is evidence that the closure of the benzofuran ring involves only the α-methyl group:



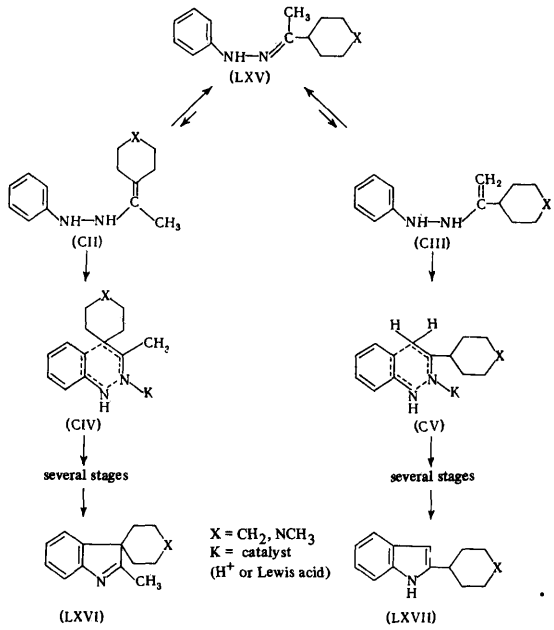
(CI) ← (XCIX) → (C)

4. FACTORS DETERMINING THE MODE OF CYCLISATION

The first attempt to explain the formation of two isomeric products in the Fischer reaction was made by Lyle and Skarlos [91]. In their discussion of the reaction mechanism they suggested that the mode of cyclisation of phenylhydrazones of asymmetric ketones should be related to the

energy of the transition state for two different cyclisation pathways.

For phenylhydrazones of cyclohexyl methyl ketones (LXV), there is a possibility of the formation of two enehydrazines (CII) and (CIII), which should subsequently cyclise via the transition states (CIV) and (CV) respectively. For the formation of a new C–C bond, the benzene ring must approach the π electrons of the double bond. Conformational analysis of the molecules of the enehydrazines (CII) and (CIII) showed that such approach is prevented by the 2- and 6-axial hydrogen atoms on approach from one side and the 3- and 5-axial hydrogen atoms on approach from the other side (cyclisation involving the methine group) [Fig. 3, compounds (CII, a and b)].



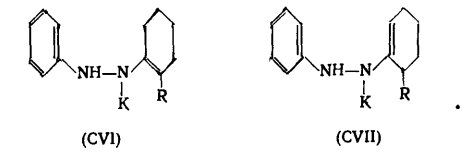
In cyclisation involving the methyl group, the steric interaction between the cyclohexane ring and the catalyst is enhanced [Fig. 3, compound (CIII)].

Therefore in the presence of "small" catalysts "K", such as a proton derived from polyphosphoric acid, cyclisation should proceed via the energetically more favourable transition state (CV) in which there is no interaction between the benzene ring and the axial hydrogen atoms of the cyclohexane ring. In the presence of "large" catalysts "K" such as zinc chloride or an acyl group (the authors apparently find it more convenient to assume that acetic acid behaves not as a protic acid but as an acylating agent[91]), the energy of the transition state (CV) increases in consequence of the interaction between the bulky catalyst and the cyclohexane ring. In this case the reaction proceeds via the transition state (CIV), since the enehydrazine (CII) is energetically more favourable.

Ultimately, when the cyclisation proceeds via the transition state (CIV), the products are 3*H*-indoles (LXVI), while cyclisation via the transition state (CV) gives rise to 2-substituted indoles (LXVII).

Lyle and Skarlos suggest that the ratio of the isomers (LXXIV) and (LXXV) formed from the phenylhydrazones of 2-substituted cyclohexanones (LXXIII) should be correlated with the steric $A^{(1,2)}$ strain (Johnson and Malhotra[106])

in the corresponding pairs of intermediate enehydrazines (CVI) and (CVII)[91]:



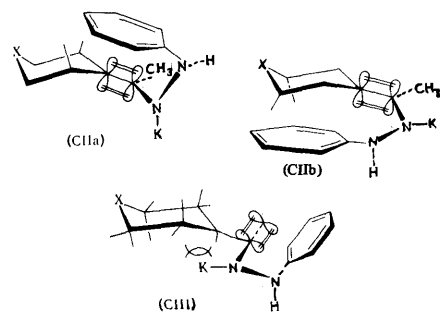


Figure 3. Conformation of the molecules of the enehydrazines (CII, a and b) and (CIII) (Dreiding models).

The authors believe that the transition state in the cyclisation of the enehydrazine (CVII) is preferable when a protic acid is employed as a catalyst or in a thermal rearrangement. Lewis acids or acetic acid should lead to an unfavourable steric interaction between K and the substituent R in the tautomer (CVII) and should favour the formation of the transition state from the enehydrazine (CVI) (Fig. 4).

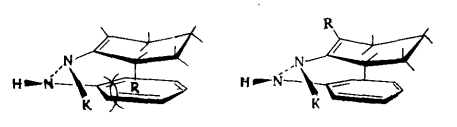

Figure 4. Conformations of the molecules of the enehydrazines (CVI) and (CVII) (Dreiding models).

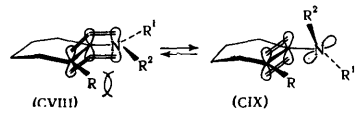
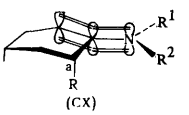
These considerations are based on the following factors. The enamines obtained from 2-substituted ketones are known to exist as a mixture of isomers[107,108]. The isomer ratio is determined by different steric and electronic factors, which influence the conjugation of the n-electron pair of the nitrogen and the C=C double bond. Complete conjugation requires the coplanarity of the substituent at the nitrogen atom and the olefinic groups:

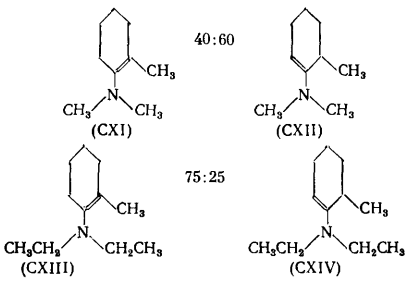


Steric interaction between the groups and the nitrogen atom (R^1 or R^2) on the one hand and the substituent R in the cyclohexane ring of (CVIII) on the other hinders the coplanarity of the substituents and a high degree of overlapping. Therefore the groups are displaced from coplanarity with a consequent weakening of their steric interaction and a simultaneous decrease of the degree of conjugation of the n-electron pair of the nitrogen with the C=C double bond of compound (CIX). The isomer (CX) with an axial R group is free from such steric interaction and therefore it can remain coplanar with a high degree of overlapping[109]:



(CX)

However, with increase of the size of the substituent R^1 or R^2 (in phenylhydrazones of ketones one of the substituents is the "large" NHC_6H_5 group), the relative degree of conjugation may prove to be low in any of the three structures quoted [(CVIII), (CIX), and (CX)]. Even the isomer (CX) does not have an energetically favourable structure in consequence of the increase of the steric interactions between the substituents at the nitrogen atom (R^1 or R^2) and the substituent R in the cyclohexane ring, regardless of whether R is an axial, equatorial, or vicinal substituent. It has been shown[108] that the isomer ratio (CXI) : (CXII) differs markedly from (CXIII) : (CXIV). The authors suggested that, with increase of the intensity of the steric interactions, the isomer (CXIV) with an axial methyl group is not energetically more favourable[108]. In order to weaken these interactions, the groups are displaced from coplanarity and the factors determining the stability of the normal (not conjugated) double bond operate independently—the more substituted double bond is preferred.



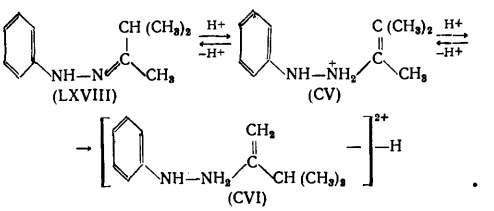
(CXI) (CXII) (CXIII) (CXIV)

Consequently, as suggested by Lyle and Skarlos, when an attempt is made to predict the mode of conversion of the phenylhydrazones of asymmetric ketones into indoles, account must be taken of the fact that the two possible intermediate enehydrazines are sterically hindered to different extents and the stabilisation due to the polyalkyl substitution of the C=C bond in the enehydrazine tautomer[91]. Robinson adheres to this view in his latest review[10].

However, this concept is inconsistent with Pausacker's experimental data[94] and those of Canadian workers[54] (Table 1). The steric interactions between the substituents and the catalyst K in structure (CVII) should be greater the greater the bulk of the substituent R and hence the formation of the transition state from the other enehydrazine (CVI) should be favoured. On the other hand, experimental data show that the opposite situation obtains, i.e. that the isomer (LXXIV), formed from the sterically hindered isomer (CVII), predominates in the mixture of indole products isolated (particularly in a thermal rearrangement). Thus the explanation proposed for the formation of two isomers in the cyclisation of the phenylhydrazones of asymmetric ketones[91], based on the correlation between the steric strain of the $A^{(1,2)}$ type in the intermediate enehydrazines (CVI) and (CVII) and the ratio of the isomeric indoles (LXXIV) and (LXXV), does not take into account all the factors which determine this ratio.

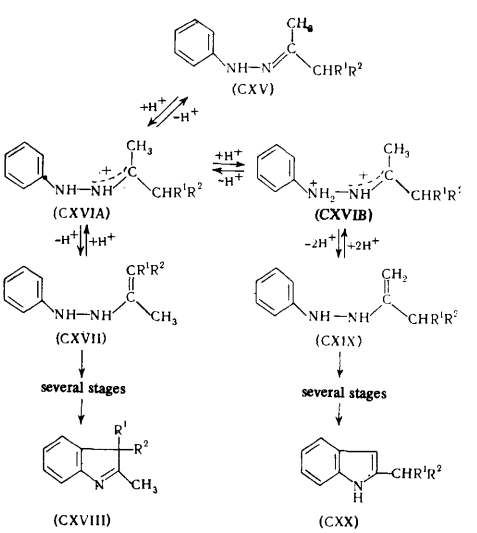
Moreover, it is difficult to explain by the steric influence alone the formation of two products from the phenylhydrazones of ethyl methyl and isopropyl ethyl ketones in which there is no strain of the $A^{(1,2)}$ type. Nor is there any answer to the question concerning the influence of the concentration of the catalyst on the isomer ratio.

The approach to the consideration of the possible formation of two isomers in the Fischer reaction from other standpoints proved to be more promising. In an endeavour to account for the influence of the acidity of the medium on the proportions of the products of the Fischer reaction of the phenylhydrazone of isopropyl methyl ketone (LXVIII), Illy and Funderburk[92] suggested that an increase of the acidity of the medium (Fig. 2) entails double protonation of the molecule of the hydrazone (LXVIII), which causes the process to proceed via a different mechanism, leading to the formation of compound (CVI):



(LXVIII) (CV) (CVI)

This hypothesis was confirmed by the formation of 2-isopropylindole (LXXII) only when more than two moles of hydrochloric or sulphuric acid are involved in the reaction. Weak acids do not result in double protonation, because the acidity H_0 does not increase to the required value with increase of the concentration of the acid. Palmer and McIntyre also suggest that at a low concentration of the acid catalyst monoprotonation takes place, while on increase of the acidity of the medium to $H_0 \simeq -4.40$ the hydrazone molecule may be doubly protonated[86].



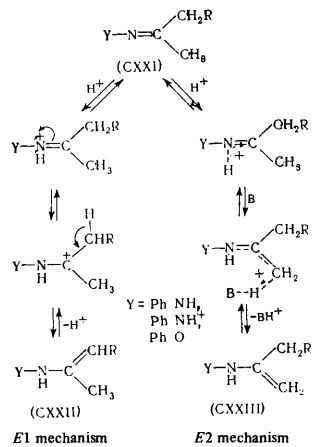
(CXV) (CXVIA) (CXVIB) (CXVII) (CXIX) (CXVIII) (CXX)

The authors believe that in solutions of weak acids the formation of the enehydrazines (CXVII) or (CXIX) from the cation (CXVI) is the slow stage in the sequence (CXV) → (CXVI, A) → (CXVII) or (CXIX). This is analogous to an

$E1$ elimination reaction where the product in which the C=C double bond is substituted by alkyl groups to the maximum extent should predominate. In very acidic solutions, there is an additional inductive withdrawal of electrons from the alkyl groups in the diprotonated molecule of compound (CXVIB), which increases the probability of the attack of the C–H bond by the anion. This is analogous to an $E2$ elimination reaction.

In a study of the rearrangement of the O-phenyl ethers of ketone oximes (XCVI) to benzofurans (XCVII) and (XCVIII), the authors concluded that the reaction constitutes a satisfactory model of the Fischer synthesis of indoles in highly acidic media[52,105]. Comparison of the pK_a values for the phenylhydrazones of the same ketones shows that the basicity of O-phenyloximes is smaller by factor of approximately 10^3 than the basicity of the corresponding phenylhydrazones.

The formation of two isomeric benzofurans (XCVII) and (XCVIII) is evidently associated with two possible modes of "migration" of the double bond in the tautomeric transformation caused by different mechanisms, analogous to the mechanisms of $E1$ and $E2$ elimination. It is clearly seen when one examines the fragment responsible for the pathway followed in the β-elimination reaction.



The double bond $N{=}\overset{|}{C}{-}\overset{|}{C}{-}H$, which dissociates on protonation, plays the role of the group X split off on β-elimination from $X{-}\overset{|}{C}{-}\overset{|}{C}{-}H$. The lower the basicity of the nitrogen atom the more difficult it is to protonate it, which in turn makes it more difficult to dissociate the N=C bond. This is analogous to the hindrance of the dissociation of the substituent X, which always leads to the $E2$ mechanisms becoming predominant.

In the usual Fischer reaction carried out in a weakly acid medium (Y = PhNH), the enehydrazine is formed via the $E1$ mechanism. After protonation of the β-N atom, there is a rapid shift of π-electrons with formation of a carbonium ion stabilised by the ejection of a proton with transformation into the thermodynamically favourable structure in which there is a maximum degree of branching at the double bond (cyclisation involving the CH_2 group).

As a result of the formation of the diprotonated structure (Y = $\overset{+}{P}h\overset{+}{N}H_2$), in an acid medium the fragment $Ph\overset{+}{N}H_2\overset{+}{N}H{=}$ becomes such a weak acceptor ($-I$ effect) that the hydrogen atoms in the α-alkyl groups become much more acidic. The α-hydrogen atoms are then split off from the most "acidic" CH_3 group via a synchronous mechanism under the influence of the nucleophilic agents present in the reaction medium.

If Y is a fairly strong acceptor (Y = PhO) with a high $-I$ effect, its electron-accepting activity favours the tautomeric transformation via the $E2$ mechanism even in a weakly acid medium. Naturally the kinetically more favourable isomer is then formed under the influence of solvent molecules (cyclisation involving the CH_3 group). Thus the mode of conversion of the phenylhydrazones of asymmetric ketones into indoles and the mode of cyclisation of the O-phenyl ethers of the oximes of the ketones are determined by the ratio of the probable intermediate enehydrazines and vinylhydroxylamines formed on tautomeric transformation of the initial compounds under acid conditions. The ratio depends on the probability of the tautomeric transformation via one of the possible β-elimination mechanisms.

Rearrangements of Biradicals With Migration of an Alkyl Group or Hydrogen

R.Kh.Freidlina and A.B.Terent'ev

Studies published during the last decade on the rearrangement of biradicals are reviewed. In contrast to monoradicals for which reliably established examples of rearrangements with 1,2-migration of an alkyl group or hydrogen are unknown, such rearrangements have been observed with biradicals. Data on the types of rearrangements of biradicals with 1,2-migration of an alkyl group and 1,2-, 1,4-, and 1,5-migrations of hydrogen from carbon to carbon or from carbon to oxygen are reviewed. The available data on the mechanisms of the rearrangements are discussed.
The bibliography includes 65 references.

2. Migration of hydrogen from carbon to oxygen

I. INTRODUCTION

The study of the rearrangements of organic radicals constitutes a comparatively new branch of chemistry, The results obtained in this field have been described in a number of reviews[1-4]. As far as we are aware, no single review has been specially devoted to the rearrangements of biradicals. Nevertheless such somewhat exotic compounds can yield unique results[5]. Indeed, the study of the rearrangements of biradicals yielded results of fundamental importance both for synthetic organic chemistry and particularly for the understanding of the chemical properties of biradicals and for their comparison with those of monoradicals. We believe that the most interesting and newest feature in this field is the observation of rearrangements of biradicals with 1,2-migration of an alkyl group and hydrogen. Such rearrangements are unknown in the chemistry of monoradicals, although 1,2-migrations of hydrogen or the methyl group have been postulated in many investigations. However, the reactions usually described in such reports can be given an alternative interpretation which does not involve the above rearrangements[1-4,6,7]. Unusual types of rearrangements were described for the first time for biradicals generated photochemically but subsequently they were also noted in biradicals obtained by thermal and other procedures. Thus the ability of biradicals to undergo a rearrangement is probably a general property.

The field of rearrangements is still very new and a significant proportion of the known examples have been described only in "Letters to the Editor" and in brief communications. There are very few experimental data concerning the mechanisms of the observed reactions. Nevertheless the ability of biradicals to undergo rearrangements unknown in the chemistry of monoradicals must apparently be regarded as established.

In contrast to the rearrangements in monoradicals, which proceed according to the formal mechanism[4]

$$\underset{(I)}{\dot{A}-(B)_n-\overset{X}{\overset{|}{C}}} \xrightarrow{\text{rearrang.}} \underset{(II)}{A-(B)_n-\dot{\overset{X}{\overset{|}{C}}}} , \qquad (1)$$

where the migrating species (X = phenyl, halogen, hydrogen, etc.) forms a bond with the atom having an unpaired electron and therefore radical (I) isomerises to radical (II), which is usually more stable, the rearrangements of biradicals proceed in many cases in such a way that all the electrons in the product may be paired, for example in accordance with the following formal mechanism:

$$\cdot O-\overset{CH_3}{\overset{|}{C}}-CR'=CR''-O\cdot \xrightarrow{\text{rearrang.}} O=\overset{CH_3}{\overset{|}{C}}-CR'-C=O . \qquad (2)$$

It has been suggested in some studies that the formation of compounds of this kind constitutes one of the driving forces of the rearrangement of biradicals.

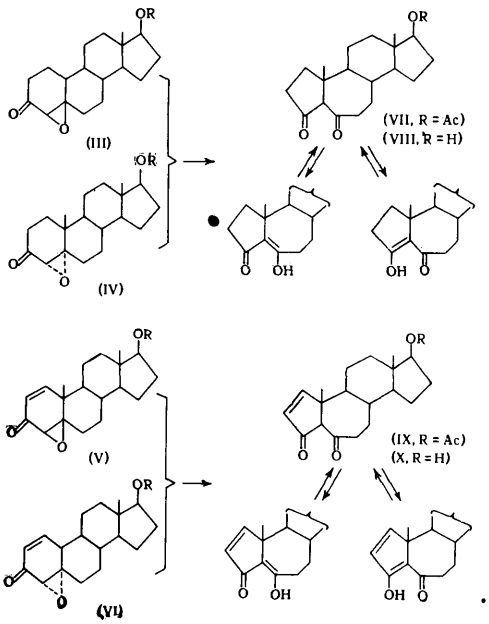
II. REARRANGEMENTS WITH 1,2-MIGRATION OF AN ALKYL GROUP

Rearrangements with 1,2-migration of an alkyl group have been observed in biradicals generated photochemically in systems with both $n-\pi^*$-excitation ($\alpha\beta$-epoxyketones) and with $\pi-\pi^*$-excitation (arylethylenes), thermally by the decomposition of the peroxides of substituted lactones, and also by the addition of triplet methylene to olefins.

a. Photochemical Rearrangement of $\alpha\beta$-Epoxyketones

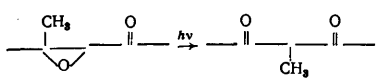
A photochemical rearrangement with 1,2-migration of an alkyl group was first described in 1962 for steroid epoxyketones[6]. Thus saturated and unsaturated diastereomeric 4,5-epoxy-3-oxosteroids (III)–(VI) isomerise in

high yields to compounds (VII)—(X) respectively on irradiation with ultraviolet light regardless of the configuration of the epoxy-ring in the molecule (see Scheme 3).



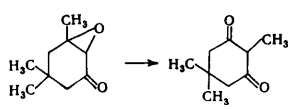
(3)

Soon a similar rearrangement was established in simpler examples: 3,4-epoxy-4-methyl-2-pentanone, isophorone oxide, and the stereoisomeric pulegone oxides[8]. In all cases products of isomerisation with 1,2-migration were accompanied by other compounds which can be described by the following formal scheme in the simplest instance:



(4)

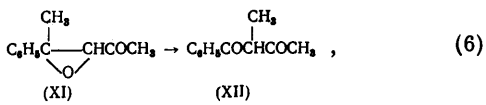
The reaction mechanism was not discussed in these first studies. However, the unusual sequence of groups in terms of their capacity for migration was pointed out[8], namely it was found that the methyl group migrates more readily in these systems than does the phenyl group. Thus isophorone oxide undergoes photochemical isomerisation, with 1,2-migration of the methyl group, to 2,5,5-trimethylcyclohexa-1,3-dione:



(5)

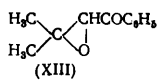
On the other hand, on prolonged irradiation with ultraviolet light, 2,3-epoxy-5,5-dimethyl-3-phenylcyclohexanone, which is an analogue of isophorone oxide, did not yield the isomerisation product 5,5-dimethyl-2-phenylcyclohexa-1,3-dione with 1,2-migration of the phenyl group. A similar difference between the capacities for migration of the methyl and phenyl groups was subsequently observed in a number of other instances[9]. This increase of capacity for migration, $C_6H_5 \ll CH_3$, conflicts with the rules observed in the rearrangements of radicals[3,4]. A molecular orbital calculation showed a decrease of the ease of 1,2-migration from carbon to carbon in the series carbonium ion > free radical > carbanion, the energy barrier being higher for the migration of an alkyl group than for the migration of an aryl group[10].

Zimmerman et al.[9] were the first to express the view in 1964 that the photochemical conversion of $\alpha\beta$-epoxyketones into β-diketones involves a rearrangement of the biradicals with 1,2-migration of an alkyl group. According to their data[9], 3,4-epoxy-4-phenyl-2-pentanone (XI) isomerises photochemically with 1,2-migration of the methyl group, forming 3-benzoyl-2-butanone (XII) as the main product (yield 25%):

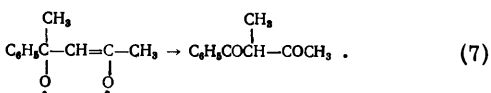


(6)

while the isomeric compound

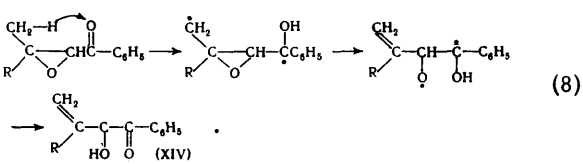


does not isomerise with 1,2-migration of the methyl group. The author suggested that in both cases there is $n-\pi^*$ excitation of the carbonyl group but in compound (XI) there is a greater localisation of the excited electron (π^*) in the carbonyl group and hence a greater probability of β-elimination with homolytic dissociation of the epoxy-ring at the C_α—O bond with the ultimate formation of a biradical, which isomerises:



(7)

In compound (XIII) the excited electron is delocalised over both the phenyl and carbonyl groups and is less accessible. 1,5- and 1,4-migration of hydrogen with formation of compound (XIV) then takes place intramolecularly†:

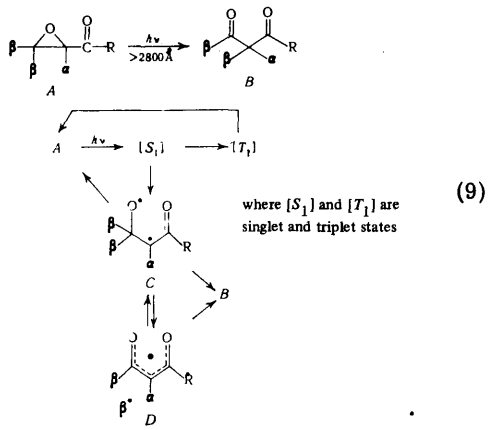


(8)

The homolytic mechanism of the photochemical rearrangement of $\alpha\beta$-epoxyketones to β-diketones is now widely recognised[11,12]. Zimmerman et al.[9] did not put forward any views concerning the mechanism of the methyl migration stage itself. This problem was discussed by other workers[11,12]. Markos and Reusch[11] considered the general case of the rearrangement of the $\alpha\beta$-epoxyketone *A* to the β-diketone *B* and described the mechanism of this rearrangement in terms of Scheme 9. Since the rearrangement of epoxyketones is not sensitive to the presence of oxygen or to a change in the nature of the solvent and since the addition of known triplet state quenching agents (piperylene and 2,5-dimethylhexa-2,4-diene) does not affect the rate or mode of the rearrangement, one may conclude that the intermediate biradical species *C* is formed preferentially from the singlet state $[S_1]$. The low quantum yield of this rearrangement, for example 0.03 for the conversion of 3,4-epoxy-4-methyl-2-pentanone into 3-methylpenta-2,4-dione, indicates either a low efficiency of the $[S_1] \rightarrow C$ transition or the competitive formation of the oxiran ring from *C*, which is unfavourable for the isomerisation. The authors believe that the

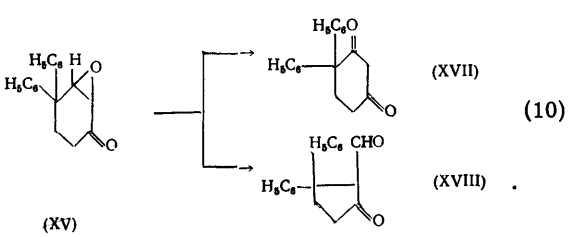
† For the formulation in terms of the symbols employed by the authors, see the Scheme in Ref. 9.

migrating group is of a radical type and that the migration can proceed either via a fragmentation (two-stage) mechanism with formation of a radical pair *D* in a solvent cage or via a synchronous (single-stage) mechanism with a transition state close to *D*. By experimental study of a number of rearrangements, the authors obtained evidence in support of both the intermediate formation of a radical pair and of the synchronous mechanism:



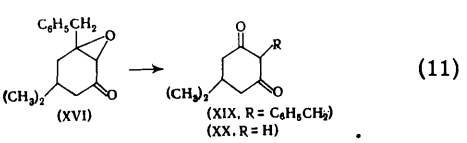
(9)

The above view concerning the rearrangement led the authors to the hypothesis that a particularly high capacity for migration should be observed for the benzyl and diphenylmethyl groups as β-substituents. This was confirmed by studying the rearrangement of 2,3-epoxy-4,4-diphenylcyclohexanone (XV) and 3-benzyl-2,3-epoxy-5,5-dimethylcyclohexanone (XVI). Thus irradiation of a solution of (XV) in ether for 3.5 h led to 50% conversion of the initial compound and the formation of a high yield of a mixture of (XVII) (1,2-migration of hydrogen in the intermediate biradical) and (XVIII) (1,2-migration of the alkyl-substituted diphenylmethyl group) in proportions of 1 : 4:



(10)

Irradiation of (XVI) yields the rearranged compound (XIX) as the main product (20%), but the reaction is accompanied by the formation of a significant amount of decomposition products [(XX), dibenzyl, and other products].

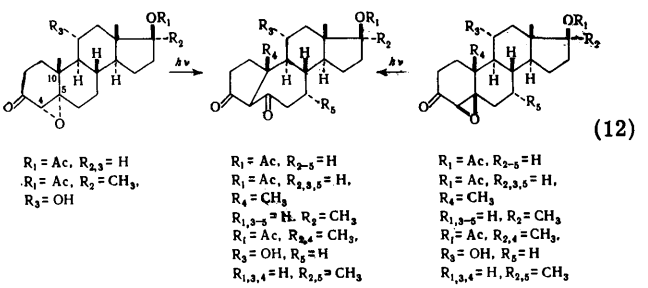


(11)

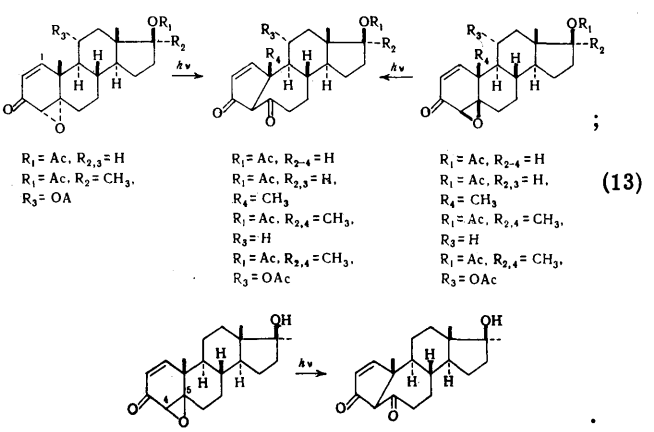
The formation of at least some fragmentation products is attributed to the conversion of *C* (Scheme 9) into the radical pair *D* and the liberation of the comparatively stable benzyl radical from the cage. By comparing their own results with data already available[8,9,12], the authors obtained the following sequence of groups in terms of their capacity for migration: diphenylmethyl and benzyl > hydrogen > methylene > methyl ≫ phenyl. The authors believe that the position of hydrogen in this series is evidence against the mechanism with fragmentation and formation of radical pairs, since a hydrogen atom is usually harder to form than an alkyl radical. Thus the migration capacity series of the groups is best explained by the synchronous mechanism of their migration in the biradical.

A team of investigators[12] who studied the photochemical conversion of a wide variety of steroid epoxyketones into β-diketones believe that this is a widely used and elegant method of synthesising β-diketones (see the references in the paper of Werli et al.[12] to other papers and reports by the authors).

These workers studied the conversion of epoxyketones with a saturated chromophoric keto-group (Scheme 12) into β-diketones on illumination with the unfiltered light of a mercury lamp ($n-\pi^*$-excitation). Unsaturated Δ^1-epoxyketones rearrange to β-diketones only on illumination with monochromatic light at λ = 253.7 ($\pi-\pi^*$ excitation) (Scheme 13).



(12)



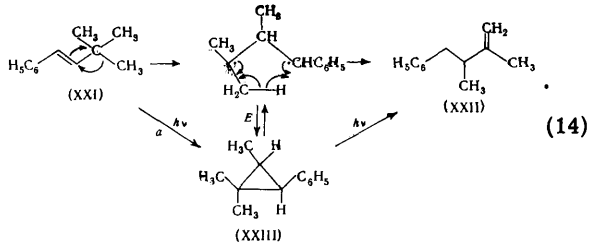
(13)

Werli et al.[12] noted that, although the rearrangement of saturated epoxyketones via Scheme 12, which involves the $n-\pi^*$ excitation, differs from the rearrangement of unsaturated epoxyketones which are unaffected by the $n-\pi^*$ excitation, selective $\pi-\pi^*$ excitation leads to an analogous rearrangement to β-diketones via Scheme 13.

The authors prefer the synchronous mechanism of the migration of an alkyl group in the biradical and note that the migrating group can be an alkyl group or hydrogen but not phenyl.

b. Photochemical Rearrangement of 3,3-Dimethyl-1-phenylbutene

The photochemical rearrangement of 3,3-dimethyl-1-phenylbutene (XXI) to 2,3-dimethyl-4-phenylbutene (XXII) via Scheme 14 was investigated[13]:



(14)

The authors noted[13] that they were first to observe the light-induced 1,2-migration of the methyl group in a hydrocarbon. The importance of this example of a rearrangement is that, whereas the $n-\pi^*$ excitation of epoxyketones can lead to the development of both heterolytic and homolytic processes[14,15], the comparatively low amount of the "ionic" character of the $\pi-\pi^*$ singlet or triplet states of alkyl- and aryl-substituted propenes is to a large extent responsible for the possibility of a homolytic process. In this case synchronous migration of the methyl group and cyclisation with formation of compound (XXIII) (pathway *a*) is possible. Indeed the *cis*- and *trans*-isomers of (XXIII) are readily converted into compound (XXII) by a photochemical reaction. The mechanism involving the formation of a common transition species, probably of type *E*, is also not ruled out. This hypothesis concerning the rearrangement entails the assumption of 1,4-migration of hydrogen in the transition state *E*. The possibility of such migration of the hydrogen atom in the related $n-\pi^*$- and $\pi-\pi^*$-states has been assumed in a number of investigations (see Section III of the present review).

c. Interaction of Tritium-labelled Methylene with *trans*-But-2-ene

The reaction of the photolytically generated methylene with *trans*-but-2-ene in the gas phase leads to the formation of various compounds containing five carbon atoms, among them a number of pentenes and 1,2-dimethylcyclopropane[6]. At higher pressures pentenes are also detected, which cannot be explained by the reaction with singlet methylene[17]. The formation of *cis*-pent-2-ene, 2-methylbut-1-ene, and 3-methylbut-1-ene is therefore attributed to the reaction with triplet methylene. It has been suggested that the first reaction step is the addition of methylene to the double bond according to the following scheme:

$$CH_2{:} + CH_3CH{=}CH{-}CH_3 \rightarrow CH_3\underset{\cdot}{C}H{-}\underset{\cdot}{C}HCH_3 \quad (15)$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\quad CH_2$$

followed by a rearrangement of the biradical.

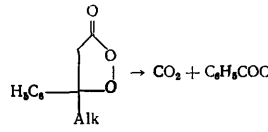
In order to investigate the mechanism of this rearrangement, the interaction of tritium-labelled methylene with *trans*-but-2-ene was studied[16]. In this case the biradical formed via Scheme 15 has the structure $CH_3-\underset{\cdot}{C}HT-\underset{\cdot}{C}HCH_3$ and the different modes of rearrangement should lead to different locations of tritium in the reaction products. The authors investigated the structures of two products important for the determination of the rearrangement mechanism: 3-methylbut-1-ene and *cis*-pent-2-ene. 1,2-Migration of the methyl group in the triplet biradical should lead to the formation of $(CH_3)_2CHCH{=}CHT$ and *cis*-$CH_3CHTCH{=}CHCH_3$, while $CH_3\underset{|}{C}H{=}CH_2$ might have been formed by 1,4-migration of hydrogen. The authors also examined the possible structures of the product generated by other reaction mechanisms (the closure of the three-membered ring and its subsequent opening at other bonds, the abstraction of hydrogen from but-2-ene by methylene, and subsequent recombination of the radicals). It was found that 3-methylbut-1-ene contained tritium in the alkyl and olefinic parts of the molecule, which indicates the operation of more than one mechanism in its formation. The presence of tritium-containing moieties in the olefinic part of the molecule suggests that the 1,2-migration of methyl plays an important role in the formation of 3-methylbut-1-ene. The authors believe that the formation of a double bond in this case provides an additional driving force for the rearrangement in the 1,3-biradical. Under the conditions investigated, *cis*-pent-2-ene did not contain tritium in the olefinic part of the molecule. This can be accounted for both by the mechanism involving 1,2-migration of the methyl group and by the hypothesis of the recombination of radicals. According to the authors, the fact that 3-methylbut-1-ene is not formed in the presence of oxygen and the product is propene constitutes additional evidence for the formation of the biradical. The propene obtained in the reaction of triplet CHT with *cis*- and *trans*-but-2-enes has the structure $CH_3CH{=}CHT$, which is consistent with the product expected via Scheme 16:

$$CH_3\underset{\cdot CHT}{C}HCH_3 + O_2 \rightarrow CH_3{-}\underset{\cdot CHT}{C}H\underset{O_2\cdot}{C}HCH_3 \rightarrow CH_3CH{=}CHT + \text{oxidation products.} \quad (16)$$

d. Rearrangement with 1,2-Migration of an Alkyl Group in Biradicals Generated by the Thermolysis of Organic Compounds

A series of publications appeared very recently[18-21] on the 1,2-migration of alkyl groups in biradicals which were not generated photochemically but by the thermolysis of β-alkyl-β-phenyl-β-peroxypropiolactones[18-20] and also 4,4,6,6-tetramethyl-1-oxaspiro[2,3]hexan-5-one[21].

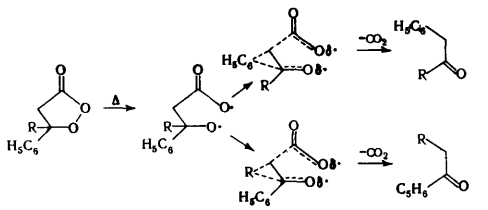
It has been shown[18] that CO_2 is evolved and ketones are formed with 1,2-migration of the alkyl or phenyl group in the thermolysis of β-alkyl-β-phenyl-β-peroxypropiolactones:



$$\rightarrow CO_2 + C_6H_5COCH_2Alk + C_6H_5CH_2COAlk\ . \quad (17)$$

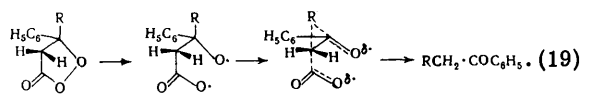
Comparison of a number of examples showed that the substituents can be arranged in the following sequence in terms of decreasing capacity for migration: isopropyl > benzyl > ethyl > methyl > phenyl. The authors drew attention to the fact that there are no instances in the literature of the preferred migration of the alkyl group compared with the phenyl group in thermally generated radicals. On the other hand, such

preference was observed in the 1,2-migration of a substituent in the photolysis of $\alpha\beta$-epoxyketones. The study of the kinetics of the thermal decomposition of β-alkyl-β-phenyl-β-peroxypropiolactones showed that the reaction is described by equations for first-order kinetics and the activation parameters are independent of the nature of the β-alkyl group. The authors put forward the following mechanism for this reaction:



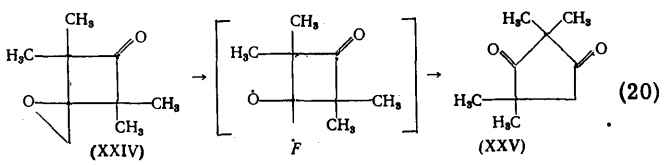
(18)

In subsequent studies[19,20] stereochemical investigations confirmed the hypothesis of the formation of non-classical bridge-type radicals. In particular, it was shown[20] in 1971 that the thermolysis of the optically active peroxide where R = $CH(CH_3)CH_2C_6H_5$ yields the optically active ketone $RCH_2COC_6H_5$ with complete retention of the configuration of the migrating group. The authors represent the stereochemical mechanism of this rearrangement as follows:



(19)

The thermolysis of 4,4,6,6-tetramethyl-1-oxaspiro-[2,3]hexan-5-one (XXIV) was carried out in a quartz tube at 650°C; the main reaction product was 2,2,4,4-tetramethylcyclopentane-1,3-dione (XXV):



(20)

The authors suggest[21] that the reaction proceeds via the homolytic opening of the oxiran ring with formation of the biradical F the rearrangement of which with 1,2-migration of the alkyl group leads to the formation of the diketone (XXV).

III. REARRANGEMENTS WITH MIGRATION OF HYDROGEN

The migration of hydrogen was studied in biradicals with different relative positions of the radical centres: (a) $\alpha\beta$-homobiradicals and $\alpha\beta$-heterobiradicals with radical centres at adjacent atoms; these are biradicals incorporating the groups

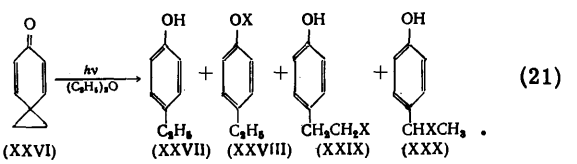
They are formed in the photolysis of the double bonds  or ; (b) $\alpha\gamma$-homobiradicals containing radical centres in the 1,3-positions:  ; biradicals of this type are usually formed in the photolysis of compounds incorporating the cyclopropane ring; (c) $\alpha\omega$-heterobiradicals incorporating, for example, the group  ; such biradicals are formed in the photochemical decomposition of *endo*-peroxides.

We shall examine the available data in the following sequence: instances of 1,2-migration of hydrogen first and then examples of migration from the fourth and fifth carbon atoms to a radical centre at a carbon or oxygen atom.

1. MIGRATION OF HYDROGEN FROM CARBON TO CARBON

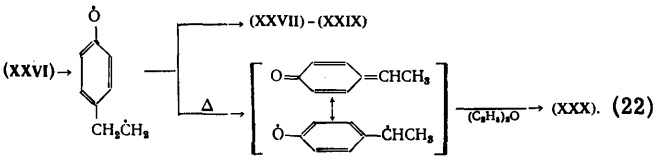
a. 1,2-Migration of Hydrogen

The photolysis of the spirodienone (XXVI) in ether[22] yields a series of *para*-substituted ethylphenols (XXVII)–(XXX), two of which [(XXIX) and (XXX)] contain the residue of an ether molecule $CH_3\dot{C}HOCH_2CH_3$ (X) in the α- and β-positions of the alkyl group:



(21)

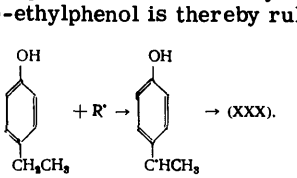
The overall yield of products (XXVII) and (XXVIII) is 15–25%. The phenols (XXIX) and (XXX) are formed in the proportion 37 : 63. The radical mechanism of the reaction is confirmed by the fact, when illumination is switched off, the reaction ceases and when the light is switched on again the reaction proceeds at the previous rate. This confirms the nature of the products, incorporating the ether residue, formed after the abstraction of hydrogen from the ether molecule. The mechanism of these reactions can be represented as follows:



(22)

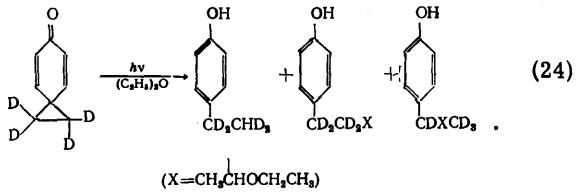
The authors believe that the intermediate quinonoid structure stabilises the transition state corresponding to the rearranged radical as a result of pairing all the electrons. The structure of the products isolated was demonstrated both by identification with compounds obtained by a specific synthesis and by ^1H NMR and mass spectrometry.

The same reaction was investigated in various solvents[23] (toluene, acetonitrile, t-butyl alcohol, and benzene). In all the solvents except toluene only polymers were obtained. It was shown that the products (XXIX) and (XXX) are not formed by the thermal process (100° and 200°C). The authors note that the proportions of these substances are independent of the initial concentration of compound (XXVI). This is evidence of a common intermediate species which leads to both substances; the formation of compound (XXX) as a result of a secondary reaction involving the abstraction of hydrogen from the α-position of *p*-ethylphenol is thereby ruled out:



(23)

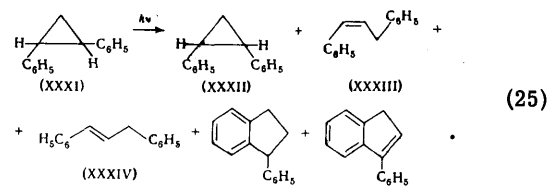
The study of the deuteriated analogue (XXVI) yielded convincing evidence for the rearrangement in the biradical[24]:



(24)

The distribution of deuterium in the reaction products was investigated by ^{1}H NMR and mass spectrometric methods. The authors showed that at least 95% of deuterium is retained in the products after the reaction. The distribution of deuterium in the products agrees almost exactly with predictions on the assumption of a biradical mechanism involving 1,2-migration of hydrogen (deuterium) rather than a series of intermolecular reactions with abstraction of hydrogen. The ratio (XXX)/(XXIX) not only does not increase but actually decreases on photolysis of (XXVI) in the presence of (XXVII), which confirms the intramolecular mechanism of the 1,2-migration of hydrogen.

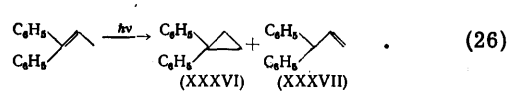
The hypothesis of the 1,2-migration of hydrogen in the biradicals has been put forward in a number of studies[25-27] to account for the mechanism of the formation of the individual products in reactions involving the opening or formation of the cyclopropane ring. Irradiation of *trans*-1,2-diphenylcyclopropane in benzene solution[25] yields a series of products with the following structures:



(25)

The authors believe that these substances are formed via the biradical C_6H_5 C_6H_5 (XXXV). The formation of compounds (XXXIII) and (XXXIV) from (XXXV) requires the hypothesis of 1,2-migration of hydrogen. The structure of compound (XXXIII) was demonstrated by its reduction to 1,3-diphenylpropane and by examining the mass and ^{1}H NMR spectra. In addition, an independent synthesis of compound (XXXIII) was achieved. Irradiation of (XXXIV) yields, apart from other products, compounds (XXXI) and (XXXII), which also requires the assumption of 1,2-migration of hydrogen in the biradical.

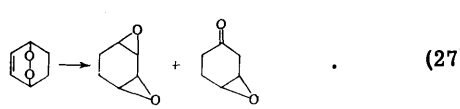
A similar example was quoted in another investigation[26]:



(26)

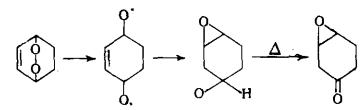
The formation of compound (XXXVI) can be explained by 1,2-migration of hydrogen and that of compound (XXXVII) by two 1,2-migrations or one 1,3-migration of hydrogen. However, in the above study a radical mechanism for the reaction was merely postulated without any evidence.

endo-Peroxides of the type of ascaridole yield diepoxides and ketoepoxides on photolysis (or thermolysis)[27]:



(27)

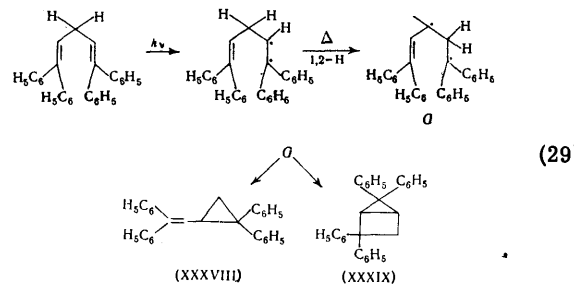
The formation of diepoxides is the normal reaction of compounds of this type. On the other hand, the authors explained the formation of ketoepoxides by a rearrangement in the intermediate biradical with 1,2-migration of hydrogen:



(28)

Since the diepoxides are stable under the chosen conditions, there is no reason to suppose that the formation of ketoepoxides is a result of secondary reactions of the diepoxides.

In one of their latest studies, Zimmerman and coworkers[28] considered the rearrangement of the biradicals formed as a result of the photolysis of 1,1,5,5-tetraphenylpenta-1,4-diene:



(29)

The conversion of the initial diene over a period of 24 h (in t-butyl alcohol solution) is 23%, the yields of compounds (XXXVIII) and (XXXIX) being 12 and 11% respectively.

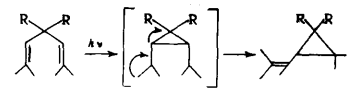
The structure of compound (XXXIX) was confirmed by hydrogenation to 1,1,3,3-tetraphenylcyclopentane. In addition the ^{1}H NMR spectra of (XXXVIII) and (XXXIX) were recorded and confirmed the above structure‡. The hypothesis of 1,2- or 1,5-migration of the hydrogen atom has been used to explain the formation of some of the products of the photolysis of various cyclo-octatrienes[39], but on the basis of the data put forward by the authors it is difficult to tell whether a rearrangement with migration of hydrogen or a stepwise isomerisation of the skeleton with the dissociation or migration of the double bond takes place.

A rearrangement of biradicals with 1,2-migration of hydrogen was noted in the photolysis of cycloalkanones (see Table 1).

b. 1,4- and 1,5-Migrations of Hydrogen

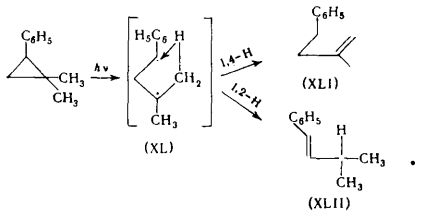
Rearrangements of biradicals with migration of hydrogen to centres in the molecule more remote than the adjacent atom are encountered much more frequently and have been investigated in a number of instances. The study of the opening and closure of the cyclopropane ring

‡ The photochemical rearrangements of cyclic and non-cyclic compounds containing the divinylmethane group, which leads to the formation of the cyclopropane ring in the molecule, for example via the mechanism



have been called the di-π-methane rearrangements[29-38].

also yielded examples of rearrangement with 1,4-migration of hydrogen in the biradical. 2,2-Dimethyl-1-phenylcyclopropane[40] was irradiated with ultraviolet light for 24 h in hexane solution. The authors postulated the formation of the biradical (XL), where 1,4- and 1,2-, migration of a hydrogen atom via the mechanism



(30)

Table 1.

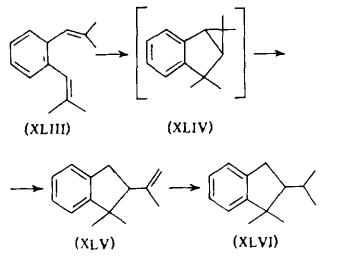
Initial ketone	Reaction conditions	Main products	References (type of migration)
 *cis*- and *trans*-isomers	u.v. (methanol + benzene)	RCH=CCH$_2$CH$_2$CH$_2$CHO R *cis*- and *trans*-isomers RCH$_2$CHCH$_2$CH$_2$CH$_2$COOCH$_3$ R RCH$_2$CHRCH$_2$CH$_2$CH=C=O	47, 48 (1,5-migration of hydrogen)
	u.v.		12 (1,4-migration of hydrogen)
 n=1,2,3	u.v. (λ=3130 Å)	 n=1,2,3	49 (1,2-migration of hydrogen)
	u.v. (λ=3130 Å)	CH$_3$CH=CHCH$_2$CH$_2$CH$_2$CHO *cis*- and *trans*-isomers CH$_2$=CHCH$_2$CH$_2$CHCHO CH$_3$	50 (1,5-migration of hydrogen)

is possible in principle. This results (in the given example) in the formation of 2-methyl-4-phenylbut-1-ene (XLI) with a yield exceeding 80%. On the other hand, the reaction involving 1,2-migration also plays an appreciable role in the case of 2,3-dimethyl-1-phenylcyclopropane. It is interesting to note that, when the isomerisation is carried out in benzene instead of hexane, the yield of the type (XLII) olefin is increased. This leads to the conclusion that benzene sensitises the 1,2-migration of hydrogen in the biradical.

These examples show that, other conditions being equal, the 1,4-migration of hydrogen in the biradical is preferred to 1,2-migration.

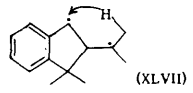
The same authors found[13] that 3,3-dimethyl-1-phenylbut-1-ene isomerises almost completely on photolysis in benzene with 1,4-migration of hydrogen in the intermediate biradical (see Scheme 14).

The authors suggested that the ultraviolet irradiation of *o*-di-isobutenylbenzene (XLIII) results in the formation of the cyclic compound (XLIV) with two ring closures, which is subsequently converted into compound (XLV) with opening of the cyclopropane ring[41]:



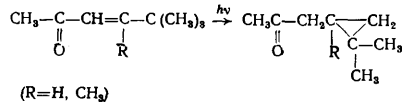
(31)

The structure of the product (XLV) was confirmed by ^{1}H NMR and also by its hydrogenation to (XLVI). The latter was also obtained by an independent procedure. It is suggested that the conversion of (XLIV) into (XLV) proceeds via the intermediate formation of the biradical (XLVII) and subsequent 1,4-migration of hydrogen.



It is noteworthy that in the studies mentioned above[13,40,41] the radical mechanism of the process was merely postulated and the problem of the intramolecular mechanism of hydrogen migration was not always specially considered.

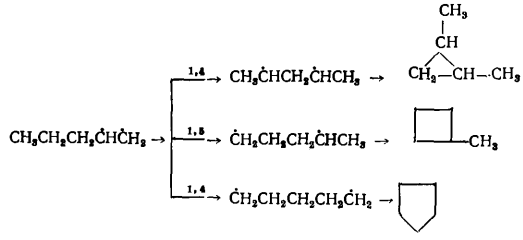
The photochemical conversion of 5,5-dimethyl-3-hex-2-enone into the isomeric ketone via the mechanism



(32)

has been described[42]. The structure of the products was confirmed by ^{1}H NMR and by independent synthesis. Although the authors in fact refrained from discussing the mechanism of the reactions (see Scheme 32), here too one can postulate 1,4-migration of hydrogen in the biradical with subsequent closure of a three-membered ring.

The formation of high yields of cyclic products (methylcyclobutene and dimethylcyclopropane) in the mercury-sensitised photolysis of pent-1-ene has been explained by a combination of 1,4- and 1,5-migration of hydrogen atoms[43]:

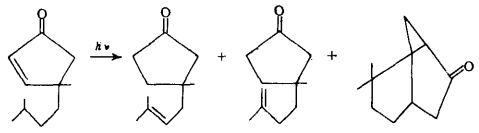


(33)

Cyclopentane is formed (Scheme 33) with greater difficulty (the radical centre moves from a secondary to a primary carbon atom) and therefore the yield of cyclopentane is low (1—2.5%). The yield of methylcyclobutane is 2.5 times greater than the yield of dimethylcyclopropane. Ethylcyclopropane was not found among the products identified, which the authors regard as evidence indicating that 1,2-migration of hydrogen does not occur.

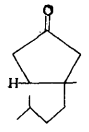
The isomerisation of the biradical with 1,2-, 1,4-, and 1,5-migration of hydrogen is possible in principle in this case, but the results show that 1,2-migration is relatively more difficult in the biradical, while migration to a more remote radical centre proceeds more readily.

Photolysis of 4-isopentyl-4-methylcyclopentenone (XLVIII) ($\lambda \simeq 3300$ Å) yields a mixture of three products (XLIX), (L), and (LI) (Scheme 34), which were isolated by gas–liquid chromatography and characterised by infrared spectroscopy and ^{1}H NMR.[44] In addition the structure was confirmed by a series of chemical reactions:



(XLVIII) (XLIX) (L) (LI) (34)

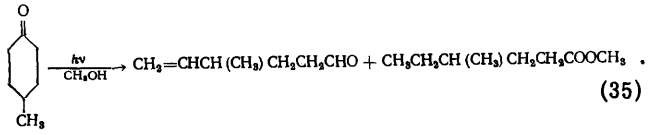
It is suggested that the formation of all the products can be explained by a sequence of rearrangements with migration of hydrogen via the intermediate biradical (LII) formed as a result of the 1,5-migration of hydrogen in the excited molecule of compound (XLVIII). However, the authors themselves refrained from a more concrete discussion of the mechanism of the formation of the reaction products:



(LII)

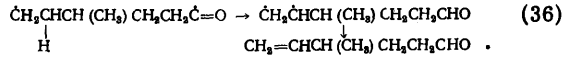
There are reviews[45,46] dealing with photochemical reactions of cycloalkanones. In particular, they deal also with reactions accompanied by rearrangements of biradicals with 1,4- or 1,5-migration of hydrogen atoms.

We shall consider in greater detail the last of a series of new studies[47-51] on the photolysis of cycloalkanones (Table 1), where the authors also devote some attention to the stereochemical aspect of the migration of hydrogen. When 4-methylcyclohexanone is irradiated in methanol solutions[51], products involving the dissociation of the 1,2-linkage are formed via the mechanism



(35)

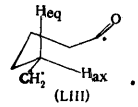
The formation of the aldehyde is explained by the 1,5-migration of hydrogen in the intermediate biradical:



(36)

By carrying out the reaction with deuterated analogues, it was possible to establish that 1,5-migration does in fact occur; moreover, having discovered by ^{1}H NMR the configuration of the initial deuteroketones and the distribution of deuterium in the final products, the authors established that there is a preferential (to the extent of 2/3) migration of the hydrogen in the axial position in the initial ketone but 1/3 of the hydrogen in the equatorial position also migrates, i.e. the stereospecificity of the reaction is low.

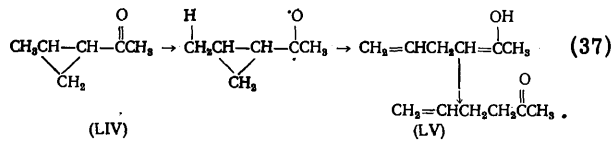
The authors regard this result also as confirmation of the intermediate formation of the biradical (LIII) with free rotation of the groups:



(LIII)

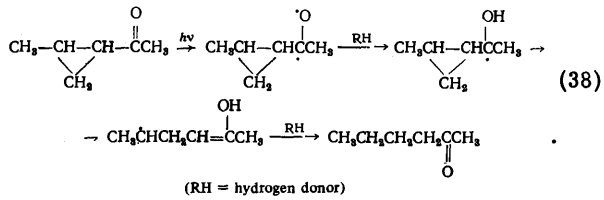
2. MIGRATION OF HYDROGEN FROM CARBON TO OXYGEN

The migration of hydrogen from carbon to oxygen was noted in the biradicals formed photochemically from conjugated cyclopropyl ketones with different structures[52,53]. For example, photolysis of the *cis*-isomer of compound (LIV) yields hex-1-en-5-one (LV) via the mechanism



(LIV) (LV) (37)

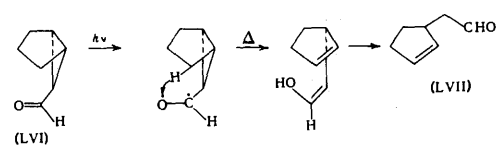
The structure of compound (LV) was established by comparing its[11]H NMR spectrum with that of an authentic specimen. The *trans*-isomer of compound (LIV) yields compound (LV) only after preliminary isomerisation to the *cis*-isomer (in pentane), whereas in isopropyl alcohol solution there is only abstraction of hydrogen from the solvent without isomerisation and with formation of aliphatic ketones via the mechanism



(RH = hydrogen donor) (38)

On the other hand, the *cis*-isomer gives rise to compound (LV) in yields up to 70% (determined by gas–liquid chromatography) even in isopropyl alcohol. According to the authors, this means that, when a rearrangement is possible, it proceeds faster than other parallel processes (for example, intermolecular abstraction of hydrogen from the solvent).

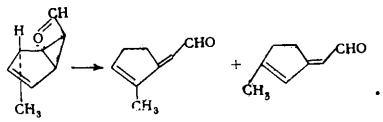
The isomerisation of the bicyclic *endo*-form of the aldehyde (LVI) also involves a rearrangement in the biradical to the extent of 30%:[54]



(LVI) (LVII) (39)

The fact that the *exo*-form of (LVI) does not give rise to (LVII) is evidence that the rearrangement proceeds without preliminary ring opening and confirms the necessity of forming a six-membered cyclic transition state which is most favourable for the rearrangement. A similar

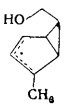
rearrangement was demonstrated also under thermal conditions (130° and 160°C in hexane) when the five-membered ring contains a double bond[55-57], for example:



(40)

(LVIII)

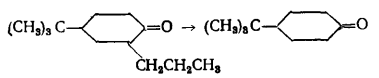
The aldehyde (LVIII) is formed preferentially. It is suggested that the rearrangement proceeds via the biradical (LIX).



(LIX)

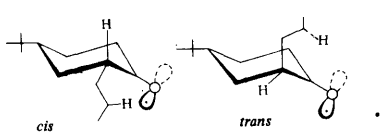
Judging from the previous investigation, this type of hydrogen migration is extremely probable, but Gilbert et al.[55] failed to quote any data which would make it possible to infer in greater detail the mechanism for the formation of the reaction products. In the photolysis of 2,3-epoxy-4,4-diphenylcyclohexanone it proved possible to compare the capacity of the hydrogen atoms and the diphenylmethyl group for migration in the biradical formed[11] (see Scheme 10).

Investigators who studied the photolytic cleavage of *cis*- and *trans*-4-t-butyl-2-propylcyclohexanones noted a significant role of stereochemical factors in the mechanism of the migration of hydrogen from the propyl group to oxygen[58,59]. The *cis*-isomer yields 4-t-butylcyclohexanone as the main product of the intramolecular hydrogen migration:



(41)

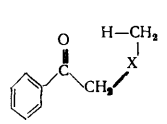
Under these conditions, the *trans*-isomer undergoes only epimerisation, yielding a ketone with the *cis*-configuration as the main product. The formula shows that conditions for the easy formation of a six-membered transition state for the intramolecular migration of hydrogen from carbon to oxygen are created only in the *cis*-conformation of cyclohexanones in the excited state:



cis *trans*

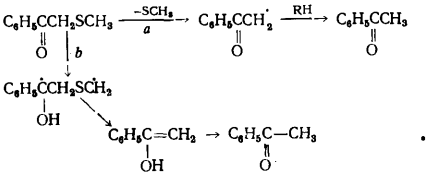
The addition of penta-1,3-diene does not affect the reaction of the *cis*-isomer. According to the authors, this shows that either the reaction proceeds via a singlet state or that cleavage of this type has a rate constant higher than 8×10^{10} s^{-1}.

A number of studies have been made on the photolysis of aliphatic-aromatic ketones with various heteroatoms X in the aliphatic chain:



The behaviour of such compounds depends significantly on the nature of X. Thus, when X = CH_2, O, S, or SO, a rearrangement with 1,5-migration of hydrogen in the triplet state proceeds to some extent, while for X = SO_2 only decomposition occurs.

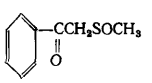
Acetophenone is formed in the photolysis of α-alkylthioacetophenone[60]. Two pathways leading to its formation can be postulated:



(42)

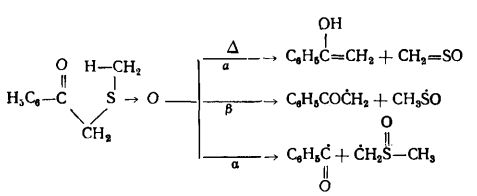
Pathway *a* involves β-elimination of the RS group with subsequent abstraction of hydrogen from a solvent molecule. Pathway *b* involves initial migration of hydrogen in the excited molecule with subsequent β-elimination in the biradical. When the photolysis was carried out in deuterated chloroform, the resulting acetophenone did not contain deuterium, which rules out pathway *a*. On the other hand, the photolysis of $C_6H_5COCH_2SCD_3$ yielded acetophenone with an appreciable deuterium content, which confirms pathway *b*. Separate experiments performed with a mixture of deuterated and non-deuterated starting materials showed that the formation of deuterated acetophenone in the corresponding yield cannot be accounted for by simple deuterium exchange or intermolecular deuterium transfer in the reaction.

Photolysis of the sulphoxide[61]



proceeds with formation of acetophenone, 1,2-dibenzoylethane (dimer), and $CH_3SO_2SCH_3$. The products were identified by gas–liquid chromatography using authentic specimens.

Various ways in which the reaction products can be formed are shown schematically in the original paper:



(43)

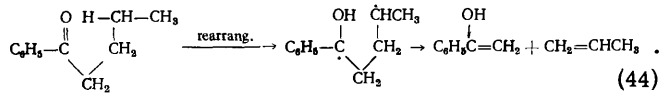
(α-cleavage, β-cleavage).

Judging from the reaction products, the α-decomposition pathway does not play a significant role. It was established that the relative yields of the final products depend significantly on the nature of the solvent. In methanol and acetonitrile the yield of acetophenone does not exceed 30%, while in isopropyl alcohol it reaches 80%, which is explained by the ease of abstraction of hydrogen from isopropyl alcohol. On the other hand, in benzene, which is a weak hydrogen donor, the yield of acetophenone is 67%. The authors believe[61] that in benzene solution acetophenone is most probably formed via pathway *a* (Scheme 43), which involves the initial 1,5-migration of hydrogen from carbon to oxygen and then β-cleavage of the biradical.

β-Decomposition (β pathway, Scheme 43) is preferred in polar solvents (alcohols, acetonitrile). Naturally, in this case the increased ease of hydrogen abstraction from the solvent (on passing from methyl to isopropyl alcohol) should imply an increase in the yield of acetophenone by facilitating the intermolecular hydrogen transfer. In the photolysis of valerophenone[62] the yield of acetophenone

increases significantly in the presence of polar solvents, but changes little when non-polar solvents are varied.

It is believed that more polar solvents accelerate β-decomposition after rearrangement with migration of hydrogen:



(44)

Table 2.

Solvent	C_6H_6	C_6H_{14}	$(CH_3)_3COH$	$(CH_3)_2CHOH$	C_6H_5OH	CH_3CN
Quantum yield of acetophenone	0.37	0.40	0.90	0.68	0.70	0.85

Table 2 shows that in this case the increase of the hydrogen-donating capacity of the solvent is hardly reflected in the yield of acetophenone, which makes it very likely that it is in fact formed as a result of the rearrangement.

It has been shown that the introduction of substituents into the ring of aliphatic aromatic ketones also affects the course of the reaction[63,64] (Table 3). The data in Table 3 show that it is so far difficult to note any consistent trend in the influence of substituents. Thus the introduction of the p-CH_3O group into the ketone (LX) increases the yield of acetophenone, while the introduction of the same substituent into the ketone (LXI) causes a sharp reduction of the yield.

Table 3.

Ketone (in benzene)	Quantum yield of aceto-phenone	Ketone (in benzene)	Quantum yield of aceto-phenone
$C_6H_5COCH_2OCH_3$ (LX)	0.57	$C_6H_5COCH_2OCH(CH_3)_2$	0.59
p-CH_3O—$C_6H_4COCH_2OCH_3$	0.72	$C_6H_5COCH_2CH_2CH_3$ (LXI)	0.34
p-CF_3—$C_6H_4COCH_2OCH_3$	0.43	p-CH_3O—$C_6H_4COCH_2CH_2CH_3$	0.09
$C_6H_5COCH_2OCH_2CH_3$	0.38		

The authors suggest that the formation of acetophenone reflects a rearrangement with migration of hydrogen. However, one also cannot rule out at least partial formation of acetophenone by the mechanism involving intermolecular abstraction of hydrogen.

When sulphones of the type $RSO_2CH_2C(O)R'$ [R = $C_6H_5CH_2$ or $(CH_3)_3C$; R' = CH_3 or C_6H_5] are irradiated, hydrogen migration does not occur[65].

The results presented here show that certain features of the rearrangements in biradicals differ from those in monoradicals. Thus, while the possibility of the 1,2-migration of hydrogen in monoradicals remains controversial, the above results indicate the occurrence of such rearrangements in biradicals. It is noteworthy that, in contrast to monoradicals, biradicals with a specific structure probably have a greater ability to stabilise the transition state or the final biradical, which facilitates for example, 1,2-migration of hydrogen in biradicals. Therefore one can hardly agree with certain investigators[22] who questioned the results obtained in the study of biradicals on the basis of the view expressed in a number of reviews that the probability of the 1,2-migration of hydrogen in the radical is low.

Thus the study of the reactions of biradicals reveals new types of possible rearrangements and their characteristic features.

The Silyl Method of Synthesis of Nucleosides and Nucleotides

E.Lukevics, A.E.Zablotskaya, and I.I.Solomennikova

Data on the silylation of pyrimidine and purine bases and on the application of trimethylsilyl derivatives of nitrogen-containing heterocycles in the synthesis of nucleosides, nucleotides, and their analogues have been reviewed systematically. The bibliography includes 205 references.

I. INTRODUCTION

The silyl method discovered in 1963[1,2] rapidly gained a firm position among numerous methods for the synthesis of nucleosides. More than 500 syntheses of various nucleosides have already been carried out by the silyl method and their number continues to grow without interruption. This can be explained by the many advantages and distinctive features of the silyl method compared with others, particularly the Hilbert–Johnson method[3] of which it is a modification.

The principal stage in the synthesis of nucleosides by the silyl method is the interaction of silylated heterocyclic bases with acylated halogenoses. The silyl derivatives can be obtained in high yield directly from the heterocyclic bases (not only pyrimidines but also their aza-analogues, triazole, purine, and other nitrogen-containing condensed systems), while the trimethylsilyl groups remaining after the reaction can be readily removed by treating the product with water or alcohol. By varying the conditions of the reaction, it can be driven towards the preferential formation of the α- or β-anomer. The use of phosphorylated sugars in the reactions makes it possible to obtain nucleotides.

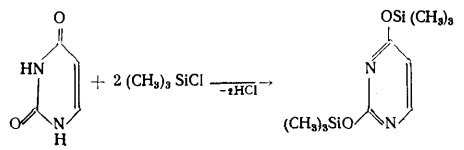
The first results obtained by the silyl method in the synthesis of nucleosides were described in a number of incomplete and now obsolete reviews[3-7] and examples of the silylation of heterocyclic bases published up to the middle of 1968 have been compiled in a table in a handbook on the silylation of organic compounds[8].

We have reviewed data on the silylation of pyrimidine and purine bases and on the application of trimethylsilyl derivatives of nitrogen-containing heterocycles in the synthesis of nucleosides† and nucleotides published up to May, 1973.

† Following Townsend and Revankar[9], in the present review the term "nucleosides" is applied to the *N*-glycosides of nitrogen-containing heterocycles.

II. SILYLATION OF PYRIMIDINES AND PURINES

When uracil is allowed to react with chlorotrimethylsilane in the presence of triethylamine, 2,4-bis(trimethylsilyl)uracil is obtained in 72% yield[1,10-21]:



The reaction is carried out in benzene[1] or dioxane[14,17], pyridine[22] or triethylamine being used as the hydrogen chloride acceptor.

When uracil is heated with hexamethyldisilazane, 2,4-bis(trimethylsilyl)uracil is formed in a high yield 90–96%).[23-27] To accelerate the silylation, chlorotrimethylsilane[28-33] or ammonium sulphate[29] is added to the reaction mixture.

For the purpose of chromatographic and mass-spectrometric analysis, uracil was silylated with *NO*-bis(trimethylsilyl)acetamide in the presence of a catalytic amount of chlorotrimethylsilane[31,34], ammonium chloride[31] (or without them[31,35,36]), and bis(trimethylsilyl)trifluoroacetamide[34,35].

In the silylation of thymine, a high yield (90–92%) of the 2,4-bis(trimethylsilyl) derivative is achieved both with chlorotrimethylsilane as the silylating agent[1,10,14,17,22,37] and on silylation with hexamethyldisilazane[11-13,16,20,21,23-25,28,30,32,38-43]. The latter reaction is carried out either in dimethylformamide (DMF) solution[38] or in an excess of hexamethyldisilazane[23]. The silylation of thymine with bis(trimethylsilyl)acetamide is carried out in acetonitrile solution[31] or at 100°C in the absence of solvent[34].

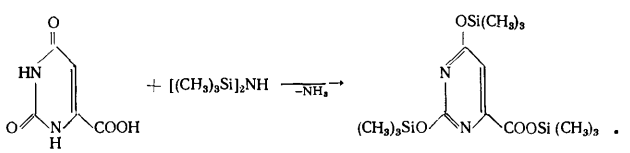
5-Alkyluracils[21,44], 5-alkoxymethyluracils[45], 5-substituted thiouracils[37,46], 6-chlorouracil[47], and 5- and 6-bromouracils[48] have also been silylated with chlorotrimethylsilane in the presence of triethylamine.

The reaction with hexamethyldisilazane yielded 2,4-bis(trimethylsilyl)derivatives of 5-trifluoromethyluracil[30,49,50], 5-alkoxyuracils[51], 5-alkoxymethyluracils[25,52],

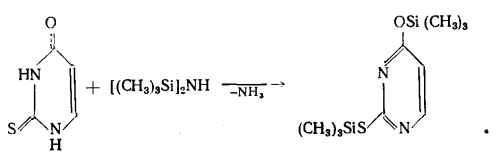
5-fluorouracil[25,30,50,53,54], 5-chlorouracil[25], 5-bromouracil[25], 5-iodouracil[25], 5-formyluracil[30,52,55], 5-alkyluracils[56], 5,6-dialkyluracils[57,58], 5-bromo-6-methyluracil[57], 5-iodo-6-methyluracil[57], 6-alkyluracils[57,58], 6-alkylthiouracils[59,60], and orotic acid esters[57]. 6-Vinyluracil has been silylated by bis(trimethylsilyl)acetamide in acetonitrile solution[61].

When 5-hydroxymethyluracil reacts with chlorotrimethylsilane in the presence of triethylamine[62] or with hexamethyldisilazane in the presence of chlorotrimethylsilane[30] or ammonium sulphate[52], all three hydroxy-groups are silylated with formation of a tris(trimethylsilyl) derivative. The reaction between barbituric acid and hexamethyldisilazane takes place quantitatively with formation of 2,4,6-tris(trimethylsiloxy)pyrimidine[53,63]. A similar tris(triethylsiloxy)-derivative is formed when barbituric acid reacts with aminotriethylsilane[64].

The carboxy-group of orotic acid is also silylated by hexamethyldisilazane, which leads to the formation of the trimethylsilyl ester of 2,4-bis(trimethylsilyl)orotic acid[57]:



When hexamethyldisilazane or its mixture with chlorotrimethylsilane reacts with 2-thiouracil[65,66], 5-alkyl-2-thiouracils[56,65-67], 5-ethoxycarbonylmethyl-2-thiouracil[66,68,69], 2,4-bis(trimethylsilyl) derivatives containing Si—O and Si—S bonds are formed. For example:

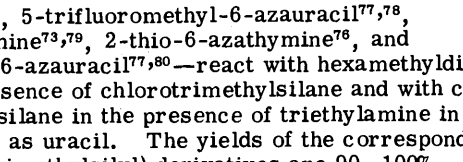


2-Selenouracil is silylated by hexamethyldisilazane similarly[70].

One trimethylsilyl group can be introduced with the aid of these reagents into the molecules of 4-*O*-ethyluracil[11,14,15,24,26], 4-*O*-ethylthymine[24,38,41,42], 4-methylthiopyrimidin-6-one[71], and 6-methyl-4-methylthiopyrimidin-2-one[58].

6-Azauracil[32,72-75] and its derivatives—2-thio-6-azauracil[65,76], 5-trifluoromethyl-6-azauracil[77,78], 6-azathymine[73,79], 2-thio-6-azathymine[76], and 5-bromo-6-azauracil[77,80]—react with hexamethyldisilazane in the presence of chlorotrimethylsilane and with chlorotrimethylsilane in the presence of triethylamine in the same way as uracil. The yields of the corresponding 3,5-bis(trimethylsilyl) derivatives are 90—100%.

When cytosine was allowed to react with chlorotrimethylsilane in the presence of triethylamine[1,10] or pyridine[22], the bis(trimethylsilyl) derivative containing Si—O and Si—N bonds was obtained in 70% yield:

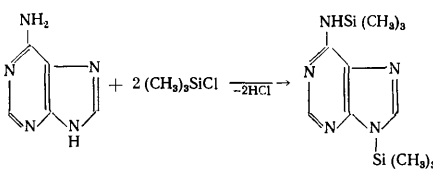


The use of hexamethyldisilazane as a silylating agent makes it possible to obtain *NO*-bis(trimethylsilyl)cytosine in 90% yield[24,29-31]. For the purpose of chromatography, cytosine has also been silylated with bis(trimethylsilyl)-acetamide[31,34,35] and bis(trimethylsilyl)trifluoroacetamide[31].

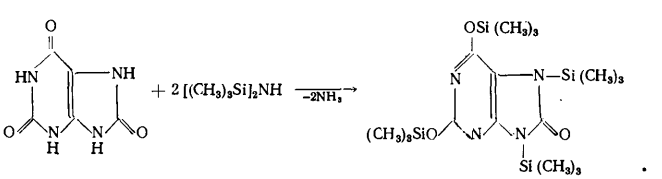
5-Methylcytosine[35], 6-methylcytosine[58], 4-acetylcytosine[1,10,16,20,24,28,32,81,82], 5-bromocytosine[83], 5-fluoro-4-*p*-toluoylcytosine[53], and 5-hydroxymethylcytosine[24] are silylated similarly.

High yields of trimethylsilyl derivatives are obtained also by the silylation with hexamethyldisilazane of other aminopyrimidines: 4-aminopyrimidin-6-one[71], 4-amino-6-hydroxypyrimidine-2-thione[59], 6-aminouracil[59], 5,6-diaminouracil[84,85], 6-alkoxy-2,4,5-triaminopyrimidines[86], and also 5-azacytosine[63,87,88], and 2-thio-5-azacytosine[87,89]. The hydrogen atom in all these hydroxy-, mercapto-, and amino-groups is substituted by the trimethylsilyl group.

When adenine[1,10,22,27], 6-benzoyladenine[1,10,11,15,28,32,90,91], hypoxanthine[1,10,14,15,91], xanthine[1,10,22], guanine[1,10,29], and theophylline[11,14,15] were allowed to react with chlorotrimethylsilane in the presence of triethylamine or pyridine, their mono-, bis-, and tris-(trimethylsilyl) derivatives were obtained respectively in 80—90% yield. In all cases one trimethylsilyl group is linked to a nitrogen atom of the imidazole ring. For example, the reaction with adenine proceeds as follows:



On heating with hexamethyldisilazane, hypoxanthine[22,23] is converted into 6,9-bis(trimethylsilyl)hypoxanthine; under analogous conditions, xanthine[29] gives rise to 2,6,9-tris(trimethylsilyl)xanthine; 6,9-bis(trimethylsilyl)-adenine is formed from adenine[29,31,92] and guanine[29] is converted into the 2,6,9-tris(trimethylsilyl) derivative. On heating with hexamethyldisilazane in an autoclave at 200°C (14 h), uric acid is converted into 2,6,7,9-tetrakis-(trimethylsilyl)uric acid in 70% yield[64,84]:



Tetrakis(triethylsilyl)uric acid was obtained in 90% yield by the reaction of uric acid with aminotriethylsilane[2,64,93,94].

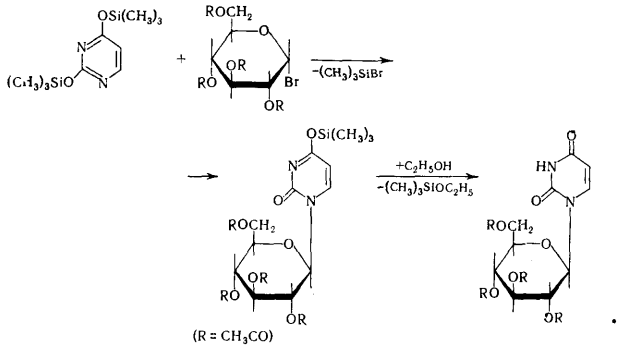
NO-Bis(trimethyl)acetamide has been used successfully in the silylation of hypoxanthine[34,35], xanthine[34,35], adenine[31,34,35], and guanine[31,34,35].

In contrast to the bases themselves, the *N*- and *O*-trimethylsilyl derivatives of hydroxy- and amino-pyrimidines are liquids or solids with comparatively low melting points and are readily soluble in non-polar solvents. They are purified by vacuum distillation or crystallisation. However, heterocyclic amines are frequently silylated by an excess of hexamethyldisilazane in the presence of a catalytic amount of chlorotrimethylsilane, the excess hexamethyldisilazane is removed after the reaction *in vacuo*, and the silyl derivative obtained is used subsequently in the synthesis of nucleosides without additional purification.

III. SYNTHESIS OF PYRIMIDINE NUCLEOSIDES

1. Uracil Nucleosides

Trimethylsilyl derivatives of hydroxypyrimidines react with acylhalogenoses, halogenotrimethylsilane being evolved and an acylated pyrimidine nucleoside being formed. Initially it was suggested that the reaction be carried out by fusing the reactants at 180—195°C at atmospheric pressure[1,12,23,28,95]. For example, when 2,4-bis(trimethylsilyl)uracil is fused with 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl bromide at 180—195°C, bromotrimethylsilane is evolved. The subsequent elimination of a second trimethylsilyl group by aqueous ethanol gives 1-(2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosyl)-uracil in 42% yield[95]:



The β-anomers were also obtained by the reaction of 2,4-bis(trimethylsilyl)uracil with 2,3,5-tri-*O*-benzoyl-D-xylofuranosyl chloride[18,19,96] (yield 73%) and 3,5-di-*O*-acetyl-2-deoxy-2-trifluoroacetamido-D-xylofuranosyl chloride[97] (yield 48%).

Mixtures of anomers with the β-anomer predominating (about 80%) were obtained by the reactions of 2,4-bis(trimethylsilyl)uracil with 2,3,5-tri-*O*-benzoyl-4-thio-β-D-arabinofuranosyl chloride[20] and 2,3,4,6-tetra-*O*-acetyl-D-galactopyranosyl bromide[98] at 130—140°C. On the other hand, when 2,3,5-tri-*O*-benzoyl-α-D-arabinofuranosyl bromide is employed as the glycosidic component, both anomers are obtained in equal amounts[12], while on fusion with 2,3,5-tri-*O*-acetyl-D-lyxofuranosyl chloride the product is 1-(2,3,5-tri-*O*-acetyl-D-lyxofuranosyl)uracil containing 78% of the α-anomer[12].

The reactants were heated at 140°C in the vacuum generated by a water pump in order to synthesise 1-(2,3,4,5,6-penta-*O*-acetyl-1-ethylthio-D-glucosyl)-uracil (yield 45%).[99] The reaction of 2,4-bis(trimethylsilyl)uracil with 3-*C*-acetoxymethyl-2,5-di-*O*-acetyl-3-deoxy-3-phthalimido-D-ribofuranosyl chloride was carried out by refluxing their solution in benzene for two days. This led to the formation of the corresponding β-nucleoside in 23% yield[100].

The silyl method has been used successfully also to synthesise nucleoside analogues in the molecules of which the pyrimidine base is linked to tetrahydrofuran or tetrahydropyran[101,102,103]. For example, 2,4-bis(trimethylsilyl)uracil reacts at a temperature as low as -20°C with 2-chlorotetrahydrofuran, the product being 1-(2-tetrahydrofuryl)uracil[102].

When 2,4-bis(trimethylsilyl)uracil is fused together with 2,3,5-tri-*O*-benzoyl-D-ribofuranosyl chloride at 190°C for 40 min, a mixture of anomeric 1-(2,3,5-tri-*O*-benzoyl-D-ribofuranosyl)uracils is formed‡. The yields of the β- and α-anomers are 58 and 9% respectively[17,23,28]. When the reaction was carried out in benzene solution at room temperature in the presence of $AgClO_4$, the overall yield of the nucleoside (52%) did not increase[24,25]. The addition of $HgBr_2$ to the reaction mixture was much more effective—after a 3 h reaction with 2,3,5-tri-*O*-benzoyl-D-ribofuranosyl bromide at room temperature, only the β-anomer was formed in 90% yield[32,105]. In an analogous reaction the yield of 1-(2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosyl)uracil was 93%.[32]

The 1-β-anomer was formed in 59% yield in the reaction of 2,4-bis(trimethylsilyl)uracil with 2-*O*-acetyl-5-*O*-benzoyl-3-deoxy-3-diethoxyphosphinylmethyl-D-ribofuranosyl chloride in the presence of a mixture of $HgCl_2$ and HgO.[33] The mixture of mercury(II) bromide and oxide proved to be a better catalyst than $AgClO_4$ also in the reaction of 2,4-bis(trimethylsilyl)uracil with 3,4-di-*O*-*p*-toluoyl-2-deoxy-D-ribopyranosyl chloride. In the first case the yield of the mixture of anomers ($\alpha:\beta$ = 77 : 23) was 78%, while in the second it was only 36%, but the anomer ratio remained almost the same (72 : 28).[26] The replacement of the *p*-toluoyl derivative by the *p*-nitrobenzoyl derivative in the reaction in benzene at room temperature in the presence of $HgBr_2$—HgO did not affect the yield and ratio of the anomers[26].

The employment of 1-(3,4,6-tri-*O*-tosyl-1-deoxy-β-D-psicofuranosyl) bromide instead of the chloride did not influence the yield of the β-nucleoside in its synthesis from 2,4-bis(trimethylsilyl)uracil in the presence of mercury(II) acetate (17%).[106]

In many cases the corresponding nucleosides were obtained in high yields also in the presence of $AgClO_4$. For example, the yields of 1-(2,3,4-tri-*O*-acetyl-L-arabinopyranosyl)uracil and 1-(2,3,4,6-tetra-*O*-acetyl-D-galactopyranosyl)uracil synthesised from 2,4-bis(trimethylsilyl)uracil and the corresponding bromo-sugars in the presence of $AgClO_4$ were 90 and 86%.[24,25] However, the yields of the nucleosides obtained by this method from 2,4-bis(trimethylsilyl)uracil and 2,3,4,6-tetra-*O*-acetyl-D-glucopyranosyl bromide, 2,3,5-tri-*O*-benzoyl-D-ribofuranosyl chloride, and 3,5-di-*O*-*p*-toluoyl-2-deoxyribofuranosyl chloride are much lower—44, 52, and 25% respectively[24,25].

When Lewis acids are used as catalysts in the synthesis of nucleosides by the silyl method, fully acylated sugars may be introduced into the reaction with 2,4-bis(trimethylsilyl)uracil. In the presence of antimony pentachloride a high yield of the nucleoside is achieved even at room temperature[107]. For example, when a solution of 2,4-bis(trimethylsilyl)uracil and 1-*O*-acetyl-2,3,5-tri-*O*-benzoyl-D-ribose in 1,2-dimethoxyethane is stirred for 100 min at 20°C in the presence of $SbCl_5$, 1-(2,3,5-tri-*O*-benzoyl-β-D-ribofuranosyl)uracil is obtained in 55% yield. Much less satisfactory results are achieved when boron trifluoride-ether is employed[107].

Depending on the nature of the catalyst employed and the reaction temperature, the interaction of 2,4-bis(trimethylsilyl)uracil with triacetylglycal gives rise to different products. When the reaction is carried out at -20°C

‡ 2,3,5-Tribenzoyl-L-uridine was synthesised similarly[104].

in the presence of BF_3-ether, the product is 3-(4,6-di-*O*-acetyl-2,3-dideoxy-D-*erythro*-hexeno-2-pyranosyl)-uracil ($\alpha:\beta = 35:32$). When a solution of the reactants in ethyl acetate is refluxed for 1 h, 1,2,3-trideoxy--3-(3'-uracilyl)-D-*arabino*-hex-1-enopyranose is formed in 78% yield, while in the presence of $SbCl_5$ an 87% yield of 1-(4,6-di-*O*-acetyl-2,3-dideoxy-D-*erythro*-hex-2-eno-pyranosyl)uracil ($\alpha:\beta = 23:26$) is obtained[108]. $AlCl_3$, $TiCl_4$, and $SnCl_4$ have an effect similar to that of BF_3, but the yields of the reaction products are lower. $FeCl_3$, $SbCl_3$, and $Cu(BF_4)_2$ act like $SbCl_5$, while $BiCl_3$ and PCl_5 do not catalyse the reaction[108].

Condensation of 2,4-bis-(trimethylsilyl)uracil with triacetylgalactal in ethyl acetate solution in the presence of $SbCl_5$ at 23°C for 5 min leads to a mixture of anomers of 1-(4,6-di-*O*-acetyl-2,3-dideoxy-D-*threo*-hexeno-2-pyranosyl)uracil from which the crystalline α-anomer and the amorphous β-anomer were isolated in yields of 40 and 24% respectively[109].

2. Thymine Nucleosides

The reaction of 2,3,4-6-tetra-*O*-acetyl-α-D-gluco-pyranosyl bromide with 2,4-bis(trimethylsilyl)thymine results in the formation of 1-(2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosyl)thymine. Its yield depends to a considerable degree on the reaction conditions and the nature of the catalyst employed (Table 1).

Table 1. Dependence of the yield of 1-(2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosyl)thymine on the conditions of the reaction of 2,4-bis(trimethylsilyl)thymine with 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl bromide[41,95].

Catalyst	Solvent	Reaction temp., °C	Duration, h	Yield, %
—	Benzene	100	20	27
—	—	100 (vacuum)	3	41
—	—	170—190	0.5	52
$AgClO_4$	ditto	20	0.25	61
$AgClO_4$	»	20	12	66
HgO	»	50	4	65
$HgCl_2$/HgO	»	50	4	72
$HgBr_2$/HgO	»	50	4	84
$HgBr_2$/HgO	»	110	5	86

Thus, while the yield of the 1-β-nucleoside in the reaction in boiling benzene is only 27% after 20 h, [41] at 170—190°C in a stream of nitrogen the yield is 52% after 30 min[95]. In the presence of $AgClO_4$ in benzene solution the yield reaches 61% after only 15 min at 20°C. The increase of the reaction time to 12 h has little influence on the yield. The maximum yield (86%) was achieved on refluxing a benzene solution of the reactants for 5 h in the presence of a mixture of $HgBr_2$ and HgO.[41] A mixture of $HgCl_2$ and HgO proved to be less active. The replacement of α-acetylbromoglucose by β-acetylchloroglucose reduced the yield of the nucleoside from 72 to 56%.[41]

In many cases the yields of the nucleosides obtained from 2,4-bis(trimethylsilyl)thymine in the presence of $HgBr_2$—HgO and $AgCl_4$ are similar. For example, the yields of 1-(2,3,4-tri-*O*-acetyl-α-L-arabinopyranosyl)-thymine were 88 and 78%,[41] which is much more than in the synthesis of the same compound by the mercury method (22%) [110] or by the Hilbert—Johnson method (13%);[111] the yields of 1-(2,3,5-tri-*O*-benzoyl-β-D-ribofuranosyl)thymine were 80 and 75%,[41] which is also higher than the yields achieved by the mercury method (50%) [110] and the Hilbert—Johnson method (8% each of the α- and β-anomer)[112]; the yields of 1-(2,3,4,6-tetra-*O*-acetyl-β-D-galactopyranosyl)thymine were 45 and 50%,[41] those of 1-(3,5-di-*O*-*p*-toluoyl-2-deoxy-D-ribofuranosyl)thymine were 55 and 45% (with the same ratio of the α- and β-anomers equal to 31:69)[41], and those of 1-(3,4-di-*O*-acetyl-2-deoxy-D-xylopyranosyl)thymine were 88 and 80%.[40] However, in the last case the ratios of the anomers in the mixtures were not the same: in the presence of $AgClO_4$ the α- and β-anomers are formed in almost equal amounts (48:52), while in the presence of $HgBr_2$—HgO the α-anomer predominates (60:40).[40]

When 2,4-bis(trimethylsilyl)thymine reacts with 2-deoxy-3,5-di-*O*-*p*-nitrobenzoyl-D-ribofuranosyl chloride in the presence of $HgBr_2$—HgO, a mixture of anomers is obtained in 80% yield, in which the α-anomer also predominates (79:21).[42] The use of the *p*-toluoyl derivative in this reaction alters the ratio in favour of the β-anomer[41]. On the other hand, mercury acetate gives a greater amount of the α-anomer ($\alpha:\beta = 56:24$) also in the reaction of 2-deoxy-3,5-di-*O*-*p*-toluoyl-D-ribofuranosyl chloride in DMF at 20°C.[41]

The β-anomers are obtained by the reaction of 2,4-bis-(trimethylsilyl)thymine with 1-deoxy-3,4,6-tri-*O*-tosyl-D-psicofuranosyl bromide in the presence of mercury(II) acetate[106], with 2,4,6-tri-*O*-acetyl-3-deoxy-D-galacto-pyranosyl chloride and 2,5,6-tri-*O*-acetyl-3-deoxy-D-galactofuranosyl chloride in the presence of $AgClO_4$,[39] and with 2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-α-D-glucopyranosyl chloride[43], 2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-α-D-galactopyranosyl chloride[113], 3,5,6-tri-*O*-acetyl-2-deoxy-2-(2',4'-dinitroanilino)-α-D-glucopyranosyl bromide[114], 3,5,6-tri-*O*-acetyl-2-deoxy-2-trifluoroacetamido-α-D-glucopyranosyl chloride[115], 3,4,6-tri-*O*-acetyl-2-deoxy-2-trifluoro-acetamido-α-D-glucopyranosyl bromide[116], 3,5-di-*O*-acetyl-2-deoxy-2-trifluoroacetamido-D-xylo-furanosyl chloride[13], and many other 2-trifluoroacetamido-halogenoses[113,115-117] at 120—140°C at water pump vacuum.

The interaction of 2,4-bis(trimethylsilyl)thymine with 2-deoxy-*C*-methyl-2-(R)-3,5-di-*O*-*p*-toluoyl-*erythro*-D-pentofuranosyl chloride in acetonitrile at room temperature for 24 h leads to a mixture of anomers from which 1-[2-deoxy-*C*-methyl-2(R)-3,5-di-*O*-*p*-toluoyl-*erythro*-D-pentofuranosyl]thymine was isolated in 42% yield[118].

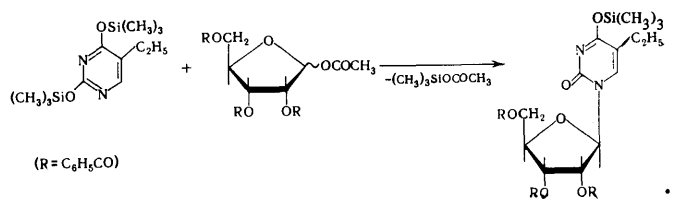
By using tin and antimony halides as catalysts, it is also possible to obtain thymine nucleosides from acylated sugars. Thus the reaction of 2,4-bis(trimethylsilyl)-thymine with 1,2,3-tri-*O*-acetyl-5-deoxy-5-fluoro-β-D-ribofuranose in 1,2-dichloroethane solution in the presence of $SnCl_4$ at 20°C for 4.5 h gave a 70% yield of 1-(2,3-di-*O*-acetyl-5-deoxy-5-fluoro-β-D-ribofuranosyl)-thymine[119]. In the analogous reaction with 1-*O*-acetyl-2,3,5-tri-*O*-benzoyl-D-ribofuranose in the presence of $SbCl_5$ in 1,2-dimethoxyethane solution the yield of the β-nucleoside was 35%.[107]

The same behaviour was observed in the reaction of 4-ethyl-2-trimethylsilylthymine[24,41,42] with halogenoses as for 2,4-bis(trimethylsilyl)thymine. For example, in the presence of $HgBr_2$—HgO the yield of 1-(2,3,4-triacetyl-α-L-arabinopyranosyl)-4-ethylthymine was higher than in

the presence of $AgClO_4$ (80 and 55% respectively)[41] and the ratio of the α- and β-anomers in the reaction with 2-deoxy-3,5-di-*O*-*p*-nitrobenzoyl-D-ribofuranosyl chloride was 64 : 36,[42] while in the reaction with the *p*-toluoyl derivative the β-anomer predominates (39 : 61).[41]

3. Nucleosides of Other 5-Substituted Uracils

The use of $SnCl_4$, $ZnCl_2$, $TiCl_4$, $AlCl_3$, or $BF_3.(C_2H_5)_2O$ as catalysts in the silyl synthesis of nucleosides in solution in 1,2-dichloroethane, acetonitrile, carbon disulphide, or DMF made it possible to employ instead of 1-halogeno-sugars the more stable and more readily available 1-alkoxy- or 1-acyloxy-derivatives[75,120]. For example, the reaction of 5-ethyl-2,4-bis(trimethylsilyl)-uracil with 1-*O*-acetyl-2,3,5-tri-*O*-benzoyl-D-ribofuranose in 1,2-dichloroethane at 22°C in the presence of $SnCl_4$ (0.72 mole per mole of sugar) for 4 h gave a 68% yield of 1-(2,3,5-tri-*O*-benzoyl-β-D-ribofuranosyl)-5-ethyluracil[75]:



Under the same conditions 5-nitro-2,4-bis(trimethylsilyl)uracil was converted after 2 h into the β-nucleoside in 62% yield[75].

However, the synthesis of 2′,3′,5′-tri-*O*-benzoyl-5-butyluridine in the presence of the $HgCl_2$—HgO mixture gave much better results than when $SnCl_4$ was employed[56].

5-Allyl-1-(3,5-di-*O*-*p*-chlorobenzoyl-2-deoxy-β-D-ribofuranosyl)uracil was obtained in a low yield (23%) by the fusion method at 125—130°C *in vacuo* (25 mmHg).[44] The fusion method (at 185—195°C for 0.5 h) gave more satisfactory results (yield 70—88%) for 5-alkoxymethyluracils[45]. A mixture of anomers containing about 80% of the β-anomers was obtained.

When 5-benzyloxymethyl-2,4-bis(trimethylsilyl)-uracil was fused together with 2-deoxy-3,5-di-*O*-*p*-toluoyl-D-ribofuranosyl chloride, 5-benzyloxymethyl-1-(2-deoxy-3,5-di-*O*-*p*-toluoyl-D-ribofuranosyl)uracil was obtained in 60.5% yield with an α- and β-anomer ratio of 1 : 4.[45] At room temperature in benzene solution the same reactants gave 66% of the nucleoside with an anomer ratio of 38 : 62. When the reaction was carried out in acetonitrile, the content of the α-anomer rose (66 : 34 for an overall yield of 71%)[52] and in the presence of $AgClO_4$ or $HgBr_2$ in benzene the main reaction product was the β-anomer[25,121]. In contrast, the reaction of 5-methoxy-2,4-bis(trimethylsilyl)uracil with 2,3,5-tri-*O*-benzoyl-D-ribofuranosyl bromide in acetonitrile solution for 45 h have a high yield (75%) of the β-nucleoside[51]. In the case of the analogous derivatives of 5-hydroxymethyluracil[52,62,121] the highest yield of the β-anomer (80—85%) was also observed when the reaction was performed in acetonitrile (30 h at 20°C)[62], while in benzene in the presence of $HgCl_2$ the yield of the α-anomer increased to 34% (for an overall yield of the anomers of 87%)[62]. The yield of the 5-formyluracil derivative was much lower (31%).[52,55]

A study of the reaction of 5-alkylthio-2,4-bis(trimethylsilyl)uracil and of 5-acetylthio-2,4-bis(trimethylsilyl)uracil with 3,5-di-*O*-*p*-chlorobenzoyl-2-deoxy-α-D-ribofuranosyl chloride showed that, under the conditions promoting the rapid removal of the chlorotrimethylsilane formed, the main reaction product is the β-nucleoside, while the addition of more chloromethylsilane to the reaction mixture results in the preferential formation of the α-anomer[37,46,122] (Table 2). In agreement with this finding, when the reaction of 5-acetylthio-2,4-bis(trimethylsilyl)uracil with 2,3,5-tri-*O*-*p*-chlorobenzoyl-α-D-ribofuranosyl chloride was carried out at 110°C *in vacuo*, the β-anomer was also formed[122].

Table 2. Dependence of the yield of the anomers of 1-(3,5-di-*O*-*p*-chlorobenzoyl-2-deoxy-D-ribofuranosyl)-5-methylthiouracil (I) and 5-acetylthio-1-(3,5-di-*O*-*p*-chlorobenzoyl-2-deoxy-D-ribofuranosyl)uracil (II) on the reaction conditions[37,46,122].

Solvent	Reaction temp., °C	Reaction time, h	Yield of (I), %	Anomer ratio $\alpha:\beta$	Yield of (II), %	anomer ratio $\alpha:\beta$
Benzene	80	1.5	51	18:82	45	More of α
Ditto	25	150	49	20:80	—	—
»	37	110	—	—	11	more of α
»	Azeotropic distillation with addition of benzene	—	36	β only	43	20:80
»	Azeotropic distillation with addition of benzene and $(CH_3)_3SiCl$	—	47	77:23	—	—
—	100–115 [without distillation of $(CH_3)_3SiCl$]	0.25	—	—	39	α only
—	100–110 (10–20 mmHg)	0.25	58	β only	50	β only

Depending on the structure of the pyrimidine derivative employed, the synthesis of 5-trifluoromethyl-1-(2-deoxy-3,5-di-*O*-*p*-nitrobenzoyl-D-ribofuranosyl)uracil from 5-trifluoromethyl-2,4-dimethoxypyrimidine and 5-trifluoromethyl-2,4-bis(trimethylsilyl)uracil can be driven towards the preferential formation of a particular anomer. In the reaction involving 5-trifluoromethyl-2,4-dimethoxypyrimidine the main reaction product was the α-anomer (83%), while the β-anomer predominated (67%) in the mixture of products in the reaction of the 2,4-bis(trimethylsilyl) derivative in the presence of mercury(II) acetate[49].

The β-anomer is also formed in 55% yield in the reaction of 5-trifluoromethyl-2,4-bis(trimethylsilyl)uracil with 3-deoxy-2,5-di-*O*-*p*-nitrobenzoyl-β-D-*erythro*-pentofuranosyl bromide in acetonitrile solution at room temperature[50].

The condensation of 5-halogeno-2,4-bis(trimethylsilyl)-uracils with various halogenoses (acetylbromoglucose, acetylbromogalactose, L-acetyl-bromoarabinose, 2,3,5-tri-*O*-benzoyl-D-ribofuranosyl chloride, and 2-deoxy-3,5-di-*O*-*p*-toluoyl-D-ribofuranosyl chloride) takes place at room temperature in benzene solution in the presence of $AgClO_4$ and the yields of products are high[25].

When 5-fluoro-2,4-bis(trimethylsilyl)uracil was heated with 2-deoxy-3,5-di-*O*-*p*-toluoyl-D-ribofuranosyl chloride in boiling toluene, a mixture consisting of 25% of the α-anomer and 75% of the β-anomer was obtained[53].

β-Anomers are formed preferentially also in the reaction of 5-fluoro-2,4-bis(trimethylsilyl)uracil with 3-deoxy-2,5-di-*O*-*p*-toluoyl-α-D-*erythro*-pentofuranosyl

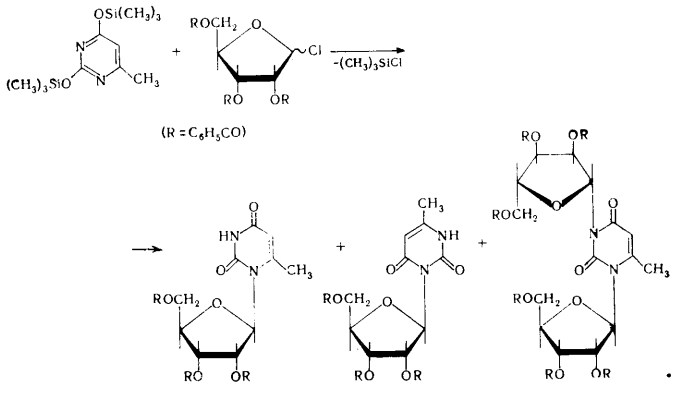
bromide[50] in acetonitrile at 20°C and with 2,3,5-tri-*O*-benzoyl-D-ribofuranosyl bromide at 150°C at a reduced pressure[54].

The reaction of 5-fluoro-2,4-bis(trimethylsilyl)uracil with 2-chlorotetrahydrofuran yielded 5-fluoro-1-(2-tetrahydrofuryl)uracil[101,103] (fluorafur), which proved to be effective in the treatment of cancer of the gastrointestinal canal[123].

The reaction of trimethylsilyl derivatives of 5-bromo- and 5-iodo-uracils with 2,3,5-tri-*O*-benzoyl-β-D-xylofuranosyl chloride in the presence of $HgBr_2$—HgO in benzene solution resulted in the formation of β-nucleosides in 36 and 43% yields respectively[96].

Nucleosides of 6-Substituted Uracils

Glycosylation of 6-methyluracil usually results in the formation of N_3-glycosides and $N_{1,3}$-diglycosides or a mixture of isomers[124]. This was also observed when an attempt was made to synthesise 6-methyluridine by the silyl method. The reaction of 6-methyl-2,4-bis(trimethylsilyl)uracil with 2,3,5-tri-*O*-benzoyl-D-ribofuranosyl chloride in acetonitrile solution at room temperature gave a low yield of the N_3-isomer[58]. An increase of the temperature of the reaction mixture to boiling and the addition of mercury(II) acetate resulted in a mixture of the N_1-, N_3-, and $N_{1,3}$-diribosyl derivatives in proportions of 4 : 11 : 33.[125] When the reaction was carried out in benzene in the presence of $HgBr_2$—HgO, a mixture of the same products was formed in proportions of 2 : 5 : 4.[57] The N_3-isomer also predominated (4 : 5 : 1) in the products of the reaction with 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl bromide:



In contrast, the reaction of 5,6-dimethyl-2,4-bis(trimethylsilyl)uracil with the same halogenoses in the presence of $HgBr_2$—HgO resulted in the formation of a high yield (about 90%) of the β-N_1-nucleosides (the yield of the $N_{1,3}$-derivatives was not more than 2—4%).[57]

In all other reactions of trimethylsilyl derivatives of 6-methylthiouracil[59,60], 6-aminouracil[59], 6-hydroxyuracil[59], and 6-chlorouracil[47] with various acylated halogenoses, N_3-derivatives were formed.

5. Nucleosides of Cytosine and Its 5- or 6-Substituted Derivatives

The reactions of 4-acetyl-2,4-bis(trimethylsilyl)-cytosine with 2,3,4-tri-*O*-acetyl-L-arabinopyranosyl chloride, 2,3,4,6-tetra-*O*-acetyl-D-galactopyranosil chloride, 2,3,4,6-tetra-*O*-acetyl-D-glucopyranosyl bromide, 2,3,5-tri-*O*-benzoyl-D-ribofuranosyl chloride, and 2-deoxy-3,5-di-*O*-*p*-toluoylribofuranosyl chloride in the presence of $AgClO_4$ give rise smoothly to the corresponding nucleosides[24]. The maximum yield (70%) was observed for the galactose derivative[24]. The yield of 4-acetyl-1-(2,3,4,6-tetra-*O*-acetyl-D-glucopyranosyl)-cytosine in this reaction was only 38%,[24] which is nevertheless higher than in its synthesis by the fusion of the initial reactants at 180—195°C (15%).[23,95] When the reactants are fused at 100—120°C *in vacuo* (80—90 mmHg) with simultaneous distillation of the halogenotrimethylsilane formed, the yield of the nucleoside is sometimes greatly increased. For example, the condensation of 4-acetyl-2,4-bis(trimethylsilyl)cytosine with 2-*O*-acetyl-5-*O*-ethoxycarbonyl-3-*O*-tosyl-D-xylofuranosyl chloride at 120°C (80—90 mmHg) for 3 h gave 4-acetyl-1-(2-*O*-acetyl-5-ethoxycarbonyl-3-*O*-tosyl-β-D-xylofuranosyl)cytosine in 80% yield[81]. The yield increases to 92% when the reaction is carried out in benzene solution at room temperature in the presence of $HgBr_2$ for 12 h.[81]

Condensation at reduced pressure was also used to synthesise 1-(3,4,6-tri-*O*-acetyl-2-deoxy-2-trifluoroacetamido-β-D-galactopyranosyl)cytosine[113] and 1-(3,5,6-tri-*O*-acetyl-2-deoxy-2-trifluoroacetamido-β-D-glucofuranosyl)cytosine[115].

The reaction of 2,4-bis(trimethylsilyl)cytosine with 2,5-*O*-benzoyl-3-deoxy-3-fluoro-D-xylofuranosyl bromide in acetonitrile at room temperature resulted in the formation in 4 days of the corresponding 1-β-nucleoside in 65% yield[126].

When $SnCl_4$ is employed as the catalyst, the 1-acetyl derivative of the sugar can be used also in the synthesis of nucleosides from cytosine and its derivatives[82,127].

On heating 4-acetyl-5-fluoro-2,4-bis(trimethylsilyl)-cytosine with 2,3,5-tri-*O*-benzoyl-α-D-arabinofuranosyl bromide in toluene solution, a mixture is formed with a 40 : 60 ratio of the α- and β-anomers[53].

β-N_1-ribosyl derivatives are formed in the reaction of 6-methyl-2,4-bis(trimethylsilyl)cytosine and 4-acetyl-6-methyl-2,4-bis(trimethylsilyl)cytosine with 2,3,5-tri-*O*-benzoyl-D-ribofuranosyl chloride in acetonitrile solution[125]. When ribosyl bromide is employed, their yield reaches 40% after 3 days[58]. The reaction with 2-deoxy-3,5-di-*O*-*p*-toluoyl-D-ribofuranosyl chloride also yields the N_1-nucleoside in the form of an anomer mixture with the β-anomer predominating[58]. However, the reaction of 2,3,5-tri-*O*-benzoylribofuranosyl chloride with 5,6-dimethyl-2,4-bis(trimethylsilyl)cytosine yields the O_2-riboside as the main product. The ratio of the O_2- and N_1-derivatives is 76 : 24.[125] Similarly the reaction of the trimethylsilyl derivative of 6-amino-2-thiouracil with 2,3,5-tri-*O*-acetyl-β-D-ribofuranosyl bromide results in the formation of the β-S_2-derivative in 40% yield[59].

6. Derivatives of Various Hydroxy-, Thio-, Seleno-, and Amino-pyrimidines

When 2,4-bis(trimethylsilyl)-2-thiouracil[65], 5-benzyloxy-2,4-bis(trimethylsilyl)-2-thiouracil[68], 5-methoxy-2,4-bis(trimethylsilyl)-2-thiouracil[69], and 5-ethoxycarbonyl-2,4-bis(trimethylsilyl)-2-thiouracil[69] react with 2,3,5-tri-*O*-benzoyl-D-ribofuranosyl chloride in benzene solution at room temperature in the presence of $AgClO_4$, the β-anomers of N_1-ribofuranosides are formed in yields of 71—78%. Under the same conditions, 5-ethyl-2,4-bis(trimethylsilyl)-2-thiouracil reacts with

2-deoxy-3,5-di-*O*-*p*-toluoyl-D-ribofuranosyl chloride to give a mixture of anomers with an overall yield of 82% and a 76 : 24 ratio of the α- and β-anomers[65,69].

A high yield (95%) of 1-(2,3,5-tri-*O*-benzoyl-β-D-ribofuranosyl)-2-thiocytosine was achieved by the reaction of 2,4-bis(trimethylsilyl)-2-thiocytosine with 1-*O*-acetyl-2,3,5-tri-*O*-benzoyl-D-ribofuranose in 1,2-dichloroethane solution in the presence of $SnCl_4$.[81] 2',3',5'-Tri-*O*-benzoyl-5-cyano-2-thiocytidine[128], 2',3',5'-tri-*O*-benzoyl-2-thiouridine[128], 2',3',5'-tri-*O*-benzoyl-5-butyl-2-thiouridine[56], and 2',3',5'-tri-*O*-benzoyl-2-selenouridine[70] were obtained by this procedure.

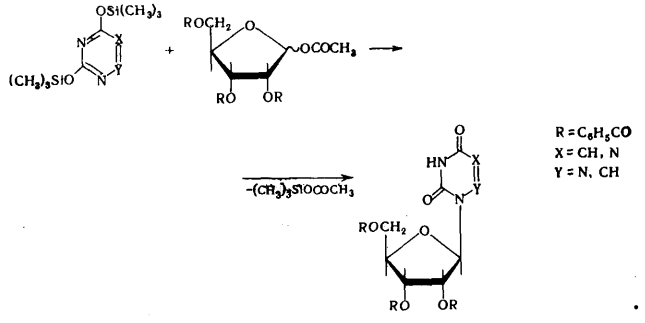
A number of nucleosides were obtained from 4,6-dihydroxy-[129], 4-amino-, and 4-alkylthio-6-hydroxypyrimidines[71]. For example, the reaction of 6-trimethylsiloxy-4-trimethylsilylaminopyrimidine with 2-deoxy-3,5-di-*O*-*p*-toluoyl-D-ribofuranosyl chloride in acetonitrile at 20°C gave a 75% yield of 4-amino-1-(2-deoxy-3,5-di-*O*-*p*-toluoyl-D-ribofuranosyl)pyrimidin-6-one containing more than 90% of the α-anomer. Under the same conditions, 2,3,5-tri-*O*-benzoyl-D-ribofuranosyl bromide gives rise to the β-anomer in 61% yield[71].

7. 6-Aza-analogues of Pyrimidine Nucleosides

The synthesis of the nucleosides of 6-azauracil and 6-azathymine by the mercury method is complicated by the formation of a mixture of N_1- and N_3-isomers[130], while the Hilbert–Johnson method is inapplicable owing to the unavailability of the initial 3,5-dialkoxy-derivatives[131].

When 2,4-bis(trimethylsilyl)-6-azauracil is fused together with various halogenoses *in vacuo*[72,73] and also when the reaction is carried out in benzene or in toluene at room temperature in the presence of mercury(II) acetate[72,74], the corresponding β-N_1-nucleosides are formed in low yields. The use of $HgBr_2$ instead of $Hg(OCOCH_3)_2$ greatly increases the yield of nucleosides (to 90%).[32]

High yields of β-nucleosides are achieved when 1-*O*-acetyl derivatives[75,120,128,134,135] are employed instead of the halogenoses[132,133]. Thus the reaction of 2,4-bis-(trimethylsilyl)-6-azauracil with 1-*O*-acetyl-2,3,5-tri-*O*-benzoyl-D-ribofuranose in 1,2-dichloroethane solution at 22°C in the presence of $SnCl_4$ for 4 h resulted in the formation of 1-(2,3,5-tri-*O*-benzoyl-β-D-ribofuranosyl)-6-azauracil in 92% yield[75]. When $SnCl_4$ is replaced by $ZnCl_2$ in this reaction and also when the latter is carried out in nitromethane, the yield of the product falls somewhat (83%). Other solvents proved to be less effective (Table 3)[128].



When 2,3,5-tri-*O*-benzoyl-D-arabinofuranosyl chloride is employed in this reaction, a mixture of 1-(2,3,5-tri-*O*-benzoyl-$\alpha\beta$-D-arabinofuranosyl)-6-azauracil containing 56% of the β-anomer is formed[75].

2,4-Bis(trimethylsilyl)-6-azathymine reacts in benzene with 2-deoxy-3,5-di-*O*-*p*-toluoyl-α-D-ribofuranosyl chloride even at room temperature. However, the yield of the β-N_1-nucleoside after interaction for 48 h was only 38%.[79] The increase of reaction temperature to 90°C in the absence of solvent has little effect on the yield of product[73]. When the reaction was carried out with 2,3,5-tri-*O*-benzoyl-D-ribofuranosyl chloride in boiling acetonitrile in the presence of $Hg(OCOCH_3)_2$, the yield of nucleoside rose to 68%,[79] while the use of the 1-*O*-acetyl derivative in the presence of $SnCl_4$ gave 1-(2,3,5-tri-*O*-benzoyl-β-D-ribofuranosyl)-6-azathymine in 77% yield[75].

Table 3. Dependence of the yield of 1-(2,3,5-tri-*O*-benzoyl-β-D-ribofuranosyl)-6-azauracil on the nature of the solvent[75,128]*.

Solvent	Reaction temp., °C	Reaction time, h	Yield of nucleoside, %	
			unpurified	recrystallised
1,2-Dichloroethane	20	4	97	92
Acetonitrile	20	4	97	82.5
Tetrahydrofuran	65	3	98	75
Carbon tetrachloride	77	4	93	73
Dimethylformamide	153	4	77.5	68.5
Carbon disulphide	46	4	87	67
Benzene	80	6	80.5	66
Toluene	111	6	86	66
1,4-Dioxane	100	4	77	57

*5 mmoles of 1-*O*-acetyl-2,3,5-tri-*O*-benzoyl-D-ribofuranose, 6.25 mmoles of 2,4-bis(trimethylsilyl)6-azauracil, 3.6 mmoles of $SnCl_4$, and 100 ml of the solvent were taken.

The corresponding 1-ribofuranosyl derivatives were obtained in 50% yield from 5-trimethylsiloxy-2,4-bis-(trimethylsilyl)methyl-6-azauracil[121,136,137] and 5-trifluoromethyl-2,4-bis(trimethylsilyl)-6-azauracil[78,138] in the presence of $Hg(OCOCH_3)_2$ in benzene at room temperature. In the second case the same yield of the nucleoside was achieved also by the fusion method[77]. The fusion method was likewise employed to synthesise derivatives of 5-bromo-6-azauracil[77,80].

The reaction of *OS*-bis(trimethylsilyl)-2-thio-6-azauracil with 2,3,5-tri-*O*-benzoyl-D-ribofuranosyl chloride in benzene solution in the presence of $AgClO_4$ resulted in the formation of 1-(2,3,5-tri-*O*-benzoyl-β-D-ribofuranosyl)-2-thio-6-azauracil in 78% yield[65,139]. Similar yields of the β-anomers were achieved when 2,3,5-tri-*O*-acetyl-1-*O*-methyl-D-ribofuranose or 1,2,3,4,6-penta-*O*-acetyl-D-glucopyranose were employed as the glycosidic components and the reaction was carried out in the presence of $SnCl_4$.[75]

8. 5-Aza-analogues of Pyrimidine Nucleosides

The application of the silyl method gave rise for the first time to the possibility of synthesising the antibiotic

5-azacytidine by the direct glycosylation of the 1,3,5-triazine ring. For this purpose, 2,4-bis(trimethylsilyl)-5-azacytosine was condensed with 2,3,5-tri-*O*-acetyl-D-ribofuranosyl bromide in acetonitrile solution at room temperature for 3 days and 5-azacytidine was obtained in 34% yield after the removal of protecting groups with ammonia[63]. 1-(2-Deoxy-$\alpha\beta$-D-ribofuranosyl)-5-azacytosine, 1-(β-D-ribofuranosyl)cyanuric acid, and 3-methyl-1-(β-D-ribofuranosyl)cyanuric acid were obtained similarly[63]. The addition of $HgBr_2$—HgO to the reaction mixture increases somewhat the yield of nucleosides[88]. When 2,4-bis(trimethylsilyl)-5-azacytosine is fused together with 2,3,5-tri-*O*-benzyl-D-arabinofuranosyl chloride at 195°C, the α-anomer is formed in 8% yield, while on carrying out the reaction at 20°C in methylene chloride for 11 days, the product is the β-anomer in 47% yield[63].

2,4-Bis(trimethylsilyl)-5-azacytosine reacts readily with 1-*O*-acetyl derivatives of sugars in 1,2-dichloroethane solution in the presence of $SnCl_4$. 1-(2,3,5-Tri-*O*-acetyl-β-D-ribofuranosyl)-5-azacytosine and 1-(2,3,5-tri-*O*-benzoyl-β-D-ribofuranosyl)-5-azacytosine (in yields of 52 and 70%)[87,140] as well as 1-(2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosyl)-5-azacytosine (yield 55%)[87] were obtained in this way. A number of nucleosides of 2-thio-5-azacytosine were synthesised by similar procedures[87,89].

IV. SYNTHESIS OF NUCLEOSIDES CONTAINING CONDENSED PYRIMIDINE SYSTEMS

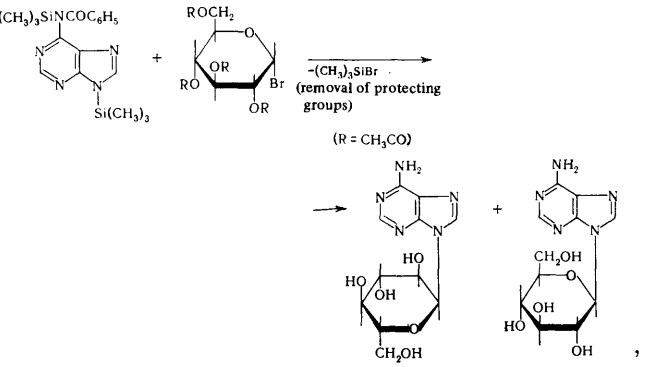
1. Purine Nucleosides

When 6,9-bis(trimethylsilyl)adenine was allowed to react with 2,3,5-tri-*O*-benzoyl-D-ribofuranosyl bromide in acetonitrile solution at 20°C the product contained 27% of the 3-β-nucleoside and 10% of the 9-β-nucleoside[92]. Under the same conditions, 8-bromo-6,9-bis(trimethylsilyl)adenine gave an 80% yield of the 3-β-nucleoside and a 7% yield of the 9-β-nucleoside. On replacing 1-bromoribose by the corresponding 1-*O*-acetyl derivative and on carrying out the reaction in the presence of $SnCl_4$, the yield of the 9-β-isomer was raised to 20%, which is still lower than the yield of the 3-β-nucleoside (39%).[92]

Condensation of 8-bromo-6,9-bis(trimethylsilyl)-adenine with 2,3,5-tri-*O*-benzoyl-D-arabinofuranosyl bromide in acetonitrile at 20°C for 24 h led to the formation of the 3-α-nucleoside in 73% yield, while condensation with 2,3,5-tri-*O*-benzyl-α-D-arabinofuranosyl chloride gave the 3-β-isomer (37%).[92]

On heating 6,9-bis(trimethylsilyl)-6-benzoyladenine with 2,3,5-tri-*O*-benzoyl-D-ribofuranosyl chloride at 150—160°C for 3.5 h and subsequent debenzoylation by sodium methoxide, adenosine was obtained[28]. A mixture of nucleosides containing the 9-β- and 7-β-isomers in proportions of 57 : 43 was obtained in benzene at room temperature in the presence of $HgBr_2$.[32,141] Under the same conditions, 3,5-di-*O*-benzoyl-2-*S*-benzyl-2-thio-D-ribofuranosyl chloride gives 22% of the 9-β-nucleoside, 5% of the 9-α-nucleoside, and 9% of a mixture of the 7-α- and 7-β-nucleosides, while 3,5-di-*O*-benzoyl-2-*S*-methyl-2-thio-D-ribofuranosyl chloride yields 34% of the 9-β-nucleoside, 10% of the 9-α-nucleoside, and 12% of a mixture of the 7-α- and 7-β-nucleosides[141].

9-β-D-Glucopyranosyladenine was obtained by the reaction of 6,9-bis(trimethylsilyl)-6-benzoyladenine with 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosyl chloride, while the reaction with α-acetylbromoglucose gave a mixture of 9-α- and 9-β-D-glucopyranosyladenines containing equal amounts of the anomers[23,90,91]:



6,9-Bis(trimethylsilyl)hypoxanthine reacts similarly[23,28,90,91].

In the synthesis of 2-acetamido-6-chloro-9-(2-deoxy-3,5-di-*O*-*p*-toluoyl-D-*erythro*-pentofuranosyl)-9*H*-purine the yield of the nucleoside increases somewhat following the addition of an excess of chlorotrimethylsilane, while an excess of the halogenose reduces it and an excess of the base has no effect whatever. The use of an excess of chlorotrimethylsilane together with mercury(II) cyanide promotes the decomposition of the sugar, best (almost quantitative) yields of the nucleoside being achieved in the presence of $Hg(CN)_2$ without the introduction of additional chlorotrimethylsilane. A mixture of the α- and β-anomers with the α-anomer predominating is then formed. The addition of chlorotrimethylsilane has little influence on the anomer ratio[142].

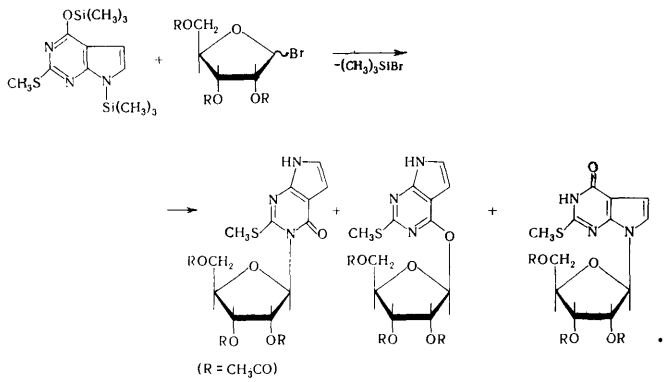
The first nucleoside obtained from xanthine by direct glycosylation was 3-(2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosyl)xanthine formed by the reaction of 2,6,9-tris-(triethylsilyl)xanthine with 2,3,4,6-tetra-*O*-acetyl-D-glucopyranosyl bromide in nitromethane in the presence of $AgClO_4$.[86,94] When the reaction is carried out with 2,6,9-tris(trimethylsilyl)xanthine in acetonitrile, the 3,7-β-diglucoside is obtained[143]. The 3,7-disubstituted product is formed also in the reaction with 2-deoxy-3,5-di-*O*-*p*-toluoyl-D-ribofuranosyl chloride in acetonitrile at 35° or 65°C. Under milder conditions (polar solvent, room temperature), the products of this reaction are 7-(2-deoxyribosyl)- and 7,9-di-(2-deoxyribosyl)-xanthines[143]. The reaction of 2,6,9-tris(trimethylsilyl)-xanthine with 3,4,6-tri-*O*-acetyl-2-deoxy-2-(2′,4′-dinitroanilino)glucopyranosyl bromide yields a mixture of products, among which the 1- and 7-glucosides were identified[143]. The condensation of 2,6,7,9-tetrakis(triethylsilyl)uric acid with 2,3,4,6-tetra-*O*-acetyl-D-glucopyranosyl bromide, 2,3,5-tri-*O*-acetyl-D-ribofuranosyl bromide, and 2,3,5-tri-*O*-benzoyl-D-ribofuranosyl bromide in toluene in the presence of $AgClO_4$ resulted in the formation of the 3-β-nucleosides in yields of 70, 56, and 90% respectively[2,86,94].

After the successful application of the silyl method in the synthesis of purine nucleosides, the range of condensed heterocycles employed in this reaction was greatly extended by the inclusion of systems in which the pyrimidine ring is linked not only to the imidazole ring but also to the pyrrole, pyrazole, triazole, benzene, pyridine, or pyrazine ring.

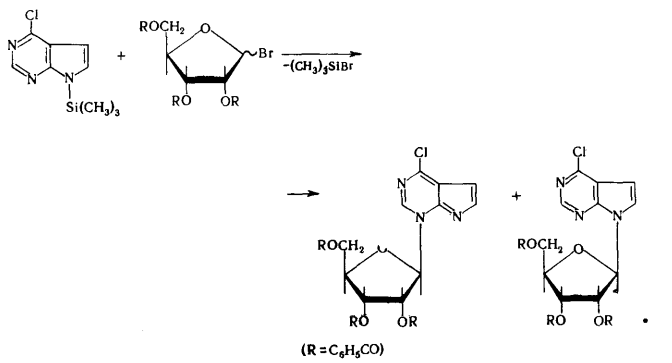
2. Derivatives of Pyrrolo[2,3-*d*]- and Pyrazolo[3,4-*d*]-pyrimidines

When 4-chloro-7-trimethylsilylpyrrolo[2,3-*d*]pyrimidine was allowed to act with 2,3,5-tri-*O*-benzoyl-D-ribofuranosyl bromide in boiling benzene in the presence of HgO for 18 h, a mixture of the 1-β- and 7-β-nucleosides was obtained, the yields of the isomers being 11 and 18% respectively[144]. Under the same conditions, the main products of the reaction with 4-chloro-5-cyano-6-methyl-7-trimethylsilylpyrrolo[2,3-*d*]pyrimidine are the 1-β- and 3-β-ribosides (yields 46 and 31%), while the 7-β-isomer is formed in a smaller amount (17%). The reaction of 4-chloro-2-methylthio-7-trimethylsilylpyrrolo[2,3-*d*]pyrimidine and 5-bromo-4-chloro-2-methylthio-7-trimethylsilylpyrrolo[2,3-*d*]pyrimidine with 2,3,5-tri-*O*-benzoyl-D-ribofuranosyl bromide in acetonitrile at 25°C in the presence of Ag_2O for 3 days gives exclusively the 7-isomers in yields of 82 and 48% respectively[144].

A mixture of the 3-, and 4-, and 7-ribosides is formed in overall yields of 79 and 94% on ribosylation of 2-methylthio-4,7-bis(trimethylsilyl)pyrrolo[2,3-*d*]pyrimidin-4-one with 2,3,5-tri-*O*-acetyl-D-ribofuranosyl bromide in boiling benzene in the presence of $HgBr_2$—HgO for 18 h or in acetonitrile at room temperature for 48 h:



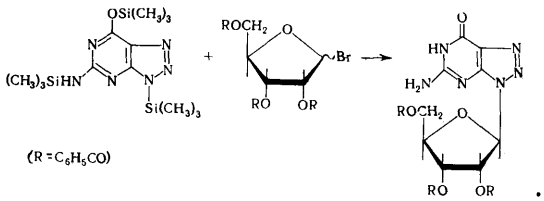
The 7-isomer predominates in the first case (64%) and the 4-isomer in the second (76%):[144]



The analogous reaction of 4-chloro-*N*-trimethylsilylpyrazolo[3,4-*d*]pyrimidine at 105—110°C *in vacuo* gave the 7-β-nucleoside in 30% yield[145].

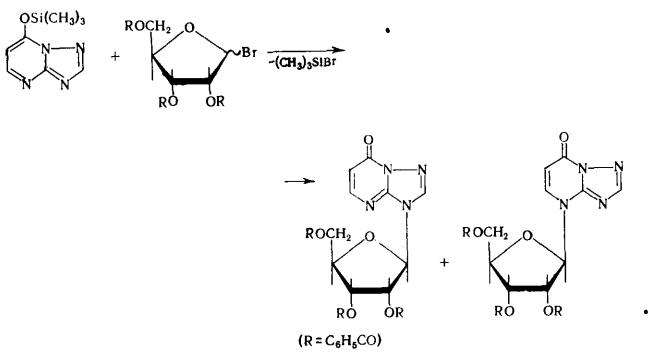
3. Derivatives of Triazolopyrimidines

When 3-tri-methylsilyl-5-7-trimethylsiloxy-trimethylsilylamino-v-triazolo[4,5-*d*]pyrimidine reacted with 2,3,5-tri-*O*-benzoyl-D-ribofuranosyl bromide in acetonitrile solution at 20°C for 6 days, 5-amino-3-(2,3,5-tri-*O*-benzoyl-β-D-ribofuranosyl)-v-triazolo[4,5-*d*]pyrimidin-7-one was formed in 43.5% yield[146].



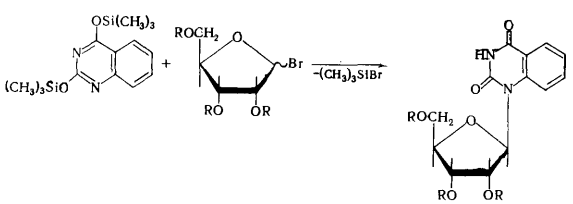
In contrast to this, the trimethylsilyl derivatives of thiazolo]5,4-*d*]pyrimidine-5,7-dione yielded a mixture of the 4-α- and 4-β-nucleosides[147]. A mixture of the 2- and 3-nucleosides (α- and β-anomers) was formed in the reaction of 7-methylthio-3-trimethylsilyl-v-triazolo-[4,5-*d*]pyrimidine with 2,3,5-tri-*O*-benzyl-D-arabinofuranosyl chloride at 120°C *in vacuo*[148].

When 7-trimethylsiloxy-*sym*-triazolo[2,3-*a*]pyrimidine reacts with 2,3,5-tri-*O*-benzoyl-D-ribofuranosyl bromide in acetonitrile at room temperature, a mixture of 3- and 4-(2,3,5-tri-*O*-benzoyl-β-D-ribofuranosyl)-*sym*-triazolo-[2,3-*a*]pyrimidin-7-ones is obtained in which the amount of the 3-isomer exceeds by a factor of 1.7 that of the 4-isomer[149]:



4. Quinazoline Nucleosides

The reaction of 2,4-bis(trimethylsiloxy)quinazoline with 2,3,5-tri-*O*-benzoyl-D-ribofuranosyl bromide in acetonitrile at room temperature for 2 days resulted in the formation of 1-(2,3,5-tri-*O*-benzoyl-β-D-ribofuranosyl)quinazoline-2,4-dione in 80% yield[144]. A similar result was obtained when the reaction was carried out in boiling benzene in the presence of $HgBr_2$—HgO.[57]

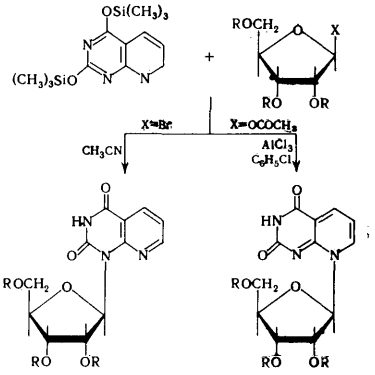


When 2-deoxy-3,5-di-*O*-*p*-toluoyl-D-ribofuranosyl chloride was employed in this reaction, the product was a mixture of anomers in 60% yield, from which it was possible to isolate 25.4% of the β-anomer and about 1% of the α-anomer[150].

β-Anomers were obtained on ribosylation of 2- and 4-trimethylsiloxyquinazolines in acetonitrile in the presence of $SnCl_4$.[151]

5. Pyrido[2,3-*d*]pyrimidine Nucleosides

The reaction of 2,3,5-tri-*O*-benzoyl-D-ribofuranosyl bromide with 4-trimethylsiloxy- and 2,4-bis(trimethylsiloxy)-pyrido[2,3-*d*]pyrimidine in acetonitrile results in the formation of the corresponding 1-β-nucleosides[152]. On the other hand, if the second compound is introduced into the reaction with tetra-*O*-acetyl-β-D-ribofuranose in chlorobenzene in the presence of $AlCl_3$ at 20°C, the product is 8-(2,3,5-tri-*O*-acetyl-β-D-ribofuranosyl)-pyrido[2,3-*d*]pyrimidine-2,4-dione[152]:

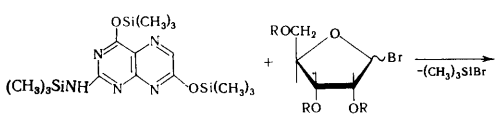


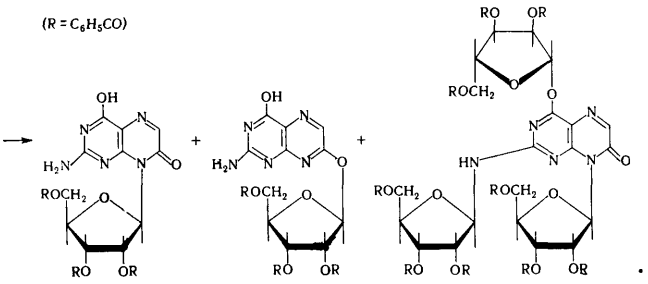
When tetra-*O*-acetyl-β-D-ribofuranose is heated with the bis(trimethylsilyl) derivative of 6-ethoxycarbonyl-2-methylthiopyrido[2,3-*d*]pyrimidine-4,5-dione at 155–160°C *in vacuo*, the 8-β-nucleoside is also formed[153].

6. Pteridine Nucleosides

The study of the reaction of trimethylsilyl derivatives of hydroxy- and amino-pteridines with halogenoses and fully acylated sugars established that, when the hydroxy-group is in the 7-position of pteridine (i.e. in the pyrazine ring), β-N_8-nucleosides are formed in most cases in the reaction with 2,3,5-tri-*O*-benzoyl-D-ribofuranosyl bromide in boiling benzene in the presence of $HgBr_2$–HgO,[154] and also with 1-*O*-acetyl-2,3,5-tribenzoyl-β-D-ribofuranose in the presence of $SnCl_4$ [155] or $ZnCl_2$.[156]

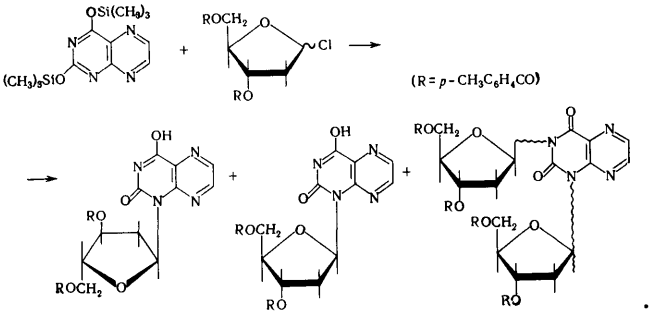
However, the 6-methyl-2-dimethylamino-[154,155] and 4-alkoxy-2-amino-derivatives[155] give rise to the formation of a mixture of the β-N_8- and β-O_7-isomers. The reaction with the 2-amino-7-hydroxy-derivative gives rise to the β-N_8-riboside (21%) and the 2,8-diriboside (4.5%).[156] But 2-amino-4,7-dihydroxypteridine yields, apart from the β-N_8- and β-O_7-isomers, also the 2,4,8-tririboside (4%):[155]





On the other hand, when the hydroxy-group is in the 2-position of pteridine (i.e. in the pyrimidine ring), then the reaction with 2,3,5-tri-*O*-benzoyl-D-ribofuranosyl bromide in the presence of $HgBr_2$–HgO yields the β-N_1-nucleoside[157] with a small admixture of the 1,3-diriboside in the case of the 2,4-dihydroxy-derivatives.

