In the Institute of Physical Chemistry of the Ukrainian SSR Academy of Sciences, under the direction of K. B. Yatsimirskii, a series of studies have been made on the application of crystal-field theory to atoms having f-electrons, experimental and theoretical work has been done on the interaction of ligands, and the role of the symmetry of the last occupied and first vacant molecular orbitals for the physicochemical characteristics of inorganic compounds has been established. In the Institute of Chemistry of the Moldavian SSR systematic investigations are being made on vibronic interactions, and chemical aspects of the Jahn–Teller effect are being studied (I. B. Bersuker). Calculations of atomic orbital energies have been made in the Institute of New Chemical Problems, and the results have been used to analyse the stereochemistry and thermodynamics of inorganic compounds.

Comprehensive calculations have been made on the fluorides of the inert gases (O. P. Charkin).

Increasing attention is now being paid to quantum-chemical calculations. Quantum chemistry provides the theoretical foundation for interpreting the results of physical investigations on inorganic compounds.

Crystal Chemistry

The development of crystal chemistry in our country is associated with the names of A. E. Fersman, A. F. Kapustinskii, N. V. Ageev, A. I. Kitaigorodskii, and other scientists.

The work of E. S. Makarov led to formulation of the principle of the structure of "interstitial phases" and to elucidation of the structure of berthollides and daltonides. G. B. Bokii examined processes of ordering in solid solutions, which suggested a crystal-chemical criterion for the composition of an ordered system. B. F. Ormont considered structural and thermodynamic aspects of the chemistry of defective crystals and phases of variable composition, as well as problems of interpreting the physicochemical properties and structure of real crystals.

V. G. Kuznetsov, G. B. Bokii, Z. G. Pinsker studied the crystal structure of semiconducting compounds. A systematic description has been given of the structure of several types of semiconductors.

N. V. Belov showed that a second, diortho-group Si_2O_7 exists in addition to the main Bragg structural unit—the orthosilicate tetrahedron—and that the "configuration" of silicate structures is determined primarily by the cations.

The crystal chemistry of minerals and their synthetic analogues has been developed by E. S. Makarov, V. A. Frank-Kamenetskii, Yu. A. Pyatenko.

Neutron diffraction, the Mössbauer effect, and other methods have been used to investigate double oxides A_2BO_5, and also ferroelectrics, antiferroelectrics, and ferromagnetics. This led to a crystal-chemical theory of ferroelectricity and to a new class of compounds—ferroelectromagnetics (G. S. Zhdanov).

An important branch of crystal chemistry is the study of complex compounds (G. B. Bokii, M. A. Porai-Koshits, G. S. Zhdanov, A. V. Ablov, T. I. Malinovskii, A. I. Kitaigorodskii, and others). The work of crystal chemists made it possible to establish the structure of various types of complexes, interpret their properties, and lay the foundation for theoretical concepts. Systematic structural investigations on compounds of cobalt, nickel, copper, zinc, palladium, and platinum established regularities in exchange of the coordination polyhedron and several peculiarities of the metal–ligand bond (Porai-Koshits).

Chemistry of Complex Compounds

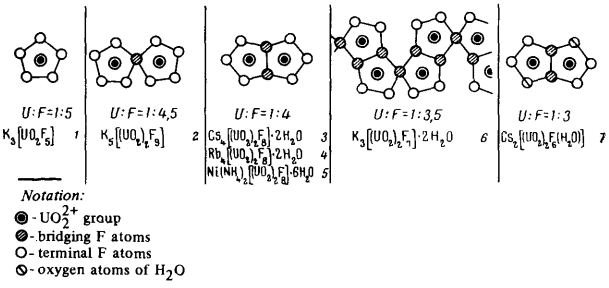
The founder of the chemistry of complex compounds in the Soviet Union was L. A. Chugaev, who discovered several inner-complex compounds of platinum, nickel, and other metals, and established the "rule of rings". The coordination theory of the structure of complex compounds was developed by L. A. Chugaev, I. I. Chernyaev, A. A. Grinberg, V. V. Lebedinskii, B. V. Nekrasov, N. K. Pshenitsin, and many other investigators. Chernyaev's rule of the *trans*-effect of ligands in complexes having a square configuration of the inner sphere underlay the study and preparation of new coordination compounds of platinum, rhodium, palladium, and other noble metals. Grinberg observed also a weaker *cis*-effect of ligands. He based a theory of the acid–base properties of complex compounds on platinum(II) complexes as example.

Several comprehensive investigations have recently been published on the interaction of ligands—a central trend in the chemistry of coordination compounds—revealing finer aspects of the metal–ligand bond. To them may be added an interesting treatment of the *trans*-effect (I. B. Bersuker, A. V. Ablov), K. B. Yatsimirskii's discovery of a kinetic effect in the interaction of ligands and the channels through which it is transmitted in complexes, and the establishment of a model of the *trans*-effect in six-coordinated complexes of transition metals containing a multiple metal–ligand bond (E. M. Shustorovich, Yu. A. Buslaev, M. A. Porai-Koshits).

Dozens of previously unknown complexes of platinum, rhodium, iridium, thorium, uranium, cobalt, nickel, iron, copper, zinc, and other metals have been obtained with various types of ligands containing nitroso-, nitro-, thiocyanato-, cyano-, and sulphato-groups. More than sixty new compounds of uranium and thorium were prepared in 1972 alone.

Developing the chemistry of the actinides, I. I. Chernyaev and R. N. Shchelokov established the law of the replacement of ligands in coordination compounds of uranyl and related complexing groups, which enabled them to prepare many new uranyl compounds. Examination of fluoride complexes of uranyl by X-ray diffraction (Yu. N. Mikhailov) revealed the presence of diverse structural motifs [Table 2].

Table 2.



Procedures based on complex formation have been worked out for separating many valuable metals, e.g. the platinum metals and gold, under both industrial and laboratory conditions. A method has been suggested for isolating copper, silver, and gold by means of sodium tetrahydroborate in the presence of complexing agents from baths used for the deposition of coatings.

Genetic series of complex compounds of uranium, thorium, plutonium, and zirconium have been obtained (I. I. Chernyaev, V. A. Golovnaya, G. V. Ellert, R. N. Shchelokov). Significant differences between complex compounds of radioactive elements and those of platinum metals are evident in the structure of the coordination sphere, the absence of a pronounced *trans*-effect, and a great "affinity" for oxygen-containing, not for nitrogen-containing, ligands. Many compounds predicted by coordination theory have been prepared.

I. V. Tananaev made a systematic study of fluoride and oxofluoride compounds of uranium, plutonium, and thorium, and the higher fluorides of elements of the chromium subgroup, vanadium, and titanium. He developed fluoride processes for the refining of uranium-containing materials.

D. I. Ryabchikov discovered the existence of a large new class of complex compounds of rare-earth metals, whose stability increased with atomic number from lanthanum to lutetium. An important role in the separation of rare-earth metals by the most diverse methods—liquid extraction, ion-exchange chromatography, fractional crystallisation, cathodic reduction—is played by complex formation. A new method of separation—partial complex formation—has been developed. New analytical procedures for rare-earth metals have also been established.

Heteropoly-compounds were investigated by E. A. Nikitina, and inner-complex compounds by S. A. Voznesenskii. A theory that complex formation is amphoteric in character was based on complexes having a non-metallic central atom (Ya. A. Fialkov). The thermodynamic and thermochemical parameters of complexes, used to determine their stability, have been studied by Yatsimirskii.

Direct experimental evidence has been obtained for the existence of stable complex molecules in the gas phase. Equimolecular complexes—$NaBeF_3$, $NaAlF_4$, $NaZrF_5$—and higher complexes—Li_2BeF_4, $(LiAlF_4)_2$, etc.—have been detected.

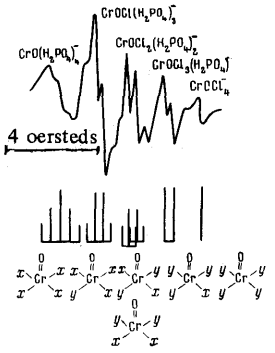


Figure 37. Electron spin resonance spectrum of chromium(V) complexes dissolved in phosphoric and hydrochloric acids.

The application of physical and physicochemical research methods—spectropolarimetry, dielectric measurements, electron spin resonance, nuclear magnetic resonance, etc.—will give valuable information on the structure of complex compounds. K. I. Zamaraev and N. N. Tikhomirova used e.s.r. to investigate the reactions of copper and molybdenum complexes. This method was combined with ultraviolet and infrared spectroscopy to study copper and cobalt complexes. A. N. Ermakov, P. N. Marov, and G. M. Larin are using e.s.r. to study the formation in solution, the nature of the bond, and the structure of coordination compounds of molybdenum(V), chromium(V), cobalt(II), copper(II), vanadium(IV), europium(II), and other paramagnetic ions. Labile *cis*- and *trans*-isomers of coordination compounds of yl ions (oxo-cations) have been discovered in a series of molybdenum(V) and chromium(V) complexes. Fig. 37 illustrates the e.s.r. spectrum of chromium(V) complexes dissolved in phosphoric and hydrochloric acids.

A theoretical model has been constructed for the interaction of ligands attached mainly by σ-bonds to the central atom. The *cis*-effect has been explained for compounds of non-transition elements from a single approach (V. I. Nefedov, Yu. A. Buslaev).

Chemistry of Rare Elements, Semiconducting Compounds, and Materials for Quantum Electronics

It is very important to obtain pure and superpure rare-earth metals, many of which could be separated only after the appearance of nuclear power and the production of their radioactive isotopes. A technology has also been elaborated for the production of pure zirconium, a constructional material for atomic reactors. This problem was one of the most difficult in the chemistry of the rare elements. Methods have been worked out and introduced into industry for obtaining ultrapure tellurium and selenium, necessary for the preparation of semiconductors, rubidium, caesium, beryllium, scandium, and germanium. The chemistry of simple and complex compounds of more than thirty rare elements (halides, oxides, phosphates, chalcogenides, acido-complexes with molecular ligands and with a metal–metal bond) is being studied in the Division of Rare Elements of the Institute of General and Inorganic Chemistry of the USSR Academy of Sciences (I. V. Tananaev).

During recent years new applications and new methods of isolation have been found for rare elements. For example, phosphors have been based on lanthanum and ytterbium orthophosphates activated with europium and terbium. Phosphors emitting in a specific region and very durable high-temperature binding materials have been obtained from scandium and gallium phosphates. Several procedures have been worked out for obtaining the spectra of sexivalent rhenium compounds in solution and determining their parameters, which are important for technical processes. New compounds of rhenium have been obtained, as well as polymeric compounds of this metal with heterochains. The problem of producing the ion-exchange resins required for purifying rare elements has been solved. Methods of separation by means of complex formation have been developed.

Many studies are connected with the chemistry of semiconductors. Carbides, silicides, fluorides, and borides of rare elements possess valuable properties. An important trend is the production of ceramet articles and glasses with additions of cerium, neodymium, praseodymium, and other metals.

The chemistry of semiconducting compounds, which has developed during recent decades, forms a separate branch of inorganic chemistry. Solutions have been obtained for the problem of obtaining highly pure germanium (N. P. Sazhin, D. A. Petrov, I. P. Alimarin, I. V. Shmanenkov, and others), silicon (B. A. Sakharov, M. I. Iglitsyn, and others), selenium, and tellurium. Semiconducting properties have been found in grey tin (A. I. Blum, N. A. Goryunova).

Semiconducting binary compounds were obtained by G. G. Urazov, N. A. Goryunova, A. R. Regel', N. P. Luzhna. The types of compounds that are now being prepared and studied are $A^{III}BV$ (BN, AlN, GaP, BP, BAs, InP, etc.), $A^{II}BVI$ (ZnS, ZnSe, ZnTe, CdS, HgS, etc.), $A_2^{III}B_3^{IV}$

(chalcogenides of gallium, indium, and thallium), chalcogenides of rare-earth metals, and many others. Bismuth and antimony chalcogenides are most often used for the production of semiconductors, and arsenic sulphides and selenides for semiconducting glasses. Semiconducting properties have been observed in many oxides (Cu_2O, ZnO, V_2O_5, UO_2, etc.), nitrides, carbides, and silicides of chromium, boron, manganese, iron, etc.

Many more complicated semiconducting compounds—$CuFeS_2$, $AgFeTe_2$, $Cu(Ag)Ge_2P_3$, $Cu_2(Ag_2)SnS_3(Se_3, Te_3)$, etc.—have been prepared and studied during recent years. Several criteria have been suggested for predicting the presence of semiconducting properties in tetrahedral ternary phases (N. A. Goryunova, V. P. Zhuze). Methods used to prepare semiconducting compounds comprise the decomposition of more complicated compounds, chemical transfer reactions, syntheses with counter-pressure, gas-phase reactions, purification by zone melting, etc.

Techniques have been developed for preparing semiconductors having specified properties. Materials have been produced for obtaining filamentous alloyed silicon crystals by gas-diffusion reactions. They have been used as a basis for sensitive miniature strain resistors and temperature and pressure sensors. A new process has been found for obtaining weakly alloyed epitaxial films of gallium arsenide on a strongly alloyed support. A rotating container heated by light has been suggested for growing crystals.

Several semiconducting compounds, e.g. antimony thioiodide, possess both piezoelectric and ferroelectric properties, which makes them promising for use in radioelectronics. Pressure–temperature–composition diagrams have been studied for the antimony(bismuth) iodide—sulphide(selenide) systems, which include the semiconducting ferroelectrics SbSI, BiSI, SbSeI, and BiSeI. Conditions for growing single crystals of these compounds from the gas phase and from the melt have been optimised. Single crystals of considerable size have been obtained with certain of them. Fundamental investigations have been made on complex phosphides and arsenides of the type $A^{II}B^{IV}C_2^V$, which show prospects for semiconductor and laser technology.

Physicochemical methods of analysis are used to obtain "equilibrium microdiagrams" for semiconductors and alloying additives (V. M. Glazov, V. S. Zemskov). These investigations make a considerable contribution to the theory of the alloying of semiconductors. Ternary systems based on antimonides of aluminium, gallium, indium, etc. have been examined. Departures from stoichiometry are under investigation (N. Kh. Abrikosov, M. S. Mirgalovskaya, and others). Physicochemical principles are being elucidated for the preparation of semiconducting materials, based on lead chalcogenides and their solid solutions, with specified properties (A. V. Novoselova and Ya. I. Gerasimov). Procedures have been worked out for the polarographic monitoring of the composition of single crystals with preliminary separation of the elements by ion-exchange chromatography.

Considerable progress has been made in the chemistry of materials for quantum generators and paramagnetic amplifiers. Special methods have been developed for growing crystals (S. A. Peskovetskii) and for producing crystals with a uniform distribution of impurities (S. V. Grum-Grzhimailo), and manufacture of the necessary compounds—the ethyl sulphates of lanthanum, gadolinium, and cerium, corundum (S. K. Popov), fluorite (I. V. Stepanov, B. P. Feofilov), calcium tungstate, etc.—has been set in motion. A search is being made for new materials for quantum electronics, in particular the production of chemical lasers (V. L. Tal'roze), and lasers based on liquid and vitreous media (G. V. Ellert). Methods are being worked out for obtaining ultrapure materials for the microelectronic, semiconductor, and other industries (G. G. Devyatykh).

Radiochemistry

Radiochemistry, which arose after the discovery of radioactivity by Henri Becquerel, began to develop in Russia at the beginning of the twentieth century, mainly in the laboratories of Moscow and St. Petersburg Universities. Study of the radioactive elements and their practical application have been the concern of V. I. Vernadskii, L. S. Kolavrat-Chervinskii, N. N. Beketov, A. P. Sokolov, V. I. Spitsyn, E. S. Bersuker, L. V. Pisarzhevskii, V. A. Borodovskii, K. P. Yakovlev, and many others.

V. G. Khlopin, B. A. Nikitin, A. E. Polesitskii, P. I. Tolmachev, M. A. Pasvik, A. P. Ratner, I. E. Starik investigated the partition of elements between a crystalline phase and a solution, and formulated a rule linking the distribution of trace elements with chemical composition and molecular structure.

Investigations of the distribution of compounds of radioactive elements between two liquid phases and the fundamental problems of extraction are of great practical importance (B. A. Nikitin, V. M. Vdovenko, V. V. Fomin, A. V. Nikolaev, I. P. Alimarin, Yu. A. Zolotov, and others). On the basis of these investigations extraction methods were worked out for the complete and partial separation of the radioelements in lumps of uranium, the isolation of uranium and other elements from industrial wastes, the separation of rare-earth metals, the partition of lanthanides from actinides, etc. Ratner put forward a quantitative theory of adsorption, which is important for separating rare elements on adsorbents and ion exchangers. Studies in this field were made by B. P. Nikol'skii, B. N. Laskorin, A. M. Trofimov, V. I. Paramonova.

Aspects of the qualitative and quantitative analysis of mixtures of rare-earth metals by ion exchange and complex formation, partition and paper chromatography, have been investigated by A. P. Vinogradov, D. I. Ryabchikov, K. V. Chmutov, A. K. Lavrukhina, and others. Significant results were obtained by A. D. Gel'man on the separation of transuranium elements—neptunium, plutonium, americium—by means of complexing agents. Starik examined the state of a substance under conditions of extreme dilution.

Radiochemical analysis—the separation, identification, purification, and quantitative determination of radioisotopes in natural specimens, irradiated targets, etc.—is very important in present-day radiochemistry. The analytical principles were worked out by Vinogradov, Khlopin, Polesitskii, Starik. Methods for the radiochemical analysis of the fission products of heavy nuclei and isotopes formed by the action of neutron and other types of irradiation have been elaborated by B. V. Kurchatov, Yu. M. Tolmachev, V. P. Shvedov, and others.

The establishment of nuclear reactors and accelerators led to the synthesis of new elements—from neptunium to element 107. G. N. Flerov was the first to synthesise elements having atomic numbers 104 and 105. Methods were worked out for isolating elements 106 and 107 from the products of the action of accelerated xenon ions, and for their identification.

Hitherto unknown isotopes and compounds have been obtained. The existence of californium, einsteinium, and fermium in the bivalent state has been discovered. V. I. Spitsyn, N. B. Mikheev, together with scientists at the Joint Institute for Nuclear Research (in the town of Dubna), obtained univalent mendelevium for the first time, the first element to be obtained in this state of oxidation, which is abnormal for actinides. An. N. Nesmeyanov developed a technique and regulations for obtaining technetium (No. 95) from a niobium and molybdenum target that had been exposed in a cyclotron, by extraction with an aliphatic ketone from sulphate solutions containing small quantities of fluoride and nitrate ions. B. F. Myasoedov developed a chromatographic method of ultrapurification from contamination with californium, providing a source of neutrons for small-scale equipment.

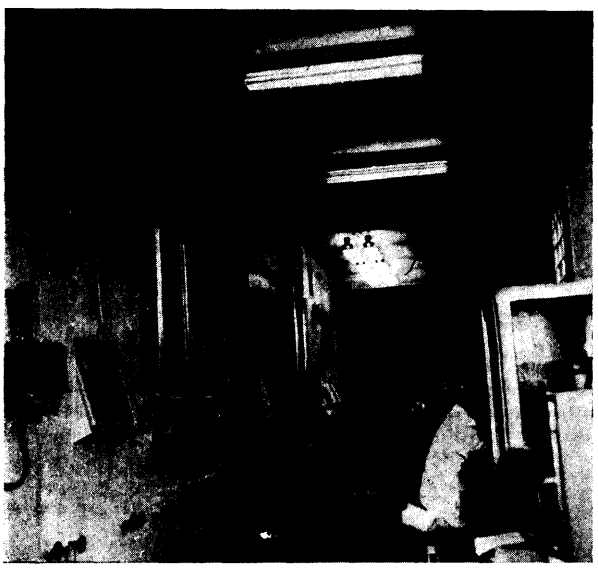

Figure 38. "Hot chambers" for work with highly radioactive substances (Institute of Physical Chemistry of the USSR Academy of Sciences).

Lavrukhina designed and constructed assemblies of low-background radiometric units permitting the examination of minute quantities of radioactive isotopes (down to 1 disintegration min^{-1} kg^{-1}) in large quantities of material (up to 1 kg). A method was proposed for determining subatmospheric dimensions of meteorites by radiochemical analysis of radioactive isotopes. A series of researches has been completed on the radiochemical analysis of the content of the cosmogenic isotopes—aluminium-26 and sodium-22—in a lunar regolith supplied by the automatic station Luna-16.

Great attention is being paid to the contamination of the environment with radioactive materials, the burial of wastes, the estimation of radioactivity in the vicinity of atomic installations, and problems of dosimetry (Spitsyn). An investigation of the behaviour in sea-water of fission products from a nuclear fuel (plutonium-239, ruthenium-106, technetium-99, cobalt-60, manganese-54, etc.) has been completed by V. V. Gromov. Study of the behaviour of radioactive isotopes and elements during their bioassimilation by phytoplankton under natural conditions in the South-eastern region of the Pacific Ocean has shown that radioactive fission products are efficiently assimilated and concentrated by the phytoplankton within 1–2 days. This promotes rapid transmission of the fission products of a nuclear fuel along the biological chain.

phytoplankton → zooplankton → fishes → man

which is a further justification for demanding a ban on the dumping of fission products in the ocean.

Almost all radioactive and stable isotopes—cobalt-60, caesium-137, strontium-90, phosphorus-32, iodine-131, boron-10, nitrogen-15, carbon-13, etc.—are now produced in the Soviet Union.

Chemistry of Natural Salts

The Soviet Union occupies the leading position in the world with respect to reserves, richness, and variety of composition of natural salts and brines.

Physical chemists and chemical hydrologists have made laboratory and field investigations of salt lakes in various regions of our country—the Crimea, Western and Eastern Siberia, the Caspian Depression, etc.—in which an important part was played by N. S. Kurnakov, V. I. Nikolaev, V. P. Il'inskii, S. Z. Makarov, B. L. Ronkin, I. N. Lepeshkov, M. G. Valyashko, Yu. P. Nikol'skaya, A. V. Nikolaev, and many others. New mineral salts were discovered, industrial methods for extracting salts were developed, and the salt equilibria in the lakes were studied, which contributed to optimising technical processes for the isolation of salts from natural brines.