The reaction of 2,4-bis(trimethylsiloxy)pteridine and 2-trimethylsiloxy-4-trimethylsilylaminopteridine with 2-deoxy-3,5-di-*O*-*p*-toluoylfuranosyl chloride in the presence of $HgBr_2$–HgO gives rise to the formation of a mixture of 1-α-, 1-β-, and 1,3-dideoxyribosides in which the 1-β-anomer predominates[157]:

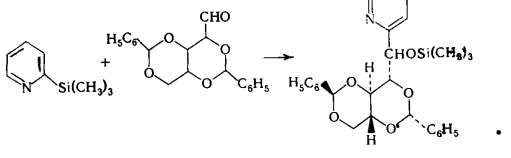


V. SYNTHESIS OF NUCLEOSIDES CONTAINING OTHER HETEROCYCLIC BASES

1. Pyridine Derivatives

The reaction of 2-trimethylsiloxypyridine with 2,3,4,6-tetra-*O*-acetyl-D-glucopyranosyl bromide in nitromethane at 20°C in the presence of $AgClO_4$ gave 1-(2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosyl)-2-pyridone in 70% yield[86,94]. 1-(2,3,5-Tri-*O*-benzoyl-β-D-ribofuranosyl)-4-hydroxy-2-pyridone was obtained in 68% yield from 2,4-bis-(trimethylsiloxy)pyridine and 2,3,5-tri-*O*-benzoyl-D-ribofuranosyl bromide in acetonitrile[158–160], while heating of the same silyl derivative with 2-deoxy-3,5-di-*O*-*p*-toluoylribofuranosyl chloride *in vacuo* at 110°C gave 4-hydroxy-1-(2-deoxy-3,5-di-*O*-*p*-toluoyl-αβ-D-ribofuranosyl)-2-pyridone[159,160]. The N_1-nucleosides of 4-hydroxy-5-methoxycarbonyl-2-pyridone were obtained in acetonitrile at room temperature[159,161].

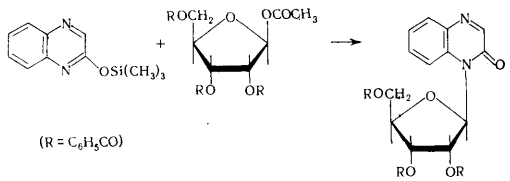
The enhanced reactivity of the Si–C bond in trimethyl-(2-pyridyl)silane permits its employment for the synthesis of *C*-nucleosides (for example, by the reaction with 2,4:3,5-di-*O*-benzylidene-D-ribose)[162]:



2. Pyridazine, Pyrazine, and Quinoxaline Nucleosides

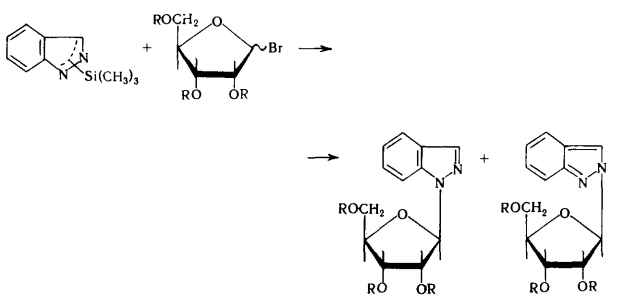
The reaction of 3,6-bis(trimethylsiloxy)pyridazine with 2-chlorotetrahydrofuran at temperatures between −20° and 10°C for 6 h or with 2-chlorotetrahydropyran at 15—50°C for 7 h in benzene solution resulted in the formation of analogues of pyridazine nucleosides—1-(2-tetrahydrofuryl(-3-hydroxypyridazin-6-one (yield 50%) and 3-hydroxy-1-(2-tetrahydropyranyl)pyradazin-6-one (yield 44.5%)—which inhibit DNA polymerase[163].

1-(2,3,5-Tri-*O*-acetyl-β-D-ribofuranosyl)-1,2-dihydropyrazin-2-one was obtained by the reaction of 2-trimethylsiloxypyrazine with 1,2,3,5-tetra-*O*-acetyl-β-D-ribofuranose in boiling 1,2-dichloroethane in the presence of $TiCl_4$.[164] 2-(Trimethylsiloxy)quinoxaline reacts similarly[165]. The yield of 1-(2,3,5-tri-*O*-benzoyl-β-D-ribofuranosyl)quinoxaline when the reaction was carried out in the presence of $SnCl_4$ did not exceed 10%, as in the presence of $HgBr_2$—HgO:[165]



3. Indazole Nucleosides

The 1- and 2-(β-D-ribofuranosyl)indazoles were obtained in proportions of 1:5 by heating *N*-trimethylsilylindazole with 2,3,5-tri-*O*-acetyl-D-ribofuranosyl bromide at 75—80°C *in vacuo* (1.5 mmHg) in the presence of sodium iodide[166]:



The 2-β-D-ribofuranosyl derivatives of 4-, 5-, and 6-nitroindazoles[166] and 3-cyanoindazole[167] were synthesised similarly. In the last case the yield of the nucleoside was 23%. The yield in boiling benzene in the presence of $HgBr_2$—HgO reached 85%.[167]

4. Pyrazole, Imidazole, Benzimidazole, and Imidazo-[4,5-*c*]pyridine Nucleosides

When 1-trimethylsilylbenzimidazole is fused *in vacuo* with various *O*-acylhalogenoses, a mixture of the α- and β-anomers of the corresponding N_1-nucleosides is formed[168-173]. The ratio of the anomers in the mixture obtained from 1-trimethylsilylbenzimidazole and 2,3,4,6-tetra-*O*-acetyl-α-D-galactopyranosyl bromide is 43:57,[168] while in the case of the glucopyranosyl derivative the ratio is 56.5:43.5.[168]

Condensation of 2-chloro-1-trimethylsilylbenzimidazole with 2,3,5-tri-*O*-acetyl-D-ribofuranosyl bromide at 110°C in the presence of NaI resulted in the formation of 2-chloro-1-(2,3,5-tri-*O*-acetyl-β-D-ribofuranosyl)-benzimidazole in 69% yield[174]. 2-Chloro-5,6-dimethyl-1-trimethylsilylbenzimidazole[175], 1-trimethylsilyl-2-trimethylsilylthiobenzimidazole[174], and 4,6-dichloro-1-trimethylsilylimidazo[4,5-*c*]pyridine[176] react similarly. The ratio of the α- and β-anomers in the synthesis of 1-(2,3,5-tri-*O*-acetyl-αβ-D-ribofuranosyl)-5-carbamoyl-4-(3,3-dimethyl-1-triazino)imidazole is 65:35.[177] Only the 1-β-riboside was isolated after the reaction of the analogous pyrazole derivative[178].

1-Methyl-2-trimethylsilylimidazole reacts with 1,6-diformyl-1,2:3,4-di-*O*-isopropylidene-α-D-galacto-1,5-pyranoside like trimethyl-(2-pyridyl)silane with formation of the corresponding *C*-nucleoside[162,179].

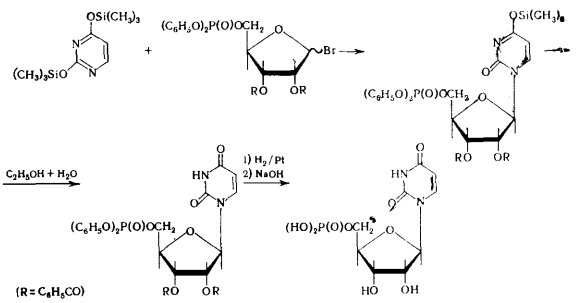
5. Triazole and Benzotriazole Nucleosides

The silyl method has been used successfully also in the synthesis of 1-(β-D-ribofuranosyl)urazole[180] and its 2- and 4-methylderivatives[180], 1-(β-D-2-deoxyribofuranosyl)-urazole[180], the methyl esters of 1-(2,3,5-tri-*O*-acetyl-β-D-ribofuranosyl)-1,2,4-triazole-3- and 5-carboxylic acids[181,182], and N_1-nucleosides of benzotriazole[170,171,183,184].

VI. SYNTHESIS OF NUCLEOTIDES

The commonest method of synthesising nucleotides involves the phosphorylation of the protected nucleoside. The possibility of the direct condensation of phosphorylated sugars with derivatives of pyrimidine or purine bases has been much less thoroughly investigated[185,186]. The silyl method proved to be very convenient for this purpose.

When 2,4-bis(trimethylsilyl)uracil was heated with 2,3-di-*O*-benzoyl-5-diphenylphosphoryl-D-ribofuranosyl bromide at 100—110°C for 30 min, 1-(2,3-di-*O*-benzoyl-5-diphenylphosphoryl-α-D-ribofuranosyl)uracil was formed in 38% yield together with its β-anomer in 11% yield[11,13,15]; after treatment with aqueous ethanol and catalytic dephenylation followed by deacylation, the latter was converted into uridine 5′-phosphate[11]:



Under analogous conditions, 2,3-di-*O*-benzoyl-5-diphenylphosphoryl-L-ribofuranosyl bromide gives the α- and β-anomers in yields of 34.5 and 18% respectively[16]. The yields of 1-[2,3,4-tri-*O*-acetyl-6-bis-(*p*-nitrophenyl)-phosphoryl-β-D-glucopyranosyl]uracil[11], 1-[2,3-di-*O*-benzoyl-5-diphenylphosphoryl-β-D-ribofuranosyl]-4-ethyluracil[11], and the α- and β-anomers of L-ribofuranosylthymine 5′-phosphate[16] are 18.5%, 35%, 34.3, and 17% respectively.

The α-anomer was obtained in 26% yield on heating 2,4-bis(trimethylsilyl)thymine with 2,3-di-*O*-benzoyl-5-diphenylphosphoryl-D-ribofuranosyl bromide at 100–110°C.[13] When the same reaction was carried out *in vacuo* (80–100 mmHg), the β-anomer was formed in 48% yield[15]. In the presence of $HgBr_2$ the reaction can be carried out in benzene at room temperature. The yield of the β-anomer then reaches 92% after 3 h.[32] In the presence of $HgBr_2$, 4-acetyl-1-(2,3-di-*O*-benzoyl-5-diphenylphosphoryl-β-D-ribofuranosyl)cytosine was also obtained in a high yield[32], while fusion of the reactants leads to a mixture of the α- and β-anomers in proportions of 68 : 32.[16,187]

6-Benzoyl-9-(2,3-di-*O*-benzoyl-5-diphenylphosphoryl-D-ribofuranosyl)adenine was obtained in 37.6% yield[14,15,187,188] and with a 43 : 57 ratio of the α- and β-anomers[188] by fusing 6-benzoyl-6,9-bis(trimethylsilyl)-adenine with 2,3-di-*O*-benzoyl-5-diphenylphosphoryl-D-ribofuranosyl bromide. When the reaction is carried out in benzene at room temperature in the presence of $HgCl_2$, the yield of the β-nucleotide is increased to 67% but a mixture of the 9- and 7-isomers is then formed in proportions of 58 : 42.[32]

Condensation of 6,9-bis(trimethylsilyl)hypoxanthine and trimethylsilyltheophylline with 2,3-di-*O*-benzoyl-5-diphenylphosphoryl-D-ribofuranosyl bromide at 100–110°C leads to the formation of 9-(2,3-di-*O*-benzoyl-5-diphenylphosphoryl-β-D-ribofuranosyl)hypoxanthine in 59.2% yield and of the 7-β-nucleotide of theophylline in 73% yield[11,15].

ADDENDUM

A series of studies on the synthesis of nucleosides and their analogues using trimethylsilyl derivatives of heterocyclic bases were published recently (from May to October, 1973), which is evidence of a growing popularity of the trimethylsilyl method of synthesis. For example, 2,3,5-tri-*O*-benzoyl-5-isopropyl- and 2,3,5-tri-*O*-benzoyl-5-t-butyl-uridines (*anti*-conformations)[189] as well as 1,2-dihydro-1-(3,5-di-*O*-*p*-chlorobenzoyl-2-deoxy-$\alpha\beta$-D-*erythro*-pentofuranosyl-2-oxopyrazine 4-oxide[190], which is an analogue of deoxyuridine, were resynthesised by this method. Condensation of 2,4-bis(trimethylsilyl)-uracil[191] and 5-trimethylsiloxy-2,4-bis(trimethylsilyl)-uracil[192] with 2-chlorotetrahydrofuran and with 2-chlorotetrahydropyran led to the formation of the corresponding N_1-tetrahydrofuryl and N_1-tetrahydropyranyl derivatives.

5-Hydroxy-1-(β-D-ribofuranosyl)pyrimidin-2-one[193] and 3-methoxycarbonyl-, 3-cyano-, and a number of other 3-substituted 1-(β-D-ribofuranosyl)-1,2,4-triazoles[194] were also successfully synthesised via the silyl derivatives of the bases. Studies have been made on the condensation of trimethylsilyl derivatives of thymine with acyclic sugars[195] and of a number of trimethylsilyl derivatives of uracil, 6-azauracil, and their 2-thio-derivatives with oligosaccharides[196].

Nucleoside analogues containing various condensed systems as the aglycones were obtained by the silyl method: 3-($\alpha\beta$-D-galactopyranosyl)-2-methyl-7-nitroimidazo[4,5-*c*]pyridine[197], 6-bromo-1-(β-D-glucopyranosyl)-2-methyl-1*H*-imidazo[4,5-*b*]pyridine[198], 6-bromo-1-(β-D-galactopyranosyl)-1*H*-imidazo[4,5-*b*]-pyridine[198], 5,6-dimethyl-1-(β-D-ribofuranosyl)imidazo-[4,5,*b*]-pyrazine[199], 2-β-D-(2,3,5-tri-*O*-benzoylribofuranosyl)- and 2-β-D-(2,3,4,6-tetra-*O*-acetylglucopyranosyl)-5,6-dihydro-4-hydroxymercapto-7*H*-pyrrolo[2,3-*d*]-pyrimidines[200], and 2-ethyl-6-(β-D-ribofuranosyl)oxazolo-[5,4-*d*]pyrimidin-7-one[201].

The synthesis of pteridine nucleosides from the trimethylsilyl derivatives of various hydroxy- and amino-pteridines was investigated in greater detail[202–204].

The employment of the trimethylsilyl method for the synthesis of pyrimidine nucleosides was also briefly considered in a recently published review devoted to the methods of synthesising pyrimidine nucleosides[205].

Photochemistry of Aromatic Sulphonyl Compounds

O.P.Studzinskii, A.V.El'tsov, N.I.Rtishchev, and G.V.Fomin

The spectra of aromatic sulphonyl compounds $ArSO_2X$—sulphonic acids, their derivatives, and sulphones X = OH, OAlk, OAr, Hal, NH_2, N_3, Alk, Ar)—are examined, information is reported on the photoreactions, and modern views are given on the mechanism of these processes. A list of 143 references is included.

I. INTRODUCTION

Aromatic sulphonic acids, their derivatives (esters, amides, halides, and azides), and sulphones are extremely numerous and important compounds in organic chemistry, of both purely theoretical and practical interest. In contrast to dark chemistry and the photochemistry of other sulphur-containing compounds, until fairly recently hardly any investigation had been made of the photochemical properties of the present group of compounds. The chemistry of their excited states has begun to be developed only during the past 10–15 years in connection with the appearance of new physicochemical methods and the improvement of photochemical experimental techniques. A considerable number of publications have appeared in this field, but they have not been summarised in the Soviet literature†, and an attempt is made in the present paper. The literature has been covered up to 1973 inclusive.

† A review of the photochemistry of aromatic sulphonic acids will be found in Ref. 1.

II. SPECTRA OF COMPOUNDS $ArSO_2X$

The sulphonyl group SO_2, present in all the compounds under review, contains positively charged sulphur without a lone pair of electrons and on the whole has a planar structure[2]. Most investigators consider that, as a consequence, conjugation of the π-electron system of the aromatic residue with the sulphonyl group and through the latter with the X moiety is absent. In sulphonic acids and esters, sulphonamides, and sulphonyl halides, therefore, the effect of the SO_2X substituent is regarded as purely inductive or one in which the inductive effect predominates considerably over the conjugation effect[3,4]. The electronic absorption spectrum of the aromatic ring system is little affected in these compounds, being determined by the chromophores of the unsubstituted compound weakly perturbed by the sulphonyl group. Furthermore, even this slight effect of the SO_2X group is smaller the larger the number of aromatic rings in the fused structure. Introduction of an SO_2X substituent has little effect also on the

energy characteristics of photoexcited states of the aromatic system.

Nevertheless, attempts were sometimes made to reveal conjugation of the aromatic ring with the SO_2X substituent, e.g. in compounds $C_6H_5SO_2X$ (X = OH, OCH_3, Hal), from a study of the ultraviolet spectra [5,6]. The results reported below, however, largely contradict the authors' arguments.

The main spectral features of aromatic sulphonic acids attributable to the sulphonyl group are apparent also in such derivatives as esters, amides, and halides, which is confirmed not only by their electronic spectra [5]. Thus the same conclusion is reached from an investigation of these compounds by Raman and infrared spectroscopy (in particular the effect of nuclear substituents on the spectra) [7]. This permits us to use the sulphonic acids of benzene, naphthalene, anthracene, and anthraquinone, which are most often subjected to photochemical reactions, to examine the above features of the effect of the SO_2X group on the spectral characteristics of aromatic compounds.

Three absorption bands—at 210 nm (ϵ = 5000), 255–272 nm (ϵ = 200–400, split into four narrow peaks), and 293 nm (weak)—are present in the ultraviolet spectrum of aqueous benzensulphonic acid (I) [8,9]. The appearance of a band in the region of 270 nm is attributed [9] to the electron-accepting properties of the sulpho-group, evident in a displacement of electron density from the benzene ring to the positively charged sulphur atom.

Among the anilinesulphonic acids (IIa–c) sulphanilic acid (IIc) has been most thoroughly studied. Spectral investigations, as well as conductivity measurements on its aqueous solutions [10], have shown that it is not an internal salt [11] or a zwitterion [12]. In contrast to metanilic (IIb) and orthanilic (IIa) acids, which have absorption maxima at 293 and 294 nm respectively with lgϵ = 3.21 and 3.43, the spectrum of (IIc) has a shoulder (278–302 nm) in this region, and at shorter wavelengths a band develops from the second absorption band of benzenesulphonic acid, which is sometimes explained by partial conjugation of amino- and sulpho-groups through the benzene ring [10]. On protonation of the amino-group in an acid medium the spectra of all of the anilinesulphonic acids (IIa–c) approach the spectrum of benzenesulphonic acid [10,13], but in alkaline solutions that of aniline (III) [14].

Neither benzenesulphonic acid (I) nor its salts luminesce, owing to deactivation of the benzene ring and localisation of the π-electrons under the influence of the sulpho-group [15]. Delocalisation of π-electrons, due to the strong effect of the amino-group, is dominant with the anilinesulphonic acids (IIa–c). Sodium sulphanilinate luminesce in water at 293°K (Φ = 0.07) [16]. The phosphorescence spectrum of crystals of this acid contain [17] two bands at 405–460 and 460–540 nm, which decay at different rates and are assigned [17,18] to two triplet levels (51.2 and 69.2 kcal mole^{-1}).

The spectra of naphthalene-1- and -2-sulphonic acids (IVa) and (IVb), as well as that of naphthalene itself (V), contain three electronic bands—^1L_b, ^1L_a, and ^1B_b at 290–320, 250–290, and 210–240 nm respectively—corresponding to $\pi\pi^*$-transitions [19–21] (Platt's classification [22]). The considerable difference between the molecular orbitals of the 1- and 2-isomers (IVa) and (IVb) is responsible for the difference (though slight) between their absorption spectra [23]. The presence of a 1-sulpho-group leads to a bathochromic shift of the ^1L_a and ^1B_b bands, but the 2-isomer shows a bathochromic shift of the ^1L_b band; intensification of the longer-wavelength band is observed with both isomers. No change in direction of the moments of the electron transitions was observed on migration of the substituent from the 1- to the 2-position in the above isomers (IVa) and (IVb) [24]. The direction of the transition moments is obviously unaffected not only by change in the position of the sulpho-group in the naphthalene ring system but also by its introduction into the ring. Substituents which undergo conjugation behave differently; they usually change the direction of the moments of certain transitions of fused aromatic systems [19,24]. As with naphthalene [25,26], the ^1L_b and ^1B_b transitions of its 1- and 2-sulphonic acids (IVa) and (IVb) are evidently parallel to the long symmetry axis x, while the ^1L_a transition is perpendicular to it.

Introduction of a 4-amino-group into naphthalene-1-sulphonic acid displaces the ^1B_b band to longer wavelengths and halves its intensity; the ^1L_a band undergoes a bathochromic shift, and its intensity is doubled [20,27]. This effect, as with the anilinesulphonic acids, is due to interaction of the amino-group with the naphthalene ring, which overlaps the effect of the sulpho-group. The absorption curve of naphthionic acid (VI) coincides in neutral and alkaline solutions with the spectrum of 1-naphthylamine (VII), but in acid solutions approximates to the spectrum of naphthalene-1-sulphonic acid (IVa) [20,27].

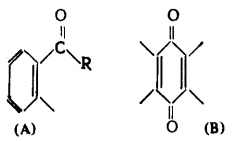
Both isomeric naphthalenesulphonic acids (IVa) and (IVb) fluoresce [28] in methanol–water matrices at 77°K. Naphthionic acid (VI) fluoresces intensely in aqueous solution (λ_{max} = 425 nm); the intensity increases over the pH range 0–6, and then remains constant with further increase in pH [29], owing to deprotonation of the amino-group. The quantum yield of the fluorescence of sodium 4-aminonaphthalene-1-sulphonate (VI) in water at 20°C is ~0.80. [30]

According to Smaller et al. [28] the fluorescence levels of naphthalene and of its 1- and 2-sulphonic acids differ by −1.2 and −1,3 kcal mole^{-1} respectively, the corresponding differences for the phosphorescence levels being −0.35 and −0.09 kcal mole^{-1}. Thus E_{S^1} and E_{T^1} for the naphthalenesulphonic acids (IVa) and (IVb) are ~89 and ~60 kcal mole^{-1}. [28] If the effect of the sulpho-group in the aminosulphonic acid (VI) is also neglected, the energies of the excited states can be assumed to be close to those for 1-naphthylamine (VII) (E_{T^1} ~ 54 kcal mole^{-1}). [31]

Both groups of absorption bands of anthracene(VIII)—shorter-wavelength ^1B_b at 230–260 nm and longer-wavelength ^1L_a at 290–390 nm—exhibit a slight bathochromic shift on introduction of a sulpho-group. With anthracene-1-sulphonic acid (IXa) the shift of the ^1L_a band is ~5–6 nm, several times larger than that of the ^1B_b band. With anthracene-2-sulphonic acid (IXb), on the other hand, the relative shift of ^1B_b exceeds that of ^1L_a. [32] These results are consistent with indications [33,34] that the introduction of an electron-accepting substituent at position 1 or 9 in anthracene displaces the longer-wavelength band more strongly than the shorter-wavelength band. Popov's study [24] of the polarisation spectra of the anthracenesulphonic acids (IXa) and (IXb) suggests that, as with anthracene (VIII) [35], the moment of the transition $^1L_a \leftarrow {}^1A_1$ is parallel to the long x-axis of the molecule, while the moment of the transition $^1B_b \leftarrow {}^1A_1$ is parallel to the short y-axis. These sulphonic acids luminesce in solution, in contrast to other anthracene derivatives containing electron-accepting substituents (nitro, carboxy) that conjugate with the anthracene ring system [36–38]. On the assumption that the energy levels of excited states of these sulphonic acids differ little from the levels of anthracene, we can estimate them as E_{S^1} = 76 and 72.5 kcal mole^{-1} for anthracene in solution and in the crystalline state, and E_{T^1} = 42.5 kcal mole^{-1}. [39]

Introduction of a sulpho-group at position 1 or 2 in

anthraquinone (X) produces a slight bathochromic shift (>5 nm) of the absorption bands with a slight increase in their intensity. The spectrum of anthraquinone itself (X) comprises six bands—at 243.5, 252.5, 262.8, 272, 325.5, and 405 nm—and is often regarded as resulting from the superposition of the spectra of two chromophores (A) and (B)[40]



(A) (B)

All these bands other than the last have been assigned to $\pi\pi^*$-electron transitions[41-44]. The moments of the transitions of bands at 252.5, 262,8, and 325.5 nm are polarised along the short y-axis of the molecule[42,44,45], and that of the 272-nm band is polarised along the long x-axis[45]. The chromophore of anthraquinone is sometimes regarded[46] as two weakly interacting *ortho*-disubstituted benzenes, the three $\pi\pi^*$-states of anthraquinone being associated with the ^1L_b, ^1L_a, and ^1B_b bands of benzene[22]. Hence the bands at 252.5, 325.5, and 272 nm are assigned to $^1B_b \leftarrow {}^1A_1$, $^1L_b \leftarrow {}^1A_1$, and $^1L_a \leftarrow {}^1A_1$ transitions in the benzene ring[44,47]. The absorption at 405 nm, which is so weak that it is not always evident, has given rise to the most contradictory conclusions[40,48]; its transition moment lies in the plane of the molecule, and is polarised along the x-axis[44]. The lifetime of the phosphorescent state on excitation in this band[49,50] and the shifts it undergoes in various solvents[51] have enabled it to be assigned quite confidently to an $n\pi^*$-level of anthraquinone. The assignment of the 405-nm absorption to a $\pi\pi^*$-transition, which was based on theoretical calculations[52], seems very questionable.

The bands in the electronic spectra of anthraquinone-1- and -2-sulphonic acids are assigned in the same way as with anthraquinone[53]. Differences between the isomers resulting from the position of the sulpho-group are more clearly evident in the infrared spectra[2]. The spectrum of the ion of the sulphonic acid (XII) in the solid state contains an absorption band corresponding to carbonyl-stretching vibrations at 1678 cm^{-1}; in the ionised form of the 1-isomer (XIa) this is split into two, at 1678 and 1692 cm^{-1}. The latter corresponds to the 9-carbonyl group, and results from donor–acceptor interaction of the SO_2O^- group with the quinoid system of the molecule. Band splitting is observed also with the covalent anthraquinone-1-sulphonic acid: the carbonyl frequency has fallen to 1684 and 1664 cm^{-1} (carbonyls at positions 10 and 9), and absorption appears at 3200 cm^{-1}, due to hydroxyl involved in an intramolecular hydrogen bond.

Photoexcitation of anthraquinone (X) and its sulphonic acids may transfer their molecules to $S_{\pi\pi^*}$, $S_{n\pi^*}$, $T_{\pi\pi^*}$, and $T_{n\pi^*}$ states. According to most authors[44,50,54,55] the lowest excited state is $T_{n\pi^*}$, above this is located the $S_{n\pi^*}$ level ($\Delta\nu \simeq 1000$ cm^{-1}), after which follow the $T_{\pi\pi^*}$ and $S_{\pi\pi^*}$ levels. This is counterbalanced by Nurmukhametov's view[50] that the $T_{\pi\pi^*}$ level is located between the $S_{n\pi^*}$ and $T_{n\pi^*}$ levels. Evidence is provided by the absence of fluorescence from the S_{n^*} level in solutions of anthraquinone and its derivatives, owing to the high efficiency of the $S_{n\pi^*} \rightarrow T_{\pi\pi^*}$ interconversion due to the increase of spin–orbital coupling between states of different electron configurations[56].

Luminescence has not been observed in solutions of anthraquinonesulphonic acids; formation is available only on the phosphorescence of (XII) in a matrix at low temperatures[57]. The presence of a sulpho-group in the anthraquinone molecule, whether at position 1 or 2, has hardly any effect on the arrangement of energy levels. The energy of the lowest triplet level of anthraquinone $T_{n\pi^*}$ is ~62.5 kcal $mole^{-1}$,[57,58] and ~62 kcal $mole^{-1}$ in the 2-sulphonic acid (determined from the phosphorescence spectrum)[57]. Because of the impossibility of determining experimentally the energy of the lowest singlet state $E_{S_{n\pi^*}}$ of anthraquinone and its sulphonated derivatives, values were calculated from the electronic absorption spectra[59]: the results were respectively 66.5, 64.3, and 64.6 kcal $mole^{-1}$ for anthraquinone and its 1- and 2-sulphonic acids.

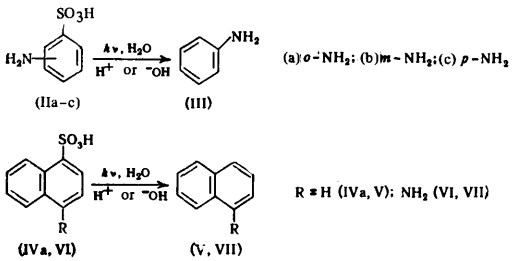
A rather different situation is found when the substituent X attached to the arylsulphonyl group possesses a sufficiently mobile π-electron system, as e.g. in diaryl sulphones and arenesulphonyl azides. Although published data on them are few and somewhat contradictory, the sulphonyl group in these compounds may be supposed to be better able to transmit the effect of conjugation. This is indicated in particular by a bathochromic shift (absorption in the range 230–245 nm) and a more than double hyperchromic effect on passing from methyl phenyl to diphenyl sulphone[60]. The measured dipole moments of a series of diaryl sulphones indicate a considerable displacement of electron density from the benzene rings to the sulphonyl group[61]. Since the sulphonyl sulphur atom does not possess a lone pair of electrons, which might have been involved in conjugation, it has been suggested[62] that 3*d*-orbitals of sulphur take part in this process.

There are indications that a similar effect occurs in aromatic sulphonyl azides[63]. The electronic spectra of the benzenesulphonyl azides that have been studied contain no bands in the region of 285 nm, where absorption by the benzene ring is absent, that might have been attributable to the azide group. The two bands observed—with a sharp maximum in the range 220–256 nm ($\lg\epsilon = 3.9$–4.5) and with a characteristic vibrational structure in the range 257–295 nm (2.5–3.4)—correspond to electron transitions between energy levels of the whole molecule. The red shifts of absorption bands I and II of benzene (by 19 and 10 nm respectively) on introduction of an azidosulphonyl group into the ring are substantially smaller than on introduction of an azido-group ($\Delta\lambda = 30$–45 nm). This is attributed[63] to a change in the character of the interaction between the substituent and the benzene ring: whereas the azido-group acts as an electron donor, the azidosulphonyl group possesses electron-accepting properties. The higher frequency of the azide-stretching vibrations in the infrared spectra of aromatic sulphonyl azides than in those of analogous aromatic azides indicates intensified localisation of bonds in the azide fragment under the influence of the sulphonyl group. Nevertheless, the correlations found between the absorption frequency of the azido-group (in the range 2120–2135 cm^{-1}) and the integral intensity of this band with the Hammett σ constants of substituents in the aromatic ring indicate that these substituents may be conjugated through the sulphonyl group with the π-electron system of the azido-group.

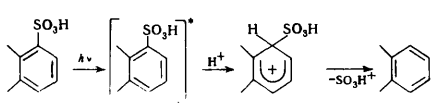
III. PHOTOCHEMICAL PROCESSES INVOLVING THE SULPHUR-CONTAINING GROUP

The simplest photochemical process directly involving the SO_2X group—elimination of the sulpho-group from certain aromatic sulphonic acids—can be accomplished by exposing their weakly acid, neutral, and weakly alkaline

aqueous solutions (pH 1–13) to ultraviolet radiation. The reaction takes place at room temperature, i.e. under conditions under which desulphonation does not take place in the dark. The yields of desulphonation products (III), (V), (VII), 1-sulphonic acids of naphthalene (IVa) and of 4-naphthylamine (VI), and *o*-, *m*-, and *p*-anilinesulphonic acids (IIa–b) increase in this sequence (from 2% to 50%) [64,65].



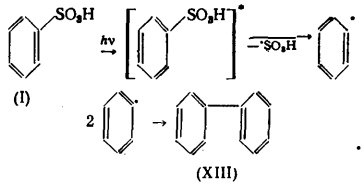
Both acidic and basic properties of aromatic molecules are strengthened by photoexcitation [66]. Which are realised in amphoteric excited states will depend on many factors. The electron affinity of the aromatic system increases in certain electrophilic photosubstitutions, e.g. isotopic hydrogen exchange, acylation, etc. [66,67]. By analogy with these reactions it has been postulated [65] that in acid media photodesulphonation involves hydrolytic detachment of the sulpho-group as a consequence of the enhanced basic properties of the aromatic ring. From the general consideration that, in comparison with the ground state, the basicity of triplet states varies less than that of singlet states, it seems more probable that a singlet excited state of the sulphonic acid takes part in the process [68]. Since the change in the acid–base properties of the π-electron system is very considerable (ΔpK_a may reach 25–30 [66]), it is quite likely that this increase in basic properties covers the decrease in hydrogen-ion concentration on passing from acid to neutral and weakly alkaline media in the pH range investigated [64] and, to all appearances, a mechanism of hydrolytic desulphonation



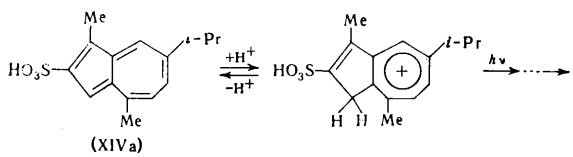
may operate not only in acid but also in neutral and even weakly alkaline media.

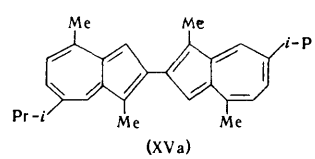
In alkaline aqueous solutions, on the other hand, reductive photodesulphonation with the hydroxide ion as electron donor is also possible [64]. It is interesting that the *meta*-isomer (IIb) is most readily desulphonated when alkaline solutions of the *o*-, *m*-, and *p*-sulphonic acids of aniline (IIa–c) undergo photolysis [64], as well as in the electrolytic detachment of the sulpho-group [69]. The reductive properties of the hydroxide ion in photochemical reactions with aromatic compounds have been discussed [70,71].

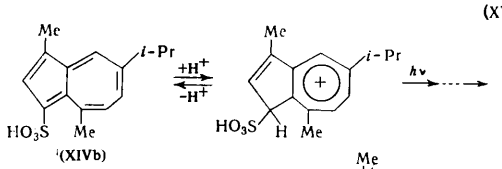
Elimination of the sulpho-group from benzenesulphonic acid (I) has a different mechanism [72]. Photolysis of its aqueous solutions produces biphenyl (XIII); the yield of the latter (up to 6%) is independent of pH (over the range 1–13 investigated) under identical conditions of irradiation, and the quantum efficiency of the process is below 10^{-4}. Desulphonation probably involves homolytic cleavage of the Ar–S bond in the photoexcited molecule of (I):

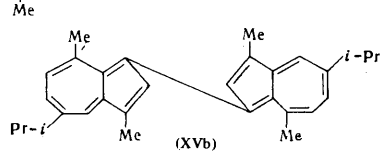


A similar result— the coupling of residues from the starting materials—is produced by photolysis of the protonated forms of guaiazulene-2- and -3-sulphonic acids (XIVa) and (XIVb). In 96% sulphuric acid they give respectively 2,2′- and 3,3′-biguaiazulyls (XVa) and (XVb) in up to 40% yield [73]:

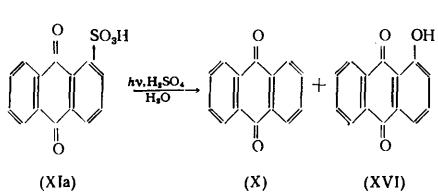








Only traces of anthraquinone (X) are formed by the irradiation of weakly acid (pH 1–7) aqueous anthraquinone-1-sulphonic acid (XIa). The efficiency of desulphonation is increased (up to 20%) by photolysis in 11 *N* sulphuric acid, and a small quantity (~3%) of 1-hydroxyanthraquinone (XVI) is obtained:



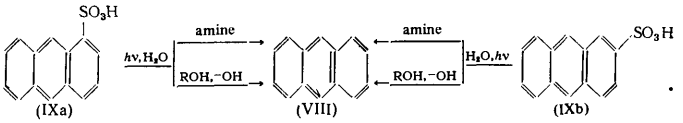
The sulpho-group of other anthraquinonesulphonic acids investigated—the 2-, 1,5-, and 1,8-acids (XII), (XIb), and (XIc)—remains unchanged under these conditions [74].

Considerable yields of anthraquinone (15–90%) have been obtained [64,65,75] by the irradiation of aqueous solutions of a sulphonate of (XIa) containing hydrazine, an aliphatic amine, or an alcohol with added alkali (the efficiency of photodesulphonation is lower with branched-chain alcohols [65]). Under identical conditions of photolysis the efficiences of complete desulphonation of anthraquinone-1,5- and -1,8-disulphonic acids (XIb) and (XIc) were substantially lower, not exceeding 10%; anthraquinone-2-sulphonic acid (XII) is not desulphonated.

Preliminary results indicate [65] that the rate of photodesulphonation is variable in the region of absorption by sulphonated anthraquinones: the maximum rate is obtained by photolysis in the far ultraviolet and decreases significantly with increase in wavelength of the exciting light.

Although elimination of the sulpho-group is effected in an alkaline medium, the initial compounds do not undergo hydroxylation (see beginning of this Section) [64], since alkoxide ions act as the main electron donor; furthermore, hydroxyl radicals, formed in considerably smaller quantity (than alkoxyl radicals), are removed by reaction with the alcohol.

Only traces of anthracene (VIII) are formed by the prolonged photolysis of aqueous solutions (in the presence of an amine) or alkaline aqueous–alcoholic solutions of anthracene-1- and -2-sulphonic acids (IXa) and (IXb) [75]:



Thus both the structure of the aromatic system and the position of the sulpho-group play important roles in this process.

When an anthraquinone-1-sulphonic acid undergoes photodesulphonation in alkaline aqueous–alcoholic and aqueous amine media, no component other than the acid is excited, and the formation of atomic hydrogen or a solvated electron as reductant is improbable. It has therefore been postulated [76] that electron transfer to the acid molecule, resulting from the enhancement of the electron-accepting properties of the latter on excitation, takes place in an excited complex of the sulphonic acid and the alkoxide ion or the amine [77]. Subsequent breakdown of the excited complex was assumed to yield the sulphite ion and an anthraquinone radical; detachment by the latter of a hydrogen atom from the alcohol or the amine yields anthraquinone.

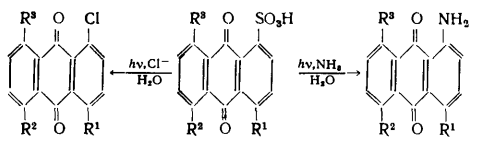
The photolysis of sulphonated anthraquinones (AS) in the above reducing media results in the corresponding products of their one- and two-electron reduction (the latter arise in secondary dark processes)—radical-ions ($AS^{\cdot -}$) and mono- and di-anions of anthraquinolsulphonic acids (ASH^-, AS^{2-})—which might have been intermediates in photodesulphonation, since in certain cases compounds of similar structure are able to eliminate electron-accepting substituents without excitation [78,79]. However, investigation of the effect of oxygen on photodesulphonation, together with the kinetics of the accumulation and destruction of the radical-anions and the formation of anthraquinone (A), has shown that the photodesulphonation of 1-sulphonated anthraquinones is actually a two-stage process with absorption of a light quantum at each stage. Absorption of the first quantum causes photoreduction of the substrate to the corresponding radical-anions with the appearance of products of their secondary dark reactions; absorption of the second quantum by one or all of the reduced forms yields anthraquinone as a result of the photochemical process and subsequent chemical reactions [80]:

$$AS \xrightarrow{h\nu} AS^*$$

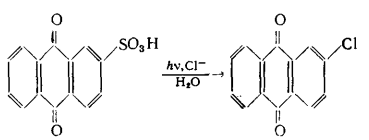
$$AS^* \xrightarrow{H_2O,ROH,\ NaOH} AS^{\cdot -} \longrightarrow ASH^- \ (AS^{=})$$

$$[AS^{\cdot -} \text{ and/or } ASH^-, AS^{=}] \xrightarrow{h\nu} [AS^{\cdot -} \text{ and/or } ASH^-, AS^{=}]^* \xrightarrow[[O_2]]{H_2O,RCH_2OH,\ NaOH} A$$

Irradiation of anthraquinone-1-sulphonic acids (XIa–g, l, m) in aqueous solutions containing chloride ions or ammonia entails replacement of the sulpho-group by a chlorine atom [81] or an amino-group [64]. Chlorination goes in quantitative yield, but the yields from photoamination do not exceed 20%, and the rate of formation of the corresponding amino-derivative decreases as the duration of exposure is increased. Such slowing down is due to secondary nuclear hydroxylation and amination of the initial anthraquinonesulphonate (see Section IV for these reactions), as the resulting water-soluble hydroxy- and amino-anthraquinonesulphonic acids inhibit substitution of the sulpho-group by filtering out the photochemically active light [82]. Special experiments on the effect of additions of such water-soluble acids on photoamination have shown that the assumed energy transfer from excited substrate molecules to by-product molecules [65] plays no appreciable part. Replacement of the sulpho-group in anthraquinone-2-sulphonic acid (XII) by a chlorine atom has a low yield (2%), but the sulpho-group in anthracenesulphonic acids (IXa) and (IXb) is replaced neither by chlorine nor by an amino-group.



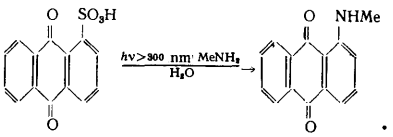
(XVIIa–g, l, m) (XIa–g, l, m) (XVIIIa–g, l, m)



(XII) (XIX)

a: $R^1=R^2=R^3=H$; (b) $R^1=R^3=H$, $R^2=SO_3H$; (c) $R^1=R^3=H$, $R^3=SO_3H$; (d) $R^1=SO_3H$, $R^2=R^3=H$; (e) $R^1=Cl$, $R^2=R^3=H$; (f) $R^1=R^3=H$, $R^2=Cl$; (g) $R^1=R^2=H$, $R^3=Cl$; (h) $R^1=NH_2$, $R^2=R^3=H$; (j) $R^1=R^3=H$, $R^2=NH_2$; (k) $R^1=R^2=H$, $R^3=NH_2$; (l) $R^1=R^3=H$, $R^2=NO_2$; (m) $R^1=R^2=H$, $R^3=NO_2$.

A 1-sulpho-group in anthraquinone does not undergo substitution by an alkylamino- or an arylamino-group: photodesulphonation occurs in the presence of aliphatic amines, as already mentioned, and no photoreaction takes place in the presence of aromatic amines. Methylamine is the only aliphatic amine in whose aqueous solutions both photodesulphonation and photosubstitution of the 1-sulphogroup in (XIa) takes place [65], the former process predominating on exposure to the complete spectrum from a mercury lamp. The second process predominates on exposure to light of wavelength exceeding 300 nm (the yield of 1-methylaminoanthraquinone (XX) is ~1%):



(XIa) (XX)

Photosubstitution of the 1-sulpho-group in (XIa) by a chlorine atom or an amino-group is not prevented by the presence of electron-accepting substituents (sulpho, chloro, nitro) at positions 4, 5, and 8 in the anthraquinone ring system, but the nature of the substituent and its position determine the rate of the process. Photosubstitution does

not take place when an electron-donating group (e.g. amino) is present at any of these three positions [74].

Light throughout the range of absorption is photochemically active in photosubstitution of the sulpho-group in anthraquinonesulphonates [82]. Photoamination and photochlorination of (XIa) have similar quantum efficiencies, which are independent of the wavelength of the exciting light over the range 250–435 nm. They vary between 10^{-4} and 10^{-3} depending on the reactant concentration: the quantum efficiency increases with the ammonia or chloride-ion concentration up to around molar, and then falls with further increase in concentration, probably owing to the concentration quenching of reactive excited states. In both cases photosubstitution is a one-photon process, as is confirmed by the linear dependence of its rate on the intensity of the light flux. The activation energy of photosubstitution (2.2–2.3 kcal mole^{-1} [83]) is typical of diffusion-controlled reactions [84]. Both photosubstitutions obey the simple Stern–Volmer equation on the addition of quenching agents (sodium iodide), with superposition of the straight lines corresponding to the observed relations when conducted simultaneously as competing reactions. Together with the equality of activation energy and closely similar quantum efficiencies of photoamination and photochlorination, this suggests that the processes have the same mechanism and involve a single excited state, probably $n\pi^*$.[65,82]

On the postulate that only the $n\pi^*$ level of the substrate is reactive, the inactivity of anthraquinonesulphonic acids with strong electron-donating substituents in reactions involving the sulpho-group can be explained by inversion of the energy levels on introduction of a donor substituent into the anthraquinonesulphonate ring system, as a consequence of which the unreactive $\pi\pi^*$ state becomes the lowest excited state of the molecule.

Two hypotheses have been put forward on the nature of the interaction between an excited substrate molecule and the reactant. According to the first the photochemical step in photochlorination is formation of a chlorine radical by electron transfer from a chloride ion to an excited molecule of anthraquinonesulphonic acid [65] (the possibility of such a process has been proved—Section IV); subsequent replacement of the sulpho-group by chlorine occurs as a dark radical process [85] with formation of the corresponding chloroanthraquinone (ACl):

$$AS \xrightarrow{h\nu} AS^* ,$$

$$AS^* + Cl^- \rightarrow AS^{\cdot-} + Cl^{\cdot} ,$$

$$Cl^{\cdot} + AS \rightarrow ACl .$$

Another possible radical substitution path does not involve formation of a chlorine radical as a kinetically independent species. On formation of the complex of the chloride ion and an excited molecule of anthraquinonesulphonic acid, almost simultaneously with the act of electron transfer, the resulting chlorine radical is trapped in a solvent cage by a sulphonate molecule in the ground (or an excited) state:

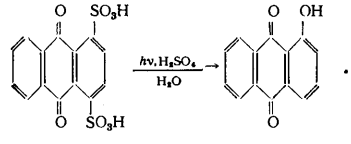
$$AS + \overset{\overset{AS}{+}}{Cl} \xrightarrow{h\nu} ([AS \ldots Cl^-]^*, AS, AS^*) \longrightarrow ACl .$$

The second possible mechanism of photochlorination is nucleophilic substitution (in the classical sense of intermediate formation of a σ-complex) of the sulpho-group by a chloride ion in a photoexcited molecule of anthraquinonesulphonic acid [65]:

$$Cl^- + AS^* \rightarrow ACl .$$

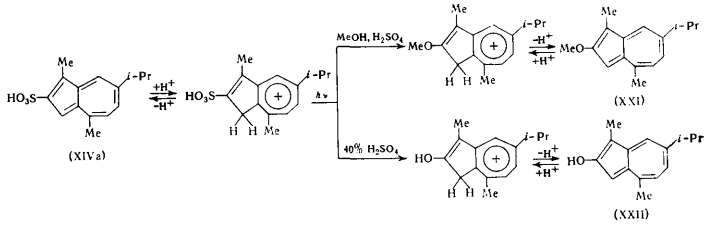
Analogous mechanisms may be suggested for the formation of aminoanthraquinones from anthraquinonesulphonic acids.

A sulpho-group in the anthraquinone ring system can sometimes be replaced photochemically by hydroxyl, as already noted. Whereas anthraquinone-1-sulphonic acid (XIa) yields only traces of 1-hydroxyanthraquinone (XVI), the latter is the main product (in 60% yield) of the photolysis of anthraquinone-1,4-disulphonic acid (XId) in 11 *N* sulphuric acid [74]:

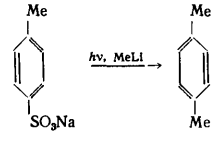


(XId) (XVI)

Considerably less study has been made of photosubstitution of the sulpho-group in systems other than anthraquinone. However, data have been published indicating that this group can be replaced also by hydroxyl, methoxyl, methyl, and the nitro-group. The first of these reactions occurs when guaiazulene-2-sulphonic acid (XIVa) is illuminated in 40% sulphuric acid, and the second on its photolysis in a mixture of methanol and sulphuric acid (3 : 2), with 40–50% yields [73]:

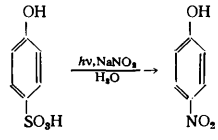


The action of light on sodium toluene-*p*-sulphonate (XXIII) in the presence of methyl-lithium gives a yield of *p*-xylene (XXIV) reaching 4.5% as a result of nucleophilic substitution:



(XXIII) (XXIV)

hardly any reaction occurs in the dark (yield <1%) [86]. Photosubstitution of the sulpho-group in phenol-*p*-sulphonic acid (XXV) gives a not very high yield (~4%) [87]:



(XXV) (XXVI)

Compounds $ArSO_2X$ other than sulphonic acids are able to undergo nucleophilic photosubstitution. This has been shown for derivatives of sulphanilic acid and related compounds, such as *p*-aminobenzenesulphonamide (XXVIIa), *p*-trifluoromethylsulphonylaniline (XXVIIb), and *p*-methylsulphonylaniline (XXVIIc) subjected to photolysis in aqueous

solutions containing cyanide, nitrite, and thiocyanate ions [87]:

$$p\text{-}NH_2C_6H_4SO_2X \xrightarrow[H_2O]{h\nu,Nu^-} p\text{-}NH_2C_6H_4Nu + PhNH_2$$
(XXVIIa-c) (XXVIII) (III)

X=NH_2 (a), CF_3 (b), CH_3 (c); Nu=CN, NO_2, SCN .

The action of the cyanide ion gives 60–65% yields of photosubstituted products from compounds (XXVIIa) and (XXVIIc), but only 12–15% from (XXVIIb) and benzenesulphonamide. Compounds (XXVIIa) and (XXVIIc) react less vigorously with the nitrite ion: yields of the corresponding nitro-compounds are 2–4%. A still lower yield is obtained from (XXVIIa) with sodium thiocyanate. The photoreaction of (XXVIIc) with sodium methoxide in methanol forms only traces of *p*-anisidine (XXIX), the main product being aniline (III):

$$p\text{-}NH_2C_6H_4SO_2Me \xrightarrow{h\nu,MeOH,MeONa} p\text{-}NH_2C_6H_4OMe + (III) .$$
(XXVIIc) (XXIX)

Attempts to replace the SO_2X group by a fluorine atom by exposing aqueous solutions of (XXVIIa) and (XXVIIc) containing fluoride ions were unsuccessful. The relative unreactivity of the fluoride ion in photosubstitutions was attributed [87] to its high redox potential.

In all cases of photolysis of the compounds (XXVIIa)–(XXVIIc) photoelimination of the SO_2X group, leading to formation of aniline, competes with photosubstitution. As with halogenobenzenes, the latter process itself is activated by electron-donor substituents in the aromatic ring. The relative immobility of the SO_2X group on reaction with the nitrite ion is due to the low energies of the singlet and triplet levels of the latter, so that it can act not only as a nucleophilic reagent but also as an acceptor of the energy of excitation of the substrate.

As with sulphonic acids (see e.g. the photolysis of benzelesulphonic acid in aqueous solution, above) substitution of the SO_2X group (X ≠ OH) may begin with homolytic cleavage of the Ar–S bond. Thus *SS*-dimethyl-*N*-arenesulphonylsulphoximines (XXX) on exposure in aromatic hydrocarbons to light of wavelength 254 nm generate radicals which arylate the solvent [88]:

$$ArSO_2N{=}\overset{\overset{O}{\uparrow}}{S}Me_2 \xrightarrow{h\nu,C_6H_6} [Ar^\cdot] \xrightarrow{C_6H_6} ArPh .$$
(XXX) (XXXI)

Diaryl sulphones (XXXII) behave similarly on photolysis in benzene. The processes involved can be represented by the scheme [89]

$$ArSO_2Ar \xrightarrow[C_6H_6]{h\nu\,(254\ nm)} Ar^\cdot + ArSO_2^\cdot ,$$
(XXXII)

$$Ar^\cdot + C_6H_6 \longrightarrow Ar\text{-}C_6H_6^\cdot ,$$

$$Ar\text{-}C_6H_6^\cdot + ArSO_2^\cdot \text{ or } Ar^\cdot \longrightarrow ArC_6H_5 + ArSO_2H \text{ or } ArH ,$$

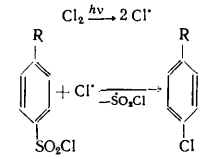
$$ArSO_2^\cdot + C_6H_6 \longrightarrow ArSO_2\text{-}C_6H_6^\cdot ,$$

$$ArSO_2\text{-}C_6H_6^\cdot + ArSO_2^\cdot \text{ or } Ar^\cdot \longrightarrow ArSO_2C_6H_5 + ArSO_2H \text{ or } ArH .$$

The suggested mechanism is supported by data on the distribution of carbon-14 in the products of photolysis of a labelled model compound—diphenyl sulphone [90].

Another type of radical photosubstitution of the SO_2X group is also possible, when the reagent—not the $ArSO_2X$ molecule—is excited, and forms radical species on photodissociation. This occurs when benzenesulphonyl and *p*-bromobenzenesulphonyl chlorides (XXXIIIa) and (XXXIIIb) in carbon tetrachloride containing excess of chlorine are exposed to the light from a tungsten lamp. The chlorosulphonyl group is replaced by a chlorine atom, and in (XXXIIIb) the bromine atom is also exchanged, the yields being 97% [91]:

$$Cl_2 \xrightarrow{h\nu} 2\,Cl^\cdot$$



(XXXIII a, b) (XXXIV a, b) .

$$^\cdot SO_2Cl \rightarrow SO_2 + {}^\cdot Cl$$

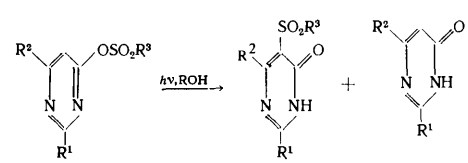
R=H (a), Br (b)

Phenyl and methyl benzenesulphonates do not undergo this reaction, but diphenyl sulphone (XXXV) gives a quantitative yield of chlorobenzene (XXXIVa) [91]:

$$Cl_2 \xrightarrow{h\nu} 2\,{}^\cdot Cl$$
$$PhSO_2Ph + {}^\cdot Cl \rightarrow PhCl + PhSO_2^\cdot$$
(XXXV) (XXXIVa)
$$PhSO_2^\cdot + Cl_2 \rightarrow PhSO_2Cl + {}^\cdot Cl$$
$$PhSO_2^\cdot \rightarrow Ph^\cdot + SO_2$$
$$Ph^\cdot + Cl_2 \rightarrow PhCl + {}^\cdot Cl$$
(XXXIVa) .

We have been discussing photochemical reactions of compounds $ArSO_2X$ in which the sulphur-containing group is either eliminated or replaced by another group, i.e. processes involving rupture of the Ar–S bond. These reactions have been most thoroughly investigated in the compounds considered. Nevertheless, we cannot disregard the considerably less studied but quite numerous photoprocesses of aromatic sulphonyl compounds $ArSO_2X$ in which the S–X bond is broken by the action of light, which leads to rearrangement or to stabilisation of the residue of the substrate molecule by interaction with the solvent (reagent).

Certain arenesulphonic esters [93,94] are arenesulphonamides [95] tend to undergo light-induced rearrangements like the Fries photorearrangement [92]. Thus exposure of 5-unsubstituted 2-dialkylaminopyrimid-4-yl arenesulphonates (XXXVI) in alcohols to the far ultraviolet (254 nm) converts them into 20–30% yields of the 5-arylsulphonyl-2-dialkylamino-4-hydroxypyrimidines (XXXVII) accompanied by small quantities of the 2-dialkylamino-4-hydroxypyrimidines (XXXVIII):

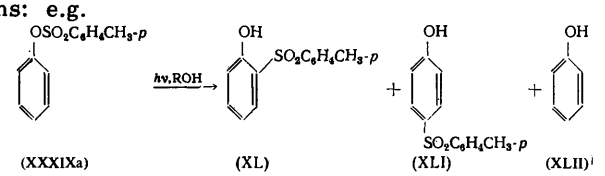


(XXXVI) (XXXVII) (XXXVIII)

R^1=NMe_2, morpholino, pyrrolidino, piperidino;
R^2 = H, Me; R^3=C_6H_5, *p*-MeC_6H_4, *p*-BrC_6H_4, *p*-ClC_6H_4, 2,5-$Me_2C_6H_3$

Phenyl and 1-naphthyl toluene-*p*-sulphonates (XXXIXa) and

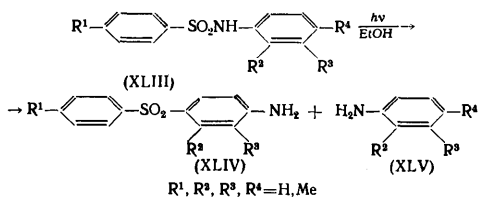
(XXXIXb) undergo photorearrangement under similar conditions: e.g.



(XXXIXa) (XL) (XLI) (XLII)

The reaction is assumed[96] to result from $\pi\pi^*$-excitation of the phenolic portion of the ester molecule.

Arenesulphonamides (XLIII) are converted photochemically into *p*-arylsulphonylarylamines (XLIV) in 6–25% yield and primary aromatic amines (XLV) in 25–70% yield:

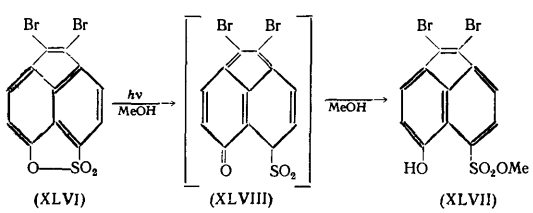


(XLIII) (XLIV) (XLV)

R^1, R^2, R^3, R^4=H, Me

The relatively low yields of rearranged products are explained[95] by filtration of the light by the resulting sulphones (XLIV) and by unidentified coloured by-products of the reaction.

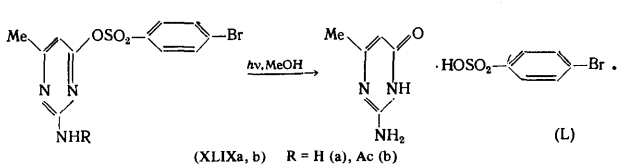
The acenaphthene sultone (XLVI), on illumination in methanol through a Pyrex filter, is converted into the corresponding methyl sulphonate (XLVII)[97] with intermediate formation of the sulphene (XLVIII):



(XLVI) (XLVIII) (XLVII)

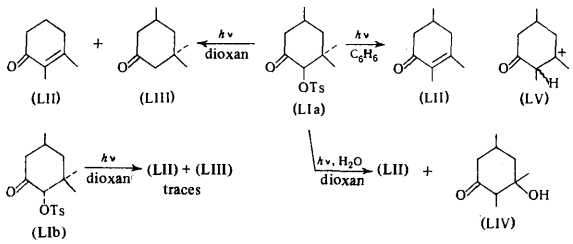
A singlet excited state of (XLVI) is assumed to take part in the photoreaction, but no strict proof of this is given.

In several cases light detaches the ester group from arenesulphonates, e.g. from 2-aminopyrimid-4-yl and 2-acetamidopyrimid-4-yl *p*-bromobenzenesulphonates (XLIXa) and (XLIXb) in ethanol. Instead of rearrangement (see above) a salt (L) of 2-amino-4-hydroxypyrimidine and the sulphonic acid is formed[93]:



(XLIXa, b) R = H (a), Ac (b) (L)

Photoelimination occurs stereospecifically in the case of oxocycloalkyl toluene-*p*-sulphonates[98]. Thus exposure of the *cis*-isomer (LIa) in benzene forms an unsaturated ketone (LII), in dioxan a mixture (4 : 1) of (LII) and (LIII), and in aqueous dioxan the ketone (LII) and the β-hydroxy-ketone (LIV); the *trans*-isomer (LIb) in more stable, forming small quantities of the ketones (LII) and (LIII) (1 : 1) only on prolonged photolysis:



(LII) (LIII) (LIa) (LII) (LV)

(LIb) (LII) + (LIII) traces (LII) + (LIV)

Photoreaction evidently requires a sterically accessible conformation of the carbonyl group and the $C_{(\alpha)}$–O bond, which is present in the ester (LIa) but not in its isomer (LIb). The $n\pi^*$ state of these ketones is regarded as reactive. Formation of the αβ-unsaturated ketone (LII) is explained by production of the cation (LV) by heterolytic cleavage of the C–O bond followed by migration of a methyl group and deprotonation of the cation[98].

In contrast to the long known de-O-tosylation of toluene-*p*-sulphonates of sugars by catalytic reduction, it has recently been suggested that this should be effected photochemically in methanolic sodium methoxide (in an inert gas)[99]. The corresponding sugars are formed in yields of 90% or more and, what is especially important, the photoreaction is not complicated by secondary processes, as occurs in the dark reaction.

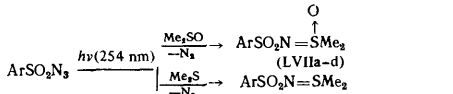
Photochemical cleavage of the sulphur–nitrogen bond (–SO_2NH–) in sulphonylated amino-acids and peptides might also have found practical application[100]. Unfortunately, however, the yields are not yet high enough for this photoreaction to be a serious competitor to the deblocking of tosylated amino-acids achieved in dark chemistry. This is due to the secondary processes of photodecarboxylation and photodeamination, and also to the photodegradation of certain unstable amino-acids (e.g. tryptophan).

We conclude this Section by considering photoreactions of aromatic sulphonyl compounds that do not affect the Ar–S and S–X bonds but involve cleavage of bonds in the X fragment of the molecule. Considerable interest has been taken in reactions of sulphonyl azides, which resemble aryl azides in photochemical behaviour, also being capable of breaking down with evolution of molecular nitrogen and formation of nitrenes—isoelectronic analogues of carbenes—on exposure to light. Like the latter, nitrenes are able to exist in singlet and triplet states $ArSO_2\ddot{N}$ and $ArSO_2\ddot{N}\cdot$. Electron spin resonance investigations have shown that the photolysis of benzenesulphonyl and toluene-*p*-sulphonyl azides (LVIa) and (LVIb) in matrices[101–103] at 77 °C yields the corresponding nitrenes in a triplet ground or excited state (the latter readily attainable by thermal activation).

The photochemical reactions of arenesulphonyl azides are usually regarded as those in which the photolytically generated nitrene undergoes rearrangement or else interacts with the solvent or the reagent. However, a critical attitude has recently been adopted towards this approach, on the assumption that in certain processes elimination of nitrogen is not the primary step (see below). The photolysis of sulphonyl azides in aprotic solvents (benzene, cyclohexane, thiophen, pyridine, etc.) usually yields insoluble resinous or polymeric products; intermediate formation of nitrenes is almost impossible to demonstrate[104,105].

Exposure of arenesulphonyl azides (LVIa–d) in dimethyl

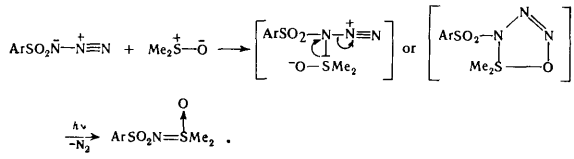
sulphoxide and in dimethyl sulphide produces *N*-sulphonylsulphoximines (LVIIa–d) (15–50%) and *N*-sulphonylsulphidimines (LVIIIa–d) (48–55%) respectively [104]:



(LVIa–d) (LVIIa–d) (LVIIIa–d)

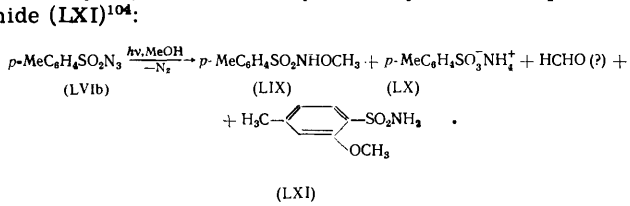
Ar=C_6H_5 (a), *p*-MeC_6H_4 (b), *p*-$NO_2C_6H_4$ (c), *p*-$MeOC_6H_4$ (d).

Whereas a mechanism of intermediate formation of nitrenes is alone assumed for the reaction with dimethyl sulphide, dimethyl sulphoxide also offers the possibility of complex formation between sulphonyl azides and the solvent (DMSO) acting as an electrophile, with expulsion of a nitrogen molecule on excitation of the complex:



The readily occurring photoreactions of sulphonyl azides in alcohols yield various compounds, which can be regarded formally as products of the insertion of nitrenes in the alcohol molecules, reduction of the nitrenes by detachment of a hydrogen atom, and the Curtius rearrangement [104–106]. It is especially difficult to determine in these photoreactions whether or not nitrenes are formed as intermediates.

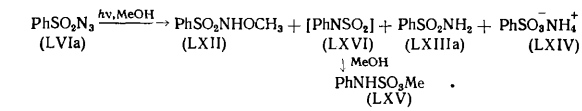
The photolysis of toluene-*p*-sulphonyl azide (LVIb) in methanol gives a 44% yield of O-methyl-*N*-toluene-*p*-sulphonylhydroxylamine (LIX) and small quantities of ammonium toluene-*p*-sulphonate (LX), a volatile substance (probably formaldehyde), and 2-methoxy-4-methylbenzenesulphonamide (LXI)[104]:



(LVIb) (LIX) (LX) (LXI)

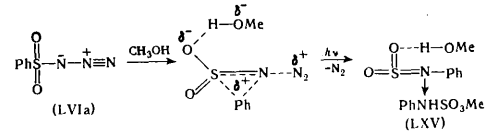
This process has an induction period: evolution of nitrogen begins after fairly long illumination of the reaction solution. If the solution is kept in the dark, however, reaction begins from the moment of exposure.

A more rigorous investigation of this reaction on benzenesulphonyl azide (LVIa) showed [105,107] that methyl *N*-phenylsulphamate (LXV) is formed together with the compounds (LXII)–(LXIV) (in yields respectively of 15, 4.5, and 8%):



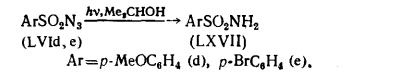
(LVIa) (LXII) (LXVI) (LXIIIa) (LXIV) (LXV)

Compound (LXV) can be assumed to result from rearrangement of the corresponding nitrene into *N*-sulphurylaniline (LXVI) followed by reaction with methanol. An alternative mechanism suggested involves protonation of the initial sulphonyl azide (formation of a hydrogen bond) and the photoinduced concerted rearrangement of such reactive complex with loss of a nitrogen molecule:



(LVIa) (LXV)

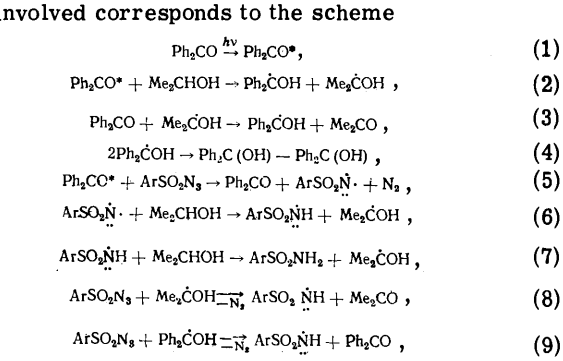
The photolysis of arenesulphonyl azides (LVId) and (LVIe) in propan-2-ol (excited by 254 or 365 nm in the presence of a sensitiser—benzophenone), in contrast to the above processes, gives only the corresponding arenesulphonamides (LXVII) in 85–95% yield [106]:



(LVId, e) (LXVII)

Ar=*p*-$MeOC_6H_4$ (d), *p*-BrC_6H_4 (e).

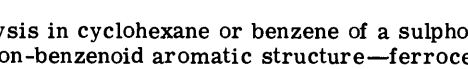
In this case detachment of a hydrogen atom predominates substantially over rearrangement, perhaps becuase of the greater mobility of the hydrogen atom attached to the carbinol carbon of the secondary alcohol. The radical-chain process involved corresponds to the scheme



(1)–(9)

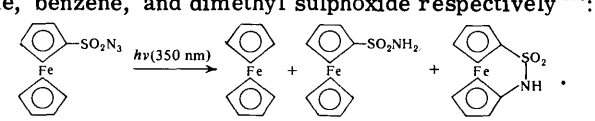
with the possible exclusion of Eqn. (2) or Eqns. (5) and (6).

Free-radical decomposition takes place also in the photolysis of benzenesulphonyl azide (LVIa) in benzenethiol, when benzenesulphonamide (LXIIIa) and diphenyl disulphide (LXVIII) are obtained [108]:



(LVIa) (LXIIIa) (LXVIII)

Photolysis in cyclohexane or benzene of a sulphonyl azide of non-benzenoid aromatic structure—ferrocenesulphonyl azide (LXIX)—results in ferrocene (LXX), ferrocenesulphonamide (LXXI), and a cyclisation product (LXXII), the last in yields of 13.3%, 67%, and 0 in cyclohexane, benzene, and dimethyl sulphoxide respectively [109]:

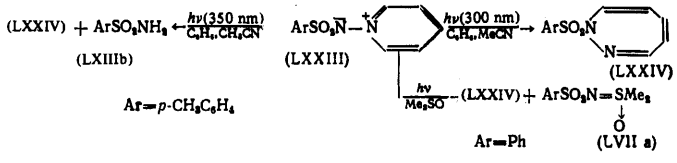


(LXIX) (LXX) (LXXI) (LXXII)

Formation of the free nitrene is postulated [109] on photolysis; cyclisation is probably a singlet reaction, since the yield of (LXXII) is not diminished by the presence of oxygen or quinol.

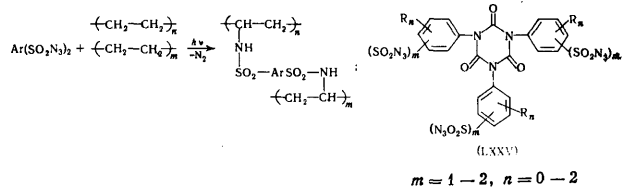
Formation of nitrenes was expected also when pyridinium ylids (LXXIII) were eliminated [110]. However, photolysis of the ylid (LXXIII: Ar = C_6H_5) in a mixture of benzene and acetonitrile by filtered radiation of wavelength 300 nm gave the compound (LXXIV) in 76% yield; compounds

which might have been formed from nitrenes (benzenesulphonamide, *N*-phenylsulphonylazepine) were not detected; in dimethyl sulphoxide the yield of (LXXIV) falls to 12%, and the sulphoximine (LVIIa) is formed in 40% yield:



Photolysis of the ylid (LXXIII: Ar = *p*-$CH_3C_6H_4$) by wavelength 350 nm resulted in low yields of the diazepine (LXXIV: Ar = *p*-$CH_3C_6H_4$) and toluene-*p*-sulphonamide (LXIIIb) (2:1). Thus under certain conditions of photolysis the stable pyridinium ylids of type (LXXIII) are able to produce sulphonylnitrenes.

We note in conclusion the practical value of sulphonyl azides as cross-linking agents for several polymeric materials. This exploits the property exhibited by sulphonylnitrenes formed on exposure of entering into carbon-hydrogen and oxygen–hydrogen bonds: e.g.



Several di- and poly-sulphonyl azides, in particular tris-azidosulphonylphenylhexahydrotrioxo-1,2,5-triazines (LXXV), find application in photographic resins [111-113].

IV. PHOTOREACTIONS NOT INVOLVING THE SO_2X SUBSTITUENT

The chief reactions of this type involve photoreduction of the carbonyl group in compounds containing an SO_2X substituent. The most thoroughly studied among them are the photochemical dehydrogenation of organic compounds by anthraquinonesulphonic acids and the oxidation by the latter of inorganic anions. An impetus to such interest in the photodehydrogenating power of anthraquinone and its sulphonic acids was provided by research on the photodegradation of natural and artificial fibres sensitised by anthraquinone vat dyes [114-126].

The mechanism of the photodehydrogenation of alcohols, which has been studied in detail, is at present regarded as

$$AS \xrightarrow{h\nu} AS^*$$

$$AS^* + R^1R^2CHOH \rightarrow ASH^{\cdot} + R^1R^2\dot{C}OH$$

$$R^1R^2\dot{C}OH + AS \rightarrow R^1R^2CO + ASH^{\cdot} \qquad ASH^{\cdot} + O_2 \rightarrow AS + HO_2^{\cdot}$$

$$2\,ASH^{\cdot} \rightarrow AS + ASH_2 \qquad R^1R^2\dot{C}OH + O_2 \rightarrow R^1R^2CO + HO_2^{\cdot}$$

$$ASH_2 + O_2 \rightarrow H_2O_2 + AS$$

$$2\,HO_2^{\cdot} \rightarrow H_2O_2 + O_2\,.$$

absent oxygen present

The hydrogen atom is abstracted from the carbinol carbon atom by an excited anthraquinonesulphonate molecule (AS*) with formation of the semiquinone (ASH$^{\cdot}$) and the radical $^{\cdot}CR^1R^2OH$. A second hydrogen atom is detached, from the hydroxy-group of the radical, this time by an unexcited substrate molecule (AS), with formation of a second semiquinone molecule (ASH$^{\cdot}$) (per light quantum absorbed) and the ketone or aldehyde respectively. The product of complete reduction of the quinone (AS)—the anthraquinolsulphonic acid (ASH_2)—is obtained by disproportionation of the semiquinones (ASH$^{\cdot}$). If oxygen is present in the reaction mixture, it oxidises the semiquinone (ASH$^{\cdot}$) and the anthraquinol (ASH_2) to the initial quinone (AS), so that the final reaction products are in effect only the ketone or aldehyde. For this reason the process has been termed a "photosensitised oxidation of alcohols". It can quite rightly be termed also "photocatalytic" or—more correctly, in the Reviewers' opinion— a "chemically sensitised process", since the role of the quinone is not to transfer energy to the carbinol radical but, as an excited molecule, to interact chemically with the alcohol.

Table 1. Ratio of rate constant of detachment of a hydrogen atom to rate constant of all other processes effecting deactivation of excited states of anthraquinone-2-sulphonate k_1/k_0 during photodehydrogenation [116,117].

Compound to be dehydrogenated	k_1/k_0	Compound to be dehydrogenated	k_1/k_0
Methanol	0.054	Ethane-1,2-diol	0.258
Ethanol	0.445	Propane-1,2-diol	0.56
Propan-1-ol	0.682	Propane-1,2,3-triol	0.374
Propan-2-ol	0.921	Cyclohexanol	2.31
Butan-1-ol	0.952	Diethyl ether	2.14
Butan-2-ol	1.270	Di-isopropyl ether	1.80
2-Methylpropan-2-ol	0.01	Acetone	0

Besides alcohols (monohydric and polyhydric), ethers and ketones can also be photodehydrogenated by sulphonated anthraquinones. The comparative reactivities of all these compounds towards photodehydrogenation has been studied [116,117] as the ratio of the photodehydrogenation rate constant to the total rate constant of the other processes by which the excited state of the substrate is deactivated (Table 1). The reactivity of alcohols towards photodehydrogenation by anthraquinone-2-sulphonic acid (XII) increases with the length and the degree of branching of the hydrocarbon chain, which is attributed to increasing mobility of the hydrogen atom attached to the carbinol carbon atom resulting from increase of the positive inductive effect of the alkyl group in the alcohol molecule [116]. The absolute rate constants of detachment of the hydrogen atom from certain alcohols, measured by flash photolysis, are around $10^6\ M^{-1}\ s^{-1}$. [120,127]

The above reactivity sequence of alcohols towards photodehydrogenation by anthraquinone-2-sulphonic acid (XII) indicates that the primary photochemical step consists in detachment of a hydrogen atom, not in transfer of an electron. An energetic assessment of photodehydrogenation leads to the same conclusion, showing that energies of excitation of anthraquinonesulphonic acids are insufficient to abstract an electron from an alcohol molecule [127]. The above results apply to alcoholic or neutral aqueous–alcoholic solution. In alkaline aqueous–alcoholic media and in alcoholic solutions of the corresponding sodium alkoxide, however, electron transfer from the alkoxide ion to the excited sulphonic acid

$$AS^* + RO^- \rightarrow AS^{\cdot-} + RO^{\cdot}$$

predominates. The possibility of this process has been confirmed [128,129] by a detailed study of the photoreduction

of sulphonated anthraquinones by electronic and electron spin resonance (e.s.r.) spectroscopy.

In ethers a hydrogen atom is abstracted from a carbon atom forming the ether bond. Increase in the length and the degree of branching of the alkyl groups diminishes the reactivity of the ether owing to the shielding effect [117].

The simplest ketone (acetone) shows little tendency to undergo photo-oxidation by anthraquinonesulphonic acids, but the rate of the process is substantially larger in alkaline aqueous solutions. This can be attributed either to reaction of acetone as the enolic form [117] $CH_3.CH(OH):CH_2$ or to involvement of the hydroxide ion in the reaction (see below).

Alcohols (and other organic compounds) undergo considerably less photo-oxidation in the presence of 1-sulphonates than of 2-sulphonates of anthraquinone (Table 2), so that less study has been made of the behaviour of the 1-isomers in this process. Thus the introduction of a sulpho-group into the anthraquinone molecule, which might be expected to influence only the solubility in organic and aqueous media, leads to substantial differences in the photodehydrogenating power of the quinonoid group depending on the position of the sulpho-group.

Table 2. Quantum efficiencies of the formation of anthraquinole in the photodehydrogenation of propan-2-ol [122].

Sulphonated anthraquinone	Quantum efficiency	Solvent
Anthraquinone	0.81	benzene–propan-2-ol (4 : 1)
2-Sulphonated	1.06	propan-2-ol
2,6-Disulphonated	1.07	
2,7-Disulphonated	1.14	
1-Sulphonated	0.05	
1,5-Disulphonated	0.015	

For a long time the spectral sensitivity of the photoreduction of anthraquinone and its sulpho-derivatives remained an unsolved problem. Investigation of anthraquinone-1-sulphonic acids in alkaline aqueous–alcoholic solutions merely showed [128] that the quantum efficiency of photoreduction was the same throughout the range of absorption of the substrate, whence it may be concluded that conversion to a reactive state with higher energy levels takes place with equal probability.

The involvement of the triplet state of anthraquinone [122] and its sulphonated derivatives [127] in the photodehydrogenation of alcohols has been shown by triplet–triplet energy transfer. Not only the 2-sulphonates, which actively dehydrogenate alcohols, but also the less active 1-isomers take part in this process in an excited triplet state [126]. Of the two possible triplet states of anthraquinones only the $n\pi^*$ state possesses dehydrogenating power, when excitation is localised in a carbonyl group, and a hydrogen atom may be abstracted by a radical-like oxygen atom. The $T_{\pi\pi^*}$ state of the substrate, characterised by delocalisation of the excitation energy in the π-electron system of the molecule, is inactive in these processes. Such an approach makes it obvious that substances in which the lowest triple level is an $n\pi^*$ level are good acceptors of hydrogen [130,131]. With compounds which hardly dehydrogenate alcohols at all—hydroxy- and amino-anthraquinones (and also anthraquinonesulphonic acids containing these electron-donor groups)—the energy levels are inverted, and the unreactive $T_{\pi\pi^*}$ state becomes the lowest [55]. Certain authors attribute the low reactivity of anthraquinone-1-sulphonates (compared with the 2-isomers) in photodehydrogenation to the low probability of the interconversion $S \rightarrow T$: with the 2-sulpho-derivatives this probability is approximately unity [132].

Anthraquinonesulphonic acids can be reduced photochemically not only by organic compounds but also by inorganic anions, e.g. hydroxide ions [133–137]. The reaction entails in effect the transfer of an electron from the ion to an excited acid molecule with formation of a hydroxyl radical and a radical-anion ($AS^{\cdot -}$), the latter being fairly stable in alkaline media. These radical-anions have been recorded by e.s.r. [133] (for the structure of the spectra see Ref. 124) and by electronic [137] spectroscopy. Use of these methods to study the kinetics of formation of the radical-ions as a function of the hydroxide-ion concentration confirmed [133,137] that the hydroxide ion—not a water molecule, as postulated previously [135]—is actually the electron donor:

$$AS^* + {}^-OH \rightarrow AS^{\dot{-}} + {}^{\cdot}OH \ .$$

The radical-ions ($AS^{\cdot -}$) interact vigorously with oxygen

$$AS^{\dot{-}} + O_2 \rightarrow AS + O_2^{\dot{-}},$$

with a rate constant $k = \simeq 10^8\ M^{-1}\ s^{-1}$. Hence accumulation of these radical-ions is observed only in deaerated media [121].

Alkaline solutions contain hardly any semiquinone ($ASH^{\cdot}$)—the protonated form of the radical-anion ($AS^{\cdot -}$)—since the pK is small (e.g. 2.3–3.2 for the radical-anion obtained from anthraquinone-2,6-disulphonic acid [127,138]). In contrast to the semiquinone, whose disproportionation rate constant lies in the range 10^8–$10^9\ M^{-1}\ s^{-1}$, the ionised form ($AS^{\cdot -}$) disproportionates far more slowly ($k_{dispr} < 10^2\ M^{-1}\ s^{-1}$) [127]. In alkaline solutions, therefore, the equilibrium

$$2AS^{\dot{-}} \rightleftarrows AS^- + AS$$

is displaced to the left, which enables a nearly quantitative yield of the radical-anions to be obtained.

The formation of hydroxyl radicals in these reactions could not be detected by physical methods, because of their great reactivity and the frequent ambiguity of their identification by characteristic reactions [136]. Direct evidence of the photochemical generation of hydroxyl radicals in alkaline aqueous solutions of anthraquinonesulphonic acids was the detection of $CO_3^{\dot{-}}$ radical-anions in the reaction mixtures on illumination by flash photolysis in the presence of added carbonate ions. This radical-ion is formed by the interaction of a hydroxyl radical and a carbonate ion [134]:

$$HO^{\cdot} + CO_3^{2-} \rightarrow HO^- + CO_3^{\dot{-}} \ .$$

The Stern–Volmer relation gave the value $k_T\tau \simeq 2000$–$3000\ M^{-1}$ for the photoreaction of the hydroxyl ion with anthraquinone-2,6-disulphonic acid (quenched by iodide, thiocyanate, thiosulphate, and hexacyanoferrate(II) ions) [132]. From this it was found that the lifetime of the reactive state of the substrate lay within the limits $\tau = 10^{-7}$–10^{-5} s depending on the value of $k_T = 10^8$–$10^{10}\ M^{-1}\ s^{-1}$ used in the calculations. Such a lifetime is more typical of a T than of an S state, from which it was concluded that a triplet state of the anthraquinonesulphonates is active in the present process as in photodehydrogenation. Flash photolysis has since been used to record the triplet states of anthraquinone-2-sulphonates and determine their absorption spectra (λ_{max} = 480–500 nm). Their deactivation

obeys a first-order kinetic equation (k_{des} = 34 000 s^{-1} for anthraquinone-2,6-disulphonic acid at pH 6.5). Deactivation is accelerated considerably by the presence of an acceptor of triplet energy (e.g. anthracene-1-sulphonic acid) because of efficient energy transfer. A similar effect is produced by the introduction of electron donors (hydroxide and carbonate ions): the rate constants of their reaction with excited anthraquinone-2,6-disulphonic acid are respectively 7.1×10^6 and 1.8×10^6 M^{-1} s^{-1}. These results finally confirmed that a triplet state of anthraquinone-2-sulphonic acids was involved in electron transfer [127].

The quantum efficiencies of the photoreduction of various anthraquinone derivatives have been compared for the photoreaction with the carbonate ion [127]. Efficiencies of around unit are obtained with mono- and di-sulphonic acids containing a 2-sulpho-group; with anthraquinone-1-sulphonic acid and hydroxyanthraquinones the quantum efficiencies are respectively 0.32 and 0. Hence compounds whose lowest triplet level is an $n\pi^*$ level are active in processes involving the phototransfer of an electron, as in photodehydrogenation.

The fairly high quantum efficiencies of photoreduction of the anthraquinone-1-sulphonate (XIa) by the carbonate ion in aqueous solution [127] and the limiting quantum efficiency of its photoreduction in a methanolic solution of sodium methoxide (Φ_{lim} = 0.40 [129]) indicate that in these cases $\Phi_{ST} \geqslant 0.3$ for 1-sulphoanthraquinone. Thus the above hypothesis, that the low reactivity of anthraquinone-1-sulphonic acids towards photodehydrogenation is due solely to the extraordinarily low probability of their occupying a triplet level, must be regarded as questionable. However, data are still lacking that would enable us to find the true reason for the low photodehydrogenating activity of anthraquinone-1-sulphonic acids in comparison with the 2-isomers.

Excited anthraquinonesulphonic acids are photoreduced not only by hydroxide and carbonate ions but also by chloride, sulphate, and thiocyanate ions. They are not reduced by fluoride, chlorate, metabisulphite, and bromate ions. This sequence has enabled the redox potential of the $AS_{T,n\pi^*}/AS^{\cdot -}$ pair to be estimated: it lies between those of the pairs $Cl^{\cdot}/Cl^-$ and $F^{\cdot}/F^-$ (2.55 and 3.6 eV) [127].

Radical-anions of sulphonated anthraquinones are formed in low yields on flash photolysis in neutral aqueous solutions containing bromide or iodide ions. Two competing processes—electron transfer and physical quenching—are assumed to occur in the exciplex of the halide ion and the sulphoanthraquinone molecule in an excited triplet state:

$$AS \xrightarrow{h\nu} AS^* \xrightarrow{X^{-n}} [AS \ldots X^{-n}]^* ,$$
$$X^{-n} + AS \xleftarrow{k_r} [AS \ldots X^{-n}]^* \xrightarrow{k_p} \dot{X}^{-(n-1)} + AS^{\cdot -} ,$$

where $k_T \gg k_P$ for iodide and bromide ions, but $k_P \gg k_T$ for carbonate, sulphate, and other ions [127].

However, the above scheme probably does not fully represent the processes occurring in the reaction system. Thus a study of the photoreduction of sulphonated anthraquinones in alkaline aqueous and aqueous–alcoholic solutions revealed regularities that cannot be explained by this scheme. Whereas with iodide ions the slowing down of the reaction conforms closely with simple Stern–Volmer equation, with chloride and bromide ions such conformity is observed only at low concentrations, and increase in the chloride-ion concentration is accompanied by an increase in reaction velocity right up to the original rate in the absence of quenching anions. These facts were explained on the hypothesis [129] that chloride ions are able to form a fairly stable charge-transfer complex with the unexcited anthraquinonesulphonic acid. Absorption of light by the complex leads to the appearance of radical-anions of the sulphonated anthraquinone. Quenching, however, occurs by interaction of a chloride ion with an excited anthraquinonesulphonate molecule:

$$AS_{fr.} + Hal^- \rightleftarrows [AS \ldots Hal^-] ,$$
$$AS_{fr.} \xrightarrow{h\nu} AS^*_{fr.} ,$$
$$AS^*_{fr.} \rightarrow AS_{fr.}$$
$$AS^*_{fr.} + Hal^- \rightarrow AS^{\cdot -} + Hal^{\cdot} ,$$
$$AS^*_{fr.} + X^- \rightarrow AS^{\cdot -} + X^{\cdot} ,$$
$$[AS \ldots Hal^-] \xrightarrow{h\nu} [AS \ldots Hal^-]^* ,$$
$$[AS \ldots Hal^-]^* \rightarrow [AS \ldots Hal^-] ,$$
$$[AS \ldots Hal^-]^* \rightarrow AS^{\cdot -} + Hal^{\cdot}$$
$$X = OH, OAlk .$$

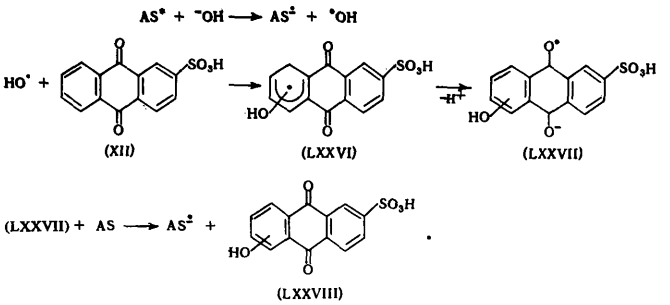
Calculation based on the kinetic scheme of photoreduction taking into account the above assumptions provides a qualitative explanation of the observed regularities [129].

The forward (photochemical) electron-transfer reaction is always accompanied by the reverse (dark) reaction of radical-anions of sulphonated anthraquinones with products of the one-electron oxidation of inorganic ions. In some cases the rate constants of such reverse reactions are extremely large: e.g. $k = 10^9$ M^{-1} s^{-1} for the reaction [127]

$$AS^{\cdot -} + CO_3^{\cdot -} \rightarrow AS + CO_3^{2-}$$

The disappearance of $CO_3^{\cdot -}$ radical-ions after the flash is due solely to the above process, since they hardly interact at all among themselves or with the initial anthraquinonesulphonic acids. Under steady illumination their yield in solutions containing carbonate ions will be extremely small (even if the reaction is conducted under conditions such that the radical-anions ($AS^{\cdot -}$) are stable, i.e. do not disproportionate).

Sometimes the reverse reaction is comparatively slow, and the photochemical electron transfers from anions to excited sulphoanthraquinone molecules are then accompanied by secondary dark processes. This occurs in the photo-oxidation of hydroxide ions, for example, when the resulting hydroxyl radicals interact mainly with the initial sulphonated anthraquinone [137]. The hydroxyl radical is weakly electrophilic [139], so that it enters only the unsulphonated ring [132]. This gives the adduct (LXXVI) or the radical-anion (LXXVII), which are oxidised by the original quinone (AS) to the corresponding hydroxyanthraquinonesulphonates (LXXVIII):



Hydroxylation actually takes place by a radical mechanism, which is confirmed by the diminished yield of hydroxy-derivatives (LXXVIII) on the introduction of acceptors of hydroxyl radicals into the reaction mass and by the fact that the same compounds are obtained by the action of Fenton's

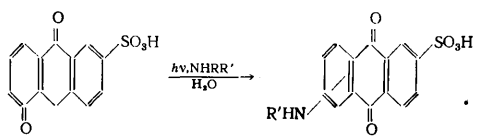
reagent on anthraquinonesulphonates as by the photochemical reaction[135,136].

The position entered by the hydroxy-group depends on the pH: at pH = 7–12 the main products of the photoreaction are 6- and 7-hydroxyanthraquinone-2-sulphonates, and these are the sole products at pH > 12; in neutral solutions hydroxylation occurs both at positions 6 and 7 and at positions 5 and 8.[136,139] Since hydroxyl radicals are able to undergo the dissociation

$$\cdot OH \rightleftarrows O^{\cdot -} + H^+,$$

with pK = 11.9,[140] the formation of different products is probably due to different hydroxylating agents according to the pH—the hydroxyl radical in neutral and weakly alkaline media and the oxide radical-anion $O^{\cdot -}$ in strongly alkaline media. All these assumptions require experimental confirmation, of course, but nevertheless the selective addition of such active radicals as these is a noteworthy fact.

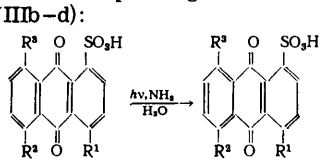
Not only anthraquinonesulphonates but also other compounds added to the solutions to be illuminated can be hydroxylated in this way. For example, phenol was obtained on the addition of benzene, which was also evidence of the formation of a hydroxyl radical in the photoreaction of the hydroxide ion with anthraquinonesulphonic acid[134]. When photohydroxylation takes place in the presence of an oxidant (molecular oxygen or potassium hexacyanoferrate(III)[133], the oxidation of hydroxide ions to hydroxyl radicals will be a cyclic process, so that the reaction may evidently be of value for the preparation of aromatic hydroxy-derivatives, especially as under certain conditions addition of a hydroxyl radical is a directed process. The photolysis of aqueous–ammoniacal solutions of anthraquinone-2-sulphonic acids probably resembles photohydroxylation. The 2-sulphonic acid (XII) forms amino-, diamino-, and amino-hydroxy-derivatives (principally 6(or 7)-aminoanthraquinone-2-sulphonates (LXXIX: R′ = H)): i.e. as in the preceding process, the unsulphonated ring undergoes substitution (amination). Photolysis of an aqueous solution of the sulphonated quinone (XII) in the presence of hydrazine (which breaks down into amino-radicals on exposure to ultraviolet radiation[141]) yields the same aminoanthraquinonesulphonic acids (LXXIX: R′ = H) as does photolysis in the presence of ammonia. The photochemical reaction of methylamine with anthraquinone-2-sulphonic acid (XII) gives the methylamino-derivatives (LXXXIX: R′ = CH_3)[142]:



(XII) (LXXIX)

R = H, NH_2; R′ = H, CH_3

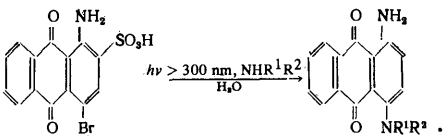
Not only hydrogen but also halogen can be replaced by an amino(or alkylamino)-group. Thus the photolysis of chloroanthraquinonesulphonic acids (XIe–g) in aqueous ammonia yields the corresponding aminoanthraquinonesulphonic acids (XVIIIb–d):



(XIe–g) (XVIIIb–d)

(XI : R^1, R^2, R^3 = H, Cl) (XVIII : R^1, R^2, R^3 = H, NH_2)

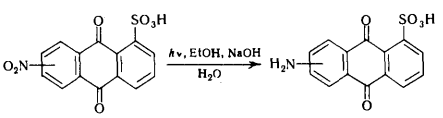
Although the yields are smaller (up to 6%), they are comparable with those of the simultaneously formed aminochloroanthraquinones (Section III)[74]. Bromine in the aminobromo-sulphonic acid (LXXX) is exchanged considerably better (probably because of the activating effect of the donor substituent). The process is conducted in aqueous solution; additions of aliphatic alcohols, dioxan, or acetonitrile increase significantly the yield of substitution products (LXXXI), which varies between 10% and 55%. Necessary conditions for the reaction are exposure to light of wavelength exceeding 300 nm and the presence of an oxidant (air or Fe^{3+} ions): only photodecomposition of the sulphonic acid (LXXX) takes place if these conditions are disrupted[143]:



(LXXX) (LXXXI)

R^1R^2NH=NH_3, $MeNH_2$ $EtNH_2$, $PrNH_2$, $BuNH_2$, piperidine

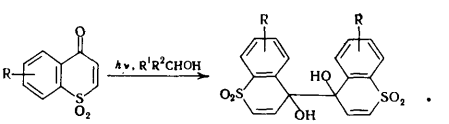
An amino-group can be formed also by photochemical reduction of a nitro-group. An attempt to effect the photodesulphonation of 5- and 8-nitroanthraquinone-1-sulphonic acids (XIl) and (XIm) in alkaline aqueous–ethanolic solution gave only a low yield (<5%) of the aminoanthraquinonesulphonic acids (XVIIIb) and (XVIIIc)[74]:



(XII, m) (XVIIIb, c)

Reduction of the nitro-group accompanied by loss of capacity for photodesulphonation is evidently due to the fact that the lowest reactive excited state of nitroanthraquinonesulphonic acids is the $T_{n\pi^*}$ level of the nitro-group, which is responsible for its photoreduction.

An example of photoreactions of non-quinonoid aromatic sulphonyl compounds that do not involve the SO_2X group is the photoreduction of 4-oxothiachroman 1,1-dioxides (LXXXII) in alcohols, when the yields of the pinacols (LXXXIII) reach 30%:



(LXXXII) (LXXXIII)

The electronic effect of the substituent is assumed to have little effect on the course of the process, with steric factors playing a considerably larger role[96].

The above account shows that the photochemistry of aromatic sulphonyl compounds is at present in an initial state of development. Future investigations of their photochemical reactions will undoubtedly provide answers to the problems examined in the present Review and to many others of importance not only for the present group of compounds but also for organic photochemistry in general.

Paramagnetic Reagents for the Investigation of the Structures of Organic Ligands

V.K.Voronov

This review illustrates the effectiveness of the methods for the investigation of the structures of organic ligands based on the characteristics of the NMR spectra of paramagnetic complexes.
The bibliography includes 109 references.

2. Lanthanide complexes

I. INTRODUCTION

Despite the fact that the first study on nuclear magnetic resonance (NMR) in paramagnetic systems was published in 1949,[1] the most fruitful investigations in this field were made in the last ten years concurrently with general progress in the technique of NMR spectroscopy. Studies carried out outside the Soviet Union by McConnell, Eaton, and others and in the Soviet Union by Molin and coworkers significantly extended our ideas concerning the mechanism of the electronic-nuclear (hyperfine) interaction in paramagnetic systems. Moreover, studies published in 1968 to 1972 showed that the specific features of the NMR of paramagnetic complexes can be used successfully to investigate the structures of organic ligands.

II. NUCLEAR MAGNETIC RESONANCE IN PARAMAGNETIC SYSTEMS

The use of NMR for the investigation of the electronic and geometrical structures of organic ligands is based on the characteristics of the NMR spectra of paramagnetic compounds[2,3]. If the resonating nucleus (for example a proton) forms part of a paramagnetic molecule, i.e. a molecule having a non-compensated electronic spin moment, it is subjected to an additional magnetic influence by the electron spin. The leads to a broadening and also to paramagnetic shifts (contact and pseudocontact) of the resonance lines in relation to the widths and positions of the lines in the NMR spectra of diamagnetic compounds. A contact shift is observed in those cases where the probability that the unpaired electron is located at the site of the resonating nucleus is non-zero. This shift is proportional to the proton–electron interaction constant and (when the spin–orbital interaction is slight) is defined by the expression[2]

$$\omega_k = -A \cdot \frac{\gamma_e}{\gamma_p} \cdot \frac{g\beta S(S+1)}{3kT}, \qquad (1)$$

where γ_e and γ_p are the gyromagnetic ratios for the electron and proton, g is the g-factor of the paramagnetic compound, S the spin of the complex, β the Bohr magneton, T the absolute temperature, and k the Boltzmann constant.

A, which can be both positive and negative, is determined by the magnetic moment of the unpaired electrons of the paramagnetic species and the orientation of the unpaired electron at the given proton. According to the Fermi formula,

$$A = \frac{4}{3}\pi g\beta g_n\beta_n\rho(N),$$

where g_n is the nuclear g-factor, β_n the nuclear magneton, $\rho(N)$ the unpaired electron spin density at the given nucleus defined by the expression

$$\rho(N) = \int \psi^* \sum_k 2S_{zk}\,\delta(N)\,\psi\,d\tau,$$

and ψ the wave function of the electrons in the molecule; the remaining symbols in the last expression have the usual significance[2,3].

The pseudocontact shift† is due to the fact, that when the g-factor of the paramagnetic compound is anisotropic, the dipole–dipole interaction between the magnetic moments of the unpaired electron and the nucleus does not average out to zero[2]. This shift is defined by the following expression in an implicit form:

$$\omega_p = \frac{\text{const}}{T} \cdot f(g)\, f(\varphi, r).$$

Here the multipliers $f(g)$ and $f(\varphi, r)$ are determined by the anisotropy of the g-factor and the geometry of the complex respectively. The explicit form of these functional relations and hence the magnitude and sign of ω_p depend on the type of symmetry of the paramagnetic complex. For a paramagnetic ion moving at random in solution, the electric field around which has a tetragonal symmetry, the pseudocontact shift is given by the expression[2]

$$\omega_p = \frac{\beta^2 S(S+1)(3\cos^2\varphi - 1)(g_\parallel - g_\perp)(g_\parallel + 2g_\perp)}{27kTr^3}, \qquad (2)$$

where φ is the angle between the symmetry axis and the radius-vector directed from the centre of the coordinating ion to the proton, r the radius-vector, and $g_\parallel$ and $g_\perp$ are the electronic g-factors in directions parallel and perpendicular to the symmetry axis.

For molecules containing different protons (i, j, ...), the pseudocontact shifts for different nuclei i and j are

† Studies on contact interaction in paramagnetic complexes with organic ligands based on NMR spectra have been described[2,4-30].

linked by the relation

$$\omega_i : \omega_j = \frac{3\cos^2\varphi_i - 1}{r_i^3} : \frac{3\cos^2\varphi_j - 1}{r_j^3} , \qquad (3)$$

which makes it possible to obviate the difficulties associated with the measurement of the g-tensor components.

The pseudocontact interaction described by Eqn.(2) was introduced by McConnell and Robertson for an anisotropic g-factor, i.e. for a paramagnetic ion with degenerate levels in the absence of an external magnetic field when the Zeeman interaction depends on the relative orientation of the external field and the symmetry axis of the paramagnetic complex[31]. Bleaney[32] showed that the pseudocontact shifts in the NMR spectra due to paramagnetic complexes of lanthanides, which are characterised by an isotropic g-factor, are a consequence of the anisotropy of the susceptibility. In this case ω_p for an axially symmetrical complex is defined by the expression[32,33]

$$\omega_p = \frac{\beta^2}{60\,(kT)^2} \times \left(\frac{3\cos^2\varphi - 1}{r^3}\right) \times 2A_0^2 \langle \bar{a}^2 \rangle \times \\ \times g^2 J\,(J+1)\,(2J-1)\,(2J+3) \langle J \| \alpha \| J \rangle \qquad (2\text{–A})$$

where A_0^2 is the crystal field coefficient, $\langle \bar{a}^2 \rangle$ the mean square of the radius of $4f$ electrons, and $\langle J \| \alpha \| J \rangle$ a numerical coefficient; the remaining symbols are analogous to those in Eqns.(1) and (2). The first multiplier in Eqn.(2–A), depends on T^{-2} and not on T^{-1} [cf. Eqn.(2)]. However, the dependence on φ and r of the second multiplier is the same as for the anisotropic g-factor of axially asymmetric complexes. The third and fourth multipliers characterise the state of the paramagnetic ion. When Eqn.(2–A) is employed in structural studies, the influence of the third multiplier may be taken into account by means of an appropriate procedure, while the fourth multipler has been tabulated for tervalent lanthanides[33]. Since Eqn.(2–A) was obtained taking into account the ground state only, the europium complex should not induce shifts because $J = 0$ for Eu^{3+}. However, Eu^{3+} has an excited level with $J = 1$, which is close to the ground level (the energy of the first excited state is about 300 cm^{-1}). Allowance for this factor leads to a non-zero value of the fourth term in Eqn.(2–A), which accounts for the appearance of shifts in the spectra of europium complexes[32]‡.

The longitudinal (T_1M) and transverse (T_2M) relaxation times of the protons in the coordination sphere are given by the formulae[2]

$$\frac{1}{NT_{1M}} = \left(\frac{2}{15}\right) S(S+1)\, g^2\beta^2\gamma_n^2 \left(\frac{n_h}{N_p}\right)\left(\frac{1}{r^6}\right)\left(3\tau_c + \frac{7\tau_c}{1+\omega_s^2\tau_c^2}\right) + \\ + \left(\frac{2}{3}\right) S(S+1)\,\frac{A^2}{\hbar^2}\left(\frac{n_h}{N_p}\right)\cdot\left(\frac{\tau_e}{1+\omega_s^2\tau_e^2}\right) , \qquad (4)$$

$$\frac{1}{NT_{2M}} = \left(\frac{1}{15}\right) S(S+1)\, g^2\beta^2\gamma_n^2 \left(\frac{n_h}{N_p}\right)\left(\frac{1}{r^6}\right)\left(7\tau_c + \frac{13\tau_c}{1+\omega_s^2\tau_c^2}\right) + \\ + \left(\frac{1}{3}\right) S(S+1)\,\frac{A^2}{\hbar^2}\left(\frac{n_h}{N_p}\right)\left(\tau_e + \frac{\tau_e}{1+\omega_s^2\tau_e^2}\right) , \qquad (5)$$

where n_h is the number of nuclei in the sphere of the paramagnetic complex, N_p the molar concentration of the resonating nuclei, N the molar concentration of paramagnetic ions, ω_s the Larmor precession frequency of the electron, and τ_e and τ_c are the correlation times of the contact and pseudocontact interactions respectively, which are defined by the expressions

$$\frac{1}{\tau_e} = \frac{1}{\tau_s} + \frac{1}{\tau_h} ; \quad \frac{1}{\tau_c} = \frac{1}{\tau_s} + \frac{1}{\tau_r} + \frac{1}{\tau_h} . \qquad (6)$$

Here τ_s is the electron spin relaxation time, τ_h the residence time of the resonating nucleus in the coordination sphere, and τ_r the time required for the reorientation of the paramagnetic species. τ_h and τ_s must satisfy the condition $\tau_h^{-1} \gg A$; $\tau_s^{-1} \gg A$.

Since τ_e and τ_c are characteristics of random processes, each specific situation must be considered separately. However, in the general case τ_e and τ_c are determined by the fastest molecular processes. Moreover, τ_e^{-1} and τ_c^{-1} may differ appreciably from ω_s, which results in different contributions by dipole and contact interactions to T_1M and T_2M. This follows from Eqns.(4) and (5) containing the products $\omega_s\tau_e$ and $\omega_s\tau_c$, which satisfy different inequalities in the case of a significant different between τ_e and τ_c. For example, at a proton resonance frequency of 30 MHz, it is found that for Mn^{2+}

$$\omega_s\,\tau_e \gg 1; \qquad \omega_s\,\tau_c \ll 1 . \qquad (7)$$

When inequalities (7) hold, Eqns.(4) and (5) are replaced by other expressions:

$$\frac{1}{NT_{1M}} = \left(\frac{4}{3}\right) S(S+1)\, g^2\beta^2\gamma_n^2 \left(\frac{n_h}{N_p}\right)\left(\frac{1}{r^6}\right)\tau_c , \qquad (8)$$

$$\frac{1}{NT_{2M}} = \left(\frac{4}{3}\right) S(S+1)\, g^2\beta^2\gamma_n^2 \left(\frac{n_h}{N_p}\right)\left(\frac{1}{r^6}\right)\tau_c + \left(\frac{1}{3}\right) S(S+1)\cdot\frac{A^2}{\hbar^2}\left(\frac{n_h}{N_p}\right)\tau_e . \qquad (9)$$

Consequently contact interaction (the second term in the last equation) will contribute to line width. This contribution may be reduced if

$$\omega_s\,\tau_c \ll 1 \quad \text{и} \quad \omega_s\,\tau_e \ll 1 . \qquad (10)$$

In this case

$$\frac{1}{NT_{1M}} = \left(\frac{4}{3}\right) S(S+1)\, g^2\beta^2\gamma_n^2 \left(\frac{n_h}{N_p}\right)\left(\frac{1}{r^6}\right)\tau_c + \left(\frac{2}{3}\right) S(S+1)\,\frac{A^2}{\hbar^2}\left(\frac{n_h}{N_p}\right)\tau_e , \qquad (11)$$

$$\frac{1}{NT_{2M}} = \left(\frac{4}{3}\right) S(S+1)\, g^2\beta^2\gamma_n^2 \left(\frac{n_h}{N_p}\right)\left(\frac{1}{r^6}\right)\tau_c + \left(\frac{2}{3}\right) S(S+1)\,\frac{A^2}{\hbar^2}\left(\frac{n_h}{N_p}\right)\tau_e , \qquad (12)$$

or

$$\frac{1}{T_{1M}} = \frac{1}{T_{2M}} .$$

Like the preceding expression, the last equation for $1/T_2$M contains a second term, but its contribution is significantly smaller. Inequalities (10) hold where the characteristic relaxation times τ_e and τ_c are equal or differ insignificantly, which can happen, in particular, when the electron spin relaxation is fast[34] ($\tau_s \ll \tau_h, \tau_r$). At a proton resonance frequency of 100 MHz, $\omega_s\tau_e \ll 1$, provided that τ_e is of the order of magnitude of 10^{-12} s. A significant enhancement of the inequality $\omega_s\tau_e \ll 1$ (i.e. a narrowing of the resonance lines) occurs also with increase of the temperature of the test specimen.

It follows from a comparison of Eqns.(1) and (12) that

$$\frac{1}{NT_{2M}} = \left(\frac{4}{3}\right) S(S+1)\, g^2\beta^2\gamma_n^2 \left(\frac{n_h}{N_p}\right)\left(\frac{1}{r^6}\right)\tau_c + \frac{24k^2T^2}{\hbar^2 g^2 S(S+1)}\left(\frac{n_h}{N_p}\right)^2 \tau_e^2\omega_k^2$$

or

$$1/T_{2M} = B\, r^{-6} + C\,(\delta_k')^2 , \qquad (13)$$

where δ'_k is the observed contact shift of the resonance line and B and C are constants for the test specimen at the given temperature. For complexes in which there is no

‡ The nature of the shifts induced by paramagnetic europium complexes has also been discussed by Weissman[109].

contact interaction, the relaxation time of the nucleus is determined by the distance from the coordinating ion:

$$1/T_{2M} = C\ r^{-6}\ . \qquad (14)$$

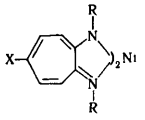
The study of the NMR phenomenon in paramagnetic systems yields important information about the structure of many-electron systems. This becomes evident if one remembers that Eqns.(1), (2), (2—A), and (3), which define the parameters of the NMR spectra of paramagnetic systems, are related to the electronic and geometric structures of molecules. Paramagnetic shifts are much greater than chemical shifts in the spectra of diamagnetic compounds and moreover they exhibit a characteristic temperature variation. A wide variety of relaxation effects are possible for paramagnetic substances and hence a broadening of the spectral lines, which significantly extends the scope of NMR as a research technique. This is because a decrease of the electron spin relaxation time leads to a broadening of the resonance lines in the ESR spectra, while NMR signals become narrower (the conditions governing the recording of the NMR spectra are improved)[4]. This interrelation between the relaxation times of electron and nuclear spins enables one to influence the form of the NMR and ESR spectra of paramagnetic systems (provided that electronic-nuclear interactions occur in them). For example, on dissolution in chloroform (0.001 M), bishexafluoroacetylacetonatocopper and bistrifluoroacetylacetonatocopper give rise to satisfactorily resolved ESR spectra in which a hyperfine structure is observed. When the stable di-t-butyl nitroxide (DBNO) radical is added to the solution to give a concentration as low as 0.01 M, the ESR spectra are broadened, so that their hyperfine structure is not resolved and the ^{19}F NMR spectra of these complexes in chloroform cannot be observed. However, when they are dissolved in DBNO [solution?], the ^{19}F NMR spectra can be recorded. This is because the spin exchange between the free radicals and the copper complexes reduces the electronic relaxation time and permits the detection of the NMR signal[35].

III. ANALYSIS OF NUCLEAR MAGNETIC RESONANCE SPECTRA USING THE NMR PHENOMENON IN PARAMAGNETIC COMPLEXES

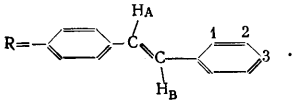
Nowadays NMR is a powerful tool for the investigation of many-electron systems, since the parameters of the NMR spectra carry valuable information about the electronic and geometric structures of the molecules[36]. However, the assignment of the resonance lines in NMR spectra on the basis of the simple rules for the analysis of the spectra (in the first-order perturbation theory) is impossible. On the other hand, it follows from Eqns.(2) and (2—A) that in the coordination of the molecules to a paramagnetic ion the resonance lines may shift unequally relative to their positions in the spectrum of the free ligand. This should make the difference between the proton chemical shifts greater than the spin—spin coupling constant between them and the analysis of the spectrum is significantly simplified.

1. Complexes of Elements in the First Transition Group

The factor noted above was apparently used for the first time to determine the spin—spin interaction constants J for substituted aminotroponeiminatonickel coordination complexes I. Eaton et al. examined this problem in detail[37]. They assumed that the spin—spin interaction in aromatic and unsaturated compounds is transmitted, predominantly by σ-electrons, over distances not greater than that corresponding to three bonds[38]. On the other hand, in paramagnetic nickel complexes (I) the contact shifts are due to the perturbation of the π-electron system of the ligand molecule[7]. Therefore one may expect that J found from the ^1H NMR spectrum of the paramagnetic complex will be close to the value of J for a diamagnetic molecule. The complex has the structure



where X = H or Br and R are different aliphatic and aromatic groups. Fig. 1B illustrates part of the spectrum of the paramagnetic complex due to the protons of the ligand molecule:



For comparison, the ^1H NMR spectrum of *trans*-stilbene taken from the catalogue of the Varian Company is also included[39]. The olefinic protons in *trans*-stilbene are chemically equivalent so that the spin—spin interaction between them is not observed and their signal in the spectrum consists of a singlet (δ = 7.10 p.p.m.). The aromatic protons form an unresolved multiplet. In a paramagnetic complex the resonating nuclei of the same molecule become significantly non-equivalent (Fig. 1*B*). The nickel complex (I) in solution is characterised by a rapid intramolecular equilibrium of the type

$$\underset{\text{(square)}}{\text{diamagnetic form}} \rightleftharpoons \underset{\text{(tetrahedron)}}{\text{paramagnetic form.}}$$

This leads to a narrowing of the resonance lines in the ^1H NMR spectra of the complexes to such an extent that it is possible to observe the spin—spin interaction characterised by J = 2—3 Hz.[7]

The high-resolution spectrum of a paramagnetic complex cannot usually be recorded owing to the considerable width of the resonance lines. However, this difficulty can be obviated by recording the spectra of specimens in which the metal/ligand ratio is much less then unity. As a result of the rapid exchange of molecules between the coordination sphere of the complex and the free ligand, an average spectrum is observed. Its form depends particularly on the nature of the electron—nuclear interaction in the paramagnetic complex. The use of this method becomes evident from an examination of the influence of exchange effects on the form of the NMR spectrum[36]. Evidently, when the proton H is involved in rapid exchange of the type HA + B $\rightleftharpoons$ HB + A, the observed shift of its signal is defined by the expression

$$\delta_H = P_A\ \delta_A + P_B\ \delta_B\ ,$$

where P_A and P_B are the mole fractions of H_A and H_B, and δ_A and δ_B are the chemical shifts of the proton signal in the environments of A and B. In our case A and B are the free molecule (P_C, δ_C) and the molecule coordinated (P_M, δ_M) to the paramagnetic ion, whence

$$\delta_H = P_C\,\delta_C + P_M\,\delta_M = \delta_C + (\delta_M - \delta_C)P_M = \delta_C + \omega\ P_M\ , \qquad (15)$$
$$\delta_M - \delta_C = \omega;\quad P_C + P_M = 1\ .$$

In order to assign the resonance lines in the spectra of specimens containing paramagnetic complexes, it is necessary that the solution should contain only one complex when the metal/ligand ratio is varied; if there are several complexes, their proportions must remain fixed. It is readily seen that the linear relation between δ_H and P_M is a criterion of the characteristics of complex formation in the test specimen. Moreover, Eqn.(15) can be used to determine ω when $P_M = 1$ and δ_C when $P_M = 0$ by the graphical extrapolation of the $\delta_H = f(P_M)$ relation. This method was used to assign the signals in the ^{1}H NMR spectra of pyridine, quinoline, and isoquinoline N-oxides[5,8].

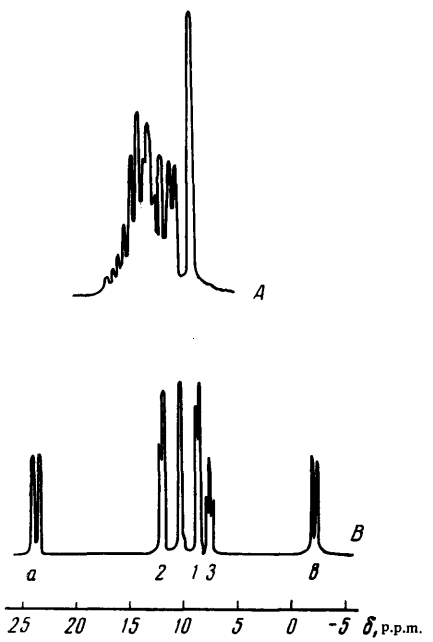


Figure 1. *A*) The ^{1}H NMR spectrum of *trans*-stilbene; *B*) part of the ^{1}H NMR spectrum of a paramagnetic complex due to the protons of *trans*-stilbene.

A method has been proposed[40] for the determination of the functional groups in organic compounds capable of forming paramagnetic complexes, which is also based on the employment of the characteristics of the NMR spectra of paramagnetic compounds. Its application is illustrated by the interpretation of the ^{1}H NMR spectra of certain methyl derivatives of pyrazole. The same method has been used also to assign the resonance lines in the spectra of N-vinylimidazole(II) and N-ethylimidazole(III).[41] The assignment was based on an estimate of the broadening (Δ) and shifts (δ) of the resonance lines due to the influence of the non-compensated electron spin of the paramagnetic complex. The estimation of Δ and δ' for labile complexes reduces to the solution of the Bloch equations modified by McConnell. For a two-component system, analysis of the Bloch–McConnell equations leads to the following expressions defining the observed Δ and δ' relative to the widths and positions of the lines in the spectrum of a diamagnetic compound[42]:

$$\Delta = \frac{P_M[(1/T_{2M})^2 + 1/T_{2M}\cdot\tau_M + \omega^2]}{\tau_M[(1/T_{2M} + 1/\tau_M)^2 + \omega^2]}, \quad (16)$$

$$\delta' = \delta'_c + \delta'_p = -\frac{P_M\cdot\omega}{\tau_M^2[(1/T_{2M} + 1/\tau_M)^2 + \omega^2]}, \quad (17)$$

where τ_M is the lifetime of the ligand molecule in the first coordination sphere of the complex, P_M the mole fraction of the complex in the specimen, $\omega = \omega_C + \omega_p$ the shift of the resonance line of the nucleus entering into the composition of the paramagnetic complex§, and T_{2M} the transverse relaxation time of the resonating nucleus in the complex.

Evidently, depending on the relative values of τ_M, T_{2M}, and ω, Eqns.(16) and (17) may be simplified[42].

1) Slow exchange:

$$\Delta = \frac{P_M}{\tau_M}, \quad (18)$$

$$\delta' = -P_M\ \omega\ \frac{T_{2M}^2}{\tau_M^2}, \quad \text{or} \quad \delta' = -\frac{P_M}{\tau_M^2\cdot\omega}. \quad (19)$$

2) Fast exchange:

$$\Delta = P_M\cdot\tau_M\cdot\omega^2 \quad (20)$$

or

$$\Delta = \frac{P_M}{T_{2M}}, \quad (21)$$

$$\delta' = -\omega\cdot P_M. \quad (22)$$

3) Intermediate case:

$$\Delta = \frac{P_M}{T_{2M}} + P_M\cdot\tau_M\cdot\omega^2, \quad (23)$$

$$\delta' = -\omega\cdot P_M. \quad (24)$$

The simplification of Eqns.(16) and (17) involves the derivation of the relations

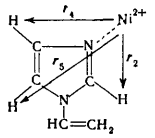
$$\Delta = f(T), \quad (25)$$

$$\delta' = f(T), \quad (26)$$

where T is the absolute temperature of the test specimen. Here it is necessary to note the importance of the fact that Δ and δ' are functions of the same variables. Therefore, depending on the nature of the complex and the experimental conditions, it is possible to obtain both Eqns.(25) and (26) or one of them. The above considerations were used to assign the ring proton signals in the ^{1}H NMR spectra of compounds (II) and (III). The experiments were performed in the presence of an excess of the ligand in the specimen. Fig. 2 presents the temperature variation of the broadening of the ring proton signals in the spectrum of compound (II) with the added paramagnetic complex $NiCl_2.4L$ [L = (II)]. The plots show that up to 313°K the broadening Δ is determined by Eqn.(18). In order to find approximate expressions for Eqns.(16) and (17) in the range 313–370°K, account was taken of the temperature variation of δ'. Moreover, the ratios $(r_5/r_2)^6$, $(r_5/r_4)^6$, and $(r_4/r_2)^6$ were estimated from data for the geometry of imidazole[43] and

§ One should note here that in a number of studies[6,10,12] the pseudocontact shifts were found to be insignificant in those cases where the nickel atom was the coordinating species.

also the ionic radius of Ni^{2+} and the van der Waals radius of nitrogen



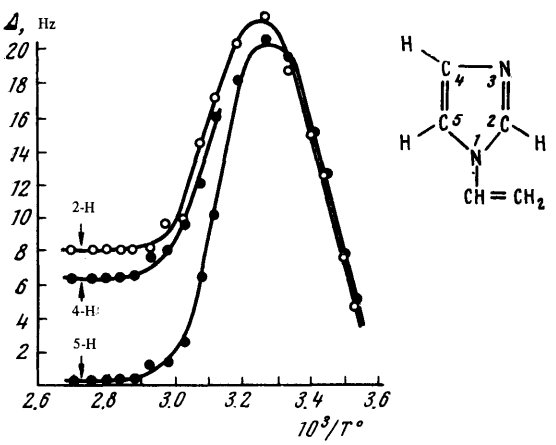


Figure 2. Temperature variation of the broadening of the signals of the imidazole ring protons.

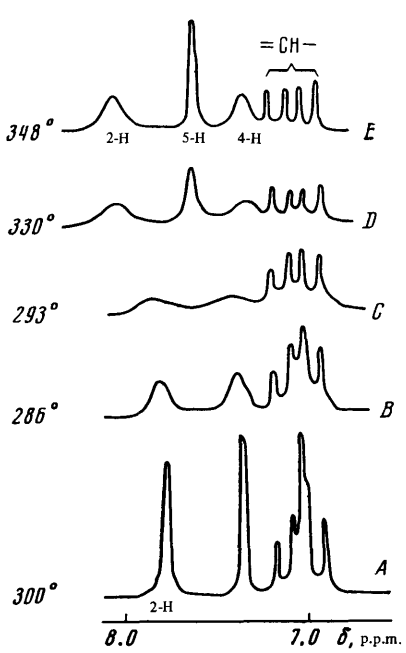

Figure 3. The positions of the ring and CH proton signals in the spectrum of *N*-vinylimidazole without the addition (*A*) and with addition (*B* –*E*) of the paramagnetic complex at different temperatures.

By comparing Δ and δ′ and taking into account the fact that the 2-H proton of imidazole resonates in a lower field than the 4-H and 5-H protons, it was found that the signals of the imidazole ring protons in the spectrum of compound (II) are in the sequence $\delta_2 > \delta_5 > \delta_4$. When the temperature of the test specimen with the added complex $NiCl_2.4L$ is altered, the signals of the vinyl protons hardly shift in relation to their positions in the spectrum of the specimen without the paramagnetic additive. Since these protons are quite far (compared with 2-H and 4-H) from the coordinating ion, their resonance lines are hardly broadened, i.e. over the entire range of variation of temperature Δ is determined by the first term of Eqn.(16). The positions of the signals of the 2-H, 4-H, 5-H, and CH protons in the spectrum of compound (II) with and without the addition of the paramagnetic complex at different temperatures are illustrated in Fig. 3. The ^{1}H NMR spectrum of compound (III) was analysed similarly. The following two examples illustrate the results of Zaev and coworkers' study [40]. Fig. 4 presents the spectrum of 1,3,5-trimethylpyrazole (IV) without the addition (*A*) and with addition (*B*) of the salt $NiBr_2.3H_2O$, which forms a paramagnetic complex with compound (IV). Fig. 4*A* shows that the assignment of the 3-CH_3 and 5-CH_3 signals is not unambiguous, since their protons resonate at high field and are responsible for the appearance of two singlets with an insignificant difference between the chemical shifts (0.03 p.p.m.).

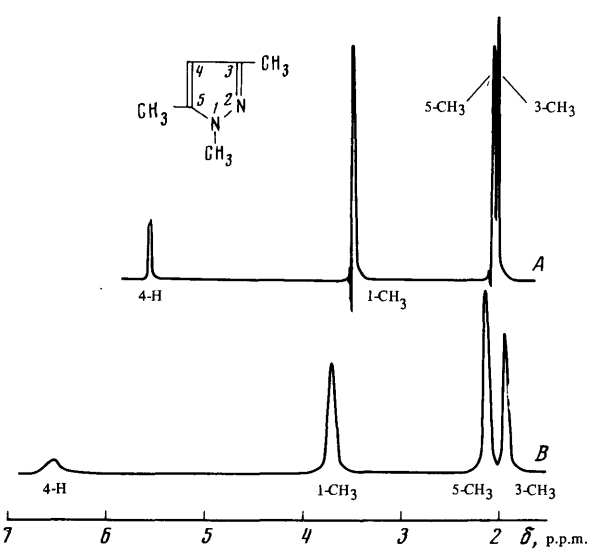

Figure 4. ^{1}H NMR spectrum of 1,3,5-trimethylpyrazole without the addition (*A*) and with addition (*B*) of $NiBr_2.3H_2O$.

The formation of complexes leads to a shift of the singlets in opposite directions and to different degrees of broadening. Comparison of the values of Δ and δ′ with the distances from the coordinating ion to the resonating nuclei showed that in the spectrum of compound (IV) without $NiBr_2.3H_2O$ the singlet in the high field is due to the protons of the 3-CH_3 group. Fig. 5 presents the spectra of one of the isomers of dimethylpyrazole without the addition (*A*) and with addition (*B*) of the same nickel salt. Since Δ for the signal of the 4-H proton, the position of

which in the spectrum is known, is significantly smaller than Δ for the signal of the other proton of the pyrazole ring, the above isomer is 1,5-dimethylpyrazole in which $r^6_{3\text{-H}} \ll r^6_{5\text{-H}}$. In the above investigations[40,41] the mole fraction of the paramagnetic complex did not exceed $10^{-2}-10^{-3}$, which ensures constancy of the composition of the complex and a linear relation between δ′ and P_M. Carbon tetrachloride, chloroform, and nitromethane were used as solvents. Any substance can be used for this purpose, provided that it does not displace the ligand molecules from the paramagnetic complex.

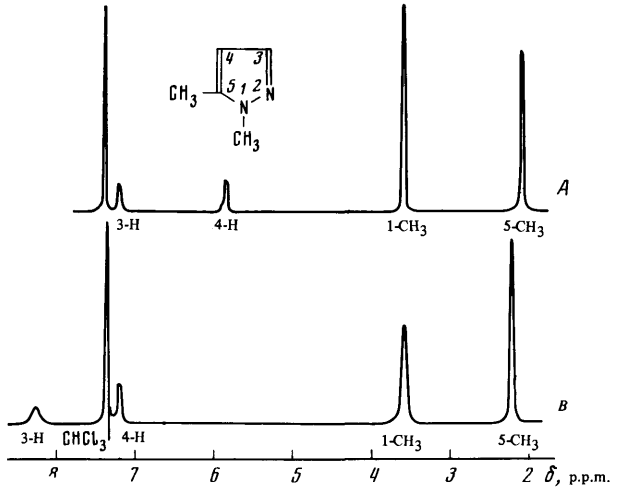

Figure 5. ^{1}H NMR spectrum of 1,5-dimethylpyrazole without the addition (*A*) and with addition (*B*) of $NiBr_2.3H_2O$.

Other investigators[13,44-46] also used the addition of salts of metals of the first transition group in order to analyse the ^{1}H NMR spectra. In particular, the relative positions of the NH_2 and NHR groups and the aromatic ring were established[13] in aniline derivatives coordinated to $Ni(AA)_2$¶ and $Co(AA)_2$. The conformation of the tropane ring was refined[44]. Account was taken of the effect of the orientation of the nitrogen atom lone pair and the paramagnetic shifts in the spectra of piperidines induced by $Ni(AA)_2$.[47] A study was made of the effect of $Co(AA)_2$, $Ni(AA)_2$, and $Cu(AA)_2$ on the ^{1}H NMR spectra of various alcohols and amines at room temperature[45].

To conclude this section, we may mention that, for different ligands and coordinating ions, which can form complexes differing in the values of ω and T_{2M}, Eqns. (16) and (17) can be represented approximately by Eqns. (18) to (24) at different temperatures of the test specimens. Since the complexes formed by elements of the first transition group are characterised by different values of τ_S (τ_S^{Mn} and $\tau_S^{Cu} \gg \tau_S^{Ni}$, τ_S^{Co}, τ_S^{Fe}),[34] it follows that comparison of the values of Δ and δ′ for the purpose of the assignment of the resonance lines is also possible at different temperatures of the test specimens. This fact is illustrated in Fig. 6.[48] A similar behaviour may be shown for the same coordinating ion with different ligands.

¶ AA = acetylacetonato-group.

2. LANTHANIDE COMPLEXES

The vast majority of studies in which the ^{1}H NMR spectra were simplified using the spectra of paramagnetic systems were made after the publication of Hinckley's paper[49], which reported a comparison of the ^{1}H NMR spectrum of a cholesterol solution with and without the addition of the paramagnetic complex $Eu(DPM)_3.2Py$ (DPM = dipivaloylmethane or 2,2,6,6-tetramethylheptane-3,5-dione[50] and Py = pyridine). The author justifies the use of the europium complex by the very short electronic relaxation time (τ_S) of lanthanide ions. Therefore (see Section II) the formation of a complex with tris(dipivaloylmethane)europium lead to only a slight broadening of the resonance lines, while their paramagnetic shifts are significant. Fig. 7 illustrates the spectrum of cholesterol (V) in carbon tetrachloride solution without addition (Fig. 7*A*) and with addition of $Eu(DPM)_3.2Py$.[49] In the free ligand the protons of the methyl and also methylene and methine groups, which are not bound to an oxygen atom, resonate in a high field, forming an unresolved multiplet in the spectrum. The remaining protons resonate in the weaker field. The coordination of cholesterol to the europium ion leads to an appreciable shift of the signals in the spectrum. The greatest paramagnetic shifts are observed for the signals of the vinyl proton *f* and the proton *e*, which indicates coordination via the hydroxy-group. The signals of the methyl groups *a*, *b*, and *c* are also displaced. Moreover, new resonance lines *g*, *h*, and *i* appear in a weak field. The assignment of the resonance

line was based on a comparison of the spectra at different $Eu(DPM)_3.2Py$ concentrations in the test specimen with allowance for the integrated signal intensities. Moreover, account was taken of the fact that, when the coordinating centre is the lanthanide ion, the paramagnetic shift is due to a pseudocontact interaction[4]. The paramagnetic shifts were therefore compared with the corresponding values of r. For this purpose, the possible structure of the complex was examined using a model of cholesterol. It was found that the metal ion is in the *trans*-position relative to the proton *e*, i.e. that the configuration of the complex depends significantly on the steric factor, determined by the mutual orientations of the proton and the hydroxy-group. The dependence of the observed paramagnetic shifts on r^{-3} shows that the paramagnetic shifts are mainly determined by the distance from the coordinating ion to the resonating nuclei. This analysis of the ^1H NMR spectra of cholesterol led to the conclusion that $Eu(DPM)_3.2Py$ can be used for the conformational analysis of steroids and similar compounds. The capacity of $Eu(DPM)_3.2Py$ to induce relatively large paramagnetic shifts, which depend on the concentration of the complex in the test specimen, without a significant broadening of the resonance line shows that this complex can be used as a shift reagent[49].

In his next paper[51] Hinckley reported the use of a paramagnetic europium complex for the assignment of the signals of the methyl protons in the ^1H NMR spectrum of (+)-camphor, since there had been no unanimous view in the literature concerning this problem. Hinckley preceded the spectrum analysis by the following justification of the use of paramagnetic additives.

When a complex $M(DPM)_3.2Py$ (M is a lanthanide element) is dissolved in carbon tetrachloride, its molecule dissociates in accordance with the equations

$$M(DPM)_3.2Py \rightleftharpoons M(DPM)_3.Py + Py,$$
$$M(DPM)_3.Py \rightleftharpoons M(DPM)_3 + Py.$$

If an organic compound B with a coordinating group is added to the solution, association of the following type will take place:

$$M(DPM)_3.Py + B \rightleftharpoons M(DPM)_3.Py.B.$$

The paramagnetic shifts in the spectrum of B are then a consequence of such association.

According to Hinckley[51], the use of lanthanide complexes must involve the following procedures: 1) the recording of the ^1H NMR spectrum of compound B dissolved in carbon tetrachloride without an additive and then with one or several additions of $Eu(DPM)_3.2Py$; the determination of the concentration variation of the observed shifts is necessary in those cases where it is difficult to analyse the spectrum at one concentration; 2) the construction of a model of compound B and the measurement of the distances r from the coordinating metal ion to the resonating protons (the ionic radius of Eu^{3+} is 0.950 Å). The spectrum of B is interpreted accordingly.

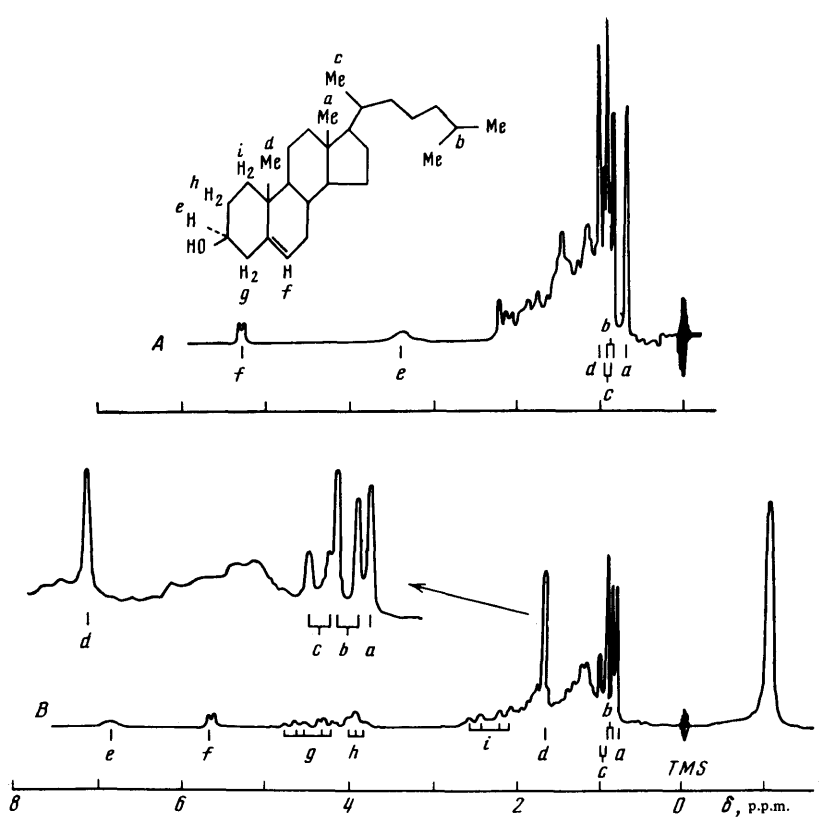

Figure 7. *A*) ^1H NMR spectrum of cholesterol in carbon tetrachloride; *B*) the spectrum of cholesterol after the addition of the complex $Eu(DPM)_3.2Py$. The high-field signal is due to the methyl protons of DPM.

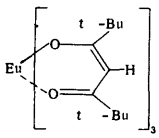
Although Hinckley's paper[49] was published in the middle of 1969, more than 200 reports of the use of shift reagents for the analysis of NMR spectra have already been published. These studies, illustrating the scope of the method of analysing NMR spectra with the aid of lanthanide complexes, are described below.



After Hinckley[49], Sanders and Williams reported that Eu(DPM)$_3$ is an excellent shift reagent[52]. This europium compound induces considerable paramagnetic shifts by coordinating the lone electron pair of the functional group. For example, the aromatic protons in the ^{1}H NMR spectra of benzyl alcohol give rise to a broad spectrum. When Eu(DPM)$_3$ is added to the solution (0.39 M), the spectrum becomes susceptible to a first-order analysis (Fig. 8).

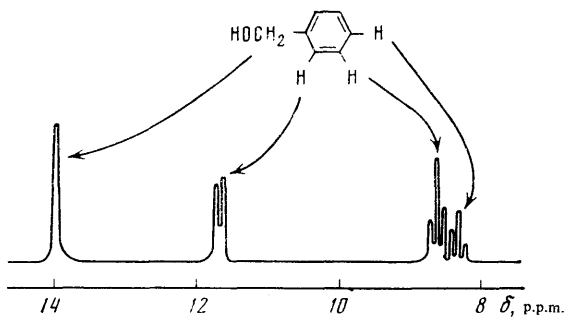


Figure 8. The ^{1}H NMR spectrum of benzyl alcohol in the presence of Eu(DPM)$_3$.