In order to establish the genesis of the natural salts, systematic investigations were made of the solubility and other properties of complicated systems containing sulphates, hydrogen carbonates, carbonates, chlorides, and other salts. The results provided a justification for existing methods or led to new technical processes for obtaining salts from natural brines. S. I. Vol'fkovich worked out a process for converting mirabilite into sodium carbonate and ammonium sulphate—a valuable nitrogen fertiliser.

Investigations of great value for the national economy were made on potassium–magnesium deposits in the Solikamsk District, the Ural, Carpathian and Volga salt beds, where deposits having an increased potassium content and minerals containing boron were discovered, the potash beds of the Hissar Ridge and Tyubeg-tan in Uzbekistan, gameto-glauberitic deposits on the Tyan'-Shan in Kirgizia, deposits of epsomite, common salt, and gypsum in the Uzboi river bed in Turkmenia, and sylvinite–carnallite deposits at Starobino in Belorussia.

Phosphate beds have been investigated, and methods developed for enriching them and converting them into fertilisers, phosphorus, phosphoric acids, and other products (E. V. Britske, S. I. Vol'fkovich, A. I. Shereshevskii, N. N. Postnikov, M. L. Chepelevetskii, N. S. Kurnakov, A. G. Bergman, M. I. Ravich, L. G. Berg, F. M. Perel'man, A. B. Bekturov, M. N. Nabiev, M. E. Pozin, and many others). Thanks to these investigations the Soviet Union is able, not only to avoid importing phosphate minerals, but also to export its production to other countries.

The phase constitution, solubility, and thermal decomposition of natural carbonates and sulphates formed by the evaporation of sea-water have been examined. (These

compounds are used in water installations and for the production of building materials, plastics, and heat-insulating materials.) Ravich showed that salts that are almost insoluble in water under normal conditions become soluble at high temperatures (up to 600°C) and water-vapour pressures (up to 2500 atm). Problems involved in an optimal technology for processing natural deposits are being solved.

Great attention is being paid to detecting rare and trace elements, and isolating them from the salt ores. Thermographic, microthermal, and high-speed thermographic methods of analysis have been developed for this purpose, together with dilatometric phase analysis.

The chemistry of silicates is the basis of many important industries—cement, glass, ceramics, refractories, etc. Its task is to study methods for the preparation of silicate materials and their properties, as well as the processes occurring in them during operation. Silicate chemistry directly related to the technology of silicate manufacture has been the concern of N. V. Belov, P. A. Rebinder, P. P. Budnikov, N. A. Toropov, and many others.

Studies have been made on the structure of cement, the relation between its properties and mineralogical composition, the effect of mineralisers on processes of exchange, the processes involved in firing, and setting. Causes of the corrosion of cements have been elucidated, and measures developed for combating it (A. A. Baikov, S. I. Druzhinin, B. S. Shvetsov, and others). Technical processes have been worked out for obtaining special types of cement by the use of new types of raw material and industrial wastes, activators, surface-active additives, plasticisers, etc. The setting of cements at high temperatures and pressures has been investigated in connection with the production of ferroconcrete, polymer cement, etc. articles (M. M. Sychev, V. I. Korneev, V. N. Yung, V. A. Kind, B. V. Volkonskii, P. F. Konovalov, S. D. Makashev, V. B. Ratinov, O. P. Mchedlov-Petrosyan, S. I. Druzhinin, B. S. Shvetsov, I. L. Znachko-Yavorskii, A. P. Kreshkov, and many others).

Research has been undertaken on the chemistry of glass (D. S. Rozhdestvenskii, N. N. Kachalov, I. V. Grebenshchikov, G. Yu. Zhukovskii, A. A. Lebedeva, I. I. Kitaigorodskii, M. A. Bezborodov, M. A. Matveev). The technology of quartz glass has been developed by M. S. Maksimenko. Studies have been made to improve industrial processes and find ways of producing glass with special properties, glass–enamel refractory coatings, organosilicate materials, etc.

Recent decades have seen the establishment of a new branch of chemical science—the chemistry of the solid state—which studies chemical processes involving solid phases, determines the relation between the reactivity of solids and structural features, and elaborates a general theory of the controlled formation of solid compounds with the aim of producing effective new materials for present-day technology.

ANALYTICAL CHEMISTRY

Research on analytical chemistry in the Academy of Sciences originated with M. V. Lomonosov, who established the principles of quantitative chemical analysis and made numerous analyses of salts, minerals, and ores. Great contributions to the development of analytical chemistry were subsequently made by T. E. Lovits, V. M. Severgin, G. I. Gess [Hess], F. F. Beil'shtein [Beilstein].

During the early years of the Soviet State development began of a theory and new methods of analytical chemistry, especially those involved in solving applied problems of importance for the national economy. L. V. Pisarzhevskii, N. A. Tananaev, I. P. Alimarin, A. K. Babko, A. M. Dymov, and many others assisted in studying the natural resources of the country. Research was undertaken on the composition of rocks and minerals, as well as the contents of rare elements in various natural materials, and standard methods of analysis were developed for heavy chemical industry, metallurgical processes, ores, and useful fossils (V. I. Vernadskii, K. A. Nenadkevich, I. D. Borneman-Starynkevich, and others). Directly related investigations were made on the degree of purity of chemical compounds and the preparation of pure chemical reagents (V. V. Longinov, E. S. Przheval'skii, A. V. Rakovskii, A. E. Uspenskii).

Problems connected with developing chemical and physical methods of controlling the production of radium, uranium, and vanadium, separating them, and concentrating them were solved under the direction of V. G. Khlopin.

During the 1920–1930s analytical methods were developed for controlling production in works laboratories and for rapid analysis (N. A. Tananaev, A. M. Dymov, E. S. Przheval'skii, V. D. Voznesenskii, F. K. Gerke, I. P. Alimarin, A. M. Zan'ko, I. V. Tananaev, G. S. Landsberg, and others). Colorimetric, spectral, electrometric, and other methods of analysis became widely used. Great attention was paid also to standardising analytical methods.

The need to determine impurities in reagents and small quantities of rare elements in natural materials led to the appearance during the 1920s of special new, highly sensitive methods, including spot tests. A non-destructive method of analysis was developed for metals and alloys, as well as a fractional method of analysis (N. A. Tananaev).

Analysis by examining crystals under the microscope, established long ago by Lovits, was further developed. L. A. Chugaev, V. G. Khlopin, O. E. Zvyagintsev used a colorimetric method to analyse metals of the platinum group. Nikol'skii developed a method of potentiometric titration, and subsequently the theory of the glass electrode. Establishment of the first polarographic laboratories in our country is associated with the names of V. I. Vernadskii and A. P. Vinogradov. Internal electrolysis was established by Yu. Yu. Lur'e and Yu. A. Chernikhov, a sedimentometric method by N. A. Figurovskii, and a new form of volumetric analysis, vanadatometry, by V. S. Syrokomskii. The classic methods of analysis—gravimetric, titrimetric (A. K. Babko, I. V. Tananaev, I. P. Alimarin, I. M. Korenman, A. I. Busev, R. P. Lastovskii, and others)—have not lost their value. In the field of photometric analysis much attention has been paid to studying the mechanism of colour reactions, the processes of complex formation in solution. New reagents have been produced for the qualitative and quantitative determination and separation of almost all elements (V. I. Kuznetsov, N. S. Poluektov, S. V. Savvin, A. M. Lukin, and others).

Theoretical principles underlying the present search for new highly sensitive reagents have been established by L. M. Kul'berg (principle of functionally analytical and analytically active groups, and of the role of the nature of the metal) and by Kuznetsov (problems of the appearance of colour, use of the intramolecular dissociation of cyclic salts, mechanism of reactions with organic precipitants, etc.). N. P. Komar' studied the photometry of multicomponent mixtures, and K. B. Yatsimirskii developed a kinetic method of analysis. The luminescence method of

analysis established by S. I. Vavilov has been developed by M. E. Konstantinova-Shlezinger, E. A. Bozhevol'nov, D. P. Shcherbov, A. V. Karyakin, and others.

Spectral emission analysis is widely used to analyse metals, alloys, ores, and high-purity materials (D. S. Rozhdestvenskii, S. E. Frish, V. K. Prokof'ev, S. A. Borovik, A. N. Filippov, G. S. Lansberg, B. A. Lomakin, A. K. Rusanov). A rapid and accurate method of flame photometry has been developed by Poluektov. Studies by N. I. Tarasevich, V. V. Nedler, A. N. Zaidel' have been concerned with methods for the spectral analysis of ultrapure substances. A theory of emission spectroscopy has been elaborated during recent years, and processes occurring at the electrodes have been studied, as well as the mechanism of the vaporisation of material, excitation in the gas phase, etc. New modifications of the method are applied, in particular with the use of lasers. X-Ray spectral analysis has been developed by I. B. Borovskii, M. A. Blokhin, N. P. Il'in, N. F. Losev, Ya. E. Vainshtein This method is successfully applied to the analysis of metals, alloys, minerals, cements, and slags, as well as for phase analysis.

Polarography is widely used by A. M. Dymov, T. A. Kryukova, V. F. Toropova, I. P. Alimarin, S. B. Tsfasman. The theory of amalgam polarography is due to A. G. Stromberg; with accumulation on the mercury drop this method has been developed by S. I. Sinyakova, E. N. Vinogradova, A. G. Stromberg. Amperometric titration is widely used by I. P. Alimarin, O. A. Songina, Yu. I. Usatenko, V. A. Khadeev, and others. Potentiometric titration was further developed by N. A. Izmailov and then by A. P. Kreshkov, especially in non-aqueous media. High-frequency titration (V. A. Zarinskii) is used for the analytical control of production.

A promising and accurate coulometric method of titration has been used by M. S. Zakhar'evskii, A. Ogarev, F. I. Grishin. Several theoretical methods in the field of coulometry have been developed by P. K. Agasyan, who has studied the interrelationship among the various electrochemical methods.

Gas analysis forms a separate branch of analytical chemistry. Gas analysers of various types, in particular photocolorimetric, have been produced. Determination of the content of gases in metals, which is extremely important for the metallurgical industries, began to be developed by N. P. Chizhevskii, P. S. Lebedev, Yu. A. Klyachko, Z. M. Turovtseva.

Gas-chromatographic analysis, which is widely employed at the present time both for analytical and preparative purposes in scientific research and for the control of production, is sensitive, accurate, and simple. Such methods have been developed by A. A. Zhukhovitskii and N. M. Turkel'taub, who have elaborated new forms—chromathermography, a dynamic thermal method, vacancy chromatography, stepwise chromatography, chromatography without a carrier gas. V. G. Berezkin has studied the application of gas chromatography to analytical chemistry.

Mass spectroscopy is used to analyse solids—pure substances, semiconductors, materials for nuclear technology. V. L. Tal'roze has developed a method combining chromatography and mass spectrometry (chromatographic mass spectrometry).

The development of radiochemistry and the atomic industry provided the opportunity for new radiochemical methods of analysis. Radioactivation analysis has been widely used by I. P. Alimarin and Yu. V. Yakovlev. Natural radioisotopes came to be utilised as indicators. Analytical methods have been based also on the scattering or the absorption of β- or γ-rays. X-Radiometry, isotopic dilution, and radiometric titration have also been developed.

Optical methods of analysis have been widely used. Refractometry has been elaborated by B. V. Ioffe, and spectropolarimetry is successfully applied by A. P. Terent'ev, V. M. Potapov, E. G. Rukhadze.

Special types of analysis—micro and ultramicro—utilise various chemical and physicochemical techniques. Ultramicroanalysis involving use of a microscope has been developed by I. P. Alimarin and M. N. Petrikova. These lines of attack have been applied to the analysis of minerals and ores in geochemistry.

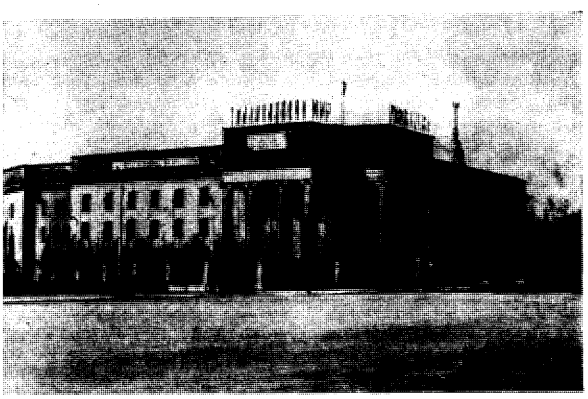

Figure 39. Vernadskii Institute of Geochemistry and Analytical Chemistry.

The problem of the analysis and control of production of atomic materials in our country has been successfully solved (A. P. Vinogradov, P. N. Palei, D. I. Ryabchikov, B. P. Nikol'skii, I. P. Alimarin, I. E. Starik, I. V. Tananaev). The efforts of a group of scientists of the USSR Academy of Sciences and of branch scientific research institutes (I. P. Alimarin, N. P. Sazhin, Yu. A. Zolotov, M. S. Chupakhin, Yu. V. Yakovlev, A. V. Karyakin, Z. M. Turovtseva, L. L. Kupin) have been concentrated on solving the problem of obtaining and analysing pure materials (high-purity metals, semiconducting materials, and chemical reagents).

A considerable contribution to the development of the analytical chemistry of rare elements and rare-earth metals has been made by A. P. Vinogradov, I. P. Alimarin, D. N. Ryabchikov, A. N. Ermakov, M. M. Senyavin, A. I. Ponomareva, and others.

The wide use of synthetic and natural organic compounds in industry and scientific research has stimulated the development of new methods of organic analysis. Important studies are being made in several institutes of the USSR Academy of Sciences on the elementary and functional analysis of organic substances using physical and physicochemical methods (A. P. Terent'eva, M. O. Korshun, V. A. Klimova, N. E. Gel'man).

The wide range of facilities of modern analytical chemistry has been applied in examining materials from the lunar surface procured by Soviet automatic stations.

Unique data have been obtained on the composition and structure of lunar rocks, the significance of which it is difficult to overestimate.

The growth of science and technology presents analytical chemistry with new problems—to enhance accuracy and sensitivity, accelerate the analysis, evolve methods of local analysis and remote analysis, and to automate analytical control.

---o0o---

Within the confines of a single paper, of course, it is impossible to cover all lines of chemical research, even in general form. For this reason there may have been omissions of names, which is especially unfortunate both intrinsically and because the Reviewer feels the deepest respect for his scientific colleagues both of the past and of the present day. Nevertheless, the hope should be expressed that this outline will reinstate in the reader's memory the glorious historic road travelled by chemistry in our country, and recall the herculean, selfless, and enthusiastic labours, filled with romance, of many generations of Russian chemists.

The USSR Academy of Sciences, in celebrating its 250th anniversary, can be justly proud of the names of its illustrious scientific chemists, who over the ages have glorified Russian chemical science.

Intermediate Compounds in Enzymic Catalysis and Their Kinetic Investigation

I.V.Berezin, S.D.Varfolomeev, and K.Martinek

Reactions catalysed by enzymes usually involve the successive formation of several intermediate compounds (enzyme-substrate complexes, covalent intermediates, conformers of the enzyme or the substrate). Kinetic methods have provided a fertile approach to the investigation of such labile intermediates. The Review summarises the kinetic laws of catalytic reactions involving labile intermediates in prestationary and stationary states. The relaxation kinetics of a multistage catalytic reaction is also examined.
The investigation of labile intermediate compounds is inseparably connected with the development of methods of "fast" kinetics. The Review therefore discusses "flow", "flash", and "temperature jump" methods and the possibility of applying them to enzymic reactions. Rather more detailed consideration is given to the formal kinetics of the appearance of intermediate compounds in reactions of the most thoroughly studied enzymes-catalase, α-chymotrypsin, peroxidase, ribonuclease, and aspartate aminotransferase. A list of 236 references is included.

I. INTRODUCTION

Physical organic chemistry is paying increasing attention to research on reactions involving biopolymer catalysts[1,2], because knowledge of the specific mechanisms through which enzymes accelerate chemical reactions should help to elucidate the driving forces of enzymic catalysis. As a result, application of the principles of the action of the active centres functioning in enzymes might facilitate solving the problem of producing selective chemical catalysts with controllable properties[3-5].

The efforts of several scientific biochemical schools during the past decade have produced considerable progress in research on catalysis by enzymes[1,2,6]. Investigations in this field are developing in two main directions: (i) the structures both of enzymes and of the active centres are being studied, the most valuable information being given by X-ray diffraction[7-9]; and (ii) a study is being made of the dynamics of enzymic action, i.e. the sequence of changes undergone by a substrate molecule at an active centre of the enzyme, leading to formation of a product molecule. The present Review is devoted mainly to discussing the achievements of the latter group of investigations.

A fundamental idea in enzymic catalysis is the multistage transformation of substances under the influence of a protein catalyst. This was first pointed out by Michaelis and Menten[10], who concluded that the mechanism of the action of invertase involves formation of an intermediate enzyme-substrate complex (a Michaelis complex)†.

Subsequently a detailed investigation of other enzymic systems confirmed that reactions involving biological catalysts actually comprise the successive formation of several intermediate compounds (non-covalent enzyme-substrate complexes, covalently formed intermediate compounds, conformers of enzyme or substrate). Thus study of the mechanism of enzyme action encounters the specific problem of determining the number and nature of intermediate compounds involved. These intermediates are usually extremely labile, and in rare cases can be isolated in individual form[1]. Chemical kinetic methods have proved very fruitful for investigating such labile intermediates.

The present Review summarises the kinetic laws observed in enzymic reactions, paying attention primarily to the kinetic evidence for intermediate compounds in both transitional and stationary stages of the reaction. More detailed acquaintance with procedural features of the kinetic methods used can be obtained by referring to reviews[1,11-13]. Certain formal kinetic aspects of the investigation of intermediate compounds in enzymic catalysis may prove useful also for analysing other classes of reactions likewise involving labile intermediates.

The simplest general mechanism of a multistage consecutive catalytic reaction occurring on an active centre of an enzyme E and involving a substance S (the substrate) can be written

$$E + S \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} X_1 \dots \underset{k_{-i}}{\overset{k_i}{\rightleftharpoons}} X_i \rightleftharpoons \dots X_n \underset{k_{-(n+1)}}{\overset{k_{(n+1)}}{\rightleftharpoons}} E + P \qquad (1)$$

where the X_i ($i = 1, 2, 3, \dots, n$) are intermediate compounds, P is the reaction product, and k_i and k_{-i} are the rate constants of forward and reverse elementary steps. This scheme covers both unimolecular [k_i, $i \neq 1$, $-(n+1)$] and bimolecular [k_1, $k_{-(n+1)}$] elementary reactions. According to the laws of chemical kinetics a differential equation describing the variation of concentration with time can be written for each of the $n + 3$ participants in the reaction. Only $n + 1$ of the resulting $n + 3$ differential equations are linearly independent, since the variable

† The term "Michaelis complex" often implies the primary non-covalent enzyme-substrate complex. This is not quite exact, since the "saturation" observed in the dependence of reaction velocity on substrate concentration, which indicates the existence of a "Michaelis complex", may represent the presence of any other intermediate compound in the reaction, including one formed covalently. In its general meaning the term "Michaelis complex" represents the totality of intermediate compounds in enzymic catalysis.

component concentrations are related by the two linear algebraic equations of material balance

$$[E]_0 = [E] + \sum_{i=1}^{n} [X_i]$$
$$[S]_0 = [S] + [P] + \sum_{i=1}^{n} [X_i] \quad (2)$$

Thus the progress of all the elementary reactions in scheme (1) with time is described by the set of $n + 1$ differential equations

$$\begin{aligned}
&\frac{d[X_1]}{dt} + (k_{-1} + k_2)[X_1] = k_1[E][S] + k_{-2}[X_2] \\
&\vdots \quad \cdots \\
&\frac{d[X_i]}{dt} + (k_{-i} + k_{i+1})[X_i] = k_i[X_{i-1}] + k_{-(i+1)}[X_{i+1}] \\
&\vdots \quad \cdots \\
&\frac{d[X_n]}{dt} + (k_{-n} + k_{(n+1)})[X_n] = k_n[X_{n-1}] + k_{-(n+1)}[E][P] \\
&\frac{d[P]}{dt} + k_{-(n+1)}[P][E] = k_{(n+1)}[X_n]
\end{aligned} \quad (3)$$

together with the two algebraic equations (2). Simultaneous solution of Eqns. (2) and (3) yields expressions for all the reaction components as functions of time. The above differential and algebraic equations constitute a non-linear set with constant coefficients (non-linear because of the presence of second-order terms containing the products of variable concentrations—$k_1[E][S]$ and $k_{-(n+1)}[E][P]$). A solution can be found by numerical integration on a digital computer[14] or by simulation on an analogue computer[15]. The character of the transitional processes in enzymic reactions involving intermediate compounds has been investigated qualitatively for various initial conditions[16]. However, the possibility of an analytical solution of the set of equations (2) and (3) is of the greatest interest for comparing the reaction mechanism with experimental kinetic results. This task can be simplified considerably by using certain conditions permitting transformation to a linear set of equations. In the kinetic analysis of the mechanism of the action of enzymes three approaches based on the premises simplifying the formal kinetic treatment—(*a*) kinetics of reactions in the transitional stage or "prestationary" kinetics, (*o*) kinetics of steady-state enzymic conversion, and (*c*) relaxation kinetics—have at present found the greatest development and application. These approaches and their application to the investigation of reaction mechanisms will be examined in detail below with reaction (1) as example.

II. TRANSITIONAL STAGE OF REACTION

1. "Prestationary" Kinetics of an Enzymic Reaction

The non-linear set of equations (2) and (3) can be simplified by conducting the bimolecular stages of reaction (1) under pseudounimolecular conditions, i.e. in the presence of a large excess of one of the reactants. Changes in the concentration of this reactant with time can then be neglected, so that the bimolecular terms in the differential equations (3) become linearly dependent only on the variable concentration of one of the reactants. This approach is usually made for the analytical treatment of so called "prestationary" kinetics.