The induced shifts decay rapidly with increase of the number of bonds separating the hydroxy-groups and the corresponding protons. When Eu(DPM)$_3$ is added to a solution of 1-hexanol, the analysis of its spectrum in accordance with the first-order rules is also possible. The signal of the OH group is then broadened to such an extent that it cannot be recorded. However, the broadening of the resonance lines of the other protons is much smaller. It was found that Eu(DPM)$_3$ induces paramagnetic shifts also in the ^{1}H NMR spectra of ketones, ethers, esters, and amines. Ketones form complexes (to an extent of about 35–40%) less effectively than alcohols, and ethers and esters are less effective still. However, amines behave similarly to alcohols. Sanders and Williams believe that Eu(DPM)$_3$ can be extremely effective in the determination of the structures of natural products and supported this view by an analysis of the changes in the ^{1}H NMR spectrum of lupeol recorded after the addition of Eu(DPM)$_3$. They discussed[52] the conditions governing the employment of Eu(DPM)$_3$. In particular, they noted its high solubility in carbon tetrachloride. One of the first studies was that of Wahl and Peterson[53], who employed Eu(DPM)$_3$ for the analysis of the ^{1}H NMR spectra of adamantan-1-ol and adamantan-2-ol.

The effectiveness of Eu(DPM)$_3$ was illustrated by Demarko et al.[54] in the analysis of the spectra of *trans*- and *cis*-4-butylhexanol, isoborneol, and borneol[54]. The signals in the spectra of these compounds were assigned on the basis of a comparison of the paramagnetic shifts with the corresponding distances r' from the resonating nuclei to the oxygen of the hydroxy-group and not to the coordinating ion†. This approach was justified by postulating that the values of $3\cos^2\varphi_i - 1$ for the protons of the test compounds would be significantly different. It is impossible to calculate them owing to the lack of information about the geometry of the paramagnetic complex in solution. It was established that a relation between the shift‡ and the distances from the protons to the oxygen atom can be expressed by a straight line on a logarithmic scale with a slope of -2.3. This is evidence of a correspondence between the induced shifts and r': $\lg(r')^{-3} = (-3)\lg r'$. The replacement of r by r' must be regarded as justified, since it implies a shift of the origin of the readings of the power base r in the functional relation $y = r^3$, the shape of the plot of which is determined by the cube of the distance. Evidently for small values the use of r' in comparing the paramagnetic shifts will yield less satisfactory results. Therefore the replacement of r by r' should be most successful for protons remote from the europium atom. Fig. 9 illustrates the results of Demarko et al.[54]. Only two signals may be assigned in the spectrum of a solution of *cis*-butylhexanol (Fig. 9*A*) without Eu(DPM)$_3$. However, for a molar ratio alcohol/Eu(DPM)$_3$ = 0.7, the recorded spectrum meets the requirements for a first-order interpretation (Fig. 9*E*). The signals were assigned on the basis of the spin–spin interaction constants taking into account double resonance experiments. Demarko et al. also illustrated the efficiency of the shift reagent method in the study of the structures of steroids and triterpenes by a detailed analysis of the ^{1}H NMR spectra of 5α-androstan-2β-ol and friedelan-3-β-ol.[56] The possibility of employing the shift reagent method for the determination of the numbers and positions of the methyl groups in molecules of natural products was demonstrated by comparing the shifts induced by Eu(DPM)$_3$ in the ^{1}H NMR spectra of 22 triterpenes[57]. In order to obtain spectra with non-overlapping signals, account was taken in the above study of both the concentration and temperature variation of the observed shifts. The compared values of the latter were normalised in relation to the low-field signal of the protons in the 4-CH$_3$ group, the chemical shift of which was assumed to be 10 p.p.m.

Briggs et al.[58] were the first to report that Pr(DPM)$_3$ induces, like Eu(DPM)$_3$, paramagnetic shifts in ^{1}H NMR spectra. It is striking that these shifts are approximately three times greater than the shifts due to Eu(DPM)$_3$ and are of opposite sign. Briggs et al.[58] quote the paramagnetic shifts induced by complexes of the type M(ClO$_4$)$_3$·{OP[N(CH$_3$)$_2$]$_3$}$_4$ in the ^{1}H NMR spectrum of a solution of acetonitrile (the shifts are quoted relative to the acetonitrile complex in which M is lanthanum; the minus sign

† The r' were calculated by determining the distances between non-linked atoms[55].

‡ The paramagnetic shifts compared with the r' were calculated subject to the condition that the molar ratio alcohol/Eu(DPM)$_3$ = 1.

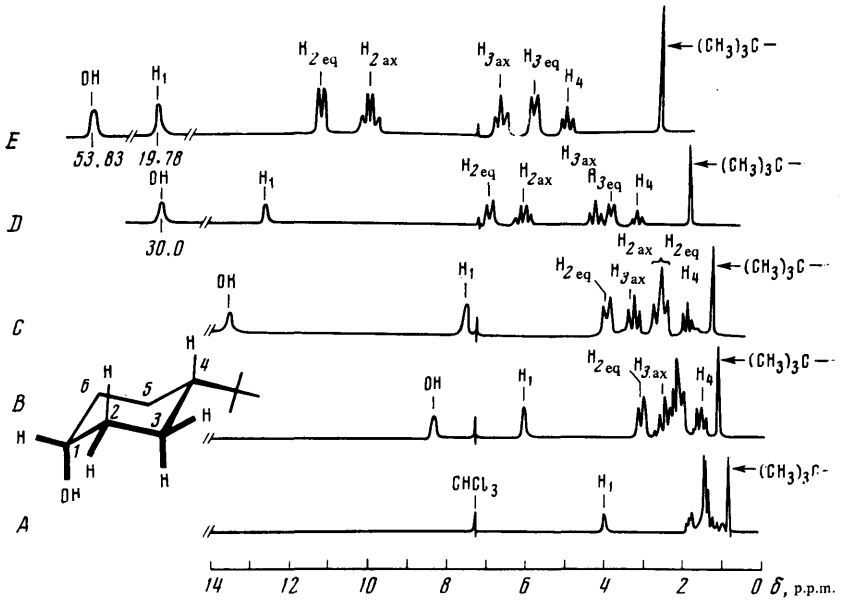

Figure 9. The ^{1}H NMR spectrum of *cis*-4-t-butylcyclohexanol (20 mg) in $CDCl_3$ (0.4 ml) with different contents of $Eu(DPM)_3$ (mg): *A*) 0.0; *B*) 10.3; *C*) 16.0; *D*) 33.1; *E*) 60.2. (The signal of the methyl protons was recorded with a lower amplification than the other signals.)

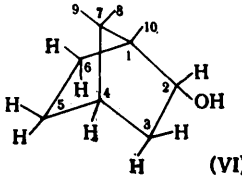
corresponds to a shift to high field:

Metal	Paramagnetic shift, p.p.m.
Ce	−1.5
Pr	−3.0
Nd	−1.75
Sm	−0.27
Eu	+1.33
Gd	not observed
Tb	−19.2
Dy	not observed
Ho	−17.0
Er	+4.4
Tm	+6.9
Yb	+6.66
Lu	0

The above example shows that complexes of other lanthanides, together with $M(DPM)_3$, can be used as shift reagents. At the same time there are important limitations to the use of these complexes, which are determined in particular by the following causes[58].

1. The $M(DPM)_3$ form complexes with a coordination number of 6, which is suitable for the coordination of organic molecules.
2. The shift reagent method is based on the use of nonpolar solvents.
3. One must bear in mind that (a) the test substance may not be coordinated to the lanthanide compound due to steric hindrance and (b) that the signals of the resonating nuclei may not be affected significantly by complex formation. For example, it has been found that $Pr(NO_3)_3(OPPh_3)_3$, $Pr(ClO_4)_3\{OP[N(CH_3)_2]_3\}_4$, $Eu(NO_3)_3(OAsPh_3)_4$, $Ce(NCS)_3 \cdot (OPPh_3)_4$, and lanthanide perchlorates induce insignificant paramagnetic shifts in the spectra of alcohols and ketones (the signal of α-protons is displaced only by approximately 0.5 p.p.m.).

Briggs et al. were the first to compare the observed and calculated paramagnetic shifts induced by $Pr(DPM)_3$.[59] They used borneol (VI), which has a fixed conformation, as the ligand

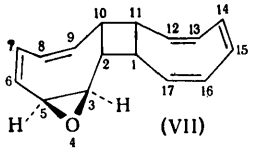


(VI)

An unambiguous assignment of the observed paramagnetic shifts was achieved by a preliminary analysis of the ^{1}H NMR spectrum of borneol recorded at three frequencies (60, 100, and 220 MHz) using the double resonance and deuteriation techniques. It was assumed (1) that the paramagnetic shifts are due to a pseudocontact interaction and (2) that the complex is axially symmetric in solution.

This implied that the induced shift must be proportional $(3\cos^2\varphi - 1)r^{-3}$. The orientation of the resonating nuclei was specified by the Pr—O distance, the Pr—O—(2-C) angle, and the Pr—O—(2-C)—(H-2)-dihedral angle. The values of these parameters in the initial model (2.6 Å, 109°, and 33°) were then varied until agreement was reached between the calculated and experimental shifts to within a constant factor. This agreement was found for the following values: 3 Å, 126°, and 25°. The authors concluded that the problem of the orientation of the hydroxy-groups in various lanthanide complexes should probably be solved separately in each specific case. The importance of the $3\cos^2\varphi - 1$ contribution to the paramagnetic shifts was also demonstrated (particularly for resonating nuclei close to the coordinating ion). This conclusion is confirmed by the ^{1}H NMR spectrum of a

tetracyclic epoxide (VII) recorded in the presence of $Eu(DPM)_3$.[60]



(VII)

It was found that, in contrast to the signals of other protons, those of 15-H and 16-H are displaced to high field. The explanation is that $\varphi_{15\text{-H}} = 58°$ and $\varphi_{16\text{-H}} = 55$, i.e. is greater than 54.7° (if $\varphi < 54.7°$, then $3\cos^2\varphi - 1 < 0$). Therefore complex formation leads to additional screening of the 15-H and 16-H protons and displaces their signals to high field. The shifts to high field induced by $Eu(DPM)_3$ were also reported in other investigations[61-63]. It is noteworthy that Tjan and Visser[62] believe that the hypothesis of a contact and pseudocontact mechanism for the interaction of unpaired electrons and resonating nuclei constitutes the most acceptable explanation of the paramagnetic shifts to high field which they observed. These two mechanisms lead to the appearance of paramagnetic shifts with opposite signs, which is in fact reflected in the ^1H NMR spectra.

Bélanger[64] examined the shifts induced by $Pr(DPM)_3$ in the spectra of certain ketones and found that the shifts are greater by a factor of 1.4 than the shifts induced by $Eu(DPM)_3$.

Wolkowski and coworkers[65,66] used addition of the ytterbium compound $Yb(DPM)_3$ for the analysis of ^1H NMR spectra. In the first study they investigated primary, secondary, and tertiary amines and established that the induced paramagnetic shifts depend on the steric factor and on the charge of the nitrogen atom. They compared the paramagnetic shifts and r for pyridine and quinuclidine, which have a characteristic orientation of a lone electron pair orbital available for coordination. The N...Yb distance was varied from 1 to 5 Å. It was found that, for a N...Yb distance of 3 ± 0.3 Å, the graphical relation between the shifts and r (on a logarithmic scale) is linear.

Wolkowski[66] illustrated the effectiveness of $Yb(DPM)_3$ for the assignment of the signals in the ^1H NMR spectra of ketones and aldehydes. A significant influence of steric factors and of the charge of coordinating atoms on the shifts induced by lanthanides was observed also by Ernst and Mannschreck[67] who found, in particular, a linear correlation between the basicity of the substitutent and the paramagnetic shifts of the signals of the *ortho*- and *meta*-protons in the ^1H NMR spectra of substituted anilines. The application of the shift reagent method to compounds having more than one coordinating centre was examined in a number of studies. It was found, for example, that *trans*- and *cis*-1-hexyl-2-phenylazetidin-3-ol is coordinated to $Eu(DPM)_3$ via the oxygen of the hydroxy-group and not via the nitrogen atom of the four-membered ring[68]. Details of the analysis of the paramagnetic shifts in the spectra of compounds with several coordination centres can be found in studies by Hinckley[69] and Sanders and coworkers[70].

The dependence of the pseudocontact interaction not only on r_i but also on φ_i complicates the assignment of the signals on the basis of a comparison of the observed paramagnetic shifts. At the same time, in the case of rapid exchange the difference between the broadening of the resonance lines at the given specimen temperature depends only on r^{-6}. Therefore, when the broadening can be determined as the signals are displaced, the values of Δ can be used for the same purpose as δ'.

This was taken into account by Morallee et al.[71] who reported that not only the shift but also the broadening of the resonance lines, due to the lanthanide ions, permits their use as excellent NMR probes for the investigation of biological systems. This was specifically illustrated in a study of the ^1H NMR spectrum of lysozyme in the presence of europium(III), holmium(III), and gadolinium(III) ions. Comparison of the broadening of the signals due to gadolinium enabled the distances from the coordinating ion to the protons of the acetamide and glycosidic methyl groups to be determined. The effectiveness of the joint analysis of δ' and Δ in the ^1H NMR spectra of pyridine and quinoline was demonstrated by Reuben and Leigh[72].

It is noteworthy that, in assigning the resonance lines in the spectra, some investigators compared the induced paramagnetic shifts with $(r')^{-2}$, motivating this approach by the uncertainty of the relative positions of the resonating nuclei and the centra ion. Rafalski et al.[73] compared the following two correlations: (1) between δ' and r^{-n} or $(r')^{-n}$ ($n = 2, 3$) and (2) between $\lg\delta'$ and $\lg r^{-n}$ or $\lg(r')^{-n}$. The values of n calculated from the experimental data of different workers served as a criterion for the comparison. The following remarks are appropriate to the study of Rafalski et al.[73].

1. The replacement of δ' and r (or r') by their logarithms implies only a change in the scale of the quantities compared. Therefore the above correlations must not be contrasted with one another.

2. The above investigations showed that the magnitude of the induced paramagnetic shifts is determined by the relative positions of the resonating nuclei and the central atom and also by the nature of the electron-nuclear interaction in the complex. Therefore the problem of choice of n is not fundamental, particularly since the pseudocontact shifts depend on $n = -3$.

Examination of NMR in paramagnetic systems showed that the observed values of Δ and δ' are determined, in particular, by the nature of the coordinating ion. Therefore Crump et al.[74] made a comparative study of complexes of the type $M(DPM)_3$, where M = Pr, Sm, Eu, Tb, Ho, or Yb§. The criteria of this comparison were (a) the position of the signal due to the protons of the t-butyl groups of DPM, (b) the slopes of the linear plot of $\delta' = \delta'(X_M)$, where X_M is the molar ratio $M(DPM)_3$/ test substance, (c) the relative shifts in the spectra of complexes of the type $M\{OP[N(CH_3)_2]_3\}_4(ClO_3)$ taken from the study of Briggs et al.[58], and (d) the ratio of the broadening (Hz) to the shift (Hz) of the signal due to the protons of the methyl groups of t-butyl alcohol in the presence of the complexes $M(DPM)_3$. The comparison showed that, in order to obtain first-order ^1H NMR spectra with retention of multiple structure, it is best to employ $Eu(DPM)_3$. The signal of the t-butyl groups of this salt appears in high field relative to tetramethylsilane and is therefore not superimposed on the signals of the test substances. Moreover, the paramagnetic shifts to low field induced by $Eu(DPM)_3$ are more suitable from the experimental standpoint. $Pr(DPM)_3$ should be used in addition to $Eu(DPM)_3$, particularly for the assignment of the signals of the t-butyl groups in the spectra of steroids. One must note that the signal of the t-butyl groups of $Pr(DPM)_3$, which

§ See also Refs. 75–77.

appears in the region of 3–5 p.p.m. (δ), may be superimposed on the signals of the test compounds. Conditions governing the use of $M(DPM)_3$ (solubility¶, effect of H_2O, etc.) have been described [74,78]. The stoichiometry in the solute (test substance)–shift reagent system has been analysed in a number of publications. It has been established [80] that, when the ligand concentration is much higher than that of the shift reagent, the paramagnetic complexes have the 1 : 2 composition and not 1 : 1, as believed by Armitage et al. [81] Shapiro and Johnston [80] also examined in detail the use of the relation between the observed paramagnetic shifts and the ratio of the ligand and lanthanide concentrations. Careful analyses of the application of the $M(DPM)_3$ complexes as displacing agents and also of the scope of the method have been made [75,82].

The investigations showed that the paramagnetic shifts induced by lanthanides depend significantly on the structure of the diketone [82–84]. It was established that the tris-[3-t-butylhydroxymethylene-(+)-camphorato]europium can be used to determine the degree of enantiometric purity [85]. However, its applicability proved to be limited [86,87] Tris-[3-heptafluoropropylhydroxymethylene-(+)-camphorato]europium proved to be a more effective optically active displacing agent [86]. At the same time the use of $Eu(DPM)_3$ for similar purposes can also be successful [87]. A comparison of $Eu(DPM)_3$, $Eu(FOD)_3$ [FOD = tris(1,1,1,2,2,3,3-heptafluoro-7,7-dimethyloctane-4,6-dionato)europium], and $Eu(FND)_3$ [FND = tris-(1, 1, 1, 2, 2, 6, 6, 7, 7, 7-decafluorheptane-3,6-dionato]europium has been made [76].

It was noted in Section II that in the general case the paramagnetic shifts δ′ and the broadening Δ of the resonance lines observed in the NMR spectra are defined by Eqns. (16) and (17). On the other hand, the practical employment of δ′ and Δ is based on Eqns. (18)–(24) the validity of which is determined by the nature of the paramagnetic complex and the temperature of the test specimens. For lanthanide complexes, this problem has been hardly discussed in the literature. Only the effect of varying temperature has been reported [57,71,77,88–92]. In this connection the effect of the specimen temperature on the paramagnetic shifts induced by $Eu(FOD)_3$ in the ^1H NMR spectra of limonoids is of interest [88]. It was found that, with increase of temperature, the δ′ for the signals of certain protons increase. This finding was regarded [88] as unexpected on the grounds that the paramagnetic shifts are inversely proportional to the temperature of the test specimen (Section II). However, in the case of a slow exchange an increase of temperature leads to a decrease of τ_M and therefore δ′ in the NMR spectra should increase. In particular, when the spectrum of the ligand molecule contains signals with significantly different values of ω, cases are possible for which Eqns. (16) and (17) can be represented approximately by different expressions from the set of Eqns. (18)–(24). Therefore the determination of the $\delta' = \delta'(T)$ relation may be not only desirable but also essential.

NMR studies on other nuclei (other than the proton) with addition of lanthanide complexes have already been published. The effect of $Eu(DPM)_3$ and $Yb(DPM)_3$ on the ^{14}N NMR spectra of pyrrolidinone, n-propylamine, pyridine, *N*-methylimidazole, acetonitrile, and dimethylformamide has been examined [93]. Briggs et al. demonstrated the effectiveness of the interpretation of ^{13}C NMR spectra with the aid of tris(dipivaloylmethane)lanthanides [94]. Duggan and Urry [95] used the paramagnetic shifts induced by $Eu(DPM)_3$ in the ^{13}C NMR spectra for structural investigations. A method of assignment of the ^{13}C NMR signals based on the joint use of $M(DPM)_3$ and $^{13}C-\{^1H\}$ heteronuclear double resonance has also been proposed [96]. Mention should be made of the work by Sanders and Williams [97] concerning the nature of the shift induced by lanthanides in the ^{31}P NMR spectra. In particular they established that $Eu(NO_3)_2{\cdot}6H_2O$ is an effective shift reagent in polar solvents for compounds with a $X-O^-$ (X = R–CO, $R_3\overset{+}{P}$, or $R_3\overset{+}{A}s$) functional group. Interesting results were obtained in studies [98,99] in which the isotope effect of deuterium on the paramagnetic shifts induced in NMR spectra by lanthanide complexes was considered. Mention should also be made of the work by Willcott and coworkers [100,101] who considered a statistical method for the analysis of paramagnetic shifts induced by lanthanide complexes. Finally a fairly complete list of publications in 1969–71 and also some of the publications in 1972 can be found in studies [102,103] on the use of shift reagents.

The following remarks must be made in conclusion. Firstly, the change in the relative contents of the ligand and the lanthanide within wide limits can influence significantly the constancy of the composition of the complex in solution. Secondly, X-ray diffraction analysis of the complexes† $Ho(DPM)_3{\cdot}(VIII)_2$ [104] and $Eu(DPM)_3{\cdot}(IX)$ [105] showed that the paramagnetic lanthanide complexes used as shift reagents can have a symmetry other than axial‡. For example, Uebel and Wing [105] found agreement between the experimental and calculated (for axial symmetry) paramagnetic shifts only for a signal assignment known to be incorrect. Thirdly, the nature of the electron-nuclear interaction in lanthanide complexes with organic ligands has been comparatively little investigated, in contrast to the complexes of the first transition series. The majority of investigators do not think it obligatory to resort to a contact mechanism in order to account for the nature of the paramagnetic shifts induced by lanthanide complexes. However, according to one view, the contribution of the contact interaction to the paramagnetic shifts induced by lanthanide complexes may be significant [20,21,72]. Therefore, caution must be exercised in using the paramagnetic shifts induced in the NMR spectra by lanthanide complexes for structural investigations. If the paramagnetic complex is used only to increase the ratio of the difference between the chemical shifts and the spin–spin interaction constants, it is sufficient to record the NMR spectrum of the test substance with one or several additions of the shift reagent. However, one must bear in mind that coordination to the lanthanide may influence the spin–spin interaction constants for the nuclei in the ligand molecule [107]. The suggestion that germanium–porphyrin systems be employed as shift reagents is interesting [108]. Maskasky and Kenney [108], who described a method for the formation of such systems, note, in particular, that they are diamagnetic, and, in contrast to the paramagnetic displacing agents, do not broaden the resonance lines in the NMR spectra.

---o0o---

The paramagnetic complexes of lanthanides can be used to facilitate significantly the interpretation of NMR spectra,

¶ For the use of carbon disulphide as a solvent, see Walters [79].

† (VIII) = 4-picoline; (IX) = 1,2-epoxy-3,3-dimethylethane.

‡ See also Honeybourne [106].

which extends the scope of the NMR method in the study of the structures of organic ligands. Further progress in the use of shift reagents requires a more profound study of the nature of the electron-nuclear interaction in the paramagnetic lanthanide complexes. The name of the method (the shift reagent method), which has become common in the literature outside the Soviet Union, reflects exactly the consequences of the use of lanthanides. However, bearing in mind the nature of the shifts and the broadening of the resonance lines, the method based on the characteristics of the NMR spectra of paramagnetic systems should be logically termed the method of paramagnetic additives.

The NMR spectrum analysed frequently satisfies the requirements for first-order spectra but its interpretation is ambiguous owing to the uncertainty of the molecular geometry. In such cases the use of complexes of elements in the first transition series for the structural determination of organic ligands may also prove to be effective.

Non-empirical Calculations of the Geometry and Conformations of Polyatomic Molecules

V.G.Dashevskii

Non-empirical methods for the calculation of the geometry, barriers to internal rotation, and conformation energies of polyatomic molecules are discussed. It is shown that the geometry can be predicted with adequate accuracy by calculations with "moderate" basis sets. Reliable estimations of barriers to internal rotation and of conformational energies require in general considerably larger basis sets. Several procedures for combining quantum-mechanical integrals are considered and the "nature" of the barriers is analysed from this standpoint.
The bibliography includes 174 references.

I. BASIS SETS EMPLOYED IN *AB INITIO* CALCULATIONS

The previous review[1] dealt with the self-consistent field approximation and the Roothaan equations of the LCAO-MO method, on which modern calculations of the electronic structures of molecules are based, were discussed. These equations will serve as our starting point. However, in the analysis of non-empirical *ab initio* calculations one should note certain factors which are less important in semiempirical theories.

In the Hartree–Fock approximation for a molecule with a closed electronic shell, the wave function Ψ is represented by the antisymmetrised products of the spin-orbitals (SMO) Ψ_i or the Slater determinant

$$\Psi = \frac{1}{\sqrt{N!}} |\psi_1\bar{\psi}_1\psi_2\bar{\psi}_2 \ldots \psi_{N/2}\bar{\psi}_{N/2}| \qquad (1)$$

where N is the number of electrons.

There are of course no conditions under which function (1) can be an exact wave function of the molecule whatever are the exact individual SMO; also the energy defined by this function differs from the true total energy. The difference between the Hartree–Fock energy and the energy corresponding to the exact wave function has come to be called the correlation energy. As a rule, the correlation energy of a molecule is greater than the sum of the correlation energies of its constituent atoms[2,3].

The exact wave function can be approached only by going outside the framework of the single-configuration approximation (one Slater determinant is usually termed a configuration). Thus in the configuration interaction method the molecular wave function is assumed to be

$$\Psi = C_1\Psi_1 + C_2\Psi_2 + \ldots, \qquad (2)$$

where Ψ_i is one of the configurations defined as the antisymmetrised product of the spin-orbitals. The coefficients C_i can be found by the variational method[4,5], but this procedure is extremely laborious, since series (2) converges slowly. For this reason, the exact wave functions are usually sought only for atoms and diatomic molecules. On the other hand, when considering polyatomic molecules the treatment is as a rule confined to the Hartree–Fock approximation.

The second assumption usually made in quantum-mechanical calculations on molecules involves the representation of the molecular orbitals, i.e. the spatial component of the spin-orbitals Ψ_i, by a linear combination of atomic orbitals (LCAO):

$$\varphi_i = \sum_{\nu=1}^{m} c_{i\nu}\varphi_\nu \qquad (3)$$

where φ_ν are the atomic orbitals (AO) the set of which is termed the basis set.

The LCAO approximation imparts to the wave function of the molecule a specific analytical form and in addition the Hartree–Fock formulation presupposes that the best molecular orbitals of the Slater determinant are found. However, it has been shown for other examples[5-7] that, when the basis set is sufficiently large (and also flexible), then the LCAO procedure can yield the Hartree–Fock energy to within about 0.5%. The minimum energy attainable by increasing the basis set has come to be called the Hartree–Fock limit, although in fact this is more correctly the limit of the LCAO-MO approximation and not at all the Hartree–Fock energy of the molecule.

All the calculations discussed below are based on the above two approximations. The LCAO-MO approximation for molecular properties such as geometry and conformational energies, expressed in terms of the Roothaan equation, is quite acceptable. It is shown below that, for a sufficiently large number of atomic orbitals in Eqn.(3), these properties can be calculated with "chemical" accuracy, i.e. with an accuracy characteristic of experimental determinations. The procedures used to go outside the framework of the above approximations are only briefly discussed at the end of the review and the possible limits of the errors are indicated.

We shall now consider the atomic orbitals entering into Eqn.(3). In the course of more than two decades (since the end of the 1920's) Slater type functions (STO≡Slater type orbitals) have been used in all quantum-mechanical calculations on molecules:

$$\varphi = Ar^{n^*-1}e^{-\zeta r}Y_{l,m}(\theta, \varphi) \qquad (4)$$

where n^* is the effective principal quantum number, A a

normalising factor, and $Yl,m(\theta,\varphi)$ are spherical harmonics. In the radial component of the STO r is the distance from the centre and ζ the orbital exponent. The STO are known to be close in form to the true Hartree–Fock atomic orbitals which are in turn obtained by a numerical calculation and have been tabulated long ago for many atoms: at any rate, at short and long distances from nuclei, the STO are virtually identical with the tabulated data. The search for the STO contants most effective in molecular calculations has continued, since the 1930's, i.e. since the time when Slater[7] proposed formulae for the calculation of n^* and the screening constants γ entering into the orbital exponents [$\xi = (Z_e - \gamma)/n^*$, where Ze is the nuclear charge]. Clementi and Raimondi[8] tabulated the STO constants found by minimising the atomic energy up to krypton inclusive. In later studies[9,10] the STO constants were selected by taking into account the properties of the atoms in molecules.

It would appear that the STO should be ideally suitable for calculations on polyatomic molecules, since the use of a slightly extended basis set makes it possible to obtain a wave function close to the true Hartree–Fock function and on energy differing only slightly from the Hartree–Fock limit. However, the application of the STO involves mathematical difficulties associated with the calculation of many-centre integrals. Indeed it has been shown[1] that the matrix elements of the Hartree–Fock operator include the integrals $(\mu\nu/\lambda\delta)$

$$(\mu\nu/\lambda\sigma) = \int\int \varphi_\mu^*(1)\varphi_\nu(1)(r_{12})^{-1}\varphi_\lambda^*(2)\varphi_\sigma(2)\,d\tau_1 \cdot d\tau_2 \qquad (5)$$

in which there are orbitals centred on different atoms. The evaluation of one- and two-centre integrals does not present special difficulties: as a rule, they can be estimated rapidly and accurately[11–13]. However, the evaluation of three- and four-centre integrals is difficult. Although several methods have been proposed for their estimation[14,15], until recently the evaluation of each integral required on average about 1 s even on the most powerful modern computers. Moreover, the number of two-electron integrals arising in the solution of the Hartree–Fock LCAO-MO problem is of the order of N^4, where N is the number of orbitals; for example, in the case of a basis set of 20 orbitals the number of integrals is 22 155 and for a basis set of 50 orbitals the number is 814 725. The total time required for the solution of the Roothaan equations using the STO for polyatomic molecules naturally becomes very long. Therefore in the last decade Gaussian type orbitals, in which the radial component is proportional to $\exp(-\alpha r^2)$ and not to $\exp(-\zeta r)$, have come to be widely used. Namely

$$\varphi = A(\alpha)\, r^{n-1} \exp(-\alpha r^2)\, Y_{l,m}(\theta, \varphi) \qquad (6)$$

where

$$A(\alpha) = 2^{n+1}[(2n-1)!!]^{-1/2}(2\pi)^{-1/4}\alpha^{(2n+1)/4}, \qquad (7)$$

and the functions $Yl,m(\theta,\varphi)$ are in this case exactly the same as in Eqn. (4).

Although the Gaussian type orbitals (GTO Gaussian type orbitals) describe incorrectly the distribution of electron density near the nuclei and at long distance from them, the evaluation of the $(\mu\nu/\lambda\delta)$ integrals no longer presents special difficulties. It is probable that the GTO, introduced into practical molecular calculations by Boys[16] and Meckler[17], have in fact made it possible to achieve in quantum chemistry an approach to the solution of the Hartree–Fock problem for polyatomic molecules, including organic molecules[18].

It is not surprising that generally speaking the Slater basis set gives a more adequate description of molecular properties than the Gaussian basis set because the STO are close in form to the Hartree–Fock orbitals. The use of the minimal Guassian basis set (one function for each electron) results in a difference of 10–20 eV between the total energy of comparatively small molecules and the Hartree–Fock limit, whereas the difference for the minimal STO basis set is only 1–2 eV. Thus much effort has been expended in attempts to approximate the Slater orbitals in terms of the Gaussian orbitals and thereby achieve the best approximation to the Hartree–Fock limit. This idea constitutes the basis of the STO-N G method[19,20], in which each STO is replaced by N GTO.

The expansion of the Slater functions φ_S in terms of the Gaussian functions φ_g can be represented in the form

$$\varphi_s = \sum_{i=1}^{N} c_i \varphi_{g,i}, \qquad (8)$$

where c_i are the expansion coefficients and N is the parameter of the STO-N G method. Huzinaga[21] showed that, for the hydrogen atom, 6–10 GTO of 1s and 2p types yield virtually the same energy as a single STO, and determined the coefficients c_i. Subsequently Stewart[32] obtained the c_i constants also for other atoms.

The choice of N in non-empirical calculations by the STO-N G method constitutes a special problem and depends on the property which must be estimated. Experiment shows that the average time required for the evaluation of many-centre integrals with GTO is approximately 1000 times less than for computation with STO. Thus, on replacing each STO by N Gaussian type orbitals, the time gain is approximately by the factor $1000/N^4$. It is easy to calculate that the STO-2G method leads to a reduction of the time of computation by a factor of 60, the STO-3G method by a factor of 12, and the STO-4G method by a factor of 4. The STO-N G methods with $N = 5, 6, \ldots$ are no longer effective and, in order to obtain the required accuracy, it is necessary to employ the STO or, even better, an extended basis set which can be made up of both STO and GTO. Subsequently it will be shown that, for adequate estimates of many properties of polyatomic molecules including their geometry, it is sufficient to introduce 3–4 GTO for each STO.

However it is absolutely obligatory to select Gaussian basis sets in such a way that they are close to the corresponding Slater basis sets. One can begin with the condition that, provided that the Gaussian basis sets are sufficiently large, they yield a fair approximation to the Hartree–Fock limit and make it possible to predict with satisfactory accuracy the properties of polyatomic molecules. Several methods of formulating such basis sets are discussed below.

Finally one should note that comparatively recently considerable advances have been achieved in the evaluation of many-centre integrals $(\mu\nu/\lambda\delta)$ in which $\varphi\mu$, $\varphi\nu\ldots$ are the STO.[23–25] Therefore in the near future one may expect the resumption of non-empirical calculations of electronic structure, geometries, conformation energies, and other properties of polyatomic molecules with the aid of Slater basis sets. Examples of such calculations already exist[26,27].

We shall now enumerate several methods of formulating the basis set which have become common in calculations of the geometries and energies of polyatomic molecules. The results of their application and the comparative assessment of their effectiveness are discussed in succeeding sections.

1. The Slater basis set. The orbital exponents ζ are optimised with respect to the atomic energies and are assumed to be unchanged in molecular calculations; in the solution of the Roothaan equations only the coefficients $c_{i\nu}$ in Eqn. (3) are varied. Both limited (minimal)[28,29] and expanded[27] basis sets are employed in the calculations.

2. The "double-zeta" basis set. The exponential factor in the STO, $\exp(-\zeta r)$, is replaced by a linear combination of two exponents—$\exp(-\zeta_1 r)$ and $\exp(-\zeta_2 r)$. The optimal values of ζ_1 and ζ_2 have been found[30,31] for atoms with $Z \leqslant 36$ and they are assumed to be fixed in molecular calculations, only the LCAO coefficients being varied.

The basis sets discussed below are constructed from Gaussian type functions.

3. Basis sets of the STO-N G type. The problem of which values of N are to be adopted in order to obtain satisfactory estimates of molecular properties was investigated by Pople and coworkers[32-35] in relation to such properties as the geometry, barriers to internal rotation, dipole moments, and Mulliken populations. It was found that the STO-3G method yields a satisafactory approximation of the STO.

4. The LEMAO-N G basis sets (LEMAO ≡ least energy minimal atomic orbitals)[36,37]. For each atomic orbital, one introduces N GTO, the parameters of which correspond to the minimum energy of the atom. For $N \to \infty$, the energy of the molecule calculated using this basis set must necessarily tend to the Hartree–Fock limit, while in the STO-N G method the Hartree–Fock limit cannot be attained in principle for $N \to \infty$ when the Slater basis set is limited. However, specific calculations have shown[37] that the convergence of the LEMAO-N G method with increase of N is extremely slow: for low values of N (3, 4, 5), the STO-N G method is more effective; on the other hand, there is no point in a further increase of N, since the time required to calculate the total energy increases rapidly and it is then better to employ an extended Slater basis set.

5. The 4-31 G basis set[38,39]. It is constructed as follows: each orbital of the inner shell is represented by the sum of four Gaussian type functions and the valence shell orbitals are divided into two groups. The orbitals of the first group are described by three GTO and those of the second group by one GTO (in particular four GTO are required for the H atom and twenty GTO are required for the C atom). The coefficients of the expansion in terms of GTO are found from the condition for the minimum energy of the atom in the ground state. The 4-31 G basis set is more flexible than STO-3G but at the same time it is much more "expensive". This basis set yields a lower energy and, what is most important, gives satisfactory differences between the energies of various nuclear configurations. Therefore, as shown in Sections II and III, it is entirely suitable for very accurate calculations of molecular geometry, conformational energies, and particularly barriers to internal rotation.

6. The contracted Gaussian basis set. Apart from the 4-31 G basis set, one can of course employ also other extended Gaussian basis sets, and the greater the number of functions introduced for each orbital the greater the accuracy of the prediction of various molecular properties. However, an increase of the basis set entails a sharp increase of computer time. It has therefore been suggested that the Gaussian functions be grouped and that not all the coefficients $c_{i\nu}$ entering into Eqn. (3) be varied, but only those which refer to the given groups of functions[40-43]. The number of Hartree–Fock equations is then significantly reduced.

The employment of contracted basis sets permits the calculation of the structures and properties of large organic molecules. For example, the energies of various conformations of cyclo-octatetraene, whose molecule consists of 8 carbon atoms and 8 hydrogen atoms, have been calculated[44]. The authors employed five s-type and two p-type Gaussian functions for each carbon atom and two s-type functions for each hydrogen atom. This basis set can be naturally designated by (5.2/2). As a result of the "contraction" procedure, this basis set was reduced to (2.1/1) and the number of Hartree–Fock equations was decreased from 72 to 32. The coefficients within each group and the orbital exponents are usually taken from calculations for simpler molecules and are assumed to be fixed. Thus the same group functions were employed for cyclo-octatetraene as for ethylene.

7. The "lobe" GTO basis set. Whitten[40] proposed Gaussian type basis sets the orbitals of which are not centred on atoms but on certain other points in space. The possibility of employing such basis sets depends on the fact that spherically asymmetric orbitals can be imitated with some approximation by a linear combination of spherically symmetrical Gaussian functions. The spherical harmonics $Yl,m(\theta,\varphi)$ in quantum-mechanical calculations then disappear and the calculation of the integrals is significantly simplified. Thus instead of p orbitals it is possible to introduce two s-type "lobes" or two "petals" the centres of which are located on a straight line passing through the nucleus at equal distances from the latter; instead of d orbitals, it is necessary to introduce now at least four "lobes". Calculations with such basis sets then yield a fairly low total energy, provided that the number of "lobes" is fairly large. Examples of the calculation of the geometry of polyatomic molecules using the "lobe" GTO basis sets have been described[45-50].

8. The "floating orbital" basis set. So far we have considered atomic orbitals with fixed exponents and centres and the molecular orbitals were optimised only with respect to the LCAO coefficients. Nevertheless it is clear that, when the molecular orbitals are also optimised in respect of the orbital exponents and the positions of the centres of the atomic orbitals, one can achieve a closer approximation to the Hartree–Fock wave function. However, this complicates the procedure in the adjustment for self-consistency: it is necessary to solve the Roothaan equation separately for various exponents or to carry out a direct minimisation of the Hartree–Fock functional by numerical methods.

Frost[51-53] proposed a model constructed on the basis of a one orbital–one Gaussian function principle. The limitation of the basis set of this model is to some extent compensated by its flexibility, since, together with the LCAO coefficients, the parameters α_i in Eqn. (6) and the positions of the atomic orbital centres are varied. The geometry of the molecule is determined by direct minimisation of the total energy with respect to independent geometrical parameters describing the positions of the nuclei and with respect to the orbital exponents α_i. As

shown in Section II, the model of "floating Gaussian orbitals" leads to surprisingly satisfactory results owing to the "liberation" of the parameter α_i, despite the fact that, in consequence of the vast limitation of the basis set, one is still a long way from the Hartree–Fock limit.

9. Ellipsoidal Gaussian basis sets. If instead of traditional Gaussian functions (6) one employs ellipsoidal Gaussian functions[54,55], then inclusion of a comparatively small number of orbitals will presumably yield even more satisfactory geometry and energy, which do not differ markedly from the Hartree–Fock parameters. Such functions are of the form

$$\varphi_l = x_l^{\lambda_l} \exp[\alpha_l x_l^2 + \beta_l y_l^2 + \gamma_l z_l^2], \quad (9)$$

where x, y, and z are the local cartesian coordinates of the ith function and α, β, γ, and λ are the parameters varied. The ellipsoidal basis set is more flexible than the floating orbital basis set and it can therefore probably find application in conformational problems.

II. CALCULATION OF THE EQUILIBRIUM GEOMETRY OF POLYATOMIC MOLECULES

Among all the molecular properties, geometry is the most "predictable". "Predictability" must be understood in the sense that, even for very small basis sets and for very unsatisfactory orbitals, the solution of the Hartree–Fock problem yields a reasonable agreement with experiment: the deviations rarely exceed 0.1 Å in bond lengths and several degrees in valence angles. The only difficulty is that in the calculation of the geometry the total energy must be calculated more than once. If there are several geometrical parameters, it is either necessary to plot a network of values of a very complex function (total energy) or direct minimisation methods must be employed. The solution of the latter problem for molecules of any complexity is still unrealistic and therefore in non-empirical calculations one must restrict the treatment to the simplest systems. Apart from the multidimensionality of the problems, one must bear in mind that the time required to calculate the energy increases very rapidly with molecular size—much more rapidly than in empirical and semiempirical methods.

Nevertheless it is easier to calculate the geometry than any other molecular property: the total energy may be approached only by very laborious calculations by the method of configuration interaction; even an approach to the Hartree–Fock limit requires calculations with very large and very carefully selected basis sets; nor is it easy to predict with satisfactory accuracy the distribution of electron density and dipole moments; finally, in order to obtain satisfactory energy differences (bond energies, barriers to internal rotation, and conformational energies), large and fairly reliable basis sets are necessary (in estimates of bond energies one must also take into account correlation effects).

The accuracy of the prediction of molecular geometry depends on the type and size of the basis set employed in the Roothaan equations. The use of Slater orbitals permits a greater accuracy of the calculation of the bond lengths and valence angles corresponding to the total energy minimum. Even better results are obtained when one uses an extended Slater basis set taking into account the polarisation of electrons, i.e. $2p$ functions are included in addition to the s functions of the hydrogen atom and d functions are included in addition to the $2s$ and $2p$ functions of the carbon atom. However, both allowance for polarisation and calculations with STO are too "expensive". Therefore the majority of quantum-mechanical calculations on polyatomic molecules have been carried out with Gaussian type basis sets.

In the search for the equilibrium geometry of polyatomic molecules, it is reasonable to try to restrict the treatment to comparatively small basis sets, since the total energy must be calculated many times. Thus Pople and coworkers[36,56] constructed a network of total energy values at 0.05 Å intervals for bond lengths and at 5° intervals for valence angles; they then subdivided the network at 0.01 Å and 0.1° intervals after which they carried out a quadratic interpolation, which resulted in an average error of about 0.001 Å in bond lengths and about 0.1° in valence angles. Frost[52,53] sought the minimum in the Hartree–Fock functional with respect to natural molecular coordinates (bond lengths, valence angles, and angles of rotation) and orbital exponents using the extremely effective Powell method[57]. Minimisation methods designed specially for quantum-mechanical calculations on molecules have been proposed[58,59]. The use of these methods makes it possible to reduce significantly the number of returns to the procedure function (total energy) and thereby reduce computer time compared with the time required to construct the network. The advantage of direct minimisation consists also in the fact that the derivatives of the Hartree–Fock function required for the selection of the direction of the descent contain the same integrals as the function itself and therefore a considerable proportion of the expensive minimisation process is carried out "free".

Table 1. Comparison of the bond lengths and valence angles calculated using different Gaussian basis sets.

We shall now consider the results of calculations of the geometries of certain simple polyatomic molecules and shall attempt to determine which basis sets are adequate

for satisfactory estimates of bond lengths and valence angles. Table 1, which is based on a number of literature data [32,36,56,60], compares the geometrical parameters obtained with the aid of various Gaussian type basis sets—LEMAO-3G, LEMAO-5G, STO-2G, STO-3G, STO-4G, and 4-31G. Table 1 shows that the LEMAO-5G method, let alone the LEMAO-3G method, is somewhat inferior to the STO-3G and 4-31G methods in terms of agreement with experiment: the HNH valence angle in the ammonia molecule is unduly high and the C–C bond in the ethane molecule and the C=O bond in the formaldehyde molecule are too long. Consequently preference must be given to the STO expansion compared with the Gaussian type orbitals even when the latter are optimised with respect to the atoms. The convergence of the STO-N G methods with increase of N is very rapid: judging from the few data obtained by Baird [60], even within the framework of the STO-2G method, it is possible to achieve a fairly satisfactory agreement with experiment and with further approximations by the STO-N G method. One can therefore formulate the problem of the calculation of the equilibrium geometry by the relatively rough STO-2G method with the aim of investigating "less predictable" properties for this geometry—the energy, electron density, etc.—by the STO-N G method with $N > 2$ and the very "expensive" 4-31 G method.

Table 2. Bond lengths and valence angles calculated by the STO-3G method [56].

We shall consider in greater detail the results obtained with the aid of the STO-3G method. They are presented in Tables 1 and 2, the latter of which is based on the results of Newton et al. [56] In the first place mention must be made of the satisfactory agreement between the calculated and experimental bond lengths and valence angles in hydrocarbon molecules. Consequently, for the prediction of the structures of these molecules, the minimal Slater basis set (or a slightly "degraded" STO-3G basis set) prove to be entirely satisfactory. The situation is worse for molecules containing electronegative atoms or atoms with lone electron pairs. Thus the changes in the C–F bond lengths in fluoroethanes are not quite accurately represented; the bond length in the HF molecule is also excessive. The calculation does not predict the sharp shortening of the O–O bond on passing from H_2O_2 to O_2F_2; the theoretical O–F bond length in the O_2F_2 molecule is much smaller than the experimental value. The calculated valence angles do not nevertheless differ much from the experimental values even in the most unfavourable cases. However, the greatest discrepancies are again characteristic of the fluorine-and oxygen-containing molecules; in particular the calculated HOO angle in the hydrogen peroxide molecule is 6% greater than the experimental value.

The question arises of the causes of the unsatisfactory agreement with experiment for fluorine- and oxygen-containing molecules. The calculations carried out by Allen's group for simple molecules [45–50] have shown that the main reason is the limitation of the basis series: when orbitals for vacant shells are introduced, the agreement with experiment can be greatly improved. Another reason is of course the correlation effects, but these are probably small. Presumably, after the attainment of the Hartree–Fock limit, the calculated molecular geometry, including that of fluorine- and oxygen-containing derivatives, should virtually agree with the experimental geometry.

Yet another confirmation of the above hypothesis is provided by a study [61] in which the Hartree–Fock calculations were carried out for molecules as complex as that of formamide ($HCONH_2$). The basis series of these calculations included eleven s-type and seven p-type Gaussian functions for the C, N, and O atoms (one d orbital was taken into account for each of the three nuclear configurations): five s-type functions and three p-type functions were considered for the hydrogen atom. After carrying out the calculations for 44 nuclear configurations, the authors showed that the minimum total energy does indeed correspond to the observed experimental geometry of the formamide molecule.

Returning now to the assessment of the results obtained by the STO-3G method, we may note that, despite the observed deviations for several molecules, the agreement between the calculation and experiment is very good. For thirty molecules incorporating 75 individual bonds and angles, Pople and coworkers [56] obtained average deviations of 0.035 Å in the bond length and 1.7° in the valence angles. This is of course much better than can be obtained by different versions of the ZDO method [1] and particularly the CNDO method. Yet another evident advantage of the STO-3G method compared with ZDO is the absence of an arbitrary choice of parameters; the *ab initio* calculations employ only the fundamental constants e, m, and h.

Thus the STO-3G method is entirely satisfactory for the prediction of molecular geometries, at least those of hydrocarbons. The STO-2G method is apparently also fairly satisfactory. The question arises whether one could make do with only one Gaussian type function. Frost [51–53,62,63], who investigated this interesting problem, was able to show that the basis constructed from "floating orbitals" leads to a fairly acceptable accuracy of the calculation of the geometries of simple hydrocarbons, despite the fact that the total energy calculated in terms of this approximation amounts to only 85% of the Hartree–Fock energy. Table 3 presents the geometrical parameters of the five molecules found by Frost [53] by direct minimisation of the Hartree–Fock functional. It is readily seen that the calculations with a very small but flexible basis set yield an entirely reasonable agreement with experiment, which is only slightly worse than that obtained by the STO-3G method. Thus an increase of the sensitivity of the basis set achieved by varying the exponent can lead to a no less effective improvement of the calculations than an increase in the size of the basis set. For STO, this procedure is probably not quite so

effective, since the atomic exponents in the STO do not differ markedly from the optimal exponents of the atomic orbitals in molecules.

The use of floating orbitals is particularly promising in studies on the geometries of large hydrocarbon molecules. Nelson and Frost[64] found the optimal parameters of the wave function of propane and, having transferred them to n-butane and isobutane, obtained entirely satisfactory geometries of these molecules: the calculated CCC angle in n-butane was found to be 112.5° compared with the experimental value of 112.2°,[65] the corresponding values for isobutane being 111° and 111.5°.[66] The total energy was minimised only with respect to the natural molecular coordinates and the orbital exponents and even the expansion coefficients of the molecular orbitals in terms of the atomic orbitals were assumed to be fixed.

Table 3. Geometrical parameters of hydrocarbons calculated by the method of "floating Gaussian orbitals"[53].

Molecule	Bond or angle	Bond length (Å) or angle	
		calc.	expt.
Methane	C—H	1.115	1.085
Ethane	C—C	1.501	1.531
	C—H	1.120	1.096
	HCH	108.2°	107.8°
Ethylene	C=C	1.351	1.330
	C—H	1.101	1.076
	HCH	118.7°	116.6°
Acetylene	C≡C	1.214	1.203
	C—H	1.079	1.061
Cyclopropane	C—C	1.533	1.51
	HCH	114.4°	114.4—115.1°

The calculation on cyclobutane, the molecular geometry of which has been the subject of controversy for a long time, is very interesting. Only comparatively recent studies[67-69] demonstrated the non-planar structure of the four-membered ring (according to experimental data, the dihedral angle is 27—35°). Calculation[64] by the floating orbital method showed that, for the non-sectorial disposition of the HCH valence angle (Fig. 1), the planar form is less favourable than the non-planar form and only when the "tilting" of this angle is introduced as an independent parameter does the non-planar form with a dihedral angle of 32° correspond to the minimum total energy. Calculation predicts a 7° tilt (which can be readily seen from the angle shown in Fig. 1), while the experimental value[70] is 4°.

Thus calculations with very small basis sets in many cases yield an approximately correct geometry. One must not of course overestimate the scope of the floating orbital method. This method is virtually unsuitable for calculations on molecules containing lone electron pairs and molecules with conjugated bonds. The barriers and conformational energies are as a rule found to be twice as high as they should be. Thus the planar form of cyclobutane is found to be less stable than the non-planar form by 3.5 kcal mole^{-1}, while the experimental barrier to ring inversion is 1.48 kcal mole^{-1}.[68]

One should note that during the last 2—3 years many non-empirical calculations have been made on the geometry of molecules of moderate dimensions. 1,4-Dioxane[71], the planar structure of which has been predicted by the method of floating Gaussian type orbitals, and also cyclo-octatetraene mentioned above[44] may be quoted as examples. The theoretical equilibrium geometry of cyclo-octatetraene in the boat conformation (D_{2h}) is defined by the following parameters: r(C=C) = 1.340 Å, r(C—C) = 1.507 Å, and $\angle$CCC = 127.37°: these agree extremely well with the experimental parameters[72] 1.340 Å, 1.476 Å, and 126.1° respectively. The planar form of this molecule has an energy higher by 17.8 kcal mole^{-1} than that of the boat form, which is in good agreement with the experimental activation energy for ring inversion (12—15 kcal mole^{-1}).[73-76] Finally, mention should be made of calculations of the geometries of bicyclic and tricyclic hydrocarbon systems[77]: bicyclobutane, tricyclo[1,1,1,0^{1,3}]pentane, and bicyclo[1,1,1]pentane. These systems are interesting because their valence angles are highly deformed and the non-bonded atoms are very close to one another. Within the framework of the molecular force field model, it is impossible to achieve for these systems an adequate agreement between calculation and experiment[78]. Nevertheless, the employment of a contracted Gaussian basis set makes it possible to estimate the equilibrium geometry with a fairly high accuracy.

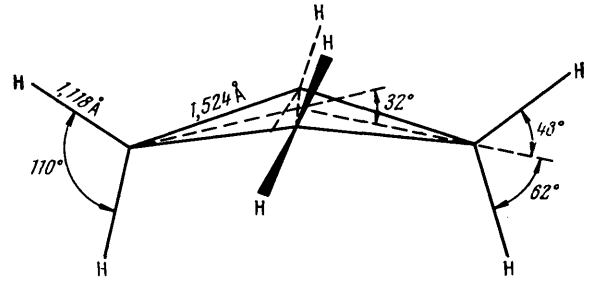

Figure 1. The calculated equilibrium geometry of the cyclobutane molecule.

III. BARRIERS TO INTERNAL ROTATION AND CONFORMATIONAL ENERGIES

Experience gained in quantum-mechanical calculations has shown that the energy associated with a molecular geometry is more sensitive in relation to the choice of the basis than the equilibrium geometry itself. Therefore, generally speaking, a satisfactory prediction of conformational energies and in particular of barriers to internal rotation requires fairly large basis sets. At any rate, the floating orbital method, constructed on the basis of the one orbital—one function principle, is clearly inadequate in this instance. It will be shown in this section that the conformational energy of any molecule can be predicted in very good agreement with experiment, provided that the chosen basis set is fairly large. This means that, when the wave function is such that the total energy is very close to the Hartree—Fock limit, the total energy differences correspond to the experimental conformational energies

and consequently the correlation effects play virtually no role.

We shall consider initially ethane—the "classical" molecule for which non-empirical calculations have been made more frequently than for any other. The complete calculation of the Hartree–Fock energies of the eclipsed and staggered forms of ethane was made for the first time by Pitzer and Lipscomb [28], who employed 16 STO: 1*s* functions for the hydrogen atom and 1*s*, 2*s*, and 2*p* functions for the carbon atom. For this basis set, taking into account the intrinsic molecular symmetry, it was necessary to calculate more than 1200 integrals in each form, a problem which appeared exceptionally difficult at the time. This was the first non-empirical calculation of a barrier to internal rotation and the resulting good agreement with experiment (3.3 compared with 2.93 kcal mole^{-1}) appeared promising.

Clementi and Davis [79] were the first to employ Gaussian type orbitals. After carrying out calculations with various basis sets, they concluded that the barrier is almost insensitive to a change of basis set. After this, it became clear that the agreement with experiment achieved by Pitzer and Lipscomb was by no means fortuitous: the Clementi and Davis basis sets led to a higher total energy (which was reasonable to expect from GTO), but the barrier differed from the experimental value by not more than 20% in all cases.

Table 4 summarises the results of seven computations of the total energies of the staggered and eclipsed forms of ethane. Veillard[84], who employed a very large Gaussian basis set with eleven *s*-type and seven *p*-type orbitals for the carbon atom and six *s*-type functions for the hydrogen atoms, obtained the smallest energy; moreover, $3d_{xz}$ and $3d_{yz}$ correlation functions for carbon atoms with an exponent of 1.5 and $2p_x$, $2p_y$, and $2p_z$ functions for the hydrogen atoms with an exponent of 1.0 were introduced. The resulting basis set, consisting of 122 functions, was contracted to 68 independent functions.

We may note that in all the calculations, except those of Stevens [83] and Veillard [84], experimental bond lengths and valence angles were employed and were seen to be unchanged on rotation. Nevertheless empirical theories predict a slight extension of the C–C bond and a decrease of the HCH angle in the eclipsed conformation. Thus Sovers and Karplus [86] calculated the equilibrium geometry of each form using the atom–atom potentials and spectroscopic deformation functions and minimising the strain energy.

They employed two types of potential: (1) the usual H...H and C...H potentials obtained from molecular beam scattering data or any other physicochemical properties and (2) the "effective" potentials yielding the barrier in ethane without taking into account the torsional term. The calculations showed that the C–C bond length increases in the eclipsed conformation by 0.01 Å when potentials of the first type are used and up to 0.1 Å for potentials of the second type; the HCH valence angle in the eclipsed conformation should be smaller approximately by 0.5° than in the staggered conformation.

In the calculations of Veillard [84] and Stevens [83] account was taken of the change in geometry, i.e. the total energy minimum was found for each conformation. The estimates of Sovers and Karplus were confirmed by non-empirical calculations: according to Veillard, the C–C bond in the eclipsed conformation increases by 0.019 Å (from 1.551 Å in the staggered form to 1.570 Å in the eclipsed form), while according to Stevens the increase is by 0.011 Å (from 1.518 Å to 1.529 Å); the HCH angle is close to the experimental value (107.8°) in both calculations, being reduced by 0.3–0.4° in the eclipsed conformation.

Veillard achieved the closest approach to the Hartree–Fock limit—according to his estimate the remaining distance to the "limit" was only 0.09 a.u. However, Levy and Moireau [87] believe that an infinite basis set would yield a further 0.3–0.4 a.u. Despite the fact that the Hartree–Fock limit has been virtually attained, it is still not clear what should be the "limiting" C–C bond length. Indeed C–C bond lengths of 1.501, 1.581, 1.538, 1.529, 1.518, and 1.551 Å have been obtained respectively by Frost's method, the LEMAO-5G method, the STO-3G method, the 4-31G method, the method based on 16 optimised STO (Stevens), and finally the method of 68 GTO based on 122 GTO (Veillard). If an accuracy of bond length of the order of 0.02–0.03 Å is required, the latter may be provided by the Hartree–Fock method with fairly large basis sets. However the question arises whether correlation effects can alter the "limiting" Hartree–Fock bond lengths by hundredths or thousandths of an Ångstrom. So far an answer to this question has not been obtained.

Table 4. Total energies of the eclipsed and staggered forms of the ethane molecule.

Basis set	Total energy, a.u.		Barrier, kcal mole^{-1}	References
	staggered form	eclipsed form		
16 STO; Slater exponents	−78.9912	−79.9859	3.3	28
16 STO; exponents optimised for CH_4	−79.0980	−79.0923	3.5	80

Experiment			2.93	85

"Moderate" basis sets lead to an entirely satisfactory agreement with experiment for other hydrocarbon molecules. Hoyland [88–90], who employed Gaussian type function basis sets, made a detailed study of the internal rotation in alkanes. The calculations for propane and n-butane were made with two basis sets: (5,2,2) and (7,3,3). Five *s*-type and six *p*-type orbitals ($2p_x$, $2p_y$, and $2p_z$) for the carbon atoms and two *s*-type orbitals for the hydrogen atoms were used in the (5,2,2) basis sets. [The (7,3,3) basis set yields the same total energy as the basis sets constructed from the STO with optimised exponents.] The Hartree–Fock calculations for alkanes showed that both basis sets, (5,2,2) and (7,3,3), yield virtually indistinguishable results. Consequently it is reasonable to restrict the treatment to comparatively small basis sets for estimating the conformational energies and barriers to internal rotation of hydrocarbons.

Table 5, which is based on Hoyland's results [89], presents the results of the calculation of the conformational

energies of n-butane using two Gaussian type basis sets—(5,2,2) and (7,3,3). The most striking fact is the identity of the results obtained with different basis sets. The agreement with experiment is so good that it is impossible to say which of the two basis sets is better in this sense. Therefore the calculated values of certain properties can actually be regarded as more accurate than the experimental values. Hoyland's results constitute an undoubted achievement of theoretical methods, especially when one remembers that the n-butane molecule is by no means a trivial object for empirical schemes (the conformations of n-butane were considered in particular by Borisova and Vol'kenshtein [96] and Scott and Scheraga [97]).

Table 5. Results of the non-empirical calculations of the conformational energies of the n-butane molecule.

Property	Calc. (5,2,2) basis set	Calc. (7,3,3) basis set	Expt.	References
Barrier to rotation of methyl group, kcal mole^{-1}	2.92	2.94	3.2—3.4	91
Trans-gauche barrier, kcal mole^{-1}	3.536	3.619	3.6	91
Barrier to interconversion of two *gauche*-forms, kcal mole^{-1}	6.824	6.834	5.3	92
			6.5—6.7	93
ΔE (*gauche-trans*), kcal mole^{-1}	0.822	0.761	0.770±0.09	94
Equilibrium angle of *gauche*-form	70.9°	71.3°	72.5±1.1°	95

The calculations of the conformational energies of cycloalkanes carried out by Hoyland in another study [90] are also of considerable interest. Using the experimental bond lengths and valence angles and calculating the total energies with the (5,2,2) basis set, Hoyland obtained approximately identical energies for the envelope and half-chair cyclopentane conformations, in agreement with both experimental data [98] and with the results of empirical calculations [99]. According to the calculation, the twist conformation of cyclohexane is less stable than the chair conformation by 6.05 kcal mole^{-1} and the boat conformation is less stable by 7.19 kcal mole^{-1}; the transition state is less stable by 11.22 kcal mole^{-1} relative to the chair form. These figures are also close to various experimental estimates (about 5.6, about 6.6, and about 11 kcal mole^{-1} respectively [100]).

We shall now consider molecules containing heteroatoms or lone electron pairs. Calculations of the conformational energies and barriers to internal rotation of such molecules generally speaking require larger basis sets than hydrocarbons [101]. Table 6 presents the results of the calculation of the barriers to internal rotation in several molecules of this type. The total energies of propene and its fluoro-derivatives [102] were calculated with two basis sets (A and B); basis set B was constructed by a linear combination of the orbitals of basis set A, i.e. it was less flexible. Table 6 shows that the agreement with experiment leaves something to be desired. Even the direction in which the barrier changes in the fluoro-derivatives is not reflected by the calculation: the calculated barrier in 2-fluoropropene is too small and that in *cis*-fluoropropene (with the A basis) is too large.

The reason for the not entirely satisfactory agreement with experiment is probably inadequacy of the basis set. As we have already seen for fluorine- and oxygen-containing molecules, the smallness of the basis set leads to inaccurate estimates of molecular geometries. However, such smallness affects the barriers even more. Therefore reliable calculations of the barriers to internal rotation (to within about 20%), since the remaining discrepancy may be due to correlation effects) require larger basis sets than do calculations of the geometry.

Table 6. Barriers to internal rotation in molecules with a favourable eclipsed conformation.

Molecule	Barrier, kcal mole^{-1}		Expt.
	A basis set	B basis set	
Propene	1.48	1.25	1.98
cis-Fluoropropene	1.58	1.07	1.06
trans-Fluoropropene	1.53	1.34	2.20
2-Fluoropropene	1.20	—	2.45
Acetaldehyde		1.09[82,103]	1.16

In connection with the question of the role of the basis set and the need to improve accuracy, it is interesting to examine non-empirical calculations of the energies of internal rotation in the hydrogen peroxide molecule. Table 7, which presents the results of calculations by different workers, shows that the agreement with experiment depends in a very unusual manner on the completeness of the basis set: small basis sets predict a reasonable *cis*-barrier; then, as the basis set is improved, the calculated barrier becomes too large, becoming reduced to an acceptable value only in Veillard's very exact calculation [105]. On the other hand, the *trans*-barrier is predicted only by the most accurate calculations; in other cases the energy minimum corresponds to the *trans*-form (admittedly the $E-\varphi$ curve, where φ is the angle of rotation reckoned from the *cis*-form, acquires a very low slope for $\varphi > 100°$).

Table 7. Non-empirical calculations of the barriers to internal rotation in the hydrogen peroxide molecule.

Basis set	Total energy in *trans*-form, a.u.	Barrier, kcal mole^{-1} *cis*	Barrier, kcal mole^{-1} *trans*	References
12 STO with Slater exponents	—150.1457	9.4	0	104

32 STO	—150.8319	10.9	0.72	27
Experiment		7.0	1.1	108

The optimisation of the geometry for hydrogen peroxide is more important than for ethane. Veillard's calculation showed that, on passing from the *trans*-form of H_2O_2 to the *cis*-form, the O—O bond length increases by 0.025 Å and the HOO valence angle increases by 5.35°. The angle $\varphi = 123°$ corresponds to the equilibrium concentration, which is quite close to the experimental value [107] (111.5°).

Similar results were obtained by Dunning and Winter[106], who employed an even larger Gaussian type basis set and obtained the equilibrium value $\varphi = 113.7°$. It is remarkable that the calculation carred out with 52 STO,[57] which yielded the lowest total energy, did not give rise to entirely satisfactory barriers. The reason for this is failure to optimise the geometry.

The problem of internal rotation in yet another simple molecule—disulphane (H_2S_2)—is also interesting. The study of microwave spectra[108] showed that in this molecule there should be two barriers of approximately equal height (the *cis*- and *trans*-barriers), the equilibrium angle of rotation being $\varphi = 90°36'$. The calculation[109] performed with an extended and subsequently contracted Gaussian type basis set (58 GTO based on 106 GTO) gave 9.33 kcal mole^{-1} for the *cis*-barrier, 5.99 kcal mole^{-1} for the *trans*-barrier, and an equilibrium angle of 91°16'.

Non-empirical calculations have not been made solely for molecules with "small" barriers. Various Gaussian type basis sets (with and without *d*-type functions) lead to a barrier in formamide[61] ranging from 19.4 to 21.7 kcal mole^{-1}, while the experimental values obtained from NMR spectra are in the range from 16.8 to 21.3 kcal mole^{-1} (see the previous review[1]).

Lehn et al. investigated the mechanism of inversion in aziridine and oxaziridine[110] and also in methyleneimine and the vinyl anion[111]. Using fairly large Gaussian type basis sets, they estimated the barrier to inversion of nitrogen in aziridine CH_2-CH_2-NH as 18.3 kcal mole^{-1} and in oxaziridine CH_2-O-NH as 32.4 kcal mole^{-1}. These figures agree extremely well with the enthalpies of activation obtained from the analysis of the NMR spectra of substituted aziridines and oxaziridines: 16–19 kcal mole^{-1} [112-114] and 32 kcal mole^{-1} [115] respectively.

Methyleneimine ($H_2C=NH$), which was examined in another study by Lehn[111], can undergo inversion in two ways—by rotation about the C=N bond and by the "bending" of the N–H bond. Calculations[111] carried out with a large Gaussian type basis set showed that saddle point for the "tilting" mechanism corresponds to an energy of 26 to 28 kcal mole^{-1} and the saddle point for the rotation mechanism corresponds to 57 kcal mole^{-1}. The first of these figures is virtually identical with the barriers found experimentally for similar compounds (25–27 kcal mole^{-1} [116-119]).

Finally a few words should be said about the simplest molecule in which the inversion phenomenon occurs—the ammonia molecule. Since non-empirical calculations with limited basis sets yielded low or altogether unlikely values of the barrier[120-128], it was believed for a long time that at least half of the barrier is due to correlation effects. However a recent calculation by Rauk et al.[129], taking into account the *d* orbitals of the nitrogen atom, yielded a value very close to the experimental barrier (5.08 kcal mole^{-1} compared with the experimental value of 5.8 kcal mole^{-1} [130]). This demonstrates yet again that not only rotation barriers but also inversion barriers can be fairly satisfactorily predicted within the framework of the Hartree–Fock approximation, provided that the chosen basis set is sufficiently large.

The question arises whether it is possible to make any recommendations concerning the desirability of employing particular basis sets by analysing the results of quantum-mechanical calculations. Naturally the larger the basis set the better and basis sets of the type (11.7/6), including eleven *s* and seven Gaussian *p*-type functions for each carbon or oxygen atom, which were employed by Veillard[84,124], are best in this sense. Even better is the (13.8.2/8.1) basis set, which includes three *d*-type polarisation functions of the nitrogen atom and two *p* functions of the hydrogen atom. The above calculation of the barrier to ammonia inversion was in fact performed with this basis set[129]. However the computer time at the disposal of investigators is limited and therefore a compromise must be resorted to—it is necessary to employ "moderate" basis sets and accept a reduced accuracy of the calculations.

The 4-31G basis set is regarded as a "moderate" basis set of this type.

Pople and coworkers[131] recently employed this basis set to calculate the conformational energies of twenty organic molecules containing methyl, carbonyl, and carboxy-groups and showed that in the vast majority of cases this basis set yields results close to the experimental values. Several examples of the comparison of the calculated and experimental values of the barriers to internal rotation are given below (the experimental data in kcal mole^{-1} are indicated in brackets): ethane 3.26 (2.93); methanol 1.12 (1.07); acetaldehyde 0.74 (1.16); formamide 24.7 (19); methyl ether 3.0 (2.7); acetone 0.75 (0.78–0.83). Evidently the agreement between the calculation and experiment is moderately satisfactory and therefore basis sets of this type may be recommended for large-scale estimates of conformational energies of small molecules and for conformational analysis in organic chemistry. Admittedly, as we have already seen for the ammonia molecule, one cannot always be certain that the error of the calculation is sufficiently small. However, "moderate" basis sets in all probability yield entirely satisfactory results for hydrocarbon molecules.

Table 8. Bond separation energies.

Molecule	Reaction	Bond separation energy, kcal mole^{-1}	
		calc.	expt.
Propane	$CH_3CH_2CH_3 + CH_4 \rightarrow 2C_2H_6$	1.0	1.5
Propene	$CH_3CHCH_2 + CH_4 \rightarrow C_2H_6 + C_2H_4$	4.1	5.0
Propyl	$CH_3CH + CH_4 \rightarrow C_2H_6 + C_2H_2$	8.0	7.2
Allene	$CH_2CCH_2 + CH_4 \rightarrow 2C_2H_4$	−4.6	−4.0
Cyclopropane	$C_3H_6 + 3CH_4 \rightarrow 3C_2H_6$	−30.4	−23.5
Cyclopropene	$C_3H_4 + 3CH_4 \rightarrow 2C_2H_6 + C_2H_4$	−58.0	−45.2

The differences between the energies of rotational isomers are probably just as sensitive to the basis set as the barriers to internal rotation; admittedly few calculations of this kind have been made. We shall mention in particular the work of Pople and coworkers[132], who calculated the energies of two or several conformers with two basis sets—STO-3G and 4-31G. Thus the *gauche*-form of substituted methylamines (XCH_2-NH_2) was found to be more favourable than the *trans*-form (the C–X bond in the *trans*-form is located in the same plane as the bisector of the HNH angle), when X = CH_3, while the *trans*-form is more favourable for X = OH and F. Spectroscopic data, which are available only for ethylamine[133], show that the two forms are in equilibrium. In substituted hydrazines (NH_2-NHX), the "outer" form (the N–X bond is rotated 180° relative to the bisector of the HNH angle) is more favourable than the "inner" form when X = CH_3 and less favourable for X = OH and F. Indeed infrared spectra[134] show the advantage of the "outer"

form for methylhydrazine—it constitutes more than 90% of the mixture. Calculations predict that in compounds of the type Y=N−O−H the *trans*-form is more stable for all Y (Y = CH_2, NH, or O). The experimental data on nitrous acid (Y = O) [135,136] demonstrate the preponderance of the *trans*-form. Finally, we may mention substituted di-imides (X−N=N−H) whose *trans*-form is more favourable than the *cis*-form for all X except OH. Experimental data demonstrating the advantage of the *trans*-form are available only for di-imide itself [137].

The thermochemical properties of substances are known to bear a definite relation to molecular structure and to steric hindrance. However, absolute values cannot be obtained with adequate precision within the framework of the Hartree−Fock model: the correlation corrections to the total energies are too large. However, if we are interested in the comparative thermochemical properties of a series of molecules with similar structures, such properties can be estimated assuming mutual cancellation of the correlation corrections.

Pople and coworkers [138] introduced the concept of the "bond separation" energy: these are the heats of reactions occurring with retention of the total number of formal bonds. The "bond separation" energies are a measure of the intramolecular interactions including steric strains (on the assumption of exact additivity of the bond energies, the "bond separation" energies should be zero).

Table 8 presents several examples of reactions and the results achieved by the STO-3G and 4-31G methods are compared with experimental data adjusted to 0°K and corrected for zero point vibrations. Bearing in mind that the Hartree−Fock limit is far from being attained when using Gaussian type basis sets, the agreement between the calculations and experiment must be recognised as satisfactory (the correlation corrections can indeed cancel out in systems with identical formal bonds). The "bond separation" energies are particularly large in absolute magnitude in cyclopropane and cyclopropene in consequence of the large angular deformations.

IV. THE NATURE OF THE BARRIERS TO INTERNAL ROTATION

The "nature" of the barriers to internal rotation has been the subject of discussion for a long time at the level of empirical and semi-empirical theories. Since the interatomic potentials "do not explain" the barrier in a simple molecule such as ethane, yielding an unduly low value, many theories in which one factor or another is emphasised have been put forward. Thus the breakdown of the cylindrical symmetry of electron density in rotation about the C−C bond has been treated [139,140] as the cause of the inhibiting potential [139,140]. Pauling [141,142] attributed the barrier to the presence of hybrid orbitals of the *d*- and *f*-types assuming that pure sp^3 hybridisation does not give rise to a barrier; however, 4% of *d*-states and 2% of *f*-states give rise to a barrier of about 3 kcal mole^{-1}. Calculations of the barrier on the basis of the classical electrostatic model [143−145] taking into account the interactions between the dipole and higher moments of the C−H bond also did not yield unambiguous results.

From the standpoint of modern computational methods, these theories appear naive and can be readily criticised. Actually the fact that the correct value of the barrier to internal rotation in ethane is obtained with minimal STO basis sets or extended GTO basis sets but not including vacant orbitals is sufficient to demonstrate the lack of validity of Pauling's theory.

However, despite the considerable achievements of non-empirical methods, the problem of the nature of the inhibition of internal rotation in molecules can still not be regarded as finally elucidated. The ambiguity of the interpretation of the nature of the interactions is primarily related to the fact that the integrals arising in the Roothaan equations can be reasonably combined into certain groups in several ways. Nevertheless only two fundamentally different approaches exist.

1. The repulsion energy of the nuclei V_{nn}, the repulsion energy of the electrons V_{ee}, the kinetic energy of the electrons T, and the attraction energy between the electrons and the nuclei V_{ne} are considered separately. The total repulsion energy is written in the form

$$V_{rep} = V_{nn} + V_{ee} + T \tag{10}$$

and the attraction energy in the form

$$V_{att} = V_{ne}. \tag{11}$$

After calculating in this way the attraction and repulsion energies, one can conclude that V_{rep} and V_{att} change on passing from one conformation to another, and particularly on passing from the staggered to the eclipsed form: if ΔV_{rep} is large and ΔV_{att} is small, repulsion predominates; on the other hand, if ΔV_{att} is large and ΔV_{rep} is small, attraction predominates. One cannot rule out the possibility that both terms play equally important roles.

Apart from the above resolution of the total energy, the resolution into one- and two-electron components is also of interest. $V_{nn} + T + V_{ne}$ may be regarded as the one-electron component and V_{ee} as the two-electron component. Such representation makes it possible to understand, in the first place, the role of the repulsion of electrons and, in the second place, the possibility, scope, and disadvantages of the semi-empirical one-electron approximations, in particular the extended Hückel method.

2. Instead of investigating the interelectronic and electron−nucleus interactions, the individual contributions to the total energy from the localised bond orbitals are analysed. Thus, in discussing the nature of the barrier in ethane, one speaks of the repulsion of the localised orbitals of the C−H bond (when the calculations are carried out with such orbitals) or of the repulsion of the *p* orbitals of the carbon atoms in the eclipsed conformation [146]. This approach can be naturally referred to as the "orbital" approach. It is of course less objective than the "electronic-nuclear" approach, but the degree of involvement of particular interactions is determined to a considerable degree by the choice of the basis set; however, this approach is frequently used to justify various semi-empirical and empirical theories.

Allen, who investigated both the competition between attraction and repulsion [102,103,147] and the relative effects of the one- and two-electron components [82], has been a consistent adherent of the first approach. Table 9 presents the individual components of the total energy of ethane (V_{nn}, V_{ee}, T, and V_{ne}), whence one can also see their relative changes on passing from the eclipsed to the staggered conformation (the values of the total energy components for $\varphi = 90°$, i.e. in the intermediate conformation, are also indicated). Fig. 2, which is based on data of Fink and Allen [82], presents the ΔV_{rep} and ΔV_{att} curves (*a*), the skew conformation being adopted as the starting point of the readings ($\varphi = 0$) and also curves characterising the changes in the one- and two-electron components (*b*). It is interesting that in both representations the individual components vary with different phases

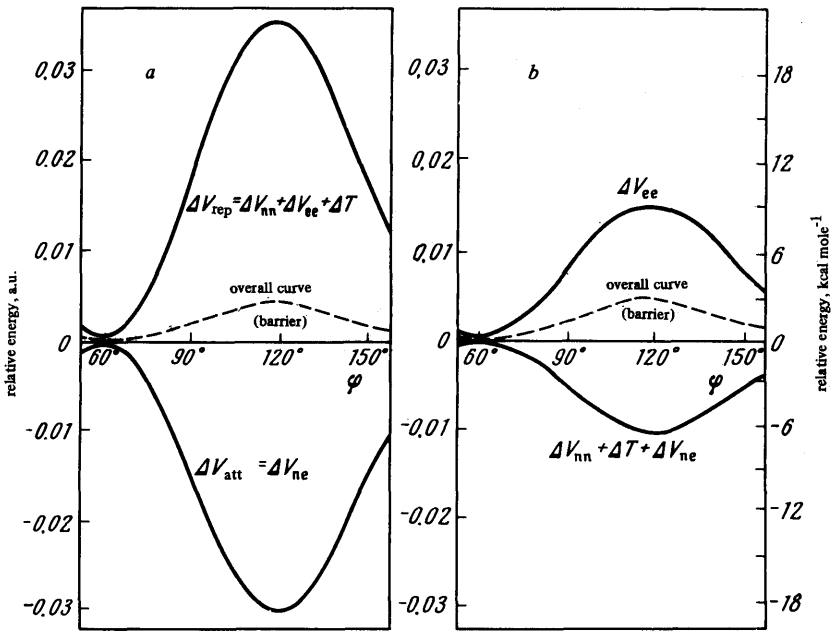

Figure 2. Variation of various components of the total energy of ethane with the internal rotation angle φ.

and the true barrier, illustrated in Fig. 2 by the dashed line, is given by a small difference between fairly large quantities. This situation is characteristic not only of ethane but also of the vast majority of molecules. This is why the experimental barriers to rotation are frequently unexpected and it is by no means always possible to make them fit any empirical rules.

The origin of the barrier in ethane can be most readily understood by examining the repulsion and attraction (Fig. 2*a*). Both terms increase markedly in absolute magnitude in the eclipsed conformation but the repulsion is nevertheless stronger. A detailed study[147] has shown that, in the space between the hydrogen atom, the electron density is significantly reduced. This leads, on the one hand, to an increase of the repulsion of nuclei in consequence of their descreening and, on the other hand, to enhanced attraction of the electrons to the nuclei. On the other hand, the repulsion of atoms constitutes a pure effect. Thus the nature of the barrier in ethane is ultimately the same as the nature of the repulsion of helium atoms at short distances[148].

Evidently the nature of the barriers in propane, n-butane, and cycloalkanes is the same (indeed, in the empirical conformational calculations used to describe these systems, one employs "ethane-like" torsional potentials). However, in molecules with a favourable eclipsed conformation, attraction is more likely to be responsible for the barrier than repulsion. In fact, it has been shown[147] that in the eclipsed conformation of the acetaldehyde molecules (CH_3CHO) the distribution of electron density between the methyl group and the oxygen atom resembles the distribution for a weak chemical bond; but on passing to the staggered form the bond is weakened.

Component-by-component analysis makes it possible to refer the barriers to internal rotation and inversion of molecules to one of two groups—R (repulsive dominant) or A (attractive dominant): if on passing from the state corresponding to the energy minimum to one corresponding to the saddle point on the energy surface, $|\Delta V_{rep}| > |\Delta V_{att}|$, then the barrier refers to group R; for opposite inequality sign, the barrier belongs to group A. In terms of this property, the barriers to rotation in methanol, methylamine, ethyl fluoride, hydrazine, ammonia, etc. belong to group R and the barriers in hydroxylamine, aziridine, hydrogen peroxide, di-imide, etc. belong to group A.[101]

Table 9. Contributions of the individual components to the total Hartree–Fock energy of ethane (in a.u.).

Conformation	V_{nn}	V_{ee}	T	V_{ne}
Eclipsed	41.93845	67.22699	79.00441	−267.3136
Intermediate ($\varphi = 90°$)	41.93469	67.21900	78.99798	−267.2972
Staggered	41.93098	67.21208	78.99142	−267.2823
Δ (eclipsed–intermediate)	0.00376	0.00799	0.00643	−0.0164
Δ (eclipsed–staggered)	0.00747	0.01491	0.01299	−0.0313

Unfortunately it is impossible to say that the component-by-component analysis does indeed reveal the "nature" of the barriers, at least in the sense which would satisfy the chemist who is unable to carry out the calculations *ab initio*. In fact having looked at the structural formula of the compound and even knowing many of its properties, the chemist is hardly able to guess whether the barrier in the given compound belongs to group R or A, let alone being able to predict the magnitude of the barrier. Component-by-component analysis is useful *aposteriori*, i.e. when the quantum-mechanical calculation has already

been performed. However, in this case too it is not always unambiguous, since the sign of the above inequality has been shown to depend for H_2O_2, H_2S_2, and PH_3 on the basis set and on whether or not the geometry has been optimised [101].

The second, "orbital" approach can also be hardly recommended, at least at the present time, since the interpretation of the results depends significantly on the choice of the basis set. We may note, in particular, that Veillard and Demuyck [109], who investigated internal rotation in disulphane (58 independent GTO based on 106 GTO), found that the cause of the *trans*-barrier is the interaction of the electrons of the S–H σ bond with the π electrons of another S atom, which may be classified as hyperconjugation. It may be that this kind of interpretation will find many supporters in the future and will even acquire some predictive power but for this it is necessary that the calculations of the barrier and the analysis of the overlap populations for a large set of molecules are carried out with equivalent basis sets.

Thus the elucidation of the nature of the barriers *aposteriori* is still hardly likely to be of serious interest to the chemist. However, accumulation of new data from quantum-mechanical calculations as well as new experimental data makes it possible to refine and in many cases reformulate the concepts established previously. An attempt to formulate rules which help to predict the least stable conformations has been made [149]: (1) the lone electron pair–lone electron pair, lone electron pair–polar bond, and polar bond–polar bond interactions lead to a considerable increase of the barrier and (2) if the lone electron pairs are located at neighbouring pyramidal atoms (or the polar bonds adjoin these atoms) then the *syn*- and *anti*-periplanar orientations are energetically unfavourable compared with the structure having the maximum number of *gauche*-interactions.

It is possible to quote many examples concerning rule (1): these are the conformations of almost all the halogenoethanes, bis-1,3-dioxolane, [150] etc. However, contrary to expectation, 1,1,2-trichloro- and tribromoethanes exist in the *gauche*-form and not the *trans*-form [151,152]. Rule (2), which Wolfe [153] called the *gauche*-effect, is confirmed both by experimental data and by non-empirical calculations on H_2O_2, H_2S_2, H_2N_2, [154] and H_2P_2. [155,156] The electron pairs in these molecules can be regarded as ligand, which are just as important as the substituents.

The so called anomeric effect [157–160], which is known in the chemistry of carbohydrates and consists in the fact that axial orientations are preferred for electronegative substituents at the anomeric 1-C centre of the pyranose ring, is an exception to rule (2). However, if one supposes that the lone electron pairs of the oxygen atom have the form of "rabbit ears" and "deviate" from one another by an angle of 120°, then the anomeric effect can be readily explained and is no longer an exception to rule (2) but provides conformation of it.

Evidently the state of affairs in this field is by no means satisfactory: despite the fact that non-empirical calculations make it possible to estimate with good precision the conformational energies and barriers to internal rotation in simple molecules, sufficiently convenient methods for the interpretation of the results have not yet been found. Neither have theories satisfactory from the chemist's point of view, whereby one can predict stable and unstable conformers without resorting to laborious computer calculations, yet been established. This is why each new calculation and each new experimental fact are valuable.

V. CALCULATIONS WITH LOCALISED ORBITALS

The ideas of the theory of localised valence bond orbitals (LVBO = localised valence bond orbitals) rest on fundamental empirical chemical postulates. Since the bond energies in molecules are additive with fair accuracy, presumably carefully selected LVBO can be transferred from one molecule to another. This implies that the wave functions for molecules of homologous series can be constructed from the same LVBO. However, the main difficulty of this approach consists in the fact that the transferred orbitals are generally speaking non-orthogonal and when account is taken of the non-orthogonality, the mathematics of the Hartree–Fock method becomes much more complicated [161]. The unitary transformation of molecular orbitals, which does not alter the Slater determinant, makes it possible [162–164] to obtain the localised orbitals b_k from the atomic orbitals φ_i:

$$b_k = \sum_i t_{ki}\varphi_i \,. \qquad (12)$$

The localised orbitals of the C–H bonds in the methane molecule are determined by symmetry considerations. However, for molecules whose symmetry is not quite so high, the localised orbitals cannot be found unambiguously and therefore in choosing the localised orbitals it is necessary to resort to particular criteria [165,166]. The criterion, examined in detail by Edmiston and Ruedenberg [166] and consisting in the fact that the b_k orbitals must correspond to the maximum in the function $\Sigma(kk/kk)$, has found the widest practical application.

Pitzer [167] used the criterion of Edmiston and Ruedenberg to calculate the LVBO for the staggered and eclipsed conformations of ethane. The localised C–C, C–H, and inner shell orbitals obtained by an iterative procedure proved to be not entirely identical for the two conformations: the greatest changes occur on internal rotation in the C–H orbitals.

The principal disadvantage of the localised orbitals determined in this way is that it is difficult to use them to explain the nature of the interactions responsible for the nature of the interactions responsible for the barrier, since the localised orbitals of the staggered conformation of ethane differ from the corresponding orbitals of the eclipsed conformation. Therefore, in order to elucidate the nature of the interactions and to prove the validity of additive empirical schemes, it appears more promising to employ orbitals transferred from one molecule to another.

Hoyland [168] attempted to apply the idea of the transferability of orbitals to hydrocarbon molecules—those of methane, ethane, propane, n-butane, and propene. The localised orbitals of the C–H bond in methane were sought in the form

$$b^{(i)}_{C\text{-}H} = N(t_i + \lambda h_i) \qquad (13)$$

where t_i are hybrid tetrahedral functions on the carbon atom directed towards the ith hydrogen atom, h_i are the 1s orbitals centred on the same hydrogen atom, and N is a normalising factor. The parameter λ was determined from the condition of the correspondence of the calculated and experimental C–H bond lengths: $\lambda = 1.097$ for the (5,2,2) Gaussian basis set and $\lambda = 1.056$ for the (5,3,3) basis set.

The orbital of the C–C bond in ethane was defined thus:

$$b_{C\text{-}C} = N(t_1 + t_2) \qquad (14)$$

where t_1 and t_2 are the hybrid orbitals on the two carbon

atoms directed to the central point in the molecule. The b_{C-H} orbitals were assumed to be exactly the same as in methane.

Calculation of the total energy of ethane using the LVBO yielded −78.493 a.u. for the (5,2,2) basis set and −78.696 a.u. for the (5,3,3) basis set, which are a little higher than the values quoted in Table 4. The calculated barrier amounts to 2.66 kcal mole^{-1} for the (5,2,2) basis set and 2.83 kcal mole^{-1} for the (5,3,3) basis set.

The results for the barrier to internal rotation in propene were not so satisfactory: 0.46 kcal mole^{-1} for the (5,2,2) basis set and 0.80 kcal mole^{-1} for the (5,3,3) basis set (the experimental value is 1.98 kcal mole^{-1}). The reason for the poor agreement between the calculation and experiment becomes understandable if one takes into account the fact that each term V_{ee} and V_{ne} in Eqn. (10) for propene changes on passing from the eclipsed to the staggered conformation by 12−26 kcal mole^{-1} (only ΔT is small), which is a factor of ten greater than the barrier. The errors associated with the inadequacy of the orbitals are fairly large for each total energy component and there is no reason to expect their mutual cancellation.

In another study[169] Hoyland employed the extended (7,3,3) Gaussian basis set and sought the localised orbitals of the C−H bond in methane in the form

$$b^{(i)}_{C-H} = N(2s + \lambda 2p_i + \delta h_i) \qquad (15)$$

where $2p_i$ are linear combinations of the $2p_x$, $2p_y$, and $2p_z$ orbitals. Instead of the single parameter (λ), two parameters (λ and δ) were varied. After transferring the localised orbitals b_{C-H} from methane to ethane, Hoyland obtained for the latter a total energy of −79.093 a.u. and a barrier to internal rotation of 2.40 kcal mole^{-1}. The author explains the comparatively low barrier by the fact that in the eclipsed conformation the wave function constructed from the LVBO is closer to the LCAO-MO wave function for the eclipsed conformation than for the staggered conformation.

Table 10 compares the calculated conformational energies of propane obtained by the LCAO-MO and LVBO methods. In the LVBO method the b_{C-H} orbitals were transferred from methane and the b_{C-C} orbitals from ethane. The closeness of the results obtained by the two methods shows that in many respects the LVBO are entirely satisfactory. However, it is clear that from a quantitative standpoint a better approximation to experiment can be achieved with delocalised LCAO-MO. This is not in fact surprising, since in using the orthogonalised valence bond orbitals one does not take into account satisfactorily the weak interactions which determine the conformational energies and the isomerisation energies of alkanes. However, the agreement with experiment for alkanes may be improved by distinguishing the C−C and C−H bonds as a function of the immediate environment as is done in Tatevskii's method[170,171]. But in this case the non-empirical calculations are reduced to the level of empirical schemes: in fact this is equivalent to postulating the desired result.

VI. CONCLUDING REMARKS

As shown in the previous sections, molecular geometry and conformational energies are quite satisfactorily predicted within the framework of the Hartree−Fock method, provided that one employs delocalised orbitals and fairly large basis sets. Since the Hartree−Fock limit has been approached for only 2−3 molecules, it is still difficult to say what corrections are introduced by allowance for correlation effects; it is only clear that these corrections are small for delocalised orbitals and very large when localised valence bond orbitals are employed.

Table 10. Barriers to internal rotation in propane calculated with delocalised and localised orbitals.

Angles of rotation, deg		ΔE, kcal mole^{-1}	
φ_1	φ_2	LCAO-MO[83]	LVBO[167]
60	60	0	0
60	0	3.134	2.616
0	0	6.971	6.097

The Hartree−Fock model, in which the electrons are considered to move in the effective field due to other electrons and nuclei, does not take into account the "collisions" of electrons, which, as shown by Gruninger et al.[172], makes the average kinetic energy too low and the average electron repulsion energy too high. The correlation energy, which is by definition[173] that difference between the exact non-relativistic energy and the Hartree−Fock energy, amounts on average to 1% of the total energy of the molecules (for example, it is 230 kcal mole^{-1} for the ammonia molecule[126]). Apart from correlation, one could also take into account relativistic corrections, but in calculations on molecules, at least those with fairly light atoms, such corrections are quite insignificant. Thus the relativistic correction for the ammonia molecule is 15 kcal mole^{-1}; however, it is determined mainly by the motion of electrons in atoms and one must suppose that it is the same for different conformations and in general for different relative positions of the nuclei.

In the calculation of the correlation energy, the many-configuration approximation or perturbation methods are employed. In the many-configuration approximation the wave function of the molecule Ψ is represented by a linear combination of functions made up of Slater determinants.

For the function to be exact, it is necessary to employ an infinitely large number of expansion terms. However, one usually restricts the treatment to finite sums and the expansion coefficients are determined from the condition for the energy minimum. The methods of perturbation theory are less accurate, but they make it possible to estimate a considerable proportion of the correlation energy by a relatively simple procedure[174].

It has been known for a long time that the second-order correlation energy $E^{(2)}$, found using perturbation theory, is small for delocalised orbitals and large for localised orbitals (although no one has found a simple explanation for this finding). Levy and Moireau[87], who investigated the effect of the correlation energy on the barrier to internal rotation in ethane, found that $E^{(2)}$ is of the order of 0.01 kcal mole^{-1} for the Slater basis set employed by Pitzer and Lipscomb[28], about 0.1 kcal mole^{-1} for the basis set constructed from the LVBO satisfying the minimal exchange conditions[167], and 0.6−0.8 kcal mole^{-1} for the basis set constructed from hybrid molecular orbitals.

Thus allowance for correlation corrections is important only for localised orbitals. Incidentally, it is precisely in this case that the correlation corrections are most

readily applied and the main idea of the semi-empirical PCILO method discussed in the author's previous review[1] does in fact consist in applying perturbation theory to localised orbitals. The correlation corrections in the non-empirical methods based on atomic orbitals should probably be small and a further approach to the Hartree–Fock limit by extending the basis set and optimising the STO or GTO exponents may serve as the main means of achieving the required accuracy.

The question arises of the prospects for the non-empirical conformational analysis. In the first place one must say that calculations of the electronic structures of molecules with average dimensions, such as those of benzene or pyridine, require several hours of computer time for a single nuclear configuration. It is also significant that such calculations require a large set of programs available hitherto only to individual specialists working in this field. Nevertheless examples are already appearing of predictions of the geometries of complex molecules such as those of bicyclobutane and bicyclopentane. Presumably in the immediate future the number of such examples will increase significantly and towards the end of the 1970's and the beginning of the 1980's, when the speed of computers is increased to 10^9 operations per second, theoretical conformation analysis of organic molecules with average dimensions will become an important instrument in the hands of chemists and physical chemists. However even then, as long as significantly new methods are not devised, the non-empirical calculations of the conformations of complex systems such as steriods, alkaloids, peptides, sugars, nucleic acids, etc. will be hardly possible. Therefore empirical models based on atom–atom potentials and semi-empirical quantum-mechanical methods retain their importance.

Polymerisation of αβ-Unsaturated Sulphur-containing Compounds

A.V.Sviridova and E.N.Prilezhaeva

The review deals with the present state of the problem of the polymerisation of unsaturated sulphur-containing monomers with sulphide, sulphoxide, and sulphone groups in the immediate vicinity of the double bond. The mechanisms of polymerisation reactions involving various catalytic systems and the effect of the heteroatom on the polymerisation of the above monomers as well as the fields of practical application of the polymers based on them are discussed.
The bibliography includes 167 references.

CONTENTS

1. Polymerisation of vinyl sulphides, divinylmercaptals, and divinylmercaptols
2. Polymerisation of vinyl thioloacylates
III. Polymerisation and copolymerisation of vinyl monomers containing oxidised sulphur 204
1. Synthesis of polymers containing sulphoxide groups
2. Polymerisation and copolymerisation of vinyl sulphones

I. INTRODUCTION

Numerous studies dealing with the polymerisation of unsaturated sulphur-containing compounds have now been published. However, these investigations have not been discussed from a single standpoint and brief reviews [1-3] on this problem in certain monographs cannot claim to cover the literature completely.

Nevertheless, examination of the polymerisation of such compounds is important from both theoretical and practical points of view. For example, many polymers with enhanced thermal stability and resistance to ozone [4], organic solvents, radiation, and ageing [5] are known to contain in sulphur atoms their structure. Moreover, the problem of the polymerisation of unsaturated sulphur-containing compounds has a direct bearing on the elucidation of the nature of the interaction between the sulphur atom and the π-electron system.

The aim of the present review was to give a general and systematic account of the available data and to draw the attention of research workers to this interesting and hitherto inadequately investigated field. The review deals with the polymerisation of unsaturated compounds with sulphur-containing functional groups in the immediate vicinity of the double bond. The polymerisation of ethylenesulphonic acids and their esters will not be considered, since a fairly complete review on this subject has already been published [4].

II. POLYMERISATION AND COPOLYMERISATION OF VINYL MONOMERS CONTAINING BIVALENT SULPHUR

1. Polymerisation of Vinyl Sulphides, Divinylmercaptals, and Divinylmercaptols

A comprehensive study of the physical and chemical properties of unsaturated sulphides [6] led to the conclusion that, depending on the conditions, in the conjugation with neighbouring multiple carbon–carbon bonds the sulphur atom can (1) exhibit electron-donating properties—in the attack on the substrate by electrophilic reagents or in its interaction with electron-accepting groups, (2) can behave as an electron acceptor owing to the involvement of the d-orbitals, which occurs in certain systems where there is attack by powerful electron-donating reagents, and (3) can stabilise the free-radical state of the system when the latter is attacked by free radicals or subjected to excitation by light owing to the overlapping of the p_C-d_S or p_C-p_S orbitals formally imitating the C=C group.

However, it has been established [6] that, in contrast to alkylthioacetylenes, the sulphur atom does not behave as an electron acceptor in alkylthio-olefins, for example in their reaction with amines.

In accordance with the foregoing considerations, there are literature data only for cationic and free-radical polymerisation of both substituted and unsubstituted alkyl vinyl and aryl vinyl sulphides.

a. Cationic polymerisation and copolymerisation of vinyl sulphides. The polymerisation of αβ-unsaturated sulphides was described for the first time by Reppe [7-10], who employed BF_3, SO_2, and I_2 as catalysts. Later it was noted that in the presence of $AlCl_3$ or other Friedel–Crafts catalysts vinyl sulphides undergo copolymerisation with alkenes, forming rubber-like materials [11,12] suitable as additives to lubricating oils [13].

The polymerisation of vinyl sulphides under cationic conditions was investigated in greater depth by Soviet workers [14-18]. It was found that cationic catalysts such as $FeCl_3.6H_2O$ and $SnCl_2$, in the presence of which alkyl vinyl ethers [19] polymerise in high yields, are completely inert with respect to alkyl vinyl sulphides. In the presence of $BF_3.OEt_2$ or $SnCl_4$, alkyl vinyl sulphides form low-molecular-weight oligomers [15] ($M \simeq 1000-2000$). The nature of the reaction differs significantly from the polymerisation of vinyl ethers where negligible traces of $BF_3.OEt_2$ give rise to an explosive reaction. A considerable amount of the catalyst and prolonged heating are necessary for the polymerisation of vinyl sulphides.

The low reactivity of vinyl sulphides in relation to cationic catalysts can be explained on the one hand by the lower nucleophilicity of their double bond compared with vinyl ethers and on the other by the possibility of the formation via the sulphur atom of comparatively stable complexes of the donor–acceptor type [16,17].

It is believed[20] that the reason for the weaker mesomeric effect of the sulphur atom compared with the oxygen atom is its greater covalent radius (r) compared with the atomic radius (R). This gives rise to steric hindrance to the overlapping of the $p_C - p_X$ orbitals (a measure of the tendency towards such overlapping is provided by the ratio R/r, which amounts to 1.90 for oxygen and 1.54 for sulphur). However, the order of the reactivities of the sulphur-containing monomers in polymerisation,

$$CH_2{=}CHSPh > CH_2{=}CHOCH_2CH_2SCH{=}CH_2 > CH_2{=}CHSCMe_3 > CH_2{=}CHSEt > CH_2{=}CHSCH_2CH_2OBu > CH_2{=}CHOCH_2CH_2SEt > CH_2{=}CHSCH_2CH_2SEt$$

cannot be accounted for solely by the differences between the nucleophilic properties of the double bond. The observed phenomenon is related to changes in the basicity of the sulphur atom, which constitutes the second reaction centre in the molecule or, in other words, to the capacity of the catalyst for complex formation via this atom. The decrease of the effective concentration of the catalyst must constitute an additional factor reducing the rate of cationic polymerisation. Thus phenyl vinyl sulphide shows the highest reactivity in ionic polymerisation and yields a polymer in the presence of iron(III) chloride which is inert with respect to all other monomers of this series, while 2-ethylthioethyl vinyl sulphide does not polymerise even on very prolonged heating with $BF_3.OEt_2$. All attempts[21] at the polymerisation of the optically active (+)-s-butyl *o*-vinylbenzyl sulphide under the influence of cationic catalysts ($SnCl_4$, BF_3, $TiCl_4$, $FeCl_3$, $ZnCl_2$, and ZnI_2) at temperatures ranging from $-78°$ to 115°C did not lead to the desired results either. Moreover, the above compound not only does not polymerise under these conditions but actively inhibits the polymerisation of styrene. The fairly marked tendency of t-butyl vinyl sulphide towards ionic polymerisation[16] is consistent with its enhanced tendency towards hydrolysis in an acid medium and may be accounted for by the greater nucleophilicity of the double bonds and the steric hindrance to the formation of a complex with the catalyst.

Cationic copolymerisation data[17] are in full agreement with the results obtained in homopolymerisation. Thus phenyl vinyl sulphide forms copolymers with styrene in the presence of $SnCl_4$ and with butyl vinyl ether in the presence of both $SnCl_4$ and $FeCl_3.6H_2O$. On the other hand, ethyl vinyl sulphide forms on initiation by $SnCl_4$ only an insignificant amount of a copolymer with butyl vinyl ether. Styrene, which usually polymerises very readily under the influence of $SnCl_4$, not only does not enter into copolymerisation with ethyl vinyl sulphide but is itself not polymerised in its presence.

The polymers and copolymers obtained on the basis of vinyl sulphides have many valuable properties: they can be used as ion exchangers[22] and dielectrics[23,24], and some are fire resistant[25]. In the copolymerisation[26] of α-alkenes with compounds having the general formula $ArS(CH_2)_nCH = CH_2$ (where X = Ar or Alk; $n = 1-12$) under the influence of $TiCl_4$, Et_3Al, Et_2AlCl, and $Et_3Al_2Cl_3$, polymers were obtained which did not lose their elasticity at 140°C in the course of 360 h, whereas polypropylene becomes brittle after only 12 h.

In conclusion one must note that the cationic polymerisation of sulphur-containing monomers is determined to a smaller extent by the properties of the double bond and to a greater extent by the nature of the sulphur atom, since the latter behaves as a second reaction centre binding the catalyst and lowering thereby its effective concentration. In other reactions such as hydrolysis or the addition of an alcohol, occurring under the influence of hydrogen chloride which does not show a tendency to form thionium complexes, vinyl sulphide and particularly sulphur-containing vinyl ethers can exhibit a fairly high nucleophilic reactivity of the double bond.

b. Polymerisation and copolymerisation of vinyl sulphides under the influence of radical initiators. In contrast to cationic polymerisation, free-radical polymerisation of vinyl sulphides is faster than the polymerisation of their oxygen analogues. Thus under the influence of azobisisobutyronitrile (AIBN) vinyl sulphide polymerises readily[18,27,28] giving a high yield of comparatively high-molecular-weight products, while vinyl ethers form only low-molecular-weight compounds after prolonged heating[29]. Benzoyl peroxide (BP) cannot be employed as the initiator, since it adds to vinyl sulphides via the mechanism[30]

$$(PhCOO)_2 + CH_2{=}CHSEt \rightarrow PhC(O)OCH_2\overset{\displaystyle SEt}{\underset{\displaystyle O(O)CPh}{CH}}.$$

The enhanced reactivity of vinyl sulphides compared with vinyl ethers is difficult to explain without resorting to the hypothesis of the expansion of the valence shell of sulphur with employment of its d orbitals. The considerable contribution of the d-orbital interaction is indicated also by the higher value of the stabilisation factor for vinyl sulphides[31] ($Q = 0.3-0.5$) compared with vinyl ethers[32] ($Q = 0.015$).

The possibility of the stabilisation of the intermediate free radical by the involvement of the d orbitals of the sulphur atom was indicated for the first time by Price[33-36].

An analogous state but of a biradical type arises when unsaturated sulphide molecules are excited by light, which explains the bathochromic shifts in their ultraviolet spectra[36].

The breakdown of coplanarity is of course found to entail a decrease of the resonance stabilisation of the radical[36]. Thus, in the copolymerisation of pentachlorophenyl vinyl sulphide initiated by AIBN, Holly[37,38] obtained $Q = 0.23$, whilst for phenyl vinyl sulphide[35] $Q = 0.32$. The decrease of Q for pentachlorophenyl vinyl sulphide is due to the *ortho*-effect of the chlorine atoms, resulting in a breakdown of coplanarity. The high value of the factor Q (0.6 ± 0.1) for divinyl sulphide[33] can be explained by the possibility of the additional resonance stabilisation of the intermediate radical:

$$\sim CH_2{-}\dot{C}H \leftrightarrow \sim CH_2{-}\underset{\displaystyle :S:}{\underset{|}{CH}}{-}\dot{C}H_2 \leftrightarrow \sim CH_2{-}\underset{\displaystyle :S}{\underset{\|}{C}}{-}\dot{C}H_2$$
$$\quad\quad\quad

A study of the polymerisation of *para*-substituted phenyl vinyl sulphides[40] established that the reactivity of the monomers in relation to the polymeric radical is directly related to the σ constants of the substituents. A similar tendency was observed also in the copolymerisation of such monomers with one another. It was found that their reactivity depends markedly only on the polar effect of the substituent, while in the polymerisation of substituted styrenes[41] the polar and resonance effects play equally important roles. The fairly high values of Q (Table 1) yet again indicate the possibility of the 3*d* orbital interaction of the sulphur atom with an adjacent radical centre.

Table 1. Copolymerisation of *p*-substituted phenyl vinyl sulphides (M_2) with styrene (M_1) and methyl methacrylate (M_1) at 60°C.

M_1	*p*-Substituent in M_2	r_1	r_2	Q	e
Styrene	MeO	3.98	0.18	0.35	−1.40
	Me	3.65	0.25	0.35	−1.10
	H	3.88	0.36	—	—
	Cl	3.57	0.32	—	—
	Br	3.42	0.31	—	—
Methyl methacrylate	MeO	0.77	0.04	0.46	−1.47
	Me	0.81	0.07	0.47	−1.29
	H	0.85	0.08	0.45	−1.26
	Cl	0.89	0.08	0.45	−1.24
	Br	0.85	0.20	—	—

Vinyl sulphides not only readily polymerise under free-radical conditions but they also copolymerise vigorously with other monomers[39,42–49]. The reactivities of the radicals derived from various monomers in relation to vinyl sulphides decrease in the sequence vinylcaprolactam[50] > methyl acrylate > methyl methacrylate > styrene, which is consistent with the reactivities of these radicals in relation to other monomers described in the literature[51].

It has been noted that any mixtures of ethyl vinyl sulphide with butyl vinyl ether in the presence of AIBN yield copolymers greatly enriched in ethyl vinyl sulphide units. Data for the compositions of the copolymers obtained from these monomers and methyl methacrylate show that in this case the sulphide monomers are more reactive than their oxygen analogues. Whereas the copolymers of vinyl ethers with the majority of monomers (for any composition of the initial mixture) contain as a rule not more than 50 mole % of vinyl units, vinyl sulphides can yield copolymers with a very high content of sulphide units. For example, in the copolymerisation of bis-(4-vinylphenyl)-sulphide (M_2) with styrene (M_1) the following monomer reaction factors were obtained[52]: $r_1 = 0.60$; $r_2 = 1.50$.

The reactivities of alkyl vinyl sulphides $AlkSCH{=}CH_2$ (M_2), where Alk = Me, Et, i-Pr, n-Bu, i-Bu, t-Bu, $PhCH_2$, and Ph, and of ethyl vinyl ether (M_3) in relation to various polymeric radicals M_1 (styrene, methyl methacrylate, and acrylonitrile) have been compared[31]. The authors obtained the empirical relation $\lg(k_{1,2}/k_{1,3}) = -0.188e_1 + 1.14$, which is in good agreement with the rearranged Alfrey-Price equations $\lg(k_{1,2}/k_{1,3}) = \lg(Q_2/Q_3) - (e_2 - e_3)e_1$. The differences between the polar and resonance factors for alkyl vinyl sulphides and ethyl vinyl ether were determined from the latter expression:

$$e_2 - e_3 = 0.43; \quad Q_2/Q_3 = 13.8.$$

The nature of the second substituent in vinyl sulphides does not influence significantly either their polymerisation or the degree of their involvement in copolymerisation[31,43]. However, it has been noted that, in the copolymerisation with styrene, phenyl vinyl sulphide is somewhat more reactive than alkyl vinyl sulphides and in homopolymerisation the rate of reaction decreases for $R = CH_2CH_2OH$ and particularly for R=  . B. On the other hand it has been stated[53] that vinylthiobenzothiazole polymerises readily in the presence of boron trialkyls or AIBN.

The rate of copolymerisation of vinyl sulphides with other monomers and their capacity for the formation of alternating copolymers increases in the sequence[31] styrene < methyl methacrylate < acrylonitrile, which parallels the sequence of the electron-accepting capacities of the monomers.

Although a spectrophotometric study of the synthesis of alternating copolymers of alkyl vinyl sulphides with acrylonitrile failed to reveal charge-transfer complexes[31] (CTC), the finding that isobutyl vinyl sulphide can copolymerise with acrylonitrile also in the absence of a radical initiator shows that charge-transfer complexes of the contact type can be formed and can be involved at least in the initiation of such copolymerisation.

At the same time the formation of such a complex has been confirmed spectrophotometrically[54] for the copolymerisation of vinyl sulphides with maleic anhydride. The equilibrium constant for its formation has been determined as 0.035 ± 0.007, while the analogous constant for vinyl ethers is 0.027 ± 0.002. This is related to the difference between the ionisation potentials of vinyl sulphides and vinyl ethers.

The copolymerisation of benzyl vinyl sulphide with SO_2 also proceeds with formation of charge-transfer complexes[55]. Copolymers with equal numbers of units were obtained from methyl vinyl sulphide and vinylene carbonate[56]. Attempts to copolymerise vinyl sulphides with phenylacetylene were unsuccessful[57].

Unfortunately the kinetics of the polymerisation of vinyl sulphides have so far been investigated very inadequately. One can mention the study of Tsuda et al.[58], who carried out the homopolymerisation of phenyl vinyl sulphide and calculated the apparent rate constant, the activation energy, and the entropy of reaction. In the course of a study of the copolymerisation of methyl vinyl sulphide with styrene, the propagation rate constant was determined[59] as 240 litre $mole^{-1}$ min^{-1}. Finally Koton and coworkers[60] determined the activation energy for the polymerisation of phenyl *p*-vinylphenyl sulphide, which proved to be 15.5 ± 1.2 kcal $mole^{-1}$.

In the majority of cases the information concerning the polymerisation of vinyl sulphides is descriptive. Thus it has been reported that the optically active (+)-s-butyl *o*-vinylbenzyl sulphide polymerises spontaneously[21]. When the process is carried out in the presence of AIBN, the product is a polymer with a high optical activity, which completely disappears when the polymer is acted upon by Raney nickel.

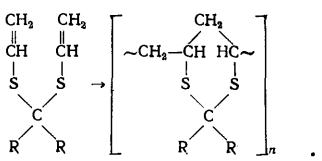
Graft-polymers from amine-containing vinyl sulphides and poly(alkyl acrylates) were obtained by radiation-induced polymerisation[61].

According to patent data, alkoxyalkyl vinyl sulphides readily polymerise and copolymerise with vinyl-containing compounds [62-66], such as derivatives of acrylic acid, vinyl chloride, vinylidene chloride, vinyl, allyl, and methylallyl ethers, and styrene and its derivatives. The polymers and copolymers are capable of being cross-linked [63,66] on heating as a result of transesterification or, in oxidation under mild conditions, as a result of the formation of a disulphide linkage. More vigorous oxidation (aqueous solution of hydrogen peroxide in an acid medium) leads to the formation of sulpho-groups and cation-exchange resins [63,64] which are superior in their ion-exchange properties to the cation exchangers based on polystyrenesulphonic acid [64].

Many patents describe the properties of the polymers and copolymers of vinyl sulphides [22,23,67-69]. It has been stated that thermoplastic polymers [70] with rubberlike properties [71-74], which are suitable for the formation of films and auxiliary materials in the textile industry, can be obtained on the basis of vinyl sulphides. Elastomers [75] with exceptional stability at high temperatures are formed in the copolymerisation of alkyl vinyl sulphides with ethylene in the presence of a small amount of allyl acrylate employed as the vulcaniser. Rubberlike copolymers have been obtained from butadiene and divinyl sulphide by copolymerisation in an emulsion [73]. The same sulphides are recommended as additives to styrene in order to improve the dielectric properties of polystyrene in relation to high-frequency currents [76].

It has been noted [77] that poly(alkyl vinyl sulphides) have higher glass points than the corresponding poly(alkyl vinyl ethers), which is due to the greater density of cohesion energy in the former.

More complex derivatives of the vinyl sulphide series (divinylmercaptals and divinylmercaptols), obtained by the dehydrochlorination of the corresponding bis-(β-chloroethyl)mercaptals and bis-(β-chloroethyl)mercaptoles, polymerise with formation of rubberlike polymers [78]. The polymerisation of the above monomers is carried out in the presence of AIBN (0.1–2 mole%) at 60–80°C both in bulk and in solution. The study of the properties of these polymers showed that the polymerisation proceeds mainly via an intermolecular–intramolecular mechanism with formation of rings in the chain, as in the radical polymerisation of divinylacetals [79]:



Depending on the conditions, linear or cross-linked polymers are obtained [80]. Polymerisation in solution and a low degree of conversion favour the formation of a linear polydivinylmercaptal containing cyclic units in the main chain and soluble in chloroform, benzene, and tetrahydrofuran (THF). Divinylthioacetal, divinylthiobutyral, and the divinylthioketal of acetone cyclopolymerise under the influence of AIBN, [81] forming soluble rubberlike polymers with $[\eta] = 0.1-0.2$. Under analogous conditions, divinylthioformal gives rise to a cross-linked polymer.

The polymerisation of a series of formaldehyde *S*-vinyl mercaptals under the influence of various initiators was investigated by Ringsdorf and coworkers [82]. In contrast to benzoyl peroxide, AIBN leads to polymers with $M = 27\,000$. In the presence of cationic catalysts, only small amounts of oligomers are obtained (owing to the formation of sulphonium ions).

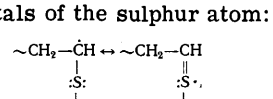
2. Polymerisation of Vinyl Thioacylates

The polymers synthesised on the basis of vinyl thioacylates have aroused considerable interest primarily because they can be used to prepare high-molecular-weight products containing mercapto-groups. The combination of the mercapto-group with a macromolecular structure leads to substances which are important in practice. Such polymers have been suggested as specific ion exchangers and protective agents against radiation [83,84] and also as model compounds for the elucidation of the role of the mercapto-group in certain enzymes [85]. The synthesis of the above polymers by the direct polymerisation of vinylmercaptans presents considerable difficulties owing to the low availability of the latter. Nevertheless, hydrolysis of polymers of vinyl thioacetate, preferably with a 10% NaOH solution in methanol, leads to the formation of polymers containing free mercapto-groups [86]. Polymeric protecting agents against radiation have been obtained by treating with hydrazine hydrate copolymers of vinyl thioacetate with *N*-vinylsuccinimide and *N*-vinylphthalimide [87]. However, these copolymers proved to be very unstable and were readily oxidised on standing in air, yielding insoluble strongly swelling products. The study of the kinetics of the oxidation of polyvinylmercaptan and its model low-molecular-weight analogues with molecular oxygen in various aprotic solvents in the presence of iron sulphate showed [88,89] that the rate of the reaction involving polyvinylmercaptan is more than ten times faster than that involving pentane-1,5-dithiol. For this reason, polythiols are used as cross-linking agents [86]. In most cases the oxidation of polythiols leads to the synthesis of insoluble polymers as a result of the formation of intermolecular disulphide bridges, but, depending on the oxidant, other derivatives can also be obtained. Thus, when stronger oxidising agents (for example HNO_3) were employed, polysulphonic acids were isolated [90].

Water-soluble copolymers containing mercapto-groups have been synthesised from *p*-vinylphenyl thioacetate [91,92]. The polymerisation and copolymerisation have been carried out under the influence of radical initiators. The solubility of the polymers decreased markedly on acidification.

The polymerisation of vinyl thioacetate has been investigated in greater detail [87,93]. It was established that the monomer polymerises fairly readily in the presence of AIBN and copolymerises under these conditions with *N*-vinylsuccinimide, *N*-vinylphthalimide, and *N*-vinylcarbazole. The polymerisation kinetics are characterised by a constant for chain transfer to the vinyl thioacetate molecule $C_M = 0.056$ at 60°C. For comparison Table 2 presents the constants for chain transfer by the monomer for certain vinyl esters.

The authors explained the observed phenomenon by the stabilisation of the radical centre as a result of the involvement of the *d* orbitals of the sulphur atom:



This is in full agreement with spectroscopic data and the chemical behaviour of vinyl thioacetate in free-radical addition reactions [98].

When the reactivities of vinyl acetate ($Q = 0.028$; $e = -0.30$) and vinyl thioacetate ($Q = 1.67$; $e = -1.34$) in

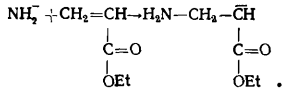
copolymerisation with *N*-vinylsuccinimde were compared, it was found that the replacement of oxygen by sulphur greatly enhances the reactivity of the monomer in copolymerisation.

Table 2. Constants for chain transfer by the monomer (C_M) for certain vinyl esters.

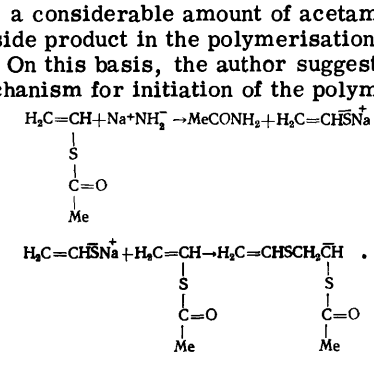
Monomer	Temp., °C	$10^3 C_M$	References
Vinyl acetate	60	0.15	94
Vinyl pelargonate	60	1.5	94
Vinyl stearate	60	2.3	94
Vinyl benzoate	79.6	0.7	95
Vinyl salicylate	70	8.0	96
Allyl acetate	70	0.723	97

Vinyl thioacetate copolymerises with methyl methacrylate [99], vinylene carbonate [100], diethyl maleate [101], maleic anhydride, and diethyl and dimethyl fumarates [102]. The products of the hydrolysis of the copolymers of vinyl thioloacetate and diethyl maleate can be used as cation-exchange resins and bases for coatings. After treatment with concentrated KOH solution in methanol, the copolymers of vinyl thioacetate and ethylene are converted into elastic materials which do not burn even at 250°C. [103,104]

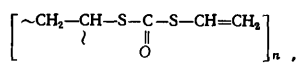
Liquid polymers of vinyl thioacetate have been obtained by its polymerisation with sodium in liquid ammonia [105]. According to elemental analysis and infrared spectra, under these conditions the polymers underwent ammonolysis and contained disulphide rings. The polymers have been used as protective agents against radiation. The polymerisation of vinyl thioacetate was investigated in greater detail by Leonard et al. [106] who showed that, in the polymerisation of vinyl thioacetate under the influence of sodium in liquid ammonia, polymers containing intramolecular and intermolecular disulphide bridges and mercapto-groups are formed, while thioacetate groups are completely absent (as a result of ammonolysis). It was established by elemental analysis that the polymers formed contain less than one amide group per polymer chain, which distinguished them from methacrylonitrile, methyl acrylate, ethyl acrylate, and n-propyl acrylate polymers for which initiation under these conditions takes place with participation of the amide anion [107,108]:



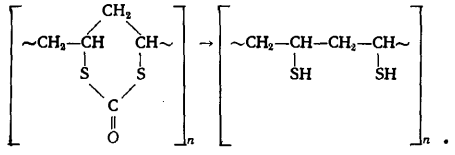
Moreover, a considerable amount of acetamide is formed as a side product in the polymerisation of vinyl thioacetate. On this basis, the author suggested the following mechanism for initiation of the polymerisation [106]:



Depending on the conditions, the *SS'*-divinyl ester of dithiocarbonic acid $(H_2C{=}CH{-}S{-})_2C{=}O$ forms a mixture of soluble and insoluble polymers [109], the soluble part consisting mainly of a polymer with *S*-vinyl thiocarbonate side chains:



If the polymerisation proceeds via an intramolecular-intermolecular mechanism, a soluble polymer containing trimethylene dithiocarbonate rings linked by methylene bridges is formed. These polymers can be converted into polyethylenethiols by subsequent alkaline hydrolysis:



III. POLYMERISATION AND COPOLYMERISATION OF VINYL MONOMERS CONTAINING OXIDISED SULPHUR

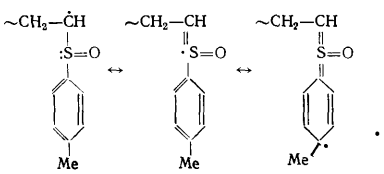
In contrast to α-vinyl sulphides, the double bond in α-vinyl sulphones and sulphoxides is highly activated in relation to nucleophilic reagents [6]. On the other hand, free-radical addition reactions are not very characteristic of such compounds. For example, thiols hardly react with vinyl sulphones on prolonged standing in air; in the presence of AIBN and on heating, a very slow reaction is observed [110]. The lower tendency of αβ-unsaturated sulphones to undergo homolytic addition reactions is explained by the fact that the sulphonyl group is incapable of stabilising adequately the free-radical state [34].

Numerous studies have been made on the structures of the sulphoxide and sulphone groups, the majority of which have been analysed in reviews [111-113]. Despite some conflict among the data obtained using different physical and chemical methods, one can regard it as proved that in the sulphone and sulphoxide groups there are linkages between sulphur and oxygen approaching in their properties a double bond. The *d* orbitals of the sulphur atom play a significant role in these linkages; the linkages are not of the "pure" semipolar type as has been suggested [36,114,115]. There is of course no complete analogy between these multiple bonds and the C=O bond of the keto-group. Firstly the S=O bonds are formed by atoms with much greater electronegativity differences than those between C and O, which enhances their polarity. Secondly these are $p_\pi - d_\pi$ bonds, in contrast to the $p_\pi - p_\pi$ double bonds. Therefore the problem of the conjugation of these bonds with unsaturated systems is also more complex. Nevertheless, the majority of investigators believe that conjugation with a sulphonyl group does not involve the S=O bonds but is limited to the involvement of the *d* shell of the sulphur atom. Examination of the polymerisation of these compounds leads to the same conclusion.

1. Synthesis of Polymers Containing Sulphoxide Groups

Polymers containing sulphoxide groups should in principle possess a set of interesting properties characteristic of their low-molecular-weight analogues, which serve as extracting agents for metals [116] and flotation

agents [117], and behave as physiologically active substances [118]. However, until recently these polymers were not obtained by the direct polymerisation of vinyl sulphoxides. It was believed [3] that the sulphoxide group inhibits both radical and ionic polymerisation. Indeed it was noted that methyl vinyl sulphoxide does not undergo homopolymerisation in the presence of radical initiators [119]. However it does copolymerise with styrene and methyl methacrylate giving low yields of copolymers with a low content of sulphoxide groups. Nevertheless, this was sufficient to determine the copolymerisation parameters and to calculate $Q = 0.10$ and $e = 0.9$. The low value of the resonance stabilisation factor compared with, for example, methyl vinyl sulphide [34] ($Q = 0.35$), led to the conclusion that there is no conjugation between the vinyl and sulphoxide groups or such conjugation is very weak. On the other hand, in the copolymerisation of the optically active *p*-tolyl vinyl sulphoxide (M_1) with styrene (M_2) a higher value of r_1 ($r_1 = 0.1 \pm 0.07$; $r_2 = 5.77 \pm 0.10$) was found [120] than for methyl vinyl sulphoxide (M_1) in its copolymerisation with the same monomer ($r_1 = 0.01$; $r_2 = 4.2$). This is probably related to the additional possibility of the delocalisation of the unpaired electron:



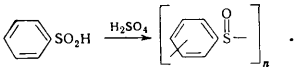
Polymers containing sulphoxide groups have been obtained by an indirect method†: by the polycondensation of sulphoxide-containing bifunctional compounds and by the oxidation of polythioethers or the products of the reaction of mercaptans with rubbers. Thus a sulphoxide-containing polycarbonate with a melting point of 230–250°C was obtained [121] by the reaction of phosgene with bis-(4-hydroxyphenyl) sulphoxide. The polycarbonate [122] based on bis-(4-hydroxy-3-methylphenyl) sulphoxide melts at 190°C.

Poly(phenylene sulphoxides) suitable for the formation of fibres, films, and high-temperature adhesives have been obtained [123] by the oxidation of the sulphide bridges in poly(phenylene sulphide) with nitric acid. The polymers are stable above 600°C. Other poly(phenylene sulphoxides) were obtained similarly [124] and were used to prepare, after heat treatment at 350–700°C in argon, thermostable non-combustible polymers [125].

The oxidation of polythietanes with one equivalent of hydrogen peroxide leads to the corresponding sulphoxides [126].

Polymers containing the sulphoxide group in the side chain have been obtained by the oxidation with hydrogen peroxide of the products of the addition of mercaptans to polybutadiene [127]. The authors noted that in all such cases sulphone as well as sulphoxide groups are formed and explained this observation by the different solubilities of the polymer in the course of the oxidation process. However, we showed [128,129] that, even when the medium remains homogeneous in the course of the oxidation of polymeric thioethers, selective oxidation cannot be achieved. The polymer contains sulphone as well as non-oxidised sulphide groups in addition to the sulphoxide groups. Moreover, the non-selectivity of the oxidation is also observed when acetic anhydride is used as a solvent, although it was established previously that monomeric sulphides are oxidised selectively in this medium to the sulphoxides [130,131]. The unusual behaviour in the oxidation of the sulphur atoms in the polymer is probably associated with the conformation of the polymer chain which hinders the approach of the oxidant to certain sulphide groups.

A polymer of the sulphonium type was obtained by the reaction of poly(methyl *p*-vinylphenyl sulphide) with dimethyl sulphate; this can be converted in turn into a sulphoxide polymer by treatment with a mixture of dimethyl sulphoxide and benzaldehyde in the presence of potassium t-butoxide [132]. Finally arenesulphinic acids form polymeric sulphoxides on dissolution in concentrated sulphuric acid [133]. Thus benzenesulphinic acid gives a 50% yield of a solid product which swells in alcohol and was shown subsequently to have the following structure [134]:



Direct polymerisation of vinyl sulphoxides was achieved for the first time by ourselves [129,135]. It was found that, contrary to the existing hypothesis concerning the inhibition of the polymerisation by the sulphoxide group, vinyl sulphoxides undergo homopolymerisation when acted upon by anionic catalysts. Naphthylsodium and the sodium–naphthalene complex were used as such catalysts. The process is fairly rapid and leads to the formation of oligomers ($M \simeq 2000$).

We may note that the rate of polymerisation of ethyl vinyl sulphoxide is somewhat lower than that of the corresponding sulphone, which may be related both to the lower nucleophilicity of the double bond in vinyl sulphoxides [6] and to the reduction of the efficiency of the catalyst in consequence of complex formation involving the sulphoxide group [136].

All attempts to polymerise vinyl sulphoxides under free-radical conditions failed despite the wide variety of initiators and conditions employed [129]. Nevertheless an inhibiting effect of sulphoxide groups is unlikely in this instance. It is sufficient to recall that dimethyl sulphoxide is quite widely used as a solvent in radical polymerisation processes and does not cause the destruction of the radical centres.

2. Polymerisation and Copolymerisation of Vinyl Sulphones

The polymerisation of $\alpha\beta$-unsaturated sulphones has been little investigated hitherto and is largely described in patents. According to these data, the polymers obtained from vinyl sulphones have valuable technical properties [137–141]. Thus the introduction of the sulphone group into the polymer increases its thermal stability and resistance to benzene [142,143]. The copolymers of dialkenyl sulphones [144] are recommended as additives to lubricating oils to improve their viscosity index. Vinyl sulphones are copolymerised with acrylonitrile and vinyl ethers in dimethylformamide [145] in order to obtain very strong thermostable and readily dyed fibres. Copolymers based on isopropenyl sulphones $RSO_2(CH_3)C{=}CH_2$ (R = alkyl, aryl, or alkylaryl) and vinyl acetate, methyl acrylate,

† Although these methods have no direct bearing on the polymerisation of vinyl sulphoxides, nevertheless it is thought necessary to examine them in this review since, as stated above, until recently polymers containing sulphoxide groups were not obtained by direct polymerisation.

styrene, acrylonitrile, and vinyl chloride are recommended for the synthesis of strong sheets, films, and compositions susceptible to mechanical treatment (moulding, extruding)[146]. Materials suitable for the formation of films and protective coatings and distinguished by a satisfactory capacity for being dyed are obtained by the copolymerisation of aromatic vinyl sulphones having the general formula $XC_6H_4(CH_2)_nY(CH_2)_2SO_2CH=CH_2$, where $X = SO_3H$, or SO_2CH_3 and $Y = O$, NH, or NC_2H_5, with acrylonitrile and vinyl chloride[147].

The study of the polymerisation of vinyl sulphones established that, despite their low tendency to undergo free-radical addition reactions, radical polymerisation of ethyl vinyl sulphone is fairly rapid and leads to a quantitative yield of the polymer[129,148]. Moreover, the rate of polymerisation of ethyl vinyl sulphone is higher than that of the corresponding sulphide[128], which may be explained by the absence of conjugation between the sulphenyl and vinyl groups in ethyl vinyl sulphone. This hypothesis had been proved earlier by Price[34,35], who obtained a very low reactivity factor ($Q = 0.07-0.11$) in a study of the copolymerisation of methyl vinyl and phenyl vinyl sulphones with styrene and vinyl acetate, in contrast to the corresponding sulphides ($Q = 0.35$).

At the same time one should note that, although the rate of homopolymerisation of ethyl vinyl sulphone is fairly high, it is possible to obtain only polymers with a low molecular weight. It was established subsequently[129] that the chain transfer constant for ethyl vinyl sulphone ($C_M = 0.087$) is very high, approaching the value of C_M for allyl acetate[97] and allyl chloride[149].

It might have been supposed that this is due to the presence of the mobile α-hydrogen atom, as happens in the polymerisation of various *S*-vinylmethylene disulphones[150,151]. The latter are known to form only oligomers under both free-radical and ionic conditions. This is due to the chain transfer by the active methylene group, the degree of polymerisation falling with increase of the acidity of the CH_2 group.

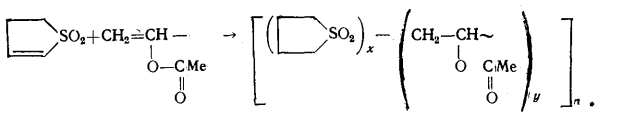
However, a study[129] of the kinetics of the polymerisation of ethyl vinyl sulphone under the influence of benzoyl peroxide showed that not only a high constant for chain transfer to the monomer and independence of the molecular weight of the polymer of initiator concentration but also an approach to unity of the reaction order with respect to the initiator is observed. Moreover, the activation energy for the process proved to be 23.8 kcal mole^{-1}, which is also somewhat high. All these findings indicate the formation of stable radicals in the process.

Stable radicals are probably formed as a result of the involvement of the SO_2 group in the chain transfer reaction. This is demonstrated also by the decrease of the rate of polymerisation in the presence of diethyl and dimethyl sulphones[129].

As expected, the anionic polymerisation of vinyl sulphones proceeds at a high rate, but, as in radical polymerisation, it leads to the formation of only low-molecular-weight products[129]. The low efficiency of the catalysts employed is also striking. In this case intense chain transfer is probably accompanied by the deactivation of the catalyst both as a result of metallation[152] and the formation of a complex via the oxygen atom of the sulphonyl group[153]. The unsuccessful attempts at the polymerisation of ethyl vinyl sulphone under the influence of Ziegler catalysts and boron alkyls[129] can also be evidently explained by the possibility of complex formation.

In the anionic copolymerisation of butyl vinyl sulphone with acrylonitrile a tendency was noted towards the formation of alternating polymers, which the authors attributed to steric effects[154]. $\alpha\beta$-Unsaturated sulphones copolymerise fairly readily with other monomers[155,156].

It has been noted that the copolymerisation of allyl sulphones with vinyl monomers leads to high-molecular-weight products[157]. 3-Sulpholene  does not polymerise at a "moderate" temperature (about 60°C); at an elevated temperature (80–140°C) a copolymer with alternating butadiene and SO_2 units is formed[158,159]. Although 2-sulpholene does not form homopolymers it does copolymerise with vinyl acetate[160]:



The highest sulpholene content in the copolymer does not exceed 50%, and an appreciable decrease of the viscosity of the copolymer is observed with increase of the sulpholene content in the monomer mixture.

Numerous data have been published in patents on the copolymerisation of vinyl sulphones[142-147,161-167]. Thus an interesting method for the preparation of cross-linked sulphone polymers includes the synthesis of oligomers capable of further polymerisation or copolymerisation with vinyl monomers[162]. The oligomers were obtained by the reaction with glycols or primary amines of monosulphones having the general formula $SO_2(CR=CR'R'')_2$ or polysulphones of the type $R'''(SO_2CR=CR'R'')_n$, where R''' is an organic substituent without functional groups whose valency is 2–6, R, R', and R'' = H, alkyl, or aryl. The oligomers are synthesised in the presence of an excess of the monosulphone (divinyl, propenyl vinyl, and ethyl vinyl sulphones) or polysulphone [1,4-bis(vinylsulphonyl)butane, 4,4-bis(vinylsulphonyl)biphenyl, etc.]. The polymerisation and copolymerisation of the oligomers are carried out under the influence of peroxide initiators such as H_2O_2, benzoyl peroxide, etc. Polymers of aminoaryl vinyl sulphones are recommended for the manufacture of polymeric dyes in view of the presence of a fairly large number of amino-groups susceptible to diazotisation[163,164]. Organometallic compounds and alkali metal hydrides or amides are employed as catalysts. Homopolymerisation and copolymerisation are carried out in bulk, in solution, or in a dispersion. The copolymers are suitable for the formation of fibres and also as stabiliser and auxiliary materials in the textile industry[165,166].

Polymeric dyes have also been obtained by the anionic polymerisation and copolymerisation of vinyl sulphones having the general formula $H_2C=CHSO_2ArN=NRNH_2$, where Ar is an aryl radical which can contain ring substituents[167].

It is noteworthy that, under free-radical conditions, vinyl sulphones copolymerise vigorously with inactive monomers, for example with vinyl acetate[34]. At the same time in the copolymerisation of methyl vinyl sulphone (M_1) with styrene (M_2) the percentage of its involvement is very slight ($r_1 = 0.01$; $r_2 = 2.0$).[34] Ethyl vinyl sulphone does not copolymerise with butadiene and behaves under these conditions merely as a diluent i.e. with increase of its concentration in the initial mixture the rate of homopolymerisation of butadiene falls[129].

In conclusion of this section one should note that the polymerisation of vinyl sulphones is fairly rapid both under

free-radical and ionic conditions. At the same time, owing to the specific features of the sulphone group, this entails the formation of only low-molecular-weight products, because of the intense chain transfer to the monomer. The polymerisation process is also complicated by side reactions leading to a decrease of the efficiency of the catalysts: interaction of the radical centre with the SO_2 group and metallation or complex formation involving the sulphone group in polymerisation under the influence of anionic catalysts.

The data presented above show that, despite the large number of studies on the polymerisation of unsaturated sulphur-containing compounds, there have been only a limited number of kinetic investigations. This hinders appreciably the interpretation of the results. Much still remains to be done in the field of the polymerisation of this interesting class of compounds.

Light Fastness of Coloured Polymeric Materials

Yu.A.Ershov and G.E.Krichevskii

The paper examines the photochemical phenomena underlying the photodegradation of dyes in coloured polymeric materials and determining the rate and degree of fading of the dyeings. Methods are described for assessing quantitatively the light fastness of coloured materials, and the principles of a scientifically based standardisation of methods for testing the light fastness of dyeings are discussed. The effects of the conditions of exposure and the physicochemical properties of the dye and the polymer matrix on the light fastness of the dyeing are also considered. A list of 106 references is included

I. INTRODUCTION

Investigations of the action of light on coloured polymeric materials (films and fibres) are continually increasing every year. More than five hundred original papers have been published on this problem merely during the past five years. Such a wealth of publications is due to the increased ranges of dyes and polymer materials and the enhanced demands made on their light resistance.

The qualitative concept of the light fastness of a material is fairly definite. It implies the ability of the material to retain its initial properties under the influence of electromagnetic radiation in both visible and ultraviolet regions of the spectrum. In coloured materials both the dye and the polymer substrate undergo degradative processes under the influence of light.

In a coloured polymeric material both the polymer itself and the dye on it should have adequate resistance to light. If they differ markedly, the material will cease to function before its potential light fastness is exhausted. From this point of view an ideal material will be one in which polymer and colorant will have closely similar and high degrees of resistance to light.