With $[S]_0 \gg [E]_0$ and only slight occurrence of reaction (1) ($[P] \simeq 0$ is formally equivalent to formation of the product P at an irreversible stage of the reaction, $k_{-(n+1)} = 0$) under conditions such that consumption of the substrate can be neglected, $[S] = [S]_0$, the set of equations (2) and (3) becomes

$$\left\{\begin{aligned}
&\frac{d[X_1]}{dt} + (k_{-1} + k_2)[X_1] = k_1[S_0][E] + k_{-2}[X_2] \\
&\vdots \quad \cdots \\
&\frac{d[X_i]}{dt} + (k_{-i} + k_{i+1})[X_i] = k_1[S]_0[E] + k_{-2}[X_2] \\
&\vdots \\
&\frac{d[X_n]}{dt} + (k_{-n} + k_{n+1})[X_n] = k_n[X_{n-1}] \\
&[E]_0 = [E] + \sum_{i=1}^{n} [X_i]
\end{aligned}\right. \quad (4)$$

$$\frac{d[P]}{dt} = k_{(n+1)}[X_n] \quad (5)$$

Several standard procedures—reduction to a single linear differential equation of higher order, application of Laplace transforms, etc.—are available for solving sets of linear differential equations[17]. The method of solution in the kinetic analysis of complicated chemical reactions has been described[18-22], and several approaches to a solution have been discussed for the progress of enzymic reactions[15,23-26]. The use of graph theory for these purposes has been described[27,28].

The general solution of Eqns. (4) is

$$[X_n] = \sum_{j=1}^{n} A_j e^{\lambda_j t} + B \quad (6)$$

where the λ_j are the n eigen values or real roots of the corresponding characteristic equation of order n. The quantity $-1/\lambda_j$ has the dimension of time and is a complicated function of the elementary rate constants of reaction (1). Particular solutions describing the time variation of the concentrations of all intermediate compounds X_i can be obtained from the general solution (6) by introducing initial conditions. The dependence of the concentration of the reaction product on time follows from the differential equation (5) when (6) is substituted and the resulting expression is integrated:

$$[P] = k_{n+1} \sum_{j=1}^{n} \frac{A_j}{\lambda_j} (e^{\lambda_j t} - 1) + k_{n+1} B t \quad (7)$$

Equations (6) and (7) generalise for n intermediate compounds earlier equations obtained for the kinetics of reactions involving one intermediate[29-33]

$$E + S \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} X \xrightarrow{k_2} E + P \quad (8)$$

or two intermediates[15,34]

$$E + S \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} X_1 \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} X_2 \xrightarrow{k_3} E + P \quad (9)$$

Considering scheme (8) in greater detail, we find that the time variation of the concentration of the intermediate X is given by

$$[X] = \frac{k_1[S]_0[E]_0}{k_{-1} + k_2 + k_1[S]_0} (1 - e^{-t/\tau}) \quad (10)$$

Analysis of the curve corresponding to function (10) (Fig. 1*A*) enables the characteristic time τ to be determined. The dependence of τ^{-1} on the substrate concentration

$$\tau^{-1} = k_1[S]_0 + k_{-1} + k_2 \qquad (11)$$

will then yield the formation and decomposition rate constants k_1 and $k_{-1} + k_2$ of the intermediate compound.

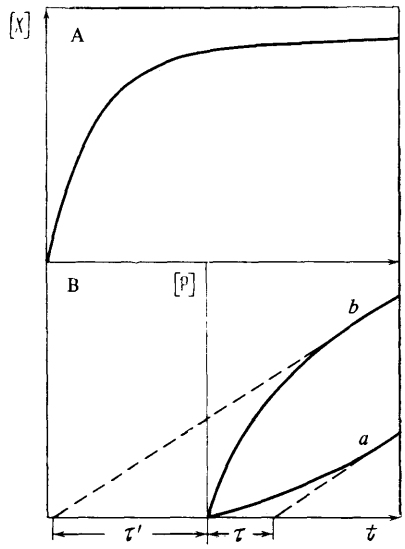

Figure 1. Kinetics of an enzymic reaction involving one intermediate under prestationary conditions.
(A) Dependence of concentration of intermediate compound X on time for the prestationary occurrence of the reaction by mechanism (8). (B) Rate curve for the prestationary formation of the product by different mechanisms:
a) Michaelis–Menten (scheme 8); *b*) Henry (scheme 14).

If direct experimental observation of X is difficult, information on the presence of such intermediate and on the reaction mechanism can be obtained by examining the kinetics of formation of the final product. The concentration of P as a function of time is given [32] by

$$[P] = \frac{k_2[E]_0[S]_0}{[S]_0 + K_m}t + \frac{k_1k_2[E]_0[S]_0}{k_1[S]_0 + k_{-1} + k_2}\left(e^{-(k_1[S]_0 + k_{-1} + k_2)t} - 1\right) \qquad (12)$$

where $K_m = (k_{-1} + k_2)/k_1$. The [P] curve approaches asymptotically a straight line whose slope is the steady-state rate of the process (Fig. 1*B*, curve *a*):

$$v_{stat} = \left(\frac{d[P]}{dt}\right)_{max} = \frac{k_2[E]_0[S]_0}{[S]_0 + K_m} \qquad (13)$$

Formula (11) holds for the observed induction period τ. The presence of an induction period in the product–time curve (in the absence of a chain or autocatalytic reaction) is a reliable indication of the presence of an intermediate (or at least one intermediate—see below). Analysis of the dependence of $(d[P]/dt)_{max}$ and τ on the enzyme and substrate concentrations will enable rate constants to be determined for all the elementary reactions.

Consecutive formation of an enzyme–substrate complex (Michaelis–Menten, scheme 8) and its concurrent formation

$$E + S \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} ES \qquad (14)$$
$$E + S \xrightarrow{k_2} P + E$$

(Henry [35]) can be distinguished by the formal kinetic analysis of enzymic reactions in the prestationary state. Scheme (14), which assumes the formation of an unreactive complex ES and a bimolecular reaction of the substrate with the free enzyme, leads to the steady-rate equation (13) for scheme (8). However, significant differences have been found [36] between the kinetics of reactions (8) and (14) in the prestationary stage. No induction period is present in the product–time curve for reaction (14) (Fig. 1*B*, curve *b*), and the asymptote corresponding to the steady state makes the negative intercept

$$\tau' = -\frac{[S]_0}{k_1K_m(K_m + [S]_0)} \qquad (15)$$

on the abscissa axis. Mechanisms (8) and (14) can be distinguished also by the methods of relaxation kinetics [37].

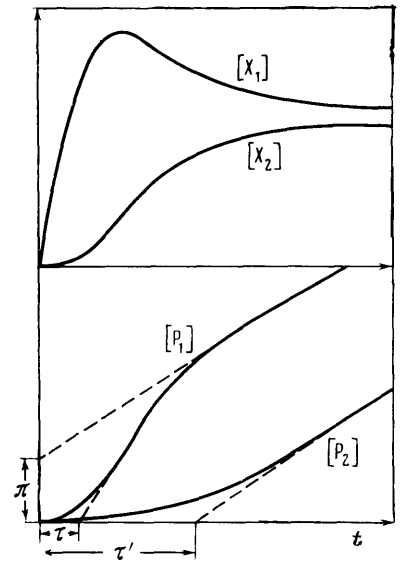

Figure 2. Prestationary kinetics of the formation of intermediates and products for a three-stage mechanism (16).

The mechanism of the action of proteolytic enzymes has been discussed in detail in terms of the formation of two intermediates and two products

$$E + S \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} X_1 \rightarrow X_2 \overset{k_3}{\rightarrow} E + P_2 \qquad (16)$$
$$\searrow P_1$$

Fig. 2 illustrates the variation of $[X_1]$ and $[X_2]$. The analytical time dependence of the concentration of product P_1 (Fig. 2) is [38]

$$[P_1] = \frac{k_2R}{Q}t + \frac{k_2N}{G}(e^{Gt} - 1) + \frac{k_2M}{F}(e^{Ft} - 1) \qquad (17)$$

where R, Q, F, G, M, and N are functions of the rate constants k_1, k_{-1}, k_2, and k_3. All the elementary rate constants of mechanism (16) can be determined[38] by analysing the steady-state reaction velocity and also τ, τ', and π

$$\tau = \frac{1}{k_1[S]_0 + K_m}; \quad K_m = \frac{k_2 + k_{-1}}{k_1} \tag{18}$$

$$\tau' = \frac{k_2^2 - k_1 k_2 [S]_0}{k_1 k_3 (k_2 + k_3)([S]_0 + K_m')}; \quad K_m' = K_m \frac{k_3}{k_2 + k_3} \tag{19}$$

$$\pi = [E]_0 \left\{ \frac{k_2^2 [S]_0^2}{(k_2 + k_3)^2 ([S]_0 + K_m')^2} - \frac{k_2 k_3^2 [S]_0}{k_1 (k_2 + k_3)^2 ([S]_0 + K_m')^2} \right\} \tag{20}$$

as functions of enzyme and substrate concentrations (see also Fig. 2).

We must emphasise an important general kinetic peculiarity of multistage catalytic reactions of type (1) in the prestationary state. Equations (6) and (7) show that the functional time dependence of the concentration of intermediate compounds is given by the sum of n exponential terms and a constant, whereas that of the concentration of the final product is represented by the sum of n exponential terms $(e^{\lambda_j t} - 1)$ together with a linear function of time. Hence the number of exponential terms in Eqns. (6) and (7) corresponds to the number of intermediate compounds in reaction (1) (cf. in particular mechanisms (8) and (16) with Eqns. (10) and (17)). Thus a reaction involving n intermediate compounds will ideally yield an experimental set of n characteristic times. In an actual experiment, however, a smaller number of exponential terms may be observed, primarily because of the method of recording the kinetic curve. The most widely used spectrophotometric method requires appreciable spectral differences between the components of reaction (1). Furthermore, the time resolution of the apparatus imposes significant limitations. A characteristic time can be determined experimentally only provided that it exceeds the "dead" time of the apparatus. As a consequence of these limitations, the number of exponential terms observed experimentally will give only an estimate of the minimum number of intermediate compounds involved in the reaction.

2. Experimental Methods

The kinetics of the prestationary stage of enzymic reactions (approximated by the above restriction to excess of one of the reactants and a slight extent of conversion of the substrate) has been studied mainly by flow methods. Such methods for measuring the kinetics of fast reactions in solution were first used by Hartridge and Roughton[39-41] and have since been developed by Chance[42-47]. At the present time the stopped-flow method is most widely used[48-53,181]. The main feature of flow methods is the rapid mixing of solutions of the reactants in a specially designed mixing chamber. Much attention has been paid to the problem of efficient mixing[11,54]. The main conclusion was that rate constants determined by means of flow apparatus can be regarded as reliable only for reactions with half-lives exceeding 0.2–1 ms. The "dead" time of current flow equipment is about 0.1–0.3 ms[50,51,55]. Nevertheless, the development of sufficiently simple and convenient apparatus has led to the widespread use of flow methods (especially the stopped-flow method) for studying intermediate compounds in enzymic reactions. Table 1 lists the enzymic systems that have been studied by flow methods.

The use of flash photolysis in enzymology will further increase the resolving power of apparatus for investigating non-stationary kinetics[109-112]. In contrast to flow methods, the flash method does not require rapid mixing of the reactants. With use of a photosensitive substrate precursor, capable of conversion into the substrate by the action of light, two parameters—(i) duration of the flash and (ii) time of photochemical formation of the substrate—govern the "dead" time of the method[110]. The xenon pulse technique yields powerful flashes of light lasting 10–100 ms.[113] The duration of a flash can be shortened without diminishing the power by use of a laser technique[111]. The duration of the photochemical reaction may be quite short.

Table 1.

Enzyme	Substrate or activator	Ref.
Alcohol dehydrogenase	aromatic aldehydes	56
	p-nitrosodimethylaniline	57
	benzaldehyde, acetaldehyde	58-60
α-Amylase	*o*-nitrophenol-α-maltose	61
Hydroxylase	*p*-hydroxybenzoic acid	62
Glyceraldehyde phosphate dehydrogenase	NAD*	63
Glutamate dehydrogenase	glutamic acid	64,65
Enolase	interaction of subunits	66
Carbamate kinase	carbamoyl phosphate, ADP**	67
Carbonic anhydrase	sulphonamides	68,69
	Zn^{2+}	70
Carboxypeptidase A	*N*-dansylated peptides	71
Catalase	hydrogen peroxide	72
Catalase-hydrogen peroxide	hydrogen peroxide, ethanol	72,73
Xanthin oxidase	xanthin oxygen	74
Lactate dehydrogenase	NAD*, lactic acid	75-77
D-Amino-acid oxidase	β-chloroalanine	78
Papain	nitrophenyl esters of benzyloxycarbonyl-glycine	79
	p-nitrophenyl ester of benzyloxycarbonyl-L-lysine	80
Peroxidase	hydrogen peroxide, ethyl and methyl hydroperoxides	81
Peroxidase-hydrogen peroxide	ascorbic acid, quinol	73
	cytochrome C	82
	hexacyanoferrate(II)	83
Staphylococcal nuclease	isomerisation (pH jump)	84
Trypsin	ethyl ester of *N*-benzoyl-L-arginine	31,86
	p-nitroanilide of *N*-benzoyl-L-arginine	87
	p-nitrophenyl acetate	108
	structural changes	89
Tryptophan synthetase	L-serine, indole, tryptophan	90
Ficin	ethyl ester of *N*-acetyl-L-arginine	31,86
	p-nitrophenyl hippurate	88
	p-nitrophenyl ester of benzyloxycarbonyl-L-lysine	80
Chymotrypsin	*p*-nitrophenyl acetate	85,91-94
	methyl and ethyl esters of *N*-acetylated L-amino-acids	95-100
	amide of *N*-furovlacryloyl-L-tryptophan	98
	methyl ester of *N*-furoylacryloyl-L-tryptophan	99
	p-nitrophenyl esters of *N*-benzyloxycarbonyl-L-amino-acids	101,102
	N-furoylacryloyl-L-tryptophan (pH jump)	103
	cyclic sulphonates	104
	Proflavin	105
Cytochrome C	Cr^{2+}	106
Alkaline phosphatase	*O*-*p*-phenylazophenyl phosphorothioate	107

[* NAD = nicotinamide–adenine dinucleotide.]
[** ADP = adenosine diphosphate.]

Catalase, peroxidase, and α-chymotrypsin have been studied in greatest detail by the above methods, and therefore the mechanism by which these enzymes function will be more fully discussed below.

3. α-Chymotrypsin

The proteolytic enzyme α-chymotrypsin catalyses the hydrolysis of peptide linkages, as well as that of ester and amide bonds in synthetic model substrates. The first hint that an intermediate compound of the enzyme with the acidic portion of the substrate is formed at the stage of

formation of the main product P_1 (scheme 16) was Hartley and Kilby's observation[114,115] that the separation of *p*-nitrophenol in the hydrolysis of *p*-nitrophenyl acetate by α-chymotrypsin takes place in two stages: an initial "burst" of *p*-nitrophenol in approximately stoichiometric concentration with respect to the added enzyme is followed by a slower, steady-state further hydrolysis of the substrate (a critique of the conclusions of this research will be found in Ref. 1). Careful investigation of the kinetics of both stages by later workers[85,91-94], using the stopped-flow method, showed that the rate curve for the separation of *p*-nitrophenol is described by Eqn. (17) provided that $k_1[S]_0 \gg k_2$, k_3. The time variation of $[P_1]$ then assumes the simpler form[91]

$$[P_1] = At + B(1 - e^{-kt}) \tag{21}$$

$$A = \frac{\frac{k_2 k_3}{k_2 + k_3}[E]_0[S]_0}{[S]_0 + K_m \frac{k_3}{k_2 + k_3}}; \quad K_m = \frac{k_{-1} + k_3}{k_1} \tag{22}$$

$$B = \frac{\left(\frac{k_2[S]_0}{K_m + [S]_0}\right)^2 [E]_0}{\left(\frac{k_2[S]_0}{K_m + [S]_0} + k_3\right)^2} \tag{23}$$

$$k = \frac{k_2[S_0]}{K_m + [S]_0} + k_3 \tag{24}$$

In fact, when $[S]_0 \gg K_m$ and $k_2 \gg k_3$, we have $B = [E]_0$, so that the initial "burst" of *p*-nitrophenol corresponds to the initial concentration of the enzyme (Fig. 3)‡. These results established the presence of the intermediate compound X_2 (the acylated enzyme), which was subsequently shown to be the ester of the hydroxyl group of serine-195, present in the active centre of the enzyme, and the acyl part of the substrate[117,118]§.

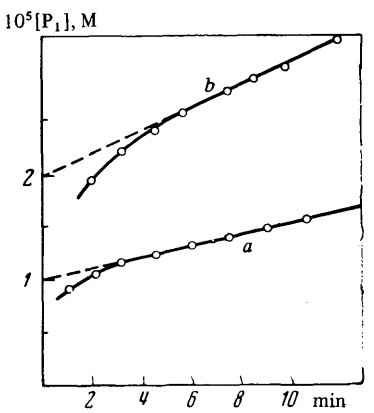

Figure 3. Kinetics of the formation of *p*-nitrophenol in the hydrolysis of *p*-nitrophenyl acetate catalysed by α-chymotrypsin[115] (enzyme concentration for curve *b* double that for *a*).

‡ Current methods for determining the concentration of active centres in many enzymes are based on this principle[116].

§ Several acylated enzymes, which are stable at low pH, have been isolated in pure form (acetylchymotrypsin[117], the homologous series of acylated enzymes formed by aliphatic carboxylic acids from C_1 to C_7[119], *cis*- and *trans*-isomers of cinnamoylchymotrypsin[120-122], etc.).

The kinetics of acylation of the active centre in α-chymotrypsin by *p'*-nitrophenyl *trans*-*p*-nitrocinnamate has been studied[110] by flash photolysis using the *cis*-ester as photosensitive substrate precursor. Steric features of the active centre are such that the reactivity of the *trans*-isomers of substrate derivatives of β-arylacrylic acids exceeds that of the corresponding *cis*-isomers by factors of 10^3–10^4 (*trans*-specificity)[123]. The action of a flash of light on a solution of α-chymotrypsin with *p'*-nitrophenyl *cis*-*p*-nitrocinnamate forms the highly reactive *trans*-isomer, which acylates the active centre of the enzyme. Spectrophotometric monitoring of the separation of *p*-nitrophenol was used to study the kinetics of the reaction.

p-Nitrophenyl acetate and the other substrates used in the above researches are relatively unreactive ("non-specific") substrates of α-chymotrypsin. Gutfreund and Sturtevant[91,92] suggested that the catalysis by chymotrypsin of specific ester substrates derived from α-*N*-acylated L-amino-acids takes place by the same mechanism (16) as does the hydrolysis of *p*-nitrophenyl acetate. Special attention was paid to proving this hypothesis[96-100].

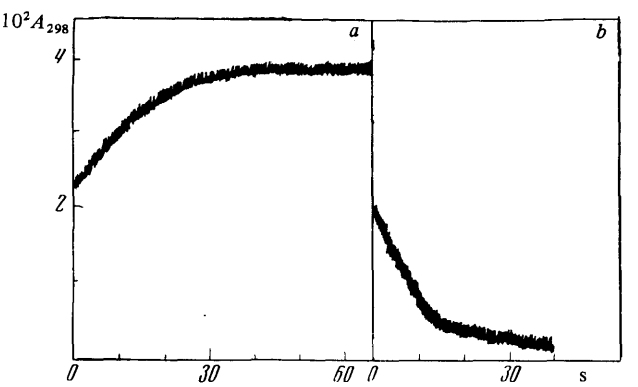

Figure 4. Prestationary kinetics of the hydrolysis of the methyl ester of *N*-acetyl-L-phenylalanine investigated by stopped-flow method[98]: *a*) variation of optical density when 3.7×10^{-5} M α-chymotrypsin and 0.017 M substrate solutions are mixed at pH 3.2; *b*) pH of solution obtained in expt. (*a*) raised from 3.2 to 5.7.

Formation of an acylated enzyme in the hydrolysis of the ethyl ester of *N*-furoylacryloyl-L-tyrosine is indicated by the effect that separation of the alcohol anticipates establishment of a steady-state concentration of the intermediate compound (as with *p*-nitrophenyl acetate).[95] Direct kinetic confirmation of the formation of intermediate compounds X_1 and X_2 in the catalysed hydrolysis of esters of *N*-acylated L-amino-acids has been obtained[98,124]. In the latter case analysis of the reaction kinetics at the wavelengths of absorption by the intermediate compounds (~ 290 nm) revealed that the rate curve was represented by the sum of at least two exponential terms, which according to Eqn. (6) indicates the formation of at least two intermediate compounds. Thus mixing a solution of α-chymotrypsin with the methyl ester of *N*-acetyl-L-phenylalanine produces a rapid, kinetically unresolved variation of the spectrum (with a half-time < 3 ms), which evidently indicates formation of the primary enzyme–substrate complex X_1; this is followed by slow formation of the acylated enzyme (Fig. 4, curve *a*). In the steady

state, under conditions such that consumption of the substrate can be neglected, the concentration of the acylated enzyme remains constant; consumption of the substrate ultimately leads to disappearance of the intermediate compounds from the solution (curve *b*). A similar pattern is found in the chymotrypsin hydrolysis of other specific ester substrates—the methyl esters of the *N*-acetylated amino-acids L-tyrosine, L-tryptophan, and L-leucine, and also the ethyl ester of *N*-acetyl-L-tyrosine—the acylation rate curves for all these substrates being used to determine the formation and hydrolysis rate constants k_2 and k_3 of the acylated enzymes by means of Eqn. (24).[124]

The rate of hydrolysis of amides is limited at the stage of formation of the acylated enzymes ($k_2 \ll k_3$)[97,98]. A more detailed picture of formation of the enzyme–substrate complex X_1 could be obtained for this class of substrates. Use of a combined "stopped flow–temperature jump" apparatus (see below) showed[98] that formation of a reactive enzyme–substrate complex in the hydrolysis of *N*-furoylacryloyl-L-tryptophanamide involves formation of a metastable intermediate compound:

$$E + S \underset{10^4\ s^{-1}}{\overset{6\cdot10^7\ M^{-1}\ s^{-1}}{\rightleftharpoons}} ES \underset{30\ s^{-1}}{\overset{1.5\ s^{-1}}{\rightleftharpoons}} ES' \rightarrow E + P \qquad (25)$$

The rate constants of formation of the primary complex ES and of the conformational change ES $\rightleftharpoons$ ES′ (scheme 25) were determined from an analysis of the rate curve described by the sum of two exponential terms.

The conformational mobility of the active centre of α-chymotrypsin was discovered kinetically from an analysis of the interaction of the acridine colorant Proflavin with the active centre. Analysis of the kinetics of complex formation shows[105] that the active centre exists in solution as two conformations, which are able to bind the colorant at significantly different rates. The concentration ratio of the conformers depends on the pH.

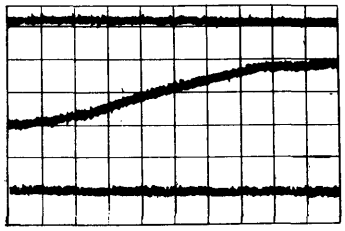

Figure 5. Oscillogram of variations of transmittance after the flash exposure of *cis*-*p*-nitrocinnamoylchymotrypsin (0.1 M KCl + 0.01 M KH_2PO_4 (pH 8.8) at 25°C). The horizontal lines mark 0 and 100% transmittance, and the time base is 0.25 s per large division[109].

A conformational change in the active centre has been recorded at the hydrolysis stage of the acylated enzyme in the hydrolysis of *trans*-*p*-nitrocinnamoylchymotrypsin induced by flash exposure of the *cis*-isomer[109]. Such exposure at the absorption wavelength of the cinnamoyl chromophore (320–360 nm) produces a variation in optical density comprising three kinetically resolved processes (Fig. 5). The reaction mechanism involves three stages:

$$cis\text{-EA} \overset{h\nu}{\rightleftharpoons} trans\text{-EA}' \overset{k}{\rightarrow} trans\text{-EA} \overset{k_3}{\rightarrow} E + P \qquad (26)$$

The spectrophotometric analysis and the pH dependence show that the first, rapid stage involves photochemical *cis*–*trans* isomerisation of the cinnamoyl group in the active centre of the enzyme, whereas the slow concluding stage entails hydrolysis of the resulting *trans*-isomer. The induction period observed on the rate curve for separation of *trans*-nitrocinnamic acid (the stage *trans*-EA′ → *trans*-EA) is probably associated with specific conformational changes in the active centre, which will thus acquire a catalytically active structure.

Thus the detailed kinetic analysis which has hitherto been made of reactions catalysed by α-chymotrypsin shows that the mechanism by which the enzyme acts involves labile intermediate compounds comprising the covalently formed acetylated enzyme, non-covalent complexes, and conformers of the enzyme.

4. Catalase and Peroxidase

The visible absorption spectra of the complexes formed by the haem-containing enzymes—catalase and peroxidase—with hydrogen peroxide and organic peroxides differ substantially from those of the original enzymes. This enabled Chance to monitor directly the formation and consumption of these labile intermediates by the accelerated- and stopped-flow methods using highly sensitive spectrophotometric apparatus[72,73,81,82].

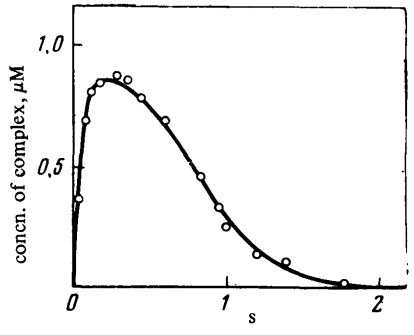

Figure 6. Variation of concentration of peroxidase–hydrogen peroxide complex when 1.0 μM peroxidase and 4.0 μM H_2O_2 solutions are mixed (pH 4.0).[126]

Rapid mixing of solutions of catalase with hydrogen peroxide enabled the rates of formation of the complexes formed by the enzyme with hydrogen peroxide and with organic peroxides to be recorded, as well as the slower rate of disappearance resulting from consumption of the peroxy-compound (Fig. 6). The rate of disappearance of the complex is increased by the presence of electron-donating substrates (aliphatic alcohols and glycols were used for this purpose)[125,128]. These results suggested that the mechanism of the peroxidase action of catalase involved a stage of formation of an intermediate enzyme–substrate compound and a stage of bimolecular reaction of this compound with a donor molecule AH_2:

$$E + S \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} ES \xrightarrow[(AH_2)]{k_2} E + P \qquad (27)$$

The formal kinetic description of a two-substrate reaction with one intermediate compound has been discussed [32,125-127]. Provided that the concentration of the second substrate remains almost unchanged during the reaction ($[AH_2] \gg [E]_0$, $[S]_0$) the kinetics of reaction (27) is described by the equations

$$\frac{d[S]}{dt} = k_{-1}[ES] - k_1([E]_0 - [ES])[S] \quad (28)$$

$$\frac{d[ES]}{dt} = k_1([E]_0 - [ES])[S] - (k_{-1} + k_2[AH_2]_0)[ES] \quad (29)$$

The rate constant k_1 was determined [125] in conformity with Eqn. (29) from the initial rate of formation of the intermediate compound when formation of the complex has not proceeded far:

$$k_1 \cong \frac{1}{([E]_0 - [ES])[S]_0} \cdot \frac{d[ES]}{dt} \quad (30)$$

Adding Eqns. (28) and (29) yields the relation

$$\frac{d[S]}{dt} + \frac{d[ES]}{dt} = -k_4[AH_2]_0[ES] \quad (31)$$

Integration of this formula for complete consumption of intermediate compound and substrate ($t = 0$, $[S] = [S]_0$, $[ES] = 0$; $t \to \infty$, $[S] = 0$, $[ES] = 0$) gives

$$k_2 = \frac{[S]_0 \int_0^\infty}{[AH_2]_0 \cdot \int_0^\infty [ES]\,dt} \quad (32)$$

which enables us to find the rate constant k_2 (scheme 27). The integral $\int_0^\infty [ES]dt$ was evaluated numerically from the area bounded by the kinetic curve representing formation and consumption of the enzyme–substrate complex (Fig. 4). Reaction of the complex ES with the donor molecule is bimolecular, but does not involve formation of an enzyme–peroxide–donor ternary complex [129]. Thus the value of k_2 determined for the catalase–methyl hydroperoxide–methanol system was found to be independent of the methanol concentration (0.2–0.08 M).

According to Chance [125] the mechanism of the catalase action of catalase does not differ significantly from that of its peroxidase action. A second hydrogen peroxide molecule acts as donor in this case:

$$E + S \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} ES \xrightarrow[[S]]{k_2} E + P \quad (33)$$

The mechanism of catalysis by peroxidase is more complicated than the reaction mechanisms involving catalase. Peroxidase forms at comparable rates two spectroscopically distinct complexes with hydrogen peroxide. Complex (I) is formed immediately on the addition of hydrogen peroxide, and is an unstable green compound rapidly converted into the red complex (II). This conversion takes place more rapidly in the presence of a hydrogen-donor. The general scheme of the process based on fast kinetic measurements can be written [125,130]

$$E + H_2O_2 \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} ES^I \xrightarrow[(AH_2)]{k_3} ES^{II} \xrightarrow[(AH_2)]{k_4} E \quad (34)$$

$$\searrow AH^\cdot \qquad \searrow AH^\cdot$$

$$2AH^\cdot \to A + AH_2$$

III. STATIONARY STAGE OF REACTION

1. Multistage Catalytic Reactions

Steady-state occurrence of reaction (1) permits considerable simplification of its kinetic description. Experience shows that a steady state is usually established some time after the start of the reaction. This follows from Eqns. (6) and (7), since, at sufficiently large values of t, the concentrations of the intermediate compounds reach constant (stationary) values

$$[X_n]_{t\to\infty} = B \quad (35)$$

while the concentration of the product increases linearly with time

$$[P]_{t\to\infty} = k_{n+1}Bt - k_{n+1}\sum_{j=1}^{n}\frac{A_j}{\lambda_j} \quad (36)$$

provided that consumption of the substrate during the initial period of reaction can in effect be neglected.

The conditions limiting the validity of using the equations of stationary kinetics to investigate the mechanisms of enzymic reactions have been analysed [15,131,132]. If the rate of change of the concentration of the intermediate compounds X_i is much smaller than the rates of change of the concentrations of reaction products and starting materials, each of the derivatives of the intermediate concentrations can be equated to zero: $d[X_i]/dt = 0$ (see Eqns. 3). The problem reduces to the simultaneous solution of $n + 2$ algebraic equations and one differential equation [133-136]. The steady-state reaction velocity in this case is given by the usual Michaelis equation for reversible reactions

$$v = \frac{\frac{V_S}{K_S}[S]_0 - \frac{V_P}{K_P}[P]_0}{1 + [S]_0/K_S + [P]_0/K_P} \quad (37)$$

in which, however, the parameters—the maximum rates V_S, V_P and the Michaelis constants K_S, K_P—are functions of the rate constants of the elementary stages. These quantities have been expressed in terms of the rate constants of the kinetic scheme (1). [133]

Many papers have appeared on the theory of stationary kinetics and its practical application to investigating the specific mechanisms of enzymic reactions [15,131-145]. It must be noted, however, that study of the steady-state kinetics of an enzymic reaction is of very limited value for an understanding of the multistage mechanism of enzyme action. The primary reason is that in general, without the use of additional data, experimental rate constants cannot be assigned unambiguously to elementary chemical stages, since the dependence of the rate of the process on the initial concentrations of S and P will yield only the four kinetic parameters—K_S, K_P and V_S, V_P—whereas the number of rate constants of elementary reactions in process (1) is $2(n + 1)$. Determination of all the elementary constants of reaction (1) obviously becomes impossible when $n > 1$.

Nevertheless, lower limits to rate constants of elementary stages can be determined from steady-state kinetics. The reason is that the parameters of the stationary kinetics are determined by the limiting stage. The lower limit to the rate constant of any unimolecular stage in the forward direction of reaction (1) is given by [133]

$$k_{i+1} \geqslant \frac{V_S}{[E_0]}; \quad i \neq 0 \quad (38)$$

Similarly, for the reverse reaction we have

$$k_{-i} \geqslant \frac{V_P}{[E]_0}; \quad i \neq n+1 \quad (39)$$

These formulae enable data on the stationary kinetics of enzymic reactions to be analysed, and the rates of the slowest stages to be estimated. For this purpose Table 2 lists values of $V_{max}/[E]_0$ for several enzyme systems [12].

These results represent the efficiency of enzymic catalysis. Table 2 shows that rate constants of the limiting processes of unimolecular conversion of intermediate compounds lie in the range 10^2–10^3 s^{-1} for the majority of enzymes.

Table 2.

Enzyme	$V_{max}/[E]_0$, s^{-1}	Enzyme	$V_{max}/[E]_0$, s^{-1}
Acetylcholinesterase	10^3	Kinase	10^3
Chymotrypsin	10^2–10^3	Urease	10^4
Trypsin	10^2–10^3	Fumarase	10^3
Ribonuclease	10^2	Aldolase	10^2
Papain	10	Dehydrogenase	10^3
Carboxypeptidase	10^2	Catalase	10^7
Myosin-ATPase*	10^2	Peroxidase	10

[* ATP = adenosine triphosphate.]

Lower limits to the rate constants can be determined[133] also for the bimolecular stages of reaction (1). They are respectively

$$k_1 \geqslant \frac{V_S + V_P}{[E]_0 K_S} \tag{40}$$

$$k_{-(n+1)} \geqslant \frac{V_S + V_P}{[E]_0 K_P} \tag{41}$$

Table 3 gives the results of analyses[12,133] of the limiting values of rate constants for several specific enzymic reactions. The minimum value of the bimolecular rate constant k_1 for certain reactions (of fumarase) approaches the limit predicted by the theory of reactions controlled by diffusion of the reactants.

The study of stationary kinetics may be useful, not only for estimating lower limits to the reactivity of intermediate compounds, but also for obtaining more detailed information on their properties. However, this requires that the reaction mechanism should be sufficiently well known. As example we consider some results of the investigation of catalysis by α-chymotrypsin.

2. Steady-state Kinetic Study of Intermediate Acylated Enzyme in Catalysis by α-Chymotrypsin

Investigation of the prestationary kinetics of reactions catalysed by α-chymotrypsin showed that the mechanism of catalysis involved a stage of formation and hydrolysis of an intermediate acylated enzyme (scheme 16). The steady-state rate of such a reaction is described by the equation[146]

$$v = \frac{k_{cat}\,[E]_0[S]_0}{K_{m(app)} + [S]_0} \tag{42}$$

where

$$k_{cat.} = k_2k_3/k_2 + k_3 \tag{43}$$

$$K_{m(app)} = K_S k_3/k_3 + k_2; \quad K_S = \frac{k_{-1} + k_2}{k_1} \tag{44}$$

Equations (42)–(44) indicate that the experimental parameters k_{cat} and $K_{m(app)}$ are complicated functions of the rate constants of both chemical stages of the enzymic process. Hence it follows that, with comparable values of k_2 and k_3, such parameters do not characterise the reactivity of any individual intermediate. Nevertheless, abundant experimental information, describing the reactivity both of the enzyme–substrate complex and of the intermediate acylated enzyme, has now been obtained from stationary kinetic data. Apart from certain indirect methods[146] two main approaches have been used for analysing reactivity in catalysis by α-chymotrypsin.

Table 3.

Enzyme	Substrate	$k_{1,min}$, $M^{-1}\,s^{-1}$
β-Amylase	amylose	5.8×10^7
Urease	urea	5.0×10^6
ATPase	ATP	8×10^6
Cytochrome C reductase	cytochrome C	9×10^7
Acetylcholinesterase	acetylcholine	10^9
Fumarase	fumaric acid	0.5×10^8
	L-malic acid	1.6×10^8
	fumaric acid at zero ionic strength	3×10^{10}

(a) Investigation of substrates with a known limiting stage

The rate constant of the limiting stage can be determined from steady-state kinetic data k_{cat} and $K_{m(app)}$ only if the difference in reactivity between the intermediate species ES and EA is sufficiently large. This is evident from Eqns. (42)–(44), whence it follows that, when $k_2 \gg k_3$,

$$k_{cat.} = k_3; \quad K_{m(app)} = K_S k_3/k_2 \tag{45}$$

Different relations hold when $k_3 \gg k_2$:

$$k_{cat.} = k_2; \quad K_{m(app)} = K_S \tag{46}$$

This approach has been used[147–150] to analyse the relation between structure and reactivity k_3 of the intermediate acylated enzymes formed in the hydrolysis of p-nitrophenyl esters of aliphatic carboxylic acids (C_1–C_7).

(b) Determination of elementary constants by selective action on rates of individual stages of enzymic reaction

Use of this method has been considered for a reaction with a single intermediate[151–153]. The approach has been analysed[154–161] for the three-stage catalytic reaction mechanism (16). Thus the reversible inhibiting effect of heavy-metal cations on the acylation stage k_2 of α-chymotrypsin[162–165] or even the effect of the ionic strength of the solution[155] on the same stage has been used for this purpose. Fig. 7 illustrates the effect of ionic strength on the steady-state hydrolysis of the ethyl ester of *N*-benzoyl-L-tyrosine in the presence of α-chymotrypsin. The abscissa of the point of intersection gives[155] the value of $-1/K_S$, and the ordinate $1/k_3$.

However, the method which has been most greatly developed and systematically applied to reactions involving migration of an acyl group is that of competing reactions,

based on competition between water and an added nucleophilic reagent for reaction with the acylated enzyme[156-159, 166]. According to the scheme

$$E + S \underset{}{\overset{K_S}{\rightleftharpoons}} ES \xrightarrow{k_2} EA \begin{cases} \xrightarrow{k_3[H_2O]} E + P_2 \\ \xrightarrow{k_4[N]} E + P_3 \end{cases} \quad (47)$$

the experimental parameters are related to the concentration of the nucleophile by the formulae

$$k_{cat(1)} = \frac{k_2(k_3 + k_4[N])}{k_2 + k_3 + k_4[N]} \quad (48)$$

$$k_{cat(2)} = \frac{k_2 k_3}{k_2 + k_3 + k_4[N]} \quad (49)$$

$$K_{m(app)} = K_S \frac{k_3 + k_4[N]}{k_2 + k_3 + k_4[N]} \quad (50)$$

where $k_{cat(1)}$ and $k_{cat(2)}$ are the kinetic parameters determined by means of Eqn. (42) for the steady-state rates of formation of the products P_1 and P_2 respectively. From the dependence of k_{cat} and $K_{m(app)}$ on the concentration of the added nucleophile, using Eqns. (48)–(50), we can determine separately the rate constants at the stages of acylation and hydrolysis of the acylated enzymes, as well as the equilibrium constant K_S.

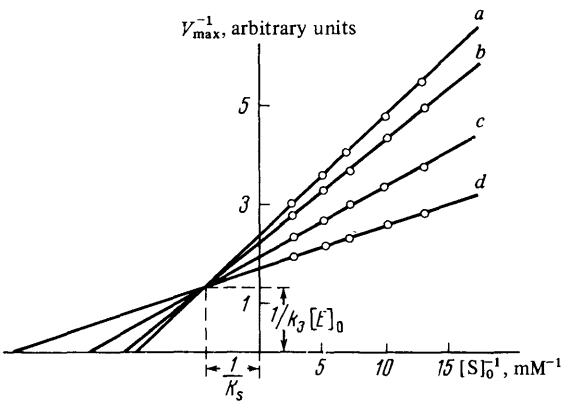

Figure 7. Dependence of initial steady-state rate of α-chymotrypsin hydrolysis of ethyl ester of *N*-benzoyl-L-tyrosine (6 vol.% of acetonitrile with pH 7.8 (pH-stat) at 25°C) on ionic strength (KCl, M): *a*) 0.1; *b*) 0.2; *c*) 0.5.[155]

Among the disadvantages of this technique are uncertainty on the mechanism of the effect of the nucleophile on the acylated enzyme and also the need to allow for the inhibiting effect of the nucleophile[158].

This approach has found systematic application in an investigation[158,159] of the reactivity of intermediate acylated enzymes using butane-1,4-diol as added nucleophile. Rate constants of formation and hydrolysis have been determined[159] for the homologous series of acylated enzymes formed by *N*-acylated derivatives of L-amino-acids. The results enabled certain conclusions to be drawn on the structure of the active centre and the mechanism of the specificity of α-chymotrypsin[147,160].

IV. METHODS OF RELAXATION KINETICS

1. Multistage Catalytic Reactions

Relaxation methods of investigating the kinetics of chemical reactions are based on the principle that, when a system is subjected to a rapid external constraint (change of temperature, pressure, or electric field), the time required for the system to reach a new equilibrium (or stationary) state will depend on the rate of chemical reaction (or sometimes on the rate of diffusion of the reactants). Transition of the system to the new equilibrium reactant concentrations is termed "chemical relaxation"[167]. The external constraint perturbing the system may be either discontinuous (temperature jump, pressure, or electric field pulse) or periodic (ultrasonic absorption). The resolving power of relaxation methods lies between 10^{-5} s (temperature jump) and 10^{-10} s (absorption of ultrasound)[11-13,26]. Formal aspects of the relaxation kinetics of complicated chemical reactions have been discussed[12,26,168,182].

The relaxation kinetics of an enzymic reaction involving *n* intermediate compounds (reaction 1) was analysed by Hammes and Alberty[169] and also by Eigen and Hammes[12]. With the system at equilibrium the concentrations

$$[\bar{E}],\ [\bar{S}],\ [\bar{X}_1] \ldots [\bar{X}_n],\ [\bar{P}]$$

of all the species are constant. When a rapid external constraint is applied, the reactant concentrations assume new values corresponding to the new equilibrium. The instantaneous concentrations of the components can be written

$$([\bar{E}]+\Delta[E]),\ ([\bar{S}]+\Delta[S]),\ ([\bar{X}_1]+\Delta[X_1]) \ldots ([\bar{X}_n]+\Delta[X_n]),\ ([\bar{P}]+\Delta[P]),$$

where the symbol Δ denotes the changes in the reactant concentrations. In order to find the functional dependence of each component concentration on time, we must solve Eqns. (2) and (3). This set of equations will be linear if the displacement of the equilibrium is small. The bimolecular terms $k_1[E][S]$ and $k_{n+1}[E][P]$, which are responsible for the non-linearity of the system, can then be written

$$k_1([\bar{S}]+\Delta[S])([\bar{E}]+\Delta[E]) = k_1([\bar{E}][\bar{S}]+[\bar{E}]\Delta[S]+ +[\bar{S}]\Delta[E]+\Delta[S]\Delta[E])$$

and hence

$$k_{(n+1)}([\bar{E}][\bar{P}]+[\bar{E}]\Delta[P]+[\bar{P}]\Delta[E]+\Delta[P]\Delta[E]).$$

For a small shift of the equilibrium, terms containing Δ^2 can be neglected. Hence Eqns. (2) and (3) can be simplified to

$$\frac{d\Delta[S]}{dt} = a_{1,1}\Delta[S] + \sum_{j=1}^{n} a_{i,j+1}\Delta[X_j]$$
$$\frac{d\Delta[X_j]}{dt} = a_{j,1}\Delta[S] + \sum_{j=1}^{n} a_{i,j}\Delta[X_j] \quad (51)$$

where the constants $a_{i,j}$ are functions of the rate constants of the elementary chemical reactions and the initial equilibrium concentrations of the components of the reaction

$$E + S \underset{k_{2,1}}{\overset{k_{1,2}}{\rightleftharpoons}} X_1 \underset{k_{3,2}}{\overset{k_{2,3}}{\rightleftharpoons}} \ldots \rightleftarrows X \rightleftarrows \ldots \underset{k_{n+1,n}}{\overset{k_{n,n+1}}{\rightleftharpoons}} X_n \underset{k_{n+2,n+1}}{\overset{k_{n+1,n+2}}{\rightleftharpoons}} E + P \quad (52)$$

Somewhat as for the set of equations (4), a general solution can be sought (accurate to a constant) in the form

$$\Delta[S] = \sum_{j=1}^{n+1} A_j e^{\lambda_j t}$$
$$\Delta[X_j] = \sum_{j=1}^{n+1} B_{i,j} e^{\lambda_j t} \quad (53)$$

where the λ_j are the roots of the characteristic equation of degree $n + 1$.