The most obvious results of photodegradation are a change in the colour of the material and impairment of its mechanical properties. The changes in these properties during a given time of exposure are naturally most often chosen as criteria of resistance to light[1-4]. Despite the apparent obviousness and simplicity of such criteria, their practical use encounters very considerable and fundamental difficulties. A quantitative assessment of the colour of a material is already difficult because it must depend on subjective assessments by different observers. Certainly, the elaboration of formal systems of trichromatic coordinates, making possible the widespread use of instrumental estimates, shows promise. We must acknowledge the great importance of work[3,5-12] aimed at estimating objectively and instrumentally (photometrically) the change in colour undergone by coloured fibres during illumination.

No difficulty is presented by the quantitative evaluation of the mechanical properties of polymeric materials, since appropriate experimental methods have been well developed. However, the mechanical characteristics of a material are in general non-linear functions of time of exposure, so that results obtained for short exposures cannot form a reliable basis for prognostication[13]. Furthermore, little study has been made of the relation between chemical changes in the structure of a polymeric material and changes in its mechanical properties. It is therefore difficult to predict quantitatively the change in mechanical properties from the extent of chemical change, which causes the variation in the properties of the material[14].

The above comments make clear why the past years have seen an increase in the number of quantitative studies of photochemical processes occurring in coloured materials. Special mention may be made here of Refs. 15-22.

Information on the mechanism and the kinetics of the photodegradation of coloured polymer materials, revealing the factors determining their resistance to light, is of great interest for various fields of technology in which these materials (primarily films and fibres) are employed. The Soviet literature contains no reviews on the photostability of coloured polymer materials; among foreign publications the surveys by Giles[23] and by Brunnschweiler[2] may be noted. The present Review pays close attention to the main factors governing the resistance of coloured polymer materials to light, and summarises information on methods for its quantitative evaluation.

II. MONOCHROMATIC ILLUMINATION

1. Determination of Photostability from Quantum Efficiency of Photochemical Conversion

The change in properties of a coloured material under the influence of light is due to photochemical reactions occurring in the material. At least in principle, therefore, the light resistance with respect to any parameter can be related with a quantitative characteristic of the photochemical changes. The most rigorous of such characteristics is the quantum yield γ of a photochemical reaction, which is the reciprocal of the number of quanta of radiation absorbed in decomposing one reactant molecule or forming one product molecule. The quantum efficiency can obviously serve as a measure of the photostability. It is therefore useful to examine in greater detail the quantitative relation between quantum efficiency and the photochemical processes occurring in coloured polymers.

Wity monochromatic illumination the quantum yield[24] is calculated by definition from the relation

$$W = \gamma\Phi \qquad (1)$$

where W is the rate of the given chemical change and Φ the

rate of absorption of light, i.e. the number of quanta absorbed by the specimen in unit time. Formula (1) shows that the quantum yield γ is a coefficient of proportionality linking these two quantities.

If we denote by m the quantity of material undergoing conversion, we have

$$W = dm/dt . \qquad (2)$$

Here m is the integral of the concentration x throughout the volume v of the specimen:

$$m = \int_{(v)} x\, dv . \qquad (3)$$

If the concentration is the same throughout ($x = c$), then

$$m = cv \qquad (4)$$

and, as is usual with homogeneous dark and also liquid-phase photochemical reactions with stirring, the rate W is proportional to the change in concentration in unit time:

$$W = v\, dc/dt . \qquad (5)$$

When coloured polymer materials are illuminated, the concentration of absorbing centres varies non-uniformly through the thickness of the specimen, and the more general expression (2) must be used.

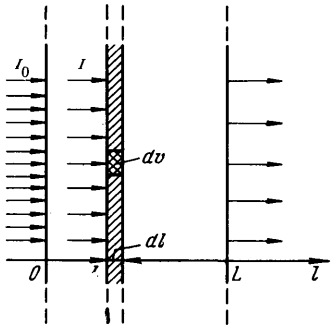

Figure 1. Diagram of plane-parallel specimen undergoing illumination.

The quantity of light absorbed by a specimen or one of its components can in principle be calculated by means of the Bouguer–Lambert–Beer law for a specimen of any shape and with any concentration distribution of absorbing centres. However, avoiding further complications and also with no loss of generality in the conclusions, we shall henceforward consider a specimen in the form of a plane-parallel layer of thickness L (a film) exposed on one side to a parallel beam of light perpendicular to the surface (Fig. 1). Here I_0 (in einsteins dm^{-2}) is the intensity of the light flux incident on the specimen, and I the intensity of the light flux reaching a layer at an arbitrary depth l.

In a multicomponent system every component is able to absorb light and undergo changes or cause changes in other components (stabilisation and sensitisation effects), which complicates Eqn. (1). For a binary polymer–colorant system, for example, the rate of photoconversion of the colorant is

$$W_c = \gamma_c \Phi_c + \gamma_c^p \Phi_p \qquad (6)$$

where Φ_c and Φ_p are the rates of absorption of light by colorant and by polymer respectively, and γ_c and γ_c^p are the quantum efficiencies of conversion of the colorant resulting from the action of light absorbed solely by the colorant (Φ_c) and solely by the polymer (Φ_p). The corresponding formula for the rate of breakdown of the polymer is

$$W_p = \gamma_p \Phi_p + \gamma_p^c \Phi_c .$$

This last formula is used in studying the photodegradation of polymers sensitised by colorants[25–28].

Although in the present paper attention is paid mainly to revealing the kinetic mechanism of the breakdown of a colorant on a fibre, not of the fibre-forming polymer itself, the arguments and mathematical expressions given below can be successfully applied to quantitative evaluation of the photodegradation of the polymer[29].

If the absorbing centres of colorant and polymer are mutually independent, the Bouguer–Lambert–Beer law gives

$$\Phi_c = I_0 S \varepsilon_c' \int_0^L x_c(l) \exp\left[-\int_0^l (\varepsilon_c' x_c(l) + \varepsilon_p' x_p(l))\, dl\right] dl , \qquad (7)$$

$$\Phi_p = I_0 S \varepsilon_p' \int_0^L x_p(l) \exp\left[-\int_0^l (\varepsilon_c' x_c(l) + \varepsilon_p' x_p(l))\, dl\right] dl , \qquad (7a)$$

in which S is the surface area of the specimen, ϵ_c' and ϵ_p' (in $M^{-1}\ dm^{-1}$) are the natural molar extinction coefficients of colorant and polymer, and $x_c(l)$ and $x_p(l)$ are the concentrations of colorant and polymer absorbing centres at depth l. Equations (7) and (7a) cannot be integrated in the general case of arbitrary concentration distributions, which leads to great complications in kinetic investigations of photoreactions in solid polymers.

In the simplest case, if $x_c = c_c$ and $x_p = c_p$, we obtain

$$\Phi_c = I_0 S \frac{\varepsilon_c' x_c}{\varepsilon_c' x_c + \varepsilon_p' x_p}\left[1 - e^{-(\varepsilon_c' x_c + \varepsilon_p' x_p)L}\right] , \qquad (8)$$

$$\Phi_p = I_0 S \frac{\varepsilon_p' x_p}{\varepsilon_c' x_c + \varepsilon_p' x_p}\left[1 - e^{-(\varepsilon_c' x_c + \varepsilon_p' x_p)L}\right] . \qquad (8a)$$

The parameters

$$f_c = \frac{\varepsilon_c' x_c}{\varepsilon_c' x_c + \varepsilon_p' x_p} = \frac{D_c}{D_c + D_p} = \frac{D_c}{D} \qquad (9)$$

$$f_p = \frac{\varepsilon_p' x_p}{\varepsilon_c' x_c + \varepsilon_p' x_p} = \frac{D_p}{D_c + D_p} = \frac{D_p}{D} \qquad (9a)$$

(where D_c, D_p, and D are the optical densities (decadic or natural) of colorant, polymer, and specimen as a whole) define the fraction, absorbed by the given component, of the total quantity of light $\Phi = \Phi_c + \Phi_p = I_0 S(1-10^{-D})$ (on passing to decadic optical densities): i.e.

$$f_c = \Phi_c/\Phi , \qquad (10)$$

$$f_p = \Phi_p/\Phi . \qquad (10a)$$

The parameters f_c and f_p are often termed[30] "shielding coefficients", since they allow for the internal filtering effect of the second component.

When relations (10) and (10a) are incorporated, Eqn. (6) is written

$$W_c = (\gamma_c f_c + \gamma_c^p f_p)\Phi . \qquad (6a)$$

When one of the components is photochemically inactive, e.g. if the polymer does not sensitise photodecomposition of the colorant ($\gamma_c^p = 0$), formula (6) becomes

$$W_c = \gamma_c f_c \Phi = \gamma_c \Phi_c \qquad (6b)$$

which is convenient for assessing quantitatively the factors

influencing the light fastness of a colorant. If the colorant does not sensitise photodegradation of the polymer (i.e. $\gamma_p^c = 0$), the rate of breakdown of the latter is

$$W_p = \gamma_p f_p \Phi = \gamma_p \Phi_p . \quad (11)$$

It follows from (6a) that the light fastness of a colorant increases with decrease in W_c. Light fastness is therefore more conveniently characterised by the reciprocal of the rate of photoconversion

$$\tau_c = 1/W_c . \quad (12)$$

The parameters γ_c and γ_c^p represent in general the most important objective factors determining the light fastness of a colorant on a fibre, and enable a quantitative comparison to be made of the light fastness of different dyes on different kinds of fibres. However, τ_c will be a more rigorous characteristic of light fastness, taking into account not only quantum efficiency but also the rate of absorption of light by the sample.

When comparing the light fastness of different colorants by means of τ_c, we must pay special attention to the dependence of this parameter on the concentrations both of the colorant in the polymer and of the absorbing centres of the polymer. The concentration dependence of Φ_c and Φ_p is determined by the relations (7), (7a), (8), and (8a). The parameters γ_c and γ_c^p may also depend on concentration, as will be shown below. However, even without detailed analysis it is obvious that, for example, τ_c will be longer at a low colorant concentration than at a higher concentration of the same colorant (provided that no aggregation of the dye occurs, which would affect the rate of the photochemical processes), since in the former case values of Φ_c and hence of W_c will be smaller. With this definition of τ_c the light fastness of a given colorant will vary. Hence it is necessary to standardise the concentrations at which a comparison is made of the light fastness of different dyes, and this in turn requires knowledge of the specific dependence of rate of photoconversion on the concentration of colorant on the fibre.

2. Dependence of Rate of Photochemical Reactions on Concentration of Absorbing Centres

For photochemical reactions, in contrast to dark reactions, the concept of reaction order is usually devoid of meaning. According to Eqn. (1) the rate of a photochemical reaction is indeed determined by the product of the two quantities γ and Φ, each of which may be a complicated function of reactant concentrations. Only in the simplest cases, over comparatively short intervals of time, can the product approximate to a parabolic relation of the type

$$\gamma \Phi = kc^p \quad (13)$$

where k no longer has the significance of a rate constant, but is a proportionality coefficient depending in general on the reactant concentration.

If the action of monochromatic radiation on a sufficiently virogously stirred solution produces photoconversion of a dye or related compound, formula (1) leads to an equation of the type (provided that quantum efficiency is independent of reactant concentration) [31]

$$dc/dt = -\frac{\gamma I_0}{L}\frac{D_c}{D}(1-10^{-D}) \quad (14)$$

where c is the molar concentration of the dye, I_0 (in einsteins $dm^{-2}\ s^{-1}$) the intensity of the incident light flux, L (dm) the thickness of the layer of illuminated solution, $D_c = \epsilon_c c L$ the optical density of the dye, $D = D_c + D_{solv}$ the optical density of the solution, in which D_{solv} is the optical density of the solvent, and ϵ_c is the decadic molar extinction coefficient of the dye. At low optical densities $D < 0.1$ we have $(1-10^{-D})/D \simeq 2.3$ to within 10%, and the expression (14) then has the form of a first-order kinetic equation

$$dc/dt = -2.3\gamma I_0 \epsilon_c c = -k_1 c \quad (15)$$

with the rate constant $k_1 = 2.3\gamma I_0 \epsilon_c$. At high optical densities $D > 1$, we have $(1-10^{-D})/D = 1/D$ to within 10%, and the dependence of dc/dt on c is described by a hyperbolic function.

At optical densities in the range 0.01–2 different functional relations, easily approximated by power series, are obtained between W and c.[24,32] An important condition for a simple power form is that the photochemical reactant should be uniformly distributed through the thickness of the specimen. Only then is the concentration x constant through this thickness and proportional to the total quantity of substance m, while the rate of photoconversion is proportional to the change of concentration in unit time dx/dt. Conducting the photochemical reaction in a sufficiently vigorously stirred solution will guarantee the above condition.

In a coloured polymeric material—whether film or fibre—the condition of uniform distribution of absorbing centres (the optical densities of coloured materials are usually around unity) already breaks down at the start of exposure, owing to more intense fading of the dye in the surface layers. As a result, the dye concentration varies from point to point, and it is not possible to integrate Eqn. (14) for the general case. This feature of solid-phase photochemical processes has been ignored in certain publications [24,31,33]. The optical density ceases to be a linear function of thickness, and is given by the integral

$$D = \varepsilon \int_0^l x(l)\,dl,$$

where $x(l)$ is the local concentration, depending on the depth of that layer l. Yet it was concluded [31] that, if the local rate of photoconversion is proportional to the quantity of light absorbed (order of reaction with respect to absorbed light intensity $n = 1$), the local rate dx/dt and the observed total rate dm/vdt should coincide. It can easily be shown that this conclusion is in general incorrect.

On the assumption that there is no diffusion of photodecomposition products, we suppose that illumination of a film produces a colorant distribution represented by the equation

$$x_c = \sigma_c/a_c - b_c l \quad (16)$$

where σ_c, a_c, and b_c are empirical coefficients enabling us to describe the monotonic increase in colorant concentration with distance from the exposed surface. Assuming for simplicity that the polymer is non-absorbing, i.e. that $\epsilon_p' = 0$, we then find from Eqns. (6) and (7) that the mean observed rate per unit volume is

$$W_c/v = \frac{\gamma_c' I_0 \epsilon_c'}{L}\int_0^L \frac{\sigma_c}{a_c - b_c l}\exp\left[-\int_0^l \frac{\epsilon_c' \sigma_c}{a_c - b_c l}\right] dl \quad (17)$$

or, after integration,

$$W_c/v = \frac{\gamma_c' I_0}{L}\cdot\frac{\sigma_c \epsilon_c'}{a_c^\beta b_c \beta}[a_c^\beta - (a_c - b_c L)^\beta] \quad (18)$$

where $\beta = \epsilon_c' \sigma_c / b_c$. At the same time the local rate at

depth l is

$$W_c(l) = dx_c/dt = \gamma_c \epsilon_c' x_c I_0 e^{-\epsilon_c' \int_0^l x_c dl} = \gamma_c I_0 \frac{\epsilon_c' \sigma_c}{a_c^\beta}(a_c - b_c l)^{\beta-1}. \quad (19)$$

The ratio of rates (18) and (19)

$$\frac{W_c}{vW_c(l)} = \frac{[a_c^\beta - (a_c - b_c l)^\beta]}{Lb_c\beta\,(a_c - b_c l)^{\beta-1}} \quad (20)$$

obviously not only differs from unity but also depends on the depth l, which should in general be the case. It follows from the above discussion that experimental investigation of the dependence of the rate of photoprocesses (in particular fading) on the reactant concentration encounters considerable difficulties.

The most comprehensive investigations of the effect of colorant concentration on rate of fading in polymer films have been made by Giles and his coworkers [23,34-38]. Giles adopts as the main criterion of the light fastness of a dye its characteristic fading time t_f, which is the time required for the initial colorant concentration c_0 to decrease by a certain amount, e.g. by 10% or 50% ($t_{0.1}$ or $t_{0.5}$). Despite the simplicity and the convenience of the experimental determination of this criterion, its theoretical interpretation is in several cases difficult. The very definition of fading time already contains an ambiguity. The concentration of colorant in the test material becomes non-uniform as fading progresses, even if it had been uniform during coloration, and the concept of concentration for the specimen as a whole loses its meaning for optical densities exceeding 0.1. In most of Giles's experiments, therefore, t_f characterises not the time of decay of the initial colorant concentration (by a certain amount) but that of the optical density of the specimen or the mean colorant concentration.

The concept of total concentration is valid for low optical densities, and from (15) we then have

$$t_{0.5} = \ln 2/2.3\gamma I_0 \varepsilon_c = 0.3/\gamma I_0 \varepsilon_c \; . \quad (21)$$

This indicates that t_f is independent of c_0 for colorant concentrations corresponding to optical densities $D \leq 0.1$, and the graph of $\lg t_{0.5}$ against $\lg c_0$ should be a straight line parallel to the $\lg c_0$ axis, making an intercept of $-0.52 - \lg(\gamma I_0 \epsilon_c)$ on the $\lg t_{0.5}$ axis. Such a relationship was observed for small initial concentrations of colorant homogeneously distributed in a film [38]. If the light is monochromatic, such graphs can be used to determine γ for known I_0 and ϵ_c by extrapolation to $c_0 = 0$. However, Giles used polychromatic radiation in most of his experiments.

At optical densities exceeding unity we can no longer use Eqn. (14), obtained for stirred solutions, where the colorant concentration is constant throughout the thickness of the layer: instead, we must apply the equation

$$\frac{d}{dt}\int_0^L c\,dl = -\gamma I_0 \; . \quad (22)$$

Introducing the mean concentration

$$\bar{c} = \int_0^L c\,dl/L \quad (23)$$

we obtain

$$d\bar{c}/dt = -\gamma I_0/L \quad (24)$$

which in effect is used by Giles for high optical densities. Here $d\bar{c}/dt$ is the observed total rate of photoconversion, which is related in extremely complicated fashion to the local rate (see above), so that the true order of the photochemical reaction cannot be assessed from this relation, as it is determined by the local rate.

The characteristic time can be defined in terms of the mean concentration, and in the present case

$$t_{0.5} = 0.5c_0 L/\gamma I_0 \; . \quad (25)$$

The plot of $\lg t_{0.5}$ against $\lg c_0$ will then be a straight line of unit slope making an intercept $\lg(0.5L/\gamma I_0)$ on the ordinate axis. Giles obtained relations of this type in several cases for large initial concentrations [23,34-38]. With monochromatic illumination we can also determine γ from this relation. With polychromatic illumination a quantity equivalent to the product γI_0 should be the same, if γ is independent of colorant concentration, for low initial concentrations, when γI_0 occurs in the experimentally determined quantity $-0.52 - \lg(\gamma I_0 \epsilon)$, and for high initial concentrations, when γI_0 can be calculated from the experimental value of $\lg(0.5L/\gamma I_0)$.

It is in general impossible to calculate the fading time theoretically and relate it to the characteristics of coloured material and light source for the practically important range of optical densities $D = 0.1-1.0$, since this would require knowledge of the specific time variation of the distribution of absorbing centres through the thickness of the specimen. In the simplest case, when breakdown of the absorbing centres can be represented as the single reaction

$$A_1 + h\nu \rightarrow A_2$$

the distribution of the concentration of the reactant A_1 through the thickness at any instant can in principle be found by solving the set of non-linear equations in first-order partial derivatives (when A_2 does not absorb)

$$\begin{aligned} \partial x_1/\partial t &= -\gamma \varepsilon_1 I x_1 \\ \partial I/\partial l &= -\varepsilon_1 I x_1 \end{aligned} \quad (26)$$

in which x_1 is the concentration of A_1 at depth l, where the light intensity is I, and ϵ_1 is the molar extinction coefficient of A_1. The distribution $x_1 = f(l)$ would be obtained by solving Eqns. (26), but it is not yet possible to obtain a solution.

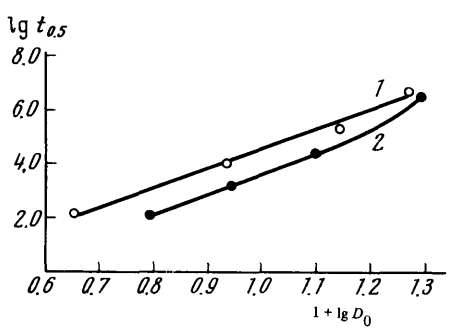

Figure 2. Dependence of characteristic fading time of the reactive dye Propionic Bright Red NZV exposed to PRK-2 lamp on initial concentration in cellulose film [25,26]: 1) covalently bound; 2) adsorbed.

With most coloured films and fibres the plots of $\lg t_f$ against $\lg c_0$ obtained by Giles [23,34-38] are only qualitatively consistent with the theoretical relation following from Eqns. (21) and (25). The slope of the linear portions of the curves at high initial concentrations usually differs from unity.

Giles explains such departure from the theoretically predicted behaviour by a purely geometrical factor—aggregation of the dye—which leads to a change in quantum efficiency with increase of concentration. It appears to the Reviewers that aggregation is only one of the possible causes.

Reactive dyes[39], which combine chemically (covalently) with certain functional groups in the fibre, are incapable of aggregation in the polymer substrate. Therefore the observed[25] increase in the light fastness of such dyes with increase in their concentration in the fibre cannot be explained by aggregation. Figs. 2 and 3 illustrate logarithmic plots of the characteristic fading time of reactive dyes against their concentration on cellulosic and polyamide films[25-27]. The appearance of a concentration effect with reactive dyes may be attributed to concentration-dependent self-quenching.

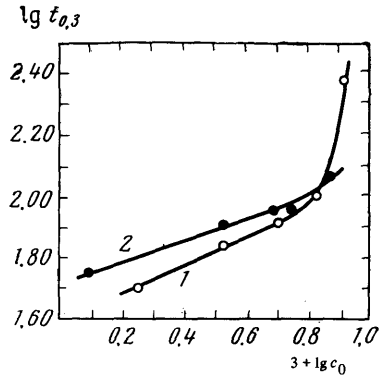

Figure 3. Dependence of characteristic fading time of the reactive dye Propionic Bright Red NZV exposed to BUV-30 lamp on initial concentration in a polyamide film[28]: 1) covalently bound; 2) adsorbed.

Analysis of the results obtained by Giles et al.[23,34-38] indicates that, although the characteristic time t_f is a convenient parameter for assessing the light fastness of a colorant, it is usually difficult to relate theoretically to photochemical parameters for the purpose of predicting light fastness.

A far more rigorous approach is to assess light fastness by means of the quantity $\tau_c = 1/W_c$ determined from the initial rates of fading at various colorant concentrations[17,26,27]. An advantage of this method is that the determination of quantum efficiency is independent of the concentration distribution of absorbing centres established during exposure. It is important merely that their concentration should be constant initially and not vary too rapidly with time. Furthermore, the quantum efficiency determined from the initial rate is independent of the accumulation of reaction products and is characteristic of the initially prepared system[28]. However, certain difficulties are encountered in determining light fastness from initial rates of fading.

1. In some cases the kinetics of fading determined for the initial period may change markedly with time. If two dyes have the same initial rate of fading and markedly different subsequent rates, for example, assessment of their light fastness from $\tau_c = 1/W_{c,0}$ will be incorrect. In this case the quantity τ_c determined from the initial rate cannot represent the real light fastness of the colorant.

2. Choosing the duration of the initial portion of the kinetic curve, along which the rate is calculated, is a very complicated matter. It is important that this section should correspond to a visually perceptible and practically important degree of fading of the dyeing. Fading is a superficial phenomenon in the sense that almost complete fading of a dyeing may be perceived, whereas the total quantity of colorant in the substrate has changed by at most 20–30%. It appears to the Reviewers that the most suitable characteristic time is $t_{0.1}$, and the initial rate in this method[17,26] should correspond to a diminution of the initial dye content by at most 10%.

III. POLYCHROMATIC ILLUMINATION

1. Calculation of Rate of Photodegradation of Coloured Materials

The large majority of investigations on photochemical changes in coloured materials have been made with polychromatic sources of ultraviolet radiation and visible light having various types of distribution of intensity with wavelength. This situation is primarily due to the practical requirement of forecasting light fastness in polychromatic sunlight and also to the simpler technique of polychromatic exposure.

Considering the principal quantitative relations determining light fastness under polychromatic illumination, we first assume that the effects of light of different wavelengths is additive and that sensitisation is absent. The total rate of photochemical conversion will then be the sum of the rates W_λ due to different portions of the incident spectrum. If this spectrum is discrete, consisting of several lines of wavelengths $\lambda_1, \lambda_2, \ldots, \lambda_n$, we have

$$W = \sum_{i=1}^{n} W_i = \sum_{i=1}^{n} \gamma_i \Phi_i \qquad (27)$$

where W_i, γ_i, and Φ_i are respectively the rate of conversion, the quantum efficiency, and the rate of absorption of light at wavelength λ_i. If, however, the radiant spectrum is continuous, extending from λ_0 to λ_m, we find that

$$W = \int_{\lambda} \omega_\lambda \, d\lambda = \int_{\lambda} \gamma_\lambda \, d\Phi_\lambda \, . \qquad (27a)$$

The quantities W_i and Φ_i correspond to Eqns. (1) and (7), while

$$\omega_\lambda = \lim_{\Delta\lambda \to 0} \frac{\Delta W}{\Delta \lambda} \qquad (28)$$

is the limit of the ratio in which ΔW is the rate of photoconversion due to the width $\Delta\lambda$ of the radiated spectrum at wavelength λ.

The quantity $d\Phi_\lambda$ is given by a formula analogous to (7):

$$d\Phi_\lambda = I_{0\lambda} S \varepsilon'_{c\lambda} \int_0^L x_c \exp\left[-\int_0^l (\varepsilon'_{c\lambda} x_c - \varepsilon'_{p\lambda} x_p) \, dl \right] dl \, d\lambda \qquad (7b)$$

where $\epsilon'_{c\lambda}$ and $\epsilon'_{p\lambda}$ are the molar extinction coefficients of colorant and polymer at wavelength λ, and $I_{0\lambda}$ is the spectral density of the radiation at the same wavelength. For

concentrations $x_c(l)$ and $x_p(l)$ constant through the thickness of the specimen Eqn. (7b) simplifies to

$$d\Phi_\lambda = \frac{D_{c\lambda}}{D_\lambda} I_0 (1 - 10^{-D_\lambda}) d\lambda \qquad (8b)$$

where $D_{c\lambda}$ and D_λ are the optical densities of the colorant and of the specimen as a whole at wavelength λ.

Since the change from summation to integration is clear from a comparison of corresponding formulae, we shall henceforward suppose for simplicity that the radiated spectrum comprises two lines at λ_1 and λ_2 (the extension to a larger number of lines is self-evident). The rate of photoconversion of the absorbing centres, when sensitisation or initiation occurs by the absorption of light by other centres, will then be (for the colorant)

$$W_c = \gamma_{c_1}\Phi_{c_1} + \gamma_{c_2}\Phi_{c_2} + \gamma^p_{i_1}\Phi_{p_1} + \gamma^p_{i_2}\Phi_{p_2}. \qquad (6c)$$

The initial rate of fading with a uniform distribution of the colorant is given by the expanded equation

$$W_{c_0} = I_{1_0} D^{-1}_{1_0} (1 - 10^{-D_{1_0}})[\gamma_{c_1} D_{c_{1,0}} + \gamma^p_{i_1} D_{p_1}] + I_{2_0} D^{-1}_{2_0} (1 - 10^{-D_{2_0}}) \times \qquad (29)$$

$$\times (\gamma_{c_2} D_{c_{2,0}} + \gamma^p_{c_2} D_{2_0})$$

in which the subscripts 1 and 2 relate to wavelengths λ_1 and λ_2, and the subscript 0 to the initial state.

Direct extrapolation of fading data obtained with a source having one spectral distribution (e.g. monochromatic) to a source having a different spectral distribution (e.g. polychromatic) is in general inadmissible, and would lead to especially marked distortions when colorants having different spectral characteristics are compared. Nevertheless, if the quantum efficiencies are known for different portions of the radiant spectrum, formula (27) or (27a) can be used to calculate the rate of photochemical conversion for any source and thus the conditions under which fastness ratings are determined can be standardised. When sensitisation occurs, Eqn. (27) for the simplest case of a binary system can be expanded to

$$W_c = \sum_{i=1}^{n} (\gamma_{ic}\Phi_{ic} + \gamma^p_{ic}\Phi_{ip}). \qquad (27b)$$

The fastness rating is then determined from the equation

$$\tau_c = 1/\sum_{i=1}^{n} (\gamma_{ic}\Phi_{ic} + \gamma^p_{ic}\Phi_{ip}) . \qquad (12a)$$

2. Standardisation of Methods of Fastness Testing

Formula (12a) contains all the parameters required to standardise the conditions for the determination of light fastness. As mentioned earlier, standardisation must be effected with respect to the initial rates of fading of the dyeing. The initial rate W_{c0} depends explicitly [Eqn. (29)] on the radiation intensities at the different wavelengths $I_{1,0}$ and $I_{2,0}$ and on the optical densities $D_{0,i}$ at these wavelengths.

Thus the main factor to be standardised is the spectral distribution of intensity of the light source. This condition is essentially satisfied automatically in all experiments on natural fading, since the same light source is used. If different sources are employed, the same values $I^{st}_{0,i}$ adopted as standard must be substituted, for all the test colorants, in an expression of type (29). Determination of light fastness from the initial rate $W_{c,0}$ will then be standardised with respect to the radiant flux.

Standardisation of the optical densities occurring in Eqn. (29) is a more complicated matter. Firstly, it is impossible to arrange that the optical densities for different substances should coincide at all wavelengths. Furthermore, the quantum efficiencies γ_i may depend on the optical density implicitly (through the colorant concentration). Therefore, although the change of optical density is most often used as a criterion of light fastness, comparison of different colorants with respect to light fastness is most correctly made at the same initial concentrations in the polymer. If the light fastness has been determined at different concentrations, values of D_{st} corresponding to the concentration adopted as standard with a specimen of standard thickness L_{st} must be substituted in a formula of type (29) in order to obtain comparable results:

$$D^{st}_i = \epsilon_i c_{st} I_{st} .$$

Dimensionally the light-fastness rating τ_c is the time required for unit molar change in concentration of the colorant in the coloured material under standard conditions. Thus it is in some measure a generalisation to rigorous conditions of the characteristic time concept widely used by Giles et al.[23,34-38].

IV. PHYSICOCHEMICAL PARAMETERS OF COLOURED MATERIAL DETERMINING ITS LIGHT FASTNESS

For the simple case of a binary system and an incident spectrum comprising two lines the light-fastness rating is related to the physicochemical parameters of the coloured material by the equation [see Eqns. (12) and (29)]

$$\tau_c = 1/(I_{1_0}\theta_1 + I_{2_0}\theta_2) \qquad (12b)$$

where the I_{0i} are the spectral characteristics of the source, and the

$$\theta_i = D_i^{-1}(1 - 10^{-D_i})(\gamma_{ic} D^p_{ic} + \gamma^p_{ic} D_{pi}) \qquad (30)$$

depend only on the spectral (D_i, D_{ic}, and D^p_{ic}) and other properties (γ_{ic}, γ^p_{ic}) of the absorbing medium at the given wavelength λ_i.

1. Spectra of Colorants and Polymers

According to Eqn. (12b) a decrease in any term $I_{oi}\theta_i$ produces an increase in light fastness. The problem of improving the light fastness of coloured fibres must therefore be attacked by analysing how these terms can be reduced. Since $I_{1,0}$ and $I_{2,0}$ are external parameters independent of the material (e.g. the time-averaged spectrum of sunlight or the spectrum of some standard source), τ_c can be lengthened only by diminishing the θ_i.

The absorption spectra of most dyes consist of an intense band in the visible, which determines the colour, and one or two bands in the ultraviolet[40] (Fig. 4). Dyes are usually most sensitive ($\lambda_{c,i}$ large) to the ultraviolet region of the solar spectrum. Hence, of two dyes possessing the same absorption bands in the visible, the one whose ultraviolet band is further displaced to wavelengths below 300 nm, i.e. to a region where the intensity of sunlight is low†, is the more stable, for the product $I_{oi}\theta_i$ is small. Thus the light fastness of a colorant can be enhanced by introducing substituents that shift the ultraviolet absorption band to a region where the source has low intensity.

† Solar rays having $\lambda > 290$ nm reach the surface of the Earth.

A theory of colour, relating the chemical structure of a colorant molecule with its spectrum, could be of great help in this respect. However, the development of such a theory, based on the quantum chemistry of the ground and excited states of polyatomic molecules[41-45], is far from complete. The controlled preparation of compounds having a specified spectrum can therefore be based only on intuition and semi-empirical rules.

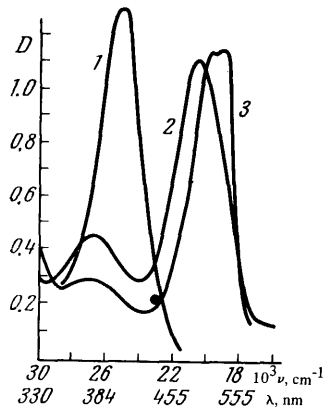

Figure 4. Absorption spectra of some reactive dyes in water[27]: 1) Reactive Yellow 2KT; 2) Reactive Scarlet 2ST; 3) Propionic Bright Red NZV.

An interesting phenomenological classification of the electronic spectra of various organic compounds has been worked out by Shigorin and his coworkers[45]. For an examination of a considerable quantity of data on absorption and luminescence spectra they formulated a rule governing the nature of the lowest energy levels responsible for long-wavelength absorption or emission: the nature of the lowest excited states (of $n\pi^*$ or $\pi\pi^*$ type) of complex molecules containing several interacting chromophoric systems is determined mainly by groups producing the smallest energy difference

$$h\nu = E_{S^*,T} - E_{S_0} \qquad (31)$$

between the lowest excited (S^*, T) and ground (S_0) electronic states. It follows that complex molecules containing different kinds of chromophoric groups should have different relative arrangements of singlet and triplet levels of $n\pi$ and nl types. On the other hand, the relative arrangement of electronic states is itself determined by the structure of the whole molecule. Hence, in order to explain the observed spectral luminescent properties of complex molecules containing $n\pi$ or nl electrons, it is necessary to know the relative arrangement of the five lowest electronic states —S_0, $S_{\pi\pi^*}$, $T_{\pi\pi^*}$, $S_{n\pi^*}$, and $T_{n\pi^*}$.

The spectrum of the polymer may have a significant effect on the light fastness of a colorant because of a shielding effect. Formula (12b) shows clearly that, if the polymer has no sensitising action ($\gamma_c^p = 0$), increase in the optical density of the polymer D_{pi} in the region of the ultraviolet absorption band of the colorant leads to an increase in the total optical density D_i, and hence a decrease in θ_i and an increase in τ_c. Absorption bands in the spectra of fibre-forming polymers (Fig. 5, curves *a* and *b*) usually lie in the far ultraviolet[13,46], so that their shielding effect is small under terrestrial conditions of exposure to sunlight ($\lambda > 300$ nm). In several cases, therefore, the shielding effect is strengthened by introducing into the polymer an ultraviolet absorber—a colourless additive having a strong absorption band in the region of the ultraviolet band of the colorant[23,46-50]—which produces an increase in D_i and hence also in τ_c.

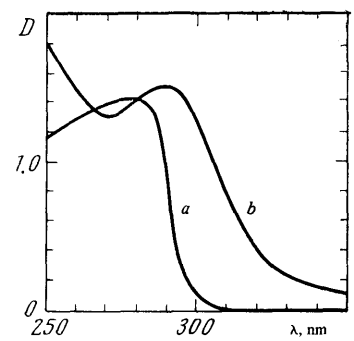

Figure 5. Absorption spectra of fibre-forming polymers[13,45]: *a*) poly(ethylene terephthalate); *b*) polyamide.

2. Factors Influencing the Quantum Efficiency of Photodecomposition of the Colorant

An obvious method for improving the light fastness of a colorant is to diminish either of the quantum efficiencies γ_c and γ_c^p. Quantum efficiency depends on several factors, whose significance can be most simply understood by using as a specific example data[15-17] showing that the photoreduction of azo-dyes can be represented by the scheme

0) $HX + h\nu \rightarrow HX^*$, $Q + h\nu \rightarrow Q^*$ } absorption of light
1) $HX^* \rightarrow HX$ (k_1)
1a) $Q^* \rightarrow Q$
2) $HX^* \rightarrow HX'$ (k_2)
3) $Q^* \rightarrow$ decomposition (k_3)
4) $HX' \rightarrow HX$ (k_4)
5) $HX' + Q \rightarrow QH + X^{\cdot}$ (k_5)

where HX is a reducing agent (e.g. phenylglycollic acid) simulating the polymer medium, Q is the colorant, HX* and Q* are excited states of reductant and colorant molecules, and HX′ is the active state of the reductant molecule initiating reaction (5), which produces fading of the colorant Q. Reaction (3) does not take place ($\gamma_c = 0$) under anaerobic conditions. With $D > 2$ the steady-state rate of fading is

$$W_c = -\frac{dQ}{dt} = I_0 S \frac{D_{HX}}{D_{HX} + D_Q} \cdot \frac{k_2}{k_1 + k_2} \cdot \frac{k_5[Q]}{k_4 + k_5[Q]} \qquad (34)$$

where D_{HX} and D_Q are the optical densities of reductant and colorant respectively, and [Q] is the concentration of the latter. Comparison of (34) with formulae (6), (7) and

(9) shows that

$$I_0 S \frac{D_{HX}}{D_{HX} + D_Q} = \Phi_p \ , \qquad (34a)$$

$$\frac{k_2}{k_1 + k_2} \cdot \frac{k_5[Q]}{k_4 + k_5[Q]} = \gamma_c^p \ . \qquad (34b)$$

Equation (34), obtained theoretically from a kinetic reaction scheme, agrees well with experimental results.

Formula (34b) gives the explicit dependence of γ_c^p on several factors, and is convenient for analysing their effects. According to this equation γ_c^p can be written as the product $\gamma_1\gamma_2$, where $\gamma_1 = k_2/(k_1 + k_2)$ characterises the ratio of the rates of processes involved in the conversion of the excited state HX* of the reductant, and

$$\gamma_2 = k_5[Q]/(k_4 + k_5[Q])$$

is the corresponding relation for the active state HX′. The transition of HX* and HX′ to the ground state (processes 1 and 4) may either be radiationless or involve radiation (luminescence). The larger the corresponding rate constants k_1 and k_4, the smaller obviously will be γ_c^p, which at the limit, when $k_1 \gg k_2$ and $k_4 \gg k_5$, will tend to

$$\gamma_{c\,(line)}^p = \frac{k_2 k_5[Q]}{k_1 k_4} \ .$$

Here γ_c^p will be proportional to the colorant concentration, which will obviously lead to considerable simplification of the concentration dependence of W_c (on $c = [Q]$—see formula (13)). The relation between the parameters k_1, k_2, and k_4 is determined by competition among processes (1), (2), and (4), and depends on the structure of the excited states HX* and HX′. The quantity k_5 characterises the chemical reactivity of the state HX′.

If an acceptor A of electronic excitation energy (such as a diene) is introduced into the system, the excited state may be deactivated[46] by induced energy transfer:

$$6)\ HX^* + A \rightarrow HX + A^* \ (k_6)$$
$$A^* \rightarrow A \ .$$

The constant k_1 is then written

$$k_1 = k_1' + k_6\ [A]$$

where k_1' characterises as before all the processes yielding the ground state, both radiationless and involving quenching. At high values of the transfer constant k_6 the quantity γ_c^p will be small, which should enhance the light fastness of the colorant.

In several cases[46] additives (e.g. benzophenone, arylates with fused rings, etc.) may transfer energy efficiently to another molecule, i.e. they may be energy donors D:

$$7)\ HX + D^* \rightarrow HX' + D \ (k_7) .$$

The constant k_2 can then be written

$$k_2 = k_2' + k_7\ [D]$$

where k_2' as before characterises process (2). In this case γ_c^p will obviously undergo a greater increase the larger is the constant k_7.

In practice the polymer in which the colorant is distributed may itself be donor or acceptor of energy. It is interesting that the same additive may be either donor or acceptor depending on the chemical structure of the colorant. Introduction of an appropriate additive can obviously improve the light fastness of a colorant to a certain extent.

The direction of the energy transfer accompanying the interaction of two molecular species one of which is excited can be determined by the application of Vavilov's rule[51] to the electronic absorption and emission (luminescence) spectra. This states that energy is transferred efficiently to a molecule having an absorption band coinciding in position with the luminescence band of the excited molecule. The physical meaning is that the luminescence level of the donor D should lie roughly at the same height as the "absorption" level of the acceptor A (quantum-mechanical resonance).

Interesting semi-empirical rules have been established[52-56] between the spectral characteristics and the photochemical reactivity of a phosphor–matrix (organic additive–polymer) system. The photochemical reactivity and the mechanism of the primary step are determined by the nature and the relative positions of the excited electronic levels of the interacting species, as well as by structural features and their capacity for complex formation. The above workers were able to make a classification permitting qualitative prediction of the character of photochemical processes.

As has been stated above, the light fastness of coloured materials is determined, according to Eqn. (12a), by the quantum efficiencies of photodecomposition of colorant and polymer at various wavelengths and by the rates of absorption of light at the same wavelengths. The quantum efficiency of photodecomposition of a colorant, and hence its light fastness in a polymer matrix, depend most strongly on the following factors—(*a*) the state of the colorant in the polymer matrix, (*b*) the reactivity of the colorant under the conditions of exposure, (*c*) the chemical nature of the polymer matrix, (*d*) the nature of the colorant–polymer bond, (*e*) the humidity and the temperature of the surrounding medium and the material, and (*f*) the composition of the ambient atmosphere.

(*a*) State of Colorant in Polymer Matrix

A colorant can be distributed in a polymeric material either as single molecules or as aggregates of various sizes[23,34-39]. The light fastness of the dyeing is substantially affected by the state of the colorant in the polymer matrix, which depends on the chemical nature of the colorant, the physical nature of the matrix, and the dyeing conditions[23,34-39].

The electron microscopy of ultrathin regenerated cellulose films coloured with direct dyes has shown[35,37,57-59] that the dyes are present in the substrate as aggregates of various sizes, and that improved light fastness is obtained with dyes that form aggregates in the film. Unfortunately, no quantitative data have been published relating the size of the aggregates and the degree of aggregation of a colorant in a substrate to its light fastness. In general, however, aggregation of a dye in a polymeric material tends to enhance its light fastness, for the reasons indicated below.

1. Aggregation of a dye is accompanied by a decrease in the ratio of the surface area to the mass. Since light acts at the interface between the dye and the surrounding medium, the rate of fading W is proportional to this ratio S/m, and will diminish as the ratio becomes smaller.
2. In an aggregate the dye molecules are in more intimate contact with one another than is the case with a molecular distribution, and transfer of excitation energy will be more probable between the molecules in an aggregate than between the individual molecules.
3. The effect of self-shielding will be more strongly

developed when the dye is aggregated, although it is present even with a molecular distribution. Such a strong effect may lead to complete absorption of light in the upper layers of aggregates and hence abnormally slow photodecomposition of the dye.

It is known from the practical dyeing of textile materials that light fastness is enhanced by all factors promoting the formation of dye aggregates in the fibre. This applies in particular to the transition from fibres of more compact structure (cotton) to fibres of less dense structure (viscose rayon)[23], for the degree of aggregation of dyes increases with increase in the proportion of amorphous regions, where such aggregates are formed. Loosening the dense structure of cotton by mercerisation also improves the light fastness of a dyeing[23,39].

The effect of dye aggregation on light fastness has been somewhat overstated by Giles[23,34-38] in his attempt to reduce the behaviour of diverse and complicated systems on exposure to the breakdown or preservation of dye aggregates, on which basis he classifies all types of fading rate curves. Such a one-sided approach is completely unjustified, since, as the Reviewers have shown earlier, the dependence of the kinetics of the photodecomposition of dyes on their concentration and on their distribution in the matrix is extremely complicated. The non-universality of Giles's "aggregate" theory is especially clearly demonstrated by reactive dyes[25,26,39], which form covalent bonds with local active centres in fibres: i.e. they are incapable of aggregating in the substrate. Nevertheless, these dyes on cellulosic and polyamide substrates give fading curves[35,60] which correspond to aggregation of the dye according to Giles's classification.

(*b*) Reactivity of Colorant

Whereas the quantity of energy absorbed by a colorant molecule is determined by the spectral properties of colorants and polymer combined with the characteristics of the incident spectrum, the effect of this energy on the colorant, i.e. the direction and the depth of photochemical changes in the colorant, depends on its reactivity. Dyes of completely different chemical structure may have closely similar spectral characteristics. For example, yellow vat, azo, and nitro dyes, while having similar absorption spectra, will differ markedly in reactivity and hence in light fastness.

The chemistry of the photochemical breakdown of various classes and groups of dyes is the least studied aspect of the problem of light fastness. A few schemes have been suggested for the photodecomposition of azo[3,17,61], nitro[62-64], cationic[65-67], vat[18-22], and other classes of dyes. Most of them, however, are hypothetical, and their experimental demonstration was usually made under conditions remote from the conditions of use of coloured materials (the colorant was usually exposed in solution). The photodecomposition of a dye begins at the most reactive group in the molecule. For example, an azo-dye undergoes degradation at the azo-group, a nitro-dye at the nitro-group, a triphenylmethane dye at the central carbon atom, and a vat dye at a carbonyl group.

The light fastness of colorants depends not only on their reactivity under the conditons of exposure but also on the reversibility and irreversibility of the photoprocesses. Thus azo-dyes undergo irreversible breakdown at the azo-group; oxidation–reduction of vat dyes under the influence of light, on the other hand, is a reversible change, so that vat dyes have exceptionally high light fastness.

Despite the specific character of the mechanism of the photodecomposition of different classes and groups of dyes, in all cases the reactions involve either oxidation or reduction[32,40]. As oxidative mechanism of photodegradation is assumed and confirmed for the vast majority of dyes, a reductive mechanism being involved only in the fading of dyes on substrates of protein character[23].

Evidence that photodecomposition takes place by an oxidative or a reductive mechanism has been found in an analogy[23,68-71] between the behaviour of dyes under illumination and in dark redox reactions: the rates of the dark redox reaction and of photodecolorisation of the dye show the same correlation dependence on the Hammett σ constant. However, the attempt to relate the rate of photochemical reactions with the Hammett σ constant by analogy with dark reactions cannot be regarded as soundly based, since the colorant molecules involved in dark reactions are in the S_0 ground state, whereas those involved in photoreactions are in the completely different quantum-mechanical states S^* and T^*.

In the Reviewers' opinion an oxidative mechanism is most plausible for the photodecomposition of dyes in a polymer matrix (fibre or film), since all the conditions of exposure promote the formation of oxidising agents from substances present in the surrounding atmosphere or in the material itself. Among such oxidants may be oxygen in its various forms, peroxy-compounds formed by photodegradation of the fibre polymers, and other oxidising agents contained in the atmosphere of industrial towns. One source of peroxide compounds is water contained in the material itself and in the surrounding atmosphere.

(*c*) Chemical Nature of Polymer Matrix

Since light acts both on the colorant and on the polymer matrix in which the latter is distributed, the chemical and physical nature of this matrix cannot fail to affect the rate of photodecomposition of the dye. Different photochemical reactions yielding different products, which are involved in breaking down the colorant, occur in the matrix under the influence of light depending on the chemical structure. Thus the ultraviolet irradiation of coloured cellulosic and polyamide fibres gives rise to peroxy-compounds capable of decolourising dyes[9]. Models of polyamides of low molecular weight, e.g. *N*-pentylhexanoamide, on exposure to ultraviolet radiation form[72] an amide hydroperoxide having the structure $-CH_2.CO.NH.CH(OOH).CH_2-$.

Protein substrates, on the other hand, exhibit reducing properties on exposure, these being due to such amino-acids as tryptophan and histidine[23,70]. The explanation is that dyes fade by different mechanisms on protein and on non-protein substrates. The rate of fading of the same colorants (e.g. azo-dyes) is considerably lower on a protein fibre than on cellulosic fibres. It appears to the Reviewers that protein substrates, several of whose amino-acids develop reducing properties, retard the photo-oxidative degradation of dyes, probably by reacting with oxidants.

(*d*) Nature of Colorant–Polymer Bond

Different types of bond—hydrogen, van der Walls, coordinate, ionic, and covalent—may be formed between the colorant and the macromolecules of the polymer matrix. The type of bond, which depends on the chemical nature of colorant and polymer, will influence the light fastness of the system to the extent that the bond can promote the

transfer of excitation energy from the colorant molecules to the polymer macromolecule (improvement of light fastness) or from the macromolecule to the colorant molecules (impairment of light fastness). Energy transfer between two components in direct contact is theoretically possible, since even in the absence of contact between molecules (removal to 100 Å) the effect of concentration-dependent self-quenching operates[31,32,67].

Transfer of excitation energy between dye and polymer could occur most simply if they were linked by a chain of conjugated double bonds, i.e. if a single chromophoric system were formed between dye and polymer. However, such coloured polymers have not yet been prepared. Even reactive dyes, which form a more stable covalent bond with the polymer than do other classes, do not yield a single chromophoric system with the substrate.

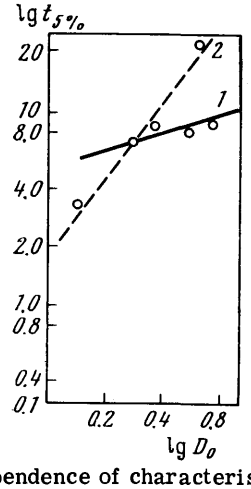

Figure 6. Dependence of characteristic fading time of Pararosaniline on initial optical density of films[23]: 1) regenerated cellulose; 2) polyacrylonitrile.

The effect of the nature of the bond is evident with cationic dyes: dyeings produced on cellulosic fibres by means of a third component (a mordant) have poor light fastness, whereas the same dyes exhibit considerably better light fastness on polyacrylonitrile fibres (ionic bond)[23] (Fig. 6).

With reactive dyes the covalent bond formed with a cellulosic fibre has a favourable influence on the light fastness, but only at low concentrations[27]. The light fastness of reactive dyeings on polyamide fibres is less affected by the covalent bond[25]. Fig. 7 illustrates the concentration dependence of the light fastness $t_{0.1}$ for the reactive dye Propionic Bright Red NZV in two forms (covalently fixed and adsorbed) on cotton cloth[27]. Only in the adsorbed form does the dye undergo aggregation with increase in its concentration in the fibre, and this aggregation effect begins to prevail over the favourable effect of the covalent bond.

(*e*) Effect of Humidity and Temperature of Atmosphere and of Textile Material

Under practical conditions of the exposure of coloured textile materials variations of the temperature and humidity of the surrounding atmosphere and of the material are interrelated, so that they can be studied separately only under laboratory conditions.

Effect of temperature. Hedges[73] investigated the effect of temperature on the fading of dyes on cotton and wool in atmospheres differing in relative humidity, and found that the activation energy of decomposition of the dye is 2 kcal mole^{-1}. Since the primary steps of photoexcitation have an activation energy close to zero[40], subsequent secondary photoreactions of decomposition must depend on the ambient temperature.

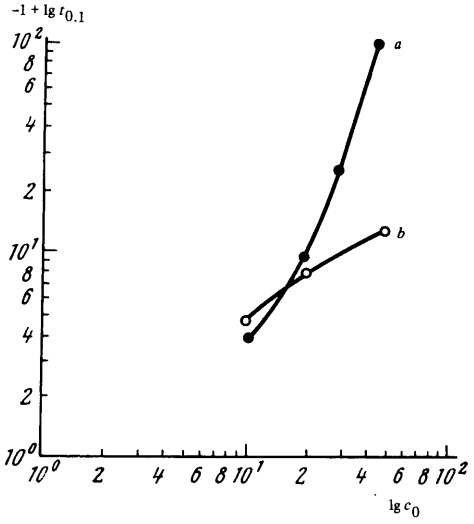

Figure 7. Dependence of characteristic fading time of the reactive dye Propionic Bright Red NZV on its initial concentration on cotton cloth[27]: *a*) hydrolysed form of dye; *b*) covalently bound form of dye.

Raising the temperature usually affects the results of light-fastness testing indirectly, the rate of fading being somewhat lower because of the diminished moisture content of the specimen. This effect is apparent with hydrophilic fibres[23]. The opposite effect is sometimes observed on hydrophobic fibres: i.e. raising the temperature causes a sharp acceleration of fading.

Investigations by the Standards Committee of the American Association of Textile Chemists and Colorists revealed[74,75] that the rates of fading of many dyes on synthetic fibres, when exposed in a Fade-Ometer and in sunlight, increase sharply with rise in temperature of the black panel (the surface temperature of a black specimen on exposure). Similar results were obtained by Friele and Selling[76].

It was suggested[23] that, in the absence of moisture on a hydrophobic fibre, (i) dye aggregates break down under the influence of atmospheric oxygen, and (ii) polar groups of the dye molecules become more accessible to attack by atmospheric oxygen, hydrogen bonds being absent between dye and water. However, these hypotheses are not supported by the experimental results. It is especially difficult to accept the last suggestion, since traces of moisture are retained as monolayers in fibrous material even at a very high temperature (up to 200°C)[77].

(*f*) Effect of Moisture in the Atmosphere and in the Specimen

The effect of moisture on the rate of fading of dyes is well known, and affects the reproducibility of light-fastness testing under natural conditions, when the intensity of irradiation varies and hence the atmospheric humidity and the moisture content of the specimen [78,79]. Increase in humidity usually accelerates degradation of the dye by light. In several cases a linear relation is observed between the light fastness and the moisture content of the specimen. The formula

$$F = K\sqrt{T}(w + c)$$

was suggested [73] to link the rate of fading of a dye, expressed as percentage decomposition F, with the temperature T °K and the moisture content w% of the specimen, K and c being constants. Lead showed [80] that the fading of dyes on wool is sharply accelerated at relative humidities of 45–80% in the surrounding air.

Despite the large number of results establishing that the light fastness of fibre dyeings is extremely sensitive both to the ambient humidity and to the moisture content of the fibrous material itself, from which quantitative relations have been elicited between them [81], the reasons for such sensitivity have not yet been finally clarified. The above mechanism of the deterioration of coloured polymers under the influence of light suggests that the role of water as a supplier (source) of species (oxygen, hydrogen, peroxide, etc.) that actively decompose the dye is extremely important and specific to various colorants and fibres. In general, however, water will be involved, either directly or indirectly, in photodecomposition of the colorant and of the fibre itself.

Assuming a photo-oxidative mechanism of breakdown for most colorants under actual conditions of use (atmospheric humidity and oxygen), we can suppose that the main function of water is to produce peroxy-compounds. Photochemical formation of a peroxide in the presence of colorants, oxygen, and water has been demonstrated with basic and vat dyes, which have a sensitising effect [73-78,80,81,83-87]. The formation of hydrogen peroxide has been shown also with dyes having no sensitising activity, but the quantity of peroxide isolated is considerably smaller in this case. The suggested [61-65] mechanism of formation of hydrogen peroxide can be reduced to the scheme

$$Q^S + h\nu \rightarrow Q^{S*} \rightarrow Q^T$$
$$Q^T + O_2^T \rightarrow Q^+ + O_2^-$$
$$O_2^- + H^+ \rightarrow HO_2$$
$$2HO_2 \rightarrow H_2O_2 + O_2^T,$$

where S and T denote singlet and triplet states, and the asterisk indicates an excited state of the colorant molecule **Q**. The resulting peroxide is able to break down not only the colorant but also the fibre itself [78,79].

Nevertheless, even when the moisture content of the fibre is very low (~5%) and the colorant content is 0.3–2%, each molecule of the latter is associated with 50–300 molecules of water: i.e. the excess of water present relative to the dye is such that further increase in the water content of the fibre should have no effect on the photochemical reactions. The actual situation, however, is quite different. Although calculations show [23] that the rate of fading should become constant at a very low moisture content (< 0.1%), in practice the rate has not become constant even at a content of 40%.

This can be explained by the fact that the relative humidity of the air in direct contact with the specimen is a very important factor influencing the light fastness of a dyeing. The humidity in this boundary zone is usually considerably lower than that of the total volume of surrounding air. McLaren [81] made a comprehensive investigation of the relation between the humidity of the surrounding air, that of the air in the boundary layer, the moisture content of the fibre, and the light fastness of the dyeings. He introduced the special concept of effective humidity, corresponding to that of the air in the boundary layer, and established a link between the effective humidity and the duration and intensity of irradiation of the specimen.

The effective humidity should be one of the exposure parameters to be standardised.

(*g*) Effect of Composition of Atmosphere

The deterioration of coloured fibres under the influence of light must be regarded as involving photochemical processes occurring in a system comprising fibre, the colorant, and the surrounding medium. Therefore the composition of this atmosphere should and does play an extremely important part in fading. Since oxidation, reduction, and hydrolysis lead to breakdown of colorants on the fibre, any pollutant of the atmosphere must be regarded as being possibly involved in these fading processes. The composition of the atmosphere is of paramount importance in the functioning of coloured materials in the open air and in light-fastness testing under natural conditions, i.e. in tests of fastness to light and weathering. However, it will be shown below that the composition of the atmosphere may also have an effect in accelerated tests under fading lamps.

Among pollutants of interest in connection with their effect on the action of light on coloured fibres are oxides of nitrogen, sulphur dioxide, carbon dioxide, ozone, and aldehydes. All these chemically active substances are present in the atmosphere, in which their contents may vary within wide limits depending on the type of locality (urban or rural), its geographical position, the season of the year, and the time of day. The Table lists the concentrations of the above substances in the atmosphere at three sites in the USA [88].

Pollutant concentrations in atmosphere of rural and urban localities of the USA.

Pollutant	Concentration, ppm by vol.		
	rural	Los Angeles	Chicago
Oxides of nitrogen	0.01	0.26	0.22
Sulphur dioxide	0.03	0.05	0.25
Carbon dioxide	—	23.00	16.00
Ozone	0.06—0.11	0.21	0.005
Aldehydes	—	0.3	—

The first to observe the effect of atmospheric composition on the rate of fading of dyes was Lazerev [88,89], who found an exponential relation between rate of deterioration and the oxygen content of the atmosphere.

The Table shows that the atmosphere of industrial towns has a well defined acidic character, which may promote the photodecomposition of dyes. These pollutants may break

down dyes even in the absence of light, i.e. by dark reactions, but illumination promotes their degrading action.

Sulphur dioxide enters the atmosphere of industrial towns from the combustion of coal containing up to 4% of sulphur. A considerable quantity accumulates from the use of coal as fuel (e.g. in Chicago), and the atmosphere is reducing in character, since sulphur dioxide is a strong reductant. When petroleum is used as fuel, oxidising products accumulate in the atmosphere. The main source of oxides of nitrogen is the exhaust from cars [90]. Ozone is present in the atmosphere of towns and of rural localities; its content varies with height above the Earth's surface [90].

Sulphur dioxide, nitrogen dioxide, and aldehydes absorb ultraviolet radiation of wavelengths 280–300 nm, and the excited molecules are involved in a series of successive reactions entailing formation of ozone. In contrast to sulphur dioxide, activated nitrogen dioxide reacts reversibly with oxygen, which may lead to the accumulation of ozone in the atmosphere even at low concentrations of N_2O_4.[91]

The products of the combustion of petroleum in diesel engines contain aldehydes, which in turn, in the presence of ozone and under the influence of light, form peroxides [92].

As already noted, sulphur dioxide is able to reduce dyes on the fibre. Azo-dyes are especially sensitive to the action of this gas, which breaks down the azo-group. Therefore azo-dyes are most fugitive to light and least durable on wool, since this fibre has enhanced affinity for sulphur dioxide, and absorbs it from the atmosphere [93-95].

Aminoanthraquinone blues, violets, and reds, as well as certain disperse azo-dyes, are very sensitive to the action of oxides of nitrogen [97]. Rowe and Chamberlain [98] established that the decomposition of aminoanthraquinone colorants under these conditions results from diazotisation of primary amino-groups and nitrosation of secondary amino-groups, together with oxidation, the direction of which depends on the nature of the colorant. The fastness of disperse dyes to light in an atmosphere of oxides of nitrogen is inversely proportional to their ability to form salts [99]. Under these conditions disperse dyes are most sensitive to illumination on cellulose acetate, polyester, and to a less extent polyamide and polyacrylonitrile fibres [100]. The effect of the nature of the fibre probably depends on its ability to adsorb oxides of nitrogen.

Ozone also activel accelerates the photochemical decomposition of disperse and other classes of dyes [101-103]. Breakdown of the former is attributed [103] to electrophilic attack by ozone on aromatic amino-groups, so that the rate of fading should depend on the nucleophilic strength of the nitrogen atom in arylamine dyes. In fact changes in the structure of the dye, tending to diminish the electron density on the nitrogen, make the latter less susceptible to attack by an electrophilic reagent, whether ozone or oxides of nitrogen, and improve the light fastness [104-106].

The rate of breakdown of a dye on illumination in an atmosphere containing ozone depends on the distribution of the dye through the fibre, and decreases with increase in the depth of penetration into the fibre [103]. This is probably due to the role of diffusion in the effect of ozone: the accessibility of the dye to all attacking reagents, including ozone, decreases with distance from the fibre surface. Heat-treatment of a coloured cellulose triacetate fibre, like its surface hydrolysis, increases the light fastness in an atmosphere containing ozone [88], which also is probably due to diminished accessibility of the dye.

Since ozone is formed in ample quantities when xenon lamps are used, measures must be taken to remove it from the atmosphere in which the specimen is exposed.

* * *

Several fundamental conclusions can be drawn from an analysis of the literature surveyed.

1. Measurement of the initial rate of photodegradation of polymer and dye should form the basis for the quantitative assessment of the light fastness of coloured polymeric materials.
2. Interaction of polymer and colorant (both stabilising and sensitising) must be taken into account in assessing the light fastness of coloured polymers.
3. The main factors influencing the light fastness of a coloured polymer depend on the quantum efficiencies of photoreactions of polymer and colorant and on their rate of absorption of light.
4. Coloured polymer materials can be protected from the action of light by lowering the quantum efficiencies of the photoreactions of colorant and polymer and by diminishing their rates of absorption of light.

Complex Fertilizers Based on the Nitric Acid Decomposition of Phosphates

S.I.Vol'fkovich and A.A.Sokolovskii

The conditions governing the equilibrium in the reaction of fluoroapatite and mineral admixtures in natural phosphate raw materials with nitric acid and also certain problems of the kinetics of the decomposition of phosphate minerals are considered in the review. The principles of several technological schemes in the manufacture of Nitrophoska are described. The most important trends in new studies designed to obtain complex fertilizers by the decomposition of phosphates with nitric acid are also indicated. It is concluded that a promising method for the manufacture of Nitrophoska involves a procedure with cooling, retaining the main, fruitful idea of employing for the decomposition of phosphates nitric acid without the addition of other acids or their salts.
The bibliography includes 96 references.

CONTENTS

III. Isolation of calcium from nitric acid-phosphoric acid solution and its neutralisation 227
IV. Conversion of ammoniated solutions into solid fertilizers 232
V. Comparative analysis of technological processes in the manufacture of complex fertilizers 232

I. INTRODUCTION

The method of processing natural phosphates with nitric acid proposed in 1908 by Pryanishnikov and Britske[1,2] for the manufacture of a phosphate fertilizer [$CaHPO_4$ (precipitate) and a nitrate fertilizer (calcium nitrate)] could not find wide application before the end of the First World War, since at that time there was no synthesis of ammonia and its oxidation to nitric acid on an industrial scale.

In recent years, with the rapid and powerful growth of the manufacture of synthetic ammonia developing along progressive and economical lines, there has been a greater possibility of obtaining cheap nitric acid and its employment not only for the above two single fertilizers but also, and mainly for combined (complex) fertilizers — nitrophosphates (Nitrophos and Nitrophoska) containing nitrogen, phosphorus, potassium, and other nutrient elements.

The growing importance of the manufacture of fertilizers based on the nitric acid decomposition of phosphates together with their processing by sulphuric acid, which has been developing most rapidly, arises because nitric acid is employed in two ways in the decomposition of phosphates: as a source of active hydrogen ions and as a carrier of nitrogen — a useful component of fertilizers.

In the most rational process unpleasant waste is not formed, as happens in the sulphuric acid decomposition of phosphates, accompanied by the formation of phosphogypsum, which has so far not found a useful application.

The employment of nitric acid permits a more complete extraction of fluorine and lanthanides from apatite An advantage of nitric acid is also the possibility of using as a starting material low-grade phosphorites containing considerable amounts of iron and aluminium compounds.

The method of nitric acid processing of phosphate raw materials has undergone extensive development since the initial studies carried out at the Fertilizers, Insecticides, and Fungicides Research Institute (NIUIF) from 1925[3-5]. Some of the versions of the manufacture of simple and complex fertilizers from nitric acid - phosphoric acid solutions investigated in the Soviet Union and elsewhere have not found large-scale applications, while others have been improved and have assumed a dominant position under modern conditions.

Technological nitric acid processing of phosphates includes the following main stages: (1) intrinsic decomposition of the phosphate raw material with nitric acid; (2) isolation of calcium from the nitric acid - phosphoric acid solution obtained after the decomposition of the phosphate; (3) neutralisation of the solution with ammonia (ammoniation) or lime; (4) conversion of the neutralised solution into a fertilizer †. In certain versions the processing of phosphates includes additional operations such as the separation from solution of the insoluble residue, the decomposition of sodium or potassium fluorosilicate, and precipitation of lanthanide phosphates.

The above stages in the manufacture of nitrophosphates are involved in a close interrelation, the nature of which is described below for individual specific procedures.

II. PHOSPHATE DECOMPOSITION PROCESSES

In a general form the decomposition of fluoroapatite with nitric acid can be represented by the equation:

$$Ca_5(PO_4)_3F + 10\,HNO_3 = 3H_3PO_4 + 5Ca(NO_3)_2 + HF + 290\ \text{kJ mole}^{-1}. \quad (1)$$

Under the industrial conditions of the interaction with nitric acid at a concentration of 50-55%, the reaction temperature is maintained at 50-60°C mainly as a result of the heat of reaction (1)[6,7].

The conditions governing the equilibrium in this process have been established with some approximation by means of a graphical analysis of the $CaO-P_2O_5-N_2O_5-H_2O$ system, which was investigated at 0°, 5°, 25°, 50°, 75°, and 100°C. The metastable state of the system at 50°C was also investigated[11].

In the acid regions of the diagram of the system the following solid phases in equilibrium with saturated solutions at the above temperatures were discovered: $Ca(NO_3)_2$ (tetrahydrate, trihydrate, dihydrate, and the anhydrous

† The present review is restricted to the analysis of the manufacture of solid fertilizers only and does not deal with the specific problems of the synthesis of liquid and suspension fertilizers based on the decomposition of phosphates with nitric acid.

salt), $Ca(H_2PO_4)_2.H_2O$, and $CaHPO_4$. More basic phosphates, including hydroxy-apatite, are found only in a narrow region of highly dilute solutions.

The main conclusion from the analysis of the system is that in the interaction of fluoroapatite with a stoichiometric amount [according to Eqn. (1)] of nitric acid (at a concentration of 47% and above) the phosphate should be completely decomposed following the attainment of equilibrium. Indeed, experimental conditions have been found ensuring in practice a high (98–99%) degree of decomposition of natural phosphates at 45–60°C [12-17].

The study of the 50° isotherm (in the equilibrium and metastable states) by the method of "secondary projections" of the system showed[18,19] that, within the limits of the nitric acid concentrations employed under technological conditions (47–60%) in amounts relative to stoichiometry corresponding to 100–140%, the composition point *C* of the resulting solutions is in the crystallisation region of $Ca(H_2PO_4)_2.H_2O$ (Table and Fig. 1). These data show that the decomposition of fluoroapatite by nitric acid at 50°C proceeds in accordance with the following equation:

$$Ca_5(PO_4)_3F + 10HNO_3 = (3-n)H_3PO_4 + 0.5n\,Ca(H_2PO_4)_2 + (5-0.5n)Ca(NO_3)_2 + n\,HNO_3 + HF \quad (2)$$

Thus both theory and industrial practice permit variation of the conditions governing the decomposition of phosphates within wide limits. This applies not only to the concentration and the specified amount of nitric acid but also to the process temperature. This situation favours the optimisation of the technological conditions in subsequent stages of the nitric acid process.

Conditions for the formation of $Ca(H_2PO_4)_2.H_2O$ in the nitric acid–phosphoric acid solution at 50°C.

Conditions	Stable equilibrium	Metastable equilibrium
Concn. of HNO_3, %	71.0—38.5	77.5—37.5
Amount of HNO_3 relative to stoichiometry, %	116.5—93.6	158.0—109.0

Under the conditions of the decomposition of fluoroapatite at 50°C presented in Table 1, $Ca(H_2PO_4)_2$ and calcium nitrate are present in solution. Analysis of the equilibrium in the $CaO-P_2O_5-N_2O_5-H_2O$ system showed that calcium nitrate may be isolated from solution in the form of the anhydrous salt directly in the course of the decomposition of the phosphate at the same temperature, provided that nitric acid at a concentration in excess of 71% is employed in an amount exceeding 116.5% relative to stoichiometry. Therefore an experimental study was made of the decomposition of the apatite concentrate under the given conditions[18].

The study of the $CaO-P_2O_5-N_2O_5-CaSiF_6-H_2O$ five-component system at 60°C [20] showed that in the presence of potassium fluorosilicate and fluoride, formed on acid treatment of phosphates, the crystallisation regions of $CaHPO_4$ and calcium nitrate expand, while that of $Ca(H_2PO_4)$ contracts. Under certain conditions (low HNO_3 and H_3PO_4 concentrations in solution), this leads to the decomposition of $Ca(H_2PO_4)_2$ with deposition of $CaHPO_4$ in the solid phase:

$$Ca(H_2PO_4)_2 \rightleftarrows CaHPO_4 + H_3PO_4.$$

Calcium fluorosilicate can in turn decompose with formation of CaF_2 and SiO_2. The observed secondary phenomena can inhibit the decomposition of the phosphate raw material as a result of the formation of a crystalline crust on the phosphate grains and can also impede the separation of an insoluble precipitate. The complex processes associated with the presence of fluorine compounds in the system require further investigation.

The study quoted above[20] also revealed the favourable effect of free H_2SiF_6 in the phosphoric acid solution, which can partly or completely prevent the decomposition of $CaSiF_6$. In this connection it was of interest to determine the fluorine balance in the course of the nitric acid decomposition of natural phosphates.

In the processing of the apatite concentrate (process temperature 50°C) it was found that, when 55% nitric acid is employed, the bulk of fluorine (77%) passes to the liquid phase[21]. In the presence of 80% nitric acid, the evolution of fluorine into the gas phase (SiF_4) increases sharply—only about 18% of fluorine remains in the liquid phase[19]. The use of Karatau phosphorites also entails an increase in the evolution of fluorine into the gas phase—the degree of extraction of fluorine into the liquid phase in the presence of 55% nitric acid is about 58%.[21] The amount of fluorine in the insoluble residue is only about 1–3% of its content in the starting material.

The appreciable content of fluorine (H_2SiF_6) in the liquid phase necessitates its isolation: conditions have been developed[6,7,14,22] for the precipitation of Na_2SiF_6 from nitric acid – phosphoric acid solutions with the aid of a sodium nitrate (or sodium carbonate) solution. The gaseous fluorine compounds evolved are absorbed. The characteristic features of the absorption of HF and SiF_4 were investigated[23,24].

The direct requirement for sodium (or potassium) fluorosilicates is limited compared with the possible volume of their manufacture in fertilizer factories where phosphate raw materials are processed. For this reason, intense studies are being made at present on various versions of the manufacture from fluorosilicate – containing waste of products such as cryolite, aluminium, sodium, and ammonium fluorides, hydrofluoric acid, and others, the requirement for which increases from year to year[25-28].

The apatite concentrate contains about 0.9% of cerium-group lanthanides the bulk of which (98–99%) passes to the nitric acid – phosphoric acid solution. A process has been developed for the isolation from solution of lanthanide phosphates at 60–80°C and for 50% neutralisation of the first hydrogen ion dissociated from H_3PO_4 by lime, ammonia, or sodium carbonate to give a pH of 2–2.5.[29] The degree of precipitation of the lanthanides reaches 75–80%. The precipitate is separated from the solution by decantation. It is useful to treat the solutions by successive procedures – initially for the isolation of sodium fluorosilicate and then for the isolation of lanthanide phosphates. A number of other methods for their isolation have also been developed.

The kinetics of the decomposition of phosphate materials have not as yet been completely elucidated. Mainly experimental studies[6,7,14,16] were undertaken to investigate the influence of individual factors on the rate of reaction with nitric acid of the apatite concentrate and phosphorite from Krolevets, Izyum, Polpinsk, Zozh, Egor'evsk, Vyatsk, and Karatau deposits. These studies established

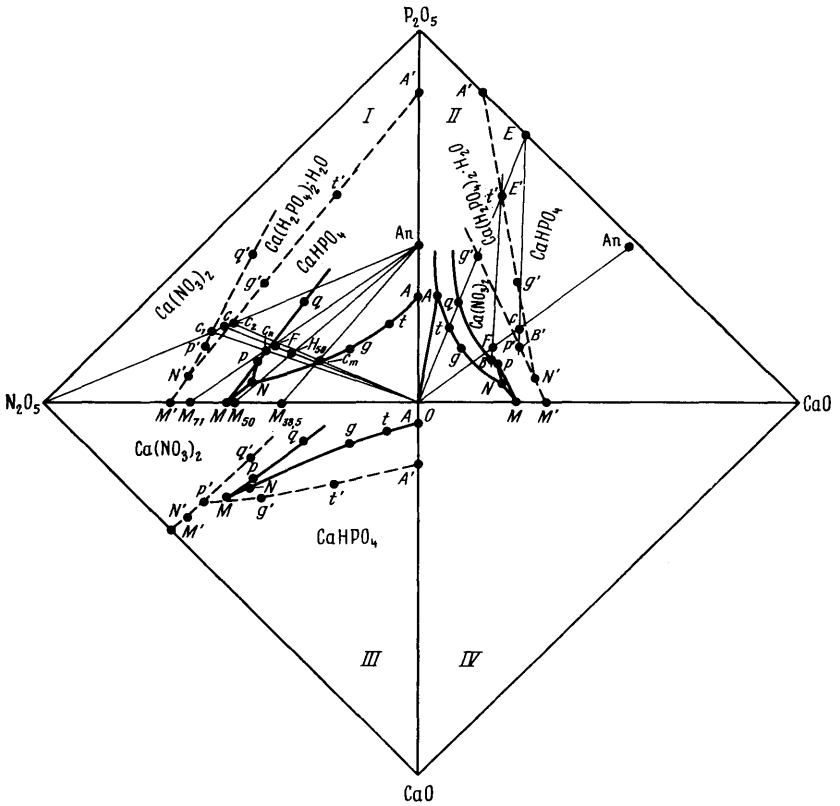

Figure 1. Graphical analysis of the $CaO-P_2O_5-N_2O_5-H_2O$ system at 50°C (decomposition of fluoroapatite with nitric acid)[18].

the principal relations: for example, the decomposition of phosphorites proceeds at a relatively high rate and the degree of extraction of P_2O_5 into the solution can reach 98–99% in the first 15–30 min. Apatite is decomposed by nitric acid more slowly — the reaction virtually reaches completion in the course of 60–90 min. The reason is that apatite is less reactive: its overall (external and internal) specific surface is smaller by a factor of 5–30 than that of phosphorites for the same degree of comminution[30].

The decomposition of natural phosphates accelerates with increase of temperature in the range 30–60°C. The temperature coefficient for each 10 deg C is about 1.3. With increase of the relative amount of nitric acid per unit amount of phosphate, the degree of neutralisation of the mixture of nitric and phosphoric acid falls, and therefore the rate of reaction increases.

The influence of the initial nitric acid concentration in the range 47–55% is small. It has been found[19] that, with increase of the HNO_3 concentration to 80%, a high degree of extraction of P_2O_5 into the solution is reached in about 3.5 h, mainly due to the precipitation under these conditions of $Ca(NO_3)_2$ crystals, which passivate the surface of phosphate grains.

The kinetics of the acid decomposition of phosphates have been investigated,[31-33] and it has been established that the interaction of apatite with inorganic acids under certain conditions (temperature and concentration) takes place entirely under diffusion-dependent conditions. The rate of reaction for 50% nitric acid is determined by the diffusion of ions from a temperature as low as 30°C. A study of the rate of decomposition of apatite by phosphoric acid[31] led to the conclusion that the driving force of the dissolution of apatite is the concentration gradient of calcium ions at the surface and in the bulk of the solution. In a study[32,33] of the kinetics of the interaction of apatite with acid, it was found that the rate of the process depends on the rate of diffusion of hydrogen ions to the interface, on the activity of hydrogen ions, on the solubility of the reaction products, and on the passivation of the surface by crystalline deposits (in this instance, of calcium nitrate), and also on the viscosity of the liquid phase and other physicochemical factors. The diffusion of H^+ and Ca^{2+} ions is accompanied by ion exchange (with NO_3^- and $H_2PO_4^-$ ions in the nitric acid decomposition), which accelerates the diffusion of the ion pair.

It has also been established experimentally[32,33] that under identical conditions the highest rate of reaction is obtained in the decomposition of apatites by hydrochloric and nitric acids: it is higher by a power of ten than in the reaction with phosphoric acid.

The behaviour of iron-containing impurities in the initial material is very important for the assessment of the nitric acid methods for the processing of phosphates. In a study of the kinetics of the decomposition by acids of the silicate mineral glauconite, which is present in phosphorites, it was established[31] that, despite the high degree of dissociation of nitric acid, it decomposes glauconite comparatively slowly. This is due to the formation of a dense SiO_2 envelope around the mineral grains, which inhibits

diffusion (passivation occurs). However, in the joint decomposition of such minerals together with phosphate, the resulting phosphoric acid accelerates the process. In practice, under continuous process conditions, the degree of extraction of $Fe_2O_3 + Al_2O_3$ into the solution amounts to about 70%. Iron and aluminium oxides react with phosphoric acid and form sparingly soluble phosphates, which leads to a loss of P_2O_5.

The presence of lower oxides of iron and also of organic substances in phosphorites leads to increased losses of nitric acid. On decomposition with nitric acid, low-grade phosphorites form considerable amounts of finely dispersed precipitates (mainly SiO_2), the separation of which by decantation or filtration is difficult.

One of the methods[6,7,12] for the decrease of the harmful influence of impurities in phosphorites in the course of nitric acid processing, which has been investigated, is heat treatment of the phosphorites. Optimal oxidative roasting conditions, which diminish the dissolution of iron and aluminium oxides, eliminate the losses of nitric acid, and improves the properties of the precipitates facilitating their decomposition, have been established for various phosphorites (from the Egor'evsk, Vyatsk, Polpinsk, Sozh, and other deposits). Thus heat treatment of phosphorites converts them into a starting material suitable for conversion by nitric acid into complex fertilizers without secondary enrichment.

The study of the problem of the separation of the insoluble residue formed in a finely dispersed state in the decomposition of the Karatau phosphorite is very important. The formation of the precipitate has been investigated[34,35] and methods and apparatus for the accelerated filtration of the sludge have been recommended.

III. ISOLATION OF CALCIUM FROM NITRIC ACID-PHOSPHORIC ACID SOLUTIONS AND ITS NEUTRALISATION

In the conversion of nitric acid–phosphoric acid solutions into fertilizers free phosphoric and nitric acids are neutralised. Technological processes based on the neutralisation of the solutions with lime or limestone, with precipitation and isolation of $CaHPO_4$ and formation of calcium nitrate as a second product were developed initially[14,36-40]:

$$3H_3PO_4 + 5Ca(NO_3)_2 + 3CaCO_3 \rightarrow 3CaHPO_4 + 5Ca(NO_3)_2 + 3CO_2 + 3H_2O. \quad (3)$$

A version of the synthesis of ammonium nitrate from calcium nitrate by treatment with ammonium carbonate solution was investigated:

$$Ca(NO_3)_2 + (NH_4)_2CO_3 \rightarrow 2NH_4NO_3 + CaCO_3. \quad (4)$$

This method for the preparation of the citrate-soluble $CaHPO_4$ and of the low-percentage (15% N) hygroscopic calcium nitrate has been applied on a limited scale[41,42].

The possibility of obtaining from nitric acid–phosphoric acid solutions of the water-soluble $CaHPO_4$ (instead of the citrate buffer-soluble $CaHPO_4$), discovered in a graphical analysis of the $CaO-P_2O_5-N_2O_5-H_2O$ equilibrium system[3], should be noted. This version merits technical development.

The common procedures for the preparation of complex nitrogen-phosphorus fertilizers include the neutralisation of phosphoric and nitric acids with ammonia. Ammonia, which is the primary product of the fixation of atmospheric nitrogen, is now the most readily available, the most concentrated, and the cheapest nitrogen carrier, which accounts for the attempts to introduce nitrogen into complex fertilizers in the form of ammonia to the maximum possible extent

The phosphoric acid obtained by the sulphuric acid decomposition of phosphate is neutralised with ammonia, which results in the formation of fertilizers (Ammophos or Diammophos), which contain between 5.2 and 2.6 P_2O_5 units per unit weight of nitrogen. Depending on the initial phosphate material, Ammophos contains different amounts of P_2O_5 in a water-soluble form: for example 95% in the processing of the apatite concentrate and 75–80% in the processing of the Karatau phosphorite.

Numerous agrochemical studies led to the discovery that the majority of soils can assimilate almost equally readily both water-soluble and citrate-soluble forms of phosphate fertilizers. In the USSR the Government Standard GOST 11365-65 specifies that in Nitrophoska not less than 55% of the P_2O_5 assimilated must be in a water-soluble form.

Mention should be made of the current trend in world practice to increase as far as possible the content of water-soluble P_2O_5 in fertilizers, which may be accounted for by the greater universality of the use of water-soluble P_2O_5 under various natural conditions.

In accordance with the requirements of agriculture, agrochemical science has established for various types of soil and agricultural crops specific and most widely used weight ratios of nutrient elements ($N-P_2O_5-K_2O$) in complex fertilizers. Fertilizers meeting these requirements have been conventionally termed balanced. A considerable proportion of the balanced fertilizers should have the ratios $N : P_2O_5 : K_2O = 1 : 1 : 1$.

Owing to its relatively low nitrogen content, in most cases Ammophos is not a balanced product. Therefore, it is either mixed with nitrogen fertilizers (ammonium nitrate, carbamide) or a mixture of ammonium phosphate and nitrate (Nitroammophoska) the composition of which is defined by the formula 17 : 17 : 17 (95% of P_2O_5 is in a water-soluble form), is produced.

Nitroammophoska is a complex fertilizer obtained by the sulphuric acid processing of natural phosphates. It was therefore of considerable interest to compare the nitric acid method with the manufacture of Nitroammophoska.

The solutions obtained under the usual conditions (Table 1) of the nitric acid decomposition of phosphates contain virtually the entire P_2O_5 and CaO from the starting material. In the processing of the Khibinsk apatite concentrate, the $CaO : P_2O_5$ weight ratio in the solutions is 1.3 and in the decomposition of the Karatau phosphorite it is about 1.6.

Complex fertilizers from nitric acid–phosphoric acid solutions (Nitrophos and Nitrophoska) are also obtained by their neutralisation with ammonia. Depending on the amount of ammonia introduced and on the calcium content in solution, the phosphate in the fertilizer can be present in water-soluble and citrate-soluble forms[43]. According to Eqn. (1), the nitric acid–phosphoric acid solution has the composition of $3H_3PO_4 + 5Ca(NO_3)_2$.

The theoretical compositions of the liquid and solid phase formed in the ammoniation of the nitric acid-phosphoric acid solutions could be determined beforehand by analysing the equilibrium five-component system $CaO-P_2O_5-N_2O_5-NH_3-H_2O$, which has been investigated in detail at 25°C and partly at 50°C.[44] This analysis has not been published but the experimental data are available,[7,43]. In order to obtain the bulk of P_2O_5 in a water-soluble form, only the first hydrogen ion of phosphoric acid should be

neutralised in the initial solution:

$$3H_3PO_4 + 5Ca(NO_3)_2 + 3NH_3 = 1.5Ca(H_2PO_4)_2 + 3NH_4NO_3 + 3.5Ca(NO_3)_2. \quad (5)$$

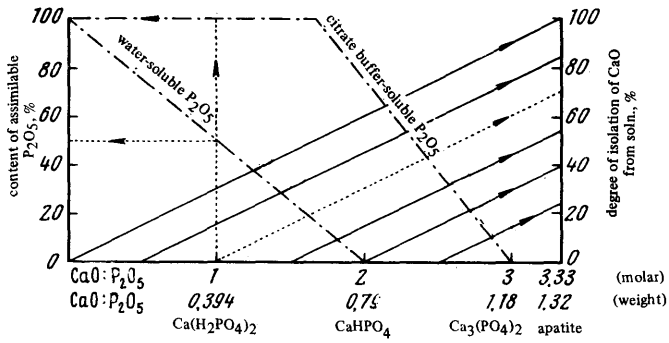

Figure 2. Dependence of the assimilable and water-soluble P_2O_5 content in Nitrophoska on the CaO : P_2O_5 ratio in the nitric acid–phosphoric acid solution from the apatite concentrate[47]; dashed line — example quoted for the Ca : P_2O_5 = 0.394 ratio.

Under these conditions, an appreciable amount of calcium nitrate remains in the reaction mixture, its presence impairing the physical properties (high hygroscopicity) of the fertilizer and reducing the concentration of nutrient materials in it. With increase of the degree of ammoniation, an increasing amount of P_2O_5 is converted into the citrate-soluble $CaHPO_4$:

$$3H_3PO_4 + 5Ca(NO_3)_2 + 6NH_3 = 3CaHPO_4 + 6NH_4NO_3 + 2Ca(NO_3)_2. \quad (6)$$

The preparation of $CaHPO_4$ for animal feed from nitric acid–phosphoric acid solution which had been freed from fluorine in a preliminary treatment is based on this reaction. The formation of $CaHPO_4$ for animal feed by the nitric acid decomposition of the apatite concentrate[45] and Karatau phosphorite[46] has been investigated.

In order to obtain Nitrophoska containing P_2O_5 partly or completely in a water-soluble form, the excess calcium must be removed from the nitric acid–phosphoric acid solution as far as possible (see the nomogram in Fig. 2).

The wide variety of methods for the binding of the excess calcium largely determine the nature of the nitrophosphate manufacturing processes. The characteristics of these processes are to a considerable extent reflected in their economic efficiency.

Two groups of methods for reducing the relative CaO content, which can be conventionally termed chemical and physicochemical, are known and widely employed. In recent years procedures of both these types have been considerably improved in the manufacture of nitrophosphates[48-60].

Among chemical methods, the nitric acid–carbonate method[49], characteristically requiring a preliminary complete ammoniation of the solution associated with the precipitation of the citrate-soluble $CaHPO_4$ [see Eqn. (6)], has found limited application. Only after neutralisation of the solution to pH 4 is it treated with NH_3 and CO_2 in order to form calcium carbonate at pH 7–8:

$$Ca(NO_3)_2 + 2NH_3 + CO_2 + H_2O = CaCO_3 + 2NH_4NO_3. \quad (7)$$

The $CaHPO_4$ and $CaCO_3$ precipitates are not separated in the nitric acid–carbonate method and remain in the fertilizer. Therefore, Nitrophoska obtained by this procedure from the apatite concentrate contains only 35–37% of nutrient substances and has the unfavourable ratios N : P_2O_5 : K_2O = 1 : 0.7 : 1.

Nitrophos from Karatau phosphorite contains up to 28.5% of nutrient substances and has the ratio N : P_2O_5 = 1 : 0.6. The entire P_2O_5 in the fertilizer is in the citrate-soluble formed. The comparatively low grade of the fertilizer and the inadequately balanced ratio of nutrient substances explain why this method has not become very common, despite its relatively favourable technical and economic characteristics.

Several procedures for the binding of calcium oxide by sulphate ions [sic] forming the sparingly soluble calcium sulphate, also belong to the class of chemical methods. Sulphate ions are introduced with sulphuric acid (the nitric acid–sulphuric acid method) with ammonium or potassium sulphate (the nitric acid–sulphate methods), and sometimes simultaneously with sulphates and with sulphuric acid.

In the preparation of Nitrophoska with 50% of P_2O_5 in a water-soluble form by the nitric–sulphuric acid method, theoretically only 30% of fluoroapatite is decomposed by nitric acid, the remainder reacting with sulphuric acid:

$$Ca_5(PO_4)_3F + 3HNO_3 + 3.5H_2SO_4 + 7H_2O = 3H_3PO_4 + 1.5Ca(NO_3)_2 + 3.5CaSO_4 \cdot 2H_2O + HF. \quad (8)$$

The neutralisation of the solution to pH 3.2 (at 80–100°C) proceeds according to equation

$$3H_3PO_4 + 1.5Ca(NO_3)_2 + 4.5NH_3 = 1.5CaHPO_4 + 1.5NH_4H_2PO_4 + 3NH_4NO_3. \quad (9)$$

It follows from Eqn. (9) that the amount of the water-soluble and citrate-soluble P_2O_5 in the product is 50% each. Under industrial conditions Nitrophoska is obtained with P_2O_5 which is assimilable (in the water- and citrate-soluble forms) to the extent of about 90%, of which up to 50% is in a water-soluble form.

According to Eqn. (9), the N : P_2O_5 ratio in the neutralised solution is 1 : 2 and therefore, in order to obtain a balanced fertilizer of the 1 : 1 grade, one introduces more than twice the amount of nitric acid required according to Eqn. (8). In practice the consumption of nitric acid per unit of nutrient substances does not differ from that in processes without the use of sulphuric acid, i.e. in fact sulphuric acid is consumed in the method described only in the binding of part of CaO and increases the cost of the raw material component.

Another important feature of the sulphuric acid method is that the calcium sulphate precipitate is not separated from the solution owing to its fairly unfavourable crystal structure and remains in the product. Consequently the concentration of Nitrophoska does not exceed 34–35% of the sum of nutrient substances. This procedure has been applied on an industrial scale in the USSR.

The above disadvantages have so far hindered a wide-scale application of the nitric acid–sulphuric acid method in world industry. In recent years the sulphuric acid method has been greatly improved[61,62] — it has been found that comparatively large readily filtered gypsum crystals are formed when part of the final solution returning to the process in order to dilute the reaction mass is circulated. This procedure makes it possible to include in the manufacturing scheme for sulphuric acid Nitrophoska the filtration and washing of the gypsum, as a result of which its concentration of nutrient substances can be increased to 50–51% for a fertilizer of the N : P_2P_5 : K_2O = 1 : 1 : 1 grade.

A version of the above scheme with replacement of

part of the sulphuric acid by ammonium sulphate was also investigated. The circulation scheme has been proved on an experimental industrial apparatus. The increased cost of the raw material, compared with other methods, persists in the circulation scheme but the improvements can enhance the efficiency of the present apparatus operating in accordance with the nitric acid–sulphuric acid procedure.

The nitric acid–sulphate method, in which a 40% solution of ammonium sulphate is used to bind the excess calcium (see Fig. 3), has found a relatively wider application in world industry[63,64]:

$$3H_3PO_4 + 5Ca(NO_3)_2 + 5(NH_4)_2SO_4 + 3NH_3 + 10H_2O = 3NH_4H_2PO_4 + 10NH_4NO_3 + 5CaSO_4 \cdot 2H_2O. \quad (10)$$

In this method the precipitated calcium sulphate is filtered off and converted by treatment with ammonium carbonate solution:

$$CaSO_4 + 2NH_3 + CO_2 + H_2O = (NH_4)_2SO_4 + CaCO_3. \quad (11)$$

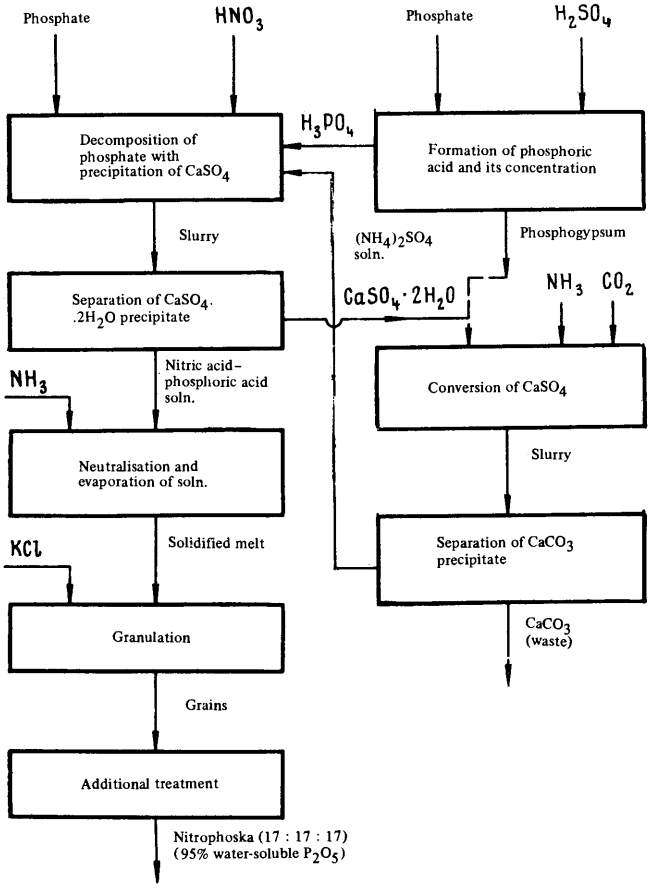

Figure 3. Fundamental scheme of the nitric acid–sulphate method for the manufacture of Nitrophoska.

The calcium carbonate precipitate is a side product and the ammonium sulphate solution formed is returned to the process The advantages of this method include the preparation of concentrated Nitrophoska in which the content of the total nutrient substances for the 1 : 1 : 1 grade is up to 51% and about 95% of P_2O_5 is in a water-soluble form.

The precipitation of calcium oxide requires the introduction of an amount of ammonium sulphate for which the $N : P_2O_5$ ratio decreases to 1 : 0.66. Thus, in order to obtain a more balanced product with the $N : P_2O_5 = 1 : 1$ ratio, it is necessary to introduce additional phosphoric acid, i.e. in this case sulphuric acid is also indirectly involved in the manufacture of Nitrophoska via the preparation of phosphoric acid by extraction.

A version has been developed, which provides for the additional introduction of sulphuric acid (together with nitric acid and ammonium sulphate solution) to decompose the phosphate, in an amount necessary to form phosphoric acid which balances the large amount of nitrogen introduced with ammonium sulphate[65].

The indirect or direct introduction of sulphuric acid into the process lowers the economic efficiency of the nitric acid method of manufacture of complex fertilizers, effectively reducing the amount of the cheapest P_2O_5 introduced in the form of natural phosphates. This version can be applied using the ammonium sulphate solution obtained as a side product in the manufacture of caprolactam.

Among the chemical methods in the next group, mention should be made of the nitric acid – phosphoric acid process based on the decrease of the $CaO : P_2O_5$ ratio in the nitric acid–phosphoric acid solution by the addition of phosphoric acid[66,67]. The process essentially differs little from the nitric acid–sulphuric acid process, since in the latter case sulphuric acid is also indirectly involved in the reaction whereby phosphoric acid is produced by extraction with formation of gypsum as waste.

Complex ternary fertilizers are usually manufactured from the commonest and cheapest potassium raw material–potassium chloride. Studies have been made on the nitric acid processing of phosphates (mainly Karatau phosphorites) also using potassium sulphate[68].

The manufacture of chlorine-free Nitrophoska is of great importance for the cultivation of many agricultural crops, the quality of which is adversely affected by the presence of chloride ions in the fertilizer. A characteristic feature of chlorine-free Nitrophoska is an enhanced content of K_2O: a product with the approximate ratios of 1 : 1 : 1.5 is obtained: the relative amount of water-soluble P_2O_5 does not exceed 50%.

The usefulness of the industrial process with introduction of potassium sulphate depends on the scale of the manufacture of potassium sulphate salts and also on the requirement for a complex fertilizer with an enhanced K_2O content. However, until recently the use of K_2SO_4 was impeded by the small scale of the manufacture of this salt.

High-grade chlorine-free Nitrophoska can be obtained by introducing potassium in the form of the carbonate (with separation of calcium carbonate) or the hydroxide (studies on the technology of the manufacture of Nitrophoska using these reagents are desirable).

The group of physicochemical methods for the reduction of the CaO content in nitric acid–phosphoric acid solutions includes the polythermal crystallisation of calcium nitrate, i.e. by reducing its solubility in the $CaO–P_2O_5–N_2O_5–H_2O$ system on lowering the temperature. This system has been inadequately investigated at temperatures below 0°C, so that the so called "freezing out" of calcium nitrate has been investigated mainly empirically under the conditions of the technological process[7,48,69]. It was shown

that the degree of precipitation of calcium nitrate tetrahydrate and hence the content of water-soluble P_2O_5 in the fertilizer (for nitric acid concentrations in the range 47 to 55% and amounts of nitric acid up to 140% of stoichiometry) depend on temperature (in the range from -15° to +20°C). With increase of the concentration and amount of nitric acid and with decrease of solution temperature, the yield of calcium nitrate and the content of water-soluble P_2O_5 in the product increase (Fig. 4).

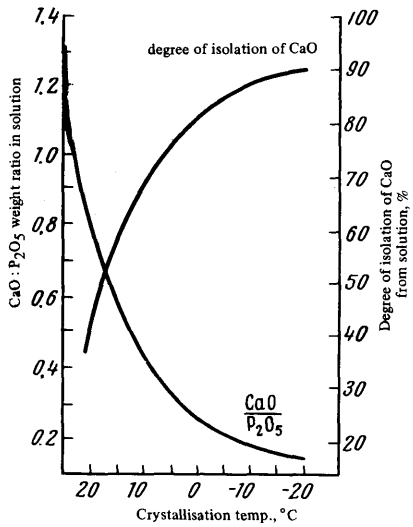

Figure 4. Temperature variation of the degree of isolation of CaO from the nitric acid–phosphoric acid solution (in the decomposition of the apatite concentrate with nitric acid at a concentration of 56–58%)[70].

In the application of the process on an industrial scale with separation of calcium nitrate by cooling, certain technical difficulties were encountered, which delayed the wide scale application of this method. The point is that calcium nitrate tetrahydrate can form an encrustation on the cooled surface of the crystalliser, gradually decreasing the heat transfer coefficient, i.e. increasing the energy expenditure on cooling.

The initial proposals[71,72] for the manufacture of Nitrophoska by the cooling method provided for the formation of the fertilizer with up to 40% of water-soluble P_2O_5 and the simultaneous manufacture of a second product – calcium nitrate (a nitrogen fertilizer containing 15.5% of nitrogen).

The manufacture of Nitrophoska with cooling of the solution to +10°C by the method of Vol'fkovich and Loginova[72] was tested in the USSR on an experimental industrial scale at a nitrogen fertilizer factory, where studies were also made on the nitric acid–carbonate and nitric acid–sulphate methods[39].

The method using polythermal crystallisation of calcium nitrate emphasises the principle of using nitric acid alone for the decomposition of phosphate with simultaneous introduction into the product of nitrogen as a nutrient element.

For the economics of the procedure, it is also important that the entire P_2O_5 enters the process only as the natural phosphate, i.e. in the cheapest form.

The potential economic efficiency of the method with cooling promoted the development of many improvements to the technological process. In recent years multistage cooling (to -5°C) of the slurry obtained in the decomposition of the phosphate raw material with nitric acid (58 to 60%) was used in several countries. The crystallisers are gradually filled and unloaded, so that a continuous flow of the cooled pulp is achieved. This ensured the formation of a coarsely crystalline calcium nitrate, which is readily separated from the mother liquor on filters and in centrifuges. After the additional treatment of the mother liquor, it is possible to obtain Nitrophoska of the 1 : 1 : 1 grade containing about 50% of the total nutrient substances. The amount of P_2O_5 assimilated in the product reaches 96%, including 80–85% of water-soluble P_2O_5.[73–77]

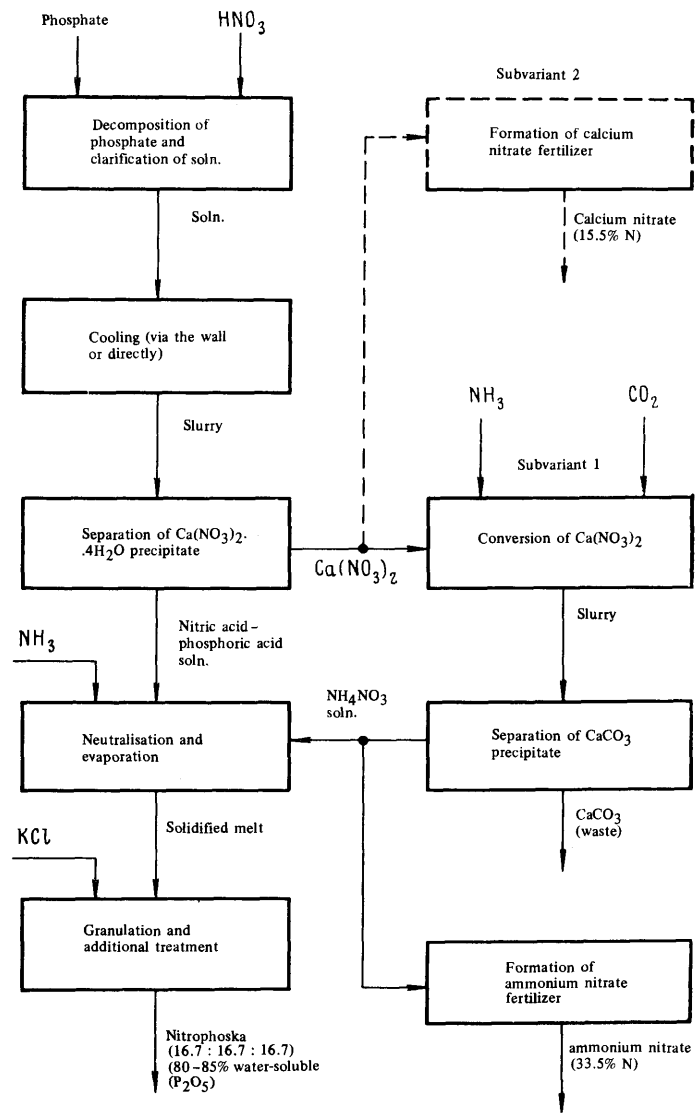

Figure 5. Fundamental scheme of the manufacture of Nitrophoska by the method with polythermal crystallisation of calcium nitrate.

The conversion of the ammoniated mother liquor into the solid fertilizer was also improved and the conversion of the calcium nitrate tetrahydrate isolated into ammonium nitrate [see Eqn. (4)] was introduced. The 95% ammonium nitrate solution can be added in different amounts to the mother liquor in order to maintain the specified $N:P_2O_5$ ratio in Nitrophoska. The remaining ammonium nitrate is issued as a second product — a nitrogen fertilizer with 34% of nitrogen (Fig. 5).

The conversion of calcium nitrate yields a side product (calcium carbonate), which can be used in agriculture for the impregnation of soils with lime and in many manufacturing processes: in the formation of $CaHPO_4$, $Ca(H_2PO_4)_2$, etc. The weight of calcium carbonate is about 75% of that of calcium sulphate (calculated for the anhydrous form) produced in the manufacture of phosphoric acid by extraction for the same amount of phosphate raw material.

The comparatively low cost of the raw material, the satisfactory quality of the product, the possibility of altering the $N:P_2O_5$ ratio in the fertilizer without much difficulty, and the more satisfactory situation as regards industrial waste explains why the manufacture of Nitrophoska by the cooling method has expanded in many countries. During recent years, the output capacity of the existing factories and factories under construction for the manufacture of Nitrophoska by this method in Norway, German Federal Republic, Denmark, France, USA, and Romania reached 6 000 000 tons per year[77].

A further improvement of the cooling method was developed in Czechoslovakia[70,78]. It consists in the replacement of heat exchange via the cooled surface by direct removal of heat by the cooling liquid (for example white spirit), which is immiscible with the slurry The process is continuous, eliminating the encrustation of the cooled surfaces by calcium nitrate crystals. The energy expenditure on the cooling of the slurry is reduced by approximately 10%. This process has been adopted on an industrial scale.

Fig. 6 shows the dependence of the $N:P_2O_5$ ratio and the content of the citrate-soluble or water-soluble P_2O_5 in Nitrophoska obtained by the above method for different amounts of nitric acid used for the decomposition of the apatite concentrate[47]. The possibility of precipitating part of the calcium nitrate as the anhydrous salt directly in the decomposition of natural phosphates with concentrated (80%) nitric acid at a temperature of the order of 60°C has been established experimentally[18,19]. The amount of calcium nitrate isolated makes it possible to obtain Nitrophoska containing up to 80% of P_2O_5 in the water-soluble form. The scheme of the technological process developed on the basis of these studies is close to the usual scheme for sulphuric acid extraction. The development of a modern technology for the concentration of nitric acid makes this process for the manufacture of Nitrophoska very promising. It is useful to continue this study of the process on an experimental industrial scale.

A new trend has arisen in the conversion of nitric acid–phosphoric acid solutions into fertilizers by extracting phosphoric and nitric acids with organic solvents[79]. One of these methods[80–83] consists of extraction with t-pentyl alcohol. The washed organic phase is neutralised with ammonia. On standing, the extract separates into the pure organic solvent and an aqueous slurry containing ammonium nitrate and phosphates. After evaporation and addition of potassium chloride, Nitrophoska of 18 : 18 : 18 grade is obtained.

For the complete isolation of calcium nitrate, the organic phase is washed with a solution of ammonium nitrate. The resulting aqueous phase together with the wash solution is treated with ammonium carbonate to convert calcium nitrate into ammonium nitrate [see Eqn. (4)]. The method has not yet found wide scale application in industry.

A further procedure of this kind has been developed, in which isobutyl alcohol is used as the organic solvent[84–86]. The final products are ammonium dihydrogen phosphate and ammonium nitrate and the waste is calcium carbonate. The method has been applied on an experimental industrial apparatus.

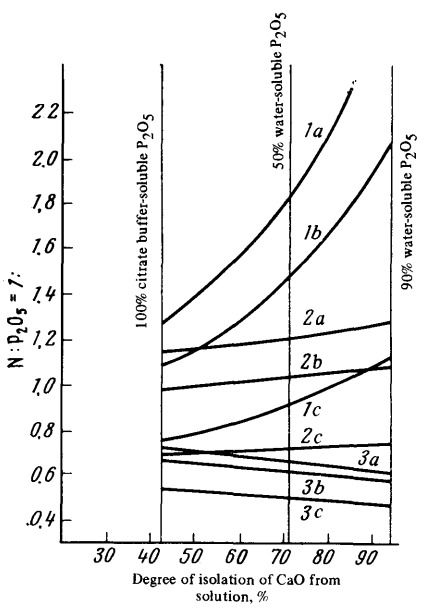

Figure 6. Variation of the $N:P_2O_5$ ratio with the degree of isolation of CaO from the nitric acid–phosphoric acid solution in the decomposition of the apatite concentrate with nitric acid[47]: *1*) method with cooling, no recycling ammonium nitrate; *2*) nitric acid–sulphuric acid method; *3*) nitric acid–sulphate method, without recycling of ammonium sulphate and method with cooling and with recycling of ammonium nitrate; percentage of nitric acid relative to the stoichiometric amount required to decompose the apatite; *a*) 100; *b*) 110; *c*) 140.

Another new trend in the nitric acid processing of phosphates is associated with the use of carbamide[87–90]. Its importance is that carbamide, which forms the readily soluble carbamide phosphate $CO(NH_2)_2.H_3PO_4$ and binds calcium nitrate in the complex $Ca(NO_3)_2.4CO(NH_2)_2$, makes it possible to obtain fertilizers with a high proportion of P_2O_5 in the water-soluble form with a smaller amount, than in other procedures, of calcium isolated from the nitric acid–phosphoric acid solution. It would be useful to investigate further the nitric acid processing of phosphates using carbamide in order to develop effective versions of the manufacturing process for concentrated and balanced water-soluble nitrophosphates.

The preparation of the nitric acid–phosphoric acid solutions for subsequent conversion into fertilizers is not exhausted by the procedures enumerated above. Other versions and methods have been proposed and investigated.

IV. CONVERSION OF AMMONIATED SOLUTIONS INTO SOLID FERTILIZERS

The concluding stages of the processing of the solutions include a number of operations such as the isolation of water (by evaporation or drying), granulation with addition of potassium salts, conditioning (cooling, screening, powdering, librication, encapsulation, pressing, and others). These operations depend to only a slight extent on the methods of preparation of the solutions and therefore different types of apparatus may be employed regardless of the methods used to decrease the relative amount of calcium and for the ammoniation process.

The ammoniated slurry is granulated under industrial conditions with recycling and simultaneous drying of the product in a drum drier ("spherodiser") or in a drum granulator-drier in the industrial application of the nitric acid–sulphuric acid, nitric acid–sulphate, and nitric acid–phosporic acid methods. Such apparatus for the isolation of water and granulation does not use the heat of neutralisation of the acid and therefore entails a high energy expenditure.

The nitric acid–phosphoric acid method is also employed with preliminary neutralisation of the ammoniating-granulating solution and drying of the product in a drum drier. In this version the heat of neutralisation is largely used for the removal of water.

Numerous varieties of industrial apparatus are used to evaporate the neutralised solutions until the formation of a solidified melt and to granulate the latter in spray towers without additional drying of the product. Abroad this process is termed "prilling". The advantage of this method consists in a minimal energy expenditure.

In other schemes neutralised solutions are also evaporated and then granulated in a blade granulator with recycling and subsequent drum drying of the product. Certain companies outside the Soviet Union employ also a different variety of apparatus for technological processes which are essentially of the same type.

V. COMPARATIVE ANALYSIS OF TECHNOLOGICAL PROCESSES IN THE MANUFACTURE OF COMPLEX FERTILIZERS

In the manufacture of complex fertilizers by modern methods 76–87% of the cost is represented by that of the raw materials. The consumption and quality of the raw material are therefore important factors, which reflect the economic efficiency of the methods of manufacture.

For all types of complex fertilizers of the same grade, the consumption of N, P_2O_5, and K_2O is virtually identical: for example, for fertilizers with the $N:P_2O_5:K_2O = 1:1:1$ ratios, it amounts to 0.33–0.35 tons per ton of each nutrient substance. However, the unit costs of nitrogen and P_2O_5 in different raw materials are not the same. The cheapest types of raw material are synthetic ammonia and natural phosphates (apatite and phosphorite concentrates). Therefore, the method of manufacture of a complex fertilizer which requires the cheapest raw materials containing nitrogen and phosphorus will be economically the most efficient ‡.

Comparison of the technological processes used to manufacture complex fertilizers shows[91] that the relative consumption of nitrogen introduced with ammonia (synthetic ammonia or ammonium sulphate) and nitric acid is virtually the same for all the methods considered here. The amount of ammonia nitrogen is in the range 57–62% and that of the nitrogen introduced with nitric acid is 43–38%.

All the methods for the manufacture of both Nitroammophoska and Nitrophoska involve the additional consumption of sulphuric acid (directly or in the manufacture of phosphoric acid). The only exception is the manufacture of Nitrophoska with isolation of calcium nitrate by cooling. The cooling method differs from all others for the synthesis of complex fertilizers also by the fact that the entire P_2O_5 is introduced in the cheapest form — as the natural phosphate. In other words the decomposition of the phosphate raw material in this method is achieved with nitric acid alone, without the additional consumption of sulphuric or phosphoric acid.

The above analysis leads to the conclusion that the cost of the manufacture of Nitroammophoska by treatment with phosphoric and nitric acids and also of Nitrophoska by the nitric acid–sulphuric acid and nitric acid–phosphoric acid methods is highest. The nitric acid–sulphate methods occupy an intermediate position and the manufacture of Nitrophoska by procedures involving the isolation of calcium nitrate by cooling should be least expensive. This conclusion is confirmed by the finding that in the last manufacturing process moderate cooling is employed: a temperature from +10° to -10°C, which can be achieved by combination with the synthesis of ammonia involving a relatively low energy expenditure.

The above data disprove the common view expressed by some investigators[92,93] that the manufacture of Nitrophoska can be useful only provided that the reserves of sulphur in the country are limited or when the sulphur-containing raw material is expensive. However, in fact the cooling method permits economically efficient processing of the phosphate raw material without any consumption of sulphur, using the same amount of nitric acid as in other methods for the manufacture of Nitrophoska — a complex fertilizer.

Approximate calculations of the intrinsic unit cost of the nutrient substances obtained by different methods confirm the above conclusions[52,53,58,91,94–96].

When calcium nitrate is manufactured as a commercial by-product, the manufacture of Nitrophoska by the cooling method takes place without waste. The conversion of calcium nitrate into ammonium nitrate makes it possible to obtain calcium carbonate as a by-product. Compared with the methods for the manufacture of complex fertilizers involving the formation of calcium sulphate as waste, the formation of calcium carbonate simplifies and reduces the cost of the employment of the calcium waste.

The determination of the capital costs is important for the assessment of the different methods of manufacturing complex fertilizers. In certain published studies[94,96] the specific capital investment with the associated cost of the manufacture of Nitrophoska by the cooling method is lower than in the manufacture of Nitroammophoska, while in the manufacture by other procedures[95] the costs are at approximately the same level.

Analysis of the present development of the technology of the nitric acid processing of natural phosphates shows that the method with polythermal crystallisation of calcium nitrate and conversion of the latter into ammonium nitrate or without conversion is promising.

The main advantages of the process with cooling are the lowest cost of the raw material in consequence of the

‡ Since regardless of the method of manufacture, potassium is in most cases introduced as the chloride, its cost does not affect the comparative assessment of the manufacture of complex fertilizers.

effective processing of the cheapest phosphate raw material without the consumption of sulphuric or phosphoric acid, the possibility of obtaining complex fertilizers of different grades on the same apparatus without significant changes in the technological process, and the formation of calcium carbonate as the by-product instead of calcium sulphate (when calcium nitrate is converted into ammonium nitrate).

Studies on new technological processes for the manufacture of complex fertilizers retaining the basic and fruitful idea of employing nitric acid for the decomposition of natural phosphates without the addition of other acids or their salts are useful and merit support.

It is clear from the foregoing that the processes involving the conversion of natural phosphates by nitric acid into complex fertilizers have greatly developed in recent years both in terms of scale and the wide variety of chemical-engineering manufacturing schemes and as regards their more detailed physicochemical investigation. These processes are of great interest and promise and they have been investigated both theoretically and technically to an extent sufficient for the selection of the optimal scheme for the manufacture of Nitrophoska with polythermal crystallisation of calcium nitrate, meeting the highest technical and economic requirements among all other known methods for the synthesis of complex fertilizers.

RUSSIAN CHEMICAL REVIEWS
Uspekhi Khimii

April 1974

Translated from *Uspekhi Khimii*, **43**, 585-611 (1974)

U.D.C. 541.13 ; 546.23 ; 546.24

Electrochemistry of Selenium and Tellurium

A.I.Alekperov

The review deals with the principal advances in the electrochemistry of selenium and tellurium. Problems concerning the kinetics and mechanisms of the cathodic reduction of selenium and tellurium to different valence states and their anodic oxidation in aqueous and non-aqueous solutions are discussed.
The practical applications of electrochemistry in the isolation, refining, and determination of small amounts of the two elements are described.
The bibliography includes 178 references.

CONTENTS

I.	Introduction	235
II.	Electrochemical behaviour of selenium and tellurium electrodes in electrolytes of different compositions	236
III.	Cathodic and anodic deposition of selenium and tellurium	239
IV.	Polarography of selenium and tellurium	246

I. INTRODUCTION

Selenium and tellurium belong to the class of rare elements which are widely employed in various branches of modern engineering. These elements have many specific properties. As their purity improves, new properties are discovered and the scale and specific features of their applications are extended.

With expansion of the field of their applications, there arises the necessity for an intense investigation of the chemical and physicochemical properties and also of the technology of the preparation of pure and ultrapure selenium, tellurium, and their compounds.

The present state of the chemistry and technology of the preparation of pure and ultrapure selenium and tellurium have been described in monographs by Chizhikov and Schastlivyi[1,2], Kudryavtsev[3], Nazarenko and Ermakov[4], Bagnoll[5], and Yukhtanov[6] and in reviews[7,8].

The first study on the electrochemistry of tellurium was published at the beginning of the 19th century. Almost 100 years later the study of the electrochemical behaviour of selenium was begun. Subsequently, isolated papers, frequently containing contradictory data, appeared from time to time. Systematic study of the electrochemical properties of selenium and tellurium began in the 1950's–1960's in connection with their large-scale applications in modern engineering. Extensive data have now accumulated, a systematic account of which requires a separate review.

II. ELECTROCHEMICAL BEHAVIOUR OF SELENIUM AND TELLURIUM ELECTRODES IN ELECTROLYTES OF DIFFERENT COMPOSITIONS

1. OXIDATION-REDUCTION POTENTIALS OF SELENIUM AND TELLURIUM

Selenium

Apart from the metallic state, selenium can exist in the −2, +2, +4, and +6 states of oxidation. For the most stable states, the oxidation-reduction potentials can be represented schematically as follows[9]:

$$H_2Se \xrightarrow{-0.40} Se \xrightarrow{+0.74} H_2SeO_3 \xrightarrow{+1.15\text{в}} SeO_4^{2-}: \text{ acid solutions,}$$

$$Se^{2-} \xrightarrow{-0.92} Se \xrightarrow{-0.366} SeO_3^{2-} \xrightarrow{+0.05\text{в}} SeO_4^{2-}: \text{ alkaline solutions.}$$

The standard potential of the selenium–selenous acid system has been determined[10] by direct measurement of the equilibrium constant of the reaction

$$Se(\text{hexagonal}) + 2I_2(\text{cryst.}) + 3H_2O \rightleftarrows H_2SeO_3 + 4H^+ + 4I^-$$

and a value of +0.74 V† was adopted.

In view of the fact that a state of equilibrium is reached for the above system, it was concluded that the selenium–selenous acid system is reversible.

The steady-state potential of the selenium electrode in selenous acid solutions corresponds to the equilibrium potential of the selenium–selenous acid system[11]. The equilibrium state of the selenium–selenous acid system is also reached in solutions containing tin(II) chloride. The reduction of selenous acid by $SnCl_2$ permits the calculation of the equilibrium constant for the reaction[12]

$$H_2SeO_3 + 2SnCl_2 + 4HCl = 2SnCl_4 + Se + 3H_2O\ .$$

Titrations of selenous acid solutions with tin(II) chloride at different hydrochloric acid concentrations established[13] that in 2–8 M HCl the potential of the Se/SeO_3^{2-} system is +0.74 V. Hence it follows that in the above HCl concentration range selenium in solution in the SeO_2–HCl system exists preferentially as selenous acid.

Tellurium

It dissolves in alkalies and acids with oxidising properties. It forms compounds in both positive (Te^{2+}, Te^{4+}, and Te^{6+})‡ and negative (Te^{2-}, Te_2^{2-}) valence states. Tellurium(IV) compounds are the most stable. In the quadrivalent state tellurium forms numerous complexes[4]. In 2.5 M hydrochloric acid solution the tellurium complex has the composition H_2TeCl_6.[14] As stated by Iofa et al.,[15] in 3.5–7 M HCl there exist at least four different complex tellurium ions which are interconverted as the hydrochloric acid concentration is varied.

The potential of the tellurium electrode in hydrochloric acid solutions of tellurium(IV) was first measured by Reichinstein[16] and Kazarnovskii[17]. With increase of hydrochloric acid concentration from 0.05 to 4.5 M, the potential of the tellurium electrode also rises. It assumes the highest value (+0.567 V) in 2.5 M HCl. It was adopted[16,17] as the equilibrium standard potential of the Te/Te^{4+} system. This is not quite correct, since the authors made not altogether justified assumptions, namely that $TeCl_4$ is completely dissociated into Te^{4+} and Cl^- and that the activity coefficient is unity.

The introduction of a correction by Yakovleva and Andreev[18] in the calculation of the standard potential of the tellurium electrode in hydrochloric acid solutions cannot also be regarded as entirely justified. The authors state that, since there are no literature data for the activity coefficients of Te^{4+} ions and it is difficult to determine them, they can be assumed equal to the activity coefficients of $[Fe(CN)_6]^{4-}$ ions. The activity coefficient of an electrolyte is known to depend on the interaction between the ions with formation of ionic association complexes. Evidently the electrostatic and specific interactions between different ions must differ and hence one cannot assume the identity of the activity coefficients of different ions.

Thus +0.576 V should not be regarded as a standard potential but as an experimental or apparent potential observed in the Te/Te^{4+} system when the concentration ratio in the latter corresponds to the stoichiometry of the electrochemical reaction

$$Te^{4+} + 4e \rightleftarrows Te\ .$$

By measuring the equilibrium potential in the deposition of tellurium from hydrochloric acid solutions by tin(II) chloride, it was established[13] that at hydrochloric acid concentrations in the range 2–3 M the apparent reduction potential is almost independent of acid concentration and amounts to +0.584 V. With further increase of acid concentration, the reduction potential falls.

The surface of the tellurium electrode is rapidly oxidised, the oxide film having a significant influence on the electrode potential. The electrodes treated in an atmosphere of hydrogen at −200°C and then heated to 400°C in a high vacuum exhibit a potential in buffer solutions (free from O_2) which corresponds to the Te/TeO_2 system (in the pH range 2–12).[19]

Schuhmann[20] obtained the following data by direct measurements of the potential of the tellurium–tellurous acid system:

$$Te + 2H_2O = TeO_2(\text{solid}) + 4H^+ + 4e, \qquad \varphi = +0.529\ \text{V},$$

$$Te + 2H_2O = TeOOH^+ + 3H^+ + 4e, \qquad \varphi = +0.559\ \text{V}.$$

With increase of pH, the potential of the tellurium electrode shifts in alkaline solutions and assumes a negative value. The e.m.f. of the cell Te(solid) | TeO_2(solid) | buffer solution ‖ calomel electrode at 25°C and in the pH range 2.2–8 is described by the equation $\varphi = 0.349 - 0.058$ pH.[21] Under these conditions, the electrode can be used as an indicator electrode in acidimetric titrations.

In 1 M NaOH solution the potential of the Te/TeO_3^{2-} system is −0.395 V (s.c.e.)§.[18] The sharp change of the potential of the tellurium electrode in alkaline electrolytes is due to the reaction $3Te + 6NaOH = Na_2TeO_3 + 2Na_2Te + 3H_2O$.

As a result of this reaction, the composition of the electrolyte near the electrode probably changes, Te^{2-} ions appear and create completely different conditions at the tellurium electrode. Another cause of the fall of the electrode potential as the concentration of alkali is altered may be a change in the composition and structure of the tellurite ions.

† The standard potentials are quoted relative to the hydrogen electrode.

‡ The valence indices characterise the degree of oxidation and not the ionic structures.

§ s.c.e. = saturated calomel electrode.

The standard potential of the TeO_3^{2-}/TeO_4^{2-} system in alkaline solutions was obtained on the basis of the oxidation of tellurite with hypoiodate[9]:

$$Te_2O_3^{2-} + 2OH^- = TeO_4^{2-} + H_2O + 2e.$$

It was found that $\varphi = +0.4$ V.

Thus the potentials of tellurium systems can be represented schematically as follows:

$$H_2Te \xrightarrow{-0.72} Te \xrightarrow{+0.529} TeO_2(solid) \xrightarrow{+1.026} H_6TeO_6(solid) \text{ acid solutions,}$$

$$Te^{2-} \xrightarrow{-1.14} Te \xrightarrow{-0.57} TeO_3^{2-} \gtrless^{+0.46} TeO_4^{2-} \text{ alkaline solutions.}$$

More detailed information about the carefully adjusted potentials of tellurium systems and the variation of the potential of the tellurium electrode with pH is given by Pourbaix[22].

2. ELECTROLYTIC REACTIONS AT SELENIUM AND TELLURIUM ELECTRODES

Selenium

Comparison of the conductivities in the S, Se, Te series shows that the conductivity of sulphur is very low, tellurium resembles metals as regards its conductivity, and selenium exhibits semiconductor properties. Semiconductor properties and photosensitivity have a marked influence on the electrochemical behaviour of selenium.

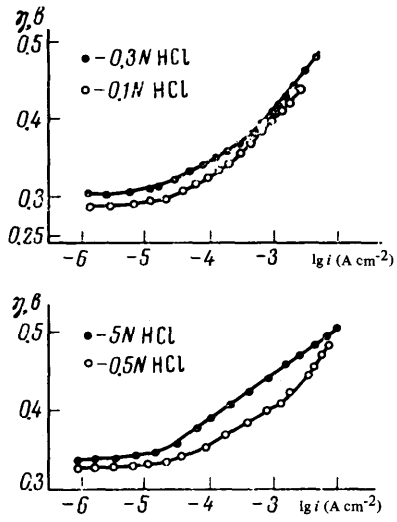

Figure 1. Polarisation curve obtained with the tellurium electrode in hydrochloric acid solutions[29].

In the polarisation of selenium with n- and p-type of conduction in 0.1 N sulphuric acid solution, Gobrecht et al.[23] noted that polarisation of n-type selenium hardly changes on illumination and is determined mainly by the ohmic resistance of the electrode. Illumination of p-type selenium lowers appreciably the cathodic polarisation. Anodic polarisation decreases much less on illumination. The different effects of illumination on the cathodic and anodic processes show that the decrease of the cathodic polarisation in the given case does not occur solely due to a decrease of the ohmic resistance of selenium under the influence of light. The high cathodic polarisation is evidently caused by the fact that in the cathodic reduction of hydrogen ions free electrons are involved, the concentration of which in p-type selenium may be very low.

A high cathodic polarisation in the dark and its decrease on illumination were noted in the electrolytic deposition of selenium at a selenium electrode from selenous acid solutions[24] and also from weakly and strongly acid solutions of selenium dioxide[25].

After the application of an external e.m.f. to the electrodes of the electrolytic cell consisting of two selenium electrodes immersed in 57% H_2SeO_3, the cathode acquires a high sensitivity to illumination, amounting approximately to 1000 ma lm^{-1}.

It is believed[26] that such high light sensitivity of a photoelectric cell of this kind is due to the formation on the surface of the selenium electrode of a blocking layer by adsorbed hydrogen atoms (a solid solution of hydrogen in selenium) generated by the reduction of H+ ions at the electrode.

The photoelectric effect at the selenium electrode (gold foil coated by red selenium) in aqueous hydrochloric acid solution has been investigated[27].

Tellurium

When a tellurium electrode is immersed in 0.1 N H_2SO_4 or 0.1 N NaOH solutions at low current densities (5×10^{-6}–1×10^{-5} A cm^{-2}), a sharp potential jump towards lower positive values associated with a fall of IR is observed in the initial stage of the cathodic polarisation. The subsequent slow variation of the potential (before attaining a steady value) is associated with the reduction of the oxide film, the formation of a double layer, the reduction of H^+ ions, and the formation of hydrogen molecules on the electrode surface.

In the anodic polarisation the rapid initial increase of the potential is associated with the ionisation of H_2 formed in the cathodic polarisation. The subsequent slow change of the potential is a consequence of the evolution of oxygen accompanied by the oxidation of the metal[28]. When the surface of the electrode is completely covered by oxides, the potential acquires a constant value and changes only with current density.

The $\eta - \lg i$ polarisation curves (the variation of the hydrogen overvoltage η with $\lg i$), measured with the aid of a tellurium electrode in 0.05–5 N H_2SO_4, in buffer solutions at pH 3–13, and in 0.1 N NaOH have two linear sections with slopes of about 0.04 V and about 0.12 V. On this basis, it has been suggested that[28] in the above media the evolution of hydrogen on tellurium takes place via an electrochemical mechanism.

In hydrochloric acid solutions the slope of the $\eta - \lg i$ curves varies with the acid concentration (Fig. 1). In solutions at hydrochloric acid concentrations below 0.3 N the $\eta - \lg i$ curves consist of two linear sections with slopes $\upsilon_1 \simeq 0.04$ V and $\upsilon_2 \simeq 0.12$ V. It was suggested[29] that in these solutions the evolution of hydrogen at tellurium proceeds via an electrochemical mechanism in which the formation of hydrogen molecules from H^+ and adsorbed hydrogen atoms is the rate-determining stage. In more concentrated hydrochloric acid solutions the $\eta - \lg i$ curve has a single linear section with a slope of 0.06 V.

In order to account for the change in slope in more concentrated hydrochloric acid solutions, it was suggested[29] that the evolution of hydrogen at tellurium proceeds via a "dual mechanism", i.e. there may be two rate-determining stages proceeding at very similar rates.

In the derivation of the kinetic equation for the possible stages in the cathodic evolution of hydrogen at tellurium, the authors calculated the slopes of the $\eta - \lg i$ curves for different mechanisms on the basis of the theoretical concept of Bockris and Potter[30]. The results showed that, in more concentrated hydrochloric acid solutions at low current densities, the evolution of hydrogen at tellurium can proceed via a dual electrochemical-catalytic mechanism with two different rate-determining stages having similar rates.

At low current densities ($1 \times 10^{-5} - 5 \times 10^{-4}$ A cm^{-2}) in hydrochloric acid solutions the evolution of hydrogen at a tellurium electrode proceeds via a slow discharge mechanism. On further increase of current density (to 1×10^{-2} A cm^{-2}), cathodic dissolution begins with formation of tellurium hydride[31].

As at mercury[33] and other electrodes[34,35], in the electrochemical reduction of $Fe(CN)_6^{3-}$ at the tellurium electrode[32] a decrease of the concentration of the indifferent electrolyte (KCl) near the zero-charge point [$\varphi = -0.30$ V (s.c.e.)] entails a decrease of the current on the $i - \varphi$ curves owing to the effect of the electrical double layer on the kinetics of the electrochemical reaction. An increase of the concentration of the indifferent electrolyte leads to a gradual removal of inhibition of the reaction and at a concentration of 0.1 N the inhibition is completely removed. Chloride and bromide ions do not have an appreciable influence on the kinetics of the electrochemical reduction of $K_3[Fe(CN)_6]$ at tellurium, while iodide ions sharply inhibit the reaction.

3. ANODIC AND CATHODIC DISSOLUTION OF SELENIUM AND TELLURIUM

Selenium

In the anodic polarisation of the selenium electrode in neutral and acid solutions vigorous anodic dissolution of selenium takes place. Depending on the electrolysis conditions and the composition of the electrolyte, the anodic reaction product can be selenous acid or a mixture of selenous and selenic acids. In selenous acid solutions the acid itself becomes concentrated, the anodic reactions occurring without appreciable inhibition with an apparent yield close to 100%.[25]

An important factor in the refining of selenium is the preparation of selenous acid, which is synthesised by the combustion of technical selenium in a stream of oxygen with subsequent dissolution of the resulting selenium dioxide in distilled water. The data obtained[25] suggest that the electrochemical method (anodic dissolution of selenium or interaction of electrically regenerated chlorine with powdered selenium in a single bath) may be promising for the synthesis of selenous acid.

The high resistance of selenium (10^5–10^{11} Ωcm) hinders the use of pure selenium as the material of anodes. For this reason, anodes consisting of a mixture of selenium and graphite have been employed. The most suitable ratio is Se : graphite = 3 : 1.

Measurements of polarisation curves with the aid of the selenium–graphite anode in different electrolytes have shown that at low current densities the anodic curves are the same to a first approximation as the curves obtained in the anodic dissolution of thin selenium films. At high currents (> 10 mA cm^{-2}) there is a linear relation between current density and polarisation.

The form of the polarisation curves shows that the principal reason for the high polarisation is the ohmic potential drop in the electrode itself, and in the electrolyte in the case of H_2SeO_3 solutions, which have a low conductivity.

Selenous acid is synthesised by the reaction of electrically regenerated chlorine with selenium without an inert current-conducting material. A mixture of HCl and NaCl solutions has been employed as the electrolyte with a current density at the anode (graphite) of 30–40 mA cm^{-2}; the cathode consists of a PVC fabric membrane impregnated with titanium. The resulting acid contains small amounts of H_2SeO_4.

In the anodic polarisation of the selenium electrode containing Br_2, HBr and $HBrO_3$ appear as impurities[36] in the solution in addition to H_2SeO_3.

By electrolysing selenous acid at the anode, it is possible to prepare selenic acid and its salts:

$$H_2SeO_3 + H_2O - 2e \rightarrow H_2SeO_4 + 2H^+.$$

The method of anodic oxidation of selenous acid was proposed for the synthesis of selenic acid and its salts free from admixtures of other elements[37–39].

A separate study on the cathodic distribution of selenium has apparently not been made. However, it has been noted[37] that in the electrolysis of KOH solutions with selenium as the cathode and platinum as the anode, polyselenide ions of the type Se_n^{2-} are formed, in which n may be 4.4.

Tellurium

In the electrolysis of alkaline solutions using tellurium electrodes tellurium dissolves both anodically and cathodically. The cathodic dissolution results in the formation of Te^{2-} and Te_2^{2-} ions.

The formation of Te_2^{2-} ions in the cathodic polarisation of tellurium in alkaline solutions was pointed out a long time ago by Le-blanc[40] and Müller and Nowakowsky[41], who observed that in the electrolysis of solutions of alkalies using the tellurium electrode a gas was not evolved at either electrode, both dissolving. In the electrolysis of KOH solution, the solution at the cathode becomes red (polytellurides are formed). The anode dissolves tellurium in an oxidation state close to four, the Te^{4+} ion passing into the solution; most of these ions react with OH^- ions, forming TeO_3^{2-}. Under the conditions where the solution contains simultaneously positive and negative tellurium ions, the equilibrium $3Te \rightleftharpoons 2Te^{2-} + Te^{4+}$ is established. In concentrated alkaline solutions with a measurable amount of products the equilibrium in this reaction is displaced to the right and on dilution of the solution the reaction proceeds in the opposite direction.

The main product in the cathodic dissolution of tellurium in solutions at pH < 9 are Te^{2-} ions, while at pH > 12 the product is Te_2^{2-} ions. In the pH range 9–12 a mixture of Te^{2-} and Te_2^{2-} is formed in the solution. According to the literature[42,43], the overall reaction in the dissolution of the tellurium cathode can be represented as follows:

$$Te + 2(n-1)H^+ + ne = (n-1)H_2Te + \frac{2-n}{2}Te_2^{2-}.$$

The number of electrons n per atom of dissolving tellurium is 2 in acid solutions and 1 in alkaline solutions.

It has been noted[44] that in alkaline solutions the steady-state potential φ_{st} of the tellurium electrode changes very slowly with time, reaching 0.15 V in 1 N KOH and 0.08 V in 0.1 N NaOH. After a preliminary cathodic polarisation of the electrode, φ_{st} is −0.75 V and gradually shifts towards less negative values. This shift takes place as a result of the spontaneous oxidation of Te_2^{2-} (formed from the tellurium electrode in the cathodic polarisation) to Te and TeO_3^{2-}.

The polarisation of the tellurium electrode in NaOH solutions[45] and $Ba(OH)_2$ and NH_4OH solutions[46] was investigated by Awad. In 0.005–0.01 N NaOH at current densities of 1×10^{-6}–1×10^{-3} A cm^{-2} the $\eta - \lg i$ curves have a single linear section with a slope of about 0.1 V. In more concentrated solutions (up to 5 N NaOH) there are two sections with the slopes $v_1 \simeq 0.04$ V and $v_2 \simeq 0.1$ V. It is suggested that at low NaOH concentrations the rate-limiting stage in the cathodic process is the discharge of Na^+ ions. At current densities of 1×10^{-4}–1×10^{-2} A cm^{-2} in 0.5–5 N NaOH solutions the $\eta - \lg i$ curves are to some extent located at potentials more positive than that of the normal hydrogen electrode. In the region near the cathode the solution becomes red, indicating the formation of polytellurides.

Comparison of the experimental slopes with the calculated value (0.06 V) obtained in accordance with the reaction $2Te + 2e \rightarrow Te_2^{2-}$ suggests that a direct formation of Te_2^{2-} by this reaction is impossible.