An important conclusion which follows from the above survey is that, when n intermediate compounds are involved, the number of exponential terms is $n + 1$. Thus the number of exponentials observed experimentally can be regarded as a criterion of the minimum number of intermediate compounds taking part in the reaction. The measured relaxation times $-1/\lambda_j$ are functions of all the rate constants of elementary reactions and the equilibrium concentrations of the reactants.

Table 4.

Enzyme	Substrate or activator	Ref.
Alcohol dehydrogenase	NAD-imidazole	176
Aspartate aminotransferase	aspartic, glutamic, oxosuccinic, oxoglutaric acids	177
	α-methylaspartic acid	178
	erythro-β-hydroxyaspartic acid	179
Aspartate transcarbamoylase	5-bromocytidine phosphate	180
	carbamoyl phosphate, L-malic and succinic acids	183-185
Glyceraldehyde 3-phosphate dehydrogenase	NAD	186-192
Acid phosphatase	*p*-nitrophenyl phosphate	193
Creatine kinase	creatine phosphate	194
Lactate dehydrogenase	NADH	195,196
Lysozyme	saccharides	197,198
	Biebrich Scarlet	199
Malate dehydrogenase	NADH, malic acid	200,201
Pyruvate kinase	bivalent metal ions, ADP	202
Ribonuclease	nucleotides	202-209
	isomerisation	210-213
Serine dehydrogenase	isomerisation	214
Serine transhydroxymethylase	glycine	215
Trypsin	isomerisation	210,211
	proflavin-benzamidine	174,216
Tryptophan synthetase	L-serine, indole, tryptophan	217,218
Urease	urea	219
Flavodoxin	interaction of coenzyme with apoprotein	220-222
Chymotrypsin	Proflavin	175,223,224
	Proflavin and methyl ester of *N*-toluene-*p*-sulphonyl-L-arginine	225
	Biebrich Scarlet	226
	isomerisation	211
Cytochrome C	hexacyanoferrate(II)	175

Particular cases of scheme (52) (one and two intermediate compounds) and specific approaches to determining the rate constants of elementary stages have been described[13,167-173]. It has been shown[13,26,174] that data on relaxation amplitudes may prove useful, besides kinetic data (relaxation times), in the analysis of reaction mechanisms.

Many enzyme systems have now been studied by relaxation methods. Those listed in Table 4 have been examined mainly by the temperature-jump method. A rapid change of temperature is usually effected by discharging a high-voltage capacitor through the reaction cell containing, in addition to the reactants, a certain quantity of an inert electrolyte to lower the electrical resistance. A temperature change of 3–10 deg occurs within 10^{-6} s.[11-13] Equipment combining stopped-flow and temperature-jump apparatus was proposed for the kinetic investigation of fast reversible stages preceding the *irreversiole* limiting stage[175]. The temperature jump can be effected in an interval from milliseconds to a few seconds after cessation of flow. Further shortening of the "dead" time of the "temperature jump" method entails the use of laser illumination to heat up the reaction cell[227,228].

The possibilities of using flash photolysis to study the relaxation kinetics of enzyme reactions have been discussed[229-231]. In this case the equilibrium is changed as a consequence of a concerted fast photochemical reaction. Light-induced rapid changes in pH (flash-induced pH jump) merit special attention[229].

2. Aspartate Transaminase and Ribonuclease

A review[232] of the study of enzyme reactions by relaxation methods discusses the mechanisms of the following—(i) reactions of aspartate transaminase with amino- and keto-acids, (ii) reaction of cytochrome C with ferrocyanide, (iii) reaction of alcohol dehydrogenase with NAD–imidazole and the combination of NADH with malate and lactate dehydrogenases, (iv) hydrolysis of *p*-nitrophenyl phosphate by acid phosphatase, and (v) reactions of pancreatic ribonuclease A. Table 4 shows that the reaction mechanisms of aspartate transaminase and ribonuclease have been studied in greatest detail. These examples give an idea both of the possibilities of relaxation kinetics and of the achievements of enzymology in investigating the mechanisms of enzymic catalysis.

Aspartate aminotransferase (AAT) catalyses the reversible transfer of an amino-group between aspartic and oxoglutaric acids with the formation of oxosuccinic and glutamic acids:

$$\begin{array}{l} \overset{\ominus}{\mathrm{COO}}\mathrm{CH_2CH}\overset{\ominus}{\mathrm{COO}} + \overset{\ominus}{\mathrm{COO}}(\mathrm{CH_2})_2\,\mathrm{COC}\overset{\ominus}{\mathrm{OO}} \xrightleftharpoons{\mathrm{AAT}} \\ \quad\quad\quad\

studied, and rate constants characterising the individual stages were determined (or estimated). The spectral characteristics of the intermediates showed them to be probably covalent compounds of the substrate with pyridoxal phosphate, including Schiff bases.

Besides the stages that were studied, more rapid spectral changes were observed in the reaction of aspartate aminotransferase, whose kinetics could not be analysed by the temperature-jump technique. In order to slow down these stages, the reaction of the enzyme with certain modified substrates was investigated. The analogous L-α-methylaspartic acid is a competitive inhibitor of amino-acid substrates and able to form an aldimine with pyridoxal phosphate on the enzyme. Because of the presence of the α-methyl group, however, transamination cannot take place. Kinetic study of this system by a combined "stopped-flow–temperature jump" method revealed that the reaction occurred in three stages[178]:

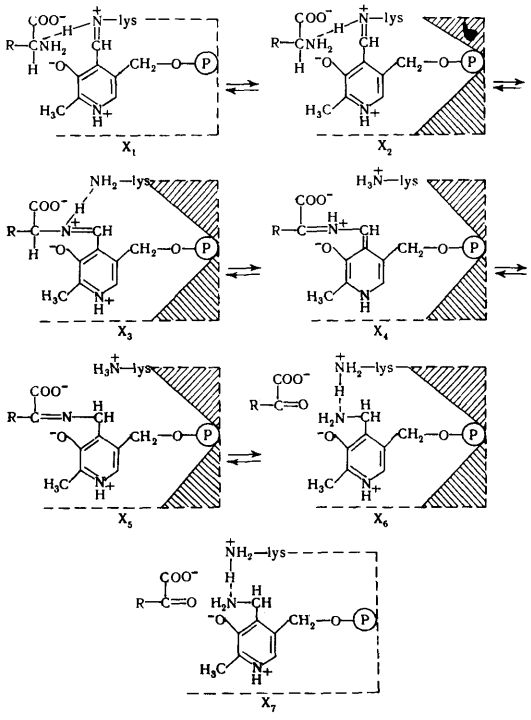
$$E + S \rightleftarrows X_1 \rightleftarrows X_2 \rightleftarrows X_3 \qquad (56)$$

All the rate constants in this mechanism were determined, and the spectral properties of the intermediate compounds were studied. The reaction was regarded[178] as involving formation of a primary complex X_1, followed by a conformational change ($X_1 \rightleftharpoons X_2$) and formation of an aldimine X_3.

The *erythro*-isomer of L-β-hydroxyaspartic acid is a substrate of the enzyme, but transamination occurs very slowly. Eight relaxation times were detected[179] in the reaction of this substrate with aspartate transaminase. The simplest mechanism consistent with this finding is

$$E_l + S \rightleftarrows X_1 \rightleftarrows X_2 \rightleftarrows X_3 \rightleftarrows X_4 \rightleftarrows X_5 \rightleftarrows X_6 \rightleftarrows X_7 \rightleftarrows E_m + S' \qquad (57)$$

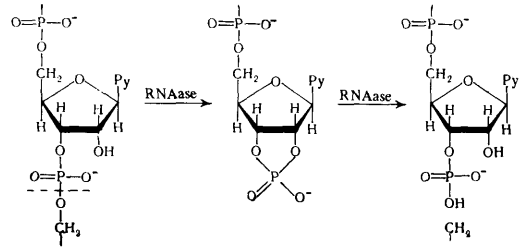
where S' represents the keto-form of the substrate. Detailed analysis of the concentration dependence of relaxation times and equilibrium constants enabled 14 and 16 rate constants to be calculated representing mechanism (57). Furthermore, the spectral characteristics of the intermediates were determined. A suggested reaction mechanism consistent with the results can be represented by the scheme[234]



(58)

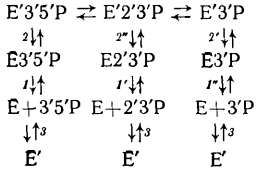
The first three intermediates have spectral characteristics similar to those of compounds X_1, X_2, and X_3 in the reaction of L-α-methylaspartic acid, and at these stages the reaction probably also terminates in formation of an aldimine (X_3). The intermediate X_4 has absorption maxima at 460 and 490 nm, the molar absorption at the latter wavelength exceeding 10^5 M^{-1} cm^{-1}. According to the authors[179] this compound has a quinoid structure; the other three compounds have absorption maxima in the region of 330 nm and are ketimines (scheme 58).

Hammes studied the mechanism of the action of ribonuclease A in as great detail as that of catalysis by aspartate aminotransferase[203–209]. The reaction catalysed by the former enzyme involves transesterification of a 3',5'-dinucleotide with formation of a 2',3'-cyclophosphate, followed by hydrolysis of the cyclic phosphate with formation of a 3'-nucleotide:



(59)

Synthetic substrates were used to investigate the relaxation kinetics, which considerably simplified the kinetic analysis. The interaction of the enzyme was studied with all three classes of substrates. On the basis of these investigations the "minimal" mechanism



(60)

was suggested. With each class of substrates (3',5'-dinucleotides, 2',3'-cyclophosphates, and 3'-nucleotides) the reaction involves a bimolecular stage of formation of the primary complex (stages *1*, *1'*, *1''*), followed by its isomerisation (stages *2*, *2'*, *2''*). Furthermore, examination of the free enzyme showed that it existed in two conformations (stage *3*). Comparison of these kinetic results with X-ray diffraction data[235,236] enabled a detailed mechanism to be postulated for the action of the enzyme[209,232].

The investigations on the mechanisms of the action of aspartate aminotransferase and ribonuclease A provide an excellent illustration of the possibilities and achievements of "fast" kinetic methods for studying the mechanisms of enzymic catalysis. The results of these investigations may be instructive for the choice of approaches to the study of other catalytic systems.

Fixation of Nitrogen in Solution in the Presence of Transition Metal Complexes

A.E.Shilov

The review presents the results of studies in the last decade on the reduction of molecular nitrogen in aprotic and protic media. The products, intermediate complexes, and mechanisms of these reactions are considered. The relation between the mechanisms of the N_2 reduction reactions discovered recently and the mechanism of biological nitrogen fixation is discussed. The bibliography includes 161 references.

V. Comparison of nitrogenase and various nitrogen-fixing systems	393

I. INTRODUCTION

Ten years have elapsed since the discovery by Vol'pin and Shur of the first system fixing molecular nitrogen in solutions of transition metal complexes[1]. During this period, the concepts of the chemistry of N_2 have undergone radical changes. In the first place it was found that nitrogen readily reacts with many low-valent transition metal derivatives to form complex nitrides and also derivatives of hydrazine and organonitrogen compounds. In a study of the reaction of hydrazine with $RuCl_3$ in 1965, Allen and Senoff obtained for the first time a complex of molecular nitrogen[2]. After several months, a similar complex was obtained directly from molecular nitrogen[3]. These studies gave rise to a new field of coordination compounds in which N_2 enters as a ligand into the coordination sphere of the metal. It was discovered that in the formation of complexes nitrogen can be very reactive, competing successfully for a coordination site with ammonia and water, for example, and complexes containing N_2 in the coordination sphere are sometimes very stable and withstand heating to 200°C.

Contrary to the expectations of the chemists who synthesised them, the N_2 complexes discovered in the first years proved to be incapable of activating nitrogen with respect to further reactions, for example with respect to reduction to ammonia. It was not until 1969 that intermediate nitrogen complexes capable of undergoing further reactions were detected[4] and in some cases subsequently isolated and investigated.

Finally, systems in which nitrogen is reduced to hydrazine and ammonia in aqueous and aqueous alcoholic solutions in the presence of molybdenum and vanadium complexes, sometimes even at room temperature and atmospheric pressure[5,6], were discovered in 1970.

Thus nitrogen ceased to be an inert gas, which had been thought capable of reacting under the usual conditions only with metallic lithium. On the other hand, the biological fixation of nitrogen achieved by many bacteria and algae in the presence of water and oxygen at the normal temtemperatures and pressures, which had previously been completely puzzling, has now lost its unique features.

The studies on the biological fixation of nitrogen in recent years permit conclusions concerning the mechanism of this reaction. The involvement of transition metal (iron and molybdenum) compounds in the reduction of N_2 can now be regarded as proved and the relation between the enzymatic process and its chemical models is becoming increasingly clear. Whereas previously biological fixation of nitrogen, which indicated the possibility in principle of N_2 reactions under mild conditions, led chemists to seek non-enzymatic model systems, nowadays further progress towards the understanding of the mechanism of the enzymatic process is undoubtedly associated with the investigation of non-biological models, where the investigation of the mechanism is always simpler than in biological systems.

Further simulation of the biological fixation of nitrogen and the study of the mechanism of enzymatic fixation can probably be carried out simultaneously, with a comparison of the results of experiments under enzymatic and non-enzymatic conditions. Such a comparison will be made in the concluding section of the present review.

The review does not deal with the results of studies on stable nitrogen complexes with transition metal compounds (see for example the reviews in the literature[7-9] concerning these substances).

II. GENERAL CONSIDERATIONS

Nitrogen fixation is understood as a process involving complete or partial dissociation of the N≡N bond. This process can be oxidation or reduction of nitrogen depending on whether the electronegativity of the atoms forming a bond with nitrogen is greater or smaller than that of nitrogen. Since reactions in which nitrogen is oxidised by molecular oxygen with formation of oxidation products such as N_2O, NO, NO_2, and N_2O_5 are endothermic, at low temperatures the equilibria are displaced towards the formation of free N_2 and O_2. Oxidants more powerful than oxygen are capable, in principle, of oxidising nitrogen; for example, it has been stated that molecular oxygen in its excited singlet state reacts with N_2 to form nitrogen oxides[10]. Oxygen atoms and carbenes can react with nitrogen to form N_2O and diazo-compounds[11-14]. However, the majority of known reactions involving nitrogen, which occur under mild conditions, may be regarded as reductive. Reagents which are thermodynamically capable of interacting with N_2, including metals and hydrogen, behave

as electron donors in relation to N_2. This review is therefore concerned with the reduction of molecular nitrogen in solutions.

The nitrogen molecule has certain characteristic features which distinguish it from other related unsaturated compounds, for example acetylene (see, for example, Borod'ko and Shilov [7]).

In the first place, in the dissociation of a triple bond most of the energy (about 130 out of 225 kcal) is consumed in the dissociation of the first linkage [15,16]. This determines the stability of the nitrogen molecule in relation to one- or two-electron reactions, i.e. reactions in which the dissociation of one π-linkage in nitrogen results in the formation of one or two new linkages with the latter. For example, the H_2 molecule and even the H atom are incapable of adding to nitrogen, since the formation of a single N–H bond (on addition of the H atom) or of two N–H bonds (on addition of the H_2 molecule) do not compensate the energy expended on the dissociation of the π-linkage in the nitrogen molecule (and of the H–H bond when H_2 is added) and these reactions are strongly endothermic:

$$\cdot H + N_2 \rightarrow \cdot N_2H - 21 \text{ kcal, (Ref.16)}$$

$$H_2 + N_2 \rightarrow N_2H_2 - 49 \text{ kcal.}$$

On the other hand, similar reactions involving carbon–carbon π-linkages are strongly exothermic. For example, we have for acetylene

$$\cdot H + C_2H_2 \rightarrow \cdot C_2H_3 + 40 \text{ kcal,}$$

$$H_2 + C_2H_2 \rightarrow C_2H_4 + 42 \text{ kcal.}$$

After the dissociation of the first π-linkage in nitrogen and the formation of an azo-compound, further successive dissociations of each of the remaining two linkages requires much less energy, so that, following the addition of three H_2 molecules to the N_2 molecule, the overall energy of the N–H bonds compensates the energy expended on the dissociation of the triple bond and the overall ammonia formation reaction is exothermic. These thermodynamic characteristics of the reactions of molecular nitrogen to a large extent determine its behaviour on reduction.

Only very powerful reducing agents (such as metallic lithium) are capable of undergoing the one-electron reactions

$$\cdot X + N_2 \rightarrow X{-}N{=}N\cdot$$

The intermediate formation of the $\cdot N_2H$ radical in aqueous solution, suggested by Bauer [17], appears very unlikely at present.

The two-electron processes $X_2 + N_2 \rightarrow XN_2X$ are much more favourable from the thermodynamic standpoint and are probably more common. However, if one begins with molecular hydrogen, then not only the reaction where the final product is di-imide(N_2H_2) but also the hydrogenation of nitrogen to ammonia with the intermediate formation of di-imide cannot occur at normal temperatures, since the activation energy for this reaction must be not less than 49 kcal, which corresponds to a negligible rate. This explains the finding that the usual hydrogenation catalysts, which catalyse the addition of hydrogen to olefins and acetylenes, are incapable of catalysing the hydrogenation of nitrogen.

In order to explain the reduction of nitrogen via the N_2H_2 stage under mild conditions (for example under the conditions of the biological fixation of nitrogen), it has been suggested [18] that the formation of N_2H_2 may be accompanied by the coupled exothermic oxidation reaction, the energy of which exceeds the deficit of energy for the formation of N_2H_2. Later, it was shown that the biological fixation of nitrogen does not require coupled oxidation, so that this mechanism is not obligatory (although of course in certain yet unknown cases it may operate).

New possibilities of obviating the thermodynamic difficulties in the reduction of molecular nitrogen are discovered when account is taken of the formation of intermediate mononuclear and dinuclear complexes of nitrogen with transition metal compounds:

$$M + N_2 \rightleftarrows MN_2;\ MN_2 + M' \rightleftarrows MN_2M'.$$

Here and henceforth M is a transition metal compound.

The reduction potential of M (as usually understood, i.e. corresponding to a one-electron transfer)† can be much lower in the formation of the complex than is required for the dissociation of a single π-linkage in the nitrogen molecule (the complexes formed are stabilised by the interaction of the filled *d* orbitals of M and the π orbitals of nitrogen). The subsequent two-electron reduction of nitrogen in the complex, even with the intermediate formation of di-imide, can be facilitated when di-imide forms a complex with M or M', [19] the heat of formation of the di-imide complex being greater than the heat of formation of the complex with molecular nitrogen.

Indeed, comparatively stable complexes of metal compounds with di-imide and its derivatives are known, although hitherto they have been obtained largely from sources other than molecular nitrogen. For example, when hydrazine reacts with $CuCl_2$, a copper(I) complex of di-imide is formed [20]. It has been shown by X-ray diffraction analysis [21] that zero-valent nickel forms a mononuclear complex with azobenzene, which has a structure of the type of π-complexes with olefins, where the interatomic distance $r(N{-}N) = 1.385$ Å, which is close to the length of a single N–N bond in hydrazine and evidently corresponds to an appreciable electron transfer to N_2Ph_2. The authors [21] regard this complex as a model of the intermediate complex with N_2H_2 in nitrogen fixation.

If a complex of this kind has a dinuclear structure, it can evidently be regarded as a hydrazine derivative:

In this connection it is easy to imagine a mechanism [7,16] in which the initial dinuclear complex with N_2 is converted into a hydrazine derivative in a single stage under the influence of an additional two-electron reducing agent 2X:

The dissociation of two π-linkages at once in the four-electron reduction under the influence of four atoms of a one-electron reducing agent is much more favourable on energy grounds than the dissociation of a single π-linkage in a two-electron process. Thus the reaction

$$N_2 + 2H_2 \rightarrow N_2H_4 - 22 \text{ kcal}$$

involves the expenditure of 27 kcal less than in the formation of di-imide from N_2 and H_2.

---

†The reduction potential E_0 is reckoned from the hydrogen potential and corresponds to the free energy of the reaction $M + H^+ \rightarrow M^+ + \frac{1}{2}H_2$ at pH 0. In the present review we are dealing with reducing agents more powerful than hydrogen and having negative values of E_0. The potential will be regarded as higher or lower if its absolute value is correspondingly greater or smaller.

Thus the M_2N_2 complex can play the role of a seed where the subsequent four-electron process removes or diminishes the thermodynamic difficulties which exist in successive one- or two-electron reduction.

The reducing agent X can exist in solution independently of the complex or can be linked to M (for example, the hydrogen atom in the hydride M–H linkage). A fairly common special case of this "four-electron" mechanism may involve the employment of additional electrons from one or both atoms of M forming the complex with N_2. For example, one can formulate the reactions

1. $M_2N_2 + X \rightarrow M{=}N{-}\overset{\displaystyle X}{\overset{|}{N}}{-}M$
2. $2M + N_2 \rightarrow M{=}N{-}N{=}M$ or

(in the second case the dinuclear complex is evidently no longer a hydrazine derivative). The latter reaction is possible when M is a fairly powerful two-electron reducing agent.

It is significant that the formation of complexes with transition metals makes it possible to distribute the dissociation energy of the π-linkages of N_2 in uniform steps, while the "usual" one- or two-electron reduction requires the main energy expenditure in the first stage, i.e. requires a particularly powerful reducing agent.

The consideration of the reduction of nitrogen in protic media, in particular in an aqueous medium, is of considerable interest. In this instance, which occurs, for example, in the biological fixation of nitrogen, solven protons are employed for forming the hydrogen atoms of ammonia:

$$N_2 + 6\bar{e} + 6H^+ \rightarrow NH_3 .$$

The thermodynamics of the successive reduction of nitrogen becomes more favourable in aqueous solution compared with non-polar media, since ammonia, hydrazine, and probably di-imide are hydrated in water with a considerable energy gain, while the initial molecular nitrogen is hardly hydrated at all. The table below lists the enthalpies of formation of ammonia and the intermediates from the elements in the gas phase, in water, and acid solution.

	$N_2 \xrightarrow{H_2} N_2H_2$	$N_2H_2 \xrightarrow{H_2} N_2H_4$	$N_2H_4 \xrightarrow{H_2} 2NH_3$
$\Delta H_{298(gas)}$, kcal mole^{-1}	49	22.7	−22
(Soln. H_2O)	(33.5) *	8.2	−38.4
(Soln. in acid)		−1.8	−64

*On the assumption that the heat of hydration of N_2H_2 is close to the heat of hydration of the N_2H_4 molecule and two NH_3 molecules.

However, in the aqueous phase the reaction with the intermediate formation of di-imide requires reducing agents which are more powerful than molecular hydrogen. An approximate estimate yields −1.1 V for the reduction potential of di-imide in water. Under these conditions, a new difficulty arises in the aqueous solution because reducing agents having reduction potentials much higher than that of molecular hydrogen cannot exist in water, since they must react with the latter to form molecular hydrogen:

$$M + H_2O \rightarrow M^+ + OH^- + \tfrac{1}{2}H_2 .$$

Therefore one- or two-electron reduction of nitrogen in aqueous solution with the intermediate formation of N_2H_2 is virtually impossible.

The reduction potential of M can be much lower than −1.1 V if a four-electron reduction mechanism is adopted. Reducing agents having a reduction potential sufficient to convert nitrogen into hydrazine (−0.23 V) are known and can exist in aqueous solution (for example Cr^{2+} or V^{2+} salts).

Protonation of N_2 in the M_2N_2 complex by an acid or the formation of a hydrogen bond with a water molecule facilitates the four-electron reduction with formation of a hydrazine derivative:

$$M_2N_2 \overset{H^+}{\rightleftarrows} M{=}N{-}\overset{\displaystyle +}{\underset{\displaystyle H}{N}}{=}M \leftrightarrow M{=}N{-}\underset{\displaystyle H}{N}{-}M^+ \xrightarrow{H^+} N_2H_4 .$$

Thus the four-electron mechanism of the reduction of nitrogen with formation of a dinuclear complex ensures, in principle, the possibility of reducing N_2 to hydrazine (as the intermediate or final product) in an aqueous medium.

However, when the reaction proceeds via hydrazine or its derivative, the free energy of the process (bearing in mind the impossibility of the existence of an unduly powerful reducing agent in aqueous solution) must be close to zero. This imposes significant limitations on the thermodynamic properties of the catalyst M which ensures the reduction of nitrogen. Its reduction potential must not be higher than that of the reducing agent and, on the other hand, it cannot be too small, since M must itself be a reducing agent strong enough to reduce nitrogen.

Under these conditions, it is necessary that the heat of formation of the complex M_2N_2 should also be optimal. With increase and decrease of the stability of the complex, the rate of reaction should rapidly decrease, in the first case owing to a decreased rate of reduction of bound nitrogen and in the second owing to a lower concentration of the intermediate complex.

Apparently the stability of dinuclear complexes with N_2 can vary within wide limits and is not related directly to the reduction potential of M, since many stable N_2 complexes are known both with powerful and weak reducing agents. Thus, in order to select a catalyst M for an aqueous medium, capable of catalysing the reducing of nitrogen with formation of hydrazine as an intermediate or final product, one must begin with the fact that both the reduction potential of M and the M–N bond energy must be restricted to comparatively narrow limits. It becomes clear from the foregoing discussion why rapid reduction of nitrogen in an aqueous medium must be a rare exception among the large number of reduction systems. We may note that a combination of suitable thermodynamic properties of the catalyst M is by itself insufficient for the reaction with nitrogen, since the reaction requires that M must have also a suitable ligand environment (a free site for nitrogen, accessibility to the action of the reducing agent) and the two atoms M in the initial complex must be separated by an appropriate distance.

Table 1 shows that on passing to acid media it is possible to employ even weaker reducing agents, since protonation stabilises the resulting hydrazine (or ammonia). However, one must bear in mind that at low pH values the reaction between the reducing agent and water to liberate hydrogen, which is usually catalysed by acids, is accelerated.

The increase of pH on passing to alkaline media can increase the reduction potential of M, since in the reaction

$$M + OH^- \rightarrow MOH + e$$

the reduction potential increases linearly with pH ($E_0 = E_0^0 + 0.059pH$). However, one must also take into account the fact that in the reactions

$$N_2 + 4e + 4H_2O \rightarrow N_2H_4 + 4OH^-,$$
$$N_2 + 6e + 6H_2O \rightarrow 2NH_3 + 6OH^-,$$

and also in

$$2e + H_2O \rightarrow {}^1/_2H_2 + OH^-,$$

the reduction potentials of NH_3, N_2H_4, and H_2 likewise increase linearly with pH, the slope being the same as for M and therefore the difference between the reduction potentials ΔE will be independent of pH. An alkaline medium will in fact favour the thermodynamics of the reduction of nitrogen in those cases where the dependence of the redox potential on Ph is more marked than for hydrazine, which should imply the formation in an alkaline medium of certain new compounds which are more powerful reducing agents than the compound existing in an acid medium [as, for example, in the case of titanium(II) salts, which are moderately strong reducing agents in an acid medium, while in an alkaline medium they liberate hydrogen from water]. Evidently, this corresponds to the formation of ionised species with a high effective negative charge at the metal atom of the reducing agent.

This discussion is based on the assumption that the most economical pathway to the reduction of nitrogen from the standpoint of energy expenditure is the formation of hydrazine derivatives from the complex with N_2.

If account is taken of the possibility of six-electron reduction of nitrogen directly to ammonia, then the process should, in principle, be achieved by weaker reducing agents. However, the probability of such a mechanism is itself apparently very low, since it requires simultaneous and considerable shifts of a large number of nuclei in a single step[22].

Thus preliminary consideration of the possible involvement of transition metal compounds in the reactions involving the reduction of molecular nitrogen shows how the formation of intermediate complexes can give rise to a mechanism in which the thermodynamic difficulties involved in the reduction of N_2 are overcome.

III. REDUCTION OF NITROGEN IN APROTIC MEDIA

1. Nitrogen-fixing Systems

Vol'pin and Shur discovered in 1964 the reduction of nitrogen at room temperature in ethereal and hydrocarbon media in the presence of transition metal compounds ($CrCl_3$, $MoCl_5$, WCl_6, $FeCl_3$, $TiCl_4$) when they react with powerful reducing agents ($LiAlH_4$, EtMgBr, i-Bu_3Al).[1] Ammonia was isolated after the hydrolysis of the reaction product in the presence of nitrogen. The results were then confirmed[23] in experiments with labelled $^{15}N_2$ nitrogen.

Some of these and similar systems were known previously and were used in catalysis, particularly as catalysts of the polymerisation and hydrogenation of olefins and acetylenes. Thus their capacity to activate unsaturated compounds was known.

Moreover, many investigators flushed their systems with nitrogen, which they regarded as inert and there is evidence (see, for example, Refs. 24 and 25) that in the presence of nitrogen certain differences in the behaviour of such systems compared with that *in vacuo* or in an atmosphere of argon were observed even before 1964. Nitrogen sometimes retarded the catalytic polyermisation reaction. Ammonia was actually isolated from the products of the reaction carried out in an atmosphere of nitrogen. Nevertheless, the widely held view that nitrogen is inert evidently prevented many investigators from reaching definite conclusions concerning this reaction before 1964 and this is why Vol'pin and Shur's work initiated a new stage in the study of the reduction of nitrogen in solution.

In the first experiments of Vol'pin and Shur appreciable yields of the reduction product [up to 25% of ammonia (after the hydrolysis of the product) relative to the amount of transition metal employed] was observed at comparatively high nitrogen pressures (150 atm). Soon Vol'pin and his coworkers succeeded in obtaining more active systems. Thus in the reaction of N_2 with the products of the reaction of Cp_2TiCl_2($Cp = \pi$-C_5H_5) with EtMgBr in ether the yield of ammonia (after hydrolysis) was 67% per mole of the titanium compound employed, even at atmospheric pressure[26]. On increasing the pressure, the yield of ammonia became nearly quantitative.

Later it was shown[27] that free metals, for example, magnesium activated by iodine, can be used as reducing agents and that simple purely inorganic systems such as $TiCl_4 + Mg(MgI_2) + N_2$ can be used to reduce nitrogen.

Evidently, the role of the non-transition metal or the organometallic compound consists primarily in the reduction of the transition metal compound, such reduction being known to proceed frequently via alkyl or aryl derivatives of transition metals. Indeed, it has been found[28] that the reduction of nitrogen can be carried out also without a specially added reducing agent on heating solutions of dialkyl and diaryl derivatives Cp_2TiR_2 in an atmosphere of N_2. In this case nitrogen is reduced under the influence of low-valent titanium derivatives formed as intermediates or as final products of the thermal decomposition of the organotitanium compounds.

The reduction of nitrogen (albeit with a low yield of the product) has been observed also on heating with nitrogen a previously prepared solution of dicyclopentadienyltitanium(II).[28] Thus molecular nitrogen was found to be capable of reacting in solution with many transition metal compounds.

Subsequent studies in many laboratories in different countries led to the discovery of various systems interacting with nitrogen (see the appropriate reviews[24,25,29-33]).

The range of transition elements and reducing agents is now very large: Henrici-Olive and Olive[34] and also van Tamelen et al.[35] used successfully as reducing agents naphthalene derivatives of alkali metals (lithium, sodium, and potassium). Bayer and Schurig[36] showed that alkali metals (Li, Na, K, Rb, and Cs), alkaline earth metals (Mg and K), and the lanthanides (La and Ce) can serve as reducing agents.

Bell and Brintzinger obtained about 1 mole of ammonia (after hydrolysis) per mole of $FeCl_3$ using as a reducing agent the doubly charged anion formed by treating 2,6-dimethylnaphthalene with lithium[37].

Apart from the transition metal compounds already mentioned, vanadium[34,38], manganese[39], and cobalt[27,39] chlorides, tetraalkoxy-derivatives of titanium[40-43], vanadium, chromium, molybdenum, manganese, and nickel acetylacetonates[40], cyclopentadienyl derivatives of zirconium[36] and niobium[44], and triphenylphosphine complexes of titanium[45] and iron[39] proved to be active.

Negative results have also been published. For example, dicyclopentadienyltitanium dichloride, which forms an exceptionally active system with organomagnesium compounds, does not reduce nitrogen in the presence of tri-

isobutylaluminium[30]. The explanation is probably that in the latter case the reduction terminates with the formation of stable titanium(III) complexes[46,47]. Cobalt and manganese compounds proved to be inactive in many cases[30].

Nickel, palladium, copper, and platinum compounds apparently could not be used at all in systems reducing N_2 in solutions[1,30,39].

The yields of ammonia (after the hydrolysis of the products) are extremely varied and in different systems can amount to between a fraction per cent and one mole of ammonia per mole of the transition metal compound employed. In several cases between one and two moles of ammonia are formed per mole of the transition metal.

It was reasonable to attempt the catalytic reduction of nitrogen, for example by a catalytic hydrogenation process. It was found that hydrogen usually inhibits the reaction, lowering the yield of the product[36,40,48] even in those systems where catalytic hydrogenation of olefins is possible. In some cases hydrogen does not have much influence on the yields of products (for example, in the reactions involving vanadyl and molybdenyl acetylacetonates with LiBu). In certain systems, for example, $Ti(OEt)_4$ + $(i\text{-}Bu)_3Al + N_2$, an appreciable increase of the yield of ammonia (after hydrolysis) was observed following the introduction of molecular hydrogen[40]. However, with increase of hydrogen pressure, the yield of ammonia passes through a maximum (increasing approximately by a factor of 1.5) and then falls.

In none of the instances was catalytic hydrogenation observed. However, Vol'pin and his coworkers[39,49,50] achieved the catalytic reduction of nitrogen under the influence of a more powerful reducing agent. Thus metallic aluminium reduces nitrogen at 130°C and a pressure of 100 atm in the presence of titanium tetrachloride and aluminium bromide. Metallic aluminium without additives is known to react with nitrogen only at much higher temperatures. The yield of ammonia after hydrolysis can reach hundreds of ammonia molecules per molecule of the added titanium compound. The reaction takes place in benzene or aluminium bromide melt, which (like titanium tetrachloride) is necessary for catalytic reduction.

Lithium aluminium hydride can be used as a reducing agent instead of aluminium. In this case up to 100 moles of ammonia (after hydrolysis) per mole of the initial titanium tetrachloride can be formed even at 60–70°C when the reactions are performed in a molten mixture of aluminium bromide and chloride. A catalytic system can also be obtained (up to 10 moles of ammonia per mole of titanium) when the nitrogen–hydrogen mixture is heated to 130°C with a mixture of $(BuO)_4Ti + (i\text{-}Bu)_3Al + AlBr_3$ in the presence of benzene. Hydrogen activates the system in this case, since in its absence only two moles of ammonia per mole of titanium are obtained.

Here we may note that, although catalytic hydrogenation of nitrogen has not so far been observed in solutions, Japanese workers showed recently that the introduction of alkali metals strongly activates heterogeneous catalysts of the gas-phase synthesis of ammonia. Thus Tamaru and coworkers[51,52] observed that the reaction of iron, cobalt, titanium, and molybdenum complexes of phthalocyanines with metallic sodium resulted in the formation of a donor–acceptor complex which can catalyse the synthesis of ammonia from nitrogen and hydrogen starting from a temperature as low as 110°C. Ozaki, Aika, and Hori[53,54] showed that alkali metals sharply increase the catalytic activity of ruthenium, osmium, iron, molybdenum, and other metals in the synthesis of ammonia, ruthenium activated by potassium being capable of catalysing the reaction at a temperature as low as 146°C and atmospheric pressure. There is no doubt that alkali metals enhance the electron-donating properties of the metal atoms in the catalyst (this is shown particularly by the activity series Cs > K > Na), which apparently occurs in many instances also in the fixation of nitrogen in solutions.

Van Tamelen and coworkers[42] achieved the cyclic hydrolysis-reduction in the $(i\text{-}C_3H_7O)_4Ti + NaNp + N_2$ system in tetrahydrofuran (THF). By adding successively small amounts of isopropyl alcohol, it was possible to hydrolyse the product to ammonia and then regenerate it with metallic sodium, after which it was again capable of reacting with nitrogen. Thus it was possible to accumulate up to 3.4 moles of ammonia per mole of titanium alkoxide in the course of 5 such cycles. Following the addition of aluminium tri-isopropoxide, the system was capable of forming 2.75 moles of ammonia per mole of titanium in only one cycle.

Van Tamelen and coworkers also reported the electrochemical reduction of nitrogen[41,43] in dimethoxyethane at a nichrome cathode using an aluminium anode. After eleven days at 40 V, the formation of 10.2 millimoles of ammonia (6.1 moles of ammonia per mole of titanium) was observed. It was noted that an appreciable amount of aluminium (15.1 millimoles) was lost under these conditions from the anode during electrolysis and that aluminium could apparently also behave as a reducing agent.

The reduction of nitrogen in solutions is usually inhibited by compounds such as carbon monoxide and acetylenes[24,29]. Moisture and oxygen naturally also reduce the yield since they interact with nitrogen-reducing systems.

2. Reaction Products

Nitrides. Ammonia is usually formed in the hydrolysis of the nitrogen reduction products in aprotic media. Among the products which hydrolyse with formation of ammonia, amides, imides (M–NH_2, M–NH–M), or nitrides might have been expected, since ammonia itself should not be stable in nitrogen-reducing systems containing metals or organometallic compounds.

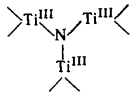
Soon after the first reports by Vol'pin, it was observed[55] that in the products of the reaction carried out in $(C_2D_5)_2O$ and using C_2D_5MgBr as the reducing agent the ammonium salt formed after decomposition of acid does not contain deuterium atoms. This evidently indicates that before hydrolysis the product did not contain deuterium atoms linked to nitrogen, i.e. that it was probably a nitride.

This conclusion was confirmed further by the observation (of ammonia) in a number of studies of systems in which the reactants did not contain nitrogen at all (for example $TiCl_4 + Mg + MgI_2 + N_2$).

If the involvement of the solvent in the reaction is not postulated, there is virtually no doubt about the formation of nitrides as the products in such a system. Aluminium nitride is evidently the product of the reduction of nitrogen in the catalytic system $Al + TiCl_4 + AlBr_3 + N_2$ (where the reduction can be carried out in the aluminium bromide melt). The detailed structures of the nitride products are unknown for the majority of the systems.

Vol'pin and coworkers[39,50] found that the complex $C_6H_6TiCl_2 2AlCl_3$, obtained in the reduction of titanium tetrachloride by aluminium in the presence of aluminium chloride and benzene by the method of Natta et al.[56],

reacts with nitrogen at 130°C with formation of the compound having the elemental composition $(C_6H_6)[TiCl_2 2AlCl_3]_3N$ and hydrolysed with formation of ammonia. This product is probably a complex nitride incorporating three titanium atoms per nitrogen atom:



A thorough investigation of the products of the reaction of nitrogen in the system $TiCl_3(THF)_3 + Mg + N_2$ and $VCl_3(THF)_3 + Mg + N_2$ was carried out by Yamamoto and coworkers [57,58]. In both systems the reaction proceeds at room temperature and atmospheric pressure, the amount of ammonia formed not exceeding one mole per mole of the transition metal. After the absorption of 0.5 mole of nitrogen per mole of titanium in the first system (2.5 gramme-atoms of magnesium are employed at the same time), a black diamagnetic powder with the composition $TiNMg_2Cl_2(THF)$ can be isolated from solution and the stoichiometry of the process can be represented by the equation

$$TiCl_3(THF)_3 + 2.5Mg + 0.5N_2 \rightarrow TiNMg_2Cl_4THF + 0.5MgCl_2(THF)_2 .$$

When the product is decomposed by HCl, ammonia and hydrogen are formed. The structure of the molecule formed in the reaction with nitrogen is not clear, but it is probably not monomeric and cannot be represented as a derivative of titanium(III) and magnesium(II), this being indicated by the evolution of hydrogen in the reaction with HCl. A complex of bipyridyl with zero-valent magnesium can be isolated when the reaction product is treated with bipyridyl. In terms of its chemical properties, the product behaves as a nitride: it evolves ammonia on hydrolysis, does not evolve nitrogen on heating to 200°C and, on treatment with pyridine, bipyridyl, and benzoyl chloride, magnesium can be removed from the product either partly or completely, but the nitrogen formed in these processes remains bound to titanium and can be evolved in the form of ammonia only by hydrolysis.

The reaction with nitrogen in the system $VCl_3(THF)_3 + Mg + N_2$ proceeds similarly (although somewhat more slowly), the product being the complex $VNMg_2Cl_2(THF)$. It is also diamagnetic, does not evolve nitrogen on heating, and hydrolyses with evolution of ammonia, i.e. it is evidently a complex nitride. However, nitrides are not the only possible products of the reduction of nitrogen in such systems.

As already stated, in certain cases hydrogen increases the yield of ammonia after the hydrolysis of the reaction products [40]. Presumably in certain instances it enters into the composition of the product. Indeed, it has been found [59] that hydrogen atoms are linked to the nitrogen atoms, i.e. a complex imide M–NH–M may be formed in this case.

In an early study by Van Tamelen [60] metallic potassium was added to a solution containing a suspension of dialkoxytitanium dichloride and nitrogen was passed into the system. The formation of free ammonia, which was driven out of the system with the nitrogen, was then observed. The evolution of ammonia continued for several weeks and after its cessation the addition of metallic potassium gave rise to the formation of fresh ammonia. The overall yield of ammonia reached only 10–15% relative to titanium. If, as claimed by the authors, ammonia is not formed owing to the traces of moisture in nitrogen, presumably the solvent serves as a source of hydrogen atoms by reacting with the nitride, which is the primary product.

Organonitrogen compounds. The studies by Vol'pin and coworkers [30,61-64] first established the possibility of forming organonitrogen compounds in the reduction of molecular nitrogen with isolation of aromatic amines after hydrolysis. In the systems $Cp_2TiCl_2 + LiPh + N_2$ and $Cp_2TiPh_2 + LiPh + N_2$ in ether the hydrolysis of the products of the reaction with nitrogen (20°C, N_2 pressure 100 atm) led to the detection of aniline (0.15 mole of aniline together with 0.65 mole of ammonia per mole of the titanium compound).

When *p*-tolyl-lithium or *m*-tolyl-lithium are employed as the reducing agents, mainly *p*- and *m*-toluidines respectively are found in the reaction products, i.e. nitrogen largely replaces the lithium.

In the presence of *o*-tolyl-lithium a mixture of all three isomers is found in the product. The authors suggest that the isomers are produced via the intermediate formation of dihydrobenzene in a complex with titanium. In analogous systems involving aliphatic organolithium compounds only insignificant yields of aliphatic amines were observed.

Van Tamelen and Rudler demonstrated the possibility of obtaining organonitrogen compounds by treating the nitrides formed as primary products with compounds containing the carbonyl group [65]. Thus when ketones or acid chlorides are added to the reaction product subsequent to the absorption of nitrogen in the $Cp_2TiCl_2 + Mg + N_2$ system, amines or nitriles are formed in the reaction mixture after several days.

$$R_2CO \rightarrow R_2CHNH_2 + (R_2CH)_2NH ,$$
$$RCOCl \rightarrow RCN .$$

These data indicate a comparatively high reactivity of the nitride derivatives, which distinguishes them from the usual nitrides, formed, for example, on combustion of metals in nitrogen. Subsequently such reactions were investigated by Dormond et al. [66]

Hydrazine. In 1969 studies by two groups of investigators demonstrated simultaneously that, in addition to ammonia, hydrazine may be formed in nitrogen-fixing systems in aprotic media [4,67], i.e. a product of incomplete reduction of nitrogen may be observed after the hydrolysis of the primary products.