Therefore Awad[46] postulated that the cathodic dissolution of tellurium proceeds in stages with participation of the electrolyte cation according to the following mechanism:

$$Te + Na^+ + e \rightarrow NaTe ,$$
$$NaTe \rightarrow Te + Na^+ + e ,$$
$$NaTe + Te + e \rightarrow Te_2^{2-} + Na^+ .$$

Awad[46] believes that in $Ba(OH)_2$ and NH_4OH solutions the multistage process can be represented in the following manner on the assumption that tellurium is present as diatomic species:

$$M^+ + Te_2 + e \rightarrow MTe_2 , \quad (1)$$
$$MTe_2 + M^+ + e \rightarrow M_2Te_2 , \quad (2)$$
$$M_2Te_2 + Te_2 + e \rightarrow M_2Te_4^- , \quad (3)$$
$$M_2Te_4^- + e \rightarrow 2M^+ + 2Te_2^{2-} . \quad (4)$$

In 0.5 N NH_4OH and 0.005 and 0.01 N $Ba(OH)_2$ solutions the rate of dissolution is controlled by the discharge of the electrolyte cation, i.e. stage (2) is rate-determining. At high $Ba(OH)_2$ concentrations, the rate is determined by the electrochemical reaction, i.e. stage (4) is slow. However, Awad's experimental data do not confirm his ideas concerning the stoichiometric numbers of the above reactions. The order of the reaction with respect to sodium ions in the double layer is inconsistent with the experimental data. Therefore Komandenko and Rotinyan[47] believe that the formation of Te_2^{2-} probably proceeds without involvement of the alkali metal cation via the mechanism

$$Te + OH^- + e \rightarrow TeOH^{2-} ,$$
$$TeOH^{2-} + Te + e \rightarrow Te_2OH^{3-} \quad \text{slow stage},$$
$$Te_2OH^{3-} + Te + e \rightarrow Te_3OH^{4-} ,$$
$$Te_3OH^{4-} + Te + e \rightarrow 2Te_2^{2-} + OH^- .$$

One can also assume that the polytelluride is formed as the result of the reaction of the Te^{2-} ion with elemental tellurium on the surface of the electrode. However, polarisation data alone, which were used to establish the mechanism of cathodic dissolution of tellurium, are insufficient. It is also necessary to establish the nature of the intermediates and to determine the current yield of the most stable product which accumulates and is responsible for the slow stage. It is therefore difficult at present to give a definite preference for a particular mechanism.

The cathodic dissolution of tellurium is used in some cases for the preparation of hydrogen tellurides[37].

The anodic behaviour of tellurium has been investigated in acid[48–51] and in alkaline[40,52,53] solutions. On the basis of polarisation measurements, Fishman et al.[50] and Awad[51] suggest that the Te^{4+} ion is formed in anodic polarisation. However, the physicochemical properties of tellurium compounds and also experimental data[48] provide adequate grounds for the belief that in acid solutions the primary anodic product is Te^{2+}. Apart from its electrochemical reaction, Te^{2+} subsequently undergoes disproportionation, and, in weakly acid electrolytes, hydrolysis.

In 1.5–3 N NaOH solutions at a current density of 10–40 mA cm^{-2} the anodic dissolution of tellurium proceeds with a 100% current yield. At higher concentrations of alkali the current yield exceeds 100%.

When lower concentrations of alkali are employed, an insoluble form of tellurous acid is formed on the surface of the anode, which markedly increases the resistance.

The anodic process proceeds via the overall reaction $Te + 4OH^- - 4e \rightarrow H_2TeO_3 + H_2O$,[52] which consists of a series of consecutive stages:

$$Te + OH^- - e \rightarrow TeOH ,$$
$$TeOH + OH^- - e \rightarrow TeO + H_2O ,$$
$$TeO + OH^- - e \rightarrow TeOOH ,$$
$$TeOOH + OH^- - e \rightarrow H_2TeO_3 .$$

III. CATHODIC AND ANODIC DEPOSITION OF SELENIUM AND TELLURIUM

1. DEPOSITION FROM AQUEOUS SOLUTIONS

Selenium

Depending on the composition of the electrolyte and the electrolysis conditions, selenium may be deposited in the form of red amorphous and grey hexagonal modifications or their mixture. The electrolytic deposition of red amorphous selenium is carried out in acid and weakly alkaline selenous acid electrolytes[54–56]. The electrolysis is performed at 20–40°C and a current density of 10–20 mA cm^{-2}.

With the development of xerography towards the end of the 1950's, interest was aroused in methods for the preparation of films of amorphous selenium on a metallic base. In order to obtain fairly strong films of red amorphous selenium in the electrolysis of selenous acid and its salts, Graham et al.[57] investigated the effect of the pH of the medium wetting the reactants, the material of the electrode, temperature, and illumination on the structure and electrophysical properties of the deposits. The electrolysis was performed in two baths: (1) acid bath: 350 g of SeO_2 per litre of water, pH 0.8; (2) alkaline bath: 211 g of SeO_2 per litre of dilute NaOH solution, pH 8.

Citric acid was employed as the wetting agent. Selenium was deposited on platinum, bright nickel, black nickel, gold, copper, silver, chromium, and lead electrodes. The electrolysis was carried out in the temperature range 5–40°C and under illumination ranging from moderate to very intense from three 500 W lamps focussed on the surface of the electrode. The most satisfactory coatings were obtained on platinum and nickel. However, the resulting red amorphous selenium deposits proved to be unsuitable for xerography. According to the authors, this is due to the high impurity content in the electrolytic amorphous selenium.

The preparation of selenium coatings by electrolysis was also reported by Krusenstiern and Meier [58].

In acid solutions selenium is deposited on iron, nickel, and copper with and without external polarisation. In neutral solutions without external polarisation it is deposited only on iron. In alkaline solutions selenium is deposited on the above metals only when external polarisation is applied. In all cases the rate of deposition of selenium depends on the nature of the metal [59].

It has been noted [25] that in the electrolysis of 2 M H_2SeO_3 (temperature 20–40°, current density 0.03–0.06 mA cm^{-2}), 2 M $KHSeO_3$ (pH ~ 7), and 2 M H_2SeO_3 + 2 M KCl (current density 2.5 mA cm^{-2}) solutions grey hexagonal selenium is deposited on platinum and nickel cathodes.

In the temperature range 45–70°C at a current density of 10–30 mA cm^{-2} a mixture of grey hexagonal and red amorphous selenium is deposited on the cathode. At elevated temperatures (70–100°C) grey hexagonal selenium (the so called metallic selenium) is deposited on the cathode [60].

The addition of H_2SO_4 and HNO_3 to the electrolyte up to a concentration of 1.2 *N* lowers the potential in the bath from 3.5 to 2.5 V but does not have an appreciable influence on the nature of the electrolytic selenium [61]. In the electrolysis of selenium-containing solutions the acidity of the electrolyte has a marked influence on the cathodic process [25]. A grey, fairly loose deposit of elemental selenium, which is weakly attached to the metallic base, is formed on the cathode from 2 M H_2SeO_3 solutions. At low current densities the current yield of selenium is 45–50%.

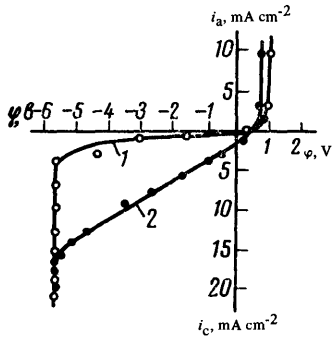

Figure 2. Cathodic–anodic polarisation curves for a 2 M H_2SeO_3 solution: 1) in the dark; 2) under illumination [25].

The cathodic process is accompanied by a high polarisation, which falls appreciably when the surface of the electrode is illuminated (Fig. 2). At high current densities the polarisation is affected by the semiconductor properties of the selenium deposited on the electrode. The high potential gradient in the surface layer of selenium leads to the electrical breakdown of the surface layer. Under the breakdown conditions, vigorous evolution of hydrogen takes place on the electrode. The current yield of selenium falls to 20–25%.

When the surface of the cathode is illuminated, the electrode potential shifts towards positive values and the electrical breakdown of the surface barrier does not occur, the discharge of H^+ diminishing sharply and the current yield of selenium coming close to the theoretical value [62].

Von Hippel and Bloom [63] deposited grey hexagonal selenium from a sulphuric acid electrolyte containing 840 g of SeO_2 per litre of 18 *N* H_2SO_4 and recommended that grey selenium be electrodeposited at 90°C, a temperature which promotes the maximum rate of formation of nuclei. Dense and homogeneous deposits of selenium firmly adhering to the metallic base were obtained on the cathode. Analogous results were achieved also when H_2SeO_4 was employed instead of H_2SO_4. Von Hippel and Bloom [63] recommend that highly acid electrolytes (18 *N* H_2SO_4 + 150 g $litre^{-1}$ SeO_2 at 55–120°C) be employed to coat various articles made of nickel, silver, antimony, and steel. The surface of the cathode was initially coated with the corresponding metal selenide.

A 9 : 1 selenium–graphite mixture was employed as the material of the anode. Under these conditions, the loss of selenous acid in the cathodic reaction is compensated by its formation by the anodic oxidation of selenium. The resulting grey hexagonal selenium coatings can be used in the manufacture of rectifiers and photocells. Selenium coatings obtained by electrolysis in highly acid electrolytes have a distinct texture [64].

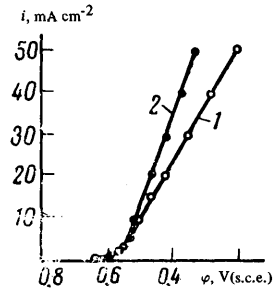

Figure 3. Cathodic polarisation curves for a solution of 840 g of SeO_2 in 1 litre of 18 *N* H_2SO_4; 1) in the dark; 2) under illumination [66].

The electrolytic deposition of the grey hexagonal modification of selenium on a platinum cathode at 95°C from concentrated sulphuric acid containing selenium dioxide has been reported [65].

The cathodic reduction of selenium in highly acid electrolytes (SeO_2 + 55–60% H_2SO_4 or H_2SeO_4) is accompanied by a relatively low polarisation.

At low current densities the polarisation of the selenium electrode hardly changes under illumination. The effect of illumination on the polarisation of the selenium electrode in concentrated sulphuric and selenic acid electrolytes begins to have an appreciable effect at current densities in excess of 10 mA cm^{-2}. The slight

decrease of cathodic polarisation (Fig. 3) under illumination is probably associated with a decrease of the ohmic resistance of selenium under the influence of light.

The $\eta - \lg i$ polarisation curves for the cathodic deposition and anodic dissolution of selenium, measured in concentrated sulphuric and selenic acid electrolytes at low current densities (1×10^{-4}–1×10^{-2} A cm^{-2}), have a single linear section with a slope of 0.7 V (Fig. 4). The exchange current found from the intersection of the anodic and cathodic curves is 1.4×10^{-4} A cm^{-2}.

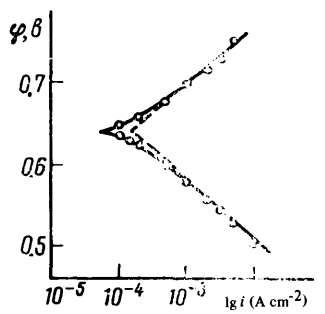

Figure 4. Cathodic–anodic polarisation curves for the solution of 840 g of SeO_2 in 1 litre of 18 N H_2SO_4.[66]

Thus in highly acid solutions the inhibition of the cathodic reaction associated with the depletion of the surface layer of selenium in free electrons, which is characteristic of weakly acid electrolytes, is not observed. The exchange current in highly acid electrolytes is higher by approximately 2 powers of 10 than in weakly acid solutions. The current yield of selenium in concentrated sulphuric and selenic electrolytes is close to 100%.

It is believed[63] that the electrochemical reduction of selenous acid in concentrated sulphuric and selenic acid electrolytes proceeds with participation of the $(H_3SeO_3)^+$ cation, which is formed in accordance with the equilibria

$$H_2SeO_3 \rightleftarrows H^+ + HSeO_3^-, \quad H_2SeO_3 + H^+ \rightleftarrows (H_3SeO_3)^+ .$$

Its concentration increases with the acidity of the electrolyte.

The absence of inhibition in the electrochemical reduction of selenium in concentrated sulphuric and selenic acid solutions is attributed by other workers[66] to the fact that the free electrons involved in the cathodic process are generated in a sufficient amount on the surface of the electrode. Possibly the products of the interaction of selenium with fairly concentrated acids of the H_2SeO_4 and H_2SO_4 type behave as electron generation centres. Despite the fact that there is no direct proof of the formation of these products and there are no data concerning their nature and properties, the polarisation and capacitance measurements as well as the properties of selenium in concentrated solutions[3] suggest that preference should be given to this explanation.

Elemental selenium dissolves readily in concentrated sulphuric acid with formation of $SeSO_3$. The electrolytic reduction of $SeSO_3$ in 98% sulphuric acid solutions proceeds via the reaction

$$SeSO_3 + 6H^+ + 6e \rightarrow Se + S + 3H_2O^{67,68} .$$

The current yield is nearly theoretical. Since $SeSO_3$ is frequently formed in the course of the manufacture of sulphuric acid (when the raw material contains selenium), the electrolytic reduction of $SeSO_3$ can be used for the quantitative separation of selenium from sulphuric acid.

The technology of the electrolytic preparation of selenium from the anodic sludge in the copper refining industry has been described[69]. The sludge is roasted with Na_2CO_3, leached with water, and the solution is saturated with boric acid, filtered, and the pH adjusted to 8–9 by the addition of an aliphatic polybasic alcohol (for example 2-amino-2-methylpropane-1,3-diol). This solution serves as the catholyte, aqueous NaOH or Na_2CO_3 being employed as the anolyte. Selenium is evolved at a potential of 4.5–6 V. The cathode can also be made of iron, copper, titanium, and aluminium and the anode can be made of materials resistant to NaOH solutions.

Selenium is deposited from solutions of alkali metals by hydrogen selenide via the reaction

$$HSe^- + OH^- - 2e \rightarrow Se + H_2O .$$

The anodic oxidation of sodium selenide has been used to coat the plates of rectifiers[70]. The electrolysis was performed at elevated temperatures and a maximum current density of 10 mA cm^{-2}. However, owing to the instability of the selenide solutions, the anodic deposition of selenium has not found wide scale application.

In the electrolysis of alkaline solutions of a selenite, the selenide is formed on the cathode via the reaction $SeO_3^{2-} + 3H_2O + 6e \rightarrow Se^{2-} + 6OH^-$ and can be used for the deposition of selenium on the anode. This process is complicated by the chemical reactions

$$2HSe + {}^1/_2O_2 = 2Se + H_2O, \quad SeO_3^{2-} + 2HSe^- + H_2O = 3Se + 4OH^- .$$

The colloidal selenium formed as a result of this reaction interacts with the selenide and forms polyselenides which are not involved in the electrochemical reaction and merely reduce the concentration of the selenide in the electrolyte. Under certain conditions, sodium selenide is formed in the cathodic compartment in the electrolysis of sodium selenite solutions[71].

2. CATHODIC DEPOSITION OF TELLURIUM FROM ACID SOLUTIONS

In the electrolysis of acid tellurium-containing solutions, coarsely crystalline or fine-grained tellurium deposits are formed on the cathode depending on the electrolysis conditions and the composition of the electrolyte. Spongy deposits are mainly produced in the electrolysis of weakly acid solutions of tellurium. TeO_2, the formation of which is associated with the hydrolysis of tellurium chloride near the electrode, has been found in the spongy tellurium deposits[72].

The best electrolytes for the electrolytic deposition of tellurium from acid solutions are hydrochloric acid solutions. The high positive potential of the Te/Te^{4+} system and the high solubilities of TeO_2 and $TeCl_4$ in hydrochloric acid solutions are extremely favourable for the electrolytic deposition of pure tellurium. The electrochemical behaviour of tellurium in hydrochloric acid solutions has been investigated[25,31,72–76].

Müller and Schlosser[73], who were the first to achieve the electrochemical deposition of tellurium from hydrochloric acid solutions (300 g litre^{-1} Te + 200 g litre^{-1} HCl), noted that pure tellurium is deposited on platinum and titanium cathodes at 30°C.

For the deposition of tellurium with a purity not less than 99.99%, the limiting permissible concentrations of impurities in solution such as selenium, silver, mercury, and gold should not exceed 5 mg litre^{-1} and those of impurities such as aluminium, iron, magnesium, and calcium, and others should not exceed 70–100 mg litre^{-1}.[25] The electrolysis conditions are as follows: $(0.5–2.0) \times 10^{-3}$ M TeO_2 or $TeCl_4$ + $(2.5–5) \times 10^{-3}$ M HCl electrolyte, current density 15–20 mA cm^{-2}, 25–30°C. Such electrolytes can be prepared by the anodic dissolution of technical tellurium in hydrochloric acid solutions[48].

Chlorine in the form of $TeCl_2$ remains in all the tellurium deposits as a mechanical impurity[72]. An increase of the acidity of the solution, the presence of alkali metal chlorides in the electrolyte, and an increase of current density lead to an increase of the $TeCl_2$ content.

A change in the electrolyte temperature has an appreciable influence on the mechanism of the cathodic deposition of tellurium and on the nature of the deposits. A fine-grained grey deposit is formed on the cathode at 25–50°C and current densities of 10–15 mA cm^{-2}. At 75 to 90°C and a current density of 20 mA cm^{-2}, coarse-grained dark-grey deposits are formed, their current yield in relation to Te^{4+} falling from 99% at 25°C to 89% at 90°C.

The formation of $TeCl_2$ is associated with a multistage mechanism of the reduction of Te^{4+} ions by Te^{2+}. Some of the Te^{2+} ions near the electrodes react with Cl^- ions to form $TeCl_2$, which is deposited on the surface of the cathode together with a freshly formed layer of elemental tellurium. Other Te^{2+} ions undergo further electrochemical reaction and disproportionation: $2Te^{2+} = Te + Te^{4+}$.

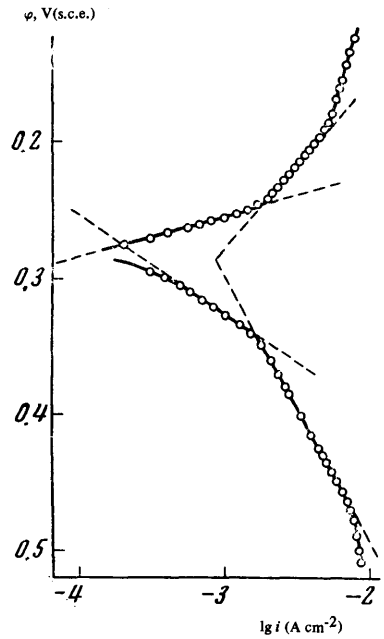

Figure 5. Cathodic–anodic polarisation curves obtained in 2 M HCl + 0.05 M $TeCl_4$ solution[74].

Vigorous formation of Te^{2+} ions and their disproportionation are observed in the anodic polarisation of the tellurium electrode in hydrochloric acid solutions. After the start of electrolysis, the electrolyte near the anode becomes greenish-yellow, then assumes a red tint, and is converted into a dirty-grey turbid suspension, black crystals (pure elemental tellurium) being formed after approximately 30–40 min.

Te^{2+} ions in the solutions after anodic polarisation were detected directly by treatment with an oxidant ($K_2Cr_2O_7$).

The study of the kinetics of the decrease in the amount of Te^{2+} ions in solution after the anodic polarisation of tellurium had ceased and chemical analysis of the solid mass established that (1) Te^{2+} is formed in the anodic dissolution of tellurium in hydrochloric acid solutions; apart from being involved in an electrochemical reaction, Te^{2+} ions subsequently disproportionate and are also deposited in the form of $TeCl_2$ on the surface of the anode; (2) the disproportionation reaction is a second-order process.

The cathodic polarisation curves measured with the aid of the tellurium electrode in hydrochloric acid solutions of tellurium(IV) show the onset of a limiting current, which increases with the concentration of tellurium in the electrolyte, temperature, and the rate of stirring. At an HCl concentration of 2.5–5 M the limiting current varies linearly with the concentration of tellurium in the electrolyte[74]. In this acidity range tellurium is present in solution in the form of the complex ions $TeCl_6^{2-}$.

As the acidity of the electrolyte diminishes, the chlorine in the complex ion is gradually replaced by H_2O or OH^-, tellurous acid is precipitated, and the concentration of Te^{4+} ions in solution falls.

The initial sections of the polarisation curves (Fig. 5) for 2.5–5 M HCl + 0.02–0.25 M Te solutions at 25–50°C show a break and two linear sections with different slopes; $b_{c1} = 0.035$ V, $b_{c2} = 0.12–0.14$ V, $b_{a1} = 0.066–0.070$ V, and $b_{a2} = 0.15–0.20$ V. The exchange currents are $i_{0.1} = 2 \times 10^{-4}$ A cm^{-2} and $i_{0.2} = 1 \times 10^{-3}$ A cm^{-2}.

Comparison of the results of the polarisation measurements with the direct detection of Te^{2+} ions permits the assumption that the cathodic deposition and anodic dissolution of tellurium in hydrochloric acid electrolytes proceed in stages.

The most probable mechanism of the process can be represented in the following form[25]:

$$TeCl_6^{2-} \rightleftarrows TeCl_2^{2+} + 4Cl^-, \quad (1)$$

$$TeCl_2^{2+} + e \rightleftarrows TeCl_2^+, \quad (2)$$

$$TeCl_2^+ + e \rightarrow TeCl_2 \quad (3)$$

$$\text{or } TeCl_2^{2+} + 2e \rightarrow TeCl_2, \quad (4)$$

$$TeCl_2 + e \rightarrow TeCl_2^-, \quad (5)$$

$$TeCl_2^- + e \rightleftarrows Te^0 + 2Cl^- \quad (6)$$

$$\text{or } TeCl_2 + 2e \rightarrow Te^0 + 2Cl^-. \quad (7)$$

If there is only one slow stage in reactions (1)–(7), the sum of the apparent transfer coefficients should be equal to the number of electrons involved in the overall reaction, i.e. $\alpha' + \beta' = 4$, which is not observed experimentally. Therefore one must postulate that the cathodic deposition and anodic dissolution of tellurium in hydrochloric acid solutions occur by more than one slow stage.

The formation of Te^{2+} ions and the increase of their concentration during electrolysis suggest that the slow stage may be reaction (5). On the other hand, reaction (3), whose product can disproportionate and also remain in the solid state apart from being involved in an electrochemical reaction, presumably also has a slow stage.

If one supposes that reactions (3) and (5) and reactions (5) and (3) are slow in the cathodic and anodic processes respectively and that the preceding electrochemical stages are reversible, then, using the characteristics of multistage processes and the proposed reaction mechanism, the following kinetic equations may be derived:

$$i_c = k_{-3}[TeCl_6^{2-}][Cl^-]^4 \exp[-(1+\alpha_3)F\varphi_c/RT],$$

whence $\alpha' = 1 + \alpha_3$, $\beta' = 1 + \beta_5$, $\alpha' + \beta' < 4$, and

$$i_a = k_{+5}[Cl^-]^2 \exp[(1+\beta_5)F\varphi_a/RT].$$

Thus $\alpha' + \beta''$ must be four, which is in fact observed experimentally.

Electrodeposition from tellurium solutions containing tellurium sulphate mixed with ammonium hydrogen tartrate was carried out by Pellini[77]. According to Gallo[78], Pellini's method[77] is unsuitable for the electrochemical deposition of relatively large amounts of tellurium and the electrolysis of pyrophosphate electrolytes is recommended. The electrolytic deposition of tellurium on a lead cathode from a $TeO_2 + HF + H_2SO_4$ electrolyte has been described[79]. However, owing to the corrosive nature of the electrolyte, the method has not found any practical application. It is occasionally recommended for the deposition of thin tellurium films on various metallic surfaces[80]. The conditions governing the electrolytic deposition of tellurium from media described by Mathers and Turner[79] were recently reinvestigated[81] and it was found that a dense deposit of tellurium with a metallic lustre and having a purity of 99.98% is formed on the cathode.

There are data[82] showing that in the electrochemical deposition of tellurium from sulphuric acid electrolytes in an ultrasonic field the limiting permissible current density for the formation of high-grade tellurium deposits is appreciably increased. In sulphuric acid solutions tellurous acid is reduced to elemental tellurium, while telluric acid is not reduced. This property can be used to separate tellurous and telluric acids[54].

The polarisation curves measured with the aid of the tellurium electrode in sulphuric acid electrolytes suggested[83] that the cathodic and anodic processes proceed in stages.

It was established, using buffer solutions in the pH range 7–10, by potentiostatic measurements[84] that at cathodic potentials the tellurium is in a state of cathodic passivation, while at anodic potentials the active state is followed by a state of secondary passivation.

The first studies of the electrochemical behaviour of ultrasmall amounts (10^{-10} M) of tellurium were made by Ghosh–Mazumder and Haissinsky[85]. The authors employed a mixture of tellurium-129 and tellurium-127 isotopes in the form of quadrivalent ions. The experiments were performed in HCl, HBr, and H_2SO_4 media or in solutions of the corresponding salts. With increase of the acidity of the medium, the tellurium deposition potential shifts towards positive values. The nature and state of the electrode surface have an appreciable influence on the tellurium deposition potential. The electrodes can be arranged in the following sequence in terms of the tellurium deposition potential:

platinised Pt > smooth Pt > Pd > Au > Ru.

Tellurium was electrochemically deposited also from nitric acid (0.5–1 M HNO_3) electrolytes at a maximum tellurium concentration of 1.5 g litre^{-1} using platinum electrodes and a current density of 1.2–1.8 mA cm^{-2}.[25] A deposit of grey tellurium firmly adhering to the electrode surface is formed on the cathode; its current yield is close to 100% and appreciable evolution of hydrogen is not observed.

At current densities of 3–5 mA cm^{-2} the deposition of tellurium on the cathode occurs with the evolution of hydrogen and the current yield of tellurium falls to 80%. The tellurium deposited by electrolysis from nitric acid solutions is purer than that deposited from hydrochloric acid electrolytes. In the electrolysis of hydrochloric acid solutions of tellurium the formation of hydrogen telluride is observed only when tellurium is deposited from solutions with very low tellurium concentrations under limiting current conditions at 0–10°C. The mechanism of the formation of H_2Te involves the reaction $Te^{2-} + 2H^+ \rightarrow H_2Te$.[86] Telluride ions are formed initially and then diffuse from the cathode and interact with hydrogen ions migrating to the surface of the cathode. When H_2Te is formed, the evolution of hydrogen ceases; Te^{2+} ions are probably adsorbed on the surface of the cathode and act as a "poison" for the evolution of hydrogen.

The electrolytic method is also used to prepare tellurides[2]. In the electrolysis of sodium sulphate solutions using an anode made of a metal whose telluride is to be obtained and tellurium as the cathode, the products are tellurides. Copper and nickel tellurides have been synthesised in this way. In the synthesis of zinc tellurides, a zinc plate was used as the anode and the cathode consisted of a tellurium–platinum alloy. Nitric and sulphuric acids serve as the electrolyte.

The conditions of the electrolytic deposition of tellurium–silver alloys from nitric acid electrolytes and of tellurium–cadmium alloys from cyanide electrolytes have been described by Klochko and Medvedeva[87] and by Trusova and Chizhikov[88] respectively. The conditions governing the joint electrodeposition of tellurium–copper[89] and tellurium–chromium[90] have also been described.

Using a tellurium cathode and an anode made of other metals in a 1 M $NH_4OH + CH_3COOH$ solution at pH 4.5, CuTe, SnTe, ZnTe, PbTe, and Bi_2Te_3 were synthesised electrolytically[91].

It has been reported[92] that Ag_2Se and Ag_2Te are formed respectively on a silver cathode in the electrolysis of 0.01 M SeO_2 and TeO_2 solutions in 1 M H_2SO_4 at 25°C and a current density up to 0.05 mA cm^{-2}. The electrolysis of acidified $CuSO_4 + H_2SeO_3$,[93,94] $H_2TeO_3 + H_2SeO_3$,[95] $AgNO_3 + H_2SeO_3$,[96] $Bi(NO_3)_3 + H_2SeO_3$,[97] and $CdSO_4 + H_2SeO_3$[98] solutions results in the formation of the corresponding metal selenides on platinum, copper, silver, cadmium, and tellurium cathodes.

The formation of selenides has also been noted[99] in the electrolysis of H_2SO_4, Na_2SO_4, and KNO_3 solutions using a selenium cathode and an anode made of copper, nickel, cadmium, and certain other metals.

3. CATHODIC DEPOSITION OF TELLURIUM FROM ALKALINE ELECTROLYTES

For the electrodeposition of tellurium from alkaline solutions, the electrolyte is usually prepared by dissolving TeO_2 in sodium hydroxide solution.

Apart from simple tellurites of the type Na_2TeO_3, the existence of sodium polytellurites of the type $Na_2Te_3O_7$, $Na_2TeO_5.3H_2O$, and $Na_2TeO_9.5H_2O$ was established in the TeO_2–Na_2O–H_2O system[100]. The reduction of tellurium at the cathode in such solutions is a fairly complex process, the final product of which is elemental tellurium.

A Japanese patent[101] reports the formation of tellurium by the electrolysis of alkaline electrolytes.

In the Soviet Union the preparation of tellurium on an industrial scale was achieved by Gaev et al.[102] The electrolysis was carried out in an electrolyte containing 100 g litre^{-1} of tellurium and 160 g litre^{-1} of free sodium hydroxide. Tellurium is deposited on the cathode in powder form and its purity is 99.5%. Tellurium with a lower impurity content can be obtained by employing a purer electrolyte.

Electrolytic units for the electrolytic isolation of tellurium have been organised in many copper-electrolytic and metallurgical works[103-106], where selenium and tellurium-containing waste accumulates.

At low current densities the electrodeposition of tellurium proceeds with chemical polarisation, while at high current densities concentration polarisation obtains[107]. The cathodic polarisation curves show a limiting current ($i$lim) (Fig. 6). With increase of the concentration of alkali in the electrolyte, the limiting current falls.

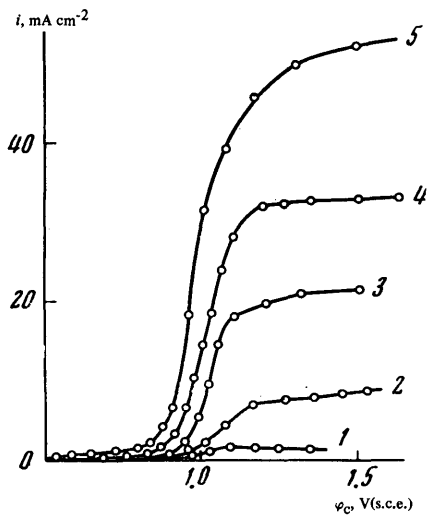

Figure 6. Cathodic polarisation curves for a 4 M NaOH solution containing different concentrations of tellurium (M): 1) 0.016; 2) 0.064; 3) 0.16; 4) 0.25; 5) 0.41.[25]

In an electrolyte with a high concentration of alkali $i$lim varies linearly with the tellurium concentration in the electrolyte and on dilution (in the absence of an excess of alkali) the increase of $i$lim with the concentration of tellurium is faster than would be expected for a direct proportionality. The difference between the values of $i$lim for tellurium in solutions with low and high concentrations of alkali has been attributed[108] to the different nature of the tellurium-containing species being discharged in concentrated and dilute solutions of alkali. In concentrated solutions of alkali the $\varphi - \lg i$ polarisation curves have a single linear section at relatively high current densities (Fig. 7). At low current densities the cathodic curves show a decrease of potential characteristic of the spontaneous dissolution of the metal[109].

Depending on the concentration of alkali in the electrolyte, the overall electrode reaction can be represented as follows:

$$TeO_3^{2-} + 3H_2O + 4e = Te + 6OH^-\ ,$$

$$HTeO_3^- + 2H_2O + 4e = Te + 5OH^-\ .$$

Bearing in mind that in a solution with a high excess of alkali the dominant species are the $[Te(OH)_6]^{2-}$ ions[18], which dissociate via the reaction $[Te(OH)_6]^{2-} \rightleftharpoons Te(OH)_3^+ + 3OH^-$,[109] it follows that, according to the hypothesis put forward[108,109], the electrodeposition of tellurium presumably corresponds to the overall electrode reaction $Te(OH)_3^+ + 4e \rightarrow Te + 3OH^-$, which proceeds in stages via the mechanism

$$Te(OH)_3^+ + e \rightarrow Te(OH)_3\ ,$$

$$Te(OH)_3 + e \rightarrow Te(OH)_3^-\ ,$$

$$Te(OH)_3^- + e \rightarrow Te(OH)_3^{2-}\ ,$$

$$Te(OH)_3^{2-} + e \rightarrow Te^0 + 3OH^-\ .$$

The rate-determining stage is the generation of the last electron. The slope of the linear sections of the $\varphi - \lg i$ curves calculated on the basis of the theory of multistage reactions using kinetic equations is satisfactorily consistent with the experimental results.

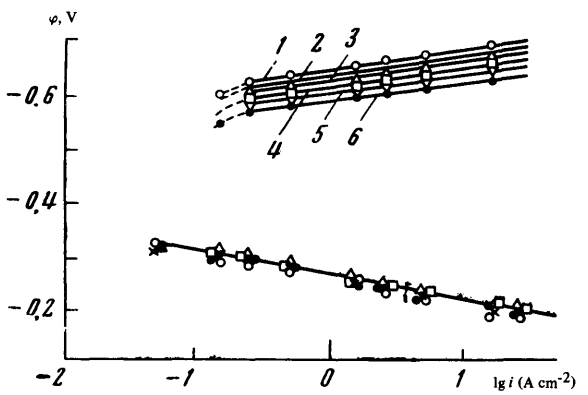

Figure 7. Cathodic–anodic polarisation curves for a 2.5 M NaOH solution containing different concentrations of tellurium (M): 1) 0.0075; 2) 0.015; 3) 0.03; 4) 0.06; 5) 0.12; 6) 0.188.[109]

In the electrolysis of thiotelluride (Na_2TeS_2) solutions tellurium is deposited on the cathode and elemental sulphur on the anode and polytellurides are formed[110]. The accumulation of polysulphides in the electrolyte leads to a decrease of the current yield of tellurium owing to the dissolution of tellurium on the cathode in the polysulphide.

In the course of the electrolysis of alkaline solutions containing tellurium and selenium, tellurium is deposited on the cathode and selenium remains in solution. Optimal conditions have been found whereby the concentration of tellurium in alkaline selenium-containing solutions can be reduced to 5×10^{-5}%.[111] Alkaline electrolytes have also been used in the refining of tellurium[112,113]. All the tellurium deposits obtained by the electrolysis of alkaline or acid solutions containing alkali metal ions contain an admixture of the latter in an amount of 0.01–0.05%.

4. CATHODIC DEPOSITION AND ANODIC DISSOLUTION OF SELENIUM AND TELLURIUM IN NON-AQUEOUS ELECTROLYTES

The conductivities of alcohols, acetic acid, and ethylene glycol increase sharply when $SeCl_4$ or $TeCl_4$ are dissolved in them. The high conductivities of the solutions have been attributed[114] to the presence of H^+ and Cl^- ions formed as the result of the dissociation of HCl produced by the reaction

$$SeCl_4\,(TeCl_4) + nCH_3OH \rightleftarrows Se\,(Te)\,Cl_{4-n} \cdot (OCH_3)_n + nHCl\ .$$

In the electrolysis of alcoholic, acetic acid, and ethylene glycol solutions of $SeCl_4$ or $TeCl_4$, selenium or tellurium is deposited on the cathode. Depending on the electrolysis conditions, primarily on temperature, the selenium deposits can be amorphous or crystalline. Crystalline selenium deposits are obtained from electrolytes heated to 45–60°C. However, under such conditions the nature of the electrolyte changes during electrolysis with formation of an organoselenium compound. Selenium is not electrodeposited from such solutions. Intermediate reduction products were not detected in the cathodic selenium deposits. The current yield of selenium does not exceed 15%. When the electrolyte contains 10% of aromatic hydrocarbons, the current yield of selenium rises to 27%.[115]

As in aqueous hydrochloric acid solutions, the cathodic deposition of selenium in the above solvents proceeds with a high overvoltage, which falls appreciably when the surface of the electrode is illuminated.

At temperatures of 5–10°C and current densities of 5–10 mA cm^{-2}, deposits of metallic tellurium firmly adhering to the surface of the electrode are formed on graphite and titanium cathodes in 0.5–1 M $TeCl_4$ solutions in acetic acid[116], alcohols, and ethylene glycol[25].

A cryptocrystalline tellurium deposit was formed on a platinum cathode in mixed aqueous alcoholic hydrochloric acid electrolytes (water content not greater than 2%) at a current density of 10–20 mA cm^{-2} and a temperature of 15–20°C. Black velvety cathodic deposits are obtained at current densities in the range 10–20 mA cm^{-2}.

Chlorine was detected in all the electrolytic tellurium deposits. Its content depends on the electrolysis conditions and the nature of the electrolyte. The greatest amount of chlorine (up to 7%) remains in deposits which were isolated from acetic acid solutions and the smallest amount (down to 0.04%) was found in deposits from ethylene glycol electrolytes. The chlorine in the electrolytic tellurium deposits is present as a mechanical admixture of tellurium dichloride[25].

Polarisation measurements made with the aid of the tellurium electrode in $TeCl_4$–CH_3OH or $TeCl_4$–C_2H_5OH solutions yield reproducible results (Fig. 8).[117] The cathodic curves show a limiting current section. The limiting current i_{lim} increases with the concentration of tellurium (curves *2*–*4*), temperature, and rate of stirring of the electrolyte, and decreases both with increase of the concentration of chloride ions as a result of the addition of HCl or LiCl to the electrolyte (curves *4* and *6*) and when alcohols with high molecular weights are employed as solvents (curves *4* and *5*).

The initial sections of the cathodic–anodic $\varphi - \lg i$ polarisation curves are described by Tafel equations with o_c = 0.055–0.060 V and o_a = 0.065–0.070 V.

In hydrochloric acid solutions in alcohols, acetic acid, and ethylene glycol both selenium and tellurium undergo vigorous anodic dissolution with formation of a mixture of chlorides. The lowest chlorides are subsequently oxidised to $SeCl_4$ or $TeCl_4$, which react with the solvent, undergoing solvolysis or solvation.

An electrolyte suitable for the electrochemical refining of tellurium can be prepared by the anodic dissolution of technical tellurium in hydrochloric acid solutions in acetic acid.

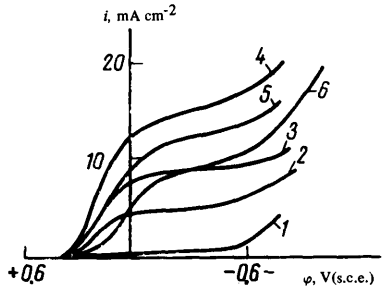

Figure 8. Polarisation curves for amine tellurium-containing solutions: 1) 0.5 M HCl + CH_3OH; 2) ditto + 0.02 M $TeCl_4$; 3) ditto + 0.03 M $TeCl_4$; 4) ditto + 0.05 M $TeCl_4$; 5) 0.05 M $TeCl_4$ + C_3H_7OH + 0.5 M HCl; 6) 0.05 M $TeCl_4$ + 5 M HCl + CH_3OH.[25]

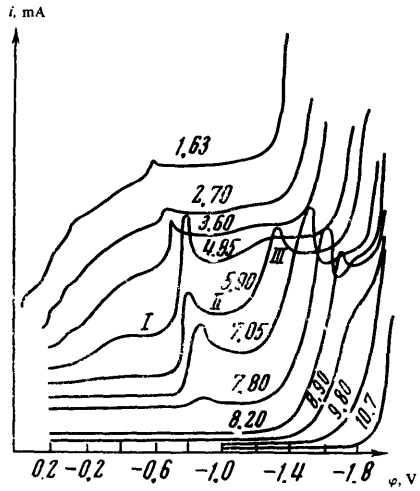

Figure 9. Polarographic curves for a 0.001 M selenium(IV) solution at different pH in the absence of surface-active substances (the pH values are indicated opposite the curves)[123].

An electrolyte with the composition 50% TeO_2 + 25% KCl + 25% LiCl was used for the electrodeposition of tellurium from fused media[118]. This composition was chosen after investigating the properties of certain TeO_2–KCl and TeO_2–LiCl binary systems and also the TeO_2–KCl–LiCl ternary system[119]. The electrolysis was carried out at 650–680°C and a current density of 0.2 A

cm^{-2}. Tellurium reduced to the elemental state accumulated in the liquid form on the bottom of the electrolyser. Impurities collected in the form of a slag on the surface of the deposited tellurium. The impurity content in the cathodic tellurium did not exceed 0.01–0.02%.

When a direct current was passed between two electrodes immersed in fused selenium, some impurities (silver, tellurium, and iron) collected in the cathodic compartment, while others (lead, arsenic, and nickel) collected in both cathodic and anodic compartments. The purest selenium remained in the central part of the cell[120].

In the cathodic–anodic polarisation of liquid selenium in the fused LiCl–KCl eutectic at 400°C, selenium is oxidised at the anode: $2Se + 2Cl^- - 2e \rightarrow Se_2Cl_2$, while the selenide is formed on the cathode: $Se + 2e \rightarrow Se^{2-}$. Under analogous conditions the oxidation of tellurium proceeds up to the formation of Te^{2+} and the cathodic process is limited to the incorporation of lithium in tellurium[121].

IV. POLAROGRAPHY OF SELENIUM AND TELLURIUM

Numerous studies have been made on the polarography of selenium and tellurium[122–178].

Selenium

Depending on the composition of the electrolyte (in the first place on the pH of the medium), the polarogram of selenous acid has up to three waves. A distinct wave, suitable for analytical purposes, appears at potentials between −1.4 and −1.5 V (s.c.e.) in the pH range 8–9. The electrode reaction then proceeds via the mechanism $HSeO_3^- + 6H^+ + 6e \rightarrow HSe^- + 3H_2O$.

There are different interpretations[122–127] of the mechanism of selenous acid reduction in acid solutions at a dropping mercury electrode.

The most likely mechanism of the formation of two waves (Fig. 9) in more acid solutions was given by Lingane and Niedrach[123]. The electrode reaction proceeds initially with participation of six electrons: $SeO_3^{2-} + 6H^+ + 6e \rightarrow Se^{2-} + 3H_2O$. The selenide ions formed at the surface of the mercury drop depolarise mercury anodically, which leads to its oxidation and the formation of a mercury selenide deposit:

$$Se^{2-} + Hg \rightarrow HgSe + 2e\ .$$

The anodic mercury oxidation wave lowers the cathodic selenite reduction wave and the overall process $SeO_3^{2-} + Hg + 6H^+ + 4e \rightarrow HgSe + 3H_2O$ corresponds to a four-electron reaction. As stated by Speranskaya[124], mercury selenide is formed as the result of the involvement of elemental selenium, formed in the reduction of the selenite, in the four-electron reaction

$$SeO_3^{2-} + 6H^+ + 4e \rightarrow Se^0 + 3H_2O,\ Se^0 + Hg = HgSe\ .$$

According to Speranskaya's data[125] the reduction of the selenite ion at dropping bismuth, lead, cadmium, zinc, and sodium amalgam electrodes entails the formation of two waves. The first wave appears at potentials between −0.2 and −0.6 V and is associated with a four-electron process which proceeds with a 100% current yield. At potentials more negative than −0.6 V the selenite is reduced to selenide ions.

According to Brdička and Wiesner[126], the polarographic waves of selenium are due to the reduction of various forms of selenous acid (SeO_3^{2-}, $HSeO_3^-$, H_2SeO_3) to elemental selenium.

In the pH range 2.7–1.6 complex waves are observed for selenium, which are a result of the occurrence of several processes, including the reduction of Se^{4+} to the elemental state and the selenide and the reduction of various forms of selenous acid.

Some information about the polarographic behaviour of selenium(IV) in acid solutions may be found in papers by Jonas[127] and Christian and Knoblock[128].

The selenide ion gives rise to an anodic wave associated with the oxidation of mercury and the formation of mercury selenide[129]. This wave can be used to determine selenides in the presence of sulphides. The electrochemical behaviour of the selenosulphide ion SeS^{2-} at a dropping mercury electrode was investigated by Tornova et al.[130]

In an ammonia buffer solution at pH 8–9.5 a single distinct wave arises on the selenium(IV) polarogram. The diffusion current is directly proportional to the concentration of selenite in solution. This wave is frequently used for a quantitative polarographic determination of selenium[131–135].

The presence of ions of heavy elements in the solutions being analysed interferes with the determination of selenium; they are either separated[136–139] or masked by the addition of suitable complex-forming reagents to the electrolyte[140–142].

The use of modern polarographic apparatus greatly extends the scope and increases the sensitivity of the selenium determination. A vector polarograph with a stationary electrode in the form of a mercury drop permits the determination of 2×10^{-7} mole of selenium or even less[143]. The alternating-current polarographic method has been used to determine selenium in semiconductor materials[144,145]. An oscilloscopic polarographic method for the determination of selenium in germanium selenide has been described[146,147].

Very small amounts of selenium (down to 5×10^{-8} M) can be determined by a pulse polarographic method[137]. Elemental selenium reacts with concentrated sulphuric acid to form $SeSO_3$. In the polarography of sulphuric acid containing selenium, a distinct wave due to the reaction

$$SeSO_3 + 6H^+ + 6e \rightarrow Se + S + 3H_2O$$

is obtained. A polarographic determination of selenium in sulphuric acid has been developed on the basis of this reaction[148].

In an alkali metal sulphite solution elemental selenium forms the selenosulphate ion $SeSO_3^{2-}$ which is reduced at a dropping mercury electrode and gives rise to a distinct wave due to the reaction $SeSO_3^{2-} + 2e \rightarrow Se^{2-} + SO_3^{2-}$.[149] The polarographic method has been used to analyse mixtures of selenothionates[150]. The polarographic determination of selenium as selenosulphate has been described[151].

In acidified solutions of sodium (or potassium) tartrate or lithium citrate at pH 1–5 in the presence of 0.01% of gelatin selenium(IV) gives rise to a distinct wave whose half-wave potential $\varphi_{1/2}$ shifts from −0.55 to −60 V when the pH is raised from 1 to 5.[152,153]

In 0.1 M ammonium acetate solution at pH 6.2 selenium(IV) gives rise to two waves with half-wave potentials of −0.81 and −0.38 V. Deshmukh and Asthana[154]

explained them by the reduction of Se^{4+} to Se^{2+} and elemental selenium. The Se^{2+} state, which was indicated at an early stage by Schwaer and Suchy[122], was not confirmed by Lingane and Niedrach[123].

The polarography of organic selenium compounds is developing successfully. The polarographic behaviour of the selenocystine–selenocysteine system, of certain five- and six-membered cyclic diselenides, and of products of the oxidation of five-membered cyclic diselenides and disulphides has been investigated in detail[155]. Certain inhibition effects of five-membered cyclic diselenides and disulphides have been studied[156]. The polarographic reduction of diphenyl diselenide and diphenyl disulphide has been described by Nygard[157].

When 3,3-diaminobenzidine or *o*-phenylenediamine is added to a solution containing selenium(IV), the product is a diazaselenole which gives rise to a distinct polarographic wave[141]. In 0.1 *N* $HClO_4$ + 0.1 *N* NH_4ClO_4 solution at pH 2.5, phenyldiazaselenole gives rise to two waves with $\varphi_{1/2} = -0.17$ and -0.64 V (s.c.e.). The height of the first wave is proportional to the concentration of selenium. The method was used to determine selenium in sulphur, sulphites, and sulphates.

Tellurium

The telluride ion gives rise to an anodic wave in acid and alkaline electrolytes. In an ammonia buffer solution Te^{2-} is oxidised reversibly to elemental tellurium[129].

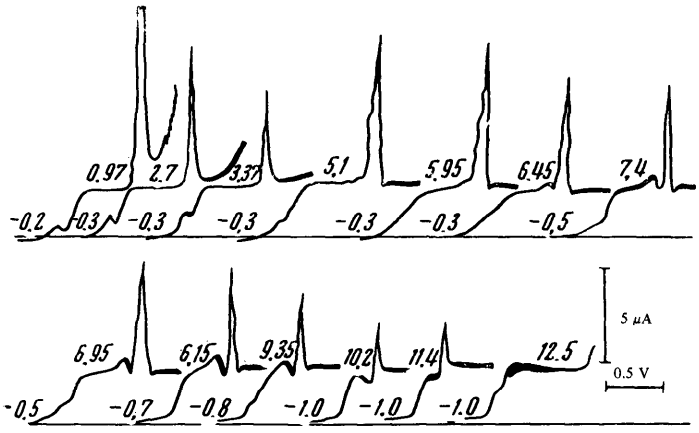

Figure 10. Polarogram for buffer solutions: CH_3COONa + $HClO_4$ + 1.46×10^{-4} M Te, pH ranging from 0.97 to 5.1, and for NaH_2PO_4 + LiOH + 1.46×10^{-4} M Te. The pH values are indicated opposite the curves (pH 5.95–12.5). The numerals at the beginning of the polarogram indicate the potentials at which the polarograms were begun[158].

Depending on the nature of the indifferent electrolyte (as in the case of selenium), there are between 1 and 3 waves on the tellurium(IV) polarogram (see Fig. 10). The mechanism of the formation of the first, main tellurium(IV) wave is similar to that of the formation of the selenium(IV) wave[123,158].

A sharp maximum, differing from the usual polarographic maxima by the fact that it occurs after the attainment of the steady diffusion current of the main wave, arises on the tellurium(IV) polarogram. Its height falls with increase of pH; at pH > 12 it does not appear at all and is readily suppressed by surface-active substances[153]. Various hypotheses have been put forward concerning the reasons for its appearance[158,159,161,162]. At the potential maximum a film of elemental tellurium is observed on the mercury drop.

It has been suggested[158] that under these conditions the anodic dissolution of mercury ceases and telluride ions [formed in the reduction of tellurium(IV)] react with tellurite ions: $2Te^{2-} + 2Te^{4+} \rightarrow 3Te$.

By titrating with hydrochloric acid 0.1 M solutions of $LiClO_4$ containing Na_2TeO_3 which had been made alkaline, it was established[158] that at pH 0.17–2.7 different tellurium species (H_2TeO_3, $HTeO_3^-$, TeO_3^{2-}) exist simultaneously in solution; the polarograms of such solutions have a complex form with several waves.

In contrast to selenium(IV), in the reduction of tellurium(IV) ions in alkaline electrolytes a distinct polarographic wave appears; it is used to determine tellurium in solutions containing selenium[160].

The nature of the reduction of tellurium(IV) and the corresponding half-wave potential depend on the concentration of H^+ ions[163,164]. In acid solutions containing tellurium(IV) catalytic evolution of hydrogen takes place. As the acidity of the electrolyte falls, the evolution of hydrogen is accompanied by partial reduction of tellurium(IV). In neutral and alkaline solutions a single wave with a maximum arises on the tellurium(IV) polarogram. The limiting current of this wave is restricted by the rate of diffusion of tellurium and is proportional to its concentration[163].

The quantitative polarographic determination of tellurium is largely based on the tellurium(IV) wave in the presence of ammonium salts as the supporting electrolyte at pH 6–9; $\varphi_{1/2}$ varies from -0.60 to -0.70 V (s.c.e.). With increase of pH, $\varphi_{1/2}$ shifts towards negative potentials, but the concentration of ammonium salts does not have an appreciable effect[136,165–170].

The polarographic determination of tellurium is interfered with by heavy metal ions (Pb, Zn, Fe, and others). Their influence is eliminated by adding Complexone III to the solution being analysed[171]. In most cases preference is given to the separation of tellurium in the elemental state by the action of reducing agents (hydrazine salts[172], $SnCl_2$,[133] hydroxylamine hydrochloride[173]).

In a tartrate–ammonia buffer solution as the supporting electrolyte, it is possible to determine down to 2×10^{-5} M of tellurium in the presence of lead, iron, and antimony[174]. The maximum arising on the tellurium wave is used for the detection and quantitative determination of microgram amounts of tellurium in selenium[161].

In the presence of large amounts of copper, KCN solutions are used as the supporting electrolyte for the determination of tellurium[175]. Tellurium in semiconductor alloys and in thin films is determined by a pulse polarographic method in the presence of 1 *N* HCl as the supporting electrolyte[176]. The polarographic determination of tellurium in the presence of antimony and gallium has been described[177]. 0.1 M NH_4CNS + Na_2SO_4 solution has been proposed as the supporting electrolyte for the determination of tellurium and selenium[178]. Distinct separate selenium and tellurium waves are obtained in this supporting electrolyte.

It should be noted that only the commonest methods for the polarographic determination of selenium and tellurium were described above. A complete description is outside the scope of this review.

Optical Methods in Corrosion-electrochemical Studies

A.G.Akimov and I.L.Rozenfel'd

The review discusses problems relating to the technique of optical measurements on the surface of a metallic electrode in an electrolyte solution. Methods for the measurement of the thickness of oxide films on the electrode surface and of the extent of adsorption at the metal-electrolyte interface are examined.
A number of examples of spectroscopic studies on metal-electrolyte and metal-oxide-electrolyte systems are quoted. The usefulness of optical methods for the investigation of the processes on the surface of a metallic electrode in solution is demonstrated on the basis of the data presented.
The bibliography includes 72 references.

I. INTRODUCTION

The extension and deepening of our knowledge of corrosion processes requires new research techniques. This was already noted in a recently published paper by Bockris et al.[1], who considered the necessity of applying a number of non-electrochemical methods to investigate the electrode surface (phase contrast, interferometric, ellipsometric, and Mössbauer spectroscopic methods).

Indeed many very important corrosion problems, for example inhibition of corrosion, and passivity, require the consideration of adsorption processes and of interactions at a molecular level and hence new methods for the investigation of the electrode surface are needed, since traditional electrochemical techniques do not yield the required information. Methods permitting measurements without disrupting the initial electrochemical system are of greatest value.

Many optical methods meet these requirements. Optical studies can be made directly in the cell for corrosion experiments. The perturbation introduced into the electrochemical system by the light beam may be minimal and, moreover, the absence of measurable photoeffects can serve as a criterion of the smallness of this perturbation. Finally, physical optics, which has been developing vigorously during the last two decades, has now provided fairly powerful theorectical and experimental techniques.

In this review we shall consider certain optical methods for the investigation of a solid electrode in an electrolyte solution, disregarding optical microscopic observations of the surface and optical methods for the analysis of the composition of the solution.

The interaction of an electromagnetic wave and matter, including solids, results in a change of the amplitude and phase of the wave. It is readily seen that this interaction can be described (on the basis of the law of conservation of energy) by means of the universal relation

$$K + R + M = 1 , \qquad (1)$$

where K, R, and M are the coefficients of absorption, relection, and scattering respectively. Thus the study of the changes in any of these coefficients can yield useful information about the properties of the test substance †.

† In the case of specular reflection, scattering may be neglected.

Since metals absorb light strongly over a wide spectral range and their transmittance (absorbance) can be studied only for very thin films (≤ 100 Å), it is clear that the optical methods for the investigation of changes in the electrode surface as a result of electrochemical reactions are mainly those employing the changes in the amplitude-phase parameters of the light reflected from the electrode.

Since in examining corrosion-electrochemical problems we are interested primarily in a number of surface parameters, the optical methods will be classified from this point of view.

II. MEASUREMENTS OF THE THICKNESS OF OXIDE FILMS FORMED ON THE ELECTRODE SURFACE

When the problem of the measurement of the thickness of oxide films on a metallic support is considered, it becomes immediately clear that many optical methods[2-6] are unsuitable for such measurements, since they require the presence of a partly uncoated support and a sharp step at the place where the film terminates.

Many metals (mainly the so called "rectifying metals") form films on anodic oxidation, which give rise to bright interference colours, arising from the partial reflection and refraction of the light incident on the oxide surface. The phase difference between the beams leading to interference is due both to the difference in the paths traversed by the beams and the phase difference arising on reflection. The phase change on reflection is different for the p- and s-components of the light beam (the electric vector of the p-beam is parallel and that of the s-beam is perpendicular to the plane of incidence) except for the case where the beam is incident on the surface at right angles. However, this difference is negligibly small for small angles of incidence: $\alpha \leq 10-15°$.

The simplest interference method for the determination of the thickness of oxide films on metals is based on a comparison of the colour of the film with that of a thin layer of air viewed in transmitted light. The thickness of the air layer must be divided by the refractive index of the material of the film. A very extensive and fairly accurate table of colours of air films was compiled by Rollet[7] and certain additions were made by Menh[8]. However, one must bear in mind that this table was compiled with a number of simplifying assumptions. Firstly, no account is taken of the

dispersion of the refractive index[9]. Secondly, it is assumed that the phase shifts at the boundaries of the layer are zero or π. However, for oxide layers on a metal, the phase shift at one boundary is characteristic of the metal and differs from both zero and π. According to the theory quoted in Methfessel's review[10], the intensity of the light reflected at right angles from a plate has minima corresponding to the thicknesses (d) and wavelengths (λ) which satisfy the relation

$$d = \left(q + \frac{\pi - \delta}{2\pi}\right)\frac{\lambda}{2n} \quad , \qquad (2)$$

where $\delta = \delta_1 - \delta_2$, δ_1 and δ_2 being the phase shifts on reflection from the front and rear surfaces of the film. For an oxide layer on a metal, we evidently have $\delta_1 = \pi$ and $\delta_2 = \delta_m$. The expression for δ_m can be derived from Fresnel's formulae:

$$\tan\delta_m = \frac{-2n_0k}{n^2 + k^2 + n_0^2} \quad , \qquad (3)$$

where k is the absorption coefficient of the metal, n_0 the refractive index of the medium traversed by the light beam, and n the refractive index of the oxide film;

$$q = \frac{\varepsilon}{2\pi} \quad , \qquad (4)$$

where ϵ is the phase difference determined solely by the difference between the optical path lengths. Estimates of the accuracy of this method quoted in Methfessel's review[10] showed that the error in determining the thickness of the layer (the thickness of a layer of silver iodide and silver was calculated) is about 200 Å towards higher values. Thus this method is applicable, if at all, to comparatively thick films giving several interference series. The unsuitability of this method for thin films was demonstrated by the present authors[11] in relation to anodic films on titanium obtained in a dilute solution of alkali. Moreover, both the present authors' investigation and others[10] show that the sequence and tints of the oxide film colours frequently disagree with Rollet's table. This shows that the formation of the film colour can depend on the structure of the film itself.

The fastest and most accurate method employing interference phenomena‡ is the spectrophotometric determination of the wavelengths giving the reflectance minima for a fixed angle of incidence of the light. Fig. 1, taken from Young's review[12], presents a curve of this kind. It shows that the wavelength at the minimum can be determined with a high degree of accuracy. It has been stated[13] that the thickness of the film and the refractive index can be determined in this way to within 1% or better. The accuracy in the determination of the refractive index n and hence of the thickness of the film is said[13] to be related to the error in the measurement of the reflectance R by the formula

$$\frac{dn}{n} = \frac{R^{1/2}}{2(1-R)}\frac{dR}{R} \quad . \qquad (5)$$

If n is known, the geometrical thickness of the film can be determined from the optical thickness corresponding to the singular point on the reflectance curve. It is then necessary to determine the interference series for the observed bands and to take into account the dispersion of the film. One should note that the dispersion of the film will have a significant influence only for thin films (single interference series). Abelès showed for a zinc sulphide film[14] that neglect of dispersion increases the error in the determination of the thickness of the film to 12%.

‡ When absorption of light by the film may be neglected.

A spectrophotometric method for the investigation of anodic films was used by Ellis[15] in a somewhat modified form. The applicability of this method and its great potentialities were confirmed by a recent study[16] whose authors investigated the kinetics of the growth of the oxide on a uranium electrode in an alkaline medium. A fairly rigorous theory of the application of interferometric methods is described by Winterbottom[17] and Heavens[13]. Heavens[13] reviews certain special interferometric methods such as polarisation interferometry and multibeam interferometry.

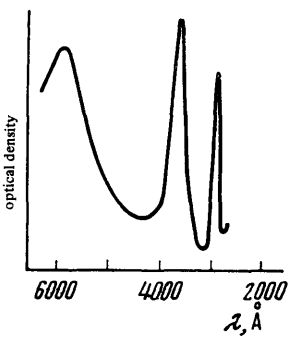

Figure 1. Spectrophotometric curve illustrating the interference minima and the reflection maxima for an oxide film on tantalum. The film is sufficiently thick to obtain several interference series[12].

Apart from studies by reflected light, transmittance measurements can be used to determine the thickness of oxide films. In this case one employs thin semitransparent layers of the metal and the change (increase) in the transmittance of this layer on oxidation is investigated. Light which is not absorbed by the oxide is employed. This method was developed long ago by Steinheil[18], who used it to investigate the oxidation of aluminium. By combining transmittance measurements with reflectance measurements on opaque metallic films *in vacuo* and in air, Hass and coworkers[19-21] established that stable films, formed spontaneously on aluminium in air, have a thickness between 30 and 40 Å and those on titanium are 35 Å thick.

Fig. 2 presents data obtained by Krüger and Yolken[22], who used ellipsometry to investigate the variation of the rate of growth of oxide films on the surface of iron with oxygen pressure. The shape of the curves shows that, even in a high vacuum, iron (and probably all metals except gold) have an oxide film on their surface. Numerous studies have shown that such thin oxide films are in fact present and constitute the main barrier to heterogeneous reactions. Perhaps the only optical method which makes it possible to measure the thickness of such thin oxide films without affecting the experimental conditions is the ellipsometric method.

The physical phenomenon which constitutes the basis of the ellipsometric method is that linearly polarised light incident on an absorbing surface becomes elliptically polarised after reflection from this surface. This method differs from those described above by the fact that measured quantities are not the change in light intensity at the angles, phase differences, and amplitude ratios of the lightwave components. The ellipsometric method is very

accurate in studies of film growth processes; according to Archer and Gobeli[23], the accuracy in the measurement of thickness reaches limits of 0.07 Å.

The method was first used to investigate the kinetics of the growth of oxides by Tronstad[24] and in the USSR elipsometry was used for similar purposes for the first time by Krylova[25], who measured the thickness of films on different metals. The ellipsometer was first applied to corrosion systems in the USSR by Andreeva[26, 27].

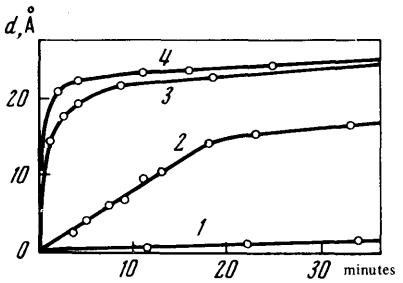

Figure 2. Variation of the thickness of the oxide film with time for iron in an atmosphere of oxygen[22] at different oxygen pressures (mmHg): *1*) 3.5×10^{-6}; *2*) 2.5×10^{-5}; *3*) 2×10^{-4}; *4*) 760.

The ellipsometric method makes it possible to measure also the refractive index of the oxide n. These measurements are simple if the film does not absorb light[28]. However, if the film does absorb light, the measurements of n must be made with a specimen immersed in liquids with different refractive indices[28]. For a fairly thick absorbing film (opaque film), the optical constants can also be determined using a single specimen.

Fig. 3 illustrates graphically the ellipsometric parameters, including the main parameters ψ and Δ.

Suppose that the incidence plane, perpendicular to the plane of the figure, forms a horizontal axis. The light incident on the specimen is initially polarised at an angle of 45° to this plane. The electric vector of the incident wave is 01 and that of the reflected wave is *OR* (Fig. 3). This picture corresponds to a dielectric specimen on which there are no surface films and the reflected light is linearly polarised. The ratio of the components of the *OR* vector corresponding to the polarisation in the incidence plane (r_p) and in the plane at right angles to it (r_s) defines the tangent of the ellipsometric parameter ψ:

$$\tan\psi = r_p/r_s \quad . \tag{6}$$

However, if there is a film on the surface of the support or the support is made of an absorbing material, the magnitude and directions of the r_p and r_s vectors will vary with time and the reflected light becomes elliptically polarised. The direction of rotation of the electric vector is indicated by arrows on the ellipses illustrated in Figs. 3*a* and 3*b*. The phase difference Δ for the r_p and r_s vectors constitutes the second ellipsometric parameter:

$$\Delta = \delta_p - \delta_s \quad , \tag{7}$$

where δ_p and δ_s are the phases of the r_p and r_s vectors respectively. Fig. 3 shows also two other ellipsometric parameters, λ and γ.

The exact theory relating the phase differences Δ to the thickness of the film is very complex; however, provided that the refractive indices of the film and the support are known, the ellipsometric measurements of the film thickness are greatly simplified. In this case it is possible to employ a linear approximation to the exact expressions relating Δ and the film thickness.

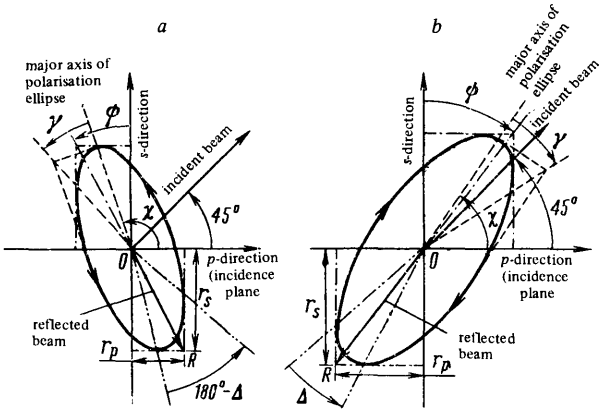

Figure 3. Graphical representation of different ellipsometric parameters: *a*) reflection at an angle of incidence smaller than the principal angle; *b*) reflection at an angle of incidence greater than the principal angle[29].

Starting with Tronstad[24], most investigators over a fairly long period employed Drude's linear approximation, which can be formulated as follows when the surrounding medium has a refractive index $n_2 > 1$:

$$\Delta - \bar{\Delta} = \frac{4\pi}{\lambda} \cdot \frac{\cos\theta \cdot \sin^2\theta\,(n_1^2 - n_2^2)}{(\cos^2\theta - n_2^2\alpha)^2 + n_2^4(\alpha')^2} \cdot [(\cos^2\theta - n_2^2\alpha) \cdot (n_1^{-2} - \alpha) + n_2^2(\alpha')^2] \cdot d \quad , \tag{8}$$

where Θ is the angle of incidence of the beam, n_1 the refractive index of the film, d the thickness of the film,

$$\alpha = \frac{1 - k^2}{\nu^2(1 + k^2)}, \quad \alpha' = \frac{2k}{\nu^2(1 + k^2)^2} \quad , \tag{9}$$

k the absorption coefficient of the metal, ν the refractive index of the metal, and λ the wavelength of the incident beam.

However, comparison of Drude's approximation with the exact theory shows that the error in the determination of the thickness using this approximation is very large and increases markedly with the thickness of the film. Comparison of curves *1* and *3* in Fig. 4, taken from Bennet and Bennet's review[29], shows this clearly. The figure also demonstrates that another linear approximation, proposed

by Archer, is much closer to the exact theory than Drude's approximation. Archer's approximation can be formulated as follows[30]:

$$\Delta - \bar{\Delta} = \frac{1}{[\cos^2\theta - a + \sin^2\theta\,(a^2 - a'^2)]^2 - (a')^2} \cdot \cdot [720\,(d/\lambda) \cdot \cos\theta \cdot \sin^2\theta\,(1 - n_1^2) \cdot \{(a - 1/n_1^2) \cdot \cdot [\cos^2\theta - a + \sin^2\theta\,(a^2 - a'^2)] - (a')^2\}] \quad , \tag{10}$$

where $\bar{\Delta}$ is the phase difference for a surface not coated by a film and $n = n' - jk$ is the complex refractive index of the support:

$$a = (n^2 - k^2)\,(n^2 + k^2)^2 \quad , \quad a' = 2nk/(n^2 + k^2)^2 \quad . \tag{11}$$

On the other hand, if the oxide film absorbs light, the use of approximate expressions for a non-absorbing film [Eqns. (8) and (10)] leads to serious errors in the simultaneous calculation of n_1 and d. This is indicated, in particular, by the experimental data of Chernykh and Yakovleva[31].

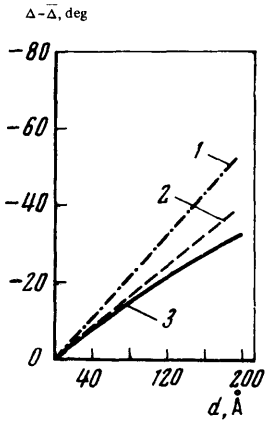

Figure 4. Comparison of Drude's (curve *1*) and Archer's (curve *2*) approximations with the exact theoretical relation (curve *3*). Data for alumina on the surface of aluminium[29].

However, there exist at least two methods, which make it possible to obviate these difficulties. The first involves the determination of the refractive index of the support and the film and of the refractive index of the film alone by independent methods, the ellipsometric method being used only to determine the film thickness in terms of Eqn. (10). Then, even if the film absorbs light, it is possible to obtain fairly accurate film thicknesses[32]. The second method, employed by Chernykh and Yakovleva[31,33] and other investigators, does not require the experimental determinations of the refractive indices and of absorption by the film and support, but in this case difficulties of another kind arise. The method is based on the exact theory of the polarisation of light on reflection and hence requires fairly complicated calculations§. The results permit the plotting of nomograms taking into account the changes in n_1 and k. Analysis of the nomograms[31,33] shows that both ellipsometric parameters, Δ and ψ, depend very significantly on the changes in n_1, k and δ.

Experimental devices permitting the determination of the principal ellipsometric parameters ψ and Δ have been described in many original papers and reviews. One should note that the fundamental scheme of the measurements has changed little since the publication of the first studies by Tronstad. The following units are probably typical for any ellipsometric apparatus: emission collimator (source, slit, collimating lens), polariser, specimen with holder, compensator (quarter-wave plate), analyser, focussing lens, and detector.

Figs. 5 and 6 illustrate schematically two possible ellipsometric systems[29]. The recording can be both visual and photoelectric. Additional components, resembling half-shadow devices which increase the accuracy of visual readings[34,35] or Faraday cells which can be used for accurate photoelectric measurements of angular orientations (the accuracy with which the angles can be read is to within 1 second), can be built into ellipsometric systems similar to those shown in Figs. 5 and 6.[36] Moreover, gas lasers[37], mainly helium–neon lasers, have begun to be used recently as light sources in ellipsometers in order to increase the accuracy of the measurements.

A fairly advanced ellipsometer, a distinctive feature of which is its construction based on a commercial GS-5 goniometer produced in the USSR, was recently built at the Karpov Physicochemical Institute[38]. Four removable units, permitting its employment as an ellipsometer, were specially constructed for this instrument. The instrument has a photoelectric recording system.

Without considering in detail the extensive literature dealing with data obtained by measurements, we would like to quote here as an illustration several studies on the ellipsometry of thin films, which we believe to have a direct bearing on the corrosion-electrochemical behaviour of metals.

Bockris et al.[33] described experimental data obtained in an ellipsometric study of the surface of nickel in sulphuric acid solution. The nickel potential was maintained with the aid of a potentiostat. The observed dependence of the thickness of the oxide film on the electrode potential was of particular interest. However, the interpretation of the results aroused quite justified criticism[39]. The results of ellipsometric studies of the growth of oxide on nickel (in an alkaline medium) were published by Chernykh and Yakovleva[31,40]. They traced the relation between the change in the structure of the oxides and the change in the optical parameters; although some of the conclusions arrived at are controversial, on the whole these studies[31,40] are of great interest.

Goswami and Stachle[41] investigated the kinetics of the growth of passive films on iron and iron–chromium, iron–nickel, and iron–chromium–nickel alloys. The oxide films were formed on anodic polarisation of the electrodes in a borate buffer solution (pH 8.4). Their[41] results show that the dependence of the change in the thickness of the oxide on the potential is greater than would be expected for the inverse logarithmic law. The optical constants of the alloys not coated by oxidates are very close. The growth of films on the electrode surface leads to significant changes of the optical constants. For the same potentials, the film thicknesses on the iron and alloy electrodes are approximately the same. Thus one may suppose that in this case, the rate of the reactions at the electrode–electrolyte interface is determined by the electrophysical parameters of the oxide film and not its thickness.

§ These are simplified when electronic computer techniques are resorted to.

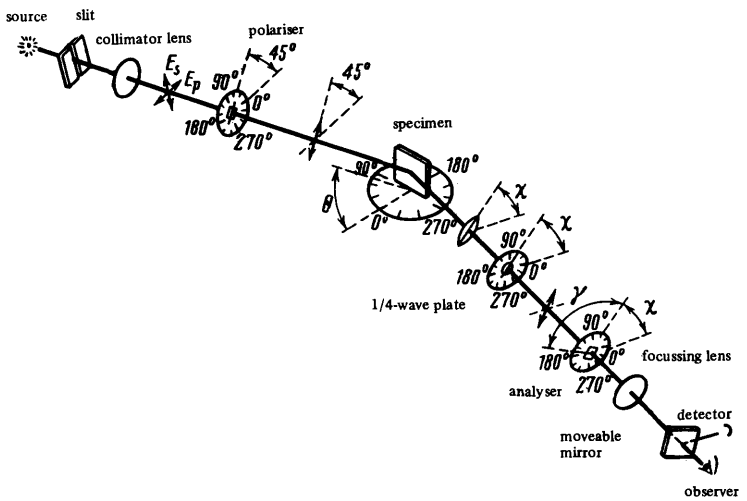

Figure 5. Ellipsometric system for the measurement of Δ and ψ for a 45° orientation of the polariser.

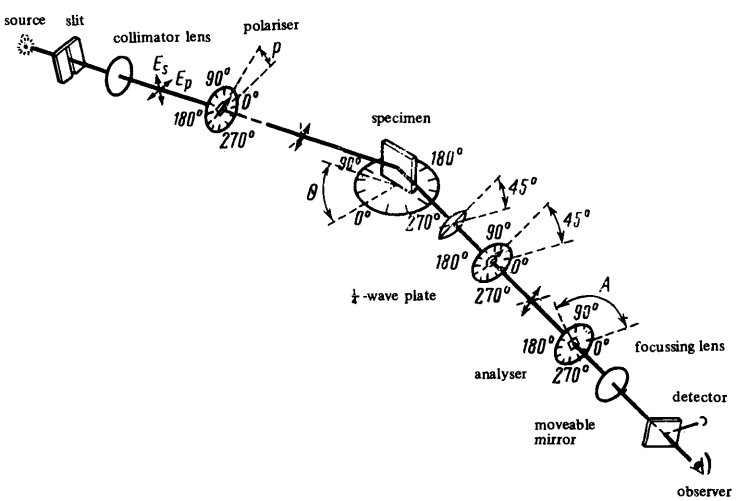

Figure 6. Ellipsometric system with a quarter-wave plate orientated at an angle of 45° for the measurement of Δ and ψ.

A recently published paper by Bockris et al.[42] describes a very extensive study dealing with the mechanism of the passivation of iron in neutral solutions. It was carried out by ellipsometric and coulometric measurements. The part of the investigation describing the methods[42] is of particular interest, since the authors described in detail the technique of the ellipsometric studies. The measured[42] refractive and absorption coefficients of iron oxides agree satisfactorily with other data. The results of the experiments of Bockris et al.[42] led them to the conclusion that at potentials more negative than the passivation potential iron is coated by a film of the hydroxide $Fe(OH)_2$. Very close to the passivation potential, the oxide γ-Fe_2O_3 begins to grow and its molar content in the film increases as the electrode potential shifts towards positive values. A potential shift by 0.5 V leads to complete recrystallisation of the film as γ-Fe_2O_3. According to the authors, the passivation of iron is in fact related to the appearance of the γ-Fe_2O_3 film on the iron surface. A number of studies in which an absorption mechanism of the passivation of iron in neutral solutions was proposed have been criticised.

Two recent studies by Sato and Kudo[43,44] deal with the same problem, namely the passivity of iron in neutral solutions. The first report[43] describes ellipsometric studies on iron in borate solution. It was observed that the oxide film can be completely removed from the electrode surface by cathodic reduction. It is stated that the minimum thickness of the surface oxide on iron is 9 Å. The oxide film exists on the electrode surface also in the region of active dissolution. At potentials between -0.3 and +0.9 V (s.c.e.)

the film thickness increases linearly with potential until the attainment of a thickness of 50 Å. The evolution of oxygen at higher anodic potentials does not disrupt the film. The problem of the distribution of potential in the iron–oxide film–electrolyte system is discussed on the basis of the experimental data obtained. According to Sato and Kudo[43,44], in the passive region the main potential jump is localised in the oxide film. The oxide film, consisting of Fe_3O_4 or γ-Fe_2O_3, was represented[43,44] as a two layer-structure with an outer hydrated layer and an inner non-hydrated layer.

In conclusion of the section dealing with ellipsometric studies on the kinetics of the growth of oxide films on metallic electrodes in electrolytes, noting yet again the extreme importance of these investigations, we should like to make certain critical remarks concerning the interpretation of the results of ellipsometric measurements. For example, Bockris and coworkers[33,42] believe it possible to infer the electronic conductivity of the oxide film from changes in the measured absorption coefficient. This approach is probably not entirely correct. Indeed, it is readily seen that a change in absorption index at a specific wavelength can only indicate a change in the number of electronic transitions from the corresponding level located in the forbidden gap of the oxides¶ and hence a change in the population of this level. In order to relate the change in the population of the level to the change in conductivity, it is necessary to show that the level is at least partially ionised at room temperature and hence can participate in the change of the equilibrium conductivity of the oxide film.

Moreover, it follows from the most general considerations that the electric fields localised in the double layer or in the oxide film can affect the ellipsometric parameters. Nevertheless, these effects are not taken into account in the studies quoted above, although the distribution of potential throughout the system has been discussed[43,44]. However, studies have been published during the last few years in which the effect of electric fields on ellipsometric parameters was in fact used to investigate the structure of the double layer and adsorption on the surface of the electrode. The next section of the review deals with these investigations.

III. ELLIPSOMETRIC STUDIES ON ADSORPTION AT THE METAL–ELECTROLYTE INTERFACE

The first study dealing with certain aspects of the effect of the double layer on the optical properties of the metal–electrolyte interface in relation to ellipsometric measurements was made by Stedman[45]. He chose a simple model of the double layer, whose parameters could be described in accordance with Delahay's theory[46]. Stedman[45] examined the effect of the structure of the double layer on the optical constants of the metal both in the absence and in the presence of specific adsorption. Stedman[45] quotes data obtained for aqueous potassium chloride–mercury and aqueous sodium fluoride–mercury systems. The wavelength of the light in the ellipsometric measurements was 546 nm and its angle of incidence was 70°. The surface charge of the metallic electrode was calculated from the experimental capacitance and potential of the electrode.

¶ One should bear in mind that the width of the forbidden gap in the majority of oxides exceeds 3 eV, while the energy of the light quantum emitted by the light sources usually employed in ellipsometers is less than 3 eV.

Fig. 7, taken from Stedman's paper[45], presents the variation of the ellipsometric parameters Δ and ψ with the electrode charge q_M at different sodium fluoride concentrations in solution. The shape of the curves shows that Δ and ψ depend very markedly on the surface charge, the dependence increasing on dilution of the solution. Thus it was shown that Δ and ψ can vary not only when a new phase grows on the surface of the electrode but also when the surface becomes charged. Moreover, the author points out that the $\Delta - q_M$ and $\psi - q_M$ (Fig. 7) relations have an inflection corresponding to the absence of a surface charge. Possibly this interesting experimental finding will permit the development of a new method for the determination of the zero-charge potential. Stedman[47] considered these problems in greater detail: in particular, he considered separately the effect of the dense and diffuse components of the double layer.

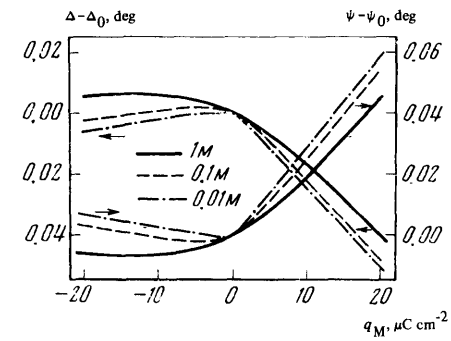

Figure 7. Variation of Δ and ψ with the surface charge of mercury in aqueous sodium fluoride; Δ_0 = 112.893, 113.125, and 113.145 and ψ_0 = 36.821, 36.831, and 36.832 for sodium fluoride concentrations of 1, 0.1, and 0.01 M respectively[45].

The Polish investigators Minc and Herbich[48] studied the influence of the double layer on the optical parameters of the metal–electrolyte interface[48]. They investigated ellipsometrically gold in 0.3 M sodium sulphate solution. To increase the sensitivity of this system, the reflecting element was made in the form of two plane-parallel gold plates between which light was repeatedly reflected. A distinct correlation was discovered between the rate of the electrochemical reactions and the "effective" reflection coefficient. The minima in the reflected light beam correspond to the minimum rates of the electrochemical reactions. Thus this study also confirms the possibility of employing ellipsometry for the investigation of the structure of the double layer.

The above problem was considered in two publications by Bockris and coworkers[49,50]. The first study[49] dealt with the ellipsometric investigation of the adsorption of anions at the solid–electrolyte interface. Silver, gold, rhodium, and nickel test electrodes were employed. The adsorption of Cl^-, Br^-, ClO_4^-, SO_4^{2-}, and OH^- ions was studied. The experimental apparatus consisted of a classical ellipsometer, but a differential recording system was employed. (A phototransistor, whose signal served as the reference signal, was introduced beyond the polariser, which made it possible to increase the sensitivity in the

measurement of the parameter Δ to within 0.002°.) The electrode potential was set by a potentiostat and was varied in 100 mV steps.

In the same study an attempt was made to relate the ellipsometric parameter Δ to the surface charge of the electrode. The authors endeavoured to allow for the electromodulation effect†, according to the interpretation of Hansen and Prostak[51]. Analysis of the equations quoted by Paik Woon-Kie et al.[49] convinced them that the changes in Δ are significantly related to the surface charge of the metallic electrode and depend very little on the charge distribution in the surface layer of the metal. The authors point out that, when the electromodulation effect is disregarded, a significant error may be made in the conversion of Δ into the amount of adsorbed substance. The main equation employed by the authors[49] is

$$\delta\alpha = \delta\Delta_{ads} \cdot (q -) + b\delta q_M \quad , \qquad (12)$$

where Δ_{ads} is the change in the parameter Δ on adsorption, q the amount of adsorbed anions in units of charge, b the electromodulation coefficient tabulated for different metals[49], and q_M the charge of the surface layer of the metal.

Fig. 8 (taken from Ref. 49) presents adsorption isotherms obtained on a gold electrode by the method described above. Similar isotherms were obtained on silver, nickel, and rhodium electrodes. The possibility of deriving such information demonstrates of course the extremely great value of the method.

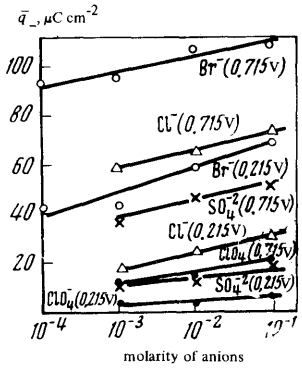

Figure 8. Adsorption isotherms of anions on a gold electrode obtained by ellipsometric measurements[49].

However, the authors themselves point out that the isotherms cannot be obtained in all cases. Thus the Δ–potential relations for the electrodes in hydroxide solutions is anomalous. The authors[49] explain this by the fact that the adsorption of even a monolayer of OH^- ions can (or should) be regarded as a new hydroxide or oxide phase. The fact that the authors[49] based their consideration of electromodulation effects on the model described by the theory of Hansen and Prostak[51] should also be noted. The reliability of the conclusions drawn from this theory is doubtful even as regards the very formulation of the problem of the mechanism of electroreflectance of metals. Moreover certain experimental data[52] disprove the fundamental conclusions of the theory[51]. We shall consider this problem in greater detail in the next section.

Paik Woon-Kie and Bockris[50] describe the results of a detailed experimental study of the joint influence of adsorption and electromodulation of the optical constants on the measured ellipsometric parameters. Although this investigation suffers from the same defects as the previous one, the experimental data and also the conclusions reached by the authors are extremely interesting.

They investigated[50] the variation of the ellipsometric parameter Δ for a gold electrode in 0.01 M NaBr in 0.001 N $HClO_4$‡ solution as a function of the wavelength. The light was made monochromatic using interference filters. The potential change from 0.11 to 0.61 V (s.c.e.). On the basis of the models described above, the authors attempted to calculate the contributions of the two effects — electromodulation and adsorption — and, having summed the two curves, to compare the resulting calculated curve with the experimental curve. A satisfactory agreement was obtained in the wavelength range from 4500 to 5500 Å; at higher wavelengths there was no agreement. The authors state[50] that characteristic contributions by the two effects probably occur for each metal.

One should note that so far experimental data have been obtained which definitely indicate that the change in the order on the electrode surface affects the fundamental ellipsometric parameters and ellipsometry can probably be used as an extremely sensitive method for the investigation of processes leading to such changes. However, so far there is no well-founded and clear theory which would allow a fairly clear-cut interpretation of the observed phenomena. This does not mean of course that studies in this field cannot be regarded as of very great value.

IV. SPECTROSCOPIC STUDIES IN THE ELECTRODE–ELECTROLYTE INTERFACE

The lack of spectroscopic studies on the electrode surface in electrochemical systems (until very recently) can probably be explained both by a number of technical difficulties and by the fact that the urgent need for such investigations arose quite late. Although the number of publications of spectroscopic data on electrodes is small, it is possible to discern a tendency for such investigations to employ the very latest advances in spectroscopy: multiple reflection and modulation methods.

The most promising spectroscopic methods, including those applicable to electrochemical systems, are related to the modulation of the intensity by some kind of external effect (for example an electric field). We then obtain a spectral distribution of the intensity of light reflected from the electrode surface differentiated with respect of this effect, i.e. instead of the I–λ relation, where I is the intensity and λ the wavelength of the light, we obtain the dI/dv–λ relation, where v is the external effect (for example a potential field or an electric field).

It is readily seen that the spectral distribution curves in a differential form have many advantages over the usual curves, primarily as a result of the sharp improvement of resolution. This aspect of the problem in relation to semiconductors and metals has been specially considered in two reviews[53,54]. The first study, dealing with the reflection spectra of metals modulated by an electric field applied in the electrolyte, was that of Feinleib[55], who obtained the electroreflectance spectra of gold and silver.

† The change in the optical constants of the metal when the electrode potential is altered.

‡ The Br^- ions were absorbed.

As regard method, the measurements of electroreflectance do not present fundamental difficulties but the measuring apparatus must be highly selective, since the signal/noise ratio at the input to the amplifier is usually small. A circuit for the measurements of electroreflectance and electroabsorption is presented in Fig. 9.

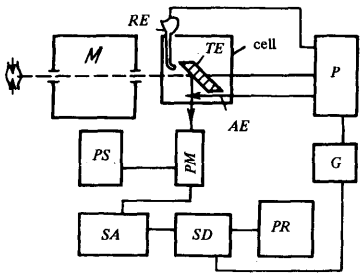

Figure 9. Circuit for the measurement of electroreflectance and electroabsorption in an electrode–electrolyte system.

Polychromatic light from the source passes through a monochromator (*M*) and falls on the surface of the electrode in the cell with the electrolyte §. The light reflected from the electrode falls on a radiation detector — a photomultiplier (PM). In addition to the test electrode (*TE*), the cell contains an auxiliary electrode (*AE*) and the reference electrode (*RE*) and is connected to a potentiostat (*P*). Moreover, a sinusoidal or pulsed alternating current from a generator (*G*) passes through the cell. This variable signal, which modulates the surface field of the electrode, also modulates the light reflected from the surface. Thus at the output from the photomultiplier there are two components of the potential: a constant component proportional to the overall flux reflected from the electrode (*R*) and a variable component proportional to the light flux modulated by the electric field (ΔR). As a rule the variable component is small — the degree of modulation is usually less than 1%. The variable signal at a fixed frequency is therefore amplified by a selective amplifier (*SA*) with a high amplification factor in a fairly narrow amplification band. After amplification the signal is detected synchronously (*SD*) and is recorded with a pen recorder (*PR*). A similar apparatus was described in detail by Akimov[56]. Different authors naturally describe somewhat modified experimental setups, but these modifications do not involve the fundamental and essential units enumerated above.

It is readily seen that the ratio $\Delta R/R$ is independent of the light source intensity spectrum and the light detector sensitivity spectrum but does depend on the changes in the optical and electrophysical (via the change in the local electric fields) properties of the electrode–electrolyte interface.

It was stated above that the electroreflectance effect on metals in an electrolyte was observed for the first time by Feinleib[55] and the mechanism of electroreflectance in this system was formulated by Hansen and Prostak[51], who suggested that the optical constants of the metal are modulated by the electric field owing to the modulation of the surface concentration of electrons (i.e. a change in the Fermi level on the surface of the metal). However, Lazorenko – Manevich and Stoyanovskaya[52], who compared their own data with the conclusions of Hansen and Prostak's theory[51], concluded on the basis of a comparison of the variation of electrode capacitance and electroreflectance with the potential of the gold electrode and the theory[51] cannot account for the mechanism of electroreflectance of metals. They[52] believe that not only the modulation of the surface concentration of electrons but also of their mobility may be the cause of electroreflectance. Incidentally, the value of their work[52] is by no means related to the critism of Hansen and Prostak's theory but is determined by their own experimental results. They obtained the variation of the electroreflectance from a metallic electrode with potential. They investigated gold, platinum, and silver electrodes and showed that the variation of the electrode potential may alter not only the intensity of the spectrum ($\Delta R/R$) but also its shape. In particular, a change in shape was observed in the oxidation of gold at a potential of about 1.5 V. Moreover, it was shown[52] that the shape of the electroreflectance spectrum of gold and silver changes significantly as a result of the specific adsorption of iodide ions from solution. They explained this phenomenon by the formation of chemical bonds between the iodide ion and the metal. The bond energy depends on the nature of the metal.

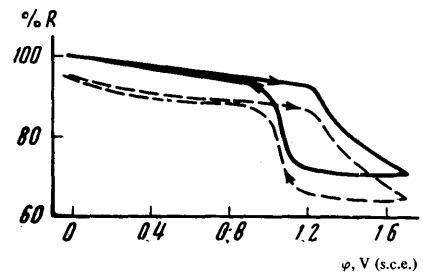

Figure 10. Measurement of the reflectance of gold in 1 *N* $HClO_4$ as a function of electrode potential. Continuous curve — in the absence of benzene; dashed curve — in the presence of benzene. Data for seven reflections are presented[57].

American investigators[57] studied the variation of the reflectance of gold under the conditions of a varying electrode potential. The main electrolyte employed was a solution of $HClO_4$. Single and multiple (sevenfold) reflection was used. The effect of adding benzene to $HClO_4$ on the variation of the reflectance with potential was examined. Fig. 10 shows the variation of the reflectance of the gold electrode with its potential in the presence and absence of benzene. The results[57] are fully consistent with those of Lazorenko – Manevich and Stoyanovskaya[52] in the sense that the variation of the potential changes not only the intensity but also the shape of the spectrum. Moreover, the

§ The requirements which must be met by the optical windows are of the usual kind for measurements of this type.

American workers[57] carried out an extremely useful analysis of the correlation between single and multiple reflection spectra. This relation may be described by the following equation:

$$(1/R)(\partial R/\partial E)_\lambda = (1/nI_n)(\partial I_n/\partial E)_\lambda \quad , \qquad (13)$$

where R is the reflectance of the electrode, $(\partial R/\partial E)\lambda$ a term related to the modulation of R by the applied field at a constant light wavelength λ, and I_n the light intensity after n reflections. It is understood that the shape and value of the (n/R) $(\partial R/\partial E)$–λ curves are independent of the number of reflections.

Mention should be made of the work of Barret and Parsons[58], who investigated the reflection spectra of a platinum electrode and the effect of the adsorption of ions of different substances (O_2, H_2, halogens, methanol, formaldehyde) on the optical constants of the electrode surface.

The data of McIntyre and Kolb[59], who investigated with the aid of reflection spectroscopy thin surface films formed on a metallic electrode, merits a more detailed consideration. They measured the $\Delta R/R$–φ (potential) and $\Delta R/R$–λ relations for platinum, gold and nickel under the conditions of anodic polarisation and the same relations for the adsorption of hydrogen and silver on platinum. Moreover, the results were used with the Kramers – Kronig dispersion relations to calculate the variation of the real and imaginary components of the dielectric constant with the energy of the light quantum. $\Delta R/R$ was calculated[59] as

$$\Delta R/R = [R(d) - R(0)]/R(0) = R(d)/R(0) - 1 \quad , \qquad (14)$$

where $R(d)$ is the reflectance of the metal–surface film–electrolyte three-phase system and $R(0)$ the reflectance of the metal–electrolyte interface. Measurements were made of the $\Delta R/R$–λ relations with light polarised parallel and at right angles to the plane of the electrode. These data permitted the calculation with the aid of equations quoted by McIntyre and Aspens[60] of both components of the dielectric constant of the surface phases. McIntyre and Kolb[59] employed a more complicated experimental apparatus than that used hitherto for analogous measurements. The more sophisticated apparatus permitted the measurement of the $\Delta R/R$ spectra up to 6.5 eV with a sensitivity of about 10^{-5} $\Delta R/R$ for a time constant of 1 s.

Having measured the $\Delta R/R$–φ and $\Delta R/R$–λ relations on platinum in 1 M $HClO_4$, McIntyre and Kolb[59] concluded that the oxide film on platinum consists of PtO (on the basis of the calculation of the absorption coefficient). Moreover, they found that the variation of the absorption coefficient of this layer, $\alpha = 4\pi k/\lambda = 2\pi\epsilon''/n_2\lambda$, has two maxima, the quantum energies of which are 3.4 ± 0.1 and 4.6 eV. At the maxima $\alpha = 5 \times 10^5$ cm^{-1}.

In spectroscopic studies of a gold electrode subjected to anodic polarisation in 1 M $HClO_4$ the authors observed that the oxide formed on gold at a potential of 1.6 V (n.h.e.) is Au_2O_3.

McIntyre and Kolb[59] quote data obtained in an optical study of the anodic oxidation of nickel in 0.1 M KOH. They made a detailed spectroscopic investigation of the surface oxide formed on the nickel electrode at a potential φ = 1.4 V (hydrogen electrode) and observed that the composition of the oxide is NiOOH. Fig. 11 presents curves relating the real (ϵ') and imaginary (ϵ'') components of the dielectric constant of the NiOOH film to the energy of the quantum calculated from the $\Delta R/R$ spectrum obtained for an electrode potential of 1.5 V (n.h.e.) in 0.1 M KOH. The ϵ' maxima corresponding to energies of 3.0 and 4.1 eV agree satisfactorily with data obtained by McClure[61] and Tippins[62] for the absorption of Ni^{3+} ions in corundum. A negative value of ϵ' is characteristic of the metallic conduction of this oxide phase.

The study of McIntyre and Kolb[59] lies at the boundary between spectroscopic investigations of the metal–electrolyte interface and investigations of metal–oxide–electrolyte systems. Below we shall consider studies dealing with systems of the latter type.

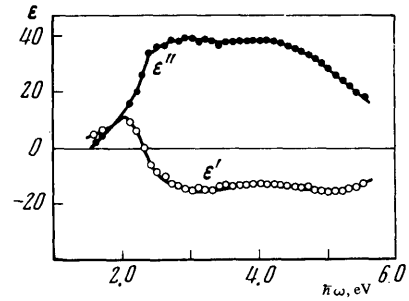

Figure 11. Spectra of real (ϵ') and imaginary (ϵ'') components of the dielectric constant of NiOOH; measurements made at a nickel potential of 1.5 V (s.c.e.)[59].

The paper of Holden and Ullman[63], describing the measurements of electroreflectance of oxidised tantalum and niobium, was published in 1969. An attempt was made to explain the mechanism of the generation of the electroreflectance signal by an interference effect arising in consequence of electrostriction in the oxide film. However, this view was criticised by Frova and Migliorato[64], who showed that the modulation of the interference bands by the electric field in the visible part of the spectrum, observed on tantalum oxide, must be accounted for by the modulation of the refractive index of the oxide. This conclusion was based on the very satisfactory agreement between the calculated and experimental data.

The present authors showed[65] that the spectrum of the light beam reflected from the surface of oxidised titanium and modulated by the field (we treat this effect as electroabsorption) can be interpreted only when the electroabsorption effect $-\Delta I/I$ can be attributed to modulation by the electric field of the optical constants of the surface oxide.

There are at present no theories of electroabsorption and electroreflectance in metal–oxide–electrolyte systems, but for a qualitative treatment one can probably assume that in a number of oxides arising on "rectifying metals" (titanium, tantalum, niobium, zirconium, tungsten, etc.) the mechanism of electroabsorption reduces to the "anomalous" Franz-Keldysh effect[66].

There are two possible research techniques based on electroabsorption in a metal–oxide–electrolyte system. In the first studies on the effect of the electric field on the position of the edge of the intrinsic absorption of crystals[67,68], it was shown that the position of the edge depends significantly on the magnitude of the applied field. This effect is entirely valid also for thin oxide layers formed on the surface of a metal, as shown in our investigation[65]. Thus it was natural to attempt the determination of the change in the electric field strength (potential jump in the oxide) as a function of the electrode potential by measuring the

change in the electroabsorption corresponding to the maximum on the electroabsorption–wavelength curve. The results of experiments of this kind have been published[65,69]. Fig. 12 presents $i-\varphi$, $C^{-1}-\varphi$, and $\Delta I/I-\varphi$ curves which we obtained[69] for a titanium electrode in 5 *N* KOH ¶. The data in Fig. 12 show that $\Delta I/I$ begins to increase on transition from active dissolution to passivation. The main growth of $\Delta I/I$ takes place in the region of passivation potentials. Since according to our data[65] the increase of $\Delta I/I$ is associated with the increase of the field in the oxide film, presumably the redistribution of the components of the overall jump in electrode potential takes place precisely in the region of passivation potentials. The potential jump in the oxide film increases not only as a result of the increase of the anodic potential but also as a result of the change in the location of the Helmholts potential jump, which leads ultimately to the inhibition of the dissolution of the metal. In the passive region the field strength in the oxide remains constant — $\Delta I/I$ is independent of the electrode potential. In the same range of potentials the surface oxide grows (the $C^{-1}-\varphi$ relation is linear). Hence it follows that the growth of the oxide is fully compensated by the increased potential jump in the oxide film due to the anodic potential shift.

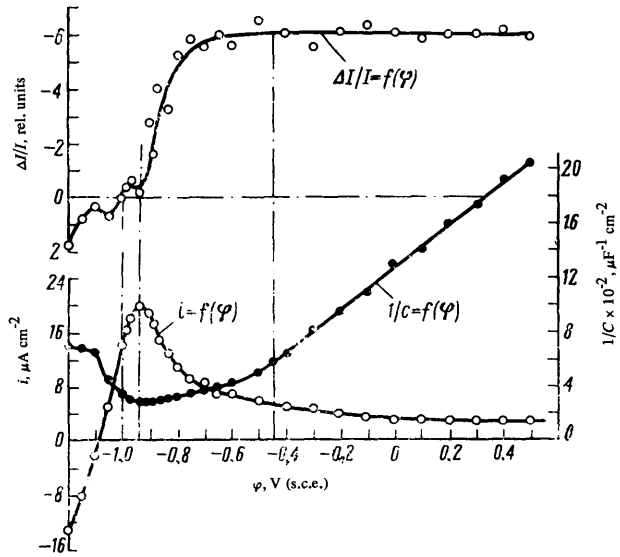

Figure 12. Variation of the current density i, the reciprocal of the capacitance C^{-1}, and the electroabsorption with the potential of a titanium electrode in 5 *N* KOH.

$\Delta I/I$ in a metal–oxide–electrolyte system also has a spectroscopic application. As already stated above, the electroabsorption spectrum has a maximum whose energy corresponds to the edge of the intrinsic absorption — the forbidden gap (ΔE_g) of the crystal. When the electroabsorption in a metal–oxide–electrolyte system is measured, the energy of the electroabsorption maximum on the electroabsorption–λ curve corresponds to ΔE_g for the oxide. Since ΔE_g is related to the main parameters of the oxide lattice, it follows that, having determined ΔE_g, it is often possible to identify the material of the oxide. Thus the maximum in the electroabsorption spectrum of the anodic oxide film on titanium[65] † agreed with ΔE_g for rutile single crystals measured by the same method[66].

The method of measurement of the electroabsorption spectra can probably be particularly useful in the study of structural transformations in surface oxides. Fig. 13 presents electroabsorption spectra which we obtained for a titanium electrode in 2 *N* H_2SO_4. The figure shows that the structure of the spectra changes significantly with the potential. Curves *1–3* (the passivation region) correspond fully to the rutile structure; however, on passing to potentials more positive than the total passivation potential, the absolute value of $\Delta I/I$ (curve with a maximum corresponding to an energy of 3.7 eV) begins to decrease (curves *4–6*) and a new short-wavelength $\Delta I/I$ maximum arises, its magnitude and energy depending on the electrode potential. Curves *7* and *8* corresponding to potentials of 0.2 and 0.5 V (s.c.e.), show that the energy of the new short-wavelength maximum is stabilised and assumes a value of 4.2 eV. We believe that the reason for the observed deformation of the electroabsorption spectra is that at more positive potentials the rutile structure may be replaced by the anatase structure, i.e. at potentials more positive than the passivation potential the rutile–anatase phase transition takes place in the oxide film on the titanium surface. It has been stated[70] that in many cases the anatase structure more readily gives nucleation.

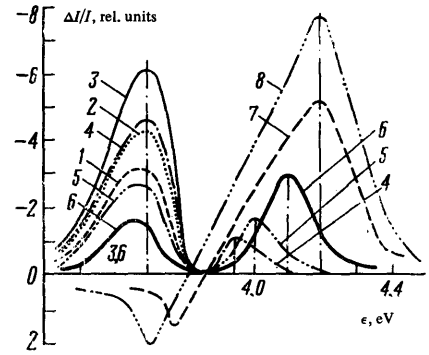

Figure 13. Electroabsorption spectrum obtained for the anodic polarisation of titanium in 2 *N* H_2SO_4 at different electrode potentials [V(s.c.e.)]: *1*) 0.45; *2*) 0.40; *3*) 0.35; *4*) 0.30; *5*) 0.25; *6*) 0.1; *7*) 0.2; *8*) 0.5.

The high sensitivity of the electroabsorption spectra to structural changes in the oxide may be demonstrated by the following example. Fig. 14 illustrates the electroabsorption spectra which we obtained from titanium–niobium alloys with different niobium contents. The measurements were made in 5 *N* KOH at a potential of 0.5 V. It is seen from the figure that the positions of the maxima in the electroabsorption spectrum depend significantly on

¶ Titanium is activated in this electrolyte and its surface oxide has the rutile structure over a wide range of potentials.

† We showed[11] that the oxide films obtained in the anodic polarisation of titanium in alkali have the rutile structure.

the niobium concentration in the alloy, which can be accounted for by the incorporation of impurity Nb^{5+} ions into the main TiO_2 oxide (rutile). Comparison of these data with the TiO_2–Nb_2O_5 phase diagram[71] suggests that the return of ΔE_g to a value characteristic of impurity-free rutile (3.7 eV), which occurs at a niobium concentration of 10%, can be explained by the fact that the initially homogeneous oxide becomes heterogeneous, since the new phase $TiO_2.Nb_2O_5$ appears. The appearance of this new phase can in fact promote the liberation of niobium from rutile.

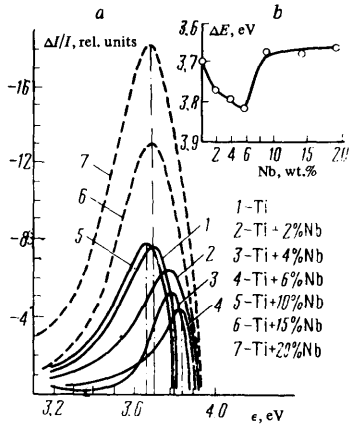

Figure 14. *a*) Electroabsorption spectra for titanium and titanium–niobium alloy electrodes obtained in 5 *N* KOH; *b*) variation of the energy of the electroabsorption maxima with niobium content in the alloys.

Gobrecht et al. [72] made a spectroscopic study of the surface of nickel under the conditions of anodic polarisation in 0.1 *N* sulphuric acid. They employed the electroreflectance method for this purpose and observed a change in the structure of the oxide in the range of potentials between primary and secondary passivation (0.8–1.3 V relative to the saturated calomel electrode). On the basis of a model which considered the inhomogeneity of the oxide film growing on the nickel surface, the authors explained the observed shift of the main absorption edge of the nickel oxide film with increased anodic potential by an increase of the concentration in the oxide film of nickel ions with a valence greater than two. The maximum rate of formation of these ions was observed at a potential of 0.97 V (s.c.e.). Thus, from an anodic potential of 0.76 V (s.c.e.), the outer layer of the oxide film is enriched in Ni^{3+} ions. This hypothesis of the authors is confirmed by a study of the variation of electroreflectance with the frequency of the modulating potential..

The data described above show that the application of various optical methods in the study of corrosion-electrochemical processes in an electrode–electrolyte system is extremely promising and may yield very valuable information about the mechanisms of these processes.

Extraction Systems with Associated Extractants

E.V.Komarov and V.N.Komarov

The review examines the characteristics of the extraction behaviour of extractants with pronounced self-association in the organic solution. The importance of the correct choice of the model of the liquid for an adequate description of the properties of the system is discussed.
The bibliography includes 127 references.

V. Distribution of acids and salts in systems with moderately associated extractants (arylammonium and alkylammonium salts) 270

I. INTRODUCTION

The problem of the processing of nuclear fuel and also the necessity of obtaining in large amounts and with a high degree of purity uranium, thorium, the individual lanthanides, and other rare and widely scattered elements to meet the requirements of nuclear power engineering have led to the vigorous development of certain fields of chemical engineering. The need for special purity of the materials led to the large-scale application of the extraction method for the isolation and purification of metal salts. During the last 10–15 years several hundreds of extractants capable of extracting metal salts and inorganic acids from aqueous solutions have been proposed and used on a laboratory and industrial scale. However, the study of the physicochemical properties of these systems has lagged appreciably behind the practical requirements. Many important details of the chemical behaviour of extractants (the effects of the hydration of the initial compounds and products, their solubilities in the organic phase, the effect of the solvent on the selectivity of the extraction and the stability of the complex extracted, the process kinetics, etc.) have been inadequately investigated.

The capacity of many extractants for self association is of special interest. Association in the organic phase is characteristic of extractants such as high-molecular-weight alcohols and phenols [1-13], carboxylic acids [14-20], alkyl- and aryl-phosphoric acids [21-44], and salts of organic ammonium derivatives [45-78]. Examination of the results of numerous studies on the properties of extraction systems including the extractants enumerated above reveals the following fundamental difficulties relating to the association of the extractant.

a. Conflicting data for the degree of association in the same systems or in systems with components of a similar chemical type obtained by different methods.

b. Unexpectedly simple linear concentration variation of the partition coefficients of metal ions (or acids) despite the non-linearity of the variation of the degree of association of the extractant.

c. Inconsistency of the experimental data for the concentration variation of the average degrees of association of the components with the thermodynamic properties of the model of the solution constituting the basis of the interpretation of these data.

The aim of the present reveiw was to examine the physical significance of models of the solution used for the description of extraction systems in connection with the chemical nature of the compounds present in solution, and also to indicate the principal studies in which ways of overcoming the above difficulties have been outlined.

II. GENERAL CHARACTERISTICS OF ASSOCIATED SUBSTANCES

1. Classes of Extractants with a Tendency towards Association

The capacity of particular substances for marked association in organic solvents is related directly to their chemical nature and the nature of the solvent. Thus alcohols, phenols, carboxylic acids, and organophosphorus acids contain both proton-donating and proton-accepting functional groups [OH, COOH, $OP(OH)_2$, etc.], which leads to the formation of a system of hydrogen bonds in the liquid.

A second mechanism of association, which plays a fundamental role for organic derivatives of ammonium salts, is the dipole–dipole interaction of the polar molecules of the extractants in a medium with a low dielectric constant.

As a rule, in real extraction systems the interaction is complex. Molecules of acid extractants and their metal salts usually have high dipole moments [72-79] and alkylammonium salts are capable of combining with "superstoichiometric" inorganic acid molecules via hydrogen bonding:

$$R_4N^+.NO_3^- \ldots HNO_3.$$

Extensive experimental data have accumulated concerning the state of the extractant in the organic solvent. Association equilibria have been investigated by methods based on partition between two liquid phases [14-16,30-45,80,81], cryoscopy [21,25,38-42,50-54,80], ebullioscopy [60,82], measurements of the vapour pressure of the solvent [13,19,22-27,30,38,42,46,60-62,82], potentiometric titration [64,65], conductimetry [15,59,63-65], viscometry [21,23,54,59,63,65], light scattering [57,58,62,71], dielectric constant measurements [20,59,63,65,74,77], infrared, ultraviolet, and Raman spectroscopy of the solutions [6,21,25-27,30,32,38,48,59,63], and NMR and ^1H NMR methods [5,41].

Depending on the chemical nature of the extractant and the solvent, the concentration range considered, and temperature, the average degree of association varies within fairly wide limits, but in general one may say that carboxylic and monobasic alkylphosphoric acids are least associated. Their average degree of association is close to two or a little more at high extractant concentrations [16,21,25,29-31,38]. The degree of association of alcohols and phenols increases with concentration more slowly than that of acids, but it reaches much higher values [2-6,13]. The association of dibasic alkyl phosphate is highest; it has been shown [42,43] to reach values of the order of several tens or above at moderate concentrations. The degree of association of alkylammonium salts depends strongly on the nature of the anion and can sometimes reach equally high values [53,57-59,65,71,82]. Evidently, without a far-reaching study of the properties of associated solutions, it is impossible to understand the complex nature of the extraction processes involving the widely employed associated extractants and to predict correctly the effect of different factors on their extraction capacity.

2. Difficulties in the Quantitative Interpretation of Partition Data in Extraction by Associated Extractants

The quantitative interpretation of partition data is complicated by the multiplicity of the reactions. As a rule, the extractants can form with the extracted species not one but a series of complexes with different contents of the extractant per species extracted. For example, in the extraction of uranium by dialkylphosphoric acids [23,39] the complexes UO_2A_2, $UO_2A_2(HA)_2$, and probably $UO_2A_2(HA)_n$ may be present in the organic phase. Most physicochemical research techniques do not permit a direct determination of the number of species formed in solution, since experimental quantities (vapur pressure of the solvent, partition coefficients between the phases, freezing point, etc.) are functions of the overall concentration of all types of species of the solute. Another fundamental difficulty is the non-ideality of both the aqueous and organic solutions. The solute species (hydrated metal ions or acids in the aqueous phase and the set of complexes of different composition and solvated to different extents in the organic phase) interact with one another and with the solvent, which is formally taken into account by the deviation of the activity coefficients from unity. There is an extensive literature on the activity coefficients of electrolytes in aqueous solutions [83,84], but the available data concerning the activities of the components in the organic phase are scanty and are quoted only for individual thoroughly investigated extractants. With increase of the concentration of the extractant and the extracted compound, there is in many cases a marked change in the dielectric constant of the medium, because the majority of extractants are highly polar substances and their dielectric constants are higher by 10–20 units than that of the pure solvent [49,72-78]. In any description of the chemical interaction in the organic phase account must be taken of the change in the properties of the medium when the range of moderate and high solute concentrations is considered. In order to deduce the reasons for the discrepancies in the experimental degrees of association of the extractant obtained over a wide range of concentration, it is necessary to examine in detail model concepts which constitute the basis of the computational equations.

III. METHODS FOR THE DESCRIPTION OF ASSOCIATED SOLUTIONS

1. Model of the Ideal Associated Solution and the Metrics of the Physicochemical Diagram

In the study of the properties of solutions the concept of the ideal associated solution is widely employed, i.e. of a solution in which all kinds of interaction between the species can be divided into two types: strong "chemical" interactions with energies of the order of 2000–10 000 cal mole^{-1} involving the formation of stable configurations and the interactions between the association complexes and the molecules of the surrounding medium; the energies of interactions of the second type are of the same order as the thermal energy (about 600 cal mole^{-1}) and they do not lead to the formation of stable solvates [85]. It is postulated that such a mixture of monomeric solvent molecules and complexes of the solute constitutes an ideal solution at all concentrations (Prigogine and Defay [86], p. 387). The special case of the ideal associated solution [monomeric solvent–associated extractant (its association complexes can include also a third component—the substance extracted)] is of interest for extraction. The following relations can be formulated for such a system:

$$f_A = \frac{\rho}{\rho_0} \cdot \frac{1}{\frac{X_A}{r} + X_B}, \qquad f_B = \frac{1}{\frac{X_A}{r} + X_B} \qquad (1)$$

where f_A and f_B are the activity coefficients in the symmetrical reference system, X_A and X_B are the mole fractions of the extractant and the solvent respectively, ρ_0 is the mole fraction of monomeric molecules in the pure extractant, ρ the mole fraction of the extractant molecules present in solution in the monomeric form, and r the average degree of association of the extractant molecules. Thus it is possible to describe fully the thermodynamic properties of the system, provided that the degree of association of the pure extractant and the law governing its variation with concentration are known. It is usually assumed that the association reactions obey the law of mass action and that the equilibrium constants remain unchanged at all concentrations.

One can assume approximately, in accordance with Mecke's hypothesis [87], which has been proved from the standpoint of statistical thermodynamics [16], that in the standard state the stepwise association constants K_r are independent of the degree of association, i.e.

$$K_2 \simeq K_3 \simeq K_4 \simeq \ldots \simeq K_r = \frac{X_{r+1}}{X_1 \cdot X_r}, \qquad (2)$$

where X_r is the concentration in solution of the association complex containing r monomeric units.

The ideal associated solution model explains the marked positive deviations from Raoult's law which are characteristic of solutions with an associated component (Prigogine and Defay [86], p. 389), but the model itself is very approximate: the solvent in the model is regarded as an inert medium which does not react in any way with the solute and does not affect its association. The concentration association constants are assumed to be independent of concentration and can be determined by studying the pure associated component. In reality the degree of association depends very markedly on the nature of the

solvent, on its dielectric constant, on its capacity to form hydrogen bonds, etc. In particular, association constants cannot remain invariant at high concentrations, since under these conditions there is a marked change in the dielectric constant of the solution and other characteristics of the medium.

Another fundamental defect of the model is the neglect of the difference between the sizes of the species formed in the system. In the case considered the species differ in dimensions by factors of several tens and even hundreds [42,43,53,57,58,67,71,82,88,89]. In such solutions the entropy component of the excess free energy of mixing is of the same order of magnitude as the thermal component, which means that, for a correct interpretation of the experimental data, it is absolutely essential to take into account the influence of the difference between the dimensions of the association complexes and monomeric species, otherwise the calculated average degrees of association will be much too low.

Finally, when the solution is regarded as an ideal associated system, it is impossible to account for its separation into two organic phases [90], which is frequently encountered and is characteristic of systems containing organophosphorus extractants or alkylammonium salts in a hydrocarbon solvent [54,59,67,91].

2. Methods for the Improvement of the Metrics of the Physicochemical Diagram on the Basis of the Lattice Model of the Solution

The study of the thermodynamic properties of high-polymer solutions led to the development of the so called "athermal" model of the solution proposed initially by Fowler in 1937. [92] Subsequently Fowler's ideas were developed by Chang, Miller [93], and particularly Guggenheim [94]. The liquid is regarded as a quasicrystal in the lattice sites of which molecules are located. This approach makes it possible to take into account readily the differences between the dimensions and shapes of the molecules if one assumes that each site can be occupied by either one monomeric species or by one statistical segment of the association complex macromolecule. The lattice is characterised by a statistical average coordination number (subsequently designated by z). The difference between the dimensions of the component molecules is taken into account by the factor R_A—the number of lattice nodes occupies by monomeric molecules of the associated substance. To a first approximation, R_A is determined from the ratio of the molar volumes of the components. Molecular shape is reflected by the quantity q. The product zq characterises the number of contacts between the molecule and its nearest neighbours. By determining z, R_A, and q for any specific system, it is possible to estimate the number of A–A, A–B, and B–B contacts between the component molecules. If long-range forces are now neglected, which is quite admissible for solutions of organic substances in solvents of low polarity, it is possible to relate the enthalpy and entropy of mixing directly to the interaction energies of the molecules, their structure, and chemical nature.

With the aid of the usual methods of statistical mechanics and the lattice model of liquids, it is possible to obtain expressions for the energy and entropy of mixing or for the activity coefficients of the components in solution. Two cases are of special interest: a regular solution, the excess free energy of mixing in which is largely determined by the heat of mixing and the dimensions of the molecules of the components are assumed to be the same, and the opposite type, the so called athermal solution, in which the heat of mixing is negligibly small and the free energy of mixing is determined by the entropy component.

In a regular solution

$$|h^E| \gg T|s^E|, \tag{3}$$

where h^E is the molar heat of mixing and s^E the excess molar entropy of mixing. In the derivation of the fundamental equations it is assumed that the differences in the intermolecular interaction of species of different kinds are fairly small and the distribution of species in the system is random. The concept of the irregular solution was subsequently extended by Hildebrand and Scatchard to mixtures of molecules having different volumes [95] and semiemperical expressions were obtained for the activity coefficients:

$$\begin{aligned} RT\ln f_A &= v_A^0\left(\frac{v_B^0 n_B}{v_A^0 n_A + v_B^0 n_B}\right)^2 \cdot (\delta_A - \delta_B)^2 \quad , \\ RT\ln f_B &= v_B^0\left(\frac{v_A^0 n_A}{v_A^0 n_A + v_B^0 n_B}\right)^2 \cdot (\delta_A - \delta_B)^2 \quad , \end{aligned} \tag{4}$$

where v^0 is the molar volume of the pure component and n_i the number of moles of component i in the system. Eqns. (4) make it possible to calculate the activity coefficients from data for the pure substances, and the regular solution model has been frequently used to describe extraction systems [44,67,96]. However, according to the significance of the assumptions underlying it, the model can describe satisfactorily only a system with intermolecular dispersion interactions and is unsuitable for systems containing species with large dipole moments which are readily polarised or are capable of forming hydrogen bonds. The second fundamental defect of the regular solution model is the by no means complete allowance for the differences between the dimensions of the species. The introduction of molar volumes or of volume fractions as units of concentration corrects only for the differences between the dimensions of the monomeric species of the components, while the formation of polymeric aggregates or molecular chains in solution is disregarded and yet, for a degree of association $r \geq 5$, the contribution of the formation of association complexes to the excess entropy of mixing frequently becomes decisive.

For an athermal solution,

$$T|S^E| \gg |h^E| \tag{5}$$

and all the deviations from the properties of the ideal solution are determined by the difference between the dimensions and shapes of the species. Typical systems of this kind were described by Meyer [97,98]. They all consist of solutions of substances with large molecular weights and chain molecules in a non-polar solvent such as benzene or hexane and are characterised by a negligible heat of mixing and considerable negative deviations from ideality. Since the heat of mixing is small, the activity coefficients of an athermal solution are almost independent of temperature. Miller [93] showed that, in terms of the $z \to \infty$ approximation,

$$\begin{aligned} f_A &= \frac{N_A + N_B}{N_A + R_A N_B} \cdot \exp\frac{(R_A - 1)N_B}{N_A + R_A N_B} \quad , \\ f_B &= \frac{N_A + N_B}{N_A + R_A N_B} \cdot R_A \exp\left[-\frac{(R_A - 1)N_A}{N_A + R_A N_B}\right] \quad , \end{aligned} \tag{6}$$

where N_i is the number of lattice sites occupied by component i.

Eqn. (6) shows that the activity coefficients are smaller than unity. By a slight extension of Eqn. (6) as a result of the introduction of the parameter q, the physical significance of which was defined above, it is possible to take into account directly not only the dimensions but also the shape of the molecules.

In real systems containing an associated extractant in an organic solvent of low polarity, the intermolecular interactions are much more complex than in the limiting cases of regular or athermal solutions discussed above. There are two methods for the description of real associated solutions involving lattice concepts.

Barker [98,99] developed a pure lattice model in which account is taken not only of the van Der Waals forces but also of directional interactions of the hydrogen bond type, which depend on the mutual orientation of the molecules. In Barker's model the different classes of contact regions, corresponding to functional groups are considered, and the interaction energies of all possible combinations of contact regions are specified, the probability of the formation of each contact pair being determined by the condition of the free energy minimum. In other respects the quasichemical method proposed by Guggenheim is employed. The fundamental defect of Barker's model is a lack of theoretical parameters measured by independent methods. The mutual exchange energies employed in the calculations are essentially converted into empirical parameters and their choice as well as the choice of the geometrical characteristic z, q, and R_i is not unambiguous. The mathematical procedure is complex, requiring the use of computers, despite the approximate nature of the physical model itself (neglect of geometrical factors in the calculation of the probability of the formation of different contact pairs, an overestimate of the degree of order in the liquid, the lack of validity of the condition of constant lattice parameters over a wide range of concentrations, etc.).

Certain difficulties of the pure lattice models of solutions can be obviated by considering separately the strong directional interactions, treating them as ordinary chemical association reactions obeying the law of mass action and specifying the law of association, i.e. the dependence of the stepwise association constant K_r on the degree of association r. Weaker non-directional interactions are treated in terms of the lattice approximation, which makes it possible to take into account the influence of the dimensions and shapes of the species.

A version of this model has been proposed [42,89,100] for the description of solutions of highly associated substances—monoalkylphosphoric acids and alkylammonium salts—in a non-polar solvent (benzene, carbon tetrachloride, etc.). In this case the partition function for a binary system can be formulated as follows:

$$Q = G(N_D, N_T)\prod_D \psi_D^{N_D}\exp\left[-\frac{U(N_D, N_T)}{kT}\right], \quad (7)$$

where the subscripts D and T are general symbols defining the kind of all possible species (including association complexes and solvates) in the system, N_D is the number of species of type D, ψ_D the partition function with respect to the internal states of the molecule, $G(N_D, N_T)$ the number of configurations of the system, and $U(N_D, N_T)$ the configuration energy of the system, which depends on the number and class of contacts of all possible species in the system.

$G(N_D, N_T)$ is calculated from the formula

$$\ln G(N_D) = \sum_D \ln\left(\frac{\rho_D}{\sigma_D}\right)^{N_D} - \sum_D \ln N_D! + \frac{\sum_D N_D(r_D-1)}{\sum_D N_D(r_D-q_D)}\ln\left(\sum_D q_D N_D\right)! - \frac{\sum_D N_D(q_D-1)}{\sum_D N_D(r_D-q_D)}\ln\left(\sum_D r_D N_D\right)! \quad , \quad (8)$$

where ρ_D is the number of ways of distributing molecules of type D among r_D sites for a single fixed unit and σ_D is the molecular symmetry factor. A molecule of type D has in the general case surface regions which are not equivalent as regards energy. Suppose that ϵ and ν are general symbols of the class of contact regions on the molecule; the fraction of contact regions on a species of type D in class ϵ is designated by the symbol v_ϵ^D and can be readily calculated in each specific case. The quantity $U_{\epsilon\nu}$ is the energy of the contact formed by regions of classes ϵ and ν on particles of the same (D) or different (D and T) kinds.

It follows from Eqns. (7) and (8) that the chemical potential of species of type D (cyclic structures of association complexes and solvates are absent) is

$$\mu_D = kT\left\{-\ln\frac{\rho_D}{\sigma_D}\psi_D + \ln N_D - \frac{z}{2}q_D\ln\sum_T q_T N_T + r_D\left(\frac{z}{2}-1\right)\ln\sum_T r_T N_T\right\} + \frac{z}{2}q_D\sum_{\varepsilon,\nu} U_{\varepsilon\nu}\cdot(v_\varepsilon^D v_\nu + v_\nu^D v_\varepsilon - v_\varepsilon v_\nu) \quad . \quad (9)$$

For a specific system, account is taken of the association law $K_r = f(r)$, where K_r is the equilibrium constant of the reaction involving the addition of a monomeric unit to an r-mer of the associated component, and of the shape of the association complex (linear, cyclic, bulky, etc. complexes), whereupon it is possible to obtain from Eqn. (9) the relation between the activity coefficient of the solvent and concentration.

Thus, for the simplest case of an athermal associated solution ($K_2 = K_3 = \ldots = K_r$) and linear association complexes, we have

$$f_B = \frac{1}{1+(R_A-1)X_A}\left\{\frac{\frac{2}{z}h(1-X_A)}{(1-h)[1+(R_A-1)X_A]} + \frac{1+\left(\frac{z-2}{z}R_A-1\right)^{-\frac{z}{2}}}{1+(R_A-1)X_A}\right\} \quad (10)$$

where h is the overall effective concentration of all r-mers in solution:

$$h = \frac{[4K_r X_A(1-X_A)+1]^{1/2}-1}{2K_r(1-X_A)} \quad (11)$$

and X_A is the analytical concentration of the solute.

The advantages of this model consist in the direct allowance for the specific interactions and the simplicity of the estimation of the effect of the difference between the dimensions and shapes of the species on the excess thermodynamic functions of mixing. The empirical choice of the interaction constants constitutes the main defect of the model, although, for example, the average degree of association can be estimated also without employing the association constants.

The defects of the lattice approximation have little influence on the final results, since it is used only to introduce corrections to the van der Waals interaction of the association complexes with one another and with the medium.

An interesting method for the description of systems with associated components was proposed by Zagorets and Ochkin [101], who employed certain conclusions of Mayer and McMillan's theory of liquids [102] for the interpretation

of experimental data obtained in a study of the association of alkylammonium salts in benzene and carbon tetrachloride. They obtained a qualitative explanation of the maximum on the curve relating the degree of association to the concentration of the alkylammonium salt and also of the influence of the dimensions of the cation and anion and of temperature on the degree of association.

However, their assessment of the rigor and universality of the proposed method is open to objection. Thus, two expressions obtained by McMillan and Mayer are used as the initial equations:

$$\ln a = \ln \rho - \sum \nu B_{\nu n} \left(\frac{\Delta a}{\gamma}\right)^{\nu-1} C^n \quad , \tag{12}$$

$$P = P_0 + kT\left[C + \frac{\Delta a}{\gamma} - \sum (\gamma + n - 1) B_{\nu n} \left(\frac{\Delta a}{\gamma}\right)^{\nu} C^n \right] \quad , \tag{13}$$

where ρ and C are the volume concentrations of the solvent and solute respectively, P_0 is the vapour pressure of the pure solvent, $B\nu n$ are the virial coefficients characterising the interactions of ν solvent molecules and n solute molecules, $\Delta a = a - a_0$, a_0 being the activity of the pure solvent, and $\gamma = a/\rho$ (here and below the notation used is that in the original report). The authors claim that "Eqns. (12) and (13) are rigorous, i.e. in their derivation no simplifying assumptions were made concerning the structure of the solutions. This constitutes an advantage of McMillan and Mayer's theory over other statistical theories of solutions (for example the lattice theory)". This is only partly true. Very important assumptions are made in Mayer's theory: the potential energy is regarded as the sum of pair interactions; the energy levels are assumed to be continuous, which is inadmissible for strong directional interactions. Apart from these fundamental simplifications of the initial theory, Zagorets and Ochkin introduced a number of further assumptions: in the expression

$$\frac{C^2}{\rho_0 \ln f_a} = \frac{1}{A_2}\left[1 - \frac{A_3}{A_2} C - \left(\frac{A_4}{A_2} - \frac{A_3^2}{A_2^2}\right) C^2 - \ldots\right] \tag{14}$$

they omitted higher terms, which restricts the applicability of subsequent expressions to low concentrations; moreover, a number of simplifying assumptions were made in the numerical calculations of Ochkin and Zagorets.

Comparison of the version of Mayer's theory proposed by Ochkin and Zagorets and the lattice models shows that both approaches constitute a very rough approximation. The simplifications of the lattice models are clearer and their validity is easier to check, while the consequences of certain approximations in the version under consideration are difficult to assess.

The considerable discrepancies between the calculation of the position of the maximum on the $n = f(m)$ curve from the formula proposed by Zagorets and Ochkin [101],

$$m_{\max} \simeq \sqrt{\frac{A_2}{-A_3 \cdot 10^{-3} M_2}} \tag{15}$$

and the experimental data is very instructive.

A similar attempt to apply a virial expansion to the description of solutions of an associated alkylammonium salt in benzene was made by Danesi et al. [62] As above, the authors make a number of simplifications: (1) they replace the second virial coefficient of the binary system (which depends on the concentrations of the components) by the corresponding coefficient for the pure solvent, (2) they neglect the higher terms of the expansion, and (3) they assume the partial molar volume of the mixture to be equal to the partial molar volume of the solvent.

As a result of these simplifications, they consider essentially the model of an ideal associated solution and, what is more, they assume implicitly its infinite dilution. Evidently the calculation of the average degree of association and other properties on the basis of such simplified models cannot yield a picture describing correctly the complex interactions in a real system.

3. Determination of the Degree of Association of Substances by Methods of Physicochemical Analysis

In order to refine the stoichiometry of the reactions, in the study of extraction equilibria many investigators attempted to determine by an independent method the degree of association of the extractant and its complexes with the metal. For these purposes, they employed cryoscopy [25,39,41,42,50–54,80], ebullioscopy [60,82], measurements of the vapour pressure of the solvent [13,19,22–26,30,32,42,61,82], light scattering [57,58,62,71], and viscosity measurements [21,23,54,59,63,65,70]. Data obtained by different methods for the same systems or systems of similar composition reveal very interesting contradictions. The average degree of association determined by cryoscopy, ebullioscopy, and measurements of the vapour pressure of the solvent proved to be appreciably lower than the value calculated from optical measurements and was inconsistent with the appreciably higher viscosities of such solutions compared with the viscosity of the pure solvent. The discrepancies may be very large. Thus, for trialkylammonium (C_7–C_{12}) nitrate solutions in benzene, cryoscopic measurements and measurements of the vapour pressures of the solvent yielded $r = 1.8$–5.0, whereas according to light scattering data [46] $r \simeq 60$. Similarly, for dialkylammonium sulphate solutions in benzene, light scattering data gave $r = 40$–50, which is higher by a power of 10 than the value derived from cryoscopic measurements [57,58,71].

In the determination of the average degree of association of the solute by methods based on the measurement of the activity of the solvent and of r over a wide range of concentrations, $r = \varphi(X)$ curves with a maximum are frequently obtained [47,52], which conflicts with the thermodynamic condition for the stability of the phase from the standpoint of the representation of the solution as an ideal mixture of all possible compounds (Prigogine and Defay [86], p. 404; Storonkin [103], p. 65):

$$\frac{\partial \mu_A}{\partial X_A} > 0 \text{ and } \frac{\partial^2 \mu_A}{\partial X_A^2} > 0 \quad \text{or} \quad \frac{\partial r_A}{\partial X_A} > 0 \text{ and } \frac{\partial^2 r_A}{\partial X_A^2} < 0 \tag{16}$$

Evidently the properties of the above class of solutions cannot be described by the theory of ideal associated solutions.

The reason for all these contradictions can be readily deduced by considering the model concepts used in the derivation of the equations for the activity of the solute. We shall consider in detail the cryoscopic method (ebullioscopy and tensimetry are based on similar postulates).

In the derivation of the computational formula

$$\Delta T = \frac{RT_{0B}}{L_B} \cdot \frac{M_B}{1000} m_A \qquad (17)$$

the following assumptions were made: (a) the components of the solution are completely miscible in the liquid state and do not form solid solutions; (b) the latent heat of fusion of the solvent is independent of temperature; (c) the solution obeys Raoult's law at all the concentrations considered; (d) the solution is very dilute.

All the deviations from properties of the ideal solution are explained by a change in the number of individual species as a result of chemical interactions:

$$r = \frac{m_A}{m_{A,\,eff}}, \qquad (18)$$

i.e. one uses essentially the model of an ideal associated solution, the fundamental disadvantages of which have already been discussed. Refined cryoscopic formulae proposed by Udovenko or Fomin [104] (p. 45) are valid for a wider concentration range but also only for an ideal associated solution.

A method has been proposed [89] for the calculation of the average degree of association of a substance in a monomeric solvent from the activities of the solvent on the basis of the theory of association equilibria in terms of the athermal approximation whereby account can be taken of the dimensions of the association complexes:

$$r = \frac{X_A}{\frac{z}{2}\left\{\left[\frac{1-X_A}{f_B X_B (1-X_A+R_A X_A)}\right]^{z/2} - 1\right\} \cdot [1+(R_A-1)X_A] + R_A X_A}, \qquad (19)$$

and the results of the calculation of the average degree of association in the trioctylammonium mononitrate–benzene system by Eqns. (17), (18), and (19) have been compared. Table 1 shows that neglect of the negative deviations from Raoult's law due to the formation in the solution of large association complexes reduces r by a power of ten. Calculations by Eqn. (19) agree satisfactorily with light scattering data [46, 57, 58, 71].

Table 1. Average degree of association of trioctylammonium nitrate in benzene according to cryoscopic data [105].

X_A	r_A (17, 18)	r_A (19) with $\begin{cases} R_A=5 \\ z=6 \end{cases}$
0.0090	2.1	2.0
0.021	3.1	5.9
0.041	3.3	32
0.068	2.6	50
0.094	2.1	>50

Similar results were obtained for the mono-n-octylphosphoric acid (MOPA)–carbon tetrachloride system from isopiestic measurements of the vapour pressure [42] (Table 2).

It follows from Tables 1 and 2 that the degree of association of the extractant is frequently found to be too low owing to an incorrect interpretation of the data. This factor must be borne in mind in considering the reactions involved in extraction by highly associated extractants.

IV. EXTRACTION OF SUBSTANCES BY HIGHLY ASSOCIATED EXTRACTANTS

1. Experimental Concentration Variation of the Partition Coefficients of Metals

We shall consider monoalkyl or monoaryl phosphoric acid esters as examples of typical highly associated extractants. The characteristic form of the variation of the partition coefficients of metals between the aqueous and organic phases $\alpha = M_{org}/M_{aq}$ and the extractant concentration in the organic phase S is striking; $\lg \alpha$ varies linearly with $\lg S$ over a wide range of compositions of both aqueous and organic phases [43, 100]:

(a) a unit slope of the concentration curve is observed for cations with different structures of the outer electron shell and in particular with different electrovalences (UO_2^{2+}, Am^{3+}, Np^{4+});

(b) the unit slope persists when the concentration of the inorganic acid in the aqueous phase, the supporting salt, and hence the degree of hydration of the cations are varied;

(c) the variation of the extractant concentration in the organic phase within wide limits (from 0.001 to 1.0 M) does not alter the slope of the concentration curve;

(d) the structure of the hydrocarbon group in the alkylphosphate molecule and the nature of the low-polarity solvent do not influence the slope of the concentration curve.

Table 2. Average degree of association of mono-n-octylphosphoric acid in carbon tetrachloride [42].

X_A	r_A (17, 18)	r_A (19) with $\begin{cases} R_A=1.3 \\ z=6 \end{cases}$
0.108	4.9	8.2
0.151	5.1	17.4
0.395	4.3	18.4
0.471	4.4	21
0.648	3.7	30
0.790	3.0	42

The slope changes only when the condition of a high degree of association of the extractant breaks down and also when solvents causing dissociation into monomers are employed, for example alcohols, or when the concentration of the metal extracted is raised above a certain limit [106]. Concentration curves have been obtained [36] for the extraction of trace amounts of europium and americium by MOPA solutions in various solvents (benzene, carbon tetrachloride, chloroform, n-hexane, and butyl chloride) and it was found that not only is the slope of the concentration curve the same in all cases but the numerical partition coefficients are very close at the same extractant concentrations [36]. This supports the hypothesis of a high degree of order in the distribution of the MOPA chain molecules in its association complexes. The $OPO(OH)_2$ polar groups are probably directed inwards and are surrounded by a stable hydration shell, while the organic groups are directed to the outside of the micelles. During extraction, cations pass from the aqueous phase to the hydration shell linked to the $OPO(OH)_2$ groups. The proposed structure provides a qualitative explanation of the independence of the partition coefficients of the nature of the low-polarity solvent and of the very high water

content in organic MOPA solutions. It has been found[42] that in 1 M MOPA solution in carbon tetrachloride up to 27 moles of water per litre dissolved on saturation, with a sharp increase of viscosity and degree of association (Table 3).