In the system $(i\text{-}C_3H_7O)Ti + NaNp + N_2$ in THF [67] the yield of hydrazine following the hydrolysis of the products increased with decrease of the molar ratio $[Ti^{IV}]/[NaNp]$ to give maximum yields of 15–19% (relative to titanium), ammonia being formed together with hydrazine (the ratio $2NH_3/N_2H_4$ varied in the range 3.3–5). The compound forming hydrazine can be reduced further to nitrides by an excess of NaNp.

When $(i\text{-}C_3H_7O)_4Ti$ is replaced by $CoCl_2$, $MoCl_5$, WCl_6, $CrCl_3$, $NiBr_2$, or $FeCl_3$, hydrazine is not formed.

A complex of molecular nitrogen, dissociating reversibly with evolution of nitrogen (see below), is formed in the system $Cp_2TiCl_2 + i\text{-}C_3H_7MgCl + N_2$ at low temperatures (between −80° and −100°C) [4,68]. At −60°C in the presence of excess isopropylmagnesium chloride nitrogen is reduced, evidently via the intermediate formation of the above complex, to a hydrazine derivative, which hydrolyses to form N_2H_4. At such low temperatures nitrides are hardly formed and subsequent reduction to ammonia derivatives proceeds only above 0°C.

Appreciable yields of hydrazine were obtained later in reactions with nitrogen in the systems $TiCl_4 + Al + AlBr_3$, [39] $FeCl_3(Ph_3P)_2 + i\text{-}C_3H_7MgCl$, [69] $MoCl_5 + i\text{-}C_3H_7MgCl$, [69] $FeCl_3 + LiPh$, [70] and $FeCl_3 + Mg$. [71] The results of some of these studies will be discussed in greater detail in the next section.

3. The Mechanism of the Reduction of Nitrogen in Aprotic Media

Many systems capable of reducing nitrogen in aprotic media in the presence of many transition metal compounds, various reducing agents, in different solutions, and under different reduction conditions refute the idea that the reaction mechanism is always the same. In most cases even the nature of the nitride reduction products is still obscure and the reaction mechanism can be discussed only in the broadest outline. The reduction of nitrogen was sometimes investigated in order to elucidate the reaction mechanism, but the results obtained in these studies are also frequently contradictory, are being revised, and cannot be regarded as unambiguous.

The involvement of powerful reducing agents together with transition metal compounds made it necessary to assume from the very beginning that N_2 is activated by compounds of transition metals in a low state of oxidation which are formed under the influence of reducing agents.

Such activation must involve the formation of a complex of nitrogen and the metal atom and, as early as 1966, it was possible to suggest on the basis of general considerations and certain analogies, including the analogy with the reaction of methylene and nitrogen discovered at that time [13,14],

$$CH_2 + N_2 \rightleftarrows CH_2N_2 ,$$

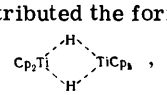
that nitrogen is activated by "carbene-like" compounds such as $Ti^{II}d^2$ and $Fe^{II}d^6$. However, the specific mechanism of the reduction remained unknown and various workers put forward different hypotheses to account for the results.

The involvement of hydrides in the reduction of nitrogen. It has been shown that hydrides which evolve hydrogen on hydrolysis (HD under the influence of D_2O) are formed in many nitrogen-fixing systems. The involvement of hydride linkages in catalytic reactions, particularly in the hydrogenation of olefins, suggested that the M–H bond can be involved also in the reduction of nitrogen, for example by the insertion of the N_2 molecule with formation of M–N=N–H.

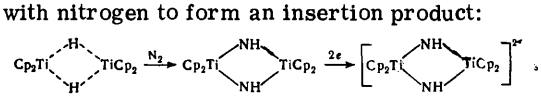
Systems incorporating Cp_2TiCl_2, which are homogeneous and in certain cases (for example, with EtMgBr) effectively reduce nitrogen even at atmospheric pressure, have been investigated in greatest detail from the standpoint of the mechanism. It has been established [55] that hydrides are formed in this system together with nitrides simultaneously with the reduction of nitrogen.

The inhibiting effect of hydrogen, which was observed for many nitrogen-fixing systems (see above), can be explained by the fact that the hydrides formed in the reaction of low-valent transition metal derivatives with hydrogen are mostly inactive in relation to nitrogen.

Nevertheless, on the basis of ESR data for the Cp_2TiCl_2 + EtMgBr + N_2 system, Brintzinger [72] concluded that the hydride, to which he attributed the formula



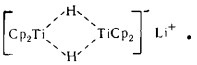
reacts with nitrogen to form an insertion product:



This hypothesis, which is attractive in view of its simplicity, was subsequently extended to biological nitrogen fixation [73]. However, it was not confirmed in subsequent investigations.

In the first place, this mechanism contradicts data [55] showing the absence of NH groups in the product. Moreover, as shown subsequently by Brintzinger himself [74], the ESR signal which has been attributed to the product of the reaction with nitrogen is not in practice associated with the nitrogen. The triplet signal of the dihydride was found to belong to a monomeric species to which Brintzinger attributed the formula of the anion $[Cp_2TiH_2]^-$. [74] This dihydride does not change in the presence of nitrogen [36] and is probably a side product.

Henrici-Olive and Olive showed by the ESR method that a species containing two hydrogen atoms per tervalent titanium atom is formed in the system Cp_2TiCl_2 + LiNp. [75] In this case the hyperfine structure of the spectrum indicates the involvement of the lithium atom in the complex and the formula of a dimer with titanium in different valent states (bivalent, tervalent) was attributed to this complex: [31]



It is suggested that nitrogen forms a complex with bivalent titanium, this being followed by reduction under the influence of lithium naphthalide.

A similar dinuclear structure of the hydride has been suggested for the system Cp_2TiCl_2 + EtMgBr, [31] it being postulated that the reaction of nitrogen with bivalent titanium in the complex does not alter the ESR signal of the titanium(III) hydride, which remains unchanged.

Presumably the hydride products are in reality related to the hydride complex observed previously—the product of the reaction of Cp_2TiCl_2 with $(i\text{-}Bu)_3Al$ and of Cp_2TiCl_2 with $(i\text{-}Bu)_2AlH$). This complex has been investigated by ESR and the formula  was attributed to it on the basis of the hyperfine structure [76]. The general formula  where n = 2, 1, or 0 for aluminium, magnesium, lithium (or sodium) respectively, can probably be attributed to the dihydride complexes. Like their aluminium precursor, titanium(III) dihydride complexes involving magnesium, lithium, and sodium are evidently inactive with respect to nitrogen and are side products.

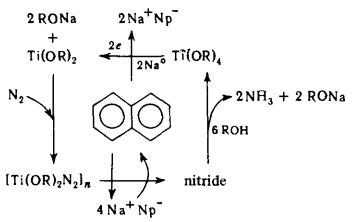
The formation of hydrides inactive in relation to nitrogen apparently constitutes a general phenomenon in the reduction of nitrogen in aprotic media. However, as already mentioned, in certain cases nitrogen can also increase the yield of the reduction product. In these systems, which usually contain alkoxy-derivatives of titanium, one cannot rule out the involvement of hydrides in the fixation of nitrogen, but the available data are still insufficient for more specific conclusions concerning the mechanism.

The degree of oxidation of the transition metal. The degree of oxidation of the transition metal in compounds active with respect to nitrogen has been discussed in a number of studies. Most of these refer to systems including titanocene derivatives. On the basis of ESR data, Vol'pin and coworkers [27] concluded that in these systems the reaction with nitrogen begins after the disappearance of titanium(III), i.e. the degree of oxidation of titanium is less than three. It has been concluded [77] that the Cp_2Ti^- ion [which may be regarded as a derivative of

titanium(I)] reacts with nitrogen. As already stated, Olive suggested that titanium(II) in a complex with a hydride derivative of titanium(III) is active in relation to nitrogen.

Maskill and Pratt [78] and Bayer and Schurig [36] postulated that zero-valent titanium complexes are active.

Bivalent titanium compounds were assumed to be active by van Tamelen and coworkers [32]. Thus in systems incorporating $Ti(OR)_4$, which have been investigated in greatest detail in these studies and which permit cyclic hydrolysis-reduction, the following mechanism in which the $Ti(OR)_2$ species reacts with nitrogen has been adopted [79]:



Titanium(II) and vanadium(II) complexes are assumed to be active in relation to nitrogen by Yamamoto et al. [37] in the systems $TiCl_3(THF)_3$ + Mg and $VCl_3(THF)_3$ + Mg. The study of the reduction of nitrogen in the systems VCl_3 + LiNp and $CrCl_3$ + LiNp [31,80] by ESR showed that the metals in these systems must be very highly reduced.

We may note that precisely in these instances, evidently involving very powerful reducing agents, the yield of ammonia per atom M under the conditions of high Red/M ratios reaches 2. It is interesting to note that the yield of reduction products in the VCl_3 + LiNp + N_2 system depends on the order in which the reducing agent and the vanadium compound are mixed in an atmosphere of nitrogen [38]. If a solution of lithium naphthalide is added to a solution of VCl_3, the amount of nitrogen absorbed reaches 0.39 mole per mole of VCl_3. If, on the other hand, a VCl_3 solution is added to a solution of lithium naphthalide, up to 0.7 mole of N_2 is reduced.

Kinetic data and preliminary conclusions concerning the structure of the intermediate complexes. Maskill and Pratt [78,81] employed a kinetic approach for the homogeneous system Cp_2TiCl_2 + EtMgBr + N_2. They established that, when the system is flushed with nitrogen, the species formed on reduction of dicyclopentadienyltitanium dichloride which is active with respect to nitrogen can exist for a long time in the absence of nitrogen, since the yield of products and the rate of their accumulation depend little on whether nitrogen is passed in immediately after mixing the reactant or after a long time‡. It was discovered that, above 0.5 atm, the rate of reaction is independent of the nitrogen pressure and, in the presence of a sufficient excess of the reducing agent, is independent of the concentration of ethylmagnesium bromide. Under these conditions, the rate was found to be proportional to the square of the initial concentration of the titanium compound.

‡We may note that in the study of Nechiporenko et al. [55] the yield fell sharply when nitrogen was introduced to the reaction mixture only when some time elapsed after the mixing of the reactants. Evidently, this difference from the result of Maskill and Pratt [81] is due to the fact that the system of Nechiporenko et al. [55] was static and the gases evolved could react with the active species. Indeed, it was subsequently shown that ethylene in the system investigated forms the π-crotyl complex $Cp_2Ti(\pi\text{-}C_4H_7)$. [82]

The results indicate the formation of a dinuclear complex when two reduced titanium derivatives interact. Evidently the interaction determines the rate of the entire process when the nitrogen pressure is in excess of 0.5 atm and the subsequent reaction with nitrogen proceeds rapidly. It is interesting to note that qualitatively similar kinetics (proportionality to the square of the concentration of the transition metal compound, the attainment of a limiting rate with respect to the nitrogen and reducing agent concentrations) were observed subsequently in a study of another homogeneous system—$FeCl_3$ + LiPh + N_2 (see below) [70]. In this case one can also conclude that a dinuclear complex is formed.

In the systems investigated by Yamamoto [37], $TiCl_3(THF)_3$ + Mg + N_2 and $VCl_3(THF)_3$ + Mg + N_2, the rate of reaction in THF is consistent with first order with respect to the concentration of the initial chlorides, the amount of unconsumed magnesium, and the N_2 pressure. The amount of reduced nitrogen does not, however, exceed one molecule for two titanium atoms. Hence, it follows that the most probable mechanism involves the formation of a complex by nitrogen with a dinulcear species containing reduced titanium and subsequent reduction of the activated nitrogen by magnesium.

In general, in those cases where the yields of products approach one NH_3 molecule (after hydrolysis) per transition metal atom the formation of a dinuclear complex, in which two transition metal atoms are linked to two nitrogen atoms, is probable. As stated above, the yield of ammonia often approaches two molecules per transition metal atom. As already mentioned, this has been observed for highly reducing systems. These results probably correspond to mononuclear complexes with subsequent reduction by non-transition metal atoms, for example:

$$MN_2 + LiNp \rightarrow M{-}N{=}N{-}Li + Np \xrightarrow{LiNp} N^{3-}.$$

On this hypothesis, it is possible to account for the different results obtained for different orders of mixing of the reactants [38]. If the vanadium compound is added to the reducing agent, i.e. the reaction proceeds in the presence of lithium naphthalide, there is a possibility of the formation of the complex V–N=N–Li and up to one mole of N_2 per mole of the transition element can be reduced. For the reverse order of mixing, the dinuclear complex includes two transition element atoms and the maximum yield corresponds to the reduction of 0.5 mole of N_2 per mole of vanadium.

The study of intermediate complexes with molecular nitrogen. Bearing in mind the very high ionisation potential of the nitrogen molecule (367 kcal mole^{-1}), the negative sign and high absolute magnitude of its electron affinity (−84 kcal mole^{-1}), [7] and the high dissociation energy of the first π-linkage which is ruptured, it might have been possible to conclude long ago that complex formation is essential as the first stage in the activation of nitrogen.

After the discovery by Allen and Senoff of the first complex with bivalent ruthenium [2] and the first proof that such complexes can be obtained directly from molecular nitrogen [3,83], it appeared that the activation of nitrogen by complex formation received direct confirmation. The first studies on the properties of the complexes appeared to support this hypothesis. It has been concluded that [2,84] nitrogen in the complex can be reduced to ammonia on treatment with sodium tetrahydroborate. However, subsequent careful tests using $^{15}N_2$ showed [7,85–87] that the reports concerning the reduction of nitrogen in the complex were incorrect and that in reality nitrogen in the complexes is

not reduced either by sodium tetrahydroborate or by other reducing agents. With increase of the number of known stable mononuclear and dinuclear complexes (see the reviews [7-9]), an increasing number of such complexes were tested to check the possibility of further reactions of the nitrogen bound in them and each time the results proved to be negative. Initially the studies on the complexes with nitrogen and the reduction reactions in the Vol'pin–Shur systems developed in parallel and there were no points of contact between them.

It was not until 1969 that the first reports of complexes with nitrogen in which the nitrogen ligand is capable of further reactions were published. The number of such complexes then began to increase and some of them could be isolated and investigated in detail. These studies in fact yield the most definite conclusions concerning the mechanism of the reduction of nitrogen.

Van Tamelen et al. [79] were the first to report a complex with nitrogen capable of further reduction. According to their data [79], this complex is formed when a benzene solution of dimeric titanocene is stirred for three weeks in an atmosphere of nitrogen. During this period, more than 0.9 mole of nitrogen is absorbed per mole of monomeric titanocene.

The infrared spectrum of a solution of the titanocene complex with nitrogen shows a band at 1960 cm^{-1}, which has been tentatively assigned to the NN vibration in the complex, although experiments with $^{15}N_2$, which would confirm this hypothesis, were evidently not carried out. Nowadays this assignment of the frequency appears doubtful, in particular because the NN frequency in the intermediate complexes is usually much lower. The complex with nitrogen is formed reversibly and decomposes with the evolution of nitrogen when the nitrogen over the solution is replaced by argon. Measurements of the molecular weights showed that the complex is dimeric and the formula $(Cp_2TiN_2)_2$ was attributed to it. On treatment with sodium naphthalide the nitrogen in the complex is reduced quantitatively to ammonia: $(Cp_2TiN_2)_2 \xrightarrow{e} \xrightarrow{H^+} 4NH_3$. We may note that this result is unusual for metallocene systems, which in other cases give rise to at most one mole of ammonia per mole of titanium. More detailed data on this complex were not subsequently published.

Complexes with quite different properties were discovered in the same year in the nitrogen-fixing systems $Cp_2TiCl_2 + RMgX + N_2$ (R = i-Pr or Et).[4] The most definite results were obtained for isopropylmagnesium chloride. On the hypothesis that the intermediate complexes must be unstable, the authors [4] attempted to detect the formation of the complexes on sharp cooling of the solution.

When the reaction of isopropylmagnesium chloride with dicyclopentadienyltitanium dichloride was carried out at −60°C and the solution was cooled further under nitrogen to between −80° and −100°C, an intensely blue complex with nitrogen was formed rapidly and reversibly (λ_{max} = 610 nm). Spectroscopic study of the reversible complex formation reaction with nitrogen subsequently showed that the complex incorporates two titanium atoms per nitrogen molecule and that its heat of formation is only 5 kcal $mole^{-1}$.[88] Evidently this complex can be isolated from solution in the system $Cp_2TiCl + i\text{-}C_3H_7MgCl + N_2$.[89] It is somewhat more stable in the solid state than in solution, but decomposes slowly at a temperature as low as −70°C with liberation of nitrogen. The composition of the complex corresponds to the formula $(Cp_2TiR)_2N_2$. A more stable intermediate complex, formed in the system $Cp_2TiCl_2 + (i\text{-}C_3H_7)MgCl + N_2$ in the presence of triphenylphosphine, has also been reported[4]. The complex with nitrogen is likewise intensely coloured (λ_{max} = 420 and 520 nm). On treatment with alcohol, the complexes evolve nitrogen and on standing in the presence of an excess of a reducing agent the nitrogen bound in the complex is converted into a nitride, which hydrolyses to form ammonia.

A more stable complex, analogous to the blue complex $(Cp_2TiR)_2N_2$ in composition, was isolated by Teuben and de Liefde Meijer in the reaction between Cp_2TiPh and N_2 in toluene at −78°C.[90] In this case the complex slowly evolves nitrogen above 0°C and rapidly at 70°C. Subsequently a number of $(Cp_2TiR)_2N_2$ complexes, where R = *o*-, *m*-, or *p*-tolyl, benzyl, or pentafluorophenyl, were obtained similarly [91,92].

In all cases the complexes are formed reversibly in toluene solution and give rise to the appearance of an intense blue colour (λ_{max} = 600–630 nm). The complexes are diamagnetic. Their infrared spectra do not show appreciable absorption corresponding to the vibration of the NN bond. The complexes with nitrogen exhibit extremely varied thermal stabilities. Thus the *m*-tolyl complex decomposes only at 75°C, the *o*-tolyl complex evolves nitrogen at −20°C, and the 2,6-dimethylphenyl derivative is not formed at all.

The structure of the complexes is still obscure but, according to infrared spectroscopic data, the nitrogen molecule is probably located symmetrically between two titanium atoms or a structure of the π-complex type is formed.

The extremely large extinction coefficient in the region of the visible absorption maximum suggests that the blue adducts with nitrogen are charge-transfer complexes. In accordance with the formula, it is reasonable to assume that the degree of oxidation of the species reacting with nitrogen is three [91,92] and that the structural formula of the complex is, for example,

$$Cp_2Ti\diagdown N \diagup\!\diagdown N \diagup TiCp_2 .$$

However, the nitrogen complexes with metal compounds having the d^1 electronic configuration are at any rate very unusual and the origin of the intense blue absorption band is not clear for this type of structure. In order to retain the earlier hypothesis that bivalent titanium must be active in the relation to nitrogen, one can postulate the structure

$$[Cp_2Ti^{II}] \rightarrow N{\equiv}N \rightarrow [R_2Ti^{IV}Cp_2]$$

or

$$[Cp_2TiR]^- \rightarrow N{\equiv}N \rightarrow [Cp_2TiR]^+$$

and regard these complexes as analogous to the intensely coloured dinuclear complexes with nitrogen containing univalent rhenium, which were first obtained and investigated by Chatt et al.[93] Here nitrogen behaves as a bridge between the donor (Re^I) and the acceptor, which can be a compound incorporating metals with the d^0 electronic configuration, for example:

$$Re^I \rightarrow N{\equiv}N \rightarrow AlR_3 .$$

The dinuclear complexes $(Cp_2TiR)_2N_2$ evidently constitute the first stage in the activation of nitrogen in the system under consideration. Their hydrolysis results in the liberation of molecular nitrogen without appreciable reduction. When $(Cp_2Ti\ i\text{-}C_3H_7)_2N_2$ is treated with an excess of $i\text{-}C_3H_7MgCl$, new complexes are formed which evolve hydrazine on hydrolysis after reduction at low temperatures or ammonia at temperatures above 0°C.

The nitrogen in the complex $(Cp_2TiPh)_2N_2$ can be reduced at −20°C with sodium naphthalide in THF.[91,92] This results in the formation of products, which hydrolyse with liberation of hydrazine and ammonia and also the formation of traces of aniline, the overall yield being quantitative with respect to the nitrogen in the complex. About half the nitrogen is converted into hydrazine. There is evidence that the cyclopentadienyl structure is destroyed on reduction.

In the search for intermediate complexes corresponding to more highly reduced states of nitrogen, the system $Cp_2TiCl + CH_3MgI$ was investigated[94,95] in ether. In this case Cp_2TiCH_3 is evidently formed in solution in the first stage and on cooling to −100°C reacts with nitrogen, forming an intensely blue complex. On standing for about 1 h at −70°C, the blue complex gradually disappears and a dark complex with the composition $(Cp_2Ti)_2N_2$, which is stable at room temperature, is deposited from the solution.

The infrared spectrum of this complex shows a band at 1285 cm^{-1}, shifting to 1235 cm^{-1} when $^{14}N_2$ is replaced by $^{15}N_2$, which shows that it belongs to the NN vibration.