Table 3. Relative water content M_{H_2O}/M_{MOPA} in organic MOPA solutions in equilibrium with 2 M aqueous HNO_3 at 20°C.

Solvent	MOPA mole fraction in organic phase					
	0.0025	0.005	0.01	0.02	0.04	0.08
1-Hexanol	1.4	1.7	2.1	2.1	2.1	2.1
n-Butyl chloride	3.7	4.2	4.5	4.6	4.7	5.1
n-Hexane	7.5	12	13	14	15	16

2. Common Methods for the Interpretation of Experimental Relations

The partition of a substance between two immiscible phases has been used for a long time as one of the methods for the determination of the composition of the complex extracted[51,107-110]. The formation of a single compound in the organic phase is usually considered:

$$M_{(aq.)} + \tau S_{(org.)} \rightleftarrows (MS_\tau)_{(org.)} . \qquad (20)$$

The following relation is valid for this reaction:

$$\alpha = K\frac{(f_S S)^\tau f_M}{f_{MS\tau}}, \qquad (21)$$

where α is the partition coefficient of the substance extracted, K the thermodynamic equilibrium constant, S the concentration of the extractant, and f_S, f_M, and $f_{MS\tau}$ are the activity coefficients. It is assumed that at moderate concentrations the activity coefficients of the uncharged species are close to unity and τ, the number of extractant species involved in the reaction, is determined from the slope of the straight line represented by the equation

$$\lg \alpha = \lg K + \tau \lg S . \qquad (22)$$

The activity of the extractant is either found independently by the usual methods[111-113] or the activity coefficients are assumed to be constant. The method described can of course yield satisfactory results only when the properties of the organic phase differ little from those of an ideal solution. Real extraction systems contain as a rule polar extractants which interact strongly with one another and with the solvent. It can be shown[104] that the association of the extractant or its solvation by the solvent reduce the slope of the curve defined by Eqn. (22) and in the general case the slope becomes a complex function of the extractant concentration and the ratio of the association and solvation constants.

In most studies of the extraction of metal ions by highly associated extractants[105,114-116] the hypothesis that the organic phase in the given concentration range contains only one association complex is employed. Its degree of association is determined independently or simply selected in order to account for the experimental relations. Thus the mechanism

$$M^{l+}_{(aq.)} + \frac{2l}{r}(H_2A)_{r(org.)} \rightleftarrows M[H(HA)_2]_{l(org.)} + l\,H^+_{(aq.)} \qquad (23)$$

was proposed in numerous studies by Peppard and coworkers[25-29,31,33,34,38,40] to account for the characteristics of the extraction of a number of lanthanides and actinides by phosphoric acid monoesters. It explains the extraction of lanthanides with $l = 3$ and of actinides with $l = 4$. The slope of the $\lg \alpha = \varphi(\lg S)$ concentration curve, which is unity, seemingly agreed with the average degree of association of the extractant $r = 6-8$ found by cryoscopic measurements in solutions of mono-2-ethylhexylphosphoric acid (M2EHPA) in dry benzene. However, this mechanism does not explain why the slope is also unity in the extraction of UO_2^{2+},[117] which leads to $l = 4$. Moreover, it has been shown[42] that the degree of association of phosphoric acid monoesters in a non-polar solvent in the presence of water is much higher than 6-8 and changes with the concentration of the extractant. The same authors regard the formation of "infinite" polymers in the organic phase,

$$M^{l+}_{(aq.)} + (H_2A)_{r(org.)} \rightleftarrows M(H_{2r-l}A_r)_{(org.)} + l\,H^+_{(aq.)} \qquad (24)$$

as an alternative mechanism. Although the authors note correctly that in this case the slope of the concentration curve will be unity when $r \to \infty$ if only one cation of the metal extracted is linked to each association complex species regardless of the valence of the cation, they unfortunately did not carry out a quantitative analysis of the proposed mechanism. This led to the incorrect conclusion that the slope of the concentration curve depends on the average degree of association of the extractant which may vary with the concentration of the extractant, temperature, and certain other factors. Another possible explanation of the variable slope of the concentration curves is based on the hypothesis of the presence of several extractable complexes with different component ratios; however, here too there are difficulties when an attempt is made to explain why the slope of the curve decreases with increase of the concentration of the extractant[118].

3. Allowance for the Multiplicity of Interactions in the Organic Phase

In considering the mechanism of extraction by highly associated extractants, one or two, more rarely three, fixed values of r are usually taken into account for the description of the state of the extractants in the organic phase in order to simplify the calculations. The constants for equilibria of the monomer–dimer–polymer type are fitted to give the best agreement with experiment. The approximate nature of the model is evident.

A scheme of interactions taking into account the formation in the organic phase of all possible association complexes of the extractant has been proposed[42,43,119]. When trace amounts of the metal extracted are employed, the overall molar concentration of the extractant is

$$S = \sum_r r[A_r] . \qquad (25)$$

If we introduce the equilibrium constant β for the addition of the cation to a specified reaction centre in the association complex and the statistical factor W_r taking into

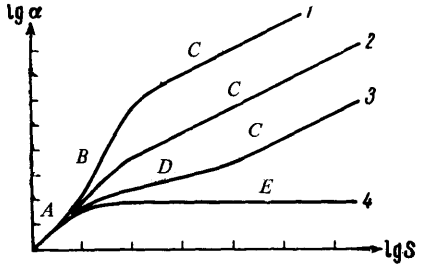
account the number of possible locations of the cation M among the reaction centres of the r-mer, it is easy to obtain the following expression for the partition coefficients:

$$\alpha = \beta f_M \sum_r W_r [A_r] \frac{f_r}{f_{A_r M}}, \quad (26)$$

where $[A_r]$ is the molar concentration of the r-mer and f_M, f_r and $f_{A_r M}$ are the activity coefficients of the M species, the association complex $[A_r]$, and the complex $[A_r M]$. It has been shown[43] that, in terms of the quasi-chemical approximation[94], for a system comprising a solvent and a mixture of r-mers with non-zero mutual exchange energies, $f_r/f_{A_r M} \simeq 1$ provided that $r \geqslant 10$ and $S \leqslant 1$. Moreover, for low concentrations $M_{(org.)}$ the formation of complexes containing several M atoms per association complex $[A_r]$ maybe disregarded. As a result, the following simple expression is obtained for the concentration curve:

$$\alpha = \beta \frac{f_M}{\nu} S, \quad (27)$$

where ν is the number of monomeric units of the association complex $[A_r]$ forming one reaction centre. Eqn. (27) is valid, provided that the condition $S/r \gg M_{(org.)}$ holds, and makes it possible to describe quantitatively the extraction of microconcentrations of metal ions by a highly associated extractant. The limits of the applicability of the ratio $f_M/f_{A_r M} \simeq 1$ depend on the parameters of the specific system; the method of their calculation has been described[119]. When the condition $S/r \gg M_{(org.)}$ breaks down, the relation $\alpha = \varphi(S)$ becomes more complicated and the partition coefficient becomes a function not only of S but also of $M_{(aq.)}$ and, as shown by the same authors[43], analysis of the concentration curve in this case does not lead to determination of the stoichiometry of the reaction.



General form of $\lg \alpha = \varphi(\lg S)$ concentration curves for different values of the parameter b: 1) $b > 1$; 2) $b = 1$; 3) $b < 1$; 4) $b = 0$ ($\partial \lg \alpha / \partial \lg S = \nu$ in region A, $\partial \lg \alpha / \partial \lg S > \nu$ in region B, $\partial \lg \alpha / \partial \lg S = 1$ in region C, $\partial \lg \alpha / \partial \lg S < \nu$ in region D, and $\partial \lg \alpha / \partial \lg S = 0$ in region E).

When the factors influencing the shape of the concentration curves are considered, the problem arises of the influence of the metal ions incorporated into the association complex of the extractant on the bond strength between the monomeric units of the complex[35]. In the general case one can foresee three possibilities: (a) the nature of the bonds in the association complex does not change and the addition of new monomeric units to the complex $[A_r M_i]$ proceeds in accordance with the same law as the addition to the complex without the metal $[A_r]$—the case considered above; (b) the monomeric units in the coordination spheres closest to the metal decrease the strength of bonds with other monomeric units; (c) the bond strength in the association complex increases under the influence of the metal. These effects can be taken into account quantitatively by introducing the bond stabilisation parameter $b = K_i/K_r$, i.e. the ratio of the constants for the addition of a monomeric unit A_1 to the association complex $[A_r]$. As before, the constant K_r is assumed to be independent of the degree of association r. If the bond perturbation zone is assumed equivalent to three coordination spheres closest to the metal atom within which the monomer addition constant $K_i \neq K_r$, the following expression is obtained for the partition coefficient:

$$\alpha = K_{M\nu} f_M \left\{ [A_1]^\nu + \frac{1}{\nu (bK_r)^2} \sum_{j=\nu+1}^{3\nu} j (bK_r)^j [A_1]^j + \frac{b^{2\nu}}{\nu K_r^\nu} \sum_{n=3\nu+1}^{\infty} n [A_1]^n K_r^n \right\}, \quad (28)$$

and

$$S = \sum_{r=1}^{\infty} r [A_r] = \sum_{r=1}^{\infty} r [A_1]^r K_r^{r-1} = \frac{[A_1]}{(1 - K_r [A_1])^2}, \quad (29)$$

where $K_{M\nu}$ is the formation constant of the complex $[MA_\nu]$, $[A_1]$ is the concentration of the monomeric extractant molecules in the organic phase, and j and n are summation indexes; the other symbols have the same significance as before.

The concentration curves calculated for different parameters S, K_r, and b are illustrated in the Figure, which shows that, when the degree of association of the extractant is high, the slope of the concentration curve approaches unity for $b > 0$ owing to the high values of K_r or S. When $b = 0$, the association complex is disrupted by the inserted species and α is independent of S over a wide extractant concentration range. A slope equal to the coefficient ν (the number of monomeric units of the association complex forming a single reaction centre) is obtained only at low concentrations where the degree of association of the extractant is still low. If the bonds in the association complex are appreciably strengthened by the inserted species ($b \gg 1$), the concentration curve shows sections where the slope is higher than ν. It follows from the foregoing that analysis of the shapes of the concentration curves requires a detailed examination of all possible types of chemical interaction in the system over a fairly wide range of concentrations and independent measurements of the degree of association of the extractant and of its solvation by the solvent are necessary.

V. DISTRIBUTION OF ACIDS AND SALTS IN SYSTEMS WITH MODERATELY ASSOCIATED EXTRACTANTS (ARYLAMMONIUM AND ALKYLAMMONIUM SALTS)

1. Certain Contradictions in the Interpretation of Experimental Relations

The considerable success of the methods for the determination of the composition and stability of solvates in extraction systems with neutral organophosphorus and other non-associated extractants left a deep impression on the methods for the interpretation of experimental data obtained with associated extractants. The traditional representation of extraction data in terms of the relation $\lg \alpha = \varphi(\lg S)$, in which the slope is identified with the

solvation number, is transferred without any changes to extraction systems with extractants associated in non-polar solvents such as alkylammonium salts, aryl- and alkyl-phosphoric acids, etc.

It is most surprising that simple linear relations are then obtained. Moreover, the equilibrium distribution of, for example, nitric acid in the extraction system with a trialkylammonium nitrate, may be described [52,120-122,123] by the simple reaction

$$B \cdot HNO_{3(org.)} + H^+_{(aq.)} + NO^-_{3(aq.)} \rightleftarrows B \cdot 2HNO_{3(org.)} \quad (30)$$

(here B = trialkylamine), i.e. seemingly there is no association of the trialkylammonium salt at all. According to the law of mass action, we have for reaction (30)

$$\alpha = K \cdot [B][H^+][NO_3^-] \cdot \frac{f_{\pm}^2 \cdot f_{B \cdot HNO_3}}{f_{B \cdot 2HNO_3}} . \quad (31)$$

However, the condition of a constant f_i usually adopted conflicts with numerous studies on the state of alkylammonium salts in solvents of low polarity. Fairly high association in such systems has been reliably established by cryoscopic [51,53,56] and conductimetric methods [64,65], by dielectric constant measurements [72-74], by light scattering [57,58,71], by viscometric measurements [54,65,70], etc. (particularly if account is taken of the correction for the effect of the difference between the dimensions of the solvent and extractant species on values found by cryoscopic and similar methods). The greater complexity of the equilibria in the extraction of hydrogen halides from aqueous solutions in the form of trialkylammonium salts compared with the simplest reaction

$$B_{(org.)} + H^+_{(aq.)} + X^-_{(aq.)} \rightleftarrows BH \cdot X_{(org.)}, \quad (32)$$

is indicated by the deviation of the $[BHX]_{(org.)} = \varphi\{[B]a_{HX(aq.)}\}$ relation from linearity at fairly low concentrations $[BH.X]_{(org.)} \simeq 0.001$ M, when there is no reason to postulate appreciable changes in f_B and $f_{BH.X}$ due to causes other than association [60,61]. Finally, when no account is taken of the association of the alkylammonium salt, it is difficult to explain the comparatively low capacity of the extractant [124], which deviates appreciably from the capacity expected on the basis of the stoichiometry of reactions (32) and (30).

2. Allowance for the Association of Extractants by a Simplified Procedure

Fomin and Potapova attempted to resolve the contradiction between the results of a cryoscopic study of the trioctylamine–nitric acid–water system and the invariance of the equilibrium constant calculated for reaction (30) without taking into account the association of the extractant. They assume [52] that the reaction equation can be written in the following general form:

$$\frac{y}{x}(BH \cdot NO_3)_{x(org.)} + y\,H^+_{(aq.)} + y\,NO^-_{3(aq.)} \rightleftarrows [B \cdot 2HNO_3]_{y(org.)} \quad (33)$$

and that the equilibrium constant can be expressed thus:

$$K'' = K' \cdot \frac{x^{y/x}}{y} \cdot \frac{1}{[HNO_3]^{2y-2}_{(aq.)} \; [BH \cdot NO_3]^{y/x-1}_{x(org.)}} , \quad (34)$$

where K' is the equilibrium constant for reaction (30). Next it is assumed that, with increase of the concentration of acid in the aqueous phase, the term $[HNO_3]^{2y-2}_{(aq.)}$ will increase and the term $[BH.NO_3]^{y/x-1}_{x}$ will decrease when $x < y$ which leads to the virtually constant value of K' observed experimentally. The main defect of this purely qualitative treatment is that there are no serious grounds for the assumption that the coefficients x and y are constant. They must evidently change with the concentrations of the acid and the amine. In this case too K' and K'' will also be functions of the concentration of the reactants.

Shmidt and coworkers [125] proposed an explanation based on Vanselow's hypothesis [126] according to which the activities of individual groups of the association complex are equal to their fractions relative to all the functional groups of the complex but in the formulation of the fundamental equations account must be taken of the activity coefficients of the association complexes themselves, which was not done by the authors. The conclusion that the degree of association of the alkylammonium salt remains unchanged when it adds to metal salts is also open to objection [69]. This conflicts with statistical considerations, particularly for a high coordination number of the complex-forming agent; Shmidt and coworkers determined the average degree of association of the extractant r by a cryoscopic method, which yielded somewhat low results [89] and, moreover, they failed to examine in detail the important problem of the multiplicity of equilibria, although they do note the constancy of the slope of the concentration curve when the average value of r varies.

Scibona's study [48] is interesting in this respect. The author considers the distribution of a singly-charged anion Y^- or a singly-charged complex anion MX^-_{n+1} between the solution of an electrolyte CX and an organic solution of the corresponding alkylammonium salt RX. The proposed reaction mechanism,

$$\sum_{1}^{I}[RX]_{i(org.)} + t[Y^-]_{(aq.)} \rightleftarrows \sum_{1}^{I}[RY]_{j(aq.)} + \sum_{1}^{A}\sum_{1}^{B}[(RX)_a(RY)_b] + t[X^-]_{(aq.)} \quad (35)$$

takes into account the association of the extractant of the complex extracted. The following equilibria are taken into consideration:

$$[RX]_{(org.)} + [Y^-]_{(aq.)} \rightleftarrows [RY]_{(org.)} + [X^-]_{(aq.)}, \quad K_{(1,X,Y)}, \quad (36)$$

$$i[RX]_{(org.)} \rightleftarrows [RX]_{i(org.)}, \quad K(i, X), \quad (37)$$

$$j[RY]_{(org.)} \rightleftarrows [RY]_{j(org.)}, \quad K(j, Y), \quad (38)$$

$$a[RX]_{(org.)} + b[RY]_{(org.)} \rightleftarrows [(RX)_a(RY)_b]_{(org.)} \quad K(a, b) . \quad (39)$$

An expression was obtained relating the partition coefficient of the anion Y^- to the concentration of the extractant. The authors extrapolated the partition coefficient (using certain auxiliary functions and not the partition coefficients themselves, which does not alter the essential feature of the procedure) to zero extractant concentration and found the constant $K_{(1,X,Y)}$, the deviations from the linear relation $\lg\alpha = \varphi\{\lg[RX]\}$ being regarded as a consequence of association in the organic phase. Although the authors interpret the experimental relations [48,68] in terms of the formation of only one complex, their equations are valid also when the solution contains a multiplicity of complexes of different compositions. Since an ideal associated solution is assumed and the activity coefficients in the organic phase are set equal to unity, the model cannot be valid over a wide range of concentrations and remains essentially semiempirical.

A similar approach has been developed by Högfeldt and Fredlund [66,127]. In their investigations the set of reactions of the associated alkylammonium salts with the complex metal-containing anion, leading to the formation of a continuous series of extractable complexes having structures of different complexity, was treated in terms of the ideal associated solution approximation. The composition of one or several complexes is chosen on the basis of the results of a two-phase potentiometric titration

whereby one can describe satisfactorily the form of the experimental relations. It has been shown [16] that this approach leads to the "discovery" of non-existent complexes or to the assumption that certain complexes are absent, whereas in reality they are formed.

3. Successive Allowance for the Association of Extractants and Extraction Complexes in the Description of Extraction by Amines

In another attempt to account for the known experimental relations governing the extraction of acids and metal ions by alkylammonium salts, taking into account the association in the organic phase, was made by Komarov and Komarov [55]. Account was taken of all interactions of the type

$$B_{r(org.)} + i\,[HA]_{(aq.)} \rightleftarrows B_r(HA)_{i(org.)}, \quad K_{ri}\ , \tag{40}$$

where B_r is an r-mer of the initial alkylammonium salt, HA a monobasic acid, and K_{ri} the thermodynamic equilibrium constant of reaction (40). If each association complex B_r has r energetically equivalent active centres capable of combining with a molecule of the acid HA, the following relation is valid:

$$K_{ri} = \beta^i W_{ri}\ , \tag{41}$$

where β is the equilibrium constant for the addition of the HA molecule to the specified reaction centre and W_{ri} is the statistical factor. It is now possible to find the concentration of each solvate with the aid of the law of mass action:

$$[B_r(HA)_i] = (\beta a)^i W_{ri}\,[B_r] \cdot \frac{f_r}{f_{ri}}\ , \tag{42}$$

where a is the activity of HA in the aqueous phase and f_r and f_{ri} are the activity coefficients of B_r and $B_r[AH]_i$. Bearing in mind that

$$W_{ri} = \frac{r!}{\sigma_r\,(r-i)!\,i!}\ , \tag{43}$$

where σ_r is the symmetry coefficient, it is easy to find the acid concentration C_H and the concentration of the alkylammonium salt C_B in the organic phase:

$$C_H = [HA] + \sum_{i=1}^{r}\sum_{r=1}^{R} (\beta a)^i [B_r] \cdot \frac{f_r}{f_{ri}} \cdot \frac{r!}{G_r\,(r-i)!\,(i-1)!}\ , \tag{44}$$

$$C_B = \sum_{r=1}^{R} r\,[B_r] + \sum_{i=1}^{r}\sum_{r=1}^{R} (\beta a)^i [B_r] \cdot \frac{f_r}{f_{ri}} \cdot \frac{r!\,r}{\sigma_r (r-i)\,i!}\ . \tag{45}$$

In contrast to the studies enumerated above, in this model the organic phase is not regarded as an ideal associated solution. With the aid of the theory of association equilibria, the value of the following function was found by the present authors:

$$\ln\frac{f_r}{f_{ri}} = iR_B\frac{2-z}{2}\left\{\ln\frac{q_s\sum_D r_D C_D}{r_s\sum_D q_D C_D} + \frac{2}{kT}\left[\omega_{as}\left(v_a^2 + v_n v_a - v_a\right) + \omega_{ns}\left(v_n^2 + v_n v_a - 2v_n - v_a\right) - \omega_{an}\left(v_n v_a - v_a\right)\right]\right\} = i\psi(C_H, C_B)\ , \tag{46}$$

where R_B is the number of quasilattice sites occupied by a single molecule of E, z the coordination number of the quasilattice, D a general symbol for a species (solvent molecule, association complex, solvate, etc.), qz the number of nearest neighbours of the species D, C_D the molar concentration of species of type D in the mixture, r_D the number of sites occupied by the corresponding species, a, n, and s are the classes of contact regions (alkyl groups, acid anions, and solvent molecules), v_i is the fraction of contact regions of class i in solution, and ω_{ij} the Guggenheim mutual exchange energy. A numerical estimate of the quantity $\psi(C_H, C_B)$ is possible for specific systems. After carrying out the summation in Eqns. (44) and (45), the following formula is obtained:

$$\beta = \frac{C_H}{(C_B - C_H)\,a}\,e^{-\psi}. \tag{47}$$

Bearing in mind that the multiplier $e^{-\psi}$ is close to unity for low values of C_H, [119] Eqn. (45) can be formally regarded as an expression of the law of mass action for reaction (32), since C_H may be interpreted as the equilibrium concentration of the extractant [B] and $C_B - C_H$ as the equilibrium concentration of the non-polymerised alkyl ammonium salt. It is clear from the above that reaction (30) in no way reflects the entire complexity of the interactions in the system, although simple equations of type (47) are in fact satisfactorily consistent with experimental data.

---o0o---

The review has demonstrated the exceptional complexity of extraction systems with associated extractants. The authors attempted to emphasise the conflicting nature of the data obtained by different methods for the same systems and to show that this is largely due to the approximate nature of the models of the solution used as a basis for a quantitative interpretation of the results of measurements of macroscopic quantities from the standpoint of the interaction between molecules. In general, one must say that a rigorous interpretation of colligative properties of systems from the standpoint of the determination of the composition and stability of complicated molecular complexes requires also the application of a rigorous theory of the liquid state. However, the only versions of solution theory at present available which meet to the required degree of sophistication are model molecular-statistical theories. Since more rigorous versions of the theory have not been developed at all and have not been used to describe the properties of associated solutions (let alone extraction systems) and in view of their personal preference, the authors attempted to demonstrate that the application of the generalised theory of association equilibria [100] would be definitely useful for the understanding of the characteristics of extraction systems with associated extractants. This standpoint can be readily understood bearing in mind that the models of solutions employed earlier [ideal solution, regular solution (Hilderand model), athermal solution, ideal associated solution, athermal associated solution] are readily described by the fundamental equations of the generalised theory of association equilibria subject to fairly approximate special assumptions concerning the properties of the species in the system.

For example, the general expression for the chemical potential defined by Eqn. (9) has the following properties:

(1) in the absence of specific linkages ($N_i = \sum_{D(i)} N_{D(i)}$, $D(i) \equiv i$, $N_0^i = N_i$) with $r_D = 1$ and $u_{\epsilon\nu} = \frac{1}{2}(u_{\epsilon\epsilon} + u_{\nu\nu})$, the expression describes the chemical potential of the component in an ideal solution;

(2) in the absence of specific linkages with $r_D = 1$ and $u_{\epsilon\nu} \neq \frac{1}{2}(u_{\epsilon\epsilon} + u_{\nu\nu})$, the expression can be readily shown to be equivalent to μ_D in a regular solution;

(3) in the absence of specific linkages with $r_D \neq 1$ and $u_{\epsilon\nu} = \frac{1}{2}(u_{\epsilon\epsilon} + u_{\nu\nu})$, the expression represents the value for an athermal solution;

(4) in the presence of specific linkages with $r_D = 1$ and $u_{\epsilon\nu} = \frac{1}{2}(u_{\epsilon\epsilon} + u_{\nu\nu})$, the expression descibes an ideal associated solution;

(5) in the presence of specific linkages with $r_D > 1$ and $u_{\epsilon\nu} = \frac{1}{2}(u_{\epsilon\epsilon} + u_{\nu\nu})$, the expression corresponds to an athermal associated solution;

(6) in the presence of specific linkages with $r_D > 1$ and $u_{\epsilon\nu} \neq \frac{1}{2}(u_{\epsilon\epsilon} + u_{\nu\nu})$, the expression corresponds to the non-athermal associated solution model.

The study of extraction systems with associated extractants is being rapidly expanded and their practical importance is growing. In this field many surprises and difficulties await the investigator, the overcoming of which may involve a wide-scale employment of modern advances of the statistical theory of solution and an extension of the range of research techniques employed (dielectric constant measurements, Rayleigh light scattering, resonance spectroscopy, diffusion, the dynamo-optical method, measurement of ultrasonic velocities, etc.).

Effective Size in Quantum-mechanical Systems

D.A.Bochvar, I.V.Stankevich, and A.L.Chistyakov

The review presents the results of a number of studies where various integral characteristics of the effective dimensions of quantum-mechanical systems have been derived and justified by interpreting the square of the modulus of the wave function using probability theory. The concepts of the types of electron delocalisation in atoms and molecules and quantities which can serve at its measure as well as hypotheses concerning the integral characteristics of the charge distribution between the effective volume of an atomic-molecular system and the surrounding space are discussed.
The above characteristics have been calculated for a number of specific quantum-mechanical systems, in particular for some of the simplest atoms and molecules.
The bibliography includes 34 references.

I. INTRODUCTION

This paper presents the result of a number of studies in which various integral characteristics of the effective dimensions of quantum-mechanical systems were derived and their validity was proved. These concepts are related primarily to hypotheses concerning the types and quantities used as measures of electron delocalisation in atoms and molecules and integral characteristics of charge distribution between the effective volume of an atomic-molecular system and the surrounding space.

One of the significant changes introduced by quantum mechanics into the description of an atomic-molecular system was the elimination of the classical concept of an atom or molecule having a specific volume. The square of the modulus of a normalised wave function of an n-particle system is interpreted as the probability density of a $3n$-dimensional continuous random quantity. The electrons of atoms and molecules can be located with a finite non-zero probability in any volume element in a three-dimensiona. pace. For this reason, the pre-quantum-mechanical concept of a definite volume is no longer applicable to an atom or molecule.

Nevertheless the concept of quantities characterising the "effective" dimensions or "effective" volumes of quantum-mechanical systems retains its physical significance and usefulness. As a rule, the methods adopted for the determination of quantities of this kind are related to specific methods for the experimental investigation of the structure of matter.

At the same time it is also possible to justify theoretically the concept of the effective dimensions of an atomic-molecular system. The definition of such concepts uses the generally accepted interpretation of the square of the modulus of the wave function on the basis of probability theory as the probability density of the configuration of the system. In order to characterise completely the distribution, it is generally speaking necessary to know the entire infinite series of its moments. The definition of the concept of the effective dimensions of an atomic-molecular system employs only some of the integral characteristics of the distributions. We shall consider briefly the most important of these characteristics.

Suppose that the state of an n-electron system is described by a normalised function $\psi(\mathbf{x})$, where $\mathbf{x} = (\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_n)$ denotes a set of cartesian coordinates of n electrons and $\mathbf{x}_i = (x_{i1}, x_{i2}, x_{i3})$ denotes the coordinates of the ith particle. We put

$$\rho(\mathbf{x}) = |\psi(\mathbf{x})|^2$$

$\rho(\mathbf{x})$ can then be treated as the density of the distribution of a $3n$-dimensional random vector $\mathbf{X} = (\mathbf{X}_1, \mathbf{X}_2, \ldots, \mathbf{X}_n)$. whose components $\mathbf{X}_i = (X_{i1}, X_{i2}, X_{i3})$ are three-dimensional random quantities with the distribution densities

$$\rho_i(\mathbf{x}_i) = \int \rho(\mathbf{x})\, d\mathbf{x}_1 \ldots d\mathbf{x}_{i-1}\, d\mathbf{x}_{i+1} \ldots d\mathbf{x}_n.$$

Each of the densities $\rho_i(\mathbf{x}_i)$ describes the distribution of the coordinates of the individual ith particle with all other particles in their average positions. We shall denote by $K(\mathbf{X})$ the covariance matrix of the n-particle system:

$$K(\mathbf{X}) = \begin{pmatrix} \mathcal{K}_{11}\mathcal{K}_{12} \ldots \mathcal{K}_{1n} \\ \mathcal{K}_{21}\mathcal{K}_{22} \ldots \mathcal{K}_{2n} \\ \ldots\ldots\ldots \\ \mathcal{K}_{n1}\mathcal{K}_{n2} \ldots \mathcal{K}_{nn} \end{pmatrix},$$

where $\mathbf{K}_{ij}$ is the covariance matrix of the ith and jth particles (see Section III, 5).

The quantity $D(\mathbf{X}) = \det K(\mathbf{X})$ is termed the general variance of the n-electron system. In model problems where the theoretical probability characteristics of a one-dimensional particle are investigated, this quantity is

identical with the variance of a one-dimensional distribution generated by the corresponding wave function. The quantity

$$H(\mathbf{X}) = -\int \rho(\mathbf{x}) \ln \rho(\mathbf{x})\, d\mathbf{x}$$

is termed the entropy of the quantum-mechanical distribution with a density $\rho(\mathbf{x})$ for an n-particle system†. We put $v = \exp H$ and $V = \sqrt{(2\pi e)^{3n} D}$. These quantities are termed respectively the internal and external effective volumes of the n-particle system.

The entropy and external and internal volumes for the distribution of the ith particle or a subsystem of particles with all other particles in their average positions can be defined similarly.

The introduction of general variances makes it possible to extend the concept of the correlation coefficient (describing the relation between two one-dimensional random quantities) to cases where the correlation of particles (i.e. of multidimensional random quantities) is investigated. Namely, if $D(\mathbf{X}_i)$ is the general variance of the ith particle and $D(\mathbf{X}_i, \mathbf{X}_j)$ the general variance of a system of two particles (the ith and jth particles) in an n-particle system, the general correlation coefficient $r(\mathbf{X}_i, \mathbf{X}_j)$ (or the correlation coefficient of two particles) is given by the formula (see Section III, 5)

$$r(\mathbf{X}_i, \mathbf{X}_j) = \sqrt{1 - D(\mathbf{X}_i, \mathbf{X}_j)/D(\mathbf{X}_i)\, D(\mathbf{X}_j)}.$$

Like the usual correlation coefficient, the above coefficient represents a measure of linear correlation. Similarly, the internal correlation coefficient $r_i(\mathbf{X}_i, \mathbf{X}_j)$, introduced in Section III, 6 and defined in terms of the internal volume, also takes into account non-linear correlation.

The entropy and variance reflect, generally speaking, different features of the distribution, significantly supplementing one another. The usefulness of the entropy of a quantum-mechanical distribution together with the variance for the characterisation of the effective size is confirmed by the close relation between this quantity and Heisenberg's uncertainty principle. This principle, together with its variance expression, also permits a formulation in terms of the entropy of distributions. The entropy expression, which is logically stronger and physically more significant, makes it possible to exclude the occurrence of certain situations which are not ruled out by the variance formulation (see Section III, 8).

The formulation of the uncertainty principle is not restricted to a pair of canonically coupled one-dimensional particles such, as, for example, the components of the vector-coordinate $\mathbf{r}_i$ and the corresponding components of the momentum-vector $\mathbf{p}_i$. The uncertainty in the position of a particle or a system of particles can be described not only by one-dimensional characteristics (variances along the coordinate axes), but also by the available volume characteristics such as the covariance matrix, the general variances, and the internal and external volumes. As shown in Section III, 8, the uncertainty principle can be expressed also in terms of all the above volume characteristics. This formulation of the uncertainty principle is stronger than the corresponding one-dimensional formulations.

The calculations of the effective volumes for the simplest atoms and molecules show that these quantities are fairly close to the values found from experimental studies on the viscosities of gases and vapours, which also demonstrates the usefulness of the theoretical definitions of the effective volumes of quantum-mechanical systems.

The variance of the distribution has been used for a long time in quantum mechanics to characterise the uncertainty of the position of the particles. However, the usefulness of the concept of entropy in quantum mechanics was considered for the first time in 1960 by Segal[1]. Hirschman[2] showed that Heisenberg's uncertainty principle can be formulated in terms of the entropies of quantum-mechanical distributions in the coordinate and momentum representations.

Bochvar, Gambaryan, Stankevich, and Chistyakov[3-5] used the concept of the entropy of the distribution to characterise the measures of the delocalisation of electrons and the effective size in atomic-molecular systems.

In a study of studies by Rubanov, Stepanov, and Sedoi[6-9] certain general properties of the entropy functional were investigated and the entropies of the distributions, associated with the wave functions of the simplest quantum-mechanical systems were found.

We shall now consider briefly the contents of this review. Section II deals with the available results of the calculations of the effective volumes of the simplest atomic-molecular systems. The reader interested only in the application of the above concepts of internal and external volumes to specific systems need peruse only this part of the article.

Section III presents a detailed analysis of the concepts of entropy and general variance for the case of many particles. The entropy formulation of the uncertainty principle is discussed in Subsection 8 of Section III.

II. EFFECTIVE DIMENSIONS OF SIMPLEST ATOMIC AND MOLECULAR SYSTEMS

The effective theoretical dimensions of quantum-mechanical systems are interesting from different points of view. One of the significant aspects of the formation of a chemical bond is the redistribution of electron density in the vicinity of atomic nuclei. This redistribution is accompanied by a change in the effective dimensions of the system, its effective internal and external volumes, and the associated change in the normality coefficient N‡.

It is important to have a correct idea concerning the charge distribution in the electron shells of the atoms and molecules between the inner part of the atom or a molecule included in the effective volume and the infinite space external to such volume.

It is interesting to compare the effective theoretical dimensions of atoms and molecules with their effective dimensions determined by the application of various experimental research techniques.

However, one should bear in mind that the entropy H and the general variance D of the distribution are sensitive to the type of wave function employed in the calculation. Therefore serious limitations in the choice of data for the calculations are inevitable. Only fairly accurate wave functions, a further refinement of which no longer has a significant influence on the calculated entropy H and general variance D of the distribution, are suitable for

†We emphasise that this concept must not be confused with the concept of entropy in thermodynamics, as is done, for example, in the book "Dialektika Razvitiya Khimii" (Dialectics of the Development of Chemistry) by V. I. Kuznetsov, Izd. Nauka, Moscow, 1973, pp. 198–199.

‡For a definition of the normality coefficient N, see Section III, 1.

the calculation of the effective dimensions of quantum-mechanical systems.

In this Section the concepts of the entropy and variance refer to the three-dimensional electron density. The information contained in the effective atomic and molecular dimensions, which is of interest primarily from the quantum-chemical point of view, is presented and discussed below. Table 1 gives the results of the calculation of the effective volumes in the ground states of one-electron systems (the H atom, the He^+ ion, and the H_2^+ molecular ion) and the ground states of two-electron systems (the H^- ion, He, Li^+, and H_2). Table 1 also includes the values of v for the H(2s) atom.

Table 1. Effective volumes of the simplest quantum-mechanical systems[a].

System[b]	References	$v\ (a_0^3)$	$V\ (a_0^3)$	N	$r\ (X_1, X_2)$
H (1s)		63.1	70.59	0.894	—
H (2s)		3330.7	3697.6	0.901	—
He^+		7.89	8.82	0.895	—
H_2^+	10	45.15	—	—	—

H_2	15	50.91	—	—	—
H_2	16	—	54.38	0.936[c]	0.1860

[a] A number of the calculations were made by S. S. Abdullaev.
[b] In the calculation of the effective volumes different approximate wave functions were employed. References are given to studies in which these wave functions were found. Where there are no references, the calculation was made using the exact wave functions. The characteristics of all the systems, with the exception of the H atom, are quoted only for the ground states.
[c] The normality coefficient was found using the internal volume calculated from James and Coolidge's function [15].

The data in Table 1 permit a number of conclusions.

1. For two-electrons spherically symmetrical neutral or positively charged systems, the difference between the external and internal effective radii (R_{ext} and R_{int} respectively) is insignificant. For He and Li^+, $R_{ext}/R_{int} \simeq \simeq 1.05$. With a negative charge, this ratio must of course be somewhat greater than for the corresponding neutral or positively charged systems. Thus $R_{ext}/R_{int} \simeq 1.14$ for H^-. For the hydrogen molecule, the ratio of the average lengths of the effective half-axes of the ellipsoids bounding v is $R_{ext}/R_{int} \simeq 1.02$.

2. For one-centre systems, the addition of a second electron to a one-electron system gives rise to a marked increase of the effective volume v, which also depends on the nuclear charge.

Comparison of H_2^+ and H_2 in the ground states also leads to the conclusion that v increases, although to a smaller extent than for one-centre systems. In this more complex case an effect involving the contraction of the internuclear distance obtains, which partly cancels the increase of v due to electron-electron repulsion.

3. In one-centre two-electron systems an increase of nuclear charge causes a marked decrease of v and V, as can be seen in the series of H^-, He and Li^+ in their ground states. The coefficient N increases—the distribution approaches significantly the normal distribution.

4. The formation of an H_2 molecule from two H atoms entails an appreciable decrease of v compared with the value for the 1s state of the H atom, namely by $11.89a_0^3$.

The fact that $v = 50.91a_0^3$, calculated by Bochvar et al. [17] using the James–Coolidge function [15], is much smaller than the value derived from the wave function of the simple MO-LCAO method [4] ($79.84a_0^3$) merits attention. Table 1 shows that the latter actually exceeds the value of v for the 1s state of the H atom. Hence it follows that the wave functions of the LCAO method in all its versions employing rigid atomic orbitals are unsuitable for a quantitative description of the properties of the electron density distribution in molecules.

5. $v = 45.15a_0^3$ for the ground state of H_2^+, i.e. is smaller by $5.76a_0^3$ than v for the ground state of the H_2 molecule. The overall positive charge and the absence of electron-electron repulsion surpass the effect of the increase in the internuclear distance R due to the weakening of the bond.

6. Comparison of the H_2 and He two-electron systems shows that, whereas v for the He atom in the ground state decreases almost by a factor of two on single ionisation (from $14.88a_0^3$ to $7.89a_0^3$, i.e. by a factor of 1.87), on removal of one electron from the H_2 molecule in the ground state with conversion into H_2^+ also in the ground state v decreases only by $5.7a_0^3$.

The explanation of this fact is that, in the vertical ionisation of H_2, v is reduced by $18.12a_0^3$, i.e. to $32.79a_0^3$ (by a factor of 1.55), but this contraction is partly compensated by the increase of R from $1.4a_0$ to $2a_0$, which leads to an increase of v from $32.79a_0^3$ by $12.36a_0^3$, i.e. to $45.15a_0^3$.

7. The correlation coefficients $r(X_1, X_2)$ for electrons in two-electron systems listed in the last column of Table 1 make it possible to infer the correlation of electrons from the standpoint of probability theory. We note in the first place that, in contrast to the correlation energy, the correlation coefficient of electrons is estimated for any approximate function (poor or satisfactory) without resorting to experimental data or the exact wave function. As the exact wave function is approached, the correlation coefficients should tend to a limit. Calculations show that the values of $r(X_1, X_2)$ for all three fairly satisfactory wave functions of the helium atom yield, to within 0.01, the same value $r(X_1, X_2) = 0.09$. It is noteworthy that (in the present authors' view) the internal correlation coefficient $r_H(X_1, X_2)$ defined by Eqn. (6, 1) allows more completely for the correlation of electrons. According to this hypothesis, $r_H(X_1, X_2)$ calculated from the Hylleraas function [14] is 0.20, which greatly exceeds $r(X_1, X_2) = 0.09$.

Proceeding now to a comparison of the correlations in different systems, we note that in many isoelectronic systems (H^-, He, Li^+) $r(X_1, X_2)$ decreases with increase of the nuclear charge. Its values are respectively 0.12, 0.09, and 0.07. The correlation coefficient of the electrons in the H_2 molecule is 0.186 and is largely determined by the correlations of the z components (directed along the lines of the bond) of both electrons: $|r(z_1, z_2)| = 0.156$.

In many systems the negative charges in regions within and outside the effective volume v were calculated from the data in Table 1. [18] The surfaces bounding the effective volumes v for one-centre systems were naturally regarded as spherical, while for the two-centre systems H_2^+ and H_2 they were assumed to be ellipsoids of rotation with the foci located at the atomic nuclei. The calculation reduced to the integration of the three-dimensional probability

density (corresponding to the three-dimensional charge density) over the corresponding regions. The calculated charges Z_{int} within the effective volumes v and the charges Z_{ext} outside the effective volumes are listed in Table 2. For the two-electron systems He and H_2, Table 2 also includes the unit probabilities defined as the probability sums

$$1 = P^{(2,0)} + P^{(1,1)} + P^{(0,2)}, \qquad (*)$$

where $P^{(2,0)}$ is the probability of finding both electrons within the volume v, $P^{(1,1)}$ the probability of finding one electron in the volume v and the other electron outside this volume, and $P^{(0,2)}$ the probability of finding both electrons outside the volume v. When calculating the charges within and outside the volume v, Eqn. (*) must be multiplied by two and account must be taken of the fact that the situation where one electron is within the volume v and the other is outside it, which has a probability $P^{(1,1)}$, makes different contributions to the charge within the volume v and the charge distributed in the space outside v.

Table 2. Charge distributions for the simplest quantum-mechanical systems (in the ground state).

System	$v\,(a_0^3)$	Z_{int}^{a}	Z_{ext}	$P^{(2,0)b}$	$P^{(1,1)}$	$P^{(0,2)}$
He^+	7.89	0.871	0.129			
H_2^+	45.15	0.893	0.103			
H (1s)	63.1	0.870	0.130			
He	14.88	1.6956	0.3044	0.7080	0.2796	0.0125
H_2	50.91	1.744	0.256	0.7525	0.1280	0.0085

[a] Z_{int} is the charge (in electronic units) in the effective volume v; Z_{ext} is the charge (in electronic units) outside the effective volume v.
[b] $P^{(2,0)}$ is the probability of finding two electrons in the volume v, $P^{(1,1)}$ the probability of finding one electron in the volume v and another electron outside this volume, and $P^{(0,2)}$ the probability of finding two electrons outside the volume v.

The comparatively small range of values of Z_{ext} (per electron) in Table 2, despite the significant differences between many systems, is striking (only from 10.7 to 14.0%). For the H(1s), He^+, and H_2 systems, Z_{ext} (per electron) is almost constant. This finding suggests the hypothesis that significant differences in charge distribution occur only within the effective volumes. Outside the effective volumes, the distributions are similar for different systems, and a spherical distribution is approached more closely the further away one moves from the system of nuclei.

As mentioned above, for the surfaces bounding the internal effective volumes of one-centre systems it is natural to adopt the geometry of the sphere with the centre at the atomic nucleus and, for homonuclear two-centre systems with cylindrical symmetry (H_2^+ and H_2), the geometry of an ellipsoid of rotation with the foci at the atomic nuclei. With these assumptions, it is possible to calculate the effective linear dimensions of the systems.

Table 3 lists the effective diameters d_{ef} of the H and He atoms in their ground states and the effective lengths of the axes $2a_{ef}$ and $2b_{ef}$ of the ellipsoids of rotation for the molecular ion H_2^+ and the molecule H_2, also in their ground states. The average values of d_{ef} obtained from the effective axes of the ellipsoids are also listed for H_2^+ and H_2.

Table 3 also contains (the extreme right-hand column) the effective diameters of He and H_2 calculated from the experimental viscosities of the gases [19] at high temperatures by Chapman's formula [20]:

$$\eta = \frac{1}{\pi\sigma_\infty^2}\sqrt{\frac{kTm}{\pi}},$$

where η is the viscosity of the ideal gas and σ_∞^2 the effective diameter of the species (atom or molecule) of the ideal gas which is assumed to be spherical. The effective external diameter of helium (1.72 Å) is closer to σ_∞ (1.91 Å) than the internal diameter.

Table 3. Effective linear dimensions for the ground states of H, He, H_2^+, and H_2 calculated from the internal volumes.

System	d_{ef}, Å	$2a_{ef}$, Å	$2b_{ef}$, Å	d_{ef}, Å	σ_∞, Å
H	2.62	—	—	—	—
He	1.61	—	—	—	1.91
H_2^+	—	2.50	2.26	2.38	—
H_2	—	2.51	2.39	2.45	2.42

We may note that r_{ef} for the hydrogen atom in the ground state, which is 1.31 Å, exceeds somewhat the van der Waals radius of hydrogen (1.17–1.20 Å). This is quite reasonable, since r_{ef} = 1.31 Å refers to an isolated atom in the ground state, while the van der Waals radius (1.20 Å) corresponds to the state of a hydrogen atom bound in the crystal.

The figures quoted in Table 3 indicate the possibility of interesting relations between the internal (and also external) effective volumes v and the approximate effective volumes of atoms and molecules from other sources (the viscosities of gases, vapours, and liquids, mean free paths in gases, etc.).

According to the foregoing considerations, the internal effective volumes v of the molecular ion H_2^+ and the molecule H_2 in their ground states are smaller than the effective volume v of the H atom in the 1s state. This is understandable, since the formation of a chemical bond should lead to a decrease of the entropy of the three-dimensional distribution of electron density.

However, it is at the same time reasonable to suppose that in each case where a chemical bond is formed there is a certain characteristic one-dimensional density distribution the entropy of which in fact increases. A test of this hypothesis [21] for the ground state of the molecular ion H_2^+ with the exact wave function [10] and for the ground state of the molecule H_2 with the James–Coolidge function [15], in relation to the ground state of the hydrogen atom, is consistent with the above hypothesis, as can be seen from Table 4. In the Table h denotes the entropies of the one-dimensional distribution of entropy density in the H_2^+ and H_2 systems in a direction parallel to the z axis passing through the protons, while for the hydrogen atom it denotes, in view of its spherical symmetry, the entropy of the one-dimensional distribution of electron density in a direction parallel to an arbitrarily chosen diameter.

The situation in the H_2 molecule is more complicated than in the ion H_2^+, since there is the additional effect of the electron-electron repulsion. This last factor tends to increase h and v. On the other hand, in contrast to the attraction of one-electron in H_2^+, the attraction of two electrons to two protons results in a decrease of the distance R between the protons, which tends to reduce h and v. As a result, the effective volume v in the ground state of the H_2 molecule is somewhat smaller than for the ground state of the H_2^+ ion, remaining, however, greater than v for the ground state of the hydrogen atom.

Table 4. One-dimensional effective volumes for the ground states of H, H_2^+ and H_2.

System	h	$v = \exp h$ (a_0)
H	1.39	4.01
H_2^+	1.47	4.35
H_2	1.43	4.18

The entropy of the distribution and the internal volumes for the wave functions in the electron gas model (the lateral cylindrical surface model) for molecules with a "sandwich" type structure were investigated by Bochvar et al.[22] In this study the entropy of the distribution was used as a qualitative characteristic of the degree of conjugation between the carbon rings in molecules of the dibenzene-chromium and ferrocene type.

In conclusion we may mention a number of studies in which the concept of the entropy of a discrete distribution is used for quantum-mechanical systems.

In conformity with studies by Daudel and coworkers[23], who were the first to introduce the concept of the "loge", Aslangul[24] employed the entropy of a discrete distribution to characterise the information which can be extracted from the wave function by considering arbitrary subdivisions of the coordinate space into regions and by assigning to each such region the probability of finding a definite number of electrons in it. The applications of certain properties of the entropy of spin operators have been considered[25].

The definition of the information contained in the state of one quantum-mechanical system relative to the state of another has been discussed[26]. In Zhdanov's book[27] the entropy is used to obtain information about the relative reactivities of conjugated molecules. Primas[28] suggested that the criterion of a minimum in the entropy function be used in certain cases for the derivation of approximate wave functions.

III. THEORY OF EFFECTIVE DIMENSIONS OF QUANTUM-MECHANICAL SYSTEMS

1. Effective Size in a One-Dimensional Quantum-Mechanical System

In order to elucidate the significance of the principal definitions of the theory of the effective volumes of quantum-mechanical systems without complicating the treatment with cumbersome mathematical formulae, we shall consider initially the simplest and most evident case of one-dimensional probability density on the coordinate of a single particle located on an infinite straight line. In this case the wave function $\psi(x)$ is a function of a single variable. Then

$$\rho(x) = |\psi(x)|^2 \tag{1.1}$$

is the probability density of the coordinate for point x on the straight line. The general variance is identical with the usual variance:

$$D = \int_{-\infty}^{\infty} (x - m)^2 \rho(x)\, dx, \tag{1.2}$$

where $m \int_{-\infty}^{+\infty} x\rho(x)dx$ is the expectation value of the coordinate for the distribution $\rho(x)$ and the entropy H is§

$$H = -\int_{-\infty}^{\infty} \rho(x) \ln \rho(x)\, dx. \tag{1.3}$$

Both the quantities D and H characterise the uncertainty in the coordinate of the one-dimensional particle. In order to emphasise the differences between these quantities, we shall resort to an example. Fig. 1*a* represents the density $\rho_1(x)$ of the uniform distribution along a section $[a, b]$ of length L. Fig. 1*b* represents the density of the distribution $\rho_2(x)$ concentrated uniformly on two sections $[a_1, b_1]$ and $[a_2, b_2]$ with an overall length L. The entropies of the distributions $\rho_1(x)$ and $\rho_2(x)$ are equal for any values of $t = a_2 - b_1 > 0$, while the corresponding variances are different, that of $\rho_2(x)$ increasing with increase of the parameter t. This example shows that the entropy is an absolute¶ characteristic of the distribution which reflects the scatter within the regions of the localisation of the distribution regardless of the relative positions of these regions. The variance of the distribution also depends on the relative scatter of the localisation regions. In this sense the variance can be regarded as a relative characteristic of the distribution.

In real problems one can encounter cases more complex than those illustrated in Fig. 1. The distribution densities may not become zero and may have several maxima (corresponding to the localisation regions). The entropy of the distribution characterises, to a rough

§For the logarithmic term in the integrand to be significant, it is necessary that the integrand should be dimensionless. To achieve this, the definition of H must be reformulated as follows[29]:

$$H = -\int_{-\infty}^{+\infty} \rho(x) \ln [\rho(x)\, l]\, dx\ ,$$

where l is a certain length. We shall assume (without restricting the generality of the treatment) that this length is unity. Then H has the significance of the average logarithm of a certain length; in the n-dimensional case H has the significance of the average value of an n-dimensional volume.

¶The absolute nature of the entropy is expressed by the fact that the integrand depends on the coordinate only through the density. This is in fact the cause of the property of entropy considered in this example.

approximation, the overall scatter within the localisation regions and the variance also takes into account the scatter of the localisation regions. The entropy and the variance each reflect the degree of delocalisation of the particle.

Entropy and variance can be used to characterise the effective dimensions of a one-dimensional particle. For this purpose, it is convenient to introduce the concept of effective volumes: the internal effective volume v defined in terms of the entropy by the formula

$$v = \exp H \tag{1.4}$$

and the external effective volume defined in terms of the variance by the formula

$$V = \sqrt{2\pi e D}. \tag{1.5}$$

We may note that, for a uniform distribution on the section $[a, b]$ with a length L (Fig. 1*a*), the internal volume is equal to the length of the section: $v = L$.

For any one-dimensional distribution, the following inequality is valid:

$$H \leqslant \frac{1}{2}\ln(2\pi e D). \tag{1.6}$$

Hence it follows that always $v \leqslant V$†. The equality of these volumes holds only for normal‡ (Gaussian) distribution.

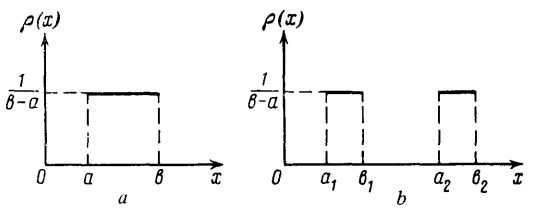

Figure 1.

Fig. 2 presents a plot of D as a function of $H = -\int \rho(x)\ln\rho(x)dx$ for normal distributions. The points located above the curve represent non-Gaussian one-dimensional distributions. When the variance is specified (for example D_0 in Fig. 2), the maximum entropy H_0 holds for the normal distribution. When the entropy is specified (for example H_0, Fig. 2) the minimum variance D_0 holds also for the normal distribution.

Evidently the following inequality is valid for any distribution:

$$v/V \leqslant 1. \tag{1.7}$$

The sign of equality in Eqn. (1.7) holds for normal distributions and only for normal distributions. Therefore it is reasonable to introduce the definition

$$N = v/V$$

and to term the quantity N $(0 \leqslant N \leqslant 1)$ the coefficient of the normality of the distribution. For all normal distributions, $N = 1$. For a uniform distribution, the normality coefficient is a constant quantity of about 0.7. The normality coefficient can be interpreted as the average "degree of population" of the external effective volume of the system with the given distribution. This interpretation presupposes a spatial localisation of the effective volumes v and V involving certain assumptions. These assumptions are chosen in accordance with the nature of the system for which the given distribution is observed. It is noteworthy that, in contrast to the effective volume V, the geometrical interpretation of the effective volume v may show it to be unconnected. We shall consider several examples.

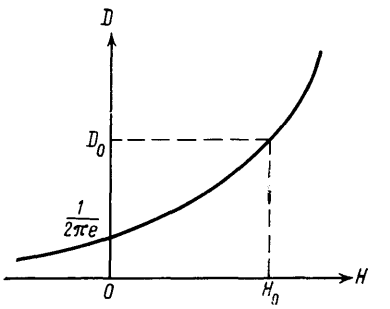

Figure 2.

A one-dimensional particle in a potential well with a finite length L, an infinitely high wall, and a constant potential within the well has a normalised wave function of the type

$$\psi_n(x) = \sqrt{\frac{2}{L}}\sin\frac{\pi n x}{L}, \quad (0 \leqslant x \leqslant L),$$

where n is the quantum number. The entropy H of the electron density distribution $|\psi_n(x)|^2$ is $\ln(2L/e)$ and therefore it depends only on L and is independent of the quantum number n. The variance of the electron density distribution $D(|\psi_n|^2)$ depends on L and n:

$$D(|\psi_n|^2) = L^2\left(\frac{1}{12} - \frac{1}{2\pi^2 n^2}\right).$$

The limiting value of $D(|\psi_n|^2)$ when $n \to \infty$ is $\frac{1}{12}L^2$. Table 5 lists the values of v, V, and the normality coefficient N.

Table 5. Effective volumes of the wave functions of a particle in a one-dimensional potential well.

n	v/L	V/L	N
1	0.736	0.747	0.985
2	0.736	1.098	0.670
30	0.736	1.192	0.617

It shows that the normality coefficient decreases with increase of n and almost attains its limiting value when $n = 30$.

†This relation justifies the terms "external" and "internal" for v and V.

‡The normal distribution has the density $\rho_N(x) = (2\pi D)^{1/2}\exp[-(x-m)^2/2D]$.

As a second example, we present in Table 6 analogous data for the first ten eigenstates of the harmonic oscillator. Evidently the normality coefficient gradually decreases with increase n.

Consider now, a particle localised at the point x_0. Its distribution density is given by the δ-function $\delta(x-x_0)$, the variance is zero, and the entropy is strictly speaking undefined. Nevertheless it is convenient to attribute $H[\delta(x-x_0)] = -\infty$ and the internal volume $v = 0$ to the δ-function, since the entropy tends to $-\infty$ for sequences of the type $\rho_1(x)$ and $\rho_2(x)$ which tend to the δ-function when $L \to 0$ and $D \to 0$. To ensure the validity of the treatment, it will be necessary to show that the entropy tends to $-\infty$ in any δ-sequence.

The introduction of the terms "internal" and "external" for the effective volumes is based on the fact that for specific geometrical interpretations of these quantities, the part of the space representing the entropy volume is contained within the part of the space representing the variance volume or is identical with it for normal distributions§.

Table 6. Effective volumes of the wave functions of a harmonic oscillator.

n	v	V	N
0	2.92	2.92	1.00
1	3.83	5.06	0.76
2	4.47	6.53	0.68
3	4.98	7.73	0.64
4	5.40	8.76	0.62
5	5.79	9.69	0.60
6	6.13	10.54	0.58
7	6.45	11.32	0.57
8	6.72	12.05	0.56
9	6.98	12 74	0.55

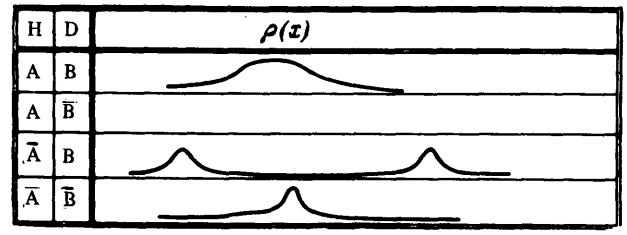
As stated above, in order to characterise fully the distribution it is necessary to know all its moments. However, a rough and purely qualitative classification of one-dimensional distributions with respect to entropy and variance can be formulated as follows: (a) each distribution belongs to one and only one of two classes $\mathbf{A}(H \geqslant 0)$ or $\bar{\mathbf{A}}(H < 0)$; (b) each distribution belongs to one and only one of two classes $\mathbf{B}[D \geqslant (2\pi e)^{-1}]$ or $\bar{\mathbf{B}}[D < (2\pi e)^{-1}]$. Four combinations of the above criteria, corresponding to four classes (one of these classes is empty), are presented in Table 7. The $\rho(x)$ column of Table 7 lists fairly typical distributions of three classes (**A**, **B**), ($\bar{\mathbf{A}}$, **B**), and ($\bar{\mathbf{A}}$, $\bar{\mathbf{B}}$). The normal or Gaussian distribution and a uniform distribution can belong to either of the two classes (**A**, **B**), and ($\bar{\mathbf{A}}$, $\bar{\mathbf{B}}$) depending on their parameters. Linear combinations of Gaussian or uniform distributions are encountered (depending on the parameters) in all non-empty classes. Among the examples of the three classes, two correspond to two sharply different extreme types of particle delocalisation and one to a marked localisation at one centre.

Between the extreme types of delocalisation, there is a continuous series of transitional cases referring, depending on the parameters, to class (**A**, **B**) or to ($\bar{\mathbf{A}}$, **B**).

§Thus the internal effective volume v of the distribution is equal in magnitude to the effective volume of the isentropic normal distribution, which is uniquely defined.

Next we proceed from the one-dimensional case to the consideration of real multidimensional (one- and many-particle) systems. The generalisation of the concept of the internal effective volume does not require additional justification, since the above definition of entropy changes on being extended to the multidimensional case only with respect to the interpretation of the variable integration symbol. However, the usual definition of variance quoted above is essentially one-dimensional. Therefore the concept of the external effective volume cannot be generalised to include multidimensional systems and it is necessary to define not only a more general but formally also a more complex concept.

Table 7. Classification of one-dimensional distributions with respect to the entropies and variances.



2. The Covariance Matrix and General Variance of a particle

We shall now consider a real physical object (the electron¶) in a potential field. Suppose that the state of the electron is described by the wave function $\psi(x_1, x_2, x_3)$ normalised to unity ($\int |\psi(x_1, x_2, x_3)|^2 d\mathbf{x} = 1$)†.

We put

$$\rho(\mathbf{x}) = |\psi(x_1, x_2, x_3)|^2, \tag{2.1}$$

where $\mathbf{x} = (x_1, x_2, x_3)$ are the coordinates of the electron. Then $\rho(\mathbf{x})$ can be treated as the probability density of a three-dimensional random quantity $\mathbf{X} = (X_1, X_2, X_3)$. Its components are one-dimensional random quantities X_1, X_2, X_3, which correspond to the coordinates x_1, x_2, x_3. The densities of the distribution of these one-dimensional random quantities are defined by the formulae

$$\rho_1(x_1) = \iint \rho(\mathbf{x})\, dx_2\, dx_3, \quad \rho_2(x_2) = \iint \rho(\mathbf{x})\, dx_1\, dx_3, \quad \rho_3(x_3) = \int\int \rho(\mathbf{x})\, dx_1\, dx_2. \tag{2.2}$$

We shall employ the probability theory for the description of the delocalisation of a three-dimensional particle. We first recall the definition of the covariance matrix which characterises the deviation of a random quantity $\mathbf{X}$ from a point $M(m_1, m_2, m_3)$ the coordinates of which are given by the formulae

$$m_s = \int x_s \rho(\mathbf{x})\, d\mathbf{x} \quad (s = 1, 2, 3). \tag{2.3}$$

¶Or any other quantum-mechanical particle.

†For brevity we put $dx = dx_1 dx_2 dx_3$ and omit the integration limits. Here and henceforth the integration is from $-\infty$ to $+\infty$ with respect to each one-dimensional variable.

The radius-vector of the point M is called the expectation value of the random quantity X and is designated by $M(\mathbf{X})$. The covariance matrix (or the second moment matrix) is defined as

$$\mathcal{K}(\mathbf{X}) = \begin{pmatrix} k_{11} & k_{12} & k_{13} \\ k_{21} & k_{22} & k_{23} \\ k_{31} & k_{32} & k_{33} \end{pmatrix}, \tag{2.4}$$

the elements of which are

$$k_{st} = \int (x_s - m_s)(x_t - m_t)\,\rho(\mathbf{x})\,d\mathbf{x}. \tag{2.5}$$

The matrix K(X) is symmetrical ($k_{ts} = k_{st}$). Its diagonal elements are the variances $D(X_s) = \sigma_s^2$ of the components X_s and the non-diagonal elements $k_{st} = \mathrm{Cov}(X_s, X_t)$ are the covariances of the components X_s and X_t. The covariance characterises the statistical correlation between the random quantities X_s and X_t. It depends on the choice of scale. In order to eliminate this dependence, the concept of the normalised correlation or the correlation coefficient of two one-dimensional random quantities X_s and X_t is introduced. It is defined by the formula

$$r_{st} = r(X_s, X_t) = \frac{\mathrm{Cov}(X_s, X_t)}{\sqrt{D(X_s)\,D(X_t)}}. \tag{2.6}$$

It can be shown[30] that the following inequality always holds:

$$|r_{st}| \leqslant 1. \tag{2.7}$$

The equality is attained only when the variables X_s and X_t are linearly related. On the other hand, if the random quantities X_s and X_t are independent, then $r_{st} = 0$‡. We shall now determine what information about the delocalisation of the particle can be derived from the matrix K. As already mentioned, the diagonal elements characterise the scatter of the coordinates x_1, x_2, and x_3. In order to determine the scatter in the direction of an arbitrary vector $\mathbf{c}(c_1, c_2, c_3)$, it is necessary to calculate the scaler product of K(X)c and c, i.e.,

$$D_{\mathbf{c}}(\mathbf{X}) = (\mathcal{K}(\mathbf{X})\mathbf{c}, \mathbf{c}) = \sum_{i=1}^{3}\sum_{j=1}^{3} k_{ij} c_j c_i. \tag{2.8}$$

Thus the covariance matrix contains the full information about the delocalisation of the particle in any direction. However, together with the matrix characteristic of the scatter, scalar quantities describing the scatter of a random vector quantity X in terms of a single integral number are of interest.

Before stating these characteristics, we shall elucidate the requirements which they must satisfy. Hitherto, the coordinate system was fixed. On passing to a new coordinate system x_1, x_2, x_3 by an orthogonal transformation (including rotations and reflections)

$$\mathbf{x}' = U\mathbf{x} \tag{2.9}$$

the random quantity X will have the distribution density

$$\tilde{\rho}(\mathbf{x}') = \rho(U^{-1}\mathbf{x}'). \tag{2.10}$$

The substitution (2.9) may be treated as a change to a new random vector (in the old coordinate system)

$$\mathbf{X}' = U\mathbf{X} \tag{2.11}$$

with distribution density

$$\tilde{\rho}(\mathbf{x}) = \rho(U^{-1}\mathbf{x}). \tag{2.10'}$$

The covariance matrix of the random vector X′ (or, what amounts to the same thing, the covariance matrix of the initial random vector in the new coordinate system) is

$$\mathcal{K}(\mathbf{X}') = U\mathcal{K}(\mathbf{X})U^{-1}. \tag{2.12}$$

Since the entire class of random vectors X′ obtained from the initial vector X by all possible orthogonal transformations describes the same state of the particle, the required scalar characteristics must be invariant in the above transformations. Such invariant characteristics are the "spur" of the matrix K(X) (the sum of its diagonal elements)

$$\mathrm{Sp}\,\mathcal{K}(\mathbf{X}) = D(X_1) + D(X_2) + D(X_3) \tag{2.13}$$

and the determinant§

$$D(\mathbf{X}) = \det \mathcal{K}(\mathbf{X}), \tag{2.14}$$

called the general variance of a random quantity X.[30] We shall also call it the general variance of the coordinates of the particle [in the state $\psi(\mathbf{x})$]. We shall now consider the geometrical significance of the above quantities. If we denote by $\Delta\mathbf{X}$ the random vector $\mathbf{X} - M(\mathbf{X})$, then it is readily seen that the spur of the matrix K(X) represents the expectation value of the quantity $|\Delta\mathbf{X}|^2$, i.e. $M(|\Delta\mathbf{X}|^2)$. This quantity has the dimensions of the square of a length. Therefore $\sqrt{M(|\Delta\mathbf{X}|^2)}$ characterises the scatter of the values in the direction of the radius-vector drawn from a point and cannot provide an answer to the question of whether the particle is localised in the vicinity of a plane or a straight line. We emphasise that the quantity $M(|\Delta\mathbf{X}|^2)$ is essentially a one-dimensional characteristic.

In contrast to the quantity $M(|\Delta\mathbf{X}|^2)$ the general variance $D(\mathbf{X})$ characterises a multidimensional scatter. In order to elucidate the geometrical significance of this quantity, we shall consider further the quantity

$$D^*(\mathbf{X}) = D(X_1)\,D(X_2)\,D(X_3). \tag{2.15}$$

The standard deviation $\sigma^*\sqrt{D^*}$ corresponding to this quantity is equal to the volume of a rectangular parallelepiped with the sides $\sigma(X_i) = \sqrt{D(X_i)}$ $(i = 1, 2, 3)$. Thus the quantity $D^*(\mathbf{X})$ characterises the three-dimensional scatter in the direction of all the coordinate axes at once, but it does depend on the choice of the coordinate system. The minimum value of $D^*(\mathbf{X})$ is attained in the coordinate system the unit vectors of which are the eigenvectors of the covariance matrix K(X) and is equal to $D(\mathbf{X})$¶. The coordinate system formed by the eigenvectors of the matrix will be called the intrinsic system of the particle

---

‡The converse assertion is incorrect. It does not follow from the equality $r_{st} = 0$ that the random quantities are independent. There are random quantities which are actually linked by a non-linear functional relation, whose correlation coefficient is zero. Therefore Eqn. (2.6) can characterise only a linear relation.

§The remaining invariant characteristics are not considered here.

¶A maximum value of D^* also exists and is $D_{\max}(\mathbf{X}) = (\frac{1}{3}\mathrm{Sp}\mathbf{K})^3$. With the aid of the quantities $D_{\max}(\mathbf{X})$ and $D(\mathbf{X})$, it is possible to define a measure of the anisotropy of the distribution: $[D_{\max}(\mathbf{X}) - D(\mathbf{X})]\sqrt{D_{\max}(\mathbf{X})D(\mathbf{X})}$.

coordinates†. In this coordinate system the covariance matrix is of the diagonal form, i.e. the components of the random vector X are not correlated.

Thus the geometrical significance of the quantity $D(\mathbf{X})$ becomes clear: it is the general variance of the particle equal to the product of the one-dimensional variances in the directions of the axes of the intrinsic coordinate system of the particle, i.e. to the product of the eigennumbers of the covariance matrix. It follows from the condition for an extremum in $D^*(\mathbf{X})$ that the following inequality always holds:

$$D(\mathbf{X}) \leqslant D(X_1) D(X_2) D(X_3), \tag{2.16}$$

where the equality sign obtains only when the components X_1, X_2, and X_3 are not correlated.

3. The Covariance Matrix of an n-Particle System

We shall now consider a quantum-mechanical system of n particles. Suppose that the state of the system is described by the normalised wave function $\psi(\mathbf{X})$, where $\mathbf{x} = (\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_n)$ denotes a set of cartesian coordinates of n particles and $\mathbf{x}_i = (x_{i1}, x_{i2}, x_{i3})$ denotes the coordinates of the ith particle. We put

$$\rho(\mathbf{x}) = |\psi(\mathbf{x})|^2. \tag{3.1}$$

Then $\rho(\mathbf{x})$ can be treated as the probability density of a $3n$-dimensional random vector:

$$\mathbf{X} = (\mathbf{X}_1, \mathbf{X}_2, \ldots, \mathbf{X}_n). \tag{3.2}$$

The components of the vector are three-dimensional random quantities $\mathbf{X}_i = (X_{i1}, X_{i2}, X_{i3})(i = 1, 2, \ldots, n)$ with the distribution densities

$$\rho_i(\mathbf{x}_i) = \int \rho(\mathbf{x})\, d\mathbf{x}_1 \ldots d\mathbf{x}_{i-1} d\mathbf{x}_{i+1} \ldots d\mathbf{x}_n. \tag{3.3}$$

Each density describes the distribution of the coordinates of the individual ith particle with all other particles in their average positions. The expectation value of the sth component of the ith particle is given by the formula

$$m_{is} = \int x_{is} \rho(\mathbf{x})\, d\mathbf{x}, \tag{3.4}$$

and the covariance matrix $\mathbf{K}_{ii}$ of the ith particle is defined by formulae of type (2.4) and (2.5). The covariance of the sth component of the ith particle and of the tth component of the jth particle is given by the formula

$$\mathrm{Cov}(X_{is}, X_{jt}) = \int (x_{is} - m_{is})(x_{jt} - m_{jt}) \rho(\mathbf{x})\, d\mathbf{x}. \tag{3.5}$$

Thus the covariance matrix of the coordinates of a system of n particles [i.e. of the random vector (3.2)] is of order $3n$ and can be represented by the block matrix

$$K(\bar{\mathbf{X}}) = \begin{pmatrix} \mathcal{K}_{11} & \mathcal{K}_{12} & \ldots & \mathcal{K}_{1n} \\ \mathcal{K}_{21} & \mathcal{K}_{22} & \ldots & \mathcal{K}_{2n} \\ \ldots & \ldots & \ldots & \ldots \\ \mathcal{K}_{n1} & \mathcal{K}_{n2} & \ldots & \mathcal{K}_{nn} \end{pmatrix}, \tag{3.6}$$

where $\mathbf{K}_{ij}$ is the covariance matrix of the ith and jth particles comprising the elements of the matrix (3.5) with $s = (1, 2, 3)$ and $t = (1, 2, 3)$. The matrix $K(\mathbf{X})$ is symmetrical. Therefore the "elements" symmetrical relative to the main diagonal are linked by the relation $\mathbf{K}_{ij} = \mathbf{K}'_{ji}$, where the prime denotes transposition. On the basis of the considerations set out in Section III, 2, one can speak of the general variance of the coordinates of an individual particle $\mathbf{x}_i$ in an n-particle system. This variance is given by the formula

$$D(\mathbf{X}_i) = \det \mathcal{K}_{ii}. \tag{3.7}$$

The general variance of the coordinates of the entire system,

$$D(\mathbf{X}) = \det K(\mathbf{X}) \tag{3.8}$$

and the general variance of the coordinates of an arbitrary subsystem of μ particles,

$$D(\mathbf{X}_1, \mathbf{X}_2, \ldots, \mathbf{X}_\mu) = \det K_\mu, \tag{3.9}$$

where K_μ is a block matrix comprising the elements of the matrix $\mathbf{K}_{ij}$ designated by the numbers of the isolated particles, can be defined by analogous formulae.

For the system as a whole (as well as for any of its subsystems), it is possible to select the intrinsic coordinate system, i.e. the coordinate system in the $3n$-dimensional space in which the covariance matrix of the entire system (called the subsystem) is diagonal. If not all the elements of the matrix $\mathbf{K}_{ij}$ are zero, the set of the intrinsic coordinate systems of the individual particles need not coincide with the intrinsic coordinate system of the n-particle system (or subsystem).

4. Effective Volumes of Quantum-Mechanical Systems

Just as the uncertainty of the position of a one-dimensional particle is described by the variance D and the entropy H, the uncertainty of the position of a real particle or a system of n particles is described by the general variance (3.8) and the entropy:

$$H(\mathbf{X}) = H(\mathbf{X}_1, \mathbf{X}_2, \ldots, \mathbf{X}_n) = -\int \rho(\mathbf{x}) \ln \rho(\mathbf{x})\, d\mathbf{x}. \tag{4.1}$$

As in the one-dimensional case, the entropy characterises the uncertainty of the position of the particles in the regions of their "localisation", while the general variance takes into account also the scatter of the localisation regions. Therefore the concepts of the internal and external volumes can be naturally extended to the multidimensional case as follows. The internal volume of an n-particle system is given by the formula

$$v(\mathbf{X}) = v(\mathbf{X}_1, \mathbf{X}_2, \ldots, \mathbf{X}_n) = \exp H(\mathbf{X}), \tag{4.2}$$

and the external volume by the formula

$$V(\mathbf{X}) = V(\mathbf{X}_1, \mathbf{X}_2, \ldots, \mathbf{X}_n) = \sqrt{(2\pi e)^{3n} D(\mathbf{X})}. \tag{4.3}$$

The usefulness of the definition of the internal volume by Eqn. (4.2) is confirmed by the following facts. If the system is concentrated in a finite region Ω and the density of its distribution is uniform, then the internal volume of such a system is equal to the volume of the region Ω. On the other hand, if the distribution of the system in the region Ω is non-uniform, its internal volume is smaller than that of the region Ω.

It follows from the properties of the general variance and the definition of the one-dimensional external volume (size) that the external volume of the particle is equal to the product of the one-dimensional external sizes in the

†It is assumed that the particle is in a fixed state $\psi(\mathbf{x})$.

directions specified by the intrinsic coordinate system of the particle. The following inequality for the external volume follows from inequality (2.16):

$$V(\mathbf{X}) \leqslant V(X_1)\,V(X_2)\,V(X_3). \tag{4.4}$$

A similar assertion is valid also for a system of n particles. It is then found that the external volumes of the particles‡ and of the system as a whole are linked by the inequality

$$V(\mathbf{X}) = V(\mathbf{X}_1, \mathbf{X}_2, \ldots, \mathbf{X}_n) \leqslant V(\mathbf{X}_1)\,V(\mathbf{X}_2) \ldots V(\mathbf{X}_n), \tag{4.5}$$

where the equality sign obtains only when the particles are not correlated, i.e., all the elements of all the matrices $\mathbf{K}_{ij}$ $(i \neq j)$ are zero.

The situation is somewhat different when one-dimensional and multidimensional internal volumes are compared. We shall demonstrate this using as an example a single particle. If $\rho(x_1, x_2, x_3)$ is the distribution density of the particle, the distribution densities of the components X_i are given by Eqns. (2.2) and the one-dimensional entropies and internal volumes are given by the equations

$$H(X_i) = -\int \rho_i(x_i) \ln \rho_i(x_i)\, dx_i \tag{4.6}$$

and

$$v(X_i) = \exp H(X_i). \tag{4.7}$$

The quantity $v^*(\mathbf{X}) = v(X_1)v(X_2)v(X_3)$ depends on the choice of the coordinate system. It has a minimum $v^0(\mathbf{X})$ which satisfies the inequality

$$v^0(\mathbf{X}) \geqslant v(\mathbf{X}), \tag{4.8}$$

where the equality sign is obtained for normal distributions. Thus the relation between one-dimensional and multidimensional internal volumes is given by the inequality

$$v(\mathbf{X}) \leqslant v(X_1)\,v(X_2)\,v(X_3). \tag{4.9}$$

Similarly the internal volume of an n-particle system is linked to the volumes of its constituent particles§ by the inequality

$$v(\mathbf{X}) = v(\mathbf{X}_1, \mathbf{X}_2, \ldots, \mathbf{X}_n) \leqslant v(\mathbf{X}_1)\,v(\mathbf{X}_2) \ldots v(\mathbf{X}_n). \tag{4.10}$$

The last two inequalities are of the same form as inequalities (4.4) and (4.5). However, the equality sign is not generally speaking attained in formulae (4.9) and (4.10) even for non-correlated components¶. This finding suggests that the entropy (and hence the internal volume) is a more refined concept which takes correlation into account more fully. We shall consider this in greater detail in Section III, 6.

As already mentioned, among distributions concentrated in a restricted region Ω the uniform distribution has the maximum internal volume. Among distributions which are not concentrated in a limited region and have a specified external volume V, the normal distributions have the maximum internal volume v (equal to V). The converse is also true; among distributions which are not concentrated in a restricted region and have a specified internal volume v, the normal distributions have the minimum external volume (equal to v).

‡The external volume of an individual particle in a system of n particles is defined in terms of the variance $D(\mathbf{X}_i)$ given by Eqn. (3.7).

§The internal volume of an individual (ith) particle is defined in terms of the entropy of the distribution with density $\rho_i(\mathbf{x}_i)$ specified by Eqn. (3.3).

¶Systems with the normal distribution density are an exception.

5. The General Covariance Matrix

The introduction of the concepts of a general variance and an external volume makes it possible to assign a definite geometrical significance to covariance and the correlation coefficient. Consider a covariance matrix $\mathbf{K}(\mathbf{X})$ specified by Eqns. (2.4) and (2.5). An arbitrary non-diagonal element k_{ij} $(i \neq j)$ of this matrix expresses the correlation of the coordinates x_i and x_j of a particle [in a state with the distribution density $\rho(x_1, x_2, x_3)$]. The covariance matrix of a two-dimensional random vector (X_i, X_j) has the form

$$\begin{pmatrix} D(X_i) & k_{ij} \\ k_{ij} & D(X_j) \end{pmatrix}. \tag{5.1}$$

The general variance of an arbitrary t-dimensional random vector is defined as the determinant of its covariance matrix [Eqns. (2.14), (3.8), and (3.9) represent special cases of this definition]. The general variance of the two-dimensional random vector (X_i, X_j) is thereby expressed by the formula

$$D(X_i, X_j) = D(X_i)\,D(X_j) - k_{ij}^2 .$$

Hence it follows that the covariance modulus k_{ij} can be put in the form

$$|\operatorname{Cov}(X_i, X_j)| = |k_{ij}| = \sqrt{D(X_i)\,D(X_j) - D(X_i, X_j)}, \tag{5.2}$$

and the modulus of the correlation coefficient in the form

$$|r(X_i, X_j)| = \frac{|\operatorname{Cov}(X_i, X_j)|}{\sqrt{D(X_i)\,D(X_j)}} = \sqrt{1 - \frac{D(X_i, X_j)}{D(X_i)\,D(X_j)}}. \tag{5.3}$$

By analogy with Eqn. (4.3), the external volume of a two-dimensional random quantity is given by the formula $V(X_1, X_2) = 2\pi e\sqrt{D(X_1, X_2)}$. It is therefore possible to express the modulus of the correlation coefficient in terms of the external volumes:

$$|r(X_i, X_j)| = \sqrt{1 - \left[\frac{V(X_i, X_j)}{V(X_i)\,V(X_j)}\right]^2}. \tag{5.3'}$$

We shall now elucidate somewhat the geometrical interpretation of covariance and the correlation coefficient using as an example two one-dimensional random quantities.

Suppose that $\rho(x_1, x_2)$ is the distribution density of a two-dimensional random quantity. In order to express the nature of the distribution, it is useful to outline the lines of the $\rho(x_1, x_2)$ density levels on the plane of the variables x_1 and x_2. As an example, Fig. 3 presents the density levels for a two-dimensional normal distribution. The point O' with the coordinates $(m_{\mathbf{X}_1}, m_{\mathbf{X}_2})$ characterises the "centre of gravity" of the distribution and the uncertainty of the position of the two-dimensional random quantity in the directions x_1 and x_2 is characterised by the standard deviations $\sigma(X_1) = \sqrt{D(X_1)}$ and $\sigma(X_2) = \sqrt{D(X_2)}$. The "volume" characteristic of the uncertainty of the position of the two-dimensional random quantity can be expressed, without taking into account the correlation of the components,

by the area of the rectangle $ABCD$, the "centre" of which is at point O', the sides are parallel to the coordinate axes, and their lengths are $2\sigma(X_1)$ and $2\sigma(X_2)$.

We shall now find the eigenvectors of the matrix (5.1) and, assuming them to be the unit vectors of a new coordinate system with origin at the point O', we obtain the intrinsic coordinate system (x_1^0, x_2^0) of the two-dimensional random quantity. The uncertainty of its position with respect to the intrinsic directions is characterised by the standard deviations $\sigma(x_1^0)$ and $\sigma(x_2^0)$, while the "volume" uncertainty is expressed by the area of the rectangle $A^0B^0C^0D^0$ with the centre at the point O' having sides with lengths $2\sigma(x_1^0)$ and $2\sigma(x_2^0)$ which are parallel to the axes x_1^0 and x_2^0 (respectively). If such rectangles are plotted for any orthogonal coordinate system, it is found that among them there is one whose area is an extremum. The area of the rectangle $A^0B^0C^0D^0$ is the smallest of all the possible values. This follows from the following inequality for a two-dimensional random quantity X:

$$D(\mathbf{X}) \leqslant D(X_1)\, D(X_2). \tag{5.4}$$

which is analogous to inequality (2.16).

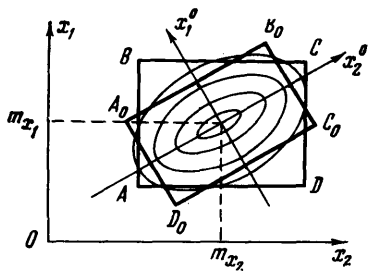


Figure 3.

We may mention further that the length of the sides of the triangles may be made proportional to the standard deviations. In particular they can be made equal to the external dimensions $V(X_i)$. In all cases the ratio of the areas of the rectangles $A^0B^0C^0D^0$ and $ABCD$ will be the same and equal to

$$s = \frac{\sigma(X_1, X_2)}{\sigma(X_1)\,\sigma(X_2)} = \frac{V(X_1, X_2)}{V(X_1)\,V(X_2)}. \tag{5.5}$$

The quantity s will be called the non-correlation coefficient. It is readily seen that its values lie in the range

$$0 \leqslant s \leqslant 1. \tag{5.6}$$

The quantity s is a maximum for non-correlated components. Indeed, in this case the equality sign obtains in formula (5.4) and consequently $s = 1$. The minimum value of s occurs when there is a linear correlation between X_1 and X_2. The minimum eigenvalue $D(X_1^0)$ of the covariance matrix then becomes zero, so that $s = 0$.

Formula (5.3) or (5.3′) shows that the relation between the correlation coefficient r and the non-correlation coefficient s is given by

$$r^2 + s^2 = 1. \tag{5.7}$$

If one remembers further that $\sigma(X_1, X_2) = \sigma(X_1^0)\sigma(X_2^0)$ and $V(X_1, X_2) = V(X_1^0)V(X_2^0)$ characterises the "volume" of the scatter of the non-correlated random quantities X_1^0 and X_2^0, one may conclude that the quantities r and s reflect the change in the "volume" uncertainty of the position of the two-dimensional random quantity on passing to the intrinsic coordinate system.

We shall now turn to the consideration of an n-particle system with the distribution density $\rho(\mathbf{x}) = \rho(\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_n)$. As already mentioned, the covariance matrix $K(\mathbf{X})$ of such a system has the form of the block matrix (3.6). This matrix contains the complete information about the uncertainty of the position of the $3n$-dimensional random vector $\mathbf{X}(\mathbf{X}_1, \mathbf{X}_2, \ldots, \mathbf{X}_n)$ in terms of the approximation defined by the second moments. However, in order to estimate the correlation between the particles (ith and jth), it is useful to have a scalar quantity as well as the matrix $\mathbf{K}_{ij}$. From physical considerations, it should be independent of the choice of the coordinate system of the particles and should reflect the correlation between the particles†.

The above considerations suggest the necessity to extend the concept of correlation based on probability theory to the case of a pair of particles or a system of particles. Therefore our immediate problem is to construct the covariance matrix Q of quantum-mechanical particles in an n-particle system which would constitute a natural extension of the usual covariance matrix‡.

One of the possible generalisations (seemingly the most natural generalisation) was proposed by Del-Re et al.[31] It is based on Eqn. (2.5), where the vectors $\mathbf{x}_s$ and $\mathbf{x}_t$ must be substituted in place of the variables x_s and x_t and the vector product must be regarded as a scalar quantity. As will be shown below, this definition of covariance is defective as regards physical significance.

Another possible generalisation of the covariance matrix was proposed by ourselves on the basis of the concept of general variance. Indeed the general variances $D(\mathbf{X}_i)$ characterising the uncertainty of the position of the coordinates of the ith particle

$$q_{ii} = D(\mathbf{X}_i), \tag{5.8}$$

are adopted as the diagonal elements of the matrix Q. The non-diagonal elements q_{ij} of the matrix Q, i.e. the covariances of the coordinates of the ith and jth particles, are determined, by analogy with Eqn. (5.2), from the formula

$$q_{ij} = \mathrm{Cov}(\mathbf{X}_i, \mathbf{X}_j) = \sqrt{D(\mathbf{X}_i)\,D(\mathbf{X}_j) - D(\mathbf{X}_i, \mathbf{X}_j)}, \tag{5.9}$$

where the plus sign was chosen for the square root term, since the correlation interaction is characterised by the

---

†We may note that in the term "correlation energy" employed in quantum chemistry the word correlation means in fact the part of the electron correlation which depends significantly on the choice of the approximate method of calculation used and the term "correlation energy" itself denotes a correction to the energy calculated by the approximate method. The correlation energy is usually understood as the difference between the energy calculated by the Hartree–Fock method and the exact energy of the system.

‡In contrast to the initial covariance matrix K of order $3n$, the generalised covariance matrix Q is of order n.

modulus of the correlation coefficient. The term correlation coefficient for two particles in an n-particle system ($n \geq 2$) will be given to the quantity

$$r(\mathbf{X}_i, \mathbf{X}_j) = \frac{\mathrm{Cov}(\mathbf{X}_i, \mathbf{X}_j)}{\sqrt{D(\mathbf{X}_i)\,D(\mathbf{X}_j)}} = \sqrt{1 - \frac{D(\mathbf{X}_i, \mathbf{X}_j)}{D(\mathbf{X}_i)\,D(\mathbf{X}_j)}}. \qquad (5.10)$$

Using Eqn. (4.3), it is possible to express the correlation coefficient in terms of external volumes:

$$r(\mathbf{X}_i, \mathbf{X}_j) = \sqrt{1 - \left[\frac{V(\mathbf{X}_i, \mathbf{X}_j)}{V(\mathbf{X}_i)\,V(\mathbf{X}_j)}\right]^2}. \qquad (5.10')$$

Therefore r will also be called the external correlation coefficient in contrast to the internal correlation coefficient defined below. Eqns. (5.10) and (5.10′) constitute natural extensions of Eqns. (5.3) and (5.3′). The concept of the non-correlation coefficients can also be evidently extended to the case of a pair of particles:

$$s(\mathbf{X}_i, \mathbf{X}_j) = \frac{\sigma(\mathbf{X}_i, \mathbf{X}_j)}{\sigma(\mathbf{X}_i)\,\sigma(\mathbf{X}_j)} = \frac{V(\mathbf{X}_i, \mathbf{X}_j)}{V(\mathbf{X}_i)\,V(\mathbf{X}_j)}. \qquad (5.11)$$

Therefore the correlation coefficient of the particles $r(\mathbf{X_i}, \mathbf{X_j})$ and the non-correlation coefficients $s(\mathbf{X_i}, \mathbf{X_j})$ have the same significance as the usual coefficients r and s: they reflect the degree of condensation of the two-particle subsystem. It is easy to verify the following properties of the correlation coefficient.

1. $r(\mathbf{X_i}, \mathbf{X_j}) = 0$ if the ith and jth particles are independent, i.e. their density is represented by the product $\rho(\mathbf{x_i})\rho(\mathbf{x_j})$.

2. $r(\mathbf{X_i}, \mathbf{X_j}) = 1$ if there is a linear relation between the coordinates of the ith and jth particles§; the converse assertion is also valid: if $r(\mathbf{X_i}, \mathbf{X_j}) = 1$, there is at least one linear relation between the coordinates.

3. The correlation coefficient satisfies the inequality

$$0 \leqslant r(\mathbf{X}_i, \mathbf{X}_j) \leqslant 1.$$

The above properties are fully analogous to those of the usual correlation coefficient. Thus, for the usual correlation coefficient property(1) is irreversible, i.e. when $r(\mathbf{X_i}, \mathbf{X_j}) = 0$, the given particles need not necessarily be independent. There can even be a functional relation between them. This factor and property (2) suggest that the correlation coefficient (the usual and extended coefficient) should be more correctly called the linear correlation coefficient.

The analogue of the correlation coefficient for the approximation of a non-linear functional relation is discussed in Section III, 6.

In conclusion of this subsection we emphasise that the quantities $D(\mathbf{X_i})$, $D(\mathbf{X_i}, \mathbf{X_j})$, $\mathrm{Cov}(\mathbf{X_i}, \mathbf{X_j})$ and $r(\mathbf{X_i}, \mathbf{X_j})$ satisfy the requirement of invariance in relation to the orthogonal transformations of the coordinate systems of the individual particles. We may note that the definitions of covariance and correlation coefficient proposed by Del-Re et al.[31] do not satisfy this invariance condition.

§This means that there is a functional relation of the type:

$$a_1 x_{i1} + a_2 x_{i2} + a_3 x_{i3} + b_1 x_{j1} + b_2 x_{j2} + b_3 x_{j3} = 0.$$

6. Non-Linear Correlation. Internal Correlation Coefficient

When we speak of a statistical relation for random quantities, we are interested primarily in the possible similarity of the given statistical relation to a functional relation. To assess this similarity, it is necessary to determine a quantity characterising its measure. The linear correlation coefficient cannot serve as such a measure since, as already shown, there exist distribution in which the variables are linked by a functional relation, while the correlation coefficient is zero.

We recall that the modulus of the correlation coefficient defined by Eqn. (2.6) for two one-dimensional random quantities is expressed in terms of the external volumes by Eqn. (5.3′). The formal replacement of the external by internal volumes permits the introduction of the quantity

$$r_H(X_i, X_j) = \sqrt{1 - [v(X_i, X_j)/v(X_i)\,v(X_j)]^2}, \qquad (6.1)$$

which we shall call the internal correlation coefficient¶. The subscript H means that this quantity is defined in terms of the entropy, namely

$$r_H(X_i, X_j) = \sqrt{1 - \exp[2H(X_i, X_j) - 2H(X_i) - 2H(X_j)]}.$$

We shall now consider the properties of the internal correlation coefficient. In the first place it follows from the inequality[29] $H(X, Y) \leqslant H(X) + H(Y)$ that the quantity $r_H(X, Y)$ also varies in the range $0 \leqslant r_H \leqslant 1$. The minimum value is reached for independent X and Y, i.e. when the probability density of the two-dimensional random quantity is a product of the densities of the quantities X and Y: $\rho(x, y) = \rho_1(x)\rho_2(y)$. Indeed for the independent quantities $H(X, Y) = H(X) + H(Y)$, $\exp[2H(X, Y) - 2H(X) - 2H(Y)] = 1$ and hence $r_H(X, Y) = 0$. On the other hand, if the random quantities are linked by a functional relation $Y = \varphi(X)$, then $r_H(X, Y) = 1$.

We shall prove this assertion. For simplicity, we shall assume that the function φ has a converse function $X = \theta(Y)$. Then the density of the joint distribution of two random quantities is of the form

$$\rho(x, y) = f(x)\,\delta(y - \varphi(x)) = f(x)\,\delta(x - \theta(y)), \qquad (6.2)$$

where the function f satisfies the condition $\int f(x)dx = 1$. In addition the convergence of the integrals is postulated:

$$H[f] = -\int f(x) \ln f(x)\,dx,\quad H[f(\theta)] = -\int f[\theta(y)] \ln f[\theta(y)]\,dy.$$

The functional of the entropy has not been defined for the density (6.2). It must be additionally defined as the limit of the functionals of the entropy H_n for the densities $\rho_n(x, y) = f(x)g_n[y - \varphi(x)]$, where g_n is a δ-sequence. We have

$$H_n = -\int\int \rho_n(x, y) \ln \rho_n(x, y)\,dx\,dy = -\int\int f(x)\,g_n(y - \varphi(x)) \ln f(x)\,dx\,dy -$$
$$-\int\int f(x)\,g_n(y - \varphi(x)) \ln g_n(y - \varphi(x))\,dx\,dy = -\int f(x) \ln f(x)\,dx -$$
$$-\int f(x)\,dx \int g_n(y - \varphi(x)) \ln g_n(y - \varphi(x))\,dy = H[f] + H[g_n].$$

By virtue of the hypothesis made in Section III, 1 concerning the entropy of the δ-function and the condition for $H(f)$, we have $\lim_{n\to\infty} H_n = H[f] + \lim_{n\to\infty} H[g_n] = -\infty$.

¶On the other hand the usual correlation coefficient, which is expressed in terms of the external volumes, can also be reasonably called the external correlation coefficient.

Moreover, $\rho_1(x) = \int f(x)\delta[y - \varphi(x)]dy = f(x)$ and $\rho_2(y) = \int f(x)\delta[x - \theta(y)]dx = f[\theta(y)]$. Therefore $H(X) = H[f]$ and $H(Y) = H[f(\theta)]$. Since both these quantities are finite, it follows that $\exp[2H(X, Y) - 2H(X) - 2H(Y)] = 0$ and therefore $r_H(X, Y) = 1$.

The definition (6.1) can be naturally extended to the multidimensional case. The internal correlation coefficient of two particles will be defined as

$$r_H(X_i, X_j) = \sqrt{1 - [v(X_i, X_j)/v(X_i)\,v(X_j)]^2}. \qquad (6.1')$$

The properties of this quantity are as follows.

1. $r_H(X_i, X_j) = 0$ if the quantities X_i and X_j are independent, i.e. $\rho(x_i, x_j) = \rho_i(x_i)\rho_j(x_j)$.

2. If there is a functional relation between the coordinates of the vectors x_i and x_j, then $r_H(X_i, X_j) = 1$; conversely if $r_H = 1$, the internal volume of a system of two particles (the ith and jth particles) is zero.

3. For any distribution density $\rho(x_i, x_j)$, the quantity $r_H(X_i, X_j)$ satisfies the inequalities

$$0 \leqslant r_H(X_i, X_j) \leqslant 1.$$

The equality $r_H(X_i, X_j) = 1$ is not a characteristic property of the functional relation. It is characteristic of the situation where the internal volume becomes zero.

7. Many-Particle Correlation

As stated above, electron correlation is usually estimated from the energy standpoint. Below we quote formulae for the estimation of many-electron correlation in the language of the concepts of probability theory. They are obtained by a natural extention of the formulae for two-particles.

The external correlation coefficient of a subsystem of μ particles ($2 \leqslant \mu \leqslant n$) will be defined as

$$r(X_1, X_2, \ldots, X_\mu) = \left[1 - D(X_1, X_2, \ldots X_\mu) \Big/ \prod_{i=1}^{\mu} D(X_i)\right]^{1/2}. \qquad (7.1)$$

This quantity can evidently be expressed also in terms of external volumes:

$$r(X_1, X_2, \ldots, X_\mu) = \left\{1 - \left[V(X_1, X_2, \ldots, X_\mu) \Big/ \prod_{i=1}^{\mu} V(X_i)\right]^2\right\}^{1/2}.$$

The internal correlation coefficient is defined similarly:

$$r_H(X_1, X_2, \ldots, X_\mu) = \left\{1 - \left[v(X_1, X_2, \ldots, X_\mu) \Big/ \prod_{i=1}^{\mu} v(X_i)\right]^2\right\}^{1/2}. \qquad (7.2)$$

The properties of these quantities are as follows.

1. If one of the particles $x_1, x_2, \ldots, x_\mu$ is independent of the others, then $r(X_1, X_2, \ldots, X_\mu) = r_H(X_1, X_2, \ldots, X_\mu) = 0$.

2. If there is a functional relation between the coordinates of the particles $x_1, x_2, \ldots, x_\mu$, then $r_H(X_1, X_2, \ldots, X_\mu) = 1$†; if this relation is linear, then also $r(X_1, X_2, \ldots, X_\mu) \leqslant 1$.

3. Both quantities satisfy the inequalities $0 \leqslant r(X_1, X_2, \ldots, X_\mu) \leqslant 1$ and $0 \leqslant r_H(X_1, X_2, \ldots, X_\mu) \leqslant 1$.

†Nothing can be said about the quantity $r(X_1, X_2, \ldots, X_\mu)$. It may even be zero.

8. The Uncertainty Principle

As noted in the introduction, the concepts of entropy, variance, and effective volumes are very closely related to one of the most important principles of quantum mechanics—the uncertainty principle.

For a quantitative expression of the uncertainty principle, the variances (or standard deviations) of canonically coupled quantities are usually employed as measures of their uncertainty. We shall consider initially the case of a one-dimensional particle and shall examine two quantities: the coordinate x and momentum p‡. Heisenberg's uncertainty principle is expressed in terms of Weyl's inequality:

$$D_x D_p \geqslant \tfrac{1}{4}(\text{at. units}) \qquad (8.1)$$

where D_x and D_p are the variances of the coordinate and the momentum respectively. Suppose that D_x is "small" which corresponds to the localisation of the coordinate of the particle; then the variance of the momentum must be large, i.e. $D_p \geqslant 1/4D_x$. Otherwise inequality (8.1) will not hold. However, the method of expressing the uncertainty principle in the form of inequality (8.1) suffers from an important disadvantage.

Suppose that is it known that the particle is localised in fairly small regions around two or a greater (finite) number of centres. The variance of this distribution can have any value, as can be seen, for example, from Fig. 4. Weyl's inequality will not rule out in this case the possibility of determining the momentum with a fairly high degree of accuracy. Nevertheless this type of situation is in reality excluded. The uncertainty principle formulated in the entropy form [2,32,33],

$$H_x + H_p \geqslant C > 0 \qquad (8.2)$$

shows that in our example the distribution density of the momentum not only cannot be fully concentrated in a small region around a certain point but it cannot be localised even in the vicinity of a finite number of points.

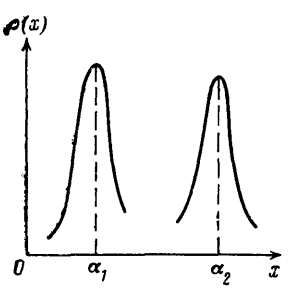

Figure 4.

Indeed if the particle is localised in a small region Ω around a certain point, then $f(x) > 1$ for $x \in \Omega$ and $f(x) = 0$ for $x \notin \Omega$. Therefore $f(x)\ln f(x) \geqslant 0$ and consequently the entropy integral is negative. The greater the degree of localisation the smaller the entropy and the smaller the

‡If the state of the one-dimensional particle in the coordinate representation is described by a wave function $\psi(x)$, then in the momentum representation it corresponds to the wave function $\psi(p) = (1/\sqrt{2\pi})\int \psi(t)e^{-ipx}dx$.

effective size. It follows from inequality (8.2) that the quantities H_x and H_p cannot assume simultaneously values so small that $H_x + H_p < C (C > 0)$.

In the general case the functionals D and H do not define one another unambiguously. However, they are linked to one another by inequality (1.6). It follows from this inequality that the expression of the uncertainty principle in the entropy form (8.2) is stronger than in the variance from (8.1), since

$$0 < C \leqslant H_x + H_p \leqslant \frac{1}{2} \ln (2\pi e D_x D_p). \tag{8.3}$$

This factor in fact makes it possible to investigate certain general physical aspects of the uncertainty principle which are not embraced by Weyl's inequality.

The problem of the value of the constant $C (C > 0)$ in inequality (8.2) is of fundamental importance. If $C = \ln \pi e$, the implication is that the two characteristics of uncertainty in the phase space $D_x D_p$ and $v_x v_p / 2\pi e$ assume identical minimum values. There is every reason to suppose that this does indeed happen and that the minimum uncertainty is achieved with Gauss functions. However, there is at present no rigorous proof of this assertion.

The derivation of inequality (8.1) has been frequently discussed in the literature and therefore we shall not consider it in detail. We shall only mention that, in order to prove Weyl's inequality, it is sufficient to employ the most general properties of the Fourier transformation in the Gilbertian space $L_2(-\infty, \infty)$§.

We shall consider briefly the proof of inequality (8.2). Let $\varphi(x) \in L_r(-\infty, \infty)$ and let $\psi(t)$ be its Fourier transform. Then $\psi(p) \in L_q(-\infty, \infty)$, where $q = r/(r-1)$. Babenko[34] showed that for even values of q the following inequality holds

$$\| \psi \|_q \leqslant M(r) \| \varphi \|_r,$$

where

$$M(r) = \left(\frac{r}{2\pi}\right)^{\frac{1}{2r}} \left(\frac{q}{2\pi}\right)^{\frac{1}{2q}}.$$

Using the Riesz theorem, the present authors showed[32] that for $r \in [4/3, 2]$ we have

$$\| \psi \|_q \leqslant M^{2(r/2-1)} \| \varphi \|_r, \tag{8.4}$$

where $M = 0.592$¶. On taking logarithms in inequality (8.4), we obtain

$$\frac{1}{q} \ln \int |\psi|^q \, dp \leqslant 2 (2/r - 1) \ln M + \frac{1}{r} \ln \int |\varphi|^r \, dx. \tag{8.5}$$

Consider the function

$$\chi(r) = \frac{1}{q} \ln \int |\psi|^q \, dp - \frac{1}{r} \ln \int |\pi|^r \, dx - 2 \left(\frac{2}{r} - 1\right) \ln M.$$

§Henceforth the following notation will be employed: $L_r(-\infty, \infty)$ is defined as a set of functions $f(x)$ of a single real variable x for which the values of the integral $\int |f(x)|^r dx = I_r$ are finite. The quantity $(I_r)^{1/r}$ is designated by $\| f(x) \|_r$ and is called the norm of the function $f(x)$.

¶The constant is quoted to within 0.001.

Then it follows from inequality (8.5) that $\chi(r) \leqslant 0$ for $4/3 \leqslant r \leqslant 2$. Moreover, $\chi(2) = 0$. Therefore $\chi'(2 - 0) \geqslant 0$. Formal differentiation of the function $\chi(r)$ leads to the expression

$$\chi'(r) = \frac{1}{r^2} \ln \int |\psi|^q \, dp - \frac{1}{r(r-1)} \frac{\int |\psi|^q \ln |\psi| \, dp}{\int |\psi|^q \, dp} +$$

$$+ \frac{1}{r^2} \ln \int |\varphi|^r \, dx - \frac{1}{r} \frac{\int |\varphi|^r \ln |\varphi| \, dx}{\int |\varphi|^r \, dx} + \frac{4}{r^2} \ln M.$$

Bearing in mind that $\| \varphi \|_2 = \| \psi \|_2 = 1$ we obtain for $r = 2$ the inequality

$$- \int |\psi|^2 \ln |\psi|^2 \, dp - \int |\varphi|^2 \ln |\varphi|^2 \, dx + 4 \ln M \geqslant 0.$$

and hence the entropy expression for the uncertainty principle can be formulated as $H_x + H_p \geqslant C$, where $C \simeq 2.100$.

We have considered hitherto the uncertainty principle in terms of a one-dimensional treatment. We shall now proceed to a real physical system—a quantum-mechanical particle or a system of such particles.

The uncertainty of the position of the coordinates of an n-particle system [in the state $\psi(x_1, \ldots, x_n)$] is characterised by the covariance matrix $K(\mathbf{X})$, the general variance $D(\mathbf{X})$, and the entropy $H(\mathbf{X})$. The one-dimensional uncertainty in the direction of the $3n$-dimensional vector $\mathbf{c}$ is expressed by the quantity $[K(\mathbf{X})\mathbf{c}, \mathbf{c}]$ and the "volume" uncertainty is expressed by the quantities $D(\mathbf{X})$ and $H(\mathbf{X})$.

In the momentum representation the same state of the n-particle system is described by the wave function $\tilde{\psi}(\mathbf{p}) = \psi(\mathbf{p}_1, \mathbf{p}_2, \ldots, \mathbf{p}_n)$, which is a Fourier transform of the initial function

$$\tilde{\psi}(\mathbf{p}) = \frac{1}{(2\pi)^{n/2}} \int e^{-i(\mathbf{p}, \mathbf{x})} \psi(\mathbf{x}) \, d\mathbf{x}.$$

The distribution density of the momenta $|\tilde{\psi}(\mathbf{p})|^2$ is also normalised to unity, which makes it possible to treat it as the distribution density of a $3n$-dimensional random quantity $\mathbf{P} = (\mathbf{P}_1, \mathbf{P}_2, \ldots, \mathbf{P}_n)$, where the random three-dimensional vector $\mathbf{P}_j$ corresponds to the momentum of the jth particle. The covariance matrix $K(\mathbf{P})$ of the random vector $\mathbf{P}$ characterises the uncertainty of the positions of the momenta in the n-particle system and the general variance $D(\mathbf{P})$ and the entropy $H(\mathbf{P})$ characterise their "volume" uncertainty.

The above characteristics of multidimensional quantum-mechanical systems based on probability theory permit the formulation of the Heisenberg uncertainty principle directly in the multidimensional form. Indeed, it is possible to prove the validity of the inequalities

$$H(\mathbf{X}) + H(\mathbf{P}) \geqslant \ln (2\pi)^{3n} \tag{8.6}$$

and

$$D(\mathbf{X}) D(\mathbf{P}) \geqslant (1/4)^{3n} \text{ (at. units)} \tag{8.7}$$

which constitute natural generalisations of inequalities (8.2) and (8.1) respectively. The uncertainty relations, expressed in terms of the internal and external volumes

$$v(\mathbf{X}) v(\mathbf{P}) \geqslant (2\pi)^{3n} \text{ (at. units)} \tag{8.8}$$

and

$$V(\mathbf{X}) V(\mathbf{P}) \geqslant (\pi e)^{3n} \text{ (at. units)} \tag{8.9}$$

follow from inequalities (8.6) and (8.7). All the inequalities (8.6)–(8.9) express the fact that the volume uncertainty of an n-particle system cannot

be fairly small in the coordinate and momentum representations simultaneously. We may note that inequality (8.2) or, what amounts to the same thing,

$$D(\mathbf{X}) - {}^1/_4 D^{-1}(\mathbf{P}) \geqslant 0$$

can be generalised also in terms of the covariance matrices. It is found that the matrix

$$T = K(\mathbf{X}) - {}^1/_4 K^{-1}(\mathbf{P})$$

is positively defined, i.e. for any $3n$-dimensional vectors c we have the inequality

$$(Tc, c) \geqslant 0. \qquad (8.10)$$

It is possible to show that inequality (8.10) follows from the uncertainty relation in the variance form for each pair of canonically coupled variables (one-dimensional variables).

Reactions of Silicon and Germanium with Halogens, Their Hydrides, and Organic Halogen Derivatives

A.I.Gorbunov, A.P.Belyi, and G.G.Filippov

Results published up to 1972 inclusive on the kinetics and the mechanism of the reactions of silicon and germanium with halogens, their hydrides, and organic derivatives are summarised. The kinetics and the mechanism of formation of the most important organic and halogenated derivatives of silicon and germanium, which have found wide industrial application, are discussed. Published data are analysed in the light of modern views on the progress of heterogeneous catalytic reactions. A list of 163 references is included.

I. INTRODUCTION

The interaction of silicon or germanium with a halogen, its hydride, or an organic derivative is a complicated heterophase catalytic process, in which a gaseous halide reacts with a solid in the presence of a catalyst with the formation mainly of gaseous reaction products. The kinetics of such "gas–solid" processes, including the gasification of coal[1], remained for a long period a little studied field.

During the past decade, however, the reactions of silicon and germanium with halogenated hydrocarbons have found wide application in the preparation of organometallic monomers[2-4] for the industrial production of novel oligomers and polymers possessing valuable technical properties. The halogenation and the hydrohalogenation of silicon and germanium are used also in various branches of semiconductor technology[5,6].

The practical significance of these reactions has arisen during recent years from extensive investigations of the kinetics and the mechanism of the formation of silicon, germanium, organosilicon, and organogermanium halides. Thorough study of this branch of chemistry became possible when elementary silicon and germanium of the required purity became available in the necessary quantities for kinetic experiments.

The reactions of silicon and germanium with halogens and organic halides appear a fortunate example for elucidating general aspects of the reactivity of solids on treatment with gaseous reactants to form volatile products—the effects of impurities and catalytic additives, the nature of the halogen, and other factors on the activation energy, the kinetic order of the reaction, etc.

Study of the kinetics and the mechanism of several preparations of silicon and organosilicon halides, forming the basis of large-scale production[7-12], has been connected with the development of modern methods of design of reaction vessels and the modelling of chemical processes[13,14].

Earlier surveys[15-19] were concerned mainly with the reactions of silicon with alkyl chlorides and hydrogen chloride, and ignored data on reactions with other halides, as well as information on the corresponding reactions of germanium—an analogue of silicon—about which a large number of publications had already appeared. It has become necessary to analyse and generalise results on the kinetics and the mechanism of the formation of silicon, germanium, organosilicon, and organogermanium halides, which is the purpose of the present Review. The chemical properties and the methods of preparation of these compounds are not dealt with, since several special publications have appeared on this aspect[2-4,20,21].

II. KINETICS OF REACTIONS

1. Reactions of Silicon and Germanium with Halogens X_2

The reaction of halogens with silicon and germanium provides the simplest method for preparing the halides. These elements form compounds of types MX_4 and MX_2, as well as polyhalogenated silanes and germanes M_nX_{2n+2}.[21,22] Quadrivalent compounds are more characteristic of silicon; germanium typically forms both quadrivalent and bivalent halides. Under normal conditions polyhalides are formed in small quantities.

Fluorination. Silicon reacts with fluorine even at room temperature to form gaseous silicon tetrafluoride. A detailed gravimetric study of this reaction has been made on single crystals of silicon[23-25]. Initially the process is slow because of the presence of an oxide film on the surface. With a fluorine pressure of 20–150 torrs the reaction on the (111) face at 20°C is of the first order with respect to fluorine[24]. Study of the fluorination of silicon plates (99.9% pure) over the pressure range 2.8–52.5 torrs at temperatures of 75–900°C established[25] that at low temperatures (120–150°C) the activation energy was 12 kcal mole^{-1} and the order with respect to fluorine $n_{F_2} = 1$. At high temperatures the effect of external diffusion lowered the activation energy to 1.3 kcal mole^{-1} and the kinetic order to $n_{F_2} = 0.6$.

No published data are available on the kinetics of the fluorination of germanium.

Chlorination. Investigations of the chlorination of silicon and germanium[26-30] have established that the purity of the solid reactant and the presence of catalytic additions of copper influence the kinetics[26,27]. At low temperatures tetrachloro-derivatives are the main products. Table 1 lists the kinetic parameters of their formation. The results show that additions of copper to pure specimens

and impurities in technical silicon tend to enhance the reactivity of the solid. This is apparent in a sharp drop in the temperature at which reaction begins, a decrease in activation energy, and a raising of the kinetic order with respect to chlorine. The activation energies of reactions with silicon (mono- and poly-crystalline specimens with added copper) are usually higher than those for comparable specimens of germanium.

Table 1. Kinetic parameters of the formation of silicon and germanium tetrahalides.

Bromination. Studies have been made on single crystals, technical silicon, and ferrosilicon (15% of iron)[33,34]. Added metals (copper, iron, cobalt, nickel, silver) lower the temperature at which bromination of monocrystalline silicon begins. Additions of copper and its bromides also enhance the reactivity of technical silicon and ferrosilicon, and tend to increase the yield of tetrabromosilane. No kinetic data have been published on the bromination of silicon or germanium.

Iodination. No kinetic data have appeared on the iodination of silicon, and results for that of germanium are contradictory. Over the temperature range in which the reaction is not complicated by diffusion the activation energy is 31 kcal mole^{-1} and the kinetic order $n_{I_2} = 0.5$.[32] The reaction on the (110), (100), and (111) faces of germanium has been ascribed[31] activation energy 18.5 kcal mole^{-1} and reaction order $n_{I_2} = 1.18$, whereas other workers[35] give $n_{I_2} = 0$. These differencies are probably due to experimental inaccuracy, since similar specimens of germanium were used and closely similar temperature ranges (280–460° and 300–500°C).[31,32]

2. Reactions of Silicon and Germanium with Hydrogen Halides HX

The main products are di-, tri-, and tetra-halogenated silicon and germanium derivatives H_2MX_2, HMX_3, and MX_4, under certain conditions with a small quantity of the monohalogeno-derivatives. The composition of the products depends on the temperature of preparation, the purity of the solid, and additions of copper, whose catalytic effect on reactions with hydrogen chloride had been noted long ago by Combes[36].

Hydrochlorination of silicon

The first kinetic study of the process was made by Trambouze[37]. The activation energy of the formation of trichlorosilane was found to be 3 and 10 kcal mole^{-1} for pure silicon and for a silicon–copper alloy. However, the higher value of 28 kcal mole^{-1} has since been obtained by Joklik and Bažant[38], who used a mixture of powdered technical silicon (98% Si) and copper (Si : Cu = 11 : 1) to prepare trichlorosilane under similar conditions over the range 180–220°C. Such contradictory values of the activation energy are due to errors of method in the earlier work[37]: experimental results obtained at the high temperatures of 250–600°C were probably distorted by diffusion factors.

Especial attention has since been paid[39-41] to improving the experimental method, and the effect of pressure has also been studied. At low temperatures silicon reacts with hydrogen chloride mainly with the formation of trichlorosilane. The variation in the surface of the solid reactant and the effect of this variation on the reaction velocity have been examined[41]. The reactivity of silicon is significantly affected by the presence of impurities. The temperature at which reaction begins and the activation energy fall as the impurity content of silicon increases in the sequence

pure (99.9999%) > purified (99.8%) > technical (98%).

In spite of a substantial difference in reactivity, the composition of the products in the region of the temperature at which reaction began was almost identical for these samples of silicon: the content of trichlorosilane in the condensate was 93–98%.

The composition of the reaction products is significantly affected by the addition of copper to the silicon. Each purity grade silicon has a definite temperature range within which the dichlorosilane content increases[41]. In the presence of copper this content rises to 30–35%.[43] The temperature ranges for the selective formation of dichlorosilane are 420–440°, 250–320°, and 220–320°C respectively for pure silicon, technical silicon, and all types of silicon in the presence of copper[43,44].

The kinetic order with respect to hydrogen chloride is close to zero with specimens of pure and purified silicon, but 0.5 with technical silicon. The reaction products —hydrogen and trichlorosilane—have no effect on the rate of the process, and the order with respect to them is zero[40].

Since the formation of trichlorosilane is almost irreversible[42], the rate equation can be written

$$r = k \cdot P_{HCl}^{n_{HCl}} .$$

The kinetic parameters of the process are affected even by small additions (0.001–0.04%) of copper to pure silicon: the temperature at which reaction begins is lowered almost by 100 deg (Table 2) and the activation energy by 6–10 kcal mole^{-1}, while the order of reaction with respect to hydrogen chloride is raised[43-45]. Table 2 reveals no correlation between the copper content and the kinetic parameters E and n_{HCl}: thus specimens with a tenfold difference in copper contents (0.04 and 0.3%) have almost the same kinetic parameters. This is probably

connected with the way in which copper is distributed during preparation of the alloys. Comparison of the reactivity of silicon of different degrees of purity showed[44] that the specific rates with pure and with chemically purified silicon are respectively around 0.01% and 1% of those with technical silicon and silicon–copper alloys.

Table 2. Effects of impurities in silicon and additions of copper on kinetic parameters of the synthesis of trichlorosilane[43–45].

Contact mass	Reaction starts at °C	Reaction order n_{HCl}	Activation energy, kcal mole^{-1}	Specific rate*, mmole m^{-2} min^{-1}
Pure Si (99.9999%)	300—320	0.0—0.1	34.4	$2.8\cdot10^{-5}$
Chemically purified Si (99.8%)	220—240	0.0—0.1	27.0	$7.1\cdot10^{-3}$
Technical Si (98.0%)	180—200	0.45—0.5	20—23	$2.7\cdot10^{-2}$
Pure Si alloyed with Cu (%)				
0.0013	250	—	27.0	—
0.04	200	0.65	24.0	—
0.08	200—240	0.24	28.4	—
0.3	180—200	0.54	24.5	—
Alloy of pure Si and Cu (%)				
2.4	180—200	0.21	29.0	$1.5\cdot10^{-1}$
8.6	180—200	0.43	23.0	$3.6\cdot10^{-1}$

*Specific rate calculated for 250 °C and p_{HCl} = 450 torrs.

Hydrochlorination of germanium

Use of copper both as an alloy[46] and as a powdered mechanical mixture[47] has a marked affect on the kinetics: the temperature at which reaction begins is lowered, and the yield of the main product (trichlorogermane) is raised. The content of tetrachlorogermane increases with rise in temperature. Formation of dichlorogermane is not observed.

Table 3. Kinetic parameters of the hydrochlorination of germanium[46,163].

Contact mass	Reaction starts at, °C	Reaction order n_{HCl}	Activation energy, kcal mole^{-1}
Pure Fe (99.9999%)	340	0.35	22—24.0
Mixture of Ge and Cu (10%) powders	300	1.0	12.5
Ge–Cu alloy (30% Cu)	180	0.8	11.4—12.3
Ge–Cu alloy (3% Cu)	210	1.3	10.2—13.1

Copper is still more effective in corresponding processes with germanium than with silicon[46]: the activation energy is roughly halved, and the kinetic order with respect to hydrogen chloride is raised from ~0.35 to 1.0 (Table 3). The value n_{HCl} = 0.8 given[46] for pure germanium is probably incorrect: repetition of the measurement has shown that n_{HCl} = 0.35.

Closely similar activation energies were obtained for reaction with germanium–copper alloys and with powdered mixtures, but reaction began at different temperatures. A more extended reactive surface of contact between copper and germanium could be regarded as most likely in the former case, or else the addition of copper tends to increase the pre-exponential factor in the reaction rate constant.

The rate of entry of germanium into reaction increases as it is consumed[18]. This is probably due to an increase in the surface area of germanium during the reaction, as was established for the hydrochlorination of silicon[41].

Hydrobromination of silicon and germanium

These processes occur similarly to hydrochlorination. Impurities in the solid reactant and additions of copper have marked effects on the kinetics. Results obtained under comparable conditions are given in Table 4. The temperature of the start of reaction and the activation energy are markedly lower in the presence of copper, while the kinetic order with respect to the gaseous reactant is higher.

Table 4. Kinetic parameters of the hydrobromination of silicon[48] and germanium[49].

Contact mass	Reaction starts at, °C	Specific rate*, mmole m^{-2} min^{-1}	Reaction order n_{HBr}	Activation energy, kcal mole^{-1}
Silicon				
Pure (99.9999%)	320	$1.2\cdot10^{-5}$	0.06—0.2	35—37
Pure Si + 10% Cu from CuCl	220	$2.9\cdot10^{-2}$	0.6—0.8	20—22
Technical (98%)	220	$1\cdot10^{-2}$	0.55—0.51	24—25
Technical Si + 10% Cu from CuCl	185	—	0.6—0.63	18.0
Germanium				
Pure (99.9999%)	325	—	0.1—0.15	24—25
Pure Ge + 10% Cu from CuCl	175	—	0.75—0.8	12.0

*At 250 °C and p_{HBr} = 300 torrs.

The value given in Table 4 for the activation energy with a pure specimen of germanium (25 kcal mole^{-1}) differs from that obtained in Ref. 50 (19 kcal mole^{-1}), the probable reason being differences in experimental conditions, primarily the higher temperature range (400–600 °C) used in this work. Raising the temperature of the hydrobromination of germanium gives rise to appreciable quantities of the tetrabromide accompanying tribromogermane[51]. The rate estimated in this paper from the loss in weight of germanium during the reaction therefore represents actually the rate of formation of two products ($HGeBr_3$ and $GeBr_4$).

Hydroiodination of germanium

Kinetic investigation of the reaction of hydrogen iodide with germanium (single crystal, (111) face) showed[52] that n_{HI} = 1 and E = 16.6 kcal mole^{-1}.

3. Formation of Organosilicon and Organogermanium Halides

The reaction of organic halides with silicon and with germanium in the presence of catalysts forms the basis of the so called direct synthesis of halogenated alkylsilanes and alkylgermanes, the chief method of obtaining organosilicon [16,22,53] and organogermanium [54,55] monomers. A mixture of products of types RMX_3, R_2MX_2, R_2MX, and $RMHX_2$ is obtained, where R = CH_3, C_2H_5, C_6H_5, etc. X = Cl, Br, and M = Si, Ge.

Highly selective preparation of these derivatives is extremely difficult in comparison with the halogenation and hydrohalogenation of silicon or germanium. Only the dimethylsilicon and dimethylgermanium dihalides can be obtained in high yields (90–95%) under fairly mild conditions. Dimethyldichlorosilane finds wide application in industry, and obviously kinetic investigations of its formation are most fully represented in the literature.

Table 5. Kinetic parameters of the synthesis of dimethyldichlorosilane.

No.	Contact mass Si + Cu (9:1)	Pressure, atm	Reaction order n_{MeCl}	Activation energy, kcal mole^{-1}	Ref.
1.	Mixed powdered Si (99.9%) + Cu	0.1—0.6	1.0	25.3	56
2.	Mixed powdered Si (98%) + Cu	1—7	1.0	20.1	57
3.	Mixed powdered Si (99.0%) + Cu from CuCl	1	1.0	26.6	16,58
4.	Si (99.98%)-Cu with added Al + Zn	4.6—12.7	1.0	25.8	16,58,59
5.	Mixed powdered Si + Cu	—	4.0	20.0	60
6.	Mixed powdered Si (99.0%) + Cu	1	1.85	9.0	61
7.	Mixed powdered Si (99.9999%) + Cu	0.15—0.9	0.96—1.1	29.0	62
8.	Mixed powdered Si (99.85%) + Cu	0.15—0.9	0.96—1.2	25.0	62
9.	Mixed powdered Si (98%) + Cu from CuCl	0.15—0.9	0.91—0.96	21.0	62
10.	Mixed powdered Si (98%) + Cu from $Cu(OH)_2$	0.15—0.9	1.1	19.2—20.0	63

Early kinetic investigations of the formation of dimethyldichlorosilane [15,56–61] disregarded the effect of the purity of the silicon, which might have been very substantial, as is evident from the above data on chlorination and hydrochlorination. Probably also because of other procedural errors, kinetic parameters obtained by different investigators varied considerably: thus values from 1 to 4 have been obtained for the order of the reaction with respect to methyl chloride, and from 9 to 27 kcal mole^{-1} for the activation energy. Although this reaction order seems [62] almost independent of the purity of the silicon, this factor nevertheless affects the activation energy (Table 5, Nos. 1, 2, and 7–9). Results for contact masses based on technical silicon, obtained by reducing copper(I) chloride and copper(II) hydroxide (Nos. 9 and 10), indicate that the chemical composition—the purity of the initial components—is of primary importance, not the mode of preparation of the contact mass.

The above experimental data are consistent with a kinetic equation of the type

$$r = K \cdot P_{MeCl}$$

for the formation of dimethyldichlorosilane. The very widely used kinetic equation proposed by Bažant et al.[56]

$$r = \frac{K \cdot P_{MeCl}}{[1 + a_{Me_2SiCl_2} \cdot P_{Me_2SiCl_2} + \sqrt{a_{MeCl} \cdot P_{MeCl}}]^2},$$

which contains the adsorption coefficients a of methyl chloride and of the product, can in several cases be considerably simplified. Kinetic data indicate first-order dependence on methyl chloride, so that the term $(a_{MeCl}P_{MeCl})^{1/2}$ can be neglected. Experimental results for the reaction under dynamic conditions with variation of P_{MeCl} from 1 to 6 atm at a low temperature could be well represented by the simplified equation [56,57], although the above term had to be taken into account with rise in temperature. This term evidently represents formally deactivation of the contact mass with rise in temperature, when the organic group undergoes appreciable pyrolysis. Published data on the retarding effect of the product $a_{Me_2SiCl_2}P_{Me_2SiCl_2}$ are contradictory. No effect of the product on reaction velocity was detected in special experiments [18] using mixtures of methyl chloride and up to 50 vol.% of dimethyldichlorosilane.

Hydrogen chloride, introduced into the reaction zone from outside [63–65] or obtained by the pyrolysis of methyl chloride [66,67] has a decisive effect on the selective formation of methyldichlorosilane under conditions of direct synthesis. Use of a mixture of methyl and hydrogen chlorides enabled the kinetics of its formation to be investigated [68] under comparatively mild temperature conditions, when the content of methyldichlorosilane in the condensate lay in the range 86–95%. The activation energy of formation of this compound from silicon of different degrees of purity was almost the same in the presence of copper (Table 6).

Table 6. Kinetic parameters of the synthesis of methyldichlorosilane [68] and ethyldichlorosilane [18].

Contact mass	Reaction order n_{RCl}	Activation energy, kcal mole^{-1}
methyldichlorosilane		
Technical Si	0.9—1.25	18.3—21.5
Technical Si + 10% Cu (mixed powders)	1.2	24.2
Technical Si + 10% Cu from CuCl	0.85	19—22
Pure Si (99.9999%) + 10% Cu from CuCl	0.9—1.1	18—20.5
ethyldichlorosilane		
Technical Si	1.2	18.3
Pure Si (99.9999%) + 10% Cu from CuCl	0.9—1.04	18—22

Technical silicon, which is sufficiently reactive for the preparation of trichlorosilane even without the addition of copper, is reactive also in the formation of methyldichlorosilane. The reaction order with respect to methyl chloride is independent of the type of contact mass and is approximately $n_{MeCl} \simeq 1$, while the activation energy lies in the range 18–24 kcal mole^{-1}.

The activation energies of formation of methyltrichlorosilane and tetrachlorosilane were estimated [18], from the

temperature dependence of the ratio of their rates of formation in the preparation of methyldichlorosilane[68], when they are present in small quantities (4–5%) among the reaction products, as respectively ~40 and 3–6 kcal mole^{-1}.

Organogermanium compounds containing hydrogen could not be obtained[68] by the reaction of germanium with methyl chloride in the presence of hydrogen chloride, and there is no information on their direct synthesis.

Voorhoeve et al.[67] obtained interesting kinetic data on the formation of methylchlorosilanes by the reaction of methyl chloride with silicon in the presence of catalytic amounts of tin and lead. In experiments with a silicon–tin contact mass (9% and 17% Sn) between 300° and 500°C the main products were methyltrichlorosilane (80–90%) and tetrachlorosilane (~10%). The activation energy of the formation of methyltrichlorosilane under these conditions was 15.6 kcal mole^{-1}.

Highly selective formation of dimethyldichlorogermane[69] results from the interaction of germanium and methyl chloride in the presence of copper. Its content in the mixture at 320–400°C is 90–98%, and is independent of the state or content (in the range 3–30%) of copper in the contact masses. The mode of preparation of the contact mass (alloy or mixture of powered germanium and copper) has no appreciable effect on the principal kinetic parameters of the process, as with silicon[62]. The kinetic order with respect to methyl chloride is n_{MeCl} = 1.5, and the activation energy 24–27.5 kcal mole^{-1}.

Comparatively little investigation has been made of the kinetics of the formation of ethylchlorosilanes. The reason is that interaction between ethyl chloride and silicon–copper contact masses yields several products in considerable quantities, which complicates interpretation of the experimental results and calculation of the kinetic parameters of the process.

Furthermore, ethyl chloride breaks down during the reaction to form ethylene and other hydrocarbons. The reaction products contain not only diethyldichlorosilane but also a large quantity of ethyldichlorosilane. The total rate of conversion of ethyl chloride on a silicon–copper contact mass is of the first order with respect to ethyl chloride[70,71]; under dynamic conditions the process is well described by the equation of Frost and Panchenkov[72]. Later Bažant and Kraus[73], on the assumption that ethylchlorosilanes and hydrocarbons (ethane and ethylene) are formed by parallel reactions, estimated activation energies respectively of 18 and 25 kcal mole^{-1} for the two overall processes.

A kinetic examination has been made also of the formation of ethyldichlorosilane as an individual reaction product on specimens of technical silicon and pure silicon in the presence of copper[18]. As with the preparation of methyldichlorosilane, a mixture of ethyl and hydrogen chlorides was used. The content of ethyldichlorosilane in the reaction products was 90–95%. The order of the reaction with respect to ethyl chloride was n_{EtCl} = 0.9–1.2, and the activation energy 18–22 kcal mole^{-1} (Table 6). As with the preparation of methyldichlorosilane, the kinetic parameters of the process are independent of additions of copper, provided that the silicon is sufficiently active in forming trichlorosilane.

No quantitative kinetic investigation has been made of the interaction of chlorobenzene with silicon–copper contact masses. Only a few data have been published on the parallel formation[15,74] of the main reaction products—phenyltrichlorosilane and diphenyldichlorosilane—and the secondary products—benzene, biphenyl, and tetrachlorosilane. Some idea of the nature of the reaction between an aryl halide and silicon can be obtained from kinetic data on the formation of phenylbromosilanes[75]. The experiments were made in a flow-type apparatus at bromobenzene pressures of 0.3–19 atm. The main product was diphenyldibromosilane, the activation energy of whose formation was 22.8 kcal mole^{-1}.

Studies[76,77] of the effect of substituents in the aryl bromide on the rate of formation of diaryldibromosilanes and aryltribromosilanes in the presence of a silicon–copper contact mass at 400°C established a linear dependence of the logarithm of the relative initial rates on the Hammett constants for the individual substituent (*p*-fluoro, *p*-chloro, hydrogen, *m*-methyl, *p*-methyl, *p*-t-butyl, and *p*-isopropyl). Kinetic equations were also obtained for the formation of di-*p*-fluorophenyldibromosilane and *p*-fluorophenyltribromosilane, regarded as occurring by parallel reactions.

Topochemical processes occurring in the solid phase are of great importance in the direct synthesis of organosilicon and organogermanium halides. Various products can be formed by interaction of copper and the solid reactant in the contact masses depending on their method of preparation. Before reaction a silicon–copper alloy consists of two phases—silicon and an intermetallic compound Cu_3Si (η-phase)[37,78–82]—the latter being formed also in contact masses from a mixture of silicon and copper(I) chloride during preliminary reduction, as well as during synthesis as the copper chloride is formed on breakdown of the organic chloride, especially in the initial (induction) period of the reaction[79,80]. It was suggested in these papers that organosilicon chlorides are indeed formed by interaction of the organic chloride with silicon liberated by breakdown of the η-phase.

The reaction of silicon–copper alloys with methyl chloride was used as example to study the kinetics of the breakdown of the η-phase[83,84], the quantity of silicon that had reacted to form methylchlorosilanes being taken as the rate of the process. It was assumed that only silicon from Cu_3Si underwent reaction. An activation energy of 16 kcal mole^{-1} was obtained; this fell to 8–10 kcal mole^{-1} in the presence of additions of 0.2% of antimony and 0.5% of arsenic, but 0.5% of titanium raised it to 28 kcal mole^{-1}. These values are extremely tentative, since silicon not combined as Cu_3Si may take part in the reaction.

Changes occurring in a silicon–copper alloy (24.7% Cu) during reaction with ethyl chloride between 280° and 360°C were monitored[81,82,85] by X-ray examination. Breakdown of the η-phase was shown to have a fairly high activation energy (30 kcal mole^{-1}) and to obey a first-order kinetic equation. The lower activation energy obtained for conversion of the ethyl chloride (20 kcal mole^{-1}) was attributed to the catalytic effect of the resulting copper.

Under conditions of direct synthesis the contact masses undergo not only structural and chemical changes but also changes in texture (grain size), specific surface, and porosity[41,86]. At higher temperatures pyrolysis of the organic groups becomes important[87–89]. Unfortunately, hardly any kinetic study has been made of the pyrolysis of organic chlorides of silicon–copper contact masses. Investigations by Bažant et al.[15,87–89] suggest a stepwise conversion of organic groups on the contact masses with the formation of polymeric products (polymethylenes, polyphenylenes, etc.).

Some data on the kinetics of the decomposition of methyl chloride on copper under dynamic conditions

appeared in a paper by Trambouze[37], who found the activation energy to vary from 4 to 7 kcal mole^{-1} depending on the type of copper. However, methane was not detected in this investigation, and a scheme was suggested in which the methyl group decomposed into carbon and hydrogen. This conclusion is inconsistent with results obtained by Bažant[89], Anderson[90], and Ivanova et al.[91] The decomposition of methyl chloride on the surface of a pure copper film sublimed in a vacuum[90] yielded hydrogen, methane, and other hydrocarbons. The activation energy of the decomposition was estimated[90,91] to be considerably lower on a silicon–copper alloy than on technical and pure silicon (respectively 14.9, 24.2, and 44 kcal mole^{-1}).

III. MECHANISM OF REACTIONS

1. Nature of Reactions

With respect to the state of aggregation of reactants and products, direct synthesis is a heterophase process. Until recently it was not clear whether the process was purely heterogeneous, occurring on the surface of the solid or heterogeneous–homogeneous, with reactive intermediates formed on the surface, passing into space, and reacting further in the gas phase.

Hurd and Rochow[92] assumed direct synthesis to be a heterogeneous–homogeneous process. They investigated the interaction of methyl chloride with silicon and copper, and suggested the formation, on the contact surface, of the reactive species CH_3 and CH_3Cu, which migrated into the gas phase and reacted with reactive silicon–chlorine intermediates (SiCl and $SiCl_2$) to give the final products. The function of copper in the suggested mechanism was to form intermediate compounds (CH_3Cu and CuCl) to act as alkylating and chlorinating agents. Rochow subsequently extended this scheme to the direct synthesis of other organosilicon halides.

An alternative view, put forward by Klebanskii and Fikhtengol'ts[78], Trambouze[37], Bažant[15], and Voorhoeve[93], regards direct synthesis as involving heterogeneous–catalytic reactions, occurring solely on the solid surface.

Certain aspects of Hurd and Rochow's mechanism appeared in several papers. At one time Andrianov et al.[94] assumed the participation of free radicals formed by dissociation of the intermediate methylcopper chloride CH_3CuCl. Holzapfel[95] considered that intermediate chlorinated compounds of silicon reacted in the gas phase. Even in the fluorination of silicon[25] it was regarded as possible that certain stages occurred in the gas phase and involved SiF and SiF_2.

The investigations of Andrianov, Golubtsov, and their coworkers[96-101] have shown that appreciable quantities of intermediate compounds of the type SiCl, $SiCl_2$, $SiCl_3$, $HSiCl_2$ may be formed in the gas phase in the reactions of copper(I) chloride and of gaseous hydrogen chloride with silicon. Thermodynamic calculations, as well as direct investigation of dichlorosilane $SiCl_2$ by mass spectrometry and ultraviolet spectroscopy, indicate comparatively high concentrations of this intermediate in the reduction of copper(I) chloride by silicon in the temperature range of direct synthesis (180°C and above)[96,97,100-102].

Attempts were made[103] to study the interaction of intermediate products in the chlorination of silicon ($SiCl_2$) with methyl chloride in the presence of copper. Ascribing great importance to copper(I) chloride, as in Hurd and Rochow's mechanism, and also allowing for the possible formation of $SiCl_2$, Andrianov, Golubtsov, et al. suggested a scheme of direct synthesis[103] in which an important part was assigned to the hypothetical compound RCl.Cu, which reacted with $SiCl_2$ to give R_2SiCl_2 and $RSiCl_3$, regenerating CuCl and Cu respectively. It is not clear from the paper where the main stages occur, in particular whether those involving $SiCl_2$ take place on the surface or in the gas phase. Alkylation stages involving R or CuR are excluded. Yet Czernotsky[104], from a study of the effect of additions of dimethyl ether on the formation of methylchlorosilanes, concludes that dimethyldichlorosilane is formed by the interaction of dichlorosilene with methyl radicals, which according to Müller and Gumbel[105] are formed from methyl chloride and copper.

Many objections have been raised against a radical mechanism of direct synthesis[15,16,93]. Special experiments in which donors or acceptors of radicals—nitric oxide[106], iodine[15], azomethane[15,58]—were introduced into the reaction mixture in the synthesis of methylchlorosilanes also did not support a radical mechanism. Comparative analysis[107] of products of the pyrolysis of chlorobenzene and by products not containing silicon also makes participation of free phenyl radicals in the synthesis of phenylchlorosilanes improbable.

Direct assessment of the homogeneous component in homogeneous–heterogeneous processes—by a method of separate calorimetry—has been used to settle the question of the nature of the reactions involved in the synthesis of silicon and germanium halides and their organic derivatives[26,27,44,108-110]. In the formation of trichlorosilane[44,110] good agreement was shown by a quantitative comparison of the rise in temperature calculated theoretically for a purely heterogeneous synthesis and observed experimentally. Consequently no significant exothermic stages take place in the gas phase. The chlorination of silicon[26], the chlorination[27] and hydrochlorination[18] of germanium, and the formation of methylchlorosilane[108,109], germanes[18], and ethylchlorosilanes[18] have been studied similarly. The results also indicate the absence of homogeneous exothermic reactions.

Thus the main stages in most of the processes investigated—for which, moreover, the most complete kinetic data are available—must be regarded as heterogeneous, taking place solely on the surface of the solid reactant.

2. Intermediate Surface Chemical Interaction

With purely heterogeneous reactions the first stage—adsorption of the gaseous reactant—may be of the most important. Rostsishevskii[113] made the first attempt at a qualitative estimate of the adsorption of methyl chloride on silicon–copper contact masses. Adsorption was found to be slight below 230°C, and was larger on alloy contact masses (15% Cu) than on a mixture of silicon and copper powders.

Bažant et al.[56] showed that methyl chloride is not adsorbed at 100°C, either on copper or on silicon, although adsorption occurs on a silicon–copper alloy (10% Cu), and at 200 torrs reaches the improbably (to the Reviewers) high value of 3.5×10^{-5} mole g^{-1}, which corresponds to roughly nine monolayers of adsorbed methyl chloride.

The adsorption of methyl chloride was studied in greater detail by Müller and Gumbel[105], who concluded that considerable adsorption occurs on the surface of a silicon–copper contact mass containing silicon–chlorine and copper–chlorine bonds (after preliminary chlorination

or remaining from the conditions of preparation of the mass). Appreciable adsorption is observed also on copper(I) chloride, which may be present in chlorine-containing contact masses. The paper contains no information on the specific surfaces of the adsorbents, and the experiments were made only at one, fairly high temperature (245–250°C), when investigations of adsorption may have been complicated by the occurrence of chemical reaction on the surface.

Contradictory views are held on the nature of the adsorption bonds holding RX to the contact masses. The concept of the dissociative adsorption of RCl is widely used in the literature on direct synthesis without adequate experimental justification. Thus adsorption on two centres of the type

is assumed by Trambouze[37] and by Bažant et al.[15]; whereas Voorhoeve[58] and Klebanskii and Fikhtengol'ts[78] take into account the electronegativity of the elements and suggest adsorption of the type

Several authors have considered the chemisorption of RCl on silicon–copper contact masses in terms of the band theory of solids. Thus Trambouze[37] used Dowden's well known views[111] concerning catalysis and chemisorption on metals. Dragojevic[112] explains chemisorption and the effect of copper and other additives in silicon on the basis of Vol'kenshtein's semiconductor theory[114], but direct experimental confirmation of the authors' conclusions is lacking; the former ignores the specific character of silicon, which has a quasi-insulated surface. Yet the discussion of adsorption on silicon–copper contact masses containing 10–20% of copper in terms of the electronic theory of semiconductor catalysis is incorrect, because such adsorbents are already strongly alloyed, degenerate semiconductors.

Work published during recent years enables a fuller assessment to be made of the character of the adsorption. Boonstra, Van Ruler[115,116], and Bootsma[117] established by a volumetric method, and Podgornyi et al.[118–124] from the contact potential difference[126], two characteristic types of adsorption of hydrogen chloride on pure polycrystalline silicon and on germanium: the γ-form involves rapid adsorption and has a lower activation energy; the β-form involves slow adsorption and requires a larger activation energy[116,119–121]. Hydrogen bromide and hydrogen iodide are adsorbed similarly[116,117]. Extremely low heats of adsorption were estimated by a chromatographic method for the low-temperature and the activated adsorption of hydrogen chloride on technical (98%) silicon[127]. The adsorption of hydrogen chloride on silicon was found to be strongly dependent on its purity, the presence of impurities, and catalytic additions of copper, the last of which promote the type of adsorption having a higher activation energy[123].

Studies have been made also of the adsorption of gaseous chlorine, chloromethane, and chloroethane[118–121] on silicon and germanium[120], as well as of chlorobenzene, vinyl chloride, and allyl chloride on silicon[122]. As with hydrogen chloride, the two forms of adsorption are found with chlorine and methyl and ethyl chlorides on pure polycrystalline silicon; but very slight adsorption effects are observed with alkyl chlorides compared with hydrogen chloride and chlorine.

Since the chemisorption of the adsorbates studied is reversible and extremely rapid even at room temperature, both on silicon and on germanium, it is evidently not the limiting stage.

With regard to the nature of the chemisorption bonds, hydrogen, methyl, and ethyl chlorides are adsorbed mainly in molecular form on silicon at room temperature[118–124]. The adsorption bond is assumed to be formed through the chlorine atom of the RCl molecule: the β-form of adsorption is effected by the donation of a pair of $3p$ electrons of the chlorine atom to a d orbital of silicon (or germanium), i.e. by a donor–acceptor bond; the γ-form corresponds to formation of a bond in which electrons from the adsorbent are directed to a $3d$ orbital of the chlorine atom. It is noteworthy in this connection that the adsorption of hydrogen halides on silicon and germanium has been assumed[115,116] to be dissociative in character.

The lack of adequate data on the first stage of surface chemical interaction—adsorption of the gaseous reactant RX—introduces some uncertainty, of course, into the description of subsequent reactions of the surface compounds on silicon (or germanium) before formation of the final products.

Two approaches have been adopted towards the stages of surface chemical interaction: the first assumes the presence of a stage limiting the whole process, and the second a steady state with no limiting stage. Thus adsorption of RX is the limiting stage in the formation of trichlorosilane and methylchlorosilanes according to Trambouze[37], and in that of ethyl-, phenyl-, and vinylchlorosilanes according to Voorhoeve[16]. However, Bažant and his coworkers[15] regard the adsorption step as extremely rapid in several processes of direct synthesis (of hydrogen-containing chlorosilanes[38], dimethyldichlorosilane[56,57], dimethyldibromosilane[127], and phenylbromosilanes[75]), assuming that the reaction velocity is limited by the surface reaction of adsorbed RX in dissociated form. Similar views were held by Müller and Gumbel[105]. The above adsorption results indicate that the opinions of the latter authors are quite well founded. Nevertheless, the hypothesis of dissociative adsorption of RX has no direct experimental support, as noted already. It has therefore been assumed in a recent series of papers[119–124] that methyl chloride is adsorbed in molecular form quite rapidly and reversibly both on silicon–copper[119] and on germanium–copper[120] contact masses. Kinetic data[62,69] on the formation of dimethyldichlorosilane (for the order with respect to methyl chloride see Section II) indicate that the activated complex of the limiting stage contains one molecule of chemisorbed methyl chloride, but in the case of dimethyldichlorogermane two methyl chloride molecules are present[18,19].

Even the simpler processes—the halogenation of silicon and germanium—are also viewed in different ways. The fluorination of silicon has been regarded[25] as limited by the adsorption stage. The iodination of germanium to the di-iodide has been represented[32] by a four-stage scheme involving dissociated forms of chemisorbed molecular iodine I_2 and bulk and surface current carriers in the crystal. The initial period of the chlorination of silicon produces linear polymeric chlorosilane molecules attached to surface atoms[128–130]. In the chlorination of germanium[30] the surface is assumed to be completely covered with the chemisorbed gaseous reactant, and the limiting stage is conversion of the surface germanium–chlorine compound; an important role is attributed to current carriers in the semiconductor.

The reactions of silicon and germanium with hydrogen halides have been more thoroughly studied. At temperatures close to the start of the reaction the hydrochlorination and the hydrobromination both of silicon and of germanium involve formation of the trihalogeno-derivative HMX_3 as main product. On the basis of adsorption data and investigations of the kinetic isotope effect in the reactions of silicon [34,131] and germanium [34,46] with HX and DX (where X = Cl, Br), and also kinetic data (Section II), the slow stage is assumed to be a surface chemical reaction of the chemisorbed hydrogen halide in molecular form. The HX molecule in the activated complex is deformed differently depending on the reactivity of the solid reactant: on highly active specimens (containing copper or an impurity) the H–X molecule is present in the activated complex essentially in a dissociated form (with the establishment of M–X and M–H bonds); on relatively inactive specimens (high-purity silicon and germanium) the state of the H–X molecule in the activated complex is similar to adsorption.

A mechanism suggested [52] for the action of hydrogen iodide on germanium, when the main product is the di-iodide GeI_2, involves as limiting stage desorption of the product formed by reaction between the surface compound HGeI and gaseous hydrogen iodide.

Alkyldichlorogermanes $RGeHCl_2$ cannot be obtained by direct synthesis [4]. Thus the desired results could not be obtained from the interaction of mixtures of methyl and hydrogen chlorides with germanium–copper contact masses over a wide range of temperatures [68]. This is probably because the surface compound GeHCl reacts rapidly with hydrogen chloride to form the surface dichloride $GeCl_2$, which reacts with methylchloride to give the final product CH_3GeCl_3. Formation of a bond with hydrogen in the direct synthesis of alkyldichlorosilanes is more probable with silicon than with germanium, owing to the specific character of the surface compound SiHCl.

Thus the first approach in interpreting surface chemical interaction in formation of the corresponding gaseous derivatives of silicon or germanium is usually based on adsorption data, but in some cases with recourse to kinetic results (type of kinetic equation representing formation of an individual product). No use at all is made of data on the selectivity of the process, which is its important characteristic [162].

In practice, however, e.g. in hydrohalogenation, the synthesis of alkyldichlorosilanes, etc., several products are very often formed simultaneously [68]. Thus, in the synthesis of methyldichlorosilane from mixtures of hydrogen and methyl chlorides, silicon tetrachloride is formed at a closely similar rate to trichlorosilane. Similarly, trichlorosilane and dichlorosilane are formed at similar rates in the hydrochlorination of silicon over a certain temperature range. In these cases, therefore, it is impossible to describe the surface chemical interaction in terms of the concept of a limiting stage.

Such more complicated situations have been discussed in recent years in terms of the Horiuti–Temkin theory of stationary reactions [132,133], which has already been widely used to describe surface chemical interaction in complicated heterogeneous catalytic reactions [13,134]. This second approach has proved extremely useful for interpreting the mechanism of the reactions

$$HCl + Si \rightarrow \text{Products}$$
$$HCl + MeCl + Si \rightarrow \text{Products} \quad .$$

It may evidently be quite effective in examining the direct synthesis of methylchlorosilanes and other organosilicon monomers [19].

It was assumed in this work that the gaseous reactant is adsorbed in molecular form, and that the intermediate surface compounds do not contain copper. A multistage mechanism was proposed for the hydrochlorination of silicon, which involved the assumed formation of the intermediate surface compounds (ZHCl), (ZHCl.HCl), (ZHSiCl), $(ZSiCl_2)$, $(ZSiCl_3)$, and (ZH), where Z denotes an active centre on the surface [133]. The process is represented by a nine-stage scheme with three independent paths

$$Si + 2HCl = H_2SiCl_2$$
$$Si + 3HCl = HSiCl_3 + H_2$$
$$Si + 4HCl = SiCl_4 + 2H_2 \quad .$$

The suggested mechanism agrees satisfactorily with kinetic data (Section II) and experimental data indicating a linear dependence of the selectivity $S = r_{II}/r_I$, the ratio of the rates by the second and first routes, on the reciprocal p_{HCl}^{-1} of the partial pressure of the gaseous reactant.

The mechanism of the more complicated reaction

$$HCl + MeCl + Si \rightarrow \text{Products}$$

has been analysed similarly [132]. Consideration is given not only to the above intermediate surface compounds but also to molecules (ZCH_3Cl) adsorbed on the silicon surface. The mechanism comprises ten stages with four independent routes

$$MeCl + HCl + Si = MeSiHCl_2$$
$$MeCl + 2HCl + Si = H_2 + MeSiCl_3$$
$$3HCl + Si = H_2 + HSiCl_3$$
$$4HCl + Si = 2H_2 + SiCl_4 \quad .$$

The kinetic equation obtained for the formation of the methyldichlorosilane is consistent with the observed first order with respect to methyl chloride. The expression for the selectivity $S = r_I/r_{IV}$ (the ratio of the rates by the first and fourth routes) was a linear function of the ratio of the partial pressures of the gaseous reactants p_{HCl}/p_{CH_3Cl}, in good agreement with experiment.

Since either (ZHCl) or (ZHSiCl) may be formed by the pyrolysis of methyl chloride, we can try to extend the multistage mechanism of the process

$$MeCl + HCl + Si \rightarrow \text{Products}$$

to the process

$$MeCl + Si \rightarrow \text{Products} \quad .$$

In particular, a possible scheme of formation of dimethyldichlorosilane may comprise the stages [19]

$$MeCl + Z \rightleftarrows ZMeCl$$
$$ZMeCl + ZMeCl \rightleftarrows ZMeCl \cdot MeCl + Z$$
$$ZMeCl \cdot MeCl + Si \rightarrow Me_2SiCl_2 + Z \quad .$$

The appearance of such byproducts as tri- and di-methylchlorosilanes can be explained by the presence of the stages

$$ZMeCl + ZMeSiMe \rightarrow Me_3SiCl + 2Z$$
$$ZMeCl + ZMeSiH \rightarrow Me_2SiHCl + 2Z \quad .$$

However, this leaves unanswered the question of the stages which will lead to formation of the intermediates (ZCH_3SiCH_3), (ZCH_3SiH), $(ZHCH_3Cl)$, and $(ZSiCl_2)$. More detailed investigations are required here on the mechanism of the pyrolysis of alkylchlorosilanes on a silicon–copper contact mass.

The idea of the formation of symmetrical derivatives such as dichlorosilane and dimethyldichlorosilane via intermediate compounds from two molecules of the gaseous

reactant is expressed in several papers, as already noted above. However, the qualitative aspect—the nature of the active centre Z—was the main concern. Thus Voorhoeve[16] suggested that the active centre in the direct synthesis of methylchlorosilanes contains two copper atoms and one silicon atom. In a series of later investigations Golubtsov et al.[135] considered that the active centre in this process is a group of the type SiCl. The theory of stationary reactions permits a quantitative approach to the inclusion of intermediate compounds of the type (ZRCl.RCl) in a multistage scheme, since its consequences can be tested experimentally. On the assumption, for example, that dichlorosilane is formed at the stage

$$ZHCl+ZHSiCl\rightarrow H_2SiCl_2+2Z,$$

in the hydrochlorination of silicon, the above selectivity $S = r_{II}/r_I$ would in general not have depended on the partial pressure of hydrogen chloride, which would have been contrary to experience.

The nature of the active centre in the kinetic analysis of multistage schemes is not significant in the Horiuti–Temkin method, since the surface is assumed to be in a steady state.

Role of copper and impurities

Comparison of kinetic data on the chlorination and hydrochlorination of silicon and germanium with data on their interaction with methyl chloride and bromide reveals the features reported below.

(*a*) Syntheses involving germanium have smaller activation energies than those involving silicon.

(*b*) A higher kinetic order with respect to the gaseous reactant is observed with germanium–copper contact masses than in the case of silicon.

(*c*) Impurities and additions of copper have a marked effect on the kinetics, lowering considerably the activation energy, and this effect is larger for reaction with germanium. Thus the order with respect to chlorine in the chlorination and hydrochlorination of silicon is higher in the presence of copper and impurities, while the activation energy falls by ~10–12 kcal mole^{-1}, i.e. by ~30% (Tables 1 and 2). The activation energy is halved with germanium. Such a relation is observed in hydrobromination (Table 4) and in the synthesis of dimethyldihalogeno-derivatives (Table 5).

(*d*) The nature of the halogen in RX (Cl or Br) has no marked effect on the kinetic parameters of the synthesis of halogenosilanes containing hydrogen or organic groups (Tables 2–4).

The decisive factor can be regarded[27,131] as the strength of the M–M bond on the surface of the solid reactant M. The higher activation energies with silicon can be explained by a more stable bond between silicon atoms, on the assumption that the same fraction of the energy of silicon–silicon and germanium–germanium bonds in the surface and adjacent layers enters as components of the activation energy[28,131]. In the hydrohalogenation of technical samples of silicon, as well as of silicon–copper and germanium–copper contact masses, the impurities and the additions of copper probably influence the energy of the M–M bond, promoting both easier rupture in the transition state and strong deformation of the H–X bond until the latter dissociates.

The effect of copper is not universal. Specimens of technical silicon even in the absence of copper are sufficiently reactive in some processes (chlorination[26], hydrochlorination[45], and hydrobromination[48] of silicon, synthesis of methyl-[68] and ethyl-dichlorosilanes[18] from mixtures of the alkyl and hydrogen chlorides). Nevertheless, specimens of high-purity silicon become considerably more active on the introduction of copper, and react at a lower temperature.

Various surface compounds of copper, regarded in several cases as independent phases, have been postulated as intermediates to explain the specific effect of copper on direct syntheses (CuR,[92] CuCl, RCuCl,[94] $HCuCl_2$,[136] Cu_3Si,[78] etc.). The role of copper is mainly to transfer chlorine atoms or R or RCl groups to the silicon atom. The regenerated copper again takes part in forming the intermediate compound.

Published mechanisms of direct synthesis do not reveal sufficiently clearly the functions of copper as a catalyst, and existing views are in some cases directly contradictory. In the first paper Hurd and Rochow[92] suggested that an indispensable condition for effective synthesis was close contact between silicon and copper phases, since rapid consumption of silicon occurred precisely at the interface. Essentially the same attitude was adopted by Bažant et al.[56,137] and also by Rossmy[138]. At the same time, beginning with the work of Klebanskii[78] and Trambouze[37] followed by the investigations of Voorhoeve[88] and of Kolster[139], silicon present as an intermetallic compound was assumed to be reactive. Andrianov, Golubtsov, et al.[140] and also Krylov and Efremov[81,82] showed that the intermediate compound acts as a donor of catalytically active copper, for contact masses not containing Cu_3Si are also catalytically active[141,142]. The functions of the copper catalyst formed by breakdown of the intermetallic compound are not clear from this work.

Such contradictory views are probably due to the absence in the above investigations of direct examination of the surface and adjacent layers of the contact masses. The reaction of hydrogen chloride, hydrogen bromide, and methyl bromide with silicon (formation of trichlorosilane[43], tribromosilane[34], methyldichlorosilane[18], and methylbromosilanes[127]) has established that copper(I) chloride, like the bromide[34], is not a catalyst, since synthesis begins only after this compound has been reduced by silicon and free copper and the Cu_3Si phase have separated.

Even a small copper content (10^{17}–10^{19} atoms cm^{-3}) proves extremely effective both for the adsorption of hydrogen chloride[124] and for sharply increasing the reactivity of the silicon[143]. This effect can be explained by a change in the collective electronic properties of the surface silicon atoms. These changes affect also the character of the adjacent layers. Thus additions of copper over the range 10^{17}–10^{20} atoms cm^{-3} lower the microhardness of a single crystal of silicon from 1250 to 700 kg mm^{-2} for a specimen with a 10^{20} atoms cm^{-3} copper content[143]. Data are also available[144,145], though less complete, on the variation of the microhardness of germanium when fairly extensively alloyed with other elements (10^{18}–10^{20} atoms cm^{-3}). A parallelism has been observed[146] between the variation of microhardness and that of specific surface energy of semiconductor crystals with covalent bonds. Such change in the state of the surface atoms should tend to enhance their reactivity, as has been observed e.g. in the synthesis of trichlorosilane. The combined electronic effect of small additions of copper, evident in the effects on the microhardness, the reactivity, and the chemisorptive power of silicon, cannot be regarded as specific to copper. This conclusion is

supported by the high reactivity of technical silicon, without the addition of copper, towards several direct syntheses (chlorination, hydrochlorination, formation of methyl- and ethyl-dichlorosilanes).

However, the change in the combined electronic properties of silicon with the introduction of small quantities of copper is insufficient for reaction with methyl chloride. Thus methyldichlorosilane is formed from a mixture of hydrogen and methyl chlorides on technical and pure silicon alloyed with copper (0.04–0.3%) in the temperature range 210–240°C, [68] which is close to the range (160–210°C) for the synthesis of trichlorosilane. But formation of dimethyldichlorosilane from methyl chloride alone and similar specimens of silicon was not observed up to 400°C. Hence it may be concluded that, in contrast to the synthesis of hydrogen-containing chlorosilanes, the formation dimethyldichlorosilane requires additional electronic changes in silicon, probably connected with the local action of copper on its surface atoms. Such an effect can be achieved only with a comparatively high content of copper in the surface and adjacent layers of silicon.

The presence of the η-phase or other intermetallic compound of silicon and copper is probably not essential for the local action of copper on the surface silicon atoms, i.e. to ensure the synthesis of dimethyldichlorosilane and probably other dialkyldichlorosilanes. In the presence of a highly active and extensive copper surface (taking into account the abnormally high rate of diffusion of copper atoms in the silicon and Cu_3Si crystal) [139], formation of an intermediate surface compound of silicon with copper may be sufficient for development of a local effect. Formation of the η-phase is a limiting case.

The long induction period in the reaction observed in practice when contact masses comprising a mixture of silicon and copper powders are used, as well as with certain alloy masses, is probably caused by formation of an active surface and of layers adjacent to the surface.

The large quantity of experimental data published on the action of impurity elements and promoters in contact masses, and also of gaseous contact poisons, represent mainly assessment of their overall and selective activity in the synthesis of hydrogen-containing halogeno-silanes and -germanes as well as corresponding organic derivatives. No quantitative data have appeared on the effect of impurities and promoters on the kinetics of the process, and therefore this question will not be examined in detail in the present Review.

The total and the selective activity of the contact masses are not significantly affected [147–149] by the usual impurities —aluminium, iron, and calcium—in silicon up to a total content of 2% and 10% of iron. However, these parameters diminish at higher contents of individual elements (1% of titanium, 2% of aluminium, 1.5% of calcium) [148]. The promoting action of individual elements (antimony, zinc, cadmium, bismuth, phosphorus, arsenic, tin, and indium) and of certain combinations (antimony plus zinc, zinc plus cadmium, antimony plus bismuth, etc.) is apparent in a higher yield of dialkyldichlorosilanes. Use of certain of these promoters (zinc, antimony, arsenic) in the synthesis of alkylhalogenogermanes [150] leads to a sharp increase in the yield of the alkyltrichloro-derivative. The yield of ethyldichlorosilane in the synthesis of ethylchlorosilanes is raised by the addition of 1.7% of aluminium, 1% of titanium, or 2% of calcium [151]. Only a certain content of promoters—not exceeding e.g. 0.001–0.005% of antimony and bismith—is optimal for the total and selective activity. Addition of higher contents of zinc and aluminium to the contact mass promotes the formation of trialkylchlorosilanes [153]. More than 0.01% of lead leads to complete deactivation of the contact mass [148,152]. Addition of aluminium and gallium increases the yield of the trimethylchlorogermane in the synthesis of methylchlorogermanes [154].

Contamination of the alkyl chloride with dimethyl ether [155], methylene dichloride [156], and sulphur dioxide [157] diminishes the activity of the contact masses.

The promoting effect of zinc, cadmium, and mercury has been explained [158] by their reaction with the organic halide in the gas phase to form their chlorides followed by transfer of a chlorine atom to copper to form cuprous chloride, which in turn is effective in the synthesis of alkylchlorosilanes by transferring its chlorine atom to silicon. However, the formation of copper(I) chloride was assumed from the content of Cu_3Si in the contact mass, although this silicide might not have been formed in this way.

Studies of the effect of promoting additions of several elements (aluminium, iron, titanium, zinc, antimony, phosphorus, arsenic, bismuth, boron, indium, gallium, tin, etc.) to samples of pure, purified, and technical silicon merit closer attention. It was concluded [159,160] from the results that promoting additives, introduced into the crystal lattice of silicon, may have either a favourable or an unfavourable effect on direct synthesis depending on their ability to react with the organic halide, and thus function as activators or inhibitors of the catalytic process.

The favourable effect of impurities and promoters in silicon has been attributed [161] to facilitation of the penetration of copper into the silicon lattice, or else the formation of silicides of low melting point.

Since the catalyst (copper) is especially sensitive to impurities, both it and surface silicon atoms can be assumed to be influenced both by gaseous impurities in the organic halide and by solid elements added to the contact masses; these effects will be still greater if a donor–acceptor type of bond can be formed on adsorption. The catalytic properties of copper and its ability to form particular compounds with silicon at the interface may be affected by adsorption on it especially of surface-active substances.

Hydrolysis of Alkyl Halides Induced by Metal Ions: M^+-S_N1 and M^+-S_N2† Reactions

E.S.Rudakov, I.V.Kozhevnikov, and V.V.Zamashchikov

Investigations of the kinetics, mechanism, and driving forces of hydrolyses of alkyl halides and several inorganic halides, induced by metal ions M^+ in aqueous media, are summarised. Relations between the rate and the Lewis acidity of M^+ are examined, together with models of M^+-S_N1 and M^+-S_N2 reactions. A list of 163 references is included.

CONTENTS

I. Introduction 305
II. Role of metal ions in the hydrolysis of t-butyl halides—correlation between rate and Lewis acidity of M^+ 305
III. Models of M^+-S_N1 reactions 307
IV. M^+-S_N1 hydrolysis of inorganic halides 309

VI. Aspects of the reactions of alkyl halides with silver ions 313

I. INTRODUCTION

The ability of silver(I) and mercury(II) ions and of certain complexes to accelerate substitution in organic and inorganic halides is well known. The early work was briefly surveyed in monographs [1-3]. In 1937 Roberts and Hammett [4] suggested that a correlation, similar to the Brønsted relation [5,6] for general acid catalysis, may exist between the rates of such reactions and the Lewis acidities of the electrophiles. This question was investigated systematically [7-9] during 1967-1972 on the hydrolysis, induced by metal ions M^+, of alkyl halides of Ingold's classic α-series [1]

$$H_2O + RX + M^+ \rightarrow H^+ + ROH + XM \qquad (1)$$

(R = CH_3, C_2H_5, iso-C_3H_7, t-C_4H_9; X = F, Cl, Br, I). As a consequence of the affinity of X for M the entry of RX into the coordination sphere of M^+ promotes heterolysis of the C-X bond (M^+-S_N1 mechanism) and reactions with a nucleophile (M^+-S_N2 mechanism). The Review is concerned mainly with reactions in aqueous media. Water is more convenient than the non-aqueous and anhydrous media generally used: the kinetics is less complicated by ionic association, extrapolation to zero ionic strength is more reliable, and ample information is available on the stability of the MX complexes [10]. The present Review deals with the kinetics and the mechanism of these reactions, the role of the structure of R, X, M^+, and the medium, the validity of correlations of the Brønsted type, and fine distinctions between the correlations for M^+-S_N1 and M^+-S_N2 mechanisms. For generality reactions of inorganic halides which might have an M^+-S_N1 mechanism are also considered.

II. ROLE OF METAL IONS IN THE HYDROLYSIS OF t-BUTYL HALIDES—CORRELATION BETWEEN RATE AND LEWIS ACIDITY OF M^+

The solvolysis of t-butyl chloride is accelerated by silver salts in acetone [11] and by mercury(II)chloride in aqueous ethanol and in acetone [12-14], while hydrogen exchange between the t-butyl group and the solvent in acetic deutero-acid is accelerated by chlorides in the sequence [15]

antimony(V) > iron(III) > tin(IV) > zinc(II) > mercury(II).

Alkali-metal ions are inactive in the hydrolysis of t-butyl chloride [16]. Detailed studies have been made of the effects of other ions in the hydrolysis of t-butyl fluoride, chloride, and bromide in aqueous media [7,17-27] (Table 1). At constant ionic strength μ the kinetics of the hydrolysis is represented by the equation [18]

$$k \equiv \frac{1}{[RX]}\frac{d[RX]}{d\tau} = k_0 + k_1[M^+] \qquad (2)$$

where k_0 corresponds to the reaction with the solvent, and k_1 to that with the M^+ ion.

The activity of the ions corresponds to the concept of "hard" and "soft" acids and bases [28]. The "hard" acids—Zr^{4+}, Th^{4+}, Sc^{3+}, Al^{3+}, etc.—are active with t-butyl fluoride (detachment of the "hard" base F^-). The activity increases with decrease in the atomic number within a subgroup of the Periodic System: e.g. $In^{3+} < Ga^{3+} < Al^{3+}$; $La^{3+} < Y^{3+} < Sc^{3+}$; and $Sr^{2+} < Mg^{2+} < Be^{2+}$. "Soft" Lewis acids are active with t-butyl chloride and bromide, and k_1 increases with increase in atomic number within a subgroup: $Hg^{2+} > Cd^{2+} > Zn^{2+}$; $Tl^{3+} > Ln^{3+} > Ga^{3+} > Al^{3+}$; $Pd^{2+} > Ni^{2+}$.

A clear relation exists between k_1 and the stability constant $K_{MX} = [MX]/[M^+][X^-]$ of the complex MX: [17,20,21]

$$\lg k_1 = A_X + \beta \lg K_{MX} \qquad (3)$$

For each X = F, Cl, Br the activity of M^+ is higher the greater the Lewis acidity of M^+. The activity series of the metals follow the variations in K_{MX}, and are different for X = F from those for X = Cl, Br. Thus Al^{3+} is active with the fluoride and relatively inactive with the chloride. The opposite situation is found for the silver ion. The independent terms A_X in Eqn. (3) are different for X = F, Cl, Br, but all the lines have roughly the same slope β. As was to be expected for reactions of acid–base type, the electronic structure (completeness of the electron shell) of the metal ions does not influence their effectiveness in the hydrolysis of alkyl halides. The acid hydrolysis ($M^+ = H^+$) of t-butyl fluoride has also been studied [21]. The nature of the anion (A = NO_3^- or ClO_4^-) does not affect the value of $k_1 = k/[H^+]$ extrapolated to $\mu = 0$ (for $\lg k_1$ varies

†Usage of the symbol "M^+" in this paper follows that of the original Russian, and does not necessarily imply "unit" positive charge: M^{n+} would have been more explicit (Ed. of Translation).

linearly with [HA])[24]. The same information is conveyed[21] by the Hammett equations: $\lg k = -1.14H_0 - 3.61$ (for perchloric acid) and $\lg k = -1.06H_0 - 3.72$ (for nitric acid), where H_0 is the acidity function. The value of k_1 for H^+ corresponds to the great stability of the complex HF, and is consistent with the general correlation (3).[26] Hydrogen chloride is significantly less stable[10]. Therefore the contribution of H^+ to the hydrolysis of t-butyl chloride becomes appreciable only in concentrated acids, e.g. perchloric acid[29].

[a]The theoretical equation for this system is $\lg(k_1/k_0K_{MX})_{theor} = -3.1Z_M/(4.5 + r_M)$, where Z_M and r_M are the charge and the radius of M^+ (in Å)(see Section III).
[b]Theoretical equation $\lg(k_1/k_0K_{MX})_{theor} = -4.1Z_M/(5.4 + r_M)$.
[c]Theoretical equation $\lg(k_1/k_0K_{MX})_{theor} = -4.6Z_M/(5.7 + r_M)$.

An important exception to the correlation (3) has been established[26] for the Cr^{3+} ion, which is inert in the hydrolysis of t-butyl fluoride despite the great stability of CrF^{2+}. Since $[Cr(H_2O)_6]^{3+}$ has an abnormally low rate of exchange of the aquo-ligands $k_{exch} = 10^{-6}$ s^{-1},[28,30] this exception indicates inner-sphere coordination in the interaction of RX with M^+, and hindrance to M^+–S_N1 reactions, when the ion is not accessible to direct contact with the substrate. Rates of exchange are high in the case of other metal ions[28,30], and departures from correlations (3) are not observed.

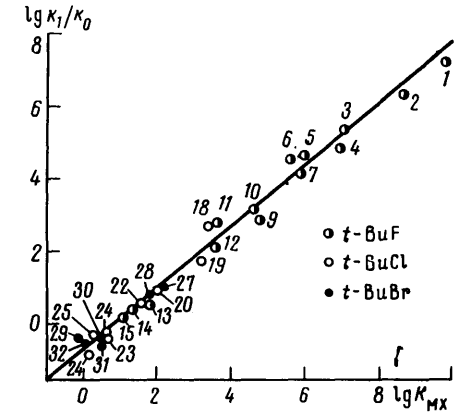

Figure 1. Dependence of $\lg(k_1/k_0)$ on $\lg K_{MX}$ for the hydrolysis of t-butyl halides in the presence of aquo-ions of metals. The numbering and the characteristics of the systems are given in Table 1.

*Theoretical equation $\lg(k_1/k_0K_{MX})_{theor} = -76/D$.

Plots of k_1/k_0 against K_{MX}, both taken at zero ionic strength, merge into a single line for different t-butyl halides (Fig. 1). This leads to a correlation of great generality

$$\lg k_1/k_0 = -0.7 + 0.84 \lg K_{MX} \quad , \qquad (4)$$

which allows for the effects of both M^+ and X.[7,23] Equation (4) represents also the effects of the solvent for the reactions of t-butyl chloride with Cd^{2+} in aqueous alcohol (Table 2) and is applicable to the reaction in nitromethane[23]

$$t\text{-}C_4H_9Cl + HCl \rightarrow t\text{-}C_4H_9^+ + HCl_2^-.$$

In the latter case the electrophile is an uncharged hydrogen chloride molecule, and values of k_1, k_0, and $K_{MX} = [HCl_2^-]/[HCl][Cl^-]$ were estimated[23] from published data[31]. Catalysis is clearly developed in aprotic media: the lithium ion accelerates heterolysis of triphenylmethyl chloride in diethyl ether[32] and of diphenylmethyl chloride in 70% dioxan[27].

No detailed study has been made of the reaction products formed from t-butyl halides and metal ions. The yield of isobutene in the hydrolysis of t-butyl fluoride falls[27] in parallel with increase in the contribution of $k_1[M^+]$ to the total rate $k_0 + k_1[M^+]$. Reaction with strong electrophiles M^+, in contrast to reaction with the solvent, is evidently not accompanied by elimination. The proportion of elimination decreases in the reactions of other alkyl halides with the silver ion[33,34].

III. MODELS OF M^+–S_N1 REACTIONS

According to Ingold[1] t-butyl halides (fluoride, chloride, bromide, and iodide) are hydrolysed by an S_N1 mechanism owing to the enhanced stability of $(CH_3)_3C^+$, in comparison with e.g. CH_3^+, $C_2H_5^+$, iso-$C_3H_7^+$, and steric hindrance to nucleophilic attack at the carbonium centre. The above results show that an S_N1 mechanism is maintained even with induced reactions. The M^+–S_N1 and S_N1 mechanisms differ in the replacement of a solvent molecule in the solvate sheath of the transition state by an M^+ ion having a higher affinity for X^-, and in the quantitative characterisation of the participation of the electrophile in the M^+–S_N1 reaction by the order and the rate constant of the reaction with M^+.

The fundamental model of an M^+–S_N1 reaction[20] is represented by the scheme

$$\begin{array}{lcccccc} & (a) & & (b) & & (c) & \\ \mathrm{A} & RX & \xrightarrow{K_0^{\neq}} & R^{\delta+} \ldots X^{\delta-} \ldots S & \xrightarrow{kT/h} & R^+ + X^- & \\ & M^+\downarrow\uparrow K_{gr.} & & \downarrow\uparrow K_{tr.} & & & \\ \mathrm{B} & RX \ldots M^+ & \xrightarrow{K^{\neq}} & R^{\delta+} \ldots X^{\delta-} \ldots M^+ & \xrightarrow{kT/h} & R^+ + XM. & (5) \\ & (d) & & (e) & & (f) & \end{array}$$

Route A comprises a slow stage of S_N1 solvolysis of RX by the solvent S, involving an activation equilibrium $(a \rightarrow b)$ and breakdown of the transition state $(b \rightarrow c)$ at a rate kT/h.[35] Formation of the complex (d) gives rise to an induced reaction (route B). The activation equilibrium constants are denoted by $K_0^{\neq}$ and $K^{\neq}$, and the equilibrium constant of formation of the complex in the ground state is

$$K_{gr.} = [RX \ldots M^+]/[RX][M^+] \quad . \qquad (6)$$

This mechanism leads to the equation

$$k = \frac{k_0 + k_1[M^+]}{1 + K_{gr.}[M^+]} \quad , \qquad (7)$$

which is well known for such reactions[19,20]; it simplifies to (2) when $Kgr[M^+] \ll 1$.

Formulation of the principle of equilibrium solvation of the transition state in S_N1 reactions[36] led to the concept of the equilibrium constant of transition states for M^+–S_N1 and S_N1 reactions. From the chain of equilibria $(b) \rightleftharpoons (a) \rightleftharpoons (d) \rightleftharpoons (e)$ (Eqn. 5) it may be concluded that the transition states (b) and (e) are in equilibrium in the sense that they appear simultaneously and in proportions corresponding to the equilibrium constant (8a)

$$K_{tr.} = \frac{[R^{\delta+}X^{\delta-}M^+]}{[R^{\delta+}X^{\delta-}][M^+]} \quad (8a), \qquad K_{MX} = \frac{[MX]}{[M^+][X^-]} \quad . \qquad (8b)$$

The species $R^{\delta+} \ldots X^{\delta-} \ldots M^+$ can be regarded as the equilibrium solvate (complex) $R^{\delta+} \ldots X^{\delta-}$ together with M^+, where the latter is regarded as a constituent of the medium. The numerical value of K_{tr} is determined directly from kinetic data[19,20].

$$K_{tr.} = K_{gr.}K^{\neq}/K_0^{\neq} = k_1/k_0 \quad . \qquad (9)$$

A quantity similar to K_{tr} has been discussed by other authors[37]. Several consequences follow from a comparison[20] of formulae (8a) and (8b): (i) since the parameters K_{tr} and K_{MX} have the same dimensions (M^{-1}) and are described by similar expressions, the relation between them should be more general than the correlation (3) between k_1 and K_{MX}; furthermore, (ii) K_{tr} and K_{MX} depend differently on the ionic strength, so that values of $K_{tr} = k_1/k_0$ and of K_{MX}, all extrapolated to zero ionic strength, should be used for the correlation. As shown above (Fig. 1) these conclusions agree with experiment. For all the systems studied the numerical values of

$$k_1/k_0 \leq K_{MX} \quad , \qquad (10)$$

which is understandable, since the energy of interaction of M^+ is smaller with the transition state $R^{\delta+} \ldots X^{\delta-}$ than with X^-.

The slope of the Brønsted correlation $\lg k = A + \beta \lg K$ usually indicates[38–41] the position of the transition state on the reaction coordinate: the structure of the transition state resembles either the final or the initial state according as $\beta = 1$ or 0. It is implied that $0 \leq \beta \leq 1$, but there are exceptions[42–47]. Charge separation is nearly complete in S_N1 reactions, so that it is reasonable that the slope of line (4) is close to unity. However, the numerical coincidence[23] of $\beta = 0.84$ and $\delta = 0.8$ [16,48,49] for the transition state in the hydrolysis of t-butyl chloride is probably fortuitous.

A quantitative model has recently been suggested[8] for an M^+–S_N1 reaction. Complete separation of charges $(\delta = 1$, Eqn. 5) is assumed for the transition states—the intimate ion-pair $R^+ \ldots X^-$ for reactions with the solvent, and the trio $R^+ \ldots X^- \ldots M^+$ for those with M^+. Solvation is discussed in terms of a simple coordination model on the assumption that the coordination number of the ion and the energy of local interaction between the ion and a molecule of the medium are the same whether the ion is isolated or present in a pair or in a trio. This applies also to the $M^+ \ldots X^-$ bond energy in the trio and in the complex MX. On these hypotheses the equilibrium constant of disproportionation of the ion-pairs

$$\overset{(b)}{R^+ \ldots X^-} + \overset{(f)}{X^- \ldots M^+} \overset{K}{\rightleftarrows} \overset{(e)}{R^+ \ldots X^- \ldots M^+} + \overset{(c)}{X^-} \quad , \qquad (11)$$

which from Eqns. (8a), (8b), and (9) is given by $K = k_1/k_0k_{MX}$, is independent of solvation interactions and is determined solely by intramolecular Coulombic interactions. The complete equation

$$\lg k_1 = \lg k_0 + \lg K_{MX} - \frac{Ne^2Z_RZ_M}{2.303RTDl_{R-M}} \qquad (12)$$

includes a Coulombic term allowing for destabilisation of the transition state[8] due to repulsion of the outer groups R^+ and M^+ in the trio $(e$, Eqn. 5). The symbol N in Eqn. (12) denotes Avogadro's number, e is the charge on the electron, Z_R and Z_M are the charges on R and M, and

$$l_{R-M} = r_M + 2r_X + r_R -$$

is the distance between R and M defined in terms of the crystallographic radii of the ions r_i. With the complex structure of R and M taken into account the Coulombic term becomes

$$\left(-\frac{Ne^2}{2.303RTD}\sum_{i\neq j}\frac{Z_iZ_j}{l_{ij}}\right) ,$$

where i and j denotes the local charges in R and M respectively.

Several important consequences follow from the theory. According to (12) the parameter k_1 is strictly proportional to k_0 and K_{MX}, and depends also on the parameters of the transition states Z_R, Z_M, and l_{R-M}. This opens up a path for studying the structure of transition states from kinetic and thermodynamic data. It is significant that the effects of reactants and reaction conditions are transmitted to k_1 along many channels: thus change in M^+ influences k_1 through K_{MX}, Z_M, and l_{R-M}; variation in X through k_0, K_{MX}, and l_{R-M}; and changes in the medium through k_0, K_{MX}, and D. It follows from (12) that

$$E_1 = E_0 + \Delta H_{MX} + \frac{Ne^2 Z_R Z_M}{l_{R-M} D}\left(1 + \frac{T}{D}\frac{dD}{dT}\right) \quad , \quad (13)$$

where E_1 and E_0 are the activation energies of the reactions of RX with M^+ and with the solvent, and

$$\Delta H_{MX} = 2.303RT^2 \frac{d \lg K_{MX}}{dT}$$

is the enthalpy of formation of the complex MX. For reactions of uncharged and cationic halides, when $Z_R Z_M \geq 0$, Eqn. (12) leads to the rule (10). With anionic substrates, however, cases are possible in which $K_{tr} > K_{MX}$. Values of $\lg k_1$ found experimentally and calculated by means of Eqn. (12) for several systems are compared in Table 1.[8] The radius of $t\text{-}C_4H_9^+$ was taken[8] to be r_R = 1.8 Å.

The good agreement between calculation and experiment (Tables 1 and 2) throughout the range of variation in conditions—M^+, X, and medium—indicates that the initial model was correct. The use of crystallographic radii instead of actual distances in the calculation is explained by the slight effect of the system of radii adopted on the Coulombic correction: thus an error of ±0.5 Å in the determination of l_{R-M} leads to an error of only ±0.1 in $\lg k_1$. It was found also[8] that formula (4) reproduces the experimental data well (Fig. 1) because of the existence of a secondary correlation between the Coulombic term and $\lg K_{MX}$, the slope of which is −0.16, corresponding to the difference between the theoretical slope of unity and the empirical slope of 0.84.

Few of the activation-energy data required for further testing of the theory are yet available. The reactions of t-butyl fluoride with water and with the ions Be^{2+}, Fe^{3+}, Al^{3+} and Sc^{3+} have the same activation energy: $E_0 = E_1 = 25 \pm 1$ kcal mole^{-1}.[26] These values satisfy Eqn. (13), since $\Delta H_{MX} = -1 \pm 1$ for the fluoride complexes of these ions, while the third term in (13) has the value −0.1 when $(T/D)dD/dT = -1.37$.

The S_N1 and M^+–S_N1 mechanisms of the reactions of t-butyl halides are regarded in the above theory as limiting in the sense that complete separation of charges along the R–X bond is achieved in the transition state. On this view there can be no reaction of greater S_N1 character, and Eqns. (12) and (13) should be satisfied for the S_N1 reactions of other substrates. Discrepancies may indicate that a different mechanism is actually operating[9] (Section V).

Results obtained by Anantaraman and his coworkers[14] illustrate the proportionality between k_0 and k_1 with variation in R for typical S_N1 reactions of aralkyl chlorides with mercury(II) chloride (Table 3). They show that changes in k_0 and k_1 by factors of 10^4 correspond to only a fourfold variation in the quantity $(k - k_0)/k_0 = k_1[M^+]/k_0$. The residual effect can be explained by a decrease in the Coulombic term due to an increase in the effective radius of R^+. The electrophile in this system may be either $HgCl_2$ or $HgCl^+$; the latter is present at a lower concentration, but is more active. To obtain an estimate we make the crude assumption that $HgCl^+$ acts as electrophile. The transition state will then have the form $R^+ \ldots Cl^- \ldots Hg^{2+} \ldots Cl^-$, from which we have

$$\lg \frac{k - k_0}{k_0} = \lg K_{MX} + \lg [HgCl^+] - 8.1\left(\frac{2}{l_{R-Hg}} - \frac{1}{l_{R-Cl}}\right) \quad (14)$$

The terms in brackets allow for the interactions of R^+ with Hg^{2+} and with the terminal Cl^-: $l_{R-Hg} = r_R + 2r_{Cl} + r_{Hg}$ and $l_{R-Cl} = r_R + 3r_{Cl} + 2r_{Hg}$. Application of Eqn. (14) to data for t-butyl chloride yields

$$\lg K_{MX} + \lg [HgCl^+] = 3.39$$

and the radii on other cations R^+ (last column of Table 3). The r_R values obtained increase with the size of the cation, with increasing transfer of positive charge to the periphery of the cation; their order of magnitude appears to be reasonable.

*Values rounded off.
**Maximum value at $r_R = \infty$, calculation based on Eqn. (14).

Winstein and his coworkers[50–53] investigated the "regeneration" of ion-pairs in the M^+–S_N1 reactions of optically active *p*-chlorophenylphenylmethyl and *exo*-norbornyl chlorides with mercury(II) chloride and acetate in 80% aqueous acetone and in formic and acetic acids. The racemisation and solvolysis rate constants k^{rac} and k^t vary linearly with the concentration of mercury(II) chloride over the range 0.001–0.01 M: $k = k_0 + k_1[HgCl_2]$, which corresponds to Eqn. (2). It is assumed that every act of ionisation (k^α) leads to racemisation[53]:

$$d\text{—RCl} + HgCl_2 \xrightarrow{k^\alpha} R^+ \ldots ClHgCl_2^- \begin{cases} \xrightarrow{dl\text{-RCl} + HgCl_2\,(k^{rac})} \text{HOS} \\ \xrightarrow{dl\text{-ROS} + HCl + HgCl_2\,(k^t)} \end{cases} \quad (15)$$

We then have $k^\alpha = k^{rac} + k^t$, and we can estimate the proportions of the intimate ion-pairs which dissociate and which revert k^t/k^α and k^{rac}/k^α‡. Table 4 lists the proportions of dissociating ion-pairs in the reactions of the organic chlorides with the solvent and with mercury(II) chloride and acetate[51–53]. Although the electrophilic effect for mercury(II) chloride reaches $k_1^t/k_0^t = 10^2$–10^3 M^{-1}, the

‡If configuration is partly maintained during the reversion of ion-pairs to the initial substrate, k^α will give a lower limit to the rate of ionisation of RX. Comparison of the rates of racemisation and of the isotopic exchange of chlorine between RCl and $Hg^{36}Cl_2$ shows[51] that *p*-chlorophenylphenylmethyl chloride is regenerated from the ion-pair $R^+[HgCl_3]^-$, in which the three chlorine atoms are equivalent.

proportion of dissociating ion-pairs amounts to 10–50% for various media, and changes little on passing from reaction with the solvent to reaction with the mercury chloride. This shows that the acceleration of S_N1 reactions on the addition of an electrophile is due mainly to increase in the rate of ionisation k^{α}, not to retardation of the reversion of ion-pairs, as is sometimes assumed [54]. A larger fraction of dissociating ion-pairs are present in the reaction of *exo*-norbornyl chloride with mercury(II) acetate in acetic acid. Mercury acetate accelerates the reaction not only as a stronger electrophile than the chloride but also by supplying acetate ions to R^+.

Table 4. Fraction of dissociating ion-pairs k_1^t/k_1^{α} and electrophilic effect of mercury salts k_1^t/k_0^t in the solvolysis of *p*-chlorophenylphenylmethyl and *exo*-norbornyl chlorides.

IV. M^+–S_N1 HYDROLYSIS OF INORGANIC HALIDES

The hydration of octahedral cobalt(III), chromium(III), etc. complexes is of the greatest interest, and is assumed to take place, in the absence of metal ions, by an S_N1 (or a dissociative) mechanism [28,41]. The hydration of $CrCl_2(H_2O)_4^+$ and $CrCl(H_2O)_5^{2+}$ is accelerated by Ag^+ and Hg^{2+} ions [55,56]. The complex $CrCl_2(H_2O)_4^+$ interacts with Hg^{2+} and $HgCl^+$ considerably more rapidly than with $HgCl_2$ and $HgCl_3^-$. Similarly, the rate of reaction between $FeCl(H_2O)_5^{2+}$ and $TlCl_n^{(3-n)}$ decreases as n increases from 0 to 3. [57] The stability of the resulting halide complexes falls in the same sequences. Variation of X^- and M^+ in $CrX(H_2O)_5^{2+}$ (X = Cl, Br, I) does not affect the distribution of the products of solvolysis in aqueous methanol $[Cr(H_2O)_6^{3+}]/[Cr(H_2O)_5CH_3OH^{3+}]$ catalysed by Tl^{3+}, Hg^{2+}, and Ag^+ ions, which is regarded as proof of an S_N1 mechanism with the slow stage

$$Cr(H_2O)_5X^{2+} + M^+ \rightarrow Cr(H_2O)_6^{3+} + MX \qquad (16)$$

followed by competing rapid reactions of $Cr(H_2O)_5^{3+}$ with water and with methanol [58]. The fractionation of oxygen-18 in the products of the hydrolysis of $CoX(NH_3)_5^{2+}$ (X = Cl, Br, I) has been studied [59] in the presence of Ag^+, Hg^{2+}, and Tl^{3+}. The reaction with Hg^{2+} yields $CoH_2O(NH_3)_5^{3+}$ enriched with the isotope by a factor of 1.012 relative to the oxygen-18 content of the solvent. An S_N1 mechanism was deduced from the fact that the effect was independent of X^-. In the reactions with Ag^+ and Tl^{3+} the fractionation coefficients are smaller and dependent on X, which indicates a possible contribution by an S_N2 mechanism. In the reaction with Tl^{3+} it is assumed that the attacking water molecule arrives from the inner sphere of the thallium ion [59].

At constant ionic strength induced hydrations are usually of the first order with respect both to the substrate and to M^+. [59,60] Detachment of the first chlorine atom from *cis*-$CoCl_2en_2^+$ (but not from the *trans*-isomer) involves a stage of formation of a stable intermediate:

$$cis\text{-}Co(en)_2Cl_2^+ + Hg^{2+} \underset{}{\overset{K}{\rightleftharpoons}} \left[(en)_2Co\begin{matrix}Cl\\ \diagdown\\ \diagup\\ Cl\end{matrix}Hg\right]^{3+} \qquad (17)$$

with $K = 650\ M^{-1}$. [60] Under the same conditions Tl^{3+}, in contrast to Hg^{2+}, does not give such a complex [61]. Replacement of chlorine in $CoClEDTA^{2-}$ by a carboxyl of ethylenediaminetetra-acetic acid is catalysed by metal ions that form stable complexes with the chloride ion [62–64]. A correlation has been noted between the reaction velocity and K_{MX}, [64] and equilibrium constants of formation of the intermediate have been found from kinetic data. However, the reaction is complicated by a protolytic equilibrium involving a complexone carboxyl uncombined with Co^{3+} and by coordination of this ligand with M^+.

Table 5. Aquation of halogeno-complexes induced by metal ions (in aqueous solution of ionic strength μ at 25°C).

[c]At 35°C.

The hydrolysis of inorganic fluorides, like that of organic fluorides, is catalysed by acids ($M^+ = H^+$). Studies have been made of the acid hydrolysis of $CoF(NH_3)_5^{2+}$, [65] *cis*- and *trans*-$CoF_2en_2^+$, [66] *cis*-$CrF_2en_2^+$, [67]

$CrF(H_2O)_5^{2+}$,[68] $CoF_2tren_2^+$,[69] etc. (tren = $N(C_2H_4NH_2)_3$). The reactions are assumed to involve protonation of the fluorine. In the case of $CoF_2tren_2^+$ formation of an intermediate has been detected from kinetic data. A linear dependence of $\lg k$ on H_0 with slope −0.97 has been found[70] for the acid hydrolysis of PF_6^- over the range 2–10 M hydrochloric acid. The hydration of $CoF(NH_3)_5^{2+}$ is accelerated by Th^{4+},[71] and the hydrolysis of XeF_2 by Th^{4+}, Al^{3+}, Be^{2+} and La^{3+} ions[72] in qualitative agreement with the stability sequence of their fluoride complexes. Clark and Jones have found that Zr^{4+}, Th^{4+}, Al^{3+}, Be^{2+}, and Ti^{4+} induce the hydrolysis of BF_4^-, PF_6^-, $AsOHF_5^-$, and AsF_6^- in strongly acid media[73]. Iron(III) complexes induce the hydrolysis of $AsOHF_5^-$.[74] All these reactions are assumed to involve the direct interaction of M^+ with the fluoride ligand[71,73], and they are regarded as similar to the splitting of the Co–Cl bond by the Hg^{2+} ion[74]. Chelate complexes of Cu^{2+}, Th^{4+}, and Zr^{4+} catalyse the hydrolysis of $(iso\text{-}C_3H_7O)_2POF$ and $iso\text{-}C_3H_7P(CH_3)OF$ (Sarin)[75–77]. The mechanism of these reactions is complicated.

The inadequacy of a simple S_N1–S_N2 classification for inorganic complexes has already been stressed[41,78]. Nevertheless, the above results indicate a certain analogy in the kinetics, mechanism, and driving force of the M^+–S_N1 hydrolysis of organic and of inorganic halides. Values of k_1 and k_0 for the hydration of cationic complexes (Table 5) show that the relation between them is close to Eqn. (4) for t-butyl halides[79]. The agreement is improved by introducing an additional term containing the product of the charges Z_1Z_2 to allow for the Coulombic repulsion of the reactants. Sykes et al.[61] had already used Coulombic repulsion to explain the greater activity of Hg^{2+} than of Tl^{3+} contrary to the sequence of K_{MX} for $HgCl^+$ and $TlCl^{2+}$ in the hydrolysis of $CoCl(NH_3)_5^{2+}$ and of *cis*- and *trans*-$CoCl_2en_2^+$. The data compiled in Table 5 satisfy the inequality (10), as would be expected. It is noteworthy that the ratio k_1/k_0 is in all cases larger for *cis*-complexes than for the *trans*-isomers[79].

Table 6. Calculation of rates of M^+–S_N1 hydrolysis of BF_4^- and PF_6^- (aqueous solutions at 25°C; k_1 in M^{-1} s^{-1} and k_0 in s^{-1}).

Ion	BF_4^- $\lg k_0 = -7.0$[68]		PF_6^- $\lg k_0 = -10.9$[68]	
	$\lg k_1$ expt.	$\lg k_1$ calc. from Eqn.(12)	$\lg k_1$ expt.	$\lg k_1$ calc. from Eqn.(12)
H^+	−3.9	−3.7	−6.8	−7.6
Be^{2+}	−1.0	−1.4	−4.3	−5.3
Al^{3+}	−0.8	0.0	−4.0	−3.9
Th^{4+}	+0.2	+1.8	−3.2	−2.1

Equation (12) cannot in general be used to process the results in Table 5: with reactants of like charge the effects of the ionic strength, which differ with different systems, may lead to overestimates of 1–2 units in $\lg k_1$. Nevertheless, several examples have shown[8] that theoretical approaches are applicable to M^+–S_N1 reactions of inorganic halides. The induced hydrolysis of BF_4^- and PF_6^- has been studied[73] in hydrochloric acid (1–2 M) without extrapolation to zero ionic strength. It is difficult to assess the accuracy of the results. An S_N1 mechanism is probable in both cases, since the central atoms in BF_4^- and PF_6^- are shielded from S_N2 attack. Covalent models of the transition states—$F_3B\ldots F^-\ldots M^+$ and $F_5P\ldots F^-\ldots M^+$—were adopted for the calculations. The theoretical equation is $k_1 = k_0K_{MX}$. The results are given in Table 6. Ionic models of the transition states of these reactions—$(F^-)_3B^+\ldots F^-\ldots M^+$ and $(F^-)_5P^{5+}\ldots F^-\ldots M^+$ with $r_F = 1.33$, $r_B = 0.20$, and $r_P = 0.35$ Å—lead to underestimates of k_1 by factors of $10–10^2$. Agreement between calculated and experimental values of k_1 has been shown[8] also for the reactions of $CoBr(NH_3)_5^{2+}$ and $RhCl(NH_3)_5^{2+}$ with Hg^{2+}, which have been studied at a low ionic strength (Table 5). The theoretical equation for the ionic model of the transition state $(NH_3)_5M^{3+}\ldots X^-\ldots Hg^{2+}$ is $(\lg k_1/k_0K_{MX})_{theor} = -27.9/l_{M\text{–}Hg}$.

Data extrapolated to zero ionic strength, as well as information on the actual geometry of the complexes and the delocalisation of charges on the ligands, are required in order to make an extensive test of the theory. It is quite possible that, with accurate values of k_0, k_1, and K_{MX}, the above approach may give valuable information on the structure of transition states.

The above regularities in the detachment of halogens by metal ions can probably be extended to the detachment of other groups. As with halides, the driving force of such reactions is the formation of a stable bond between the metal and the detached group. The hydration of $Fe(CN)_6^{4-}$ is accelerated by mercury(II) and silver(I) salts[90], that of $CrCN^{2+}$,[91] $CrSCN^{2+}$, and $CrNCS^{2+}$[92,93] by mercury(II) salts, and the hydration of $CoCO_3(NH_3)_5^+$ by bivalent mercury, lead, and barium salts[94]. As a consequence of high affinity for the sulphur atom, Ag^+ and Hg^{2+} ions accelerate reactions involving cleavage of phosphorus–sulphur[95] and carbon–sulphur[96–99] bonds. The kinetics and the mechanism of these reactions have not yet been adequately studied.

V. M^+–S_N2 REACTIONS OF PRIMARY AND SECONDARY ALKYL HALIDES

The acceleration of the reactions of primary and secondary alkyl halides by the ions Ag^+[100–108] and Hg^{2+}[4,109–112] (see also Refs. 2 and 3) was originally discussed in terms of Ingold's hypothesis[1] that the mechanism changes from S_N2 to Ag^+–S_N1 (or Hg^{2+}–S_N1) under the influence of M^+. For example, the reaction of benzyl chloride with mercury(II) nitrate in aqueous dioxan was represented by the scheme[4]

$$C_6H_5CH_2Cl + Hg^{2+} \xrightarrow[\text{slow}]{} HgCl^+ + C_6H_5CH_2^+ \longrightarrow \begin{cases} \xrightarrow{NO_3^-} C_6H_5CH_2ONO_2 \\ \xrightarrow{H_2O} C_6H_5CH_2OH + H^+ \end{cases} \quad (18)$$

An M^+–S_N1 mechanism was suggested also for the reactions of primary alkyl bromides with Hg^{2+},[111,112] but the sequence of rates—$C_2H_5Br > n\text{-}C_3H_7Br > iso\text{-}C_4H_9Br$[111]—indicates nucleophilic attack. On the other hand, cases of the rearrangement and racemisation of the alkyl group[1,3,113], indicating intermediate formation of an ion-pair, may be a consequence of a slow reaction with the solvent under the same conditions, but without M^+, also by an S_N1 mechanism. Several later attempts were made[114–121] to prove that a nucleophile was involved in the reactions of primary and secondary alkyl halides with Ag^+, but it was difficult to distinguish the roles of the anion (nitrite, nitrate, perchlorate) as a nucleophile and as a ligand changing the activity of M^+. Furthermore, the reactions were usually studied in anhydrous or nearly anhydrous media, where the effects of ionic association were significant.

The results of detailed kinetic investigations of the hydrolysis of methyl, ethyl, and isopropyl halides in the presence of metal ions in aqueous solution [9,122-130] are summarised in Table 7. These reactions outwardly resemble M^+–S_N1 reactions of t-butyl halides: the kinetics are in most cases represented by Eqn. (2), metal ions that form stable complexes MX—in particular Ag^+, Pb^{2+}, Cd^{2+}, Hg^{2+}, and Tl^{3+}—are active, and the dependence of $\lg(k_1/k_0)$ on $\lg K_{MX}$ is nearly linear for a given alkyl group with electrophiles having the same charge [125,126]. However, significant differences were revealed. Experimental values of $\lg(k_1/k_0)$ are lower than those calculated by means of Eqn. (4) (Fig. 2). The differences increase with enhancement of the S_N2 character of the reactions, i.e. in the sequence isopropyl < ethyl < methyl, and with increase in the charge on the metal ion. The Tl^{3+} ion is less active than Hg^{2+}, although the Lewis acidity of the former is greater (Table 1). Correction for the Coulombic destabilisation of the transition state (Section III) is insufficient to explain the discrepancies, which reach $\Delta \lg(k_1/k_0) = 4-6$ for Hg^{2+} and Tl^{3+}.

Table 7. Rate constants of M^+–S_N2 reactions in aqueous solutions of zero ionic strength at 25°C (k_0 in s^{-1} and k_1 in $M^{-1}\ s^{-1}$).

[a] $\lg(k_2,\ M^{-2}\ s^{-1})$.

The above reactions have therefore been included [9] in the M^+–S_N2 type, their driving force being an electrophilic contribution to heterolysis of the C–X bond with simultaneous attack by the nucleophile on the carbonium centre. Since bonds in the transition state

$$H_2O^{+\delta_B}\cdots\overset{|}{C}{}^{+\delta_C}\cdots X^{-\delta_X}\cdots M^+$$

are partly covalent (it is assumed that $\delta < 1$), the electronic effect may be transmitted by an induction mechanism. Displacement of the electrons towards M^+ lowers the electron density on the $H_2O\ldots C\lessdot$ bond in the transition state, which diminishes the S_N2 character of the reaction. This effect, termed [9] "inductive retardation", should be most intense with methyl halides, when overlapping of the orbitals at this bond is greatest, and with multicharged ions, e.g. Tl^{3+}, having a high electron affinity.

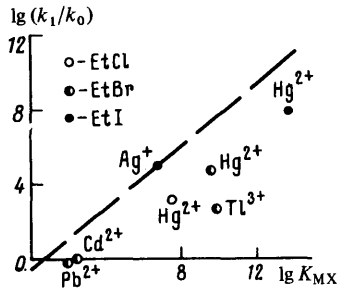

Figure 2. Comparison of values of $\lg(k_1/k_0)$ for the reactions of $C_2H_5X + M^+$ with correlation (4) for t-C_4H_9X (broken lines).

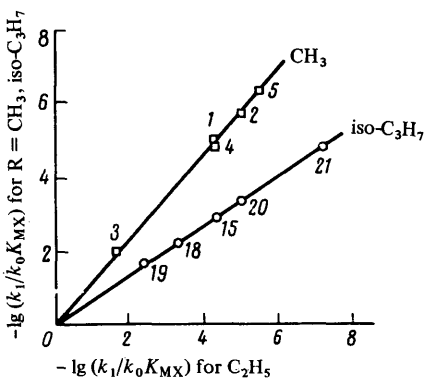

Figure 3. Correlation between values of $\lg(k_1/k_0K_{MX})$ for CH_3X, iso-C_3H_7X, and C_2H_5X with variation in M^+ and X. For the reactions of RX with two silver ions, k_1 and K_{MX} have been replaced by k_2 and K_{Ag_2X}. Numbering as in Table 7.

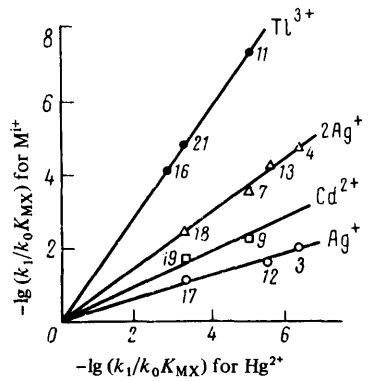

Figure 4. Correlation between values of $\lg(k_1/k_0K_{MX})$ for Tl^{3+}, $2Ag^+$, Cd^{2+}, and Ag^+ and for Hg^{2+}, with variation of R and X.

The effects of R, X, and M^+ in M^+–S_N2 reactions (Table 7) are reproduced by the equation

$$\lg (k_1/k_0) = \lg K_{MX} - P_R \cdot P_X \cdot P_M \quad , \qquad (19)$$

where P_R, P_X, and P_M are positive constants depending on the properties of the respective species. The overall effect of the metal ion is determined by competition between electrophilic bonding of X^-, represented by the term $\lg K_{MX}$, as for t-butyl halides, and inductive retardation ($P_R P_X P_M$). Equation (19) leads to the correlations

$$\left(\lg \frac{k_1}{k_0 K_{MX}}\right)_{R_1} = \frac{P_{R_1}}{P_{R_2}} \left(\lg \frac{k_1}{k_0 K_{MX}}\right)_{R_2} , \text{ varying X, } M^+ \qquad (20)$$

$$\left(\lg \frac{k_1}{k_0 K_{MX}}\right)_{X_1} = \frac{P_{X_1}}{P_{X_2}} \left(\lg \frac{k_1}{k_0 K_{MX}}\right)_{X_2} , \text{ varying R, } M^+ \qquad (21)$$

$$\left(\lg \frac{k_1}{k_0 K_{MX}}\right)_{M_1} = \frac{P_{M_1}}{P_{M_2}} \left(\lg \frac{k_1}{k_0 K_{MX}}\right)_{M_2} , \text{ varying R, X} \qquad (22)$$

which can be verified directly (Figs. 3–5). Table 8 gives values of P_R, P_X, and P_M determined [9] for the standard conditions $P_{Br} \equiv 1$ and $P_{Hg} \equiv 12.8$; Table 7 compares experimental values of k_1 with those calculated by means of Eqn. (19). For M^+–S_N1 reactions of t-butyl halides $P_R = 0$ (if Coulombic repulsion is neglected). The interpretation of P_M as an induction constant of the M^+ ion is confirmed by comparing [9] P_M and the equilibrium constant $K_{MOH} = [MOH][H_2O]/[M^+][OH^-]$, which is determined mainly by charge transfer to the aquo-ion

$$\begin{matrix} H \\ H \end{matrix}\!\!\searrow\!\!\nearrow O \rightarrow M^+ ,$$

and by the correlation of P_M with the electron affinity of the M^+ ions in the gas phase.

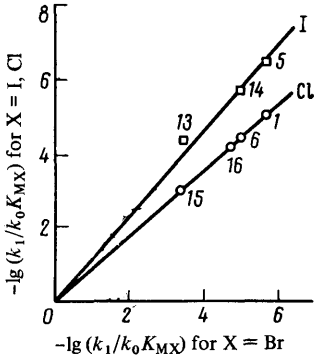

Figure 5. Correlation between values of $\lg (k_1/k_0 K_{MX})$ for I, Cl, and Br with variation of R and M^+.

The above results indicate the occurrence of a broad spectrum of S_N2 reactions depending on the overlap of nucleophile and $R^{\delta+}$ orbitals in the transition state. Here S_N1 reactions correspond to the limit at which the action of the solvent nucleophile is restricted by solvation. The overlap of the orbitals is determined by the nucleophilic character of the medium and the nature of the alkyl group; it depends little on the strength of the electrophile, at least in the range from H_2O to Tl^{3+}. The above slight diminution of S_N2 character of the reaction due to the inductive effect of M^+ is consistent with data on the reactions of alkyl halides with sodium and silver nitrites forming the basis of Kornblum's rule [114,133,134]. Since electrophiles accelerate S_N1 reactions more strongly than S_N2 reactions (Fig. 2), the variations in mechanism indicated in Table 9 are possible under the influence of metal ions.

Table 8. Values of the parameters P_R, P_X, and P_M for M^+–S_N2 reactions [9].

R		*i*-Pr		Et		Me

Table 9.

Reaction with solvent		Reaction with M^+ in same medium
S_N1	I	M^+–S_N1
	III	
S_N2	II	M^+–S_N2

Transition III, corresponding to S_N2 reactions with slight overlap of the orbitals, has not yet been demonstrated, but may occur in the solvolysis of n-propyl bromide in 90% formic acid in the presence of Hg^{2+}, when the formation of propan-2-ol can be explained [113] only by a 1–2 hydride shift in the n-propyl cation. Another approach [135–139], which describes the kinetics of the reactions of primary and secondary alkyl halides with a nucleophile N^- in terms of the general scheme of S_N1 reactions

$$RX \rightleftharpoons R^+ \ldots X^- \xrightarrow{N^-} RN + X^-$$

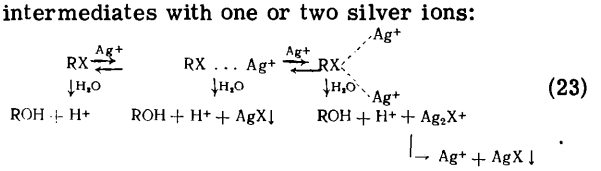
seems less probable, in view of the above differences between M^+–S_N1 and M^+–S_N2 reactions and the fact that the transition state $N^- \ldots R^{\delta+} \ldots X^{\delta-}$ for S_N reactions should be more stable than an intimate ion-pair $R^+ \ldots X^-$. Transition III can be expected also for isopropyl and benzyl halides. Results for the hydrolysis of isopropyl halides in the presence of metal ions (Table 7) are in fact reproduced by Eqns. (4) and (12) for M^+–S_N1 reactions, although less accurately than by Eqn. (19). This can be interpreted as indicating that the mechanism for isopropyl halides is intermediate between M^+–S_N1 and M^+–S_N2. The formation of propene in the hydrolysis of isopropyl bromide in the presence of silver ions [129] is consistent with an M^+–$E2$ mechanism and with elimination from the ion-pair. The electrophilic contribution of metal ions to the hydrolysis of benzyl fluoride [140,141] is conveyed approximately by correlation (4) for M^+–S_N1 reactions [26,27].

The above model of M^+–S_N2 reactions is equivalent to Swain's push–pull mechanism suggested in 1948.[142,143] However, only by the use of aquo-ions of metals has it become possible in principle to study the role of the electrophile with the nucleophile and the medium fixed.

VI. ASPECTS OF THE REACTIONS OF ALKYL HALIDES WITH SILVER IONS

Until recently the mechanism of the reactions of alkyl halides with silver salts[11,54,100–108,114–121,130,144–151] remained obscure owing to the complexity of the kinetics, especially in non-aqueous media, and the unusual reaction orders with respect to silver—from 0 to 2 and higher, including fractional orders. The traditional explanation of these anomalies was based[114,116–121,130,152] on the nucleophilic contribution of anions (nitrate and perchlorate), the influence of the ionic strength, and the effects of ionic association in low-polarity solvents. The hypothesis that these reactions were accelerated significantly by precipitated silver halides[1,3] has not been confirmed[54,123,118–121,130,153].

Detailed kinetic studies of the hydrolysis of t-butyl chloride[25], isopropyl bromide[129], ethyl bromide[123], ethyl iodide[129], and methyl iodide[127] in the presence of silver ions in aqueous media indicate that these complications are due to a special mechanism involving the formation of intermediates with one or two silver ions:

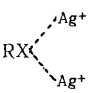


(23)

This mechanism corresponds to the kinetic equation[24,123]

$$k \equiv -\frac{1}{[RX]}\frac{d[RX]}{d\tau} = \frac{k_0 + k_1[Ag^+] + k_2[Ag^+]^2}{1 + K_{gr}[Ag^+]}, \qquad (24)$$

where k_0, k_1, and k_2 are the rate constants of reaction with the solvent and with one and two silver ions, and $K_{gr} = [RX\ldots Ag^+]/[RX][Ag^+]$ is the stability constant of the intermediate $RX\ldots Ag^+$. The concentration of the intermediate



is assumed[123,127,129] to be minute. In M^+–S_N1 reactions ($R = t\text{-}C_4H_9$) intermediates of these types dissociate with the formation of R^+, whereas in M^+–S_N2 reactions ($R = CH_3$, C_2H_5, iso-C_3H_7) they undergo nucleophilic attack by water, but the stepwise scheme (23) is the same in the two cases. Partition kinetic methods have been elaborated[19,24,26] which enable us to determine not only the rate constant but also the solubility of the substrates, which depends on complex formation between the alkyl halide and the silver ion.

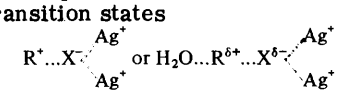
Table 10 gives the values of K_{gr} for the complexes $RX\ldots Ag^+$ together with values, obtained spectrophotometrically in aqueous solution at 25°C, for the kinetically stable $CH_2X_2\ldots Ag^+$ species. The stability of the complexes increases in the sequences Cl < Br < I and $CH_3 < C_2H_5 <$ iso-C_3H_7. Their formation is a consequence of the low hydration energy of the silver ion and its comparatively high affinity for halogen. Complex formation between RX and Hg^{2+} is considerably weaker[122,125], although HgX^+ is more stable than AgX. Mercury(II) chloride forms a complex with benzyl bromide[155]. Many observations have been made in non-aqueous media of complexes of alkyl halides with the silver ion[149,150] and other Lewis acids (see reviews[156,157]).

Values of k_1 and k_2 are given in Table 7. Reactions of the first order with respect to the silver ion do not differ from the reactions of alkyl halides with other metal ions. Reaction paths of the second order ($2Ag^+$, Table 7) occur[9,25,123,127] as a consequence of the great stability of the complexes Ag_2X^+ with the anion as centre of coordination. The composition, stability, and structure of complexes of this type—Ag_2X^+, Ag_3X^{2+}, Hg_2X^{3+}, Cd_2X^{3+}, and several others—have been widely discussed[158–161].

Table 10.

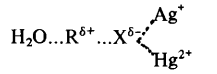
Substrate	MeI[127]	EtI[129]	EtBr[123]	*i*-PrBr[129]	CH_2Cl_2[154]	CH_2Br_2[154]	CH_2I_2[154]
K_{gr}, M^{-1}	15	32	1.6	4.2	0.1	0.5	20.2

Reactions involving two silver ions provide a further example of the generality of the correlation between the rate of the induced detachment of a halide ion and the stability of the complexes formed in the rate-determining stage. The transition states



(for M^+–S_N2 reactions), of which the complex Ag_2X^+ is a fragment in both cases, are advantageous despite the Coulombic repulsion of the two silver ions. The second silver ion acts as a catalyst, promoting detachment of the halide ion and ultimately being regenerated (Eqn. 23). Values of k_2 for the reactions of methyl iodide, ethyl iodide, ethyl bromide, and isopropyl bromide (Table 7) agree with those calculated by means of Eqn. (19), with $P_2Ag \simeq 2PAg$ (Table 8). The additivity of the effects of the two silver ions is consistent with the interpretation of P_M as a measure of the inductive effect of the metal ion. Agreement between k_2 and K_{Ag_2X} has been shown also for t-butyl chloride[25].

Reaction paths of the third order with respect to the silver ion[127] and of the second order with respect to Hg^{2+},[125] corresponding to the complexes Ag_3X^{2+} and Hg_2X^{3+}, have not yet been observed, but the stability constants suggest that such reactions are possible at salt concentrations of 5–10 M. The hydrolysis of ethyl bromide in solutions containing both Ag^+ and Hg^{2+} ions reveals[124] a component rate $k_2[RX][Ag^+][Hg^{2+}]$ of the first order with respect to each ion, which corresponds to the transition state



in which one of the two silver ions has been replaced by an Hg^{2+} ion. A cross route has been found also for silver and cadmium ions[124]. Kinetic data have been used to estimate[124] stability constants of hitherto unknown complexes with an anionic centre of coordination and two different metal ligands—$HgBrAg^{2+}$ ($10^{9.3}$ M^{-2}) and $CdBrAg^{2+}$ (10^7 M^{-2}).

A reaction path involving two silver ions has been found in the hydrolysis of 1-benzoyl-1-methylethyl bromide[162]. Competition between reactions of first and second orders with respect to silver ions has been

observed [95-99] in the cleavage of carbon–sulphur and phosphorus–sulphur bonds. Mechanism (23) can therefore be regarded as general for the reactions of silver ions with substrates having a soft basic centre such as a halogen or sulphur.

Thus the Brønsted relation is widely applicable to the effects of the electrophilic contribution to the detachment of halogens and perhaps other groups in the reactions of organic and inorganic substrates. These reactions can be included among the M^+–S_N1 and M^+–S_N2 types. In order to calculate the rate constant of an M^+–S_N1 reaction in terms of a model of the transition state with complete charge separation along the bond undergoing cleavage, it is sufficient to take into account the Lewis acidity of the electrophile. In an M^+–S_N2 reaction the electrophilic contribution is accompanied by retardation due to the inductive effect of the electrophile. Reaction paths of the second order with respect to silver ions conform to the general rules for M^+–S_N1 and M^+–S_N2 reactions.

NOTE ADDED IN PROOF

The theory of M^+–S_N1 reactions outlined in this Review has recently been generalised [163] to the S_N1 solvolysis of t-butyl halides. Interaction of the transition state with the medium is separated into Coulombic interaction in the ion-pair and actual solvation, which is taken into account on the basis of a coordination model and the solvation energies of the ions. Direct theoretical calculation gave quantitative agreement with experimental rates of solvolysis with the medium varied within wide limits, which provides reliable evidence of the generality of the S_N1 and M^+–S_N1 mechanisms.

Chemistry in the USSR Academy of Sciences

N.M.Emanuel'

Chemistry as a scientific discipline originated in our country at the time of the first Russian Academician in Chemistry, Mikhail Vasil'evich Lomonosov. As early as 1741 Lomonosov gave a completely modern definition of this science: "Chemistry is the science of the changes occurring in a compound body because it is compound". About 130 years later D. I. Mendeleev, in "The Principles of Chemistry", wrote: "The immediate object of chemistry is to study the homogeneous substances whose combination produces all the bodies in the world, their interconversions, and the phenomena accompanying such transformations". Both definitions are profoundly dialectical, for they regard chemistry as the whole set of manifestations of the chemical form of transformation of matter.

In its usual sense chemistry has always been and remains the science of the substances, products, and materials necessary to man and of the methods for their extraction and manufacture.

However, the ways of studying the composition, structure, and properties of many millions of individual substances, of knowing the detailed mechanism of the immense number of reactions at an elementary, atomic-molecular level, controlling chemical processes, and obtaining end-products with specified properties are so complicated and multifarious that modern chemistry is most intimately linked with mathematics, physics, and biology.

The Soviet period of development in chemistry is characterised by exceptionally high rates of growth of the volume of scientific research and increase in the number of lines of scientific investigation. Chemical laboratories changed radically in appearance, periodically undergoing almost complete material and technical re-equipment owing to the widespread introduction of the experimental methods of modern physics, radioelectronics, computer technology. The present time is characterised both by a process of obliteration of the boundaries between physical, organic, inorganic, and analytical chemistry and by the birth of new branches of chemical science.

Chemical research is conducted in the Soviet Union by large bodies of scientists associated in institutes of the USSR Academy of Sciences and those of the Union Republics, institutions of higher education, industrial institutes, and factory laboratories.

In many fields Soviet chemistry occupies leading positions in world science and has good prospects for further development, thanks to the constant attention of Party and Government, expressed in the resolutions of the Twenty-fourth Congress of the Communist Party of the Soviet Union.

The present paper gives a brief historical sketch of the development of chemistry in our country, mainly in the USSR Academy of Sciences.

PHYSICAL CHEMISTRY

The development of physical chemistry was directly connected with its previous history. It began with M. B. Lomonosov, who proposed the term "physical chemistry" for that branch of science which "uses the principles and experiments of physics to explain what occurs in compound bodies during chemical operations".

In pre-Revolutionary times physical chemistry developed in Russia mainly in the universities (Moscow, St. Petersburg, Kazan, Kiev, etc.). The situation changed substantially during the Soviet period, when physicochemical investigations came to be widely conducted not only

in university centres but also in institutes of the USSR Academy of Sciences, as well as in several branch scientific research establishments.

The first institute having a physicochemical outlook was the Karpov Physicochemical Institute founded in 1918 by A. N. Bakh, who remained its director for three decades.

Chemical physics—the physics of chemical processes—arose during the 1920s in the Leningrad Physicotechnical Institute, directed by A. F. Ioffe. The creation of this branch contributed to the development, in the mid-1920s, of the principles of L. V. Pisarzhevskii's electronic theory of valency and the publication in 1927 of the monograph "Elektronnaya Khimiya [Electronic Chemistry]" by V. N. Kondrat'ev, N. N. Semenov, and Yu. B. Khariton. The USSR Academy of Sciences Institute of Chemical Physics, founded in 1931 and directed by N. N. Semenov, became a most important centre of kinetic investigations. During recent years diverse kinetic researches have been made in the Institute of Kinetics and Combustion of the Siberian Division of the USSR Academy of Sciences, especially on the reactions of combustion and also the study of the structure of coordinated metal complexes.

In 1945 the Laboratory of Colloidal Electrochemistry (founded in 1930 by V. A. Kistyakovskii) formed the basis for establishing the Institute of Physical Chemistry of the USSR Academy of Sciences, where work has been done on the problems of surface phenomena, the theory of chromatography, problems of corrosion, radiochemistry, thermodynamics, and colloid chemistry.

The study of the theory of electrochemical processes, in particular the electrochemistry of organic compounds, and problems of radiation and quantum chemistry and of hydrodynamics provide the subject-matter for the Academy's Institute of Electrochemistry, founded in 1958 by A. N. Frumkin.

The Institute of Catalysis of the Siberian Division occupies a leading position in the field of heterogeneous catalysis.

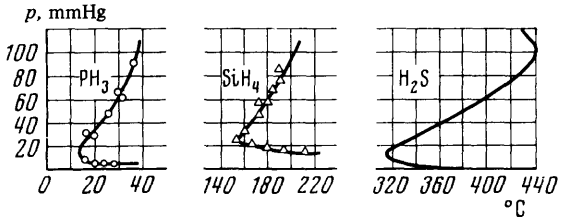

Figure 1. Regions of chain ignition of phosphine, silane, and hydrogen sulphide.

At the present time hardly any branch of chemistry and biochemistry is conceivable without the use of physicochemical methods for analysing and investigating chemical substances, their structure, and properties. Physicochemical investigations are therefore undertaken in almost all chemical institutes. Examples are the Institute of Organoelementary Compounds, in which the structures and reactivities of organic compounds are studied by infrared, nuclear magnetic resonance, and electron spin resonance spectroscopy, and the Institute of Organic Chemistry, where N. D. Zelinskii founded the theory of organic catalysis, later developed by his students, and where A. A. Balandin made his investigations on heterogeneous catalysis.

The Institute of Petroleum-chemical Synthesis, founded by A. V. Topchiev in 1958, studies the mechanism of many petrochemical and polymerisation processes, the physical chemistry of polymers, and in particular the rheology of polymers.

The Institute of General and Inorganic Chemistry (founded by N. S. Kurnakov) has become a centre for developing physicochemical methods of analysis.

Physicochemical methods of studying chemical reactions are widely used in the institutes of the Siberian Division of the USSR Academy of Sciences (Institute of Organic Chemistry), as well as in the Arbuzov Institute of Organic and Physical Chemistry (Kazan), in the Institute of Chemistry in Gorky, and in many other institutes of the USSR Academy of Sciences.

The oldest of the physicochemical institutes of the academies of Union Republics is the Pisarzhevskii Institute of Physical Chemistry of the Ukrainian SSR Academy of Sciences, which is concerned with investigating radical reactions, polymerisation processes, and heterogeneous catalysis.

Chain Reactions and Elementary Chemical Processes

One of the greatest achievements of Soviet physical chemistry is the theory of branched chain reactions. At the end of the 1920s N. N. Semenov, Yu. B. Khariton, and Z. F. Val'ta discovered that phosphorus vapour ignited only when a certain critical oxygen pressure had been reached. Addition of an inert gas (argon) enabled ignition to be observed at oxygen pressures below the critical value. The existence of a "critical" diameter of the reaction vessel was also discovered. Semenov put forward the idea of branched chain reactions to explain the new facts. The reaction was assumed to be a chain process, with an increase in the number of free radicals occurring in elementary steps which were termed chain branchings. The progressive growth in the concentration of free radicals, under conditions such that the rate of chain branching exceeded the rate of chain termination, led to chain self-ignition (Fig. 1).

Chain ignition is an isothermal explosion. The evolution of heat in this process is insignificant, since the explosion is due to a progressive growth of the number of active centres. In subsequent years the work of many scientists has demonstrated the widespread occurrence of branched-chain reactions. It was Semenov who inferred that high concentrations of free radicals are formed in branched-chain processes.

In this connection a large number of determinations were made of the concentrations of free radicals in chain reactions. After several years V. N. Kondrat'ev had developed methods enabling free atoms and radicals to be studied while reaction was proceeding (line absorption and catalytic recombination methods). Hydrogen atoms and hydroxyl radicals were detected by these methods in the combustion of molecular hydrogen, and carbonyl sulphide in that of carbon disulphide. It was also discovered that SO free radicals were formed in the slow oxidation of hydrogen sulphide. The concentrations observed exceeded by many orders of magnitude the thermodynamic equilibrium concentrations under the experimental conditions.

In 1944 E. K. Zavoiskii discovered the remarkable phenomenon of electron spin resonance (e.s.r.). Research on its extensive use in chemistry was undertaken by V. V. Voevodskii and his students and coworkers. At the end of the 1950–1960s the latter worker collaborated with A. V. Nalbandyan in recording by e.s.r. the formation of hydrogen and oxygen atoms in the combustion of hydrogen, together with other free radicals (Fig. 3).

Figure 2. Institute of Chemical Physics of the USSR Academy of Sciences, main building.

Kondrat'ev used electron bombardment to examine the dissociation of species, and was the first to apply mass spectrometry to the investigation of chemical reactions. The mass-spectrometric method was later developed by V. L. Talroze, who also developed the method of the diffusion flame in a flow system for studying the gas-phase reactions of atoms with molecules in order to determine their rate constants. This method enables reactions to be studied in the absence of the wall effect of the reaction vessel.

The possibility of heterogeneous chain initiation was suggested in 1927 by M. V. Polyakov, and experimental proof of the occurrence of this important process was given in 1948 by A. A. Koval'skii using his method of separate calorimetry.

The next stage in the development of the theory of branched-chain reactions was the concept of degenerate branching (Semenov). Such slowly evolving branched reactions were assumed to involve formation of a comparatively labile intermediate, which had a certain probability of breaking down into free radicals. Examples of products causing degenerate chain branching are formaldehyde in the high-temperature oxidation of methane and hydroperoxides in the oxidation of organic compounds at 100–150°C.

Semenov put forward the hypothesis that free radicals may be formed in bimolecular interactions between saturated molecules. Experimental evidence was given by A. E. Shilov and F. S. D'yachkovskii for the interaction of triphenylmethyl chloride and ethyl-lithium: triphenylmethyl radicals, formed by the reaction

$$EtLi + Ph_3CCl \rightarrow LiCl + Ph_3C^{\cdot} + Et^{\cdot}$$

were recorded by electron spin resonance. Subsequently the possibility of occurrence of the reactions

$$RH + O_2 \rightarrow R^{\cdot} + HO_2,\ 2RH + O_2 \rightarrow R^{\cdot} + RO^{\cdot} + H_2O,\ ROOH + RH \rightarrow RO^{\cdot} + R^{\cdot} + H_2O$$

was established.

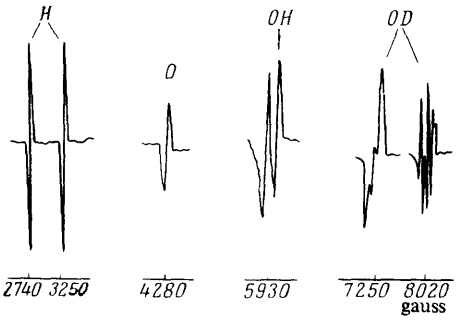

Figure 3. Electron spin resonance spectra of H and O atoms and OH and OD free radicals in the oxidation of H_2 and D_2.

Processes of this type proved to be especially characteristic of reactions involving molecular fluorine. Strong chemiluminescence in the visible region of the spectrum was observed by A. E. Shilov, L. Yu. Rusin, and A. M. Chaikin in the reaction

$$F_2 + HI \rightarrow F + HF + I$$

and this could be due only to formation of an electronically excited IF* molecule. Superequilibrium concentrations of atomic iodine were recorded by e.s.r. in this reaction. The method of diffusion flames was used to determine the rate constant both here and in the reaction of fluorine with hydrogen bromide.

Investigation of the chain reactions involved in the gas-phase fluorination of hydrogen, methyl iodide, methylene dichloride, etc. led Semenov and Shilov to the concept of energy branching—a new type of branched-chain reactions—in which excited molecules, capable of breaking down to form free radicals, were formed in chain propagation.

The reaction between hydrogen and fluorine is accompanied not only by the usual emission $HF^* \rightarrow HF + h\nu$ but also by stimulated emission, which reaches 1–2% of the energy of the chemical reaction. The duration of the flash of stimulated emission is 5×10^{-6} s, whereas that of chemiluminescence is 5×10^{-2} s (Fig. 4).

A recently developed laser, which uses the slow oxidation of hydrogen sulphide, is the first example of a chemical laser whose functioning is determined entirely by a set of elementary chemical reactions, and there is hardly time for the "leakage" of vibrational energy as a consequence of collisions during the emission.

Shock tubes began to be widely used during the 1960s. They were essentially ideal pulsed reaction vessels in which a rapid change of pressure heated the gas almost instantaneously to temperatures of the order of 1000° and even 10 000°C. A temperature pulse lasted for $(1–50) \times 10^{-4}$ s, and any surface effect was almost completely absent.

Studies were made of the elementary processes of the vibrational excitation and the dissociation of diatomic molecules—halogens, oxygen, nitrogen, and carbon monoxide (S. A. Losev)—and polyatomic molecules—hydrocarbons and nitro-compounds (A. A. Borisov, V. G. Knorre)—as well as electronic excitation and ionisation involving atoms and radicals (S. M. Kogarko and I. S. Zaslonko). Examination of the decomposition of ammonia and nitrous oxide showed directly the occurrence and the main features of "energy" chain processes, as well as the presence of critical conditions for autocatalysis due to the non-equilibrium distribution of the internal energy of the reactants. Vibrationally excited molecules N_2^V act as chain-transfer agents in the decomposition of hydrogen azide: their collisions with the initial molecules transfer vibrational energy to the latter by resonance, thereby increasing the rate of decomposition. Fig. 5 illustrates the shock tube with which G. B. Manelis and A. P. Genich studied the decomposition of ammonia.

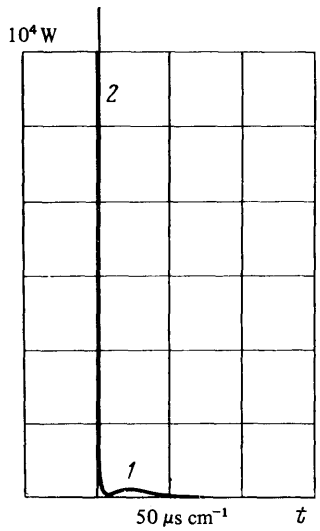

Figure 4. Intensity of chemiluminescence: 1) spontaneous; 2) induced (laser).

The development of ideas on a chain mechanism of the cracking of hydrocarbons and investigation of the kinetics and the mechanism of the elementary stages can be attributed to the work of V. V. Voevodskii and A. D. Stepukhovich.

The theory of the activated complex has been used to interpret the mechanism of a large number of elementary chemical reactions. Stepukhovich calculated the steric factors of many bimolecular reactions. E. A. Shilov and Ya. K. Syrkin introduced the concept of the formation of cyclic (four- and six-membered) transition complexes in bimolecular reactions.

V. I. Gol'danskii has recently made a detailed examination of the general theory of tunnel transitions in the kinetics of chemical reactions with a Maxwellian energy distribution of the interacting molecules. He obtained a criterion characterising the temperature below which tunnel transitions predominate over barrier transitions. A negative temperature coefficient of reaction velocity is shown to be possible because of quantum effects in barrierless transitions like inverse spontaneous predissociation. The recently discovered low-temperature quantum limit to the rate of chemical reaction in the radiation-induced solid-phase polymerisation of formaldehyde can be regarded as experimental confirmation of the possibility of sub-barrier transitions. The rate of growth of the polymer chain, induced by cobalt-60 γ-rays, was found to obey the Arrhenius law at 80–150°K, but strongly diverged from this law when the temperature fell further. At 10°K the experimental rate of addition of one monomer unit to the chain exceeded the extrapolated value by many powers of ten. It thus appeared that, instead of complete freezing of processes at temperatures close to the absolute zero, there was a measurable limiting rate of exothermic reaction, perhaps resulting from the increasing importance of tunnel transitions at extremely low temperatures.

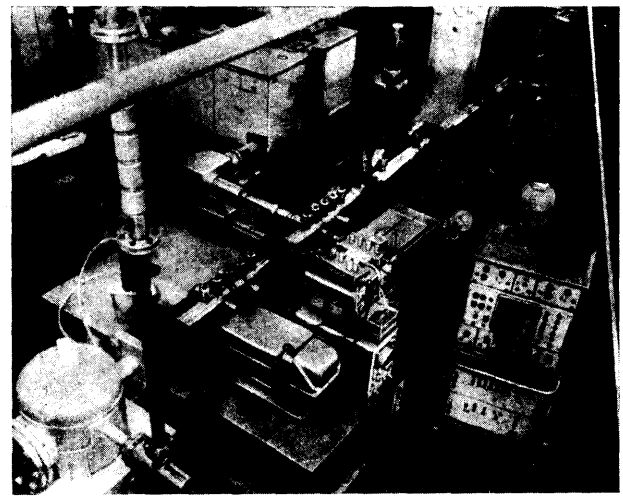

Figure 5. Equipment for investigating elementary chemical processes in a shock tube.

During recent years E. E. Nikitin has further developed the theory of the elementary acts of chemical reactions to describe the kinetics of non-equilibrium processes, which are important at high temperatures and under high vacua (e.g. in the upper layers of the atmosphere). His theory of the non-equilibrium decomposition of diatomic molecules takes into account the dependence of the probability of vibrational transitions on the vibrational quantum number. A general statistical theory of unimolecular reactions starts from the postulate that the total energy of an active molecule is redistributed statistically among active degrees of freedom, and it includes as a particular case all other theories of unimolecular reactions. N. M. Kuznetsov made theoretical calculations of vibrational temperatures and rate constants for the dissociation of certain small molecules under conditions of a non-equilibrium energy distribution. New experimental methods were proposed for studying the elementary acts of chemical reaction.

A widely used method for studying the mechanism of chemical reactions is to conduct them under ultra-high pressures, comparable with the internal pressure, when change of pressure leads to a change of the effective volume of the reaction. This enables hypothetical models of the activated complex to be tested. M. G. Gonikberg studied the effect of pressure on sterically hindered reactions and on polymerisation processes. Kinetic measurements in various solvents under high pressures have enabled the solvation of the activated complex to be studied.

Yu. N. Ryabinin suggested that the adiabatic expansion and compression of gases could be used to investigate the kinetics of fast non-isothermal reactions. Later this method was applied to the quantitative study of processes (the rate of cooling of the gaseous mixture reached 10^6–10^7 deg s^{-1}).

The rate constants of elementary reactions have been measured by means of a hydrogen maser. The method is based on measuring the reaction velocity from the change in the spin state of hydrogen on interaction of its atoms with non-paramagnetic molecules (Tal'roze).

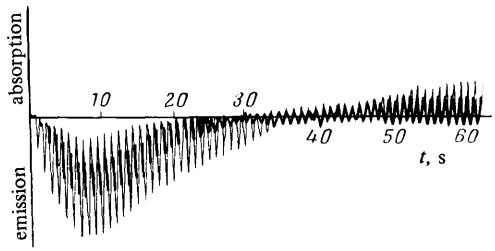

Figure 6. Kinetics of polarisation of the protons in nitrobenzene.

The mechanism of radical reactions can be investigated by studying the chemically induced dynamic polarisation of the product nuclei in a magnetic field. The basis of the method is that preferential orientation of the nuclear spins in the molecules of the products results from the occurrence of radical reactions in a magnetic field (chemically induced dynamic polarisation of the nuclei), and the nuclear magnetic resonance spectrum exhibits either abnormally large absorption or the emission of radio-frequency energy. Fig. 6 illustrates the kinetics of the variation of the n.m.r. signal (i.e. the kinetics of nuclear polarisation) obtained by A. L. Buchachenko and E. T. Lipmaa for the protons of nitrobenzene formed in the reaction of *p*-nitrobenzenediazonium tetrafluoroborate with sodium methoxide. A quantitative theory of dynamic nuclear polarisation was developed.

An interesting phenomenon was observed in the effect of a magnetic field on the proportions of the products of free-radical reactions. Thus the ratio of the yields of products obtained from the reaction of fluorobenzoyl fluoride with n-butyl-lithium changes by 37% on passing from the Earth's magnetic field of 0.5 to fields up to 25 000 oersteds (U. N. Molin).

Gol'danskii established a new "positronium" method for studying the kinetics of fast chemical reactions in gas and condensed phases. Rate constants of the formation of positronium atoms, as well as those of the excitation of electronic levels of the molecules, are determined by observing the lifetime of positronium and the intensity of the long-lived component in the annihilation.

The resolving power of a new method of microwave spectroscopy—the spin echo resulting from the action of modulated ultra high-frequency power (a series of short-lived pulses) on the specimen—exceeds that of the e.s.r. method by factors of 10–10^2 in the investigation of hyperfine interactions (Yu. D. Tsvetkov, D. G. Semenov).

Gol'danskii developed the application of γ-resonance spectroscopy to the investigation of chemical reactions. The use of Mössbauer spectroscopy enabled the rate of intramolecular electron transfer to be measured. The time of transfer in the radioactive transmutation of cobalt-57 in the compounds $^{57}Co^{II}_m[Fe^{III}(CN)_6]_n$ and $Fe^{II}_m[^{57}Co^{III}(CN)_6]_n$ was $(1-2)\times 10^{-8}$ s.

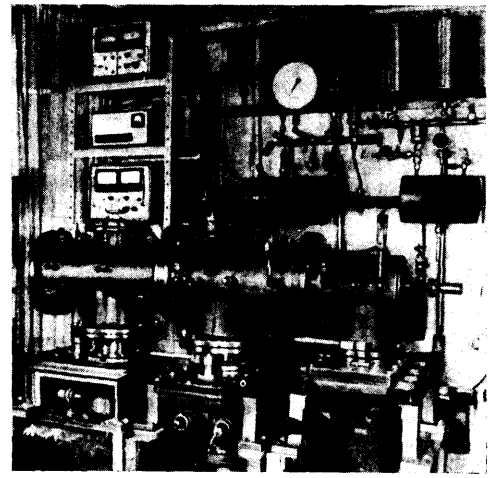

Figure 7. Equipment for studying elementary chemical reactions by the molecular beam method.

In connection with the practical importance of non-equilibrium processes the need arose for the experimental investigation of elementary reactions under conditions such that the chemical interaction of two species is an isolated process, unaccompanied by deactivation of the molecules or secondary chemical reactions, due to collisions with other molecules. Such conditions also provide new opportunities for examining the dynamics of the elementary act. Elaboration of such methods led to the design of apparatus with crossed molecular beams. Pressures of 10^{-6}–10^{-7} torr in the scattering vessel eliminate "background" collision of particles, since under these conditions any particle undergoes at most one collision in the scattering zone. The vacuum in the detector entered by the reaction products is maintained at 10^{-9}–10^{-10} torr. Fig. 7 illustrates equipment for the investigation of elementary processes in molecular beams.

Yu. B. Khariton and Ya. B. Zel'dovich worked out a chain theory of the fission of uranium.

Chain Reactions in the Liquid Phase

At the end of the nineteenth century A. N. Bakh put forward the peroxide theory of slow oxidation processes. This theory has been repeatedly confirmed in practice. During recent years kinetic methods have made it possible to extend ideas on the chemical mechanism of the liquid-phase oxidation of organic compounds. New types of elementary reactions have been discovered (in particular, new types of reactions of chain branching and chain initiation have been suggested), rate constants for various elementary stages have been measured, and processes of catalytic and inhibited oxidation have been studied quantitatively (N. M. Emanuel', I. V. Berezin, D. G. Knorre, E. T. Denisov, Z. K. Maizus, E. A. Blyumberg, V. Ya. Shlyapintokh, G. E. Zaikov, N. I. Mitskevich, R. V. Kucher, B. K. Zeinalov, and others). Heterogeneous reactions have been shown to play an important part in liquid-phase oxidations, just as in the gas-phase reactions. The effect of the solvent on individual elementary reactions has been established, and the roles of specific and non-specific solvation of the reactants in homolytic reactions have been established. Ideas on the catalysis of slow chain oxidations have been put forward and developed, and a procedure for gaseous initiation by "weak" radicals (ozone, nitrogen dioxide, etc.) is suggested.

V. Ya. Shlyapintokh and R. F. Vasil'ev studied the chemiluminescence accompanying oxidation. They showed that the chemiluminescence of hydrocarbon oxidations arises in the act of recombination of free peroxy-radicals. Measurements of chemiluminescence enable the radical-recombination rate constants to be determined (under non-stationary conditions), as well as the rate constants for the reactions of the radicals with molecules and with inhibitors of radical reactions.

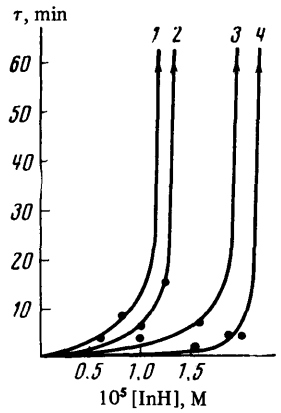

Figure 8. Dependence of induction period in the oxidation of ethylbenzene on the concentration of the inhibitors: 1) diphenylamine; 2) *N*-phenyl-2-naphthylamine; 3) 2-naphthol; 4) 1-naphthol.

The action of inhibitors on slow oxidations exhibited critical phenomena, indicating the branched-chain character of these processes (A. B. Gagarina) (Fig. 8). Study of the synergism appearing on the introduction of a mixture of inhibitors into an oxidisable medium suggested radical interaction of the inhibitors resulting in regeneration of the more effective inhibitor (G. V. Karpukhina).

The laws of liquid-phase oxidation in open systems were investigated as the scientific foundation for continuous processes in chemical technology (I. P. Skibida).

At the beginning of the present century N. A. Shilov put forward a theory of chemical induction. In his monograph on coupled oxidations he introduced the idea that chemical induction (the acceleration of a chemical reaction by another reaction taking place spontaneously in the system) is due to the formation of intermediates involved in both stages of the process. Shilov was in effect the first to draw attention to the fact that redox reactions are complicated multistage processes involving the formation of intermediate products.

The method suggested recently for the preparation of methyloxiran by oxidising a mixture of propene and acetaldehyde is based on the principles of simultaneous oxidation applied to slow chain reactions. The hydroperoxy-radical formed by oxidation of the acetaldehyde serves as epoxidising agent for propene.

A fertile application of kinetic methods has been to describe the development with time of several biological processes, such as malignant growth, aging, radiation sickness, and the action of chemical and physical factors in the environment on living organisms. Kinetic parameters have been revealed which permit the efficiencies of different methods for the therapy of malignant diseases to be evaluated quantitatively.

It has been discovered that the content of free radicals in tumour tissue increases during the initial period of growth. This relation is extremal: a maximum content of free radicals is observed before the tumour attains its maximum rate of growth. A group of compounds has been found which have an anticancer effect, which are able to diminish the scale of harmful effects of chemical contamination of the environment on the organism, which extend the life of experimental animals, and which possess radiation-protective properties. All these substances are inhibitors of free-radical processes.

Homogeneous Catalysis

One of the first investigators of homogeneous catalysis in Russia was E. I. Shpital'skii, who as early as the beginning of the present century developed the main theoretical concept of homogeneous catalysis—the formation of active intermediate products—and, in contrast to van't Hoff and Arrhenius, suggested that not one but several intermediate catalyst–substrate complexes were formed, differing in composition, stability constant, and reactivity (down to complexes that deactivate the catalyst). This theory later received convincing experimental support: intermediate products in the decomposition of hydrogen peroxide by molybdates and by tungstates (permolybdates and pertungstates respectively), etc. were isolated.

The formation of molecular complexes of compounds of metals of variable valency with hydroperoxides (in catalytic decompositions) and their role in catalysis have been confirmed quantitatively by S. K. Maizus and I. P. Skibida using kinetic and spectroscopic methods.

E. A. Shilov established that π-complexes have a decisive role as intermediate species in various reactions involving alkenes. In a study of acid catalysis (in particular by the Lewis acids—boron trifluoride, aluminium trichloride, etc.) N. M. Chirkov concluded that reactive intermediate

π-complexes of alkenes with hydrogen ions were formed. Ya. K. Syrkin and I. I. Moiseev examined the formation of π-complexes of palladium(II) chloride with alkenes in the preparation of aldehydes. These workers used phenomena such as synergism occurring in mixtures of several catalysts for the oxidation of ethylene to acetaldehyde in the presence of the palladium(II) chloride–copper(II) chloride catalytic system.

A. I. Shatenshtein proposed a new kinetic method for determining the strengths of very weak acids and bases (e.g. hydrocarbons), and traditional views on acids and bases were revised.

The study of metal-complex catalysis, which is closely connected with enzymic catalysis, began to acquire great importance during the 1950s. Organometallic (especially π-allylic) complexes are used as catalysts for stereospecific polymerisation (B. A. Dolgoplosk). Papers by L. A. Nikolaev and A. P. Purmal' reported studies of the mechanism of enzymic catalysis, investigation of the roles of ligand and metal in various types of reactions (the oxidation of ascorbic acid, the decomposition of hydrogen peroxide, etc.), and elucidation of the detailed chemical mechanism of catalysis.

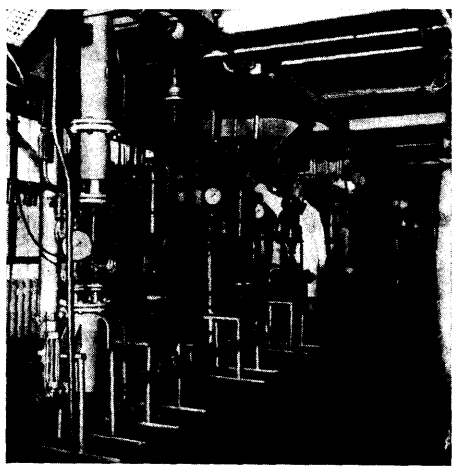

Figure 9. Pilot plant for synthesis of hydrazine from molecular nitrogen and water.

The problem of the catalytic fixation of small molecules—the activation of oxygen, nitrogen, carbon dioxide, and carbon monoxide by catalytic systems—has aroused interest recently. During the 1960s M. E. Vol'pin and A. E. Shilov discovered the catalytic fixation of nitrogen with the formation of hydrazine and ammonia (Fig. 9). Compounds of bivalent vanadium in the presence of magnesium salts form an effective catalytic system in alkaline and alcoholic aqueous media. The yield of ammonia and hydrazine increases with the ratio of magnesium to vanadium. The fixation of carbon dioxide by complexes of Group VIII transition metals has been studied.

When hydrocarbons and compounds of metals are oxidised together in organic solvents, conversion of the hydrocarbons (cyclohexane, alkanes) to alcohols is accompanied by a change in the valency of the metal.

A nevel type of catalysis—micellar catalysis—was discovered by I. V. Berezin. It consists in a marked change (by several powers of ten) in the rate of organic reactions in aqueous solutions under the influence of surface-active substances, as a consequence of solubilisation of the reactants by micelles of the surface-active compounds (Fig. 11).

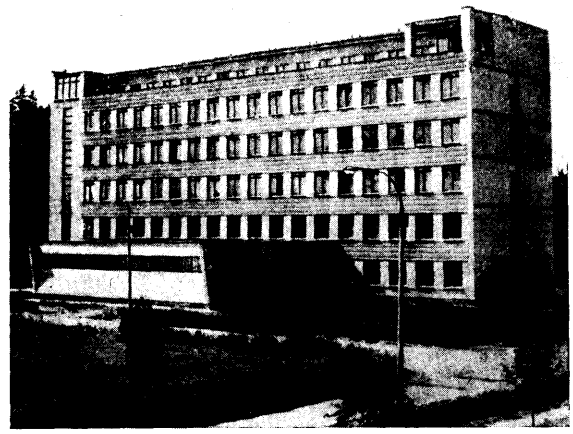

Figure 10. Laboratory building of the Department of Kinetics and Catalysis of the Institute of Chemical Physics of the USSR Academy of Sciences.

A paper by D. G. Knorre, L. G. Chuchukina, and N. M. Emanuel' established that a catalyst has a "dual function": at sufficiently high concentrations salts of metals of variable valency cease to exhibit catalytic properties, and the "catalysts" begin to inhibit the process. The dependence of the inhibiting properties on the composition of the chelate group, the redox potential, and the electron density on the central atom of the chelate has been studied, and the conversion products of the metal complexes have been isolated and examined.

Heterogeneous Catalysis

In the field of heterogeneous catalysis numerous papers have appeared on the selection of effective new catalytic systems. At the start of the 1920–1930s V. N. Ipat'ev began a comprehensive investigation of metal oxides as heterogeneous catalysts. N. D. Zelinskii discovered general-purpose hydrogenation and dehydrogenation catalysts such as nickel on alumina and platinum on carbon. In 1928 S. V. Lebedev proposed a mixed zinc–aluminium catalyst for the synthesis of butadiene from ethanol. The action of catalytic semiconductors, in particular germanium, was investigated (S. Z. Roginskii, O. V. Krylov).

Investigations of adsorption and chemisorption were very important in connection with the study of heterogeneous catalytic reactions. A theory of catalysis and chemisorption on non-uniform surfaces was elaborated (S. Z. Roginskii, O. M. Todes). A correlation between activation energy and heat of adsorption was established by M. I. Temkin. The principles of physical sorption on porous materials were studied by M. M. Dubinin.

Various methods were suggested for investigating the structure, properties, and activity of catalysts. Besides the usual X-ray diffraction, electron diffraction, magnetic methods, sedimentation analysis, and microweighing were introduced into practical heterogeneous catalysis.

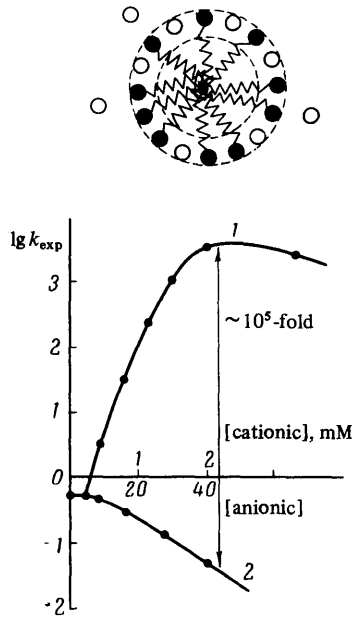

Figure 11. Formation of micelles (upper diagram) in micellar catalysis. Variation of acylation rate constant with concentration of surface-active agents: 1) cationic; 2) anionic.

A. M. Rubinshtein suggested determining specific surface from the adsorption isotherms of benzene or carbon tetrachloride vapour determined under dynamic conditions. The displacement of characteristic curves for a sorbed gas and measurement of the work of sorption of the gas (vapour) have been used to measure the specific surface of a catalyst (M. M. Dubinin and A. V. Kiselev). Various physicochemical methods (electrochemical and chromatographic) were used by A. A. Balandin and Kh. M. Minachev.

Kiselev calculated theoretically the energies of adsorption of complicated molecules on crystalline surfaces. A. N. Frumkin and A. I. Shlygin proposed to study the mechanism of hydrogenation from the charging curves for the catalytic electrodes. This made it possible to examine quantitatively the adsorption of hydrogen on the surfaces of metals (platinum).

Investigation of the properties of species adsorbed on a catalyst surface has been approached in earnest with the development of the most recent physicochemical methods. V. V. Voevodskii used electron spin resonance to study the structure of the active centres (radicals and ions), and showed their non-uniform distribution on solid surfaces. The O_2^- radical-ion adsorbed on a surface has recently been detected by γ-resonance (Mössbauer) spectroscopy (Fig. 12).

Kinetic isotope methods opened up great possibilities for investigating the mechanism of heterogeneous chemical reactions (S. Z. Roginskii, M. B. Neiman).

Balandin's multiplet theory of catalysis presupposes structural and energetic conformity between the crystal lattice of the catalyst and the molecule of the reactant. The formation of surface complexes involving active centres of catalysis (multiplets) is significant for catalysis. Physical adsorption on the catalyst surface is followed by movement of the molecule along the surface and formation of a multiplet complex at a certain orientation of reactant molecules and active centres. Bond redistribution in such a complex results in formation of the final products. Multiplet schemes, based on a large quantity of experimental information, explain almost all routes of catalytic conversion of hydrocarbons.

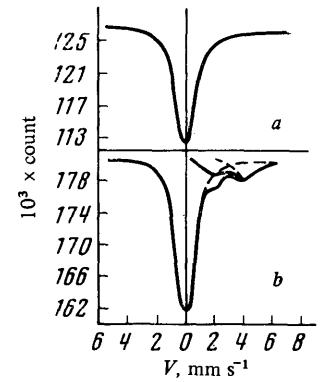

Figure 12. γ-Resonance spectra of tin–molybdenum catalyst (V = relative rate of movement of source): *a*) initial specimen; *b*) specimen after adsorption of oxygen and propene at 200 °C.

N. I. Kobozev applied a theory of active ensembles to deposited catalysts. It was based on the assumption that a certain number of catalyst atoms—not a single atom—was involved in catalysis. Such groups may be formed by the migration of atoms along the catalyst surface.

A large number of publications on aspects of the chemistry of heterogeneous catalytic reactions have appeared from G. K. Boreskov, K. V. Topchieva, V. A. Roiter, and others. Boreskov suggested that the activity of a heterogeneous catalyst should be measured by the rate of chemical conversion per unit active surface of the catalyst: i.e. he introduced the concept of specific catalytic activity. He examined the mutual influence of catalyst and substrate on the properties of the catalytic system, which may lead to a strong dependence of catalytic activity not only on the degree of conversion of the reactants but also on their initial concentration.

Roginskii proposed a new classification of catalysts linking the activity of a catalyst with the character of the interaction between catalyst and substrate. Catalysts were divided into two groups—electrical conductors (metals and semiconductors) and non-conductors (ionic crystals, gels). This classification has been tested on

many oxidation processes (S. Yu. Elovich, L. Ya. Margolis, G. M. Zhabrova).

L. V. Pisarzhevskii's electronic theory played an important part in establishing the theory of the elementary act of heterogeneous catalysis. It assumed that electrons of the catalyst took part in redox reactions. The modern form of the electronic theory of catalysis was formulated by F. F. Vol'kenshtein. Free electrons and holes of the semiconductor, acting as free valencies, are supposed to take part in chemisorption processes. The reactivity of a chemisorbed molecule depends on the form of the chemisorption (valency-saturated, radical, or radical-ionic form).

N. N. Semenov, V. V. Voevodskii, and F. F. Vol'kenshtein put forward a chain theory of heterogeneous catalysis based on the electronic theory and on their view of the role of heterogeneous factors in the formation and destruction of radicals. This theory assumes that reaction may occur on the surface of a heterogeneous catalyst by a chain mechanism. O. M. Poltorak has recently developed the concept of chains of redistribution of bonds, and used it for a theoretical analysis of diverse catalytic processes. It permits a unified approach to the mechanism of homogeneous, heterogeneous, and enzymic catalyses.

The work of A. A. Balandin, D. A. Frank-Kamenetskii, G. K. Boreskov, Ya. B. Zel'dovich, M. G. Slin'ko, O. M. Todes, D. V. Sokol'skii, G. I. Panchenkov, M. F. Nagiev, I. I. Ioffe, S. L. Kiperman introduced into practical heterogeneous catalysis methods for calculating the reaction order, rate constants, and activation energy of heterogeneous reactions in vessels with ideal mixing and displacement, examined the macrokinetics of reactions in a fluidised bed, and applied statistical methods to investigating the kinetics of heterogeneous reactions. The gradient-free methods of conducting chemical reactions (under conditions of ideal mixing) proposed by M. I. Temkin have been applied to such kinetic studies.

Various processes—dehydrogenation, dehydrocyclisation, hydrogenation, etc.—can be combined in the same apparatus as a consequence of the development of original membrane catalysts (V. M. Gryaznov, V. S. Smirnov).

The role of heterogeneous catalysts and the mechanism of their action in liquid-phase processes have been investigated in the oxidation and decomposition of hydroperoxides (E. A. Blyumberg, Yu. D. Norikov, Ya. B. Gorokhovatskii). The heterogeneous catalyst is shown to be involved in initiation, branching, and termination of the oxidation chain, and also to influence the way in which the hydroperoxide breaks down.

The catalytic properties of heterogeneous catalysts can be varied by donor–acceptor modification by means of gaseous additives.

Thermal Explosion, Combustion, Detonation

The theory of thermal ignition in exothermic reactions, formulated by N. N. Semenov and subsequently developed by his school, has been exceptionally important, both theoretically and practically. The nature of thermal ignition, resulting from the predomination of the evolution of heat over its removal from the system, is apparent in an exponential increase in reaction velocity with rise in temperature in the vessel and a corresponding temperature rise. The theory of thermal explosion was developed and refined by O. M. Todes and D. A. Frank-Kamenetskii. Conditions of ignition were determined for vessels of various geometrical shapes taking into account the thermal conductivity equation. These conditions enable flash points of various substances to be calculated with good accuracy.

The theories of flame propagation, detonation, and explosion limits were developed by Ya. B. Zel'dovich. Specific régimes of combustion were investigated by K. I. Shelkin, Ya. K. Troshin, et al., who showed that the rate of flame propagation was affected by the movement of the gas caused by expansion of the products of combustion. Investigations were made of the burning of light fuel in engines. On the basis of this work A. S. Sokolik and A. I. Voinov proposed a new mode of organisation of combustion in motors—fuel injection—which has been further developed by L. A. Gusak.

Kinetic studies of the decomposition of condensed explosives were begun in 1929 by S. Z. Roginskii. Together with Todes he elaborated a statistical theory of the kinetics of topochemical and crystallisation processes. Yu. B. Khariton and also A. F. Belyaev studied the kinetics of the breakdown of explosives. They revealed the mechanism of explosion after impact, and formulated the principle defining the conditions of persistent explosion. Belyaev's discovery that the combustion of explosives takes place in the gas phase, after they have vaporised, became widely known.

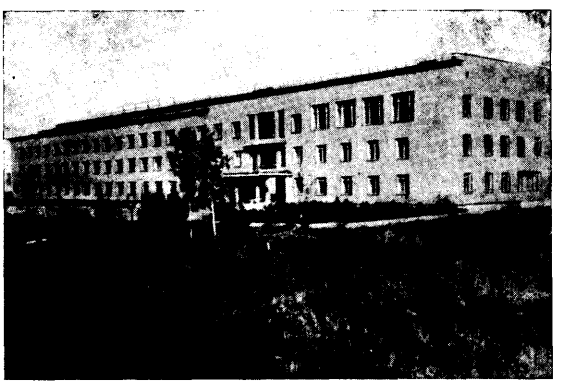

Figure 13. Institute of Chemical Kinetics and Combustion of the Siberian Division of the USSR Academy of Sciences.

P. F. Pokhil, A. Ya. Apin, A. A. Andreev, F. I. Dubovitskii, V. K. Bobolev, B. P. Zhukov, A. G. Merzhanov made many investigations of the mechanism of thermal explosion. M. A. Sadovskii studied the structure, mechanism of formation, and propagation of shock waves. The mechanical action of a shock wave in air was examined, and the dependence of the maximum pressure in the wave on the weight of the charge and the distance from the site of explosion was determined. Spherical detonation, which has found application in seismic exploration, was studied by S. M. Kogarko.

Merzhanov worked out a new method for obtaining refractory compounds (nitrides, carbides of Groups III–VI metals)—"self-propagating high-temperature synthesis"—and a new form of propagation of the seat of chemical reaction—a kind of spiral motion of the focus of combustion on the surface of the specimen—was studied. Reaction vessels have already been constructed which enable

considerable quantities of titanium carbide and molybdenum disulphide to be obtained (Fig. 14). A. N. Dremin showed that new crystalline modifications can be obtained by the action of powerful shock waves on various substances.

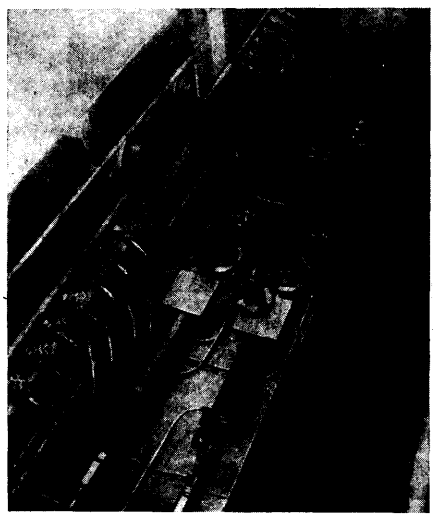

Figure 14. Equipment for the production of refractory inorganic compounds by "spontaneously propagated high-temperature synthesis".

High-energy Chemistry

This field of science is concerned with the kinetics, mechanism, and practical application of reactions in which the energies of individual atoms, molecules, and radicals exceed the energies of thermal motion and frequently the energies of chemical bonds. These result in peculiar new mechanisms of chemical reaction, which are improbable in equilibrium systems at ordinary temperatures.

Research on radiation chemistry began with the work of V. A. Kargin, V. V. Voevodskii, S. S. Medvedev, N. A. Bakh, and others. The theoretical principles of radiation chemistry are now being worked out: studies are being made of elementary processes in gas and condensed phases, of the nature and properties of short-lived intermediate products of radiolysis (solvated electrons, ions, free radicals, excited molecules), the kinetics and mechanism of radiation-chemical reactions in homogeneous systems, aspects of radiation polymerisation, problems of the radiation modification and radiation-chemical protection of various materials, etc.

Ion–molecule reactions of organic compounds have been discovered (V. L. Tal'roze), methods have been suggested and developed for the radiation cross-linking of polyalkenes and the modification of polymeric, porous, and other materials (V. L. Karpov, Kh. U. Usmanov, A. M. Kabakchi, E. E. Finkel', V. L. Tsetlin), and theories have been elaborated for the radiation-chemical oxidation of organic compounds (Bakh), gaseous and heterogeneous radiation-chemical reactions (S. Ya. Pshezhetskii), radiation polymerisation (A. D. Abkin, V. I. Gol'danskii, V. L. Tal'roze), and the radiolysis of water and aqueous solutions (P. I. Dolin, M. A. Proskurnin, B. V. Ershler, A. K. Pikaev, L. T. Bugaenko). Stabilisation of the hydrated electron has been detected in frozen aqueous solutions (Pikaev), and principles have been worked out for the chemical dosimetry of ionising radiations (S. V. Starodubtsev, A. M. Kabakchi).

The theoretical investigations have served as a basis for the development of applied radiation chemistry. Processes have already been worked out for obtaining a biodegradable sulphonate (R. V. Dzhagatspanyan), synthesising telomers of ethylene with carbon tetrachloride (A. A. Beer), and making polyheterosiloxane insulating tape and rubber–glass cloth (I. Ya. Poddubnyi et al.).

The unique phenomenon has been observed that the coefficient of dry friction is reduced by several powers of ten when non-metallic rubbing surfaces are exposed to a slight flux of short-range radiation (V. L. Tal'roze, A. N. Ponomarev, A. A. Silin, E. M. Dukhovskoi).

Experimental and theoretical research on low-temperature plasma constitutes a new sector of high-energy chemistry. General principles of non-equilibrium kinetics have been formulated, and its fundamental equations given (L. S. Polak, D. I. Slovetskii, Yu. A. Kolbanovskii). The scientific foundations of plasmachemical technology have been laid, its characteristic features being short reaction time (10^{-5}–10^{-3} s), high degree of conversion, pure products, and in several cases the accomplishment of difficultly realisable processes. Plasmachemical methods are used to prepare acetylene, pigment titanium dioxide, materials for microelectronics, and other products.

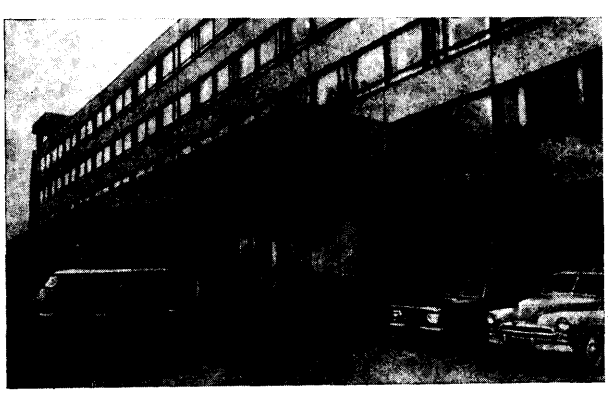

Figure 15. Radiochemical building of the Institute of Physical Chemistry of the USSR Academy of Sciences.

A shock wave provides a new method for stimulating and accomplishing chemical conversions: the chemistry of shock waves constitutes a new branch that studies the transformations of condensed substances resulting from percussive compression. These researches, started by Yu. N. Ryabinin, were developed by V. I. Gol'danskii, A. N. Dremin, P. A. Yampol'skii, S. S. Bogdanov, G. A. Adadurov, O. N. Breusov. High-pressure phases—diamond and wurtzite-like boron nitride (B–BN)—have been obtained by percussive compression. The latter has yielded especially durable polycrystals, suitable for the

production of high-quality cutting tools with the best available characteristics. Polymerisation has been observed, and the possibility shown of cross-linking macromolecules by the action of shock waves to form a three-dimensional network.

Figure 16. Linear electron accelerator of the Institute of Physical Chemistry of the USSR Academy of Sciences.

An important sector of high-energy chemistry is nuclear chemistry—investigation of the chemical consequences of nuclear processes (nuclear reactions, radioactive disintegration) and research on the chemistry of new atoms and the peculiar systems produced by the action of positrons and various mesons on matter. The high and specific reactivity of the hot species resulting from nuclear processes has been the subject of research by An. N. Nesmeyanov, A. N. Murin, V. D. Nefedov, B. G. Dzantiev, T. V. Tsetskhladze, and others. Methods have been found for the chemical stabilisation of hot atoms of tritium, carbon, nitrogen, sulphur, halogens, and certain metals in organic and inorganic media, in gas and condensed phases. The results open up new paths for the preparation of labelled compounds and for the concentration of radioisotopes.

Various types of chemical reactions of positronium have been studied, and the physical chemistry of the positron and of positronium has been established (V. I. Gol'danskii, V. P. Shantorovich). The foundations of the physical chemistry of muonium have been laid down in the works of V. G. Firsov, I. I. Gurevich, V. G. Nosov. Research has started on the chemistry of mesoatoms and mesomolecules (Yu. D. Prokoshkin, L. I. Ponomarev).

Photochemistry

The study of chemical reactions occurring under the influence of light is very important for the theory of chemical processes and for solving problems of photosynthesis, photoreception, photography, the photostabilisation of polymeric materials, etc.

P. P. Lazarev investigated the fading of dyes for the first time.

Fundamental photochemical researches were carried out by A. N. Terenin. His hypothesis of the triplet nature of the metastable states of organic molecules which are responsible for their phosphorescence has received much experimental confirmation. The properties of triplet states have been studied, and their role in various photochemical and photophysical processes has been revealed. The phenomenon of triplet–triplet energy transfer has been established (A. N. Terenin, V. L. Ermolaev). Flash photolysis was used by A. V. Karyakin and A. K. Chibisov to show the important role of the triplet state in photochemical redox reactions involving pigment and dye molecules.

Figure 17. Apparatus for studying radiation copolymerisation in the Institute of Physical Chemistry of the USSR Academy of Sciences.

The work of V. N. Kondrat'ev gave rise to study of the elementary act of interaction between light and matter. The mechanism of induced predissociation and energy-transfer processes was investigated. A. B. Nalbandyan studied the mechanism of the photochemical oxidation of hydrocarbons sensitised by mercury vapour and by chlorine. Mass spectrometry yielded several results on photoionisation in the gas phase (F. I. Vilesov).

Two-quantum reactions involving triplet states of organic molecules form a special class of photochemical processes. Kh. S. Bagdasar'yan examined the kinetics of the sensitised dehydrogenation of alcohols, which has a two-quantum mechanism, and made the first measurements of the absolute efficiencies of the two-quantum photoionisation of organic compounds in a condensed phase. N. V. Fok, M. V. Alfimov, V. E. Kholmogorov also investigated two-quantum processes.

The discovery and manufacture of laser sources of radiation led to promising new lines of research in photochemistry. It was established that infrared rays were photochemically active, ensuring the selective occurrence of a reaction whose activation energy was substantially larger than the energy of an infrared quantum (N. G. Basov, A. N. Oraevskii, A. V. Pankratov).

The development of modern pulse methods has permitted the study of extraordinarily fast photoprocesses (down to

10^{-9} s), which is of fundamental importance for investigation of the mechanism of elementary reactions. A flash fluorometer has been used to study heterolytic dissociation and the phototransfer of an electron and a proton (M. G. Kuz'min). A kinetic study has been made of the protonation of excited acridine molecules (Fig. 18). In the course of an investigation of intermediate products in the flash photolysis of solutions of various phenols in the presence of compounds of transition metals (V. A. Kuz'min and I. V. Khudyakov) complex formation was established between the *o*-methylphenoxyl radical and cobalt acetylacetonate (Fig. 19).

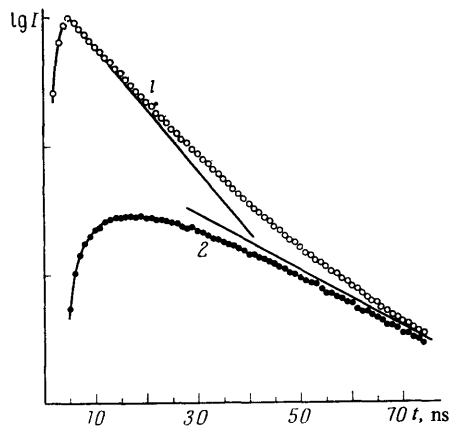

Figure 18. Kinetics of the fluorescence in aqueous solution of: 1) acridine; 2) the acridinium ion.

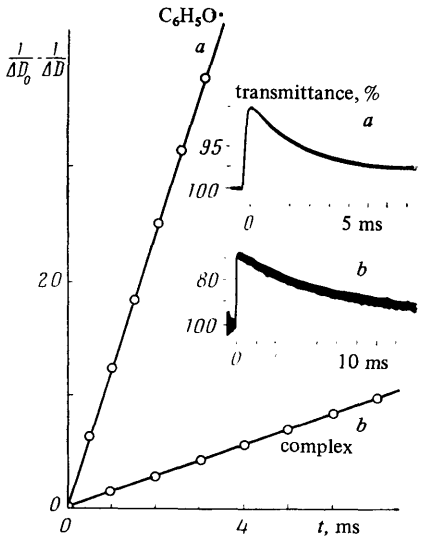

Figure 19. Kinetic curves of the decay of: *a*) *o*-methylphenoxyl radical; *b*) complex of *o*-methylphenoxyl radical with cobalt acetylacetonate.

The widespread application of photochromic compounds in technology led to an intense investigation of their properties and of the mechanism of photochromism (V. A. Krongauz, K. G. Dzhaparidze, M. A. Gal'bershtam). Work is being undertaken on the synthesis of new photochromic compounds based on spiropyrans, which absorb visible light (E. R. Zakhs, L. S. Efros).

One problem of present-day science and technology of photographic materials is to obtain emulsions that possess high sensitivity over a wide spectral range. I. I. Levkoev and A. I. Kiprianov prepared efficient new spectral sensitisers for various photographic materials, and introduced these polymethine dyes into industry.

K. V. Chibisov investigated the photochemistry of photographic processes. He discovered the nature of photographic sensitivity, and examined the mechanism of the chemical sensitisation of photographic emulsions.

Photochemical methods have proved effective in the chemistry and technology of polymers. Monolithic glasses of any thickness have been obtained by photopolymerisation for the first time on an industrial scale (S. R. Rafikov, G. P. Gladyshev).

An important sector is preparative organic photochemistry. V. F. Kucherov has studied the photoinduced *C*-addition of alcohols, acetals, ethers, and esters to acetylene and its monosubstituted derivatives. Alkene systems substituted by various functional groups have been obtained by means of this reaction.

In order to prepare materials possessing superconducting and semiconducting properties, K. N. Anisimov and N. E. Kolobova investigated the photochemical reaction of tetracarbonyl-π-cyclopentadienylniobium with silicon, germanium, and tin acetylides.

Photosubstitution in aromatic compounds and the photoreduction of aromatic nitro-compounds have been investigated (A. V. El'tsov).

S. Ya. Pshezhetskii examined the effect of the medium on the mechanism of the photoconversion of free radicals in solutions of ethers and anhydrides of monocarboxylic acids. The formation of hydrogen bonds between radicals and molecules in alcohols and acids plays an important part in such processes.

The modelling of various photobiological processes and the investigation of the photochemical reactions of biologically important molecules constitute an actively developing line of research. A. A. Krasnovskii and V. B. Evstigneev have made a series of studies of the redox photoreactions of chlorophyll and related compounds in various systems. Elementary photochemical processes involving photosynthetic pigments and other metal-containing porphyrin compounds have been investigated by A. K. Chibisov, G. P. Gurinovich, A. N. Sevchenko, K. N. Solov'ev, I. I. Dilung. Artificial photosynthetic systems are being examined by G. G. Komissarov.

Reversible photochemical changes undergone by the visual pigment rhodopsin are being investigated (M. A. Ostrovskii, V. A. Krongauz).

I. V. Berezin, K. Martinek, and N. F. Kazanskaya have proposed a new chemical system for intensifying a light signal by means of enzymic reactions. The high quantum yield (10^{10}–10^{12}) can be utilised for the production of new supersensitive materials.

Photoinduced free-radical processes involving proteins are being studied (L. P. Kayushin).

Electrochemistry

Although the first electrochemical investigations in Russia were made as early as the nineteenth century by V. V. Petrov, F. F. Grotgus, B. S. Yakobi, E. Kh. Lents, A. S. Savel'ev, A. P. Sokolov, only the applied aspects of this important branch of physical chemistry were largely developed right up to post-Revolutionary times. The Soviet period is characterised by intense activity on the problems of electrochemistry. Many investigations have been made on the structure of the electrical double layer, the effect of adsorption on the kinetics of electrode processes, the role of diffusion factors, the theory of hydrogen overpotential, the quantum-mechanical theory of electrode processes, the electrochemical theory of corrosion and passivity, the mechanism of metal electrodeposition, and the electrochemistry of melts.

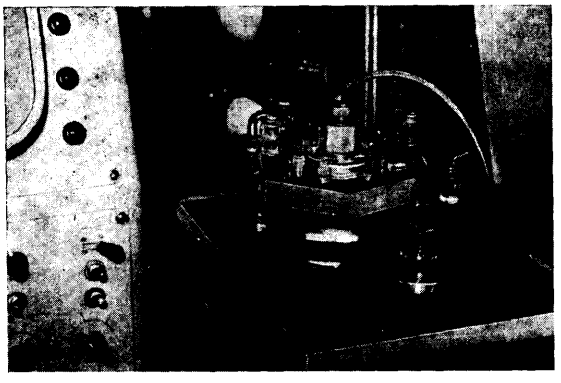

Figure 20. Apparatus for determining dependence of solid–liquid interfacial tension on surface charge (Institute of Electrochemistry of the USSR Academy of Sciences).

The most eminent electrochemical school in our country is that of A. N. Frumkin. As early as the 1930s he established the relation between the rate of reaction and the structure of the electrical double layer. The rate of discharge of ions was shown to be determined by their concentration at the electrode surface and to depend on the potential drop in the dense region of the double layer acting directly on the ions. Frumkin introduced the concept of the zero-charge potential as an individual characteristic of metals, which led to a solution of one of the problems of the theory of voltaic cells—the relation between their electromotive force and the contact potential difference between the two metals in a vacuum (the so called Volta problem). This work laid the foundations of quantitative electrochemical kinetics. Frumkin's school developed and perfected methods for investigating the metal—solution interface, measuring the capacitance of electrodes by means of alternating currents, determining charging curves and the adsorption of labelled atoms, and applying the isoelectric displacement method (P. I. Dolin, B. V. Ershler, N. A. Balashova, V. E. Kazarinov, O. A. Petrii). A quantitative theory of the double layer and a theory of adsorption at charged interfaces were elaborated (B. B. Damaskin).

During recent years advances have been made in the quantum-chemical interpretation and experimental investigation of the mechanism of the elementary step in electrode reactions and processes in the bulk solution which accompany electron transfer (R. R. Dogonadze, A. M. Kuznetsov, L. I. Krishtalik). A new electrochemical field—the electrochemistry of solvated electrons—was developed. Krishtalik has established the laws of dark emission, and A. M. Brodskii, Yu. V. Pleskov, et al. those of the photoemission of electrons from a metal into a solution. The theory of convective diffusion (V. G. Levich) helps to solve the problems of the transport of material to the electrode surface.

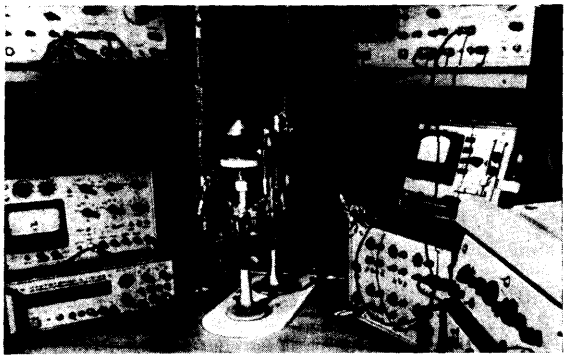

Figure 21. Apparatus for potentiometric investigation of state of surface and kinetics of electrochemical reactions using a rotating disc electrode with a ring (Institute of Electrochemistry of the USSR Academy of Sciences).

A. N. Frumkin and L. N. Nekrasov have proposed a disc electrode with a ring (Fig. 21) for investigating intermediate products of electrochemical processes.

A theory of the establishment of a potential on ion-selective membranes has appeared in papers by B. P. Nikol'skii, M. M. Shult's, and their coworkers; new types of glass and other ion-selective electrodes have also been developed.

The theory of corrosion processes and the struggle against corrosion have been widely researched, beginning with the investigations of V. A. Kistyakovskii and N. A. Izgaryshev. This work has been developed by G. V. Akimov, who put forward a theory of multicomponent systems containing metal–solution microsystems differing in structure and properties, and by Frumkin (the theory of coupled reactions). Ya. M. Kolotyrkin obtained important results on the theory of corrosion and on methods of corrosion protection. He revealed the role of complex formation and established experimentally for the first time the direct involvement of water molecules in the electrochemical stages of the dissolution of active metals (nickel, manganese). He showed that a purely chemical mechanism of dissolution of metals was possible in addition to the electrochemical mechanism. N. D. Tomashov suggested a novel method for producing corrosion-resistant alloys by cathodic alloying, i.e. by introducing into the alloy small quantities of such components as palladium, platinum, ruthenium, etc., which accelerate the cathodic evolution of hydrogen.

K. M. Gorbunova and P. D. Dankov studied the mechanism of crystal growth and nucleation during electrolysis; they worked out the theory and a technology of chemical nickel plating. Yu. Yu. Matulis is undertaking comprehensive investigations on the electrodeposition of metals and the production of the bright coatings used in industry. G. S. Vozdvizhenskii has studied the electrolytic polishing of metals.

The Ural school has made a great contribution to the development of high-temperature electrochemistry. Data have been obtained on electrochemical kinetics in molten salts and on the structure of the electrical double layer at the boundary between molten metals and electrolytes (S. V. Karpachev, O. A. Esin, M. V. Smirnov, V. A. Kuznetsov, E. A. Ukshe). Diffusion kinetics in molten salts has been investigated by Yu. K. Delimarskii. The possibility has been established of using solid electrodes for polarographic purposes and of applying polarography to the study of complex formation in melts.

The development of fuel cells—devices in which the chemical energy of the fuel is converted directly into electrical energy—has stimulated a number of theoretical investigations. The mechanism of processes occurring in fuel cells (the ionisation of hydrogen and the electrochemical reduction of oxygen) has been examined, the phenomena of electrocatalysis have been studied, model systems have been analysed, and a theory of mass transfer in porous electrodes has been developed which permits more efficient utilisation of their surface (V. S. Bagotskii, A. G. Pshenichnikov, R. Kh. Burshtein). Most of the work in this field has been undertaken by industrial institutes. The experience accumulated in work on the hydrogen—oxygen fuel cell has been used to lower the voltage in the electrolysis of water. The development of high-temperature fuel cells has led to a theory of conduction by solid electrolytes in equilibrium with the gas phase (S. F. Pal'guev).

The Institute of Electrochemistry of the USSR Academy of Sciences has recently developed electrochemical transformers (memory cells, integrators, pressure and acceleration transducers, etc.), which materially supplement semiconductor devices at low frequencies and in control by weak signals (P. D. Dukovtsev, B. M. Grafov).

Chemical Thermodynamics

The foundations of thermochemistry as a science were laid by the work of G. I. Gess [Hess]. The law which he discovered, that the total heat of a chemical reaction is independent of the intermediate states of the system, is a particular formulation of the first law of thermodynamics. Systematic and accurate thermochemical investigations have been made by B. F. Luginin, M. M. Popov, S. M. Skuratov, and others.

Generalisation and systematisation of experimental thermochemical results led to the discovery of several regularities. D. P. Konovalov (1924) proposed the well known relation for determining heats of combustion of organic compounds from their composition and their membership of a known homologous series. A. M. Berkengeim (1925) established that heats of formation of inorganic compounds can be calculated as the arithmetic means of the values for the corresponding compounds of the adjacent elements (in a series or a group of the Periodic System). A. F. Kapustinskii showed that the heats of formation of many crystalline compounds of the same type vary linearly with the logarithm of the atomic number of the elements, and suggested a formula for calculating the entropies of ions (in crystal lattices) from the atomic weights of the elements, their valencies, and the ionic radii. V. A. Kireev demonstrated the existence of a simple approximation enabling entropies of formation of crystalline compounds to be computed from their composition.

N. N. Beketov's studies of the reversibility of chemical processes—the dependence of the direction of chemical changes in a system on the concentrations (pressures) of the reactants—played an important part in the development of chemical thermodynamics. This work led to the discovery of the law of mass action—a thermodynamic relation of the greatest importance for chemistry.

Equations of state of gases play a large part in thermodynamics. The Mendeleev–Clapeyron equation of state of ideal gases is widely used. New lines of investigation appeared in the post-Revolutionary period. A general theory of thermodynamic potentials was based by S. A. Boguslavskii on statistical mechanics. The fundamental concepts of thermodynamics have been refined and its theory has been presented more rigorously, the irreversibility of processes has been studied, and the second law of thermodynamics has been analysed (G. A. Afanas'eva-Erenfest, K. A. Putilov), geometrical thermodynamics has been developed (A. B. Mlodzievskii), the thermodynamics of intermolecular interaction investigated (E. S. Rudakov), the thermodynamics of irreversible processes developed (A. I. Veinik), and interaction in multicomponent systems with a variable number of degrees of freedom examined (L. S. Palatnik, A. I. Landau). The requirements of technology for numerical thermodynamic characteristics with wide variation in physical conditions stimulated experimental lines of attack on thermodynamics and promoted the development of methods for the statistical calculation of thermodynamic data. Ya. B. Zel'dovich, A. N. Gurvich, and Yu. M. Shaulov worked out methods for the thermodynamic calculation of combustion processes and explosions. Systematic statistical calculations of thermodynamic data at high temperatures were made by A. V. Frost and I. N. Godnev.

Study of the thermodynamic properties of individual groups of substances used in the new technology (new fuels, semiconducting materials, compounds of rare metals, strong alloys, durable coatings, etc.) is most important for the national economy of the USSR. Ya. I. Gerasimov has devoted his efforts to an important branch of experimental thermodynamics—determination of the free energies of compounds used in non-ferrous metallurgy and the study of heat-resistant alloys, oxides, and semiconductors.

M. Kh. Karapet'yants has elaborated a set of methods for the comparative calculation of several physicochemical properties of various chemical compounds.

Among theoretical investigations mention must be made of the work of L. D. Landau and V. K. Semenchenko on phase transitions of the second kind and on the theory of the thermodynamic stability of systems. D. S. Korzhinskii has applied to geological processes the concept of heterogeneous equilibria in open multiphase and multicomponent systems.

Thermodynamic functions for individual inorganic compounds, groups of compounds, solutions, and alloys have been investigated by many workers in connection with theoretical generalisations and practical problems (E. V. Britske, G. V. Kurdyumov, A. F. Kapustinskii, V. A. Sokolov, N. K. Voskresenskaya, A. I. Vol'skii, A. A. Zhukhovitskii, K. P. Mishchenko, M. M. Popov, K. G. Khomyakov, A. V. Rakovskii, S. M. Skuratov, A. M. Samarin, N. V. Ageev, S. A. Shchukarev).

Liquids and Solutions

Study of the properties of pure liquids and solutions is closely related both to thermodynamics and to aspects of the theory of the structure of matter. However, thermodynamic methods for describing the properties of solutions are the most important at present, because of inadequate development of a molecular—statistical theory of liquids.

The first systematic investigations of the miscibility of liquids were made by V. F. Alekseev during 1878–1884, and played an important role in establishing a thermodynamic theory of solutions. Alekseev also enunciated the "law of the rectilinear diameters" used to estimate the parameters of the critical points of two-phase systems. He visualised dissolution as resulting from two opposing tendencies—thermal motion of the molecules and "chemical" intermolecular interaction. In his general views he was an adherent rather of the physical theory of solutions, although he acknowledged its limited character.

D. I. Mendeleev was one of the authors of the "chemical" theory of solutions. He recognised the role of "physical" factors, but did not regard them as uniquely important in the theory of solutions, especially for solutions of finite concentration. The correctness of this general view has already been quite definitely confirmed in the unification of the general ideas and methods of the physical and chemical theories. In this connection an important role was played by the views of I. A. Kablukov, who regarded solvation as the main cause of the formation of ions in solution.

D. P. Konovalov worked on the thermodynamics of solutions. His study of the vapour pressure of various binary mixtures was crowned by the formulation of his well known laws. Konovalov's laws on the one hand provided a basis for a systematic thermodynamic analysis of the properties of solutions, and on the other hand are widely used in the practical rectification of liquids and in the theory of the distillation of liquid mixtures.

D. K. Chernov made the first investigations on solid solutions and phase diagrams. His "critical points", which have an important role in practical ferrous metallurgy, are actually transition temperatures of solid phases in the iron–carbon system.

Gaseous solutions have been studied. I. R. Krichevskii, P. E. Bol'shakov, and D. S. Tsiklis discovered the limited miscibility of gases in the case of the ammonia–nitrogen system. Similar properties have since been observed in several other systems.

N. S. Kurnakov's investigations on phase equilibria in solution are closely related to the theory of solutions. They led to the foundation of physicochemical analysis on the principles of continuity and congruence, later supplemented by the concept of singular points on phase diagrams. Physicochemical analysis not only was a method for the general description of phase diagrams but also acquired great practical value in the exploitation of salt deposits in the USSR.

Ya. I. Frenkel' was the first to attempt a consistent phenomenological theory of the liquid state based on the special character of molecular motion in a liquid. The movement of a given molecule is determined by the molecular field due to its environment and by its own kinetic energy. This motion is intermittent and is governed by the mean lifetime in temporary equilibrium positions. These ideas served as a basis for much subsequent work.

A more rigorous statistical theory of liquids and solutions, using the concept of correlative distribution functions of groups of particles, was elaborated by N. N. Bogolyubov. A statistically consistent method of calculating the thermodynamic properties of solutions of strong electrolytes, based on the method of correlation functions and variational derivatives, is widely used for solving stochastic problems. This method was developed further by I. Z. Fisher, who applied it in particular to solving the problem of the structure of liquids.

S. A. Shchukarev investigated the periodicity of the properties of chemical compounds in solutions, as well as aspects of chemical hydrology.

Thermodynamic methods of describing binary and multicomponent systems, by means of which possible types of phase equilibrium curves were established in heterogeneous multicomponent systems, were examined by A. V. Storonkin. A series of investigations of phase transitions in solutions of non-electrolytes at high pressures provided a better understanding of the relation between intermolecular interactions and thermodynamic properties (Krichevskii). Thermodynamic methods of calculating phase equilibria in liquid binary and multicomponent systems were evolved by V. B. Kogan for processes of azeotropic and extractive fractionation, from which technical schemes for the separation of mixtures were worked out. V. A. Mikhailov worked on thermodynamic processes of extraction. He suggested an extraction method for determining activity coefficients of electrolytes in aqueous solution.

V. K. Semenchenko demonstrated the effect of ion-pairs on the properties of electrolyte solutions, showed the physical pattern of this phenomenon, and gave its mathematical description. He introduced the concept of the generalised moment as a parameter representing a force constant (charge, dipole and quadrupole moments) per unit dimensions of the molecule. He based a general classification of solutions on a survey of the effective forces of interaction between particles. M. I. Shakhparonov investigated the structure of liquid systems with hydrogen bonds and thermal motion of the molecules.

A. I. Brodskii carried out series of experimental and theoretical investigations on strong electrolytes in non-aqueous media. A. N. Frumkin examined liquid solutions in terms of the energetics of solvation. K. B. Yatsimirskii considered regularities in the energies of formation of ions, together with aspects of proton affinity and ionic hydration.

The only quantitative theory of the dissociation of electrolytes and the theoretical principles of acid—base titration in non-aqueous media are due to N. A. Izmailov. Heats of dissolution in aqueous solutions of electrolytes (in contrast to non-aqueous solutions) become more strongly exothermic with rise in temperature, which indicates that the specific structure of water is a decisive factor in the energetics of the solutions. The idea of a limit of complete solvation has proved extremely useful in the discussion of salting out, acid catalysis, oxygen exchange between anions and water, and many other phenomena (A. M. Sukhotin, K. P. Mishchenko). The effect of the structure of water on the properties of solutions and its variation under the influence of ions have been examined by O. Ya. Samoilov.

Nuclear magnetic resonance, electron spin resonance, and non-resonant paramagnetic absorption have recently found wide application for investigating the structure of liquid solutions. A. I. Rivkind established that the relaxation of protons in solutions of paramagnetic salts takes place mainly in the solvation spheres of the paramagnetic particles, not in the bulk of the free solvent. Study of the relaxation of the solvent nuclei can be used as a method for examining the structure of paramagnetic solutions.

Magnetic resonance has been used to investigate the mobility of water molecules in the vicinity of ions and has confirmed the negative hydration of iodide and bromide ions. Negative and positive hydration of ions has been confirmed also by determining the translational diffusion coefficients of water in electrolyte solutions by the spin echo method (K. A. Valiev).

V. I. Danilov has used X-ray diffraction to investigate liquids and solutions. Analysis of the curves for scattering intensity reveals that liquids near the melting points are characterised by short-range order of the particles resembling their arrangement in the corresponding crystals.

Adsorption and Chromatography

The first work in Russia on adsorption was done as early as in 1785 by T. E. Lovits, who studied the adsorption of dyes on activated charcoal. Fundamental investigations on the adsorption of gases were made at the end of the nineteenth century and the beginning of the twentieth century. Classic studies in this field are those by A. A. Titov on the adsorption of gases on activated carbon and by N. A. Shilov on the dynamics of such adsorption.

During the First World War N. D. Zelinskii used the adsorptive power of carbon to produce a gas mask. The analytical possibilities of adsorption phenomena, and methods for separating mixtures based on differences in the adsorption of the components, were realised in 1903 by M. S. Tsvet. This worker used adsorbents to separate dyes and termed his method "chromatography". This method has found wide practical application only in our times, some fifty years after its creation.

The scope of work on adsorption became especially wide after the Bolshevik Revolution. Shilov and his pupils (S. A. Voskresenskii, L. K. Lepin', A. P. Ivanitskii, I. A. Tserevitinov) investigated the adsorption of solutes on carbon, and revealed the characteristic features of the adsorption of non-electrolytes and strong and weak electrolytes.

Soviet scientists have conducted a long series of investigations on the theory of adsorption phenomena. B. V. Il'in studied the role of intermolecular interactions in adsorption. A. N. Frumkin was the first to obtain an equation to the adsorption isotherm allowing for the mutual attraction of the molecules in the adsorbed layer. This equation was subsequently confirmed by more rigorous molecular–statistical calculation.

M. M. Dubinin evolved a theory that the space in pores became filled during adsorption, which enabled the adsorption isotherms of various vapours to be calculated from the known affinity coefficient and a characteristic curve obtained from the adsorption isotherm of one substance. Together with L. V. Radushkevich he established a relation between the form of the characteristic curve and the porosity of the carbon. The same methods have recently been used to study adsorption on zeolites. Methods have been worked out for obtaining many adsorbents of specified porosity. Dubinin's work on the dynamics of sorption gave rise to the chromatography of vapour mixtures.

A. V. Kiselev studied the adsorption of various classes of compounds on modified and unmodified silica gels, zeolites, and graphitised carbon black. Methods of adsorption, gas chromatography, and molecular spectroscopy were used in this work to investigate intermolecular interactions in general. Views were evolved on specific and non-specific adsorption, with the use of spectroscopy to study the former. Molecular–statistical calculations were employed to compute the main adsorption and gas-chromatographic characteristics of several hydrocarbons and other compounds on graphitised carbon black and on zeolites. A relation was found between the energy of adsorption and the properties of the sorbable molecules. Not only heats of adsorption but also heat capacities of various compounds in adsorbed layers were determined. The improvement of gas-chromatographic methods enabled hundreds of adsorbate–adsorbent systems to be investigated for extremely complicated organic and organoelementary compounds. Molecular liquid chromatography and adsorption from solutions were used to study the intermolecular interactions of simple organic molecules, polymers, biopolymers, and viruses.

In connection with the study of catalytic processes many theoretical and experimental investigations were made on the chemisorption of active gases on energetically non-uniform surfaces. The logarithmic adsorption isotherm first found experimentally (A. I. Shlygin, A. N. Frumkin) was explained theoretically both by the concept of energetic non-uniformity (L. D. Landau, Ya. B. Zel'dovich, S. Z. Roginskii) and by the action of intermolecular forces of repulsion (M. I. Temkin). Zel'dovich was able to show how the distribution function of heats of adsorption could be determined from the experimental equation for the adsorption isotherm, which gave rise to a long series of studies in this field (Roginskii, Temkin).

V. K. Semenchenko studied adsorption phenomena in metallic systems, and discovered several specific effects attributable to the high surface activity of individual components of the alloy. The effect of surface-active metals on the brittleness of metals and alloys was discovered by P. A. Rebinder, Yu. V. Goryunov, and E. D. Shchukin ("Rebinder effect").

K. V. Chmutov is investigating the separation of rare-earth metals, the role of complex formation, and the simulation and intensification of chromatographic processes. V. A. Malyusov has been concerned with the theoretical principles of separation processes (chromatography, fractionation, crystallisation).

G. M. Panchenkov is concerned with ion-exchange equilibria on zeolites and the thermodynamics of heterogeneous equilibria. A. A. Zhukhovitskii has used the theory of mass transfer to describe the dynamics of sorption. The principles of mass transfer and the problems of the automation and optimisation of chemical processes are being dealt with by V. V. Kafarov. Sorption in a fluidised bed has been investigated by D. G. Romankov, who has generalised the equations of sorption dynamics.

The work of E. V. Alekseevskii and his students is widely known in the field of non-carbon adsorbents. They have developed methods for the preparation of active metal oxides and have studied the recovery of various solvents. I. V. Grebenshchikov discovered siliceous adsorbents having a spongy structure–porous glasses.

The laws of the sorption of ions by activated charcoals and silica gels, the mechanism of the adsorption of various complex compounds, and the role of electrochemical factors in these phenomena were studied by D. N. Strazhesko and his coworkers.

Colloid Chemistry

Colloid chemistry began to develop as a physicochemical discipline in the second half of the nineteenth century.

Before that time, however, there were investigations which played a significant role in the establishment of colloid chemistry and its methods. These include the discovery of electrokinetic phenomena—electrophoresis and electro-osmosis (F. F. Reiss)—the first quantitative studies of the formation of jellies and gels (F. N. Shvedov), cryoscopic measurements of the effective molecular weights of various substances in colloidal solution (N. N. Lyubavin, A. N. Sabaneev), and work on the theory of capillarity (A. Yu. Davidov, I. S. Gromeka).

Modern ideas on the nature and properties of the colloidal state are due to P. A. Rebinder and his school (A. B. Taubman, V. I. Likhtman, E. D. Shchukin, et al.). Several fundamental principles of the physical chemistry of surface phenomena in disperse systems were established (evolution and stability of structures, control of their properties by the introduction of surface-active agents). These investigations provided a scientific basis for the application of flotation agents, stabilisers, detergents, demulsifiers, etc.

A. V. Dumanskii has revealed the role of complex formation in the production of colloidal particles, and of the bonding of water in the drying and denaturation of colloids. N. P. Peskov has examined the role of kinetics and state of aggregation in the stability of colloids as functions of their degree of dispersion and their kinetic and adsorption properties. Specific features of adsorption on swollen colloids have been studied by A. V. Rakovskii.

B. V. Deryagin investigated surface phenomena in terms of the action of surface forces. A quantitative theory of the coagulation of disperse systems by electrolytes was formulated that took into account the relative molecular attraction. Direct measurement of the forces acting between surfaces at distances of the order of a micrometre provided experimental verification of the present-day physical theory of long-range molecular action. Cross-linked colloidal systems have been investigated by M. P. Volarovich, A. A. Trapeznikov, K. F. Zhigach, G. V. Vinogradov, and others.

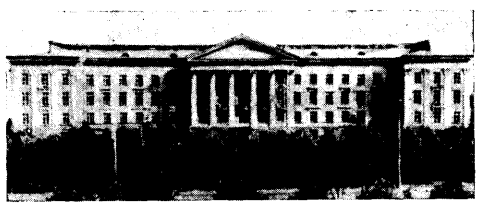

Figure 22. Zelinskii Institute of Organic Chemistry of the USSR Academy of Sciences.

Electrochemical methods are widely used in the study of colloids (A. I. Rabinovich, V. A. Kargin, N. I. Zhukov, and others). An effective method for purifying colloidal systems by high-voltage electrodialysis has been developed from this work. Electron microscopy has revealed the mechanism of the formation of colloidal particles.

The properties of solutions of polymers and the aging and syneresis of jellies have been investigated by S. M. Lipatov and S. A. Glikman. The colloidal properties of proteins were studied by A. G. Pasynskii, V. A. Pchelin.

Numerous applications of aerodisperse systems have been examined. An effective procedure for preventing the formation by radiation of mists of water droplets, based on blocking the hygroscopic condensation centres by adsorbed monolayers of higher alcohols, has been evaluated (B. V. Deryagin, P. S. Prokhorov, V. A. Fedoseev, N. N. Tunitskii, Ya. I. Kagan, A. G. Amelin, I. V. Petryanov-Sokolov).

Work has progressed on applications of colloid chemistry to the food industry (A. V. Dumanskii, N. F. Ermolenko) the rubber and synthetic rubber industry (B. A. Dogadkin, S. S. Voyutskii, A. I. Yurzhenko), dyes (N. P. Peskov, L. I. Belen'kii), cellulose (S. M. Lipatov), etc.

Trapeznikov has developed methods and apparatus for investigating the rheology of cross-linked systems and the mechanical properties of monolayers and soap films.

ORGANIC CHEMISTRY

Research on organic chemistry became widespread after the middle of the past century. Fundamental work was done by A. M. Butlerov—author of the theory of the structure of organic compounds—A. E. Favorskii, S. V. Lebedev, N. N. Zinin, N. D. Zelinskii, V. V. Markovnikov. The first institute of the Academy of Sciences to specialise in research on organic compounds was established at Moscow in 1934, and is now the Zelinskii Institute of Organic Chemistry [Fig. 22].

Modern organic chemistry, which already deals with millions of compounds, has been transformed, in the words of A. N. Nesmeyanov, into the structural architecture of molecules.

Theoretical Foundations of Organic Chemistry

A. M. Butlerov's theory of the chemical structure of organic compounds blazed a trail, in the "dense forest" (Wöhler's expression) of organic chemistry, to an understanding of the nature of quadrivalent carbon compounds. Butlerov noted the decisive importance of the interaction of atoms and groups in the molecule, explained the isomerism of the hydrocarbon residues, and was the first to direct attention to the possibility of isomeric conversion (cyanic acid, urea). In 1877 Butlerov pointed out that isodibutylene [2,4,4-trimethylpent-2-ene] was able to react according to two structural formulae or, in the modern idiom, it had dual reactivity. This was the first example of equilibrium isomerism (tautomerism), an understanding of which has been greatly assisted by the work of A. E. Favorskii and A. E. Porai-Koshits. Milestones on the road to a theory of tautomerism and dual reactivity were the discovery of a new type of dyad tautomerism in dialkyl phosphites (A. E. Arbuzov)

and investigation of the reactions of the tautomeric 2-aminopyridine and methylpyridine systems (A. E. Chichibabin). The concept of intramolecular valency tautomerism was first applied in dye chemistry.

Investigations showing the possibility of dual reactivity in the absence of tautomerism constituted a definite stage of development in theoretical organic chemistry. A. N. Nesmeyanov and M. I. Kabachnik drew a sharp distinction between equilibrium dynamic isomerism (tautomerism) and dual reactivity, and worked out a strict classification of various cases of the latter with and without migration of the reaction centre along the chain of conjugated

bonds. The influence of various factors was considered, and quantitative relations were established between the kinetic parameters of the reactions and the solvent, the temperature, and the nature of the reactants. Several general rules were formulated, the application of correlation equations was worked out, and new methods were found for investigating diverse tautomeric systems. It was shown that, in cases of strongly displaced equilibrium, the reaction product corresponding to the tautomer present in low concentration is formed from the other tautomer with transference of the reaction centre. The factors determining the conditions of such transfer have been examined.

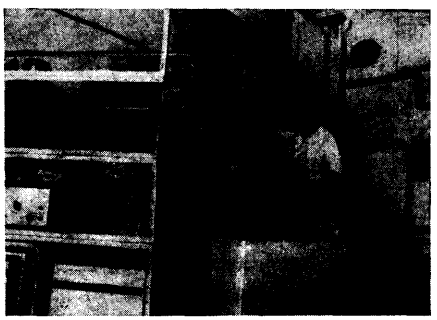

Figure 23. Radiation installation for investigating the mechanism of catalytic reactions during exposure to γ-rays (Institute of Organic Chemistry of the USSR Academy of Sciences).

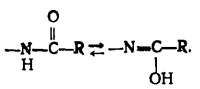
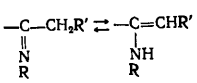
The tautomerism of many nitrogen-containing heterocyclic systems have been studied by infrared and ultraviolet spectroscopy, and the conditions of displacement of the tautomeric equilibrium have been revealed as functions of the nature of the substituent and the solvent (I. Ya. Postovskii, Yu. N. Sheinker, I. I. Grandberg). The structure of tautomeric and potentially tautomeric nitrogen-containing open-chain systems has been investigated. Thus the application of spectropolarimetry to optically active compounds has revealed amide–imidol tautomerism



It has been used to investigate the tautomeric equilibrium of the ketimide–enamine system



(V. M. Potapov, A. P. Terent'ev), previously detected from the infrared spectra (N. K. Kochetkov, Ya. V. Dombrovskii). M. M. Shemyakin discovered a variety of ring–chain tautomerism involving the amide group, and proposed an isotope method for discriminating between tautomerism and dual reactivity. This method was able to record, for example, the high rate of tautomerisation of diazoaminobenzene, which explains the specific behaviour of the triazen system.

S. S. Novikov published a series of papers on the tautomerism, structure, kinetics, and reaction mechanism of nitroalkanes and their salts. To elucidate the nature of keto–enol tautomerism use has been made of infrared and Raman spectroscopy (D. N. Shigorin, V. A. Mironov, Yu. A. Pentin), as well as high-resolution proton magnetic resonance spectroscopy (E. I. Fedin).

New types of tautomerism—metallotropy, acylotropy, and aroylotropy—have been discovered and studied in several organophosphorus compounds.

The investigation of *O*- and *C*-hetero-substituted derivatives of monocarbonyl and β-dicarbonyl compounds has revealed many examples of dual reactivity. Isomerisation has been observed with migration of the heteroatom (silicon, phosphorus, arsenic, etc.) from carbon to oxygen and from oxygen to carbon in the keto-enol. Heterotropic tautomerisations have been studied in acetone derivatives containing germanium, tin, and antimony (I. F. Lutsenko). It has thus been shown that the well known prototropic tautomeric equilibria represent a particular—though evidently most important—case of the general phenomenon of heterotropic equilibria.

The study of molecular rearrangements is of great value for understanding reaction mechanisms and in the search for paths for the controlled synthesis of compounds of definite structure. Various conversions resulting from molecular rearrangements have been investigated by E. E. Vagner, S. S. Nametkin, A. E. Arbuzov, A. E. Favorskii, N. Ya. Dem'yanov.

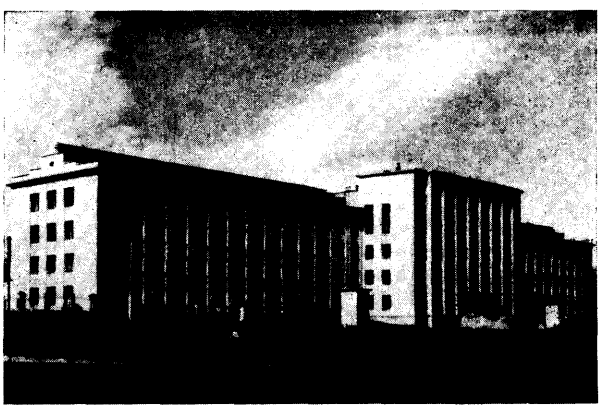


Figure 24. Arbuzov Institute of Organic and Physical Chemistry of the USSR Academy of Sciences.

B. A. Kazanskii's conversion of isopropenylcyclobutane into 1,2- and 3,3-dimethylcyclopentenes was an interesting example of the Vagner–Nametkin rearrangement. I. N. Nazarov extended the concepts of the Favorskii rearrangement to secondary and tertiary polyene alcohols. V. F. Kucherov and M. I. Ushakov discovered the rearrangement of furan derivatives involving multiple bonds. T. A. Favorskaya has found acetylene—allene and allene–diene rearrangements with acetylenic carbinols and halides. The reverse isomerisation (allene–acetylene) was described by A. A. Petrov. Favorskii's mechanism of the acyloin rearrangement of α-hydroxy-ketones was confirmed

by T. I. Temnikova. The rearrangement of α-hydroxy-aldehydes into hydroxy-ketones and α-glycols was studied by S. N. Danilov and E. D. Venus-Danilova. A mechanism was suggested for the aldehyde–ketone rearrangement by T. E. Zalesskaya. The Dem'yanov rearrangement was developed by N. I. Putokhin for the interconversion of five- and six-membered heterocycles. I. L. Knunyants found that polyfluorinated azides underwent a peculiar rearrangement into hydroxamic acids.

A. N. Nesmeyanov and R. Kh. Freidlina studied many examples of the rearrangement of radicals with 1,2-migration of chlorine and thiyl groups. The telomerisation and rearrangements of radicals in the reaction of ethylene with carboxylic acids and their derivatives were investigated, and used to develop an industrial method of producing α-branched monocarboxylic acids. The chemical behaviour of free radicals in the liquid phase was examined by G. A. Razuvaev. A study was made of chain reactions initiated by free radicals generated by irradiation or by the thermal decomposition of organometallic compounds.

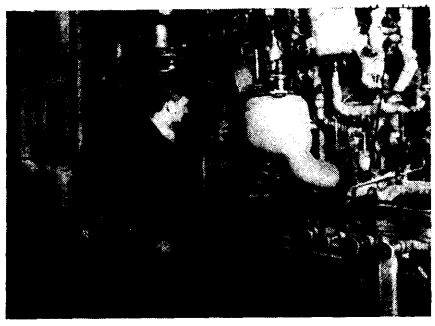

Figure 25. In the Technological Laboratory of the Institute of Organic Chemistry of the USSR Academy of Sciences.

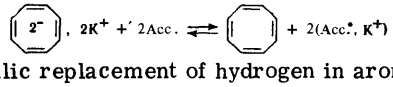
The mechanisms of various organic reactions are being investigated by modern physicochemical methods. A procedure has been worked out for studying electron-transfer reactions in homogeneous media. The cyclo-octatetraene dianion is used as electron-donor, and the extent of reaction is assessed from the yield of neutral cyclo-octatetraene:

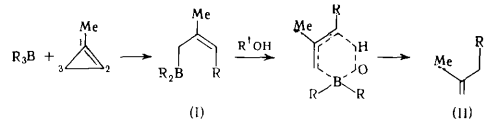


Nucleophilic replacement of hydrogen in aromatic compounds has been accomplished by abstraction of a hydride ion from anionic complexes. σ-Complexes of trinitrobenzene with acetone are oxidised by a wide range of oxidants—halogens, hypohalites, salts of metals of variable valency, peroxides, quinones, tropylium salts, etc.—to give high yields of trinitroacetone. Anionic σ-complexes of trinitrobenzene with compounds of transition metals have been obtained for the first time.

It has been suggested that double bonds can be selectively hydrogenated by silanes in acid solutions in the absence of a catalyst (ionic hydrogenation). The hydrogenation of thiophens under mild conditions gives high yields of the normally difficultly accessible thiophans, which are of great interest for their physiological (e.g. biotin) and antioxidant properties (D. N. Kursanov, Z. N. Parnes, V. N. Setkina, Z. V. Todres).

The mechanism of the oxidation of polymethylated aromatic compounds on reaction with electrophilic reagents in strongly acid media has been elucidated. The formation of intermediate species can be observed by proton magnetic resonance if the reactants are mixed at $-80°$ to $-100°$C and the system is gradually "unfrozen". Voluminous information has been obtained on the mechanisms of these reactions, and convenient methods have been found for obtaining a series of compounds of practical interest (e.g. *p*-methoxytetramethylphenol and its derivatives, which have been tried as stabilisers for certain types of polymer systems (V. A. Koptyug)).

Investigation of the action of organoboranes on the highly strained cyclopropene system showed that 1-methylcyclopropene reacts with trialkylboranes under mild conditions with cleavage of the cyclic $C_{(2)}-C_{(3)}$ single bond:



The resulting boranes of type (I) react with alcohols to give (after allylic rearrangement) the alk-1-ene (II). Conducting this reaction in alcohol will give in a single stage 60–90% yields of alkenes containing a terminal methylallyl group (B. A. Kazanskii, B. M. Mikhailov).

The mechanism of the spontaneous redox reaction of aldehydes in alkaline media (in Cannizzaro reaction) has been investigated. The kinetic data were analysed by means of the alkalinity function, which is a measure of the ability of the medium to ionise a molecule of a weak acid. This approach enabled M. I. Vinnik to establish the composition of the reactive complexes in the Cannizzaro reactions of *m*-nitrobenzaldehyde and *p*-methoxybenzaldehyde.

A systematic investigation is being made of the reactivity of complexes of transition metals with π- and σ-aromatic ligands in electrophilic and protophilic isotope exchanges of hydrogen (Kursanov).

The conformational state in solutions of simple model polyhalogenated alkanes, obtained by telomerisation and containing three- or four-spin molecular fragments, has been investigated. The complicated proton magnetic resonance spectra have been analysed by the use of double homonuclear and heteronuclear resonance, a computer, and the preparation of deuterated analogues. Methods that have been developed for evaluating the conformational composition and the fine structure of chiral molecules are required to solve stereochemical problems of the telomerisation stages—addition and substitution involving aliphatic radicals.

A. N. Nesmeyanov and A. E. Borisov investigated substitution at an alkene carbon atom in 2-chlorovinyl derivatives of various metals, and formulated the rule that geometrical configuration is conserved during substitution at an olefinic carbon. O. A. Reutov and I. P. Beletskaya studied the kinetics, mechanism, and stereochemistry of substitution at a saturated carbon atom. Their investigations led to the well known rule that configuration is preserved in S_E2 reactions.

The dissociative resonance capture of electrons by molecules of various types of organic compound has been investigated by the mass spectrometry of negative ions (S. R. Rafikov, V. I. Khvostenko, R. G. Kostyanovskii).

Many investigations have involved the use of correlation equations, a method which has been widely accepted in the study of reactivity and reaction mechanisms (V. A. Pal'm, Yu. A. Zhdanov, V. I. Minkin).

Quantum-chemical methods have been used to calculate the geometry and the electronic state of organic molecules. This work began with Ya. K. Syrkin and M. E. Dyatkina's application of the Hückel method to the properties of organic compounds having conjugated bonds. A. A. Bochvar calculated the properties of organic molecules with alternating bond lengths. A. B. Bolotin and Yu. A. Kruglyak started the use of rapid electronic computers for molecular calculations. Programs were set up for evaluating molecular integrals (Bolotin). An original density matrix method was elaborated, and successfully applied to the calculation of certain physical properties of conjugated organic compounds (M. M. Mestechkin). A consistent theory was worked out for the interaction of electrons in conjugated systems, and their spectroscopic properties were explained (A. A. Ovchinnikov). A model was suggested for the elementary act of substitution in certain simple hydrocarbons (M. V. Bazilevskii).

Chemistry of Hydrocarbons

A systematic study of the structure and properties of hydrocarbons dates from the mid-nineteenth century, when many investigations were made by A. M. Butlerov and his school. The principles of the chemistry of petroleum hydrocarbons developed in the work of V. V. Markovnikov and N. D. Zelinskii, who were the first to direct attention to the importance of synthesising model compounds. The most reliable results will usually be obtained by comparing petroleum hydrocarbons with known standard (model) substances.

Methods for the synthesis of hydrocarbon standards were developed by B. A. Kazanskii, A. F. Plate, A. L. Liberman, who prepared various substituted cycloalkanes, isolated their geometric isomers, and synthesised several new bicyclic systems. R. Ya. Levina obtained previously unknown homologues of cyclohexane, isoalkanes, alkenes, alkynes, and compounds containing a tertiary carbon atom. V. N. Ipat'ev suggested methods for the preparation of alkenes from readily available oxygen-containing compounds, based on the example of the catalytic dehydration of alcohols. S. V. Lebedev converted ethanol into butadiene, and the mechanism of this reaction was studied by Yu. A. Gorin. The mode of preparation of isoprene from acetone and acetylene discovered by A. E. Favorskii formed the basis of V. F. Kucherov's method for the continuous synthesis of pure isoprene suitable for stereospecific polymerisation. At the beginning of the 1940s N. D. Zelinskii and A. L. Klebanskii accomplished the synthesis of butenyne and later hexa-1,5-dien-3-yne and its homologues.

At the beginning of the present century Ipat'ev and Zelinskii found ways of interconverting hydrocarbons, and were the first to study the hydrogenation of the benzene ring in aromatic compounds. This discovery initiated the development of catalytic organic synthesis. Numerous catalysts, widely employed for the hydrogenation and dehydrogenation of organic compounds, were evolved, and their mode of action was studied (N. I. Shuikin, Kh. M. Minachev, A. V. Frost, L. Kh. Freidlin, D. V. Sokol'skii, Yu. S. Zal'kind, A. M. Rubinshtein, B. L. Moldavskii). The hydrogenation of substituted ethylenes on platinum and palladium catalysts, as well as the hydrogenation of conjugated, vinylacetylenic, and acetylenic hydrocarbons, was studied by S. V. Lebedev, G. G. Koblyanskii, and A. I. Yakubchik. The results of this work were generalised as "Lebedev's rules". The dependence of the rate and order of hydrogenation on the substituents and structure of the isomers and on the free energy of the reaction was investigated. During the 1920–1940s Zelinskii and his pupils carried out a series of studies of the catalytic dehydrogenation of hydrocarbons: they determined methods and conditions for the dehydrogenation of various cyclohexanes, the efficiency of diverse catalysts, and the mechanism and kinetics of the catalytic processes. The results formed the basis for A. A. Balandin's multiplet theory of catalysis. Zelinskii's catalysed dehydrogenation was transformed into the chief method for studying natural petroleum hydrocarbons and became the principal industrial method of obtaining aromatic hydrocarbons. N. D. Zelinskii and N. L. Glinka discovered the catalytic conversion of cyclohexene into cyclohexane and benzene. This reaction, termed "irreversible catalysis", became the subject of numerous investigations, during which it was found to be common to all unsaturated cyclic hydrocarbons.

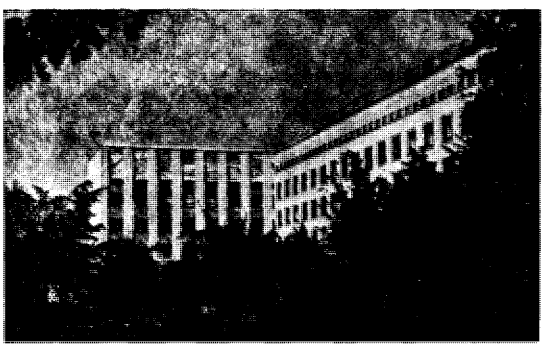


Figure 26. Institute of Organoelementary Compounds of the USSR Academy of Sciences.

Fresh results on the conversion of cyclohexane and cyclohexadiene on platinum and palladium have recently been obtained by V. M. Gryaznov and V. S. Smirnov, who show that the redistribution of hydrogen comprises a set of dehydrogenation and hydrogenation reactions. This discovery has been called membrane catalysis from the practical procedures adopted.

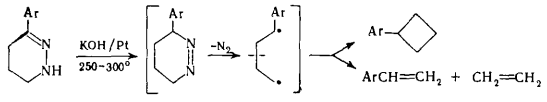
A simple transition from accessible alkanes to valuable aromatic hydrocarbons by means of dehydrogenating catalysts was achieved by three groups of investigators—B. L. Moldavskii and G. D. Kamusher, B. A. Kazanskii and A. F. Plate, and V. I. Karzhev—who studied various questions connected with the mechanism and the practical application of the dehydrogenation of alkanes. The hydrogenation of cyclopentanes—a new direct route to alkanes from the C_5 cycloalkanes widely distributed in petroleum—was discovered and studied, as well as isomeric changes in cyclic hydrocarbons.

Study of the alkylation of aromatic and aliphatic hydrocarbons, resulting from the need to synthesise high-octane components of motor fuel, was begun in the 1920s by

V. N. Ipat'ev, N. A. Orlov, and G. A. Razuvaev, after which it was developed simultaneously in many scientific establishments. Aspects of the synthesis of benzene homologues by means of various catalysts were considered by A. V. Topchiev, Yu. G. Mamedaliev, M. A. Dalin, Ya. M. Paushkin, and others. The catalytic alkylation of alkanes was studied in several investigations.

Work was done on the cracking of heavy petroleum products with the aim of obtaining motor fuel. Thermocatalytic conversions of individual hydrocarbons became one of the main subjects of investigation. M. G. Gonikberg, A. E. Gavrilova, and B. A. Kazanskii examined the effect of high pressure on the rate of thermal and catalytic cracking of alkanes. A. D. Stepukhovich suggested a reaction mechanism of cracking and a theory of the chain decomposition of alkanes. The kinetics, thermodynamics, and technology of the high-temperature processing of saturated hydrocarbon gases were studied systematically by A. M. Brodskii and K. P. Lavrovskii.

The chemistry of hydrocarbons having small rings is a comparatively young branch of organic chemistry. The publications of V. V. Markovnikov, G. G. Gustavson, N. D. Zelinskii, A. E. Favorskii, N. Ya. Dem'yanov, S. V. Lebedev, and N. M. Kizhner planned syntheses and described interesting isomerisations involving small rings, the mechanism of which has only now become clear. An explanation of the electronic structure of small rings was first given by M. E. Dyatkina and Ya. K. Syrkin. A series of studies on the mechanism of the formation of small rings from dibromides was made by Ya. M. Slobodin. Simple cyclic compounds and their isomerisation were investigated by Dem'yanov. The decomposition of pyrazolines, discovered by Kizhner, formed the basis for studies of various cyclopropanes (B. A. Kazanskii, M. Yu. Lukina, A. P. Meshcheryakov, L. V. Petrova). An interesting method of obtaining arylcyclobutanes was discovered in the 1960s by R. Ya. Levina, M. K. Kuz'min, Yu. S. Shabarov, who were studying the chemical and physical properties of arylcycloalkanes:



The stability of three- and four-membered rings was investigated (T. A. Favorskaya), as well as the dehydration and isomerisation of cycloalkylmethanols (Freidlin). The chemistry of small rings has been developed by I. A. D'yakonov, a pupil of Favorskii. This was one of the first researches on the use of carbenes for the synthesis of cyclopropane derivatives. A series of studies was made on the properties, mechanism of catalytic reactions, and spectral characteristics of three-membered rings with unsaturated and aryl substituents, together with the reactivity of cyclopropanes and halogenocyclopropanes.

The first investigations on the chemistry of acetylenic and conjugated systems were made by Favorskii and his students, who established methods of interconversion among acetylenes, allenes, and diene hydrocarbons, ways of passing from acetylenic compounds to terpenes, mechanisms of polymerisation, and various reactions of acetylenic hydrocarbons. This work opened up new fields of organic chemistry, in particular the chemistry of ethynylvinylmethanols (I. N. Nazarov, I. V. Torgov), butenyne (A. L. Klebanskii, A. A. Petrov, T. A. Favorskaya), and butadiyne (Yu. S. Zal'kind, A. D. Petrov, M. F. Shostakovskii). Research on the chemistry of acetylenic and conjugated compounds has immense value for the development of theoretical organic chemistry. Furthermore, these investigations have made available several new classes of unsaturated compounds which are important for the manufacture of synthetic materials.

The chemistry of terpene hydrocarbons has developed in our country by syntheses and studies of the structure and reactions of terpenes, investigations of the composition of native wood-chemical products such as essential oils, turpentines, and vegetable resins, as well as by industrial exploitation of the results. The chemistry of terpene hydrocarbons was studied by A. M. Butlerov, F. R. Vreden, F. M. Flavitskii, E. E. Vagner, L. A. Chugaev, and developed during the Soviet period by V. E. Tishchenko, A. E. Arbuzov, S. S. Nametkin, N. Ya. Dem'yanov, G. V. Pigulevskii, I. I. Bardyshev, V. N. Belov, V. I. Isagulyants, L. Ya. Bryusova, and many other investigators.

The oxidation, halogenation, and nitration of hydrocarbons were investigated because of the requirement by industrial developments to obtain valuable chemical raw material based on hydrocarbons of petroleum origin. The oxidation of organic compounds was studied by N. I. Chernozhukov, K. I. Ivanov, A. N. Bashkirov, V. V. Kamzolkin, V. K. Tsyskovskii, and many others. Researches on oxidising processes became especially interesting in connection with the study of their radical–chain mechanism, work which has been surveyed in the Physical Chemistry Section. Investigation of the halogenation of hydrocarbons was begun by V. V. Markovnikov and continued by A. V. Topchiev, B. A. Krentsel, N. I. Shuikin, who made many innovations both in the development of theoretical ideas in organic chemistry and in improving the technology of organic synthesis. Study of the nitration of hydrocarbons led to A. I. Titov's theoretical views, which are widely applied at the present time.

Aromatic and Heterocyclic Compounds

Aromatic compounds were already under investigation at the beginning of the nineteenth century. A. A. Voskresenskii discovered benzoquinone in 1838, and N. N. Zinin the reduction of aromatic nitro-compounds in 1842. Much work was done on the synthesis and various reactions of aromatic compounds (N. Ya. Dem'yanov, N. D. Zelinskii, N. M. Kizhner, A. E. Chichibabin, P. P. Alekseev, M. G. Kucherov), the nitration, chlorination, and sulphonation of benzene derivatives (N. N. Sokolov, F. F. Beil'shtein [Beilstein]), and the chemistry and technology of anthraquinone (M. A. Il'inskii).

Development of the chemistry of aromatic compounds during the Soviet period has promoted the establishment of a native industry of organic synthesis.

During the 1930s the mechanism of electrophilic substitution in the benzene ring was elucidated, and the dependence of sulphonation on various factors (concentration of sulphuric acid, temperature, presence of impurities) was determined (E. A. Shilov, V. A. Izmail'skii, A. M. Lukin, B. P. Fedorov, I. S. Ioffe). A kinetic study was made of the sulphonation of benzenes, the composition of the products was determined, and methods for the analysis of isomeric sulphonic acids were worked out (A. A. Spryskov). Study of the sulphonation of aromatic compounds occupied an important position in the work of N. N. Vorozhtsov, who investigated the sulphonation of naphthalene and the nature of its sulphonated derivatives, together with the effect of various catalysts on the reaction. Industrial methods were developed for the sulphonation of 2-naphthol (I. I. Vorontsov) and 2-chloronaphthalene (N. N. Vorozhtsov

Jr), as well as an effective method for sulphonating benzene in the vapour phase (R. K. Eikhman, M. I. Bogdanov, V. N. Ufimtsev).

The nitration of aromatic compounds began to be studied in the 1920s, when A. V. Kartashev detected the formation of nitrosophenols when phenol was treated with nitric acid. A. I. Titov carried out his classical work on the theory of nitration, and his suggested mechanisms and views on the nature of the nitrating agents became generally accepted. Many researches were devoted to a comprehensive study of the nitration of various aromatic molecules. The effect of boron trifluoride on the orientation of the nitro-group was determined, and a study made of the steric effect of nuclear substituents on the direction of reaction and the proportions of isomeric nitro-derivatives. Novel methods were worked out for obtaining aromatic nitro-compounds—by the batch and continuous nitration of ethylbenzene with a nitrating mixture, and simple methods for preparing *o*- and *p*-nitrobiphenyl, for obtaining chlorofluoronitrobenzenes, and for the simultaneous introduction of an iodine atom and a nitro-group into *p*-polyphenyl compounds. The nitration of anthraquinones, phenanthrene, acenaphthenes and fluorene, carbazole, dibenzopyrenes, and onium compounds has been investigated.

Vorozhtsov studied the effect of the nature of the catalyst on the kinetics of the chlorination of benzene, explained the mechanism of the catalytic action of iron(II) chloride, and worked out a continuous method of multiple chlorination. The kinetics and the mechanism of the halogenation of aromatic compounds in aqueous medium were examined by Shilov, who proposed an activity sequence of halogenating agents. He determined kinetic isotope effects in the halogenation of aromatic amines and amino- and hydroxy-sulphonic acids. The bromination of sterically hindered phenols was studied by V. V. Ershov and A. A. Volod'kin. The halogenation of more complex aromatic compounds—biphenyl, naphthalene, anthracene, anthraquinones, naphthacene, etc.—was investigated. Several new halogenating agents were suggested, e.g. *N*-chloroamides, *N*-chlorodiethylamine, *N*-bromophthalimide, and dioxan dibromide.

Considerable attention was paid to elucidating the mechanism of the alkylation of aromatic compounds in the presence of aluminium halides, in particular the chloride, whose first use in organic synthesis dates from G. G. Gustavson. The reactivity of alkylating agents towards aromatic hydrocarbons was studied, and schemes suitable for industrial use were proposed for the alkylation of benzenes by alkenes in the presence of aluminium chloride (N. N. Lebedev) and of sulphuric acid (Yu. G. Mamedaliev, M. A. Dalin).

During the 1920s V. M. Rodionov and V. K. Matveev discovered a new method for obtaining aromatic diazo-compounds from phenols and nitrous acid in a mineral medium, and this found industrial application. Azo-coupling, which with diazotisation is the principal reaction in the synthesis of azo-dyes, was studied in detail (A. E. Porai-Koshits).

Nucleophilic substitutions in the aromatic series were studied by A. N. Engel'gardt and P. A. Lachinov, N. N. Vorozhtsov Jr, D. V. Tishchenko, L. Kh. Freidlin, A. I. Kiprianov, E. Yu. Orlov, S. S. Gitis, B. I. Stepanov.

In the mid-1930s P. P. Shorygin and A. V. Topchiev began a systematic study of radical substitution in aromatic compounds. The mechanism and the chief laws of homolytic arylation were established by A. N. Nesmeyanov, Kh. S. Bagdasar'yan. Radical arylation by organometallic compounds was studied by G. A. Razuvaev. Many data on isomerisation in the aromatic series were summarised by V. A. Koptyug.

The chemistry of non-benzenoid aromatic systems has been vigorously developed during the past decades. Diphenylcyclopropenone, the cyclopentadienyl anion, cyclopentodienylides, and the tropylium and ditropylium cations have been investigated (D. N. Kursanov, M. E. Vol'pin, Yu. D. Koreshkov, Z. N. Parnes, I. S. Akhrem). Dipole moments have been measured (Ya. K. Syrkin, A. N. Shidlovskaya), and calculations made on the π-electron systems of certain compounds by the molecular orbital method (A. A. Bochvar).

The first investigations of heterocyclic compounds were made by Chichibabin, and their chemistry was developed by Rodionov's syntheses from β-amino-acids, A. I. Kiprianov and I. I. Levkoev's work on cyanine dyes, investigations of β-lactams and azalactones by I. L. Knunyants, studies by M. M. Shemyakin and V. K. Antonov on oxacyclic compounds, M. G. Voronkov on the chemistry of atran systems, B. A. Arbuzov on the diene synthesis of heterocyclic compounds, M. V. Rubtsov on azabicyclic compounds, and by many others. An original method of synthesising heterocyclic systems of diverse structure from substituted 2-chlorovinyl ketones was described by A. N. Nesmeyanov and N. K. Kochetkov. A general method for obtaining five-membered heterocycles from acetylenic α-oxides was worked out by F. Ya. Perveev.

A series of researches were made on furan derivatives. The reactions of chloromethylfurans, the preparation of nitrogen-containing heterocycles including a furan ring, diene synthesis and substitutive additions, and the reactivity of the furan ring were investigated by Yu. K. Yur'ev, K. Yu. Novitskii, N. S. Zefirov. Interconversion of five-membered heterocycles under conditions of vapour-phase catalysis by aluminium oxide was discovered to be a general reaction. Difficultly accessible 3-substituted furans were obtained, and Ya. L. Gol'dfarb elaborated a method for preparing ketones by acylating furan. A group of researches on the preparation, reactions, and practical application of furan derivatives is being conducted under the direction of S. A. Giller. Methods have been worked out for obtaining various functional derivatives of furan, and their pharmacological activity has been examined (A. L. Mndzhoyan). New methods for preparing furan derivatives —by sulphonation with pyridine—sulphur trioxide, formation of benzofurans from quinones, and production of amines of the furan series, whose oxidation yields amino-acids, some of which may be optically active—were proposed by A. P. Terent'ev. The hydrogenation and hydrogenolysis of furan compounds, as well as thermal and catalytic conversions of dihydrofurans, were studied by N. I. Shuikin.

New methods have been elaborated for the synthesis of pyrones, and their reactions have been studied (R. Ya. Levina, N. P. Shusherina, L. I. Zakharkin). Pyrylium salts, fused with a furan or a thiophen ring, have been investigated (G. N. Dorofeenko, Yu. A. Zhdanov).

The alkylation and acylation of thiophen in the presence of tin(IV) chloride has become generally accepted. A comparative study has been made of the direct metallation of the thiophen, furan, and benzene rings. A simple and effective method has been found for obtaining sulphides and thiols of the thiophen series, together with ways of preparing various functional derivatives.

Knunyants prepared propiothialactones, in which a new type of sulphur-containing four-membered ring has been formed. He also worked out original methods for alkylating 2-aminopyridine, as well as the principles for the industrial

production of quinacrine hydrochloride. N. N. Suvorov synthesised indol-3'-ylbutyric acid and found a new method of obtaining serotonin.

A. N. Kost investigated various nitrogen-containing heterocycles. Extensive investigations of diazaindenes and quinuclidines were made by L. N. Yakhontov in the search for physiologically active compounds. The chemistry of azines and azoles containing another heterocyclic atom (quinazolines, quinoxalines, phenoxazines, acridines, tetrazoles, benzimidazoles, etc.) is being investigated. New reactions non-activated heterocyclic substrates have been detected as well as the dealkylation of sterically hindered tertiary arylamines. The effects of a heterocycle and of other substituents on the amine–imine tautomerism and the conformation of formazans have been established (I. Ya. Postovskii).

Discovery of a new reaction of chlorinated aromatic and heterocyclic derivatives with hydrogen sulphide has been used to work out methods, suitable for industry, of obtaining aromatic and heterocyclic thiols and sulphides (M. G. Voronkov, A. S. Nakhmanovich, E. P. Deryagina). Aromatic and heterocyclic compounds and their fluorinated derivatives react with polyfluoroalkenes to give polyfluorobenzocycloalkenes (V. P. Mamaev).

The investigations of various classes of heterocyclic compounds have largely contributed to the development of theoretical ideas in organic chemistry and helped to solve the problems of producing novel compounds of practical value—pharmacological preparations, dyes, and intermediates for the synthesis of organic fine chemicals.

Chemistry of Organoelementary Compounds

A. N. Nesmeyanov defined organoelementary chemistry as organic chemistry extended to all elements. It has thus become an immense boundary region between organic and inorganic chemistry. Nesmeyanov notes that such boundary regions provide especially favourable soil for "growth points" of science.

Study of the first organometallic compounds was begun in the 1860s by A. M. Butlerov, A. M. Zaitsev, and E. Frankland with the development of organozinc synthesis. After Grignard had shown in 1900 the advantages of replacing zinc by magnesium, A. E. Arbuzov, N. D. Zelinskii, Zh. I. Iotsich, L. A. Chugaev, V. V. Chelintsev, V. S. Yavorskii, A. E. Chichibabin, and others conducted broad theoretical, experimental, and practical investigations on organomagnesium synthesis. In 1920 V. N. Krestinskii prepared isocrotylmagnesium bromide, and thus filled the gap in the sequence of magnesium derivatives differing in the degree of saturation of the carbon atom adjacent to the metal:

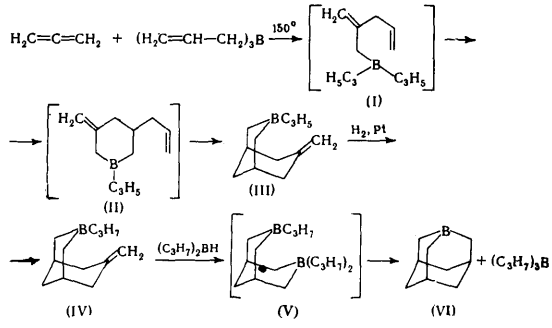
CH_3—MgX, RCH_2—MgX (Grignard) $R_2C{=}CH$—MgX (Krestinskii) $RC{\equiv}C$—MgX (Iotsich)

Theoretical work has developed since the 1920s, and questions have been posed for the first time on the structure and chemical nature of Grignard reagents (N. V. Kondyrev, A. P. Terent'ev) and on the structure of the intermediate products and the mechanism of organomagnesium reactions (A. E. Arbuzov, B. A. Arbuzov, M. I. Konovalov, A. D. Petrov, T. I. Temnikova, A. N. Pudovik). Universal methods of quantitative analysis using organic derivatives of magnesium were elaborated by L. A. Chugaev and F. V. Tserevitinov.

A new field—the chemistry of organic compounds of the alkali metals—grew from P. P. Shorygin's discovery of the formation of sodium alkyls. Methods of preparation, structure, and reactions of organolithium compounds have been studied systematically by K. A. Kocheshkov. This worker elaborated methods for obtaining organocalcium compounds, which are of interest as components of catalysts for the polymerisation of unsaturated hydrocarbons and oxiran derivatives.

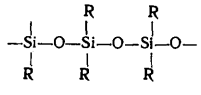
Nesmeyanov's discovery in 1929 of the diazo-method for preparing organomercury compounds started development of the chemistry of organic compounds of heavy metals (G. A. Razuvaev, M. M. Koton, O. A. Reutov, E. A. Shilov, I. P. Beletskaya, I. F. Lutsenko, Yu. K. Yur'ev, N. S. Zefirov).

Investigation of organic compounds of tervalent elements began with the preparation of aluminium and thallium derivatives by Nesmeyanov and Kocheshkov during the 1930s. The organic chemistry of aluminium and especially of boron has recently been intensively developed. New methods of synthesis and various reactions of organoboron compounds are being investigated by B. M. Mikhailov, L. I. Zakharkin, and O. Yu. Okhlobystin. Carborane derivatives are especially interesting as a promising basis for obtaining thermostable polymers. Spontaneous allylic rearrangement has been discovered in allylboron compounds. Condensation of acetylenic and allenic compounds with allylboranes is a new and effective method for the stereospecific synthesis of alicyclic compounds. The unique compound 1-boradamantane has been obtained, in which the boron atom is tetrahedral, in contrast to the usual boron trialkyls:



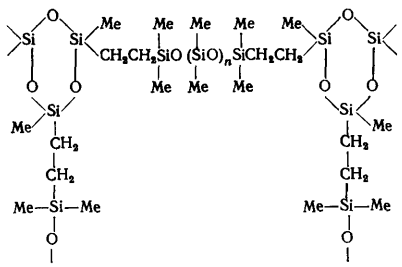
1-Boradamantane possesses several specific chemical and physical properties, in particular high complexing power with respect to various ligands, even those towards which boron trialkyls are inert. A new class of boron hydrides has been obtained—the borines—in which BH_3 is a functional group attached to a metal cation (V. S. Shpak).

The chemistry of silicon compounds had already attracted the attention of D. I. Mendeleev and A. M. Butlerov, the first to note the polymeric character of silicic acid. The ability to form polymers was a distinguishing feature of organosilicon compounds also. During the 1930s K. A. Andrianov first synthesised organosilicon polymers of the type

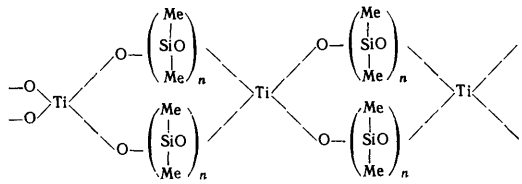


The interesting physicochemical properties of polyorganosiloxanes gave rise to numerous investigations in this

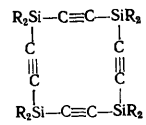
field. Hundreds of promising new compounds were obtained, e.g.



Recently efforts have been directed mainly at developing the preparation of new monomers of interest for obtaining polymers having specified properties—polysiloxanes of spirocyclic, spiral-staircase, and spirolinear structure, carbosilazanes, substituted vinylsilanes, organosilicon compounds containing other heteroatoms, e.g.

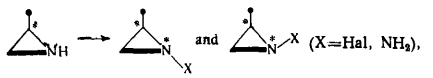


acetylenic silicon derivatives of the type



etc. The electronic interactions and special features of the silicon–heteroatom bond are being investigated, as well as the mechanisms and the kinetics of the reactions of organosilicon compounds and their biological activity (M. G. Voronkov). The chemistry of organic derivatives of the silicon analogues—germanium, tin, lead—is being explored.

Derivatives of Group V elements are being actively investigated. The long-standing stereochemical problem of synthesising systems with a non-inverting tervalent nitrogen pyramid has been solved in principle by the isolation of individual diastereomers of 2-substituted *N*-halogeno- and *N*-amino-aziridines (R. G. Kostyanovskii, Z. E. Samoilova, S. A. Giller):



Nitrogen in such compounds is comparable with the phosphorus atom in configurational stability.

The foundations of the chemistry of organic derivatives of phosphorus were laid by A. E. Arbuzov, who detected the rearrangement

This became one of the chief methods for obtaining some classes of organophosphorus compounds. A new class of aromatic compounds containing a two-coordinated phosphorus atom has been discovered—the phosphadiazoles (A. I. Shvetsov-Shilovskii).

The biological activity of organophosphorus compounds is being studied, many of them finding application as medicinals and insecticides. The possibility of practical use as lubricants, plasticisers, and non-flammable polymers stimulates fresh synthetic exploration in this extremely important field of chemical science and practice.

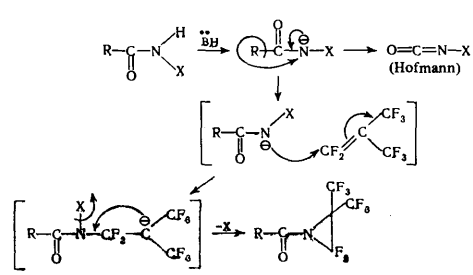
The complex-forming properties of organophosphorus molecules are of great value, in particular enabling lead and beryllium to be removed from organisms. New principles have now been developed for enhancing the selectivity of organophosphorus complexing agents towards metal cations. Introduction into the molecule of fragments that fix sterically the orientation of donor atoms and the size of chelate rings yields highly efficient and selective new extractants, several of which are produced industrially and used in technical processes. Conditions have been worked out for introducing methylphosphonic groups at the nitrogen in triethylenetetramine and polyethylenimine to yield polymeric complexing agents.

Organophosphorus ion-exchange resins have been synthesised. Methods are being sought for the directed synthesis of insecticides—derivatives of dithioic acids of phosphorus with peptide residues in the side-chain—which are relatively non-toxic to humans and animals, and do not leave toxic residues in the environment. New medicinals (diphenizide, hexaphosphamide, etc.) are being produced and introduced into clinical practice.

A young but vigorously developing field is the chemistry of organofluorine compounds, whose growth is due mainly to the work of I. L. Knunyants and his school (B. L. Dyatkin, L. S. German, Yu. A. Cheburkov, N. P. Gambaryan), N. N. Vorozhtsov, L. M. Yagupol'skii, A. Ya. Yakubovich, A. V. Fokin. In 1868 A. P. Borodin obtained the first fluorinated organic compound—benzoyl fluoride:

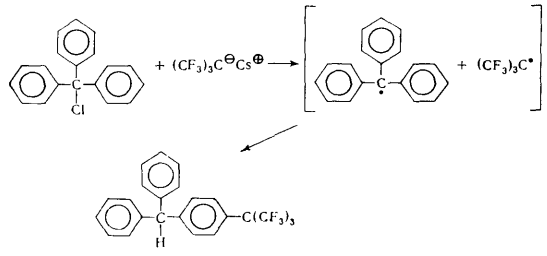
One of the chief general methods for introducing fluorine into an organic molecule—replacing a chlorine atom by fluorine by the action of a metal fluoride—was thus discovered. Fluorinated derivatives have now been obtained for almost all classes of organic compounds. Investigation of the structure, properties, and reactions of fluorinated organic compounds has introduced much that is new, often unexpected, into theoretical ideas in chemistry, and has had a widespread effect in experimental chemistry. Study of the nature of the π-bond in fluorinated alkenes, ketones, ketens, allenes, heterocumulenes, and aromatic compounds has led to the discovery of several unusual new rearrangements and reactions and to the synthesis of new types of compounds of practical importance.

The electronically amphoteric character of the double bond in fluoroalkenes is especially interesting, being responsible in several cases for reversal of the mechanism of addition of electrophilic and nucleophilic reactants. For example, the ability of fluoroalkenes to form anions under the influence of nucleophiles is used to intercept the hypothetical *N*-anion formed in the Hogmann, Curtius, etc. reactions:



The exceptionally strong basicity of the fluoride anion (e.g. in potassium and tetraethylammonium fluorides) in aprotic media has been observed for the first time. It greatly extends the opportunities for preparing various types of fluorinated organic compounds.

Great interest is taken in the chemistry of perfluorocarbanions, for whose study modern physicochemical methods are widely used. Thus the mechanism of the reaction of triphenylmethyl chloride with perfluoro-2-methylpropene in the presence of caesium fluoride, involving migration of the reaction centre, has been established from the variation in the concentration of the intermediate trityl radical measured by electron spin resonance:



Several new methods have been worked out for obtaining fluoro-organic compounds—concerted electrophilic addition to unsaturated systems in strong acids, anodic fluorination of aromatic compounds in organic solvents, and an industrial process for the direct fluorination of uracil to obtain 5-fluorouracil, an anti-tumour preparation —and hexafluorobenzene can be obtained from the more readily available hexachlorobenzene and potassium fluoride. A method has also been found for obtaining partly and completely fluorinated aromatic and heterocyclic compounds.

Processes have been developed for preparing compounds of types $Ar-ElF_n$ and $Ar-ElR_n^f$ (where El = Si, Ge, N, P, O, S, Se, I, Hg). In particular, compounds containing a pentacovalent iodine atom—aryl tetrafluoriodides—have been obtained for the first time.

The discovery and study of carbonyls of the metals—iron, nickel, and cobalt—preceded development of the chemistry of organic derivatives of transition metals. The discovery of ferrocene (dicyclopentadienyliron) began a new stage in organometallic chemistry—the study of sandwich compounds—for which the usual concepts of valency and coordination number have disappeared: here the atom of the transition metal is located between two rings, to which it is attached by a π-bond (Nesmeyanov and Razuvaev schools). Within a comparatively short time a detailed study of the reactivity of ferrocene had indicated its superaromatic character. Numerous substitutions in the cyclopentadienyl ring and reactions involving the iron atom gave rise to new classes of ferrocene compounds. Polymers based on ferrocene derivatives were obtained, including those containing silicon (A. D. Petrov, N. S. Nametkin, V. V. Korshak).

Physicochemical investigations of metallocenes were made by A. I. Kitaigorodskii, Yu. N. Sheinker, L. A. Kazitsyna, and the electronic structures of ferrocene and several other sandwich compounds were calculated by M. E. Dyatkina and E. M. Shustorovich. Cyclopentadienyl and cyclopentadienyl-carbonyl derivatives of manganese, rhenium, titanium, and other transition elements have been investigated. The chemistry of olefinic and acetylenic π-complexes of transition metals is represented by the work of Ya. K. Syrkin, B. A. Dolgoplosk, and I. I. Moiseev.

Complexes of transition metals find wide application in catalysis. Thus the compounds of graphite with low-valency palladium first obtained by M. E. Vol'pin proved to be promising catalysts for several organic reactions. A catalyst has been developed from allyl, acetate, and acetylacetonate complexes of palladium for chemical copper-plating in the manufacture of a self-cleaning foliated resin-impregnated laminated cloth for the printed circuits of high-speed electronic computers. Compounds of transition metals are used as catalysts for several novel reactions (synthesis of ammonia under mild conditions, synthesis of aromatic amines from hydrocarbons and molecular nitrogen, etc.). Lamellar compounds of graphite with several Group VIII transition metals, which are effective catalysts for the fixation of nitrogen and for the hydrogenation and isomerisation of alkenes and alkynes, have been obtained for the first time.

At the present time the chemistry of organoelementary compounds is developing along the lines of the synthesis of new compounds and fundamental research on their structure and reactivity as well as the mechanisms and the kinetics of the reactions.

Theoretical concepts are being shaped in the chemistry of organoelementary compounds. Thus the properties of organic compounds of Group V elements can be understood and predicted from the determination and calculation of the inversion barriers of the elements. In particular, a pyramidal configuration of nitrogen, phosphorus, and arsenic has been demonstrated in ethylenamines, acylphosphines, and acylarsines respectively, which disproves the long held view that they are completely analogous to ordinary amides (Kostyanovskii). During recent years a single system has been constructed for the $\sigma-\rho$ analysis of organophosphorus compounds, the electronic effects of substituents containing Groups IV–VI elements in the three-coordinated state have been studied, and quantum-chemical calculations have been made of certain specific molecules. A rebound mechanism has been suggested for the electrophilic isotope exchange of hydrogen in π-aromatic complexes of chromium and manganese. The structure of new types of compounds has been established by X-ray diffraction. Examination of the e.s.r. spectra of a number of organophosphorus radical-anions has proved unambiguously that the unpaired electron is delocalised over the substituents, and hence that the phosphorus atom is not an "insulating bridge" in the chain of conjugation (A. V. Il'yasov, Ya. A. Levin, I. D. Morozova).

E. I. Fedin developed research on the nuclear magnetic resonance spectra of organoelementary compounds under pulsed conditions (Fourier spectroscopy), which enabled spectra to be recorded not only at extremely low concentrations in solution but also for isotopes having a very small natural content (carbon-13, nitrogen-15, etc.) (Fig. 27). This produced a sharp increase in the information content of n.m.r. measurements in structural investigations and in study of the electronic characteristics of substituents. The SCAD phenomenon—statistically controlled association-complex diastereomerism—has been detected by Fourier $^{31}P-\{^1H\}$ n.m.r. spectroscopy. Thus a solution of unequal concentrations of enantiomeric phosphorus-containing depsipeptides exhibited a doublet of the phosphorus-31 signal with an intensity ratio equal to the concentration ratio of the enantiomers (Fig. 28) (M. I. Kabachnik, T. A. Mastryukova, E. I. Fedin). This unexpected phenomenon opens up, in particular, prospects of investigating the detailed causes of stereospecificity in the action of biologically active substances.

Bio-organic Chemistry

Research on peptides and proteins began with the work of N. D. Zelinskii and his school. Effective methods were found for resolving and analysing such materials, while α-amino acids were obtained by the amination of halogenated acids and by the cyanohydrin reaction. The further development of the chemistry of proteins and peptides in the USSR, as throughout the world, has become increasingly closely interwoven with physicochemical and biochemical investigations.

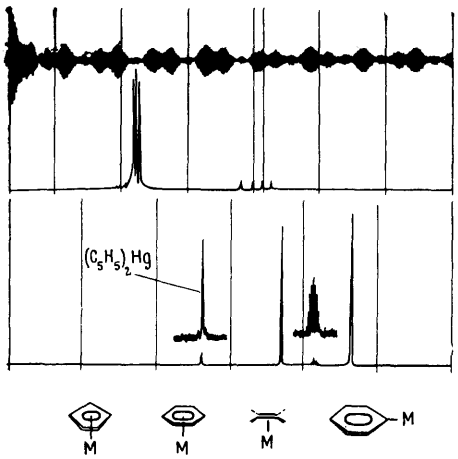


Figure 27. Fourier spectrum of ^{13}C n.m.r. with the natural content (1.1%) of the isotope.

Work on the chemical characteristics of complicated biopolymers has been directed at establishing the structure of glycoproteins (N. K. Kochetkov, V. A. Derevitskaya, E. D. Kaverzneva) and the primary structure of pepsin (V. M. Stepanov) as well as studying the biological role of enzymes (A. E. Braunshtein, V. N. Orekhovich, S. R. Mardashev, V. A. Belitser). Research is being undertaken with the aim of establishing effective new methods for analysing the primary structure of proteins and the sequence of amino-acid residues in peptides. The application of structural mass spectrometry (M. M. Shemyakin, Yu. A. Ovchinnikov, N. S. Vul'fson) has proved especially promising in this respect. Chromatographic procedures have been elaborated for separating and analysing complicated mixtures of amino-acids and methods for determining their optical purity (V. M. Belikov).

An important achievement has been the industrial production of the difficultly accessible hormone, insulin. A combined method has been worked out for separating the pituitary hormones (A. S. Khokhlov, F. Yu. Ryshka), and a technical synthesis of oxytocin and angiotensin (S. A. Giller, G. I. Chipen).

Methodical investigations are being made on the synthesis of amino-acids and peptides. A rapid new method has been suggested for obtaining polypeptides in aqueous medium without the isolation of intermediate products (D. G. Knorre), and also a new method of synthesising peptides on a polymeric carrier in solution (L. A. Shchukina). Priority is due to Soviet investigators in developing the chemistry of biologically important atypical peptides, in particular depsipeptides (M. M. Shemyakin, Yu. A. Ovchinnikov, E. I. Vinogradova). A new method has been discovered for synthesising linear and cyclic peptides and depsipeptides by the insertion of amino- and hydroxy-acyl groups into peptide systems (V. K. Antonov, A. M. Shkrob). The accumulation of empirical data deepens our understanding of the relation between the chemical structure and the biological character of peptides, which makes possible the directed synthesis of compounds having specified properties. During recent years extensive use has been made of physical methods in investigating polypeptides and proteins. Conformational analysis owes its progress to nuclear magnetic resonance (V. F. Bystrov), infrared spectroscopy (Yu. N. Chirgadze), optical rotatory dispersion, (V. T. Ivanov), X-ray diffraction (I. S. Andreeva, B. K. Vainshtein), and the combination of physicochemical methods with theoretical calculations (M. V. Vol'kenshtein, O. B. Ptitsyn).

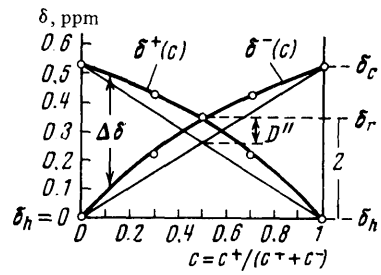

Figure 28. Dependence of ^{31}P chemical shifts (δ^+ and δ^-) of (+)- and (−)-ethoxymethylthiophosphinylthioglycolyl-valine on the concentration ratio $c^+/(c^+ + c^-)$.

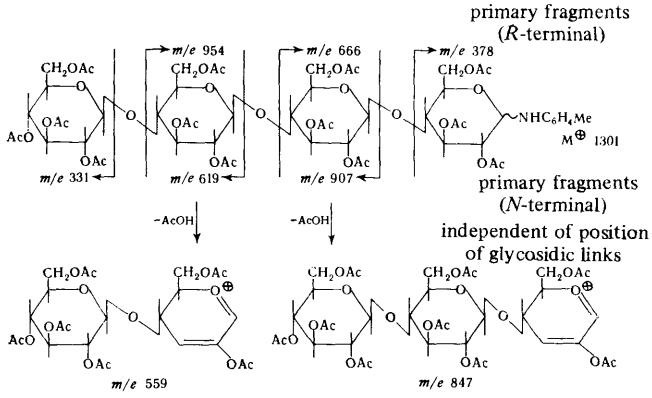
The first work on the chemistry of nucleic acids included determination and comparison of the nucleotide composition of deoxyribonucleic acids in various lower and higher organisms, from which several characteristic features could be deduced (A. N. Belozerskii). A systematic search is being made for fundamental approaches to establishing the primary structure (i.e. the sequence of nucleotides), as yet in the simpler examples—transfer ribonucleic acids (A. A. Baev, D. G. Knorre). A promising way of studying the structure and functions of nucleic acids and their components is to modify them chemically, in particular with such specific agents as substituted hydroxylamines (N. K. Kochetkov, E. I. Budovskii). Compounds of nucleic acids with proteins are under investigation. Not only natural nucleoproteins but also model compounds with different types of amino-acid–nucleotide bond are being studied (M. A. Prokof'ev).

Development of the chemistry of carbohydrates in our country began with the work of P. P. Shorygin on the preparation of previously unknown cellulose ethers and esters, which was continued by A. E. Favorskii, S. N. Danilov, M. F. Shostakovskii, Z. A. Rogovin, N. I. Nikitin, M. M. Ushakov. Many studies were made of the degradation and oxidation of cellulose and other polysaccharides. The structure and the reaction mechanisms of starch, amyloses, glycogens, dextrans, etc. have been investigated. Much attention has been paid during the past two

decades to mono- and oligo-saccharides present in biologically important carbohydrate-containing polymers. Simple models of glycopeptides with various types of bonds have also been studied. The preparation and reactivity of carbohydrate phosphites and phosphinates—intermediates for the preparation of phosphorylated sugars—are being investigated (A. A. Petrov, E. E. Nifant'ev). Methods have been worked out for the synthesis of *C*-glycosides, in particular by applying the Wittig reaction to diverse phosphoranes (Yu. A. Zhdanov), and new methods of producing a glycosidic link (A. Ya. Khorlin, A. F. Bochkov, G. B. Elyakov). Effective methods are being developed for the structural analysis of carbohydrates. A mass-spectrometric method has been worked out for determining the sequence in oligosaccharides (see Scheme) (N. K. Kochetkov, O. S. Chizhov).



secondary fragments, the presence or absence of which depends on the position of the glycosidic links.

The chemistry of steroids has been investigated in the USSR since the 1930s, when M. I. Ushakov established the foundations of the synthesis of transformed steroids, in particular 6- and 16-methyl derivatives possessing strong physiological activity. The domestic manufacture of steroidal hormones based on cholesterol was established during the post-war period. In the 1950s work was begun in I. N. Nazarov's laboratory on a complete synthesis of steroidal compounds, and was developed by L. D. Bergel'son, I. V. Torgov, V. F. Kucherov, S. I. Zav'yalov, V. I. Maksimov. Microbiological and enzymatic transformations of steroids have been investigated by G. K. Skryabin and N. N. Suvorov.

Research on the synthesis of lipids has developed in several directions—the synthesis of natural fatty acids, the search for methods of synthesising glycerides and sphingolipids, and the synthesis of new types of phospholipids.

A thorough study of the most important branches of the chemistry of natural compounds enumerated above, together with the chemistry of antibiotics, vitamins, coenzymes, and alkaloids is being made in several institutes of the Academy of Sciences, among which the leading establishments are the Shemyakin Institute of Bio-organic Chemistry, Institute of Molecular Biology, Bakh Institute of Biochemistry, Protein Institute, Institute of Biological Physics, and Institute of the Biochemistry and the Physiology of Micro-organisms.

Systematic chemical and medico-biological investigations in the USSR resulted in the establishment of the present-day antibiotics industry, which produces all the most important antibiotics. Among the most significant chemical investigations on antibiotics are the discovery of chloramphenicol and its derivatives with the establishment of their structure (Shemyakin), the synthesis of cycloserine and study of the mechanism by which it functions (N. K. Kochetkov, R. M. Khomutov, M. Ya. Karpeiskii), determination of the absolute configuration of tetracyclines (M. N. Kolosov, A. I. Gurevich), elaboration of methods for the synthesis of penicillins and their analogues (I. L. Knunyants, I. T. Strukov, S. A. Giller), and general methods for separating mixtures of streptothricins (Khokhlov).

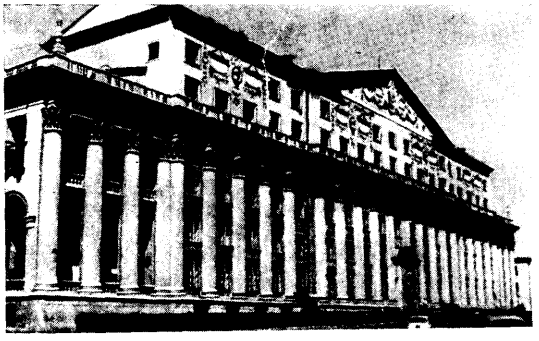


Figure 29. Shemyakin Institute of Bio-organic Chemistry of the USSR Academy of Sciences.

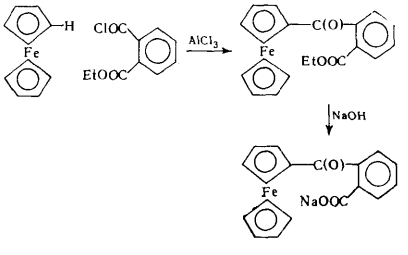
Studies of the chemistry of alkaloids, first begun by A. E. Chichibabin, were extended under the direction of A. P. Orekhov, N. A. Preobrazhenskii, A. S. Sadykov, S. Yu. Yunusov.

The complete structure has been determined for an important enzyme—the cytoplasmic aspartate aminotransferase from porcine heart muscle—containing 412 amino-acid residues (Fig. 30). This enzyme is one of the largest proteins whose structure has been deciphered (Ovchinnikov).

The achievements in the chemistry of natural compounds, together with advances in the organic chemistry of the most diverse classes of compounds, form the basis for such an important branch as the chemistry of medicinals and biologically active compounds. Among various new medicinal preparations mention must be made of ferroceron for the treatment of illnesses associated with an iron deficiency in the organism, e.g. iron-deficient anaemia of various aetiologies, ozaena, and paradentosis (A. N. Nesmeyanov). The active principle of ferroceron—sodium *o*-ferrocenylcarbonylbenzoate—is obtained by acylating ferrocene with ethyl *o*-chloroformylbenzoate:



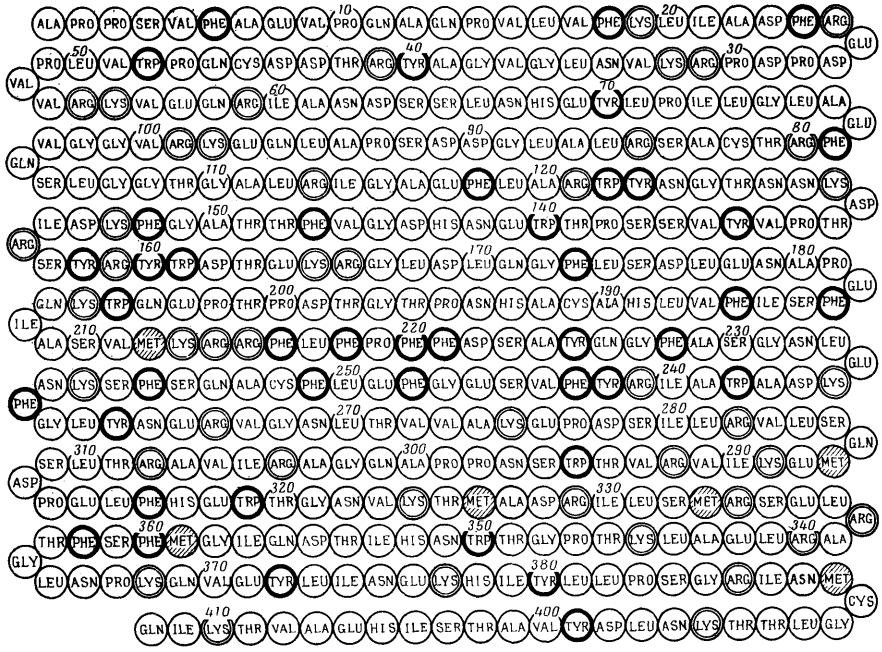


Figure 30. Amino-acid sequence of cytoplasmic aspartate aminotransferase from porcine heart muscle.

On Nesmeyanov's initiative the scientific foundations are being laid for the synthesis of artificial food—chemical and microbiological methods for the production of amino-acids, peptides, and proteins, research on the chemistry of odour and taste, study of the principles underlying the production of new types of foods. Recent years have seen the development of a convenient synthesis of DL-tryptophan by the cathodic reduction of indolylnitro-acrylates and their saturated analogues, conditions for the asymmetric synthesis of α-amino-acids in the proton exchange of racemic amino-acids on complex formation with metals of variable valency, and a synthesis of DL-glutamic acid, used as a flavouring agent (Belikov).

Convenient syntheses have been worked out for heterocyclic compounds of various structures, such as imidazolines, hydroxyhydropyrimidines, and dihydrotriazines, which are of interest with respect to their physiological activity (S. V. Rogozhin).

Petroleum Chemistry

Research on the chemistry of petroleum is associated with the names of D. I. Mendeleev, V. V. Markovnikov, N. D. Zelinskii, A. E. Favorskii, F. F. Beil'shtein [Beilstein], M. I. Konovalov, S. V. Lebedev, V. N. Ipat'ev, A. V. Topchiev, I. M, Gubkin, S. S. Nametkin. During the 1870–1890s Mendeleev studied Russia's oil-bearing deposits, foreseeing in petroleum an extremely valuable raw material for the production of organic compounds. He was the first to pose the question of the utilisation of natural gases, and put forward the idea of the subterranean gasification of coal. From the 1880s Markovnikov undertook a systematic study of petroleum, and proposed the name "naphthenes" for one of the types of hydrocarbons originating from petroleum. He isolated and identified many individual compounds, and studied their chemical and physical properties in comparison with model compounds. Zelinskii made many investigations on the interconversion of hydrocarbons, developed methods for the preparation of various compounds from petroleum raw material, and put forward a theory of the organic origin of petroleum.

Nametkin made investigations on the chemistry and technology of petroleum and natural gas. He elucidated a single mechanism for the nitrating and oxidising action of nitric acid on aliphatic and mono- and bi-cyclic hydrocarbons, studied the addition and the detachment of the elements of water and hydrogen halides to and from bicyclic compounds, as well as isomerisations of camphenic compounds, discovered the rearrangement bearing his name, and investigated the stereochemistry of mono- and bi-cyclic systems. Nametkin studied the composition of combustible natural gases and petroleums from various deposits, and investigated the chemical nature of solid hydrocarbons (paraffins and ceresins). He made various studies of oxidative cracking, catalytic aromatisation, the isomerisation of butenes into 2-methylpropene, and many other topics. He worked out valuable methods for analysing aromatic hydrocarbons, unsaturated hydrocarbons in gasolines produced by cracking, sulphur-containing compounds, and other compounds.

At the beginning of the century work on petroleum chemistry was conducted in college laboratories, mainly in Moscow University. The early years of the Soviet régime saw the foundation of specialised petroleum institutes, in which were elaborated the principles of several new manufacturing processes—the production of phenol and acetone, oxiran and methyloxiran, organic acids, alcohols, etc.—based on petroleum chemistry. The Moscow Petroleum-processing Works (directed by D. V. Ivanyukov) plays an important role in the introduction of new petroleum-chemical processes.

The main lines of development of petroleum chemistry are determined by the diverse tasks of present-day petrochemical production—study of the composition and properties of petroleums, establishment of scientific foundations for their processing and the production of various monomers, polymeric materials, synthetic rubber and fibres, surface-active agents and detergents, and solvents, and the synthesis of valuable chemical materials based on hydrocarbons. A large volume of research has been devoted to studying the composition of petroleums from different deposits (P. I. Sanin, A. F. Plate, G. D. Gal'pern, A. D. Petrov). Principles of a scientific classification of petroleums–combining chemical, geochemical, and technical aspects of the problem—have been formulated (A. A. Petrov, G. P. Kurbskii).

Hundreds of different hydrocarbons originating from petroleum have been identified. Chromatographic methods have been worked out for separating complex hydrocarbon mixtures, and also methods for isolating hydrocarbons having a certain structure. Many-sided investigations have been made of the interaction of complex compounds of metals of variable valency with hydrocarbons and non-hydrocarbon compounds of petroleum, which resulted in the suggestion of an original method for improving the quality of petroleum products (N. S. Nametkin).

A photochemical procedure has been worked out for isolating ash-forming elements from petroleums and petroleum products from various deposits in Georgia. It was shown that polycyclic aromatic hydrocarbons can sensitise the photochemical oxidation of naphthenes in mineral oils.

Organoelementary compounds present in petroleums—primarily organosulphur compounds (R. D. Obolentsev)—have been investigated. Yu. K. Yur'ev undertook the synthesis and spectroscopic examination of the many model thiolans required for the identification of those in sulphurous petroleums in the USSR. Studies have been made of the reactions involving cleavage of the thiophen and thiolan rings, which underly the industrial desulphurisation of petroleums.

A study has been made of the processes involved in pyrolysis, which is the chief industrial method for obtaining the main products—unsaturated and aromatic hydrocarbons—of petrochemical synthesis. In particular, a kinetic investigation has been made of the pyrolysis of alkanes in mixtures with alkenes, naphthenes, and alkylated arenes. The use of labelled atoms has enabled the dependence of the hydrogen concentration on the composition of the pyrolysable mixtures to be determined, and the elementary acts governing the interaction of hydrocarbons during pyrolysis to be elucidated (K. P. Lavrovskii, R. A. Kalinenko). Research is being conducted on a combined scheme for processing the liquid products of pyrolysis, involving the isolation of cyclopentadiene, methylcyclopentadiene, and aromatic hydrocarbons, together with the production of polymeric resins. A rapid process of thermal-contact pyrolysis has been elaborated which permits the efficient processing of all petroleum products, including crudes.

Carrying out chemical reactions in a plasma jet at 2000–3000°C is a promising method for obtaining several important petrochemical products (L. S. Polak). The topics studied in the field of plasma chemistry have been expanded significantly during recent years. The scientific foundations of a plasmachemical technology have been worked out—the production of acetylene and technical hydrogen from natural gas, unsaturated hydrocarbons from benzine and crude petroleum, and synthesis gas for the manufacture of vinyl chloride. These processes are in industrial operation at several chemical concerns.

The fundamental investigations by N. D. Zelinskii, B. A. Kazanskii, A. A. Balandin on the catalytic conversion of hydrocarbons formed the basis for a theory of hydrogenation and dehydrogenation catalysis and for introducing many reactions into practice. Highly efficient and selective catalysts have been developed, in particular for the hydrodemethylation of toluene and the dehydrocyclisation of hexane to produce benzene, and for the dehydrogenation of ethylbenzene to styrene. Mechanisms of the dehydrocyclisation of C_6–C_8 alkanes and alkenes have been studied. Processes of dehydrocondensation in the catalytic formation of resinous and carbonaceous products have been investigated (M. G. Gonikberg, M. I. Rozengart, I. I. Brusov, G. M. Marukyan, G. V. Isagulyants).

An economic process has been developed for the production of butadiene by the single-stage dehydrogenation of butane on an alumina–chrome catalyst (O. D. Sterligov). A palladium–zeolite catalyst has been developed for the isomerisation of hydrocarbons, a zeolite catalyst for the alkylation of benzene by alkenes, and catalysts containing added rare-earth metal oxides, which accelerate hydrogenation and dehydrogenation but produce no skeletal isomerisation (Kh. M. Minachev).

Research is being conducted on the use of π-allyl complexes of transition metals as polymerisation catalysts. Original catalytic systems have been created for the synthesis of *cis*-1,4-polybutadiene. New opportunities for stereospecific catalysis have been opened up. In order to obtain valuable chemical products, in particular novel monomers, broad investigations are being made on the dimerisation, codimerisation, oligomerisation, and co-oligomerisation of unsaturated hydrocarbons in the presence of combined catalysts (B. A. Dolgoplosk, B. A. Krentsel', G. A. Tolstikov, V. M. Vdovin, V. S. Aliev, M. M. Kaliberdo, V. S. Gutyrya).

New homogeneous catalysts, based on complexes of ruthenium, rhodium, palladium, and cobalt, have shown high selectivity: for example, it has been possible to hydrogenate *cis*-penta-1,3-diene to *trans*-pent-2-ene. Catalysts have been prepared comprising organometallic complexes of transition metals fixed to various carriers, including graphite (M. E. Vol'pin, B. A. Dolgoplosk, Yu. I. Ermakov).

Methods for the preparation of functional derivatives of hydrocarbons, especially oxygen-containing compounds, are being investigated. The principle of controlling liquid-phase oxidation by introducing so called stop-reagents—substances that convert reactive intermediates into compounds resistant to oxidation—has been developed (A. N. Bashkirov, V. V. Kamzolkin).

A combined study of the mechanisms of reactions occurring on fused iron catalysts, together with elucidation of the properties of the intermediate surface compounds, has enabled several catalytic syntheses to be predicted and accomplished (A. N. Bashkirov, Yu. A. Kogan, A. Ya. Rozovskii).

An industrially promising method—oxidative ammonolysis—for the preparation of nitrogen-containing derivatives of hydrocarbons has been applied to toluene, xylenes, pseudocumene, durene, and chlorinated hydrocarbons (S. D. Mekhtiev). A proposed process for obtaining acrylonitrile involves oxidative ammonolysis of propene on a fluidised catalyst bed (Institute of Catalysis of the Siberian Division of the USSR Academy of Sciences).

A series of comparative studies have been made of the chemistry of cyclic and unsaturated hydrocarbons and of silico-hydrocarbons. Besides broadening our views on the reactivity of these analogues, these investigations led to the production of interesting new materials, showing promise for use in the petrochemical and metallurgical industries as well as in several other branches of the national economy (N. S. Nametkin).

A petrochemical development is the chemistry of additives for improving the cleansing, dispersing, anti-wear, and other properties of motor and special oils (P. I. Sanin, A. M. Kuliev). A polymeric additive has been produced to ensure that high-alkane petroleums can be pumped through pipelines (V. P. Mamaev).

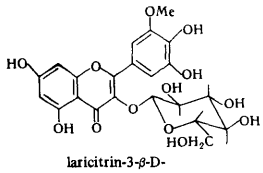
Chemistry of Wood

Significant results have been obtained in wood chemistry during recent years. The validity of regarding wood as a cross-linked polymer has been demonstrated. The number of cross-links in the cell walls of wood explains the changes in its properties and structure, which opens up the possibility of a purposeful variation in its properties.

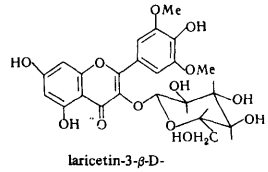
Phenolic phenylpropene compounds having a sulpho-group in the side-chain have been investigated as models of structural fragments of ligninsulphonic acids. The presence of the sulpho-group in this position is shown to stabilise the C_6–C_3 structural fragment of lignin. A procedure has been developed for preparing combined organic and mineral fertilisers based on hydrolytic lignin.

Application of salts of metals of variable valency permits controlled variation of the supermolecular structure and reactivity of cellulose (Institute of Physical Organic Chemistry of the Belorussian SSR Academy of Sciences). A technology is being worked out for a new nitric-acid method for obtaining cellulose, with use of the waste products as nitrogen-containing organic–mineral fertilisers. Fresh data have been obtained indicating that this method is promising for practical application.

Investigation of the interaction of levoglucosan with various di-isocyanates has shown that the hydroxypropylated material is suitable for the production of rigid polyurethan foams (Institute of Wood Chemistry of the Latvian SSR Academy of Sciences). Phenolic compounds from the needles, bark, and wood of conifer species of Siberia and the Far East have been studied. Two new compounds of the flavonoid series



laricitrin-3-β-D-glucopyranoside



laricetin-3-β-D-glucopyranoside

have been isolated from larch needles; they are of fundamental value for constructing a scheme of biogenesis for substances of this type (Irkutsk Institute of Organic Chemistry of the Siberian Division of the USSR Academy of Sciences).

Chemistry of Solid Fuels

M. V. Lomonosov, in his work "O sloyakh zemnykh [On the Earth's Strata]", formulated for the first time the view that coal is formed in stages from extinct plants, which have undergone the most complicated physicochemical transformations from wood through peat and lignite to coal.

An active part in establishing a science of fuel was taken by D. I. Mendeleev, V. V. Markovnikov, V. I. Vernadskii, N. D. Zelinskii, I. M. Gubkin, S. S. Nametkin, N. P. Chizhevskii, A. A. Skochinskii, Yu. A. Zhemchuzhnikov, N. M. Karavaev, A. B. Chernyshev, G. L. Stadnikov, A. F. Dobryanskii, and many others. The Committee on the Chemistry of Coal Tar and Coke, organised by the Academy of Sciences, did great work under the direction of A. E. Porai-Koshits and N. M. Karavaev. This Committee not only directed experimental work aimed at providing the growing organic synthetic industry with a continuous supply of raw material but also participated directly in studying the processes at undertakings with the aim of increasing the range of chemical products for organic synthesis based on the processing of coal.

An industrial classification of coals was worked out. The vast factual information that had accumulated on the qualitative characteristics of coals enabled native varieties to be differentiated according to their properties into power fuel for electrical generating stations and raw material for the production of high-quality coke with chemical products and materials (A. B. Chernyshov, N. G. Titov).

Studies were made on the possibility of expanding the raw-material base of coking by using abundant feebly coking coals. A theory of the formation of coke from mixtures of coals was put forward. L. M. Sapozhnikov's work on the thermal decomposition of coals and the formation of a plastic mass of carbon changed radically the view held on the effect of extreme temperatures, pressure, and oxidising and reducing media on structural changes in carbonaceous materials.

Theoretical researches were made on the genesis of coals, as a result of which new views were established on the nature of the geobiochemical processes involved in the transformation of plants into coal. A chemical theory was proposed for the formation of bogheads and the mixed humus–sapropelite origin of coals (Stadnikov). The petrological examination of coals has settled a wide range of questions concerning the classification and marking of coals, as well as the choice of raw material for industrial processing (Yu. A. Zhemchuzhnikov, I. L. Amosov, I. V. Eremin).

A fundamental scheme for the polymeric structure of the main organic substance in coals has been elaborated. It permitted generalisation of the concept of humic substances as monomeric molecular structures with fused aromatic rings and polyfunctional lateral substituents (V. I. Kasatochkin, L. L. Nesterenko). Great attention is paid to the thermal processing of coals, and catalytic methods for the hydrogenation and oxidation of hydrocarbons typical of the composition of fuels.

A procedure developed for the simultaneous hydrogenation of coal and a high-sulphur petroleum enables up to 50% of boiler fuel to be obtained with considerable quantities of motor fuel, phenols, benzene, and other chemical products (A. V. Lozovoi, A. A. Krichko). Promising methods have been studied for processing coals, peat, and bituminous shales by oxidation in alkaline medium with the production of various di- and poly-carboxylic acids (T. A. Kukharenko, A. S. Fomin).

The physicochemical and in particular thermodynamic investigation of the high-temperature processing of solid fuel led to an original method for the so called power-technical and power-chemical processing of fuel (A. B. Chernyshov, Z. F. Chukhanov). Chizhevskii carried out research with the aim of expanding the coal base of coking, and proposed an original design of coke-ovens.

Study of the distribution of rare elements and non-ferrous metals led to the so called "affinity series"

$$Ge > W > Ga > Be > Nb > Mo > Sc > Y > La > Zn$$

of these elements with respect to the organic matter in solid fossil fuels.

Processes have been worked out for obtaining a light porous filler (agloporite) for concrete by the heat-treatment of coal at 1100–1200°C.

The ion-exchange properties of peat can be increased by factors of 2.5–3 by oxidative degradation (N. I. Mitskivich, P. I. Bel'kevich, L. R. Chistova). The ammoniation of peat increases its moisture content, while its filtering power is diminished by factors of 10–15 (A. V. Tishkovich). Karavaev has completed many years of work on establishing the foundations of a general classification of fossil fuels.

Macromolecular Compounds

The chemistry of compounds of high molecular weight was founded as an independent branch at the beginning of this century. The concept of macromolecular substances as an important class of chemical compounds was due mainly to organic chemists. Research in this field began with the work of A. M. Butlerov, I. L. Kondakov, I. P. Ostromyslenskii, and P. P. Shorygin.

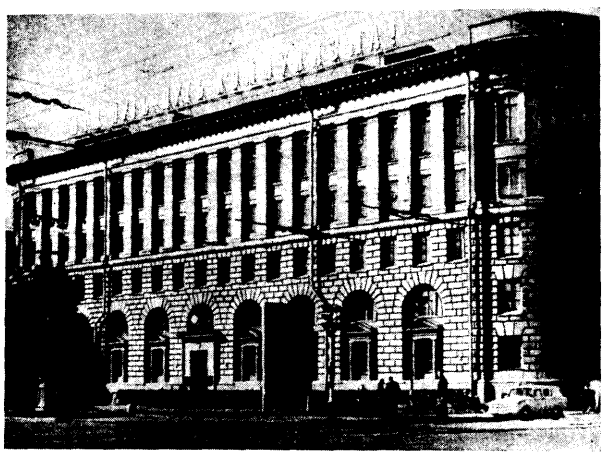


Figure 31. Institute of Macromolecular Compounds of the USSR Academy of Sciences.

S. V. Lebedev developed an industrial process for obtaining synthetic rubber based on butadiene. The study of polycondensation and polymerisation laid the foundations for the industrial production of phenol–formaldehyde resins, organosilicon polymers, synthetic rubbers, polymerisable oligomers, polymers for synthetic fibres, and other polymeric materials. Development of the science of polymerisation and isomerisation governed the growth of many branches of the chemistry of the monomers.

A. E. Favorskii, I. N. Nazarov, M. F. Shostakovskii suggested methods for obtaining ethynylvinylmethanols and vinyl ethers. These monomers have found wide application for the manufacture of various polymers and copolymers (adhesives, plasticisers, medicinals). K. A. Andrianov discovered convenient methods for the preparation of orthosilicic esters, and was the first to obtain polyorganosiloxanes, which have been widely used for the production of thermostable polymers employed for the thermal and electrical insulation of various articles, and the production of lubricants, plastics, rubbers, paints, and varnishes. Phosphorus-containing compounds (A. E. Arbuzov, B. A. Arbuzov, A. N. Pudovik, M. I. Kabachnik), organofluorine compounds (I. L. Knunyants), and various organoelementary compounds (A. N. Nesmeyanov) have been widely used for obtaining polymeric materials.

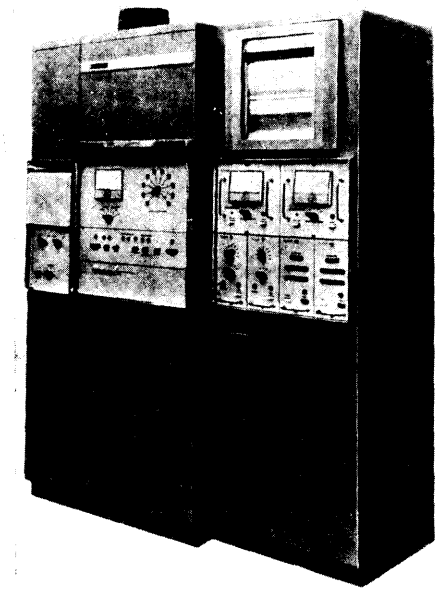

Figure 32. Automatic liquid chromatograph KhZh-1303 for determining molecular-weight distribution of polymers, developed by the Special Design Office of Analytical Instrumentation of the USSR Academy of Sciences and by the Institute of Macromolecular Compounds of the USSR Academy of Sciences.

The relations between the chemical structure and the reactivity of monomers have been studied. A new line of research began in the early 1960s, based on the possibility of varying the reactivity of monomers by complexing them with various substances. Investigations in this field, started by V. A. Kargin and V. A. Kabanov, offer the prospect of simulating the biosynthesis of polymeric compounds. The mechanisms of polymerisation and polycondensation have been investigated.

A theory of radical polymerisation and copolymerisation has been elaborated (S. S. Medvedev, Kh. S. Bagdasar'yan, A. D. Abkin). The kinetics and the mechanism of the redox initiation of chain polymerisation have been investigated (B. A. Dolgoplosk, E. I. Tinyakova), as well as the activation of radical polymerisation by complexing agents (V. A. Kargin, V. A. Kabanov, V. P. Zubov, E. B. Milovskaya, and others). Research on the elementary processes in the radical polymerisation of vinyl monomers and the cationic polymerisation of formaldehyde and oxirans led to the discovery of chain transfer (Medvedev) and of chain transfer with rupture (N. S. Enikolopov). These processes permitted control of the molecular weight, the molecular-weight distribution, and the structure of the polymers, and also enabled telomerisation to be accomplished (A. N. Nesmeyanov, R. Kh. Freidlina).

Broad investigations have been made of the uninhibited and inhibited heterophase polymerisation of polyfunctional monomers and oligomers to high degrees of conversion (G. P. Gladyshev, G. V. Korolev, N. N. Tvorogov). This work created a scientific basis for the industrial production and modification of several polymeric materials.

The influence of the supermolecular organisation of polymerising compounds on the kinetics of their conversion into chain and network polymers has been examined. Thus activation of the radical and ionic polymerisation of acrylic monomers and oligomers, due to a favourable arrangement of double bonds in liquid-crystalline and associated molecular aggregates of the liquid phase, has been detected and investigated (B. A. Krentsel', Yu. B. Amerik, N. N. Tvorogov, T. E. Lipatova), as well as in the crystallisation of monomers (V. A. Kargin, N. N. Semenov, V. A. Kalbanov, and others).

Work on polymerisation under extreme conditions has opened up a new line of research in the chemistry of polymerisation processes. Yu. S. Zaslavskii, A. A. Berlin, R. N. Zaslavskii, and M. I. Cherkashin investigated the polymerisation of various monomers and oligomers under the influence of friction, leading to the formation of polymer films which greatly diminished wear of the rubbing surfaces. N. S. Enikolopov and A. A. Zharov studied polymerisation under ultra-high pressure with shear. Work has been done on polymerisation in shock waves.

The mechanism of cationic polymerisation was first discussed by M. D. L'vov, G. G. Gustavson, and I. L. Kondakov at the end of the nineteenth century. S. S. Medvedev, A. R. Gantmakher, B. L. Erusalimskii investigated the mechanisms of the polymerisation of many unsaturated compounds in the presence of cationic catalysts, and in particular revealed the role of alkene–catalyst π-complexes. Specific aspects of the cationic polymerisation of rings appeared in papers by N. S. Enikolopov, S. G. Entelis, E. B. Lyudvig, and others.

Work on anionic polymerisation was begun by Lebedev, who made use of observations by A. A. Krakau and I. L. Kondakov that polymerisation might be accomplished in the presence of metallic sodium. The labours of S. S. Medvedev, A. R. Gantmakher, A. A. Korotkov, B. L. Erusalimskii elucidated many aspects of the kinetics and the mechanism, and established the effect of the nature of the alkali metal on the composition and structure of the polymers.

Studies of ionic telomerisation (A. A. Petrov, A. L. Klebanskii, M. F. Shostakovskii) yielded valuable products finding industrial application as polymeric materials.

Stereospecific polymerisation was studied by S. S. Medvedev, A. A. Korotkov, A. V. Topchiev, B. A. Dolgoplosk, E. I. Tinyakova, N. M. Chirkov, B. A. Krentsel', G. A. Razuvaev. The role of cobalt and titanium compounds in composite catalysts was established, and several novel catalytic systems were suggested, including π-allyl complexes for the polymerisation of diene hydrocarbons.

K. A. Andrianov, V. V. Korshak, S. R. Rafikov, L. B. Sokolov, S. V. Vinogradova made series of investigations on the mechanism of equilibrium and non-equilibrium polycondensation, revealing the effects of excess of reactants, simultaneous reactions, and experimental conditions on the mean molecular weights and the molecular-weight distribution. Berlin investigated the polycondensation of diols, polyols, and dibasic acids (or their derivatives) in the presence of unsaturated monobasic acids, and from the results worked out a general synthesis of polymerisable acrylic oligomers with terminal or regularly repeating reactive groups (condensation telomerisation). This work formed the scientific basis for the industrial production of several high polymers (polyamides, polyesters) and polymerisable oligomers (oligo(ether–acrylates) and their analogues).

The mechanism and the kinetics of the polyaddition of di-isocyanates to diols to form polyurethans have been studied (Yu. L. Spirin, T. E. Lipatova, S. G. Entelis, and others).

The development of such methods for synthesising polymers as oxidative dehydropolycondensation, polydiazotisation, polycoordination, polycyclisation, etc. led to the production of highly thermostable polymers having a system of conjugated aromatic and heterocyclic rings and exhibiting semiconductor and catalytic properties (V. V. Korshak, A. M. Sladkov, B. A. Krentsel', B. E. Davydov, Ya. M. Paushkin, I. L. Kotlyarevskii, A. A. Berlin, B. I. Liogon'kii, M. I. Cherkashin).

Among work promoting the industrial production of polymeric compounds and materials based on them mention must be made of investigations on the polymerisation of ethylene associated with the names of V. N. Ipat'ev, M. S. Nemtsov, A. I. Dintses, establishment of scientific principles for the manufacture of polypropylene (A. V. Topchiev, N. M. Chirkov, B. A. Krentsel'), and the production of Soviet synthetic rubbers (B. A. Dolgoplosk, A. I. Yakubchik, A. A. Korotkov, V. F. Evstratov).

Research aimed at obtaining poly(vinyl chloride) was initiated in our country by Ostromyslenskii in 1912. Development of this work led to organisation of the industrial production of polymers and copolymers of vinyl chloride. The work of S. M. Ushakov and P. P. Shorygin stimulated the industrial manufacture of polystyrene and poly(vinyl acetate), while the studies by G. S. Petrov mentioned above formed the basis for the production of phenol—formaldehyde and urea—formaldehyde resins and plastics. The industrial production of polyamides and aromatic polyesters is based on investigations by V. V. Korshak, I. L. Knunyants, Z. A. Rogovin, A. N. Nesmeyanov, R. Kh. Freidlina, A. A. Strepikheev, and others.

Compositions of oligomers with raw rubbers and thermoplastics were developed which enabled new industrial methods to be established for obtaining and modifying cured rubbers, elastomers, reinforced plastics, coatings, sealants, and other polymer materials (A. A. Berlin, A. S. Kuz'minskii, G. N. Petrov, I. S. Al'shits, M. S. Akutin, I. Ya. Kaplunov, and others).

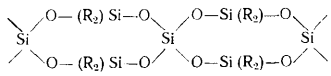
Study of the mechanochemistry of block and graft copolymerisation and reactions in the polymer chains laid the foundations for the industrial manufacture of highly impact-resistant polystyrene and poly(vinyl chloride), modified cellulosic fibres and cloth, and several other polymeric materials. Advances in the vulcanisation of

elastomers were due to original investigations by B. P. Zhukov, B. A. Dogadkin, and others.

A new field of polymer science—the chemistry of conjugated polymers—was opened up. Specific aspects of the supermolecular organisation and properties of these polymers were revealed, and the presence was demonstrated of low-lying triplet levels and paramagnetic centres influencing their reactivity and electrophysical properties (A. A. Ovchinnikov, L. A. Blyumenfel'd, A. A. Berlin, and others). The practical importance of these polymers is due to their use as photosensitive materials, organic semiconductors, inhibitors of the high-temperature degradation of elastomers and rigid-chain polymers, structural modifiers, and starting points for obtaining highly thermostable plastics.

Organosilicon polymers have acquired especial value among organoelementary polymers because of their astonishing combination of useful properties, high heat and frost resistance, excellent dielectric characteristics, good adhesive properties, absence of toxicity, etc. In 1937 Andrianov obtained the first patent in the world for the practical application of organosilicon compounds, and in 1940 he developed an industrial method for obtaining silicon tetrachloride—the most important starting material for the synthesis of polysiloxanes—by the reaction of chlorine with 35–65% ferrosilicon at 200°C. The mechanism of the formation of substituted orthosilicic esters was studied. Choice of a progressive technical procedure for obtaining organochlorosilanes in a fluidised bed enabled the large-scale industrial manufacture of methyl-, ethyl-, and phenyl-chlorosilanes to be organised.

The products of the simultaneous hydrolysis of di- and tri-functional organochlorosilanes were regarded as having a cyclolinear structure. The cohydrolysis of organochlorosilanes with aluminium chloride in alkaline media was used to obtain polyorganoaluminosiloxanes. Organospirocyclosiloxanes with the organosiloxane groups occupying a specified position in the spirocyclic ring



were prepared. Manufacture of a large range of organosilicon monomers and polymers was set up.

Study of the degradation and stabilisation of polymers was begun by S. V. Lebedev, B. A. Dolgoplosk, G. A. Razuvaev, V. A. Kargin, M. B. Neiman, A. S. Kuz'minskii. Kinetic investigations of the aging and stabilisation of polymers have been made by A. L. Buchachenko, G. P. Gladyshev, E. T. Denisov, V. V. Ershov, G. E. Zaikov, V. B. Miller, E. G. Rozantsev, D. Ya. Toptygin, V. Ya. Shlyapintokh, Yu. A. Shlyapnikov, and others. Studies have been made of the kinetics of oxidative degradation, the action of various stabilisers on the oxidation of polymers, and the synergic effect of several inhibitors. It has been discovered that chemical compounds that react rapidly with oxygen (or free radicals) to form inert products are able, when generated in polymer compositions or articles (as a result of the transformation of inert substances), to stabilise the polymeric materials against oxidative and/or thermal degradation at 300–400°C and above (Fig. 33).

Various iminoxyl radicals have been prepared which are widely used as "labels" and have proved effective stabilisers for several polymers. Work is being conducted on modifying the polymers to prolong the "life span" of polymeric compositions (N. S. Enikolopov, S. R. Rafikov, Z. A. Rogovin, Kh. U. Usmanov, N. A. Plate, and others).

The first investigations on the physical chemistry of polymers were aimed at studying their mechanical properties taking into account relaxation phenomena accompanying deformation and fracture. The results formed the basis of the contemporary physical chemistry of polymers (A. P. Aleksandrov, P. P. Kobeko, Yu. S. Lazurkin, V. A. Kargin, G. L. Slonimskii, M. V. Vol'kenshtein, S. E. Bresler, S. Ya. Frenkel', E. V. Kuvshinskii, G. I. Gurevich).

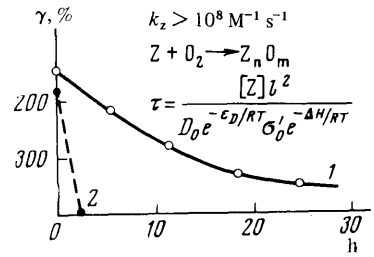


Figure 33. Stabilisation of thermostable polymers—variation in relative elongation at rupture for cured rubber based on SKTV-2 when aged in air (350°C): 1) stabilised specimen; 2) control.

The usual concepts valid for solutions of compounds of low molecular weight are shown to apply also to solutions of polymers. V. N. Tsvetkov investigated the latter in order to obtain information on the structure and conformation of the soluble molecules. A. A. Tager, V. P. Zubov studied the thermodynamics of the solutions, swelling, plasticisation, and gel formation. Research on the rheology of polymers was begun and developed by P. A. Rebinder and G. V. Vinogradov.

A. N. Zhurkov, G. M. Bartenev, V. E. Gul', A. L. Rabinovich, Yu. M. Malinskii developed theoretical ideas on the nature of the deformability and strength of polymers and reinforced plastics, and also studied the relaxation properties of polymers having rubberlike elasticity. V. A. Kargin and T. I. Sogolova established methods for modifying the supermolecular structure and physicomechanical properties of polymers.

Aspects of the physical chemistry of surface phenomena in polymer systems have been investigated by Yu. S. Lipatov, Yu. A. El'tekov, while the foundations for a theory of adhesion have been laid by B. V. Deryagin, V. E. Basin, S. S. Voyutskii. These investigations are not only of great theoretical importance but also of practical value, especially for the controlled production of adhesives, protective coatings, binders, reinforced plastics, etc.

INORGANIC CHEMISTRY

The inception of quantitative investigations on inorganic chemistry is connected with the work of M. V. Lomonosov. During the eighteenth century information accumulated on the composition and properties of various substances, and new elements were discovered. The establishment of the atomic—molecular doctrine in the nineteenth century, the discovery of the stoichiometric laws of chemical reaction, and the formulation of such concepts as atom, equivalent,

molecule, and valency enabled a start to be made in elaborating theoretical principles of inorganic chemistry.

D. I. Mendeleev's discovery of the Periodic Law and the Periodic System of the elements (1869) initiated a new stage in the development of chemistry. The discoveries of physics at the beginning of the twentieth century—the detection of radioactivity, the composite structure of the atom, and the quantum theory of atomic structure—faced inorganic chemistry with the task of studying the structure of atoms and molecules, and relating such structure to chemical properties.

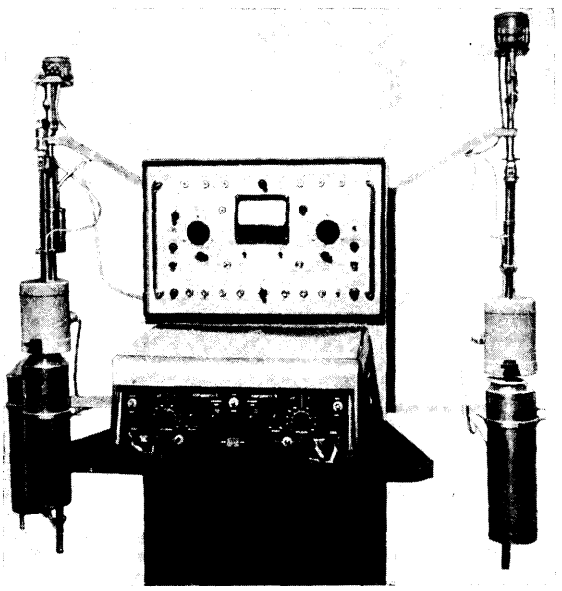

Figure 34. Automatic equipment for recording thermomechanical properties of polymers, developed in the Arbuzov Institute of Organic and Physical Chemistry of the USSR Academy of Sciences.

The Institute of Physicochemical Analysis, of which N. S. Kurnakov became director, and the Institute of Platinum under the direction of L. A. Chugaev were organised in Petrograd in 1918. These establishments were combined in 1934 with the Laboratory of General Chemistry as the Institute of General and Inorganic Chemistry. The Scientific Research Institute of Fertilisers, Insecticides, and Fungicides and the Institute of Chemical Reagents were founded in 1919, the State Institute of Applied Chemistry was established in 1920, and the Radium Institute headed by V. I. Vernadskii in 1922. Many other institutions and laboratories, concerned with all aspects of inorganic chemistry, were established in subsequent years.

Modern inorganic chemistry makes widespread use of the achievements of other branches of chemistry, the theoretical concepts and methods of physics, crystallography, crystal chemistry, and the theory of molecular structure. The principal fields of inorganic chemistry which have been most fully developed are—the chemistry of simple inorganic compounds, the chemistry of metals and alloys, the chemistry of the rare elements, radiochemistry, the chemistry of complex compounds, the chemistry of semiconductors, the chemistry of natural salts, and quantum inorganic chemistry.

Chemistry of Simple Compounds

Research on the chemistry of simple compounds came to be concerned with the structure and chemical properties of almost all elements and their simplest compounds. N. S. Kurnakov introduced the concepts of a chemical species, phases of variable composition, daltonides, and berthollides, and suggested the construction of equilibrium diagrams to represent the properties and stability of a chemical compound. Physicochemical analysis was used to study many of the simplest inorganic compounds; the unity of construction of diagrams for substances of different classes was demonstrated, compounds of unusual valency were detected, the wide distribution of phases of variable composition was established, and geometrical methods were developed for representing chemical systems (N. P. Radishchev, V. Ya. Anosov, A. G. Bergman, M. I. Ravich).

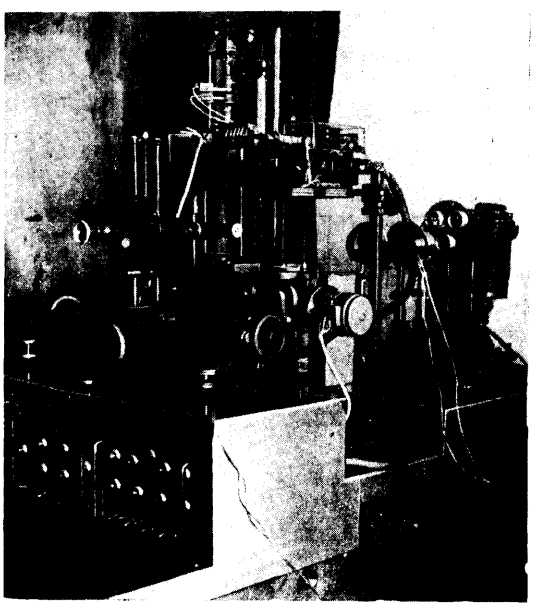

Figure 35. Opticomechanical apparatus for studying relaxation and creep in polymers (Arbuzov Institute of Organic and Physical Chemistry of the USSR Academy of Sciences).

During the 1930s physicochemical analysis became an objective method for studying complicated systems. Metals and alloys were investigated (V. A. Nemilov, N. V. Ageev, G. G. Urazov, V. I. Mikheeva), molten salts (A. G. Bergman, N. K. Voskresenskaya, N. S. Dombrovskaya, N. P. Luzhnaya), and multicomponent aqueous salt systems (V. I. Nikolaev, I. N. Lepeshkov). The chlorine metallurgy of rare and non-ferrous metals has been developed on the basis of the physicochemical analysis of systems involving chlorides of multivalent elements (G. G. Urazov, I. S. Morozov, and V. I. Evdokimov).

Methods of preparation of compounds of light elements, perchloric acid and its derivatives, hydrides of transition metals, hydroborons and their derivatives, etc. have undergone considerable development (S. Z. Makarov, A. F. Zhigach, V. I. Mikheeva, V. Ya. Rosolovskii, and others).

Many peroxides and ozonides have been obtained by I. I. Vol'nov. A series of investigations of the branched-chain decomposition of perchloric acid were made by V. Ya. Rosolovskii and G. B. Manelis.

Figure 36. Institute of Inorganic Chemistry of the Siberian Division of the USSR Academy of Sciences.

A new class of compounds—complex aluminium hydrides $AlH_3.nBH_3.mZ$, where Z is a nitrogen- or oxygen-containing ligand—have been prepared and subjected to physicochemical investigation at Moscow State University. These compounds were shown to be effective reductants and components of catalytic systems of the Ziegler–Natta type.

A. V. Novoselova has prepared novel polymeric beryllium alkoxoacetates $[Be(O.CO.CH_3)OR]_n$, as well as oxy- and hydroxy-acetates. Magnesium alkoxide halides have also been prepared, as promising catalysts for polymerisation processes.

The possibility of almost complete thermal dissociation of naturally occurring phosphates to give phosphorus pentoxide has been demonstrated by S. I. Vol'fkovich.

I. V. Tananaev, N. S. Nikolaev, and Yu. A. Buslaev have obtained important results on the acid–base equilibria of fluorides with hydrofluoric acid. A method developed for obtaining single crystals of copper(I) chloride gave a transparency equal to those of the best specimens in the world. Tungstates of thallium, barium, strontium, and the rare elements have been prepared and studied. Fluorides of Groups I–VI elements, oxofluorides, and polymeric fluorides have been studied by X-ray electron spectroscopy. Per-rhenates of copper, nickel, and lead have been prepared, as well as various barium chromates, niobates, and tantalates.

Developments have occurred in the chemistry of semiconductors (N. P. Sazhin) and dielectrics, and the chemistry of rare, trace, and rare-earth elements (I. V. Tananaev, K. A. Bol'shakov).

This is by no means a complete list of current researches on the preparation and properties of simple inorganic compounds.

The use of physical methods—X-ray diffraction, spectral methods of studying magnetic properties—is being developed in such investigations.

Methods have been elaborated for obtaining the pure metals necessary for radio-engineering and semiconductors. Under the direction of Yu. A. Zolotov investigations have been made on the extraction of more than twenty non-ferrous and noble metals by sulphur-containing organic compounds. Selective extractants have been proposed for copper, thallium, silver, and certain other metals both in the laboratory and in industrial use. Mixtures of a neutral and a cationic extractant have proved effective for the separation of transplutonic elements from rare-earth metals. L. F. Kuzina has worked out a new hydrogen-free process for the industrial production of metallic technetium.

Metals and Alloys

Many of the rules of alloy formation, methods of study, and preparation of alloys with valuable properties were first discovered and formulated by D. I. Mendeleev, N. S. Kurnakov, A. A. Baikov, P. M. Anosov, L. K. Chernov, E. S. Fedorov, A. A. Bochvar, A. A. Rzheshotarskii, and many others. An important aspect of the chemistry of metals is the character of their interatomic bonding. N. V. Ageev investigated the distribution of electron density in the interionic space, and showed that metals are bound by a continuous transfer of the electron cloud from one atom to the other.

Kurnakov established that the chemistry of alloys is the chemistry of continuous proportions: i.e. phases of variable composition (solid solutions) are formed, in which the component concentrations vary continuously. The properties of alloys are a continuous function of the component concentrations. The filling by electrons of energy bands in metallic crystals also obeys special rules.

The relation between the properties of metal—metal systems, in particular the heats of formation, and the structure of their electron shells has been shown in the work of Yu. M. Golutvin. The band theory (S. T. Konobeevskii) was of great value for understanding the solubility limits of metals one in another and the possibility of the formation of solid solutions. Research on the solid solutions formed in metallic systems was carried out over many years by N. S. Kurnakov, G. G. Urazov, N. I. Stepanov, A. T. Grigor'ev, V. A. Nemilov, P. Ya. Sal'dau, N. Kh. Abrikosov, O. S. Ivanov, I. I. Kornilov, V. I. Mikheeva, and many other scientists. It was shown that dissolution of the components in the formation of solid solutions is a special form of chemical interaction, and that this is accompanied in all cases by the evolution of heat owing to the formation of a chemical bond between atoms of the solute metal and molecules of the solvent.

Reactions occurring in solid solutions have been studied that lead to changes in the physical, mechanical, and other properties of the alloys (N. V. Ageev, A. A. Bochvar, S. A. Pogodin, V. N. Anosov, E. M. Savitskii, N. V. Grum-Grzhimailo, G. I. Chufarov). It was established that necessary conditions for the formation of solid solutions are isomorphism of the crystal structures of the separate components, similarity in size of their atoms, and a certain ratio of the electronegativity and ionisation potentials. A classification of solid solutions has been made.

The properties of solid solutions are currently being investigated in the Institute of General and Inorganic Chemistry, the Institute of Silicate Chemistry of the USSR Academy of Sciences, the Institute of Chemistry of the Ural Science Centre, and other institutions. It has been shown in particular that the ternary "alloy" based on zirconium dioxide ZrO_2–Y_2O_3–Nd_2O_3 possesses valuable electrophysical properties and refractoriness, and can be

recommended for the preparation of high-temperature electrodes of magnetohydrodynamic (MHD) generators (E. K. Keller). The properties of the hafnium dioxide–magnesium oxide system, which possesses high electrical conductivity, are being studied. A series of investigations is being made on the interaction, variation in composition of compounds, and polymorphic transitions in systems formed by alkali and rare-earth metal tungstates and molybdates. The solubility of magnesium, calcium, aluminium, lanthanum, neodymium, and zirconium oxides in $NaF-MgF_2$ melts and of lanthanum oxide in the $NaF-MgF_2(CaF_2, SrF_2, BaF_2)$ systems is under investigation.

Methods for the preparation and separation of novel compounds with special properties are being elaborated. The number of intermetallic compounds studied—binary, ternary, and multicomponent—has now reached 10 000; compounds of metals with non-metals—oxygen, hydrogen, nitrogen, silicon, boron, carbon—are also under investigation. Many of them possess special properties such as superconductivity, high-temperature strength, and hardness. A method has been worked out for obtaining intermetallic compounds with specified electrical and mechanical properties. Especially hard alloys are based on carbides of different metals—tungsten, titanium, cobalt, molybdenum, iron, etc. (N.S. Umanskii, G.V. Samsonov, V.I. Eremenko, I. I. Frantsevich, V. E. Ivanova, and others). A process has been worked out and realised under industrial conditions for the production of titanium carbonitride, from which can be obtained alloys at least as hard as those based on tungsten carbide.

Methods have been elaborated for the low-temperature preparation of oxonitrides, oxophosphides, and oxoborides of several transition metals (Yu. A. Buslaev). The properties of molybdenum disilicide, which possesses enhanced high-temperature strength, have been studied, and the production of heaters for high-temperature furnaces has been established.

A. G. Merzhanov proposed the self-propagating high-temperature synthesis method to obtain refractory compounds. Table 1 lists compounds of different classes obtained by this method (more than seventy are known), and shows that almost all of them possess properties such as heat resistance, chemical stability, hardness, etc. that are important for practical application. Compounds having melting points above 3500°K—TaC, HfC, NbC, ZrC, HfN, TaB_2—are especially interesting. A method has been worked out for obtaining zirconium carbide, one of the main constructional materials in nuclear technology. Conditions have been found under which the product has a high degree of purity.

Metallic compounds exhibiting superconductivity at the temperature of liquid helium are of great interest; about a thousand such compounds are known at the present time.

[Quantum Inorganic Chemistry]

The quantum chemistry of inorganic compounds is a young branch of inorganic chemistry, which has greatly developed only during recent years. Work in this field is done at the Institute of General and Inorganic Chemistry and the Institute of New Chemical Problems of the USSR Academy of Sciences, the Institute of Physical Chemistry of the Ukrainian SSR Academy of Sciences, the Institute of Chemistry of the Moldavian SSR, and other establishments.

During the 1950–1960s Ya. K. Syrkin and M. E. Dyatkina put forward several principles to form the basis for the further development of theoretical inorganic chemistry. Aspects of the participation of unshared pairs and vacant orbitals in chemical bonding were studied, a critical analysis was given of the concept of effective charge, and questions of chemical reactivity were considered.

Table 1. Compounds obtained by "spontaneously propagated high-temperature synthesis".

Compounds	Group in Periodic Table (metals)							Principal properties
	II	III	IV	V	VI	VII	VIII	
Nitrides	Mg_3N_2	BN AlN	TiN, ZrN, HfN	VN, NbN, TaN, Ta_2N	—	—	—	heat resistance, super- and semi-conductivity, chemical resistance, electrical and thermal insulation
Carbides	—	—	TiC, ZrC HfC, SiC	VC NbC, NbC, Nb_2C, TaC	WC	—	—	high m.p., great hardness, abrasives
Borides	MgB_2, MgB_4, MgB_6	—	TiB, TiB_2, ZrB_2, ZrB_4 HfB, HfB_2	VB, VB_2, NbB, NbB_2, TaB, TaB_2	CrB, CrB_2, MoB, Mo_2B, MoB_2, Mo_2B_5, WB, W_2B, WB_2	MnB	FeB NiB	resistance to molten metals, abrasive, small capture cross-section for neutrons
Silicides	—	—	TiSi, TiSi ZrSi, $ZrSi_2$	—	$MoSi_2$	—	—	high resistance to high-temp. oxidation
Chalcogenides			TiSe	$NbSe_2$, $TaSe_2$	MoS_2, $MoSe_2$	—	—	highly antifrictional
Solid solutions	TiC—WC, Ni—Al, MoS_2—NbS_2, BC—BN, NbC—NbN, TiC—TiN, TaC—TaN, TiB_2—MoB_2, $Nb_xZr_{1-x}C_yN_{1-y}$							great hardness, superconductivity, antifrictional

Calculations of coordination compounds by the method of molecular orbitals were initiated in the Structure Laboratory of the Institute of General and Inorganic Chemistry. Calculation of the ferrocene molecule (M. E. Dyatkina, E. M. Shustorovich) was an important stage in the development of a native quantum chemistry. The first non-empirical programme in our country for calculations of inorganic compounds by means of an electronic computer was worked out in the same laboratory jointly with the Lomonosov Moscow Institute of Fine Chemical Technology (M. E. Dyatkina, N. M. Klimenko, V. K. Belov, E. L. Rozenberg). Many fluorides and oxy-anions of non-transition elements have been calculated by means of this programme, which is used in several Soviet and foreign laboratories.

In the Institute of General and Inorganic Chemistry of the USSR Academy of Sciences a theory is being developed and systematic investigations are being made on X-ray-electron and X-ray spectra (V. I. Nefedov). Calculations are being made of the electronic structure of inorganic crystals (A. A. Levin).