Measurement of the magnetic susceptibility showed that the magnetic moment of the complex decreases reversibly with decrease of temperature, which suggests an equilibrium between the singlet and triplet states of the complex. It can be represented schematically as follows:

$$\underset{\text{triplet}}{Cp_2Ti^{III}-N=N-Ti^{III}Cp_2} \rightleftharpoons \underset{\text{singlet}}{CpTi^{IV}=N-N=Ti^{IV}Cp_2} .$$

The difference between the energies of these two states amounts to only 85 cal $mole^{-1}$ according to the measurements of Ivleva et al.[96]

When the complex is treated with a methanol solution of hydrogen chloride at −60°C, the formation of equal amounts of nitrogen and hydrazine is observed, the sum nitrogen + hydrazine being equivalent to half the amount of titanium, in agreement with the above formula. When the complex is treated with hydrogen chloride in ether, the main products are nitrogen and ammonia (the yield of ammonia is about 30% with respect to titanium) and hydrazine is hardly formed at all. These results can be explained by the fact that in the hydrolysis of the complex the primary product is di-imide, which, depending on the conditions, subsequently disproportionates to nitrogen and hydrazine or to nitrogen and ammonia:

$$(Cp_2Ti)_2N_2 + 2HCl \rightarrow 2Cp_2TiCl + N_2H_2 ,$$
$$2N_2H_2 \rightarrow N_2 + N_2H_4 ,$$
$$3N_2H_2 \rightarrow 2N_2 + 2NH_3 .$$

Thus the complex can be regarded as a derivative of di-imide, although, according to the infrared spectroscopic data, the multiplicity of the NN linkage in the complex is probably less than two.

The complex, which evidently corresponds to the next stage in the reduction of nitrogen in the coordination sphere of titanium, was isolated in the reduction of titanocene by isopropylmagnesium chloride in the presence of nitrogen at −60°C for 3 h in ethereal solution[97]. According to analysis, its composition is $(Cp_2Ti)_2N_2MgCl$. The complex is paramagnetic, its magnetic susceptibility corresponding to one electron for two titanium atoms. According to infrared spectroscopic data, the NN vibration lies at 1260 cm^{-1}, as shown by the isotopic shift of the band to 1220 cm^{-1} when $^{15}N_2$ is used in the synthesis instead of $^{14}N_2$. In accordance with these data, the structure of the complex can be represented in the following form:

$$Cp_2Ti^{III}-N=N \rightarrow Ti^{II}Cp_2 \leftrightarrow Cp_2Ti^{IV}=N-N-Ti^{III}Cp_2 ,$$
$$\qquad\qquad\quad | \qquad\qquad\qquad\qquad\quad \diagdown MgCl$$
$$\qquad\quad MgCl$$

the second formula being preferable. When the complex $(Cp_2Ti)_2B_2MgCl$ is treated with an alcoholic solution of hydrogen chloride at −60°C, more than 80% of nitrogen is converted into hydrazine, evidently via the reaction

$$(Cp_2Ti)_2N_2MgCl + 4HCl \rightarrow Cp_2TiCl_2 + Cp_2TiCl + MgCl_2 + N_2H_4 .$$

The remainder of the bound nitrogen is converted into molecular nitrogen with simultaneous evolution of hydrogen.

When the complex $(Cp_2Ti)_2N_2MgCl$ is allowed to stand with a solution of $i\text{-}C_3H_7MgCl$ in ether at room temperature, the product is $Cp_2TiN(MgCl)_2$, which hydrolyses with formation of ammonia. Thus the sequence of stages in the reduction of nitrogen in the Cp_2TiCl_2 (or Cp_2TiCl) + RMgX systems can be represented as follows:

$$Cp_2TiCl \xrightarrow{RMgX} Cp_2TiR \underset{}{\overset{N_2}{\rightleftharpoons}} 0.5[(Cp_2TiR)_2N_2] \rightarrow 0.5[(Cp_2Ti)_2N_2] \xrightarrow{RMgX} \rightarrow 0.5[(Cp_2Ti)_2N_2MgX] \rightarrow Cp_2TiN(MgX)_2 .$$
$$\downarrow H^+ \qquad\qquad \downarrow H^+ \qquad\qquad \swarrow H^+ \quad \searrow RhLi, H^+ \qquad \downarrow H^+$$
$$N_2 \qquad\qquad N_2H_2 \qquad\qquad N_2H_4 \qquad NH_3, PhNH_2 \qquad NH_3$$

It is interesting that, when the complex $(Cp_2Ti)_2N_2MgCl$ is treated with phenyl-lithium, the hydrolysis of the product results in the formation, together with ammonia, of an appreciable amount of aniline (up to 1% relative to titanium). These data and those of other investigations[91,98] concerning the formation of traces of aniline in the reduction of the complex of $(Cp_2TiR)_2N_2$ by sodium naphthalide indicate the possible mechanism of the formation of aniline in the Vol'pin–Shur systems when phenyl-lithium is employed as the reducing agent. Vol'pin and coworkers[61-64] suggest that the hydrolysis product (aniline) is formed via the insertion of nitrogen in the Ti–Ph bond:

$$Ti-Ph + N_2 \rightarrow Ti-N=N-Ph \rightarrow \text{products.}$$

We now see that the Ph–N linkage can be formed also when phenyl-lithium acts on the intermediate dinuclear complexes formed in the multistage reduction of nitrogen.

Several elegant results concerning the nature and properties of the complexes in the systems containing titanocene were obtained in Brintzinger's studies[98-100]. Titanium compounds interacting with molecular nitrogen were discovered in these investigations: bis(pentamethylcyclopentadienyl)titanium(II), dicyclopentadienyltitanium(II), and its complex with triphenylphosphine. A solution of $[C_5(CH_3)_5]_2Ti$ reacts with carbon monoxide to form the dicarbonyl and with nitrogen at very low temperatures to form a complex which may be an analogue of the dicarbonyl and at a higher temperature to form an intensely coloured blue dinuclear complex containing one nitrogen molecule for two titanium atoms. The complex is in equilibrium with nitrogen and has λ_{max} = 568 nm. Dicyclopentadienyltitanium was obtained in the reactions, discovered by the authors, involving the decomposition of the hydride Cp_2TiH at room temperature. The hydride is formed in the reaction of $Cp_2Ti(CH_3)_2$ with hydrogen. When solutions of titanocene obtained in this way are cooled in the presence of nitrogen, intensely blue solutions of the complex (λ_{max} = 597 nm, $\epsilon \simeq 10^4$) are formed. The complex can be isolated from solution and has the composition $(Cp_2Ti_2)N_2$ according to the data of Bercaw et al.[101] When it is treated with solutions of lithium naphthalide the coordinated nitrogen is reduced and ammonia is evolved on hydrolysis. The complex of titanocene with triphenylphosphine $Cp_2Ti(PPh_3)$ (λ_{max} = 521 nm) interacts with nitrogen. In toluene solution at room temperature 0.33 mole of N_2 is absorbed per mole of titanium. When the resulting adduct is heated to 110°C, approximately

half the nitrogen is converted into an ammonia derivative and the remainder is evolved in the form of free nitrogen.

Bercaw et al. reported recently [101] that at low temperatures in the presence of nitrogen the dinuclear complex $\{[C_5(CH_3)_5]_2Ti\}_2N_2$ is converted into the mononuclear complex $[C_5(CH_3)_5]_2TiN_2$. ^1H, ^{13}C, and ^{15}N NMR data led them to the conclusion that in the last complex there is a reversible rearrangement of the nitrogen in the complex:

It is readily seen that all the properties of the dinuclear nitrogen complexes with titanocene obtained in a number of investigations [98-100] agree with those of the complexes $[Cp_2TiR]_2N_2$ described above, while their compositions are analogous to those of the di-imide complex, which has completely different properties.

Further investigations should show whether the above discrepancies are related to experimental inaccuracies in any of the above investigations or whether these complex nitrogen-fixing systems can indeed contain complexes with nitrogen having the same compositions and different properties and complexes of different compositions and extremely close properties.

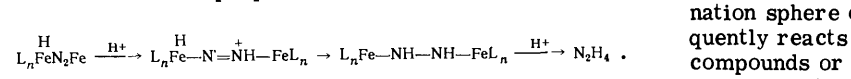
Interesting complexes with nitrogen, capable of undergoing further reduction reactions, were detected in nitrogen-fixing systems containing iron:

$$FeCl_3(PPh_3)_2 + i\text{-}C_3H_7MgCl + N_2\ ^{69,102},$$
$$FeCl_3 + LiPh + N_2\ ^{70}.$$

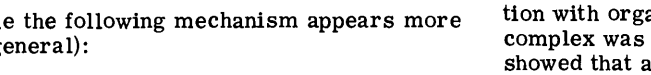
In the first of these systems in ether at −50°C a relatively unstable complex is formed with molecular nitrogen, which slowly decomposes in solution with evolution of nitrogen at a temperature as low as 0°C.

The band at 1760 cm^{-1} (there is an isotopic shift to 1710 cm^{-1} on replacement of $^{14}N_2$ by $^{15}N_2$) in the infrared spectrum corresponds to the NN vibration.

The Raman spectrum contains an exceptionally intense band at 1760 cm^{-1}.[103] This corresponds to the dinuclear fragment FeN_2Fe with high polarisability of the NN bond. Molecular nitrogen is completely evolved from the complex both on heating and on decomposition by carbon monoxide and ethyl alcohol. However, on treatment with hydrogen chloride, hydrazine is formed together with molecular nitrogen. It has been concluded [69,102] that the role of HCl consists in the protonation of the coordinated N_2 molecule, which promotes its partial reduction in accordance with the proposed mechanism:



At the present time the following mechanism appears more likely (and more general):



In the $FeCl_3$–$LiPh$–N_2 system at room temperature and atmospheric nitrogen pressure the reaction also leads to the formation of a complex with nitrogen [70]. Kinetic data (proportionality of the rate of reaction to the square of the concentration of iron, independence of nitrogen pressure above 200 torr and of the concentration of phenyl-lithium) shows that in this case the rate is limited by the formation of a dinuclear complex of the reduced iron compound (without nitrogen), which is followed by rapid coordination of nitrogen. Presumably the intermediate complex with nitrogen is also dinuclear. In this case neither the intermediate complex with nitrogen nor the final product were isolated from solution and the compositions were not determined, but the reduced iron compound is presumably stabilised by phenyl-lithium, since the independence of the rate of reaction of the concentration of phenyl-lithium is observed only in the presence of a large excess of the reducing agent.

When a solution of the product is treated with hydrogen chloride, hydrazine, nitrogen, and ammonia are formed (28, 9, and 15% of the iron content respectively). Possibly the intermediate complex is in this case to some extent analogous to the dinuclear nitrogen complex with zerovalent nickel stabilised by phenyl-lithium [104] and having the composition $\{[(PhLi)_3Ni]_2N_2.2Ft_2O\}_2$. It follows from the X-ray diffraction analysis of this stable complex [105] that the fragment Ni_2N_2 has a structure close to  , the length of the NN bond (1.35 Å) being intermediate between those of single and double bonds. The lithium atoms in the phenyl-lithium molecules in the complex adjoin nitrogen atoms and exhibit electron-accepting properties, enhancing electron transfer from the nickel atom. There have as yet been no reports stating whether or not the nitrogen bound in the complex can be converted into hydrazine or another reduced compound.

In the $FeCl_3$–Mg–N_2 system in tetrahydrofuran a dinuclear complex stable at room temperature is also formed. Its composition corresponds to the formula $[(THF)_{1.5}MgCl_3Fe]_2N_2$. The complex reacts with HCl to form hydrazine [71].

Some of the examples quoted show that the instability of the complex is not a necessary condition for the involvement of nitrogen in the coordination sphere of the metal in further reactions, at least in those cases where powerful reducing agents take part in the formation of the complexes. New attempts to introduce into the reaction the nitrogen in the coordination spheres of known stable complexes are of interest in this connection.

Vol'pin et al. [106] showed that, when the complex $(Ph_3P)_3CoHN_2$ reacts with lithium napthalide in the presence of titanium tetrachloride and other transition metal compounds, the nitrogen bound in a complex with cobalt is reduced to ammonia after hydrolysis. In the absence of added transition metal salts the nitrogen is not reduced.

However, it has been established [107] that under these conditions nitrogen is initially displaced from the coordination sphere of cobalt in the form of free N_2 and subsequently reacts in the usual way with reduced titanium compounds or other additives.

The first successful attempt to introduce into the reaction with organic compounds the nitrogen in a mononuclear complex was made by Chatt et al. [108] These workers showed that acid chlorides RCOCl (R = CH_3, C_2H_5, C_3H_7, or *p*-$CH_3OC_6H_4$) react with *trans*-$W(N_2)_2(dpe)_2$ to form $(dpe)_2W{=}N{-}NHCOR$, where dpe = $PhPCH_2CH_2PPh_2$. The nitrogen in the reaction product is protonated, presumably owing to traces of moisture, which gives rise to hydrogen chloride. The complex can be deprotonated on reaction with triethylamine to form a new series of complexes $WCl(dpe)_2N_2COR$ having a band at 1338 cm^{-1} in the infrared corresponding to a vibration of the complex (there is a shift to 1298 cm^{-1} when the nitrogen is replaced by $^{15}N_2$). An analogous reaction with RCOCl has been discovered for the molybdenum complex of *trans*-$Mo(N_2)_2(dpe)_2$.

Another interesting reaction, discovered by Chatt et al.[109], consists in the protonation of nitrogen in *trans*-$M(N_2)(dpe)_2$ with formation of an N_2H_2 complex:

$$trans\text{-}M(N_2)_2(dpe)_2 \xrightarrow[(THF)]{HX} M(dpe)_2X_2N_2H_2 + N_2$$

(M = W or Mo; HX = HBr or HCl for W and HBr for Mo). It is suggested that the N_2H_2 group is bound to M, giving the structure

$$M\langle^{NH}_{NH}\| \quad \text{or} \quad M{=}N{-}NH_2 .$$

Thus the reduction of nitrogen to a di-imide derivative or hydrazine is caused by protonation (as suggested above for the iron complex). However, in mononuclear complexes protonation has so far precluded the isolation of the reduced products (N_2H_2, N_2H_4, or NH_3) from the coordination sphere of the metal and these results are naturally also consistent with the view that the reduction of nitrogen in a dinuclear complex should in general proceed more readily than in a mononuclear complex.

Sellman and coworkers[110-113] recently obtained new data for mononuclear and dinuclear complexes of manganese, tungsten, and chromium, with di-imide as a possible intermediate in the reduction of nitrogen. In this case the complexes were formed by the oxidation of hydrazine and not directly from molecular nitrogen and their structures and properties should naturally be examined with a certain degree of caution in relation to the mechanism of the reduction of nitrogen in the coordination sphere of the metal.

IV. REDUCTION OF NITROGEN IN PROTIC MEDIA

For a long time the biological fixation of nitrogen achieved by certain micro-organisms and algae constituted the only known nitrogen reduction reaction involving protons derived from water:

$$N_2 + 6e + 6H^+ \rightarrow 2NH_3 .$$

The attempt to carry out this reaction under non-biological conditions was begun a very long time ago. As early as 1916 Zenghelis[114] claimed that, when nitrogen is passed into hydrochloric acid in which metallic zinc dissolves a certain amount of ammonia is formed evidently by the action of hydrogen *in statu nascendi* on nitrogen.

Subsequently analogous attempts were frequently repeated. It was reported in a patent[115] that nitrogen is hydrogenated to ammonia in aqueous solutions of molybdenum hydride derivatives.

Haight and Scott[116] reported in 1964 the formation of small amounts of ammonia in the electrochemical reduction of nitrogen or in its reduction by chemical reducing agents in the presence of molybdate or tungstate. Subsequently similar results were obtained[117] using compounds of a whole series of transition metals.

It is noteworthy that, in view of the low yield of ammonia and the comparatively large amounts of the starting materials, there was always some doubt whether or not molecular nitrogen was the source of the detected ammonia. Small amounts of ammonia can be formed from impurities in the initial reagents, for example, metal nitrides or nitrogen oxides (which are reduced to ammonia under the reaction conditions). The studies by the present author and his coworkers frequently led to the detection of small amounts of ammonia in attempts to reduce nitrogen in protic media, but subsequent careful tests showed that molecular nitrogen was not the source of ammonia.

In testing for the fixation of small amounts of nitrogen one usually employs a technique involving labelled $^{15}N_2$ nitrogen, which was developed previously and was used successfully to investigate the reduction of nitrogen in biological systems. The formation of $^{15}N_2$ and $^{15}N^{14}N$ nitrogen, in amounts appreciably exceeding its natural content, in the hypobromite oxidation of the ammonia formed constitutes qualitative evidence of the fixation of nitrogen and can be used in quantitative measurements of the yield of ammonia. This method has been employed[118] in an attempt to reproduce the data for the fixation of nitrogen described by Haight and Scott[116] and Yatsimirskii and Pavlova[117], but the result was negative. There is also other evidence (see, for example, Hardy and Knight[119]) that the reduction of nitrogen under the conditions employed by the above authors[116,117] does not in fact occur.

Positive results with $^{15}N_2$ constitute an essential criterion of the validity of the results obtained when the amounts of ammonia formed are small (this must be recalled if only because analogous studies without a special test of the results continue to be reported). However, one should note that the excess of mass 29 over its natural abundance in the mass spectrum of nitrogen obtained by the oxidation of the evolved ammonia does not by itself constitute unambiguous evidence for the reduction of nitrogen and has to be tested, since it may be the result of a random contamination of the ionisation chamber of the mass spectrometer by organic substances (for example ether), which yield on ionisation fragments having a mass of 29. Evidently reproducible agreement between the results of chemical analysis (with $^{14}N_2$) and mass spectrometric analysis (with $^{15}N_2$) must be obtained.

Considerable advances have been made recently in the study of nitrogenase—the enzyme which catalyses the biological fixation of nitrogen (see, for example, the reviews of Hardy et al.[19] and Ohmes and Grundemann[20]). It is useful to examine simultaneously biological and non-biological nitrogen fixation, since progress in this field is undoubtedly largely due to the joint efforts of chemists and biologists.

1. Nitrogenase as a Catalyst of the Reduction of Nitrogen

Detailed data on nitrogenase are of course the scope of the present review. Here we shall briefly describe the features of the reduction of nitrogen in the presence of nitrogenase from the chemists' point of view.

The enzyme isolated from micro-organisms is a combination of two proteins, one of which (MoFe-protein) contains molybdenum, iron, sulphide groups, and mercapto-groups, with 1 or 2 molybdenum atoms and 20–30 iron atoms per molecule. The other (Fe-protein) contains 2 iron atoms and also sulphide and mercapto-groups. In the presence of the isolated enzyme nitrogen can be reduced by a specially added reductant—sodium dithionite. The reaction requires the presence of ATP, the reduction of nitrogen to ammonia being accompanied by the coupled hydrolysis of ATP.

In the absence of nitrogen hydrogen is evolved owing to transfer of electrons to water protons. All three nitrogenase reactions (hydrolysis of ATP, evolution of hydrogen, and the reduction of nitrogen) are possible only in the presence of both nitrogenase components—MoFe-protein and Fe-protein.

Apart from nitrogen, in the presence of the nitrogenase component other compounds containing a triple-bond can

be reduced: acetylene, nitrous oxide, isonitriles, and nitriles. Ethylene (*cis*-dideuterioethylene when the reaction is carried out in heavy water) is the product of the reduction of acetylene. Ethylene is not a substrate of nitrogenase and does not undergo further reduction.

When the system is saturated by the substrate, the rates of all the nitrogenase reactions are determined by the transfer of electrons and are thus independent of the nature of the substrate. The activation energy for the reaction amounts to 14 kcal mole^{-1} above 20°C. The presence of magnesium ions is essential for the nitrogenase reaction, possibly in order to carry out the ATPase process.

An important result concerning the structure of the enzyme was obtained by Likhtenshtein (see, for example, Ref. 120). It was found that the iron atoms entering into the composition of the MoFe-protein are combined with one another, forming a cluster of linked atoms.

It is interesting that molybdenum, which is absolutely essential for the catalysis of the reduction of nitrogen by nitrogenase, can nevertheless be replaced by vanadium. The remaining elements proved to be inactive. It proved possible recently to isolate nitrogenase containing vanadium instead of molybdenum [121,122] and showing activity for N_2.

2. Reduction of Nitrogen by Mixed Hydroxides in the Presence of Molybdenum and Vanadium Compounds

Positive and reproducible results in attempts to reduce nitrogen in protic media were obtained for the first time in 1970 and were published in a number of reports [5,6,123,124]. In their search for systems of this kind, the authors began with predictions [7] based on a theoretical treatment [16], taking into account results obtained in the study of the biological fixation of nitrogen. In the first place reagents with a reduction potential close to that of active nitrogenase and sufficient for the formation of hydrazine from nitrogen ($E_0 = -0.23$ V at pH 0) were chosen. These reducing agents must simulate the section of nitrogenase which activates electrons. It follows from theoretical considerations that the activators of molecular nitrogen must have a fully defined set of properties. It was therefore natural to select, by analogy with the biological fixation of nitrogen, compounds of molybdenum (and also vanadium, which can replace molybdenum in nitrogenase), on the hypothesis that at a sufficient reduction potential these compounds form species suitable for the activation of nitrogen.

It was suggested that the intermediates formed (for example, Mo=N–NH–Mo) must be hydrolysed with formation of hydrazine, which appears as the final or intermediate product. This hypothesis was largely responsible for success in the search for nitrogen-fixing systems, since, in contrast to ammonia, the appearance of small amounts of hydrazine from impurities is unlikely, the available analytical tests for hydrazine are very sensitive, and, having detected hydrazine, it was possible to select optimal conditions empirically.

The first system in which the formation of hydrazine from nitrogen in a protic medium was observed was Ti^{3+}–$Mo^{V\text{-}VI}$–N_2 (in aqueous or anhydrous alcohol in an alkaline medium). Subsequently the Cr^{2+}–Mo^{V}–N_2 and V^{2+}–Mo^{V} systems were discovered and it was found that, as in biological systems, vanadium compounds can replace molybdenum with retention of activity in relation to N_2. In this connection vanadium(II) compounds proved to be capable of reducing nitrogen in an aqueous medium without the addition of other transition metal compounds.

The Ti^{3+} – $Mo^{V\text{-}VI}$ – N_2 system [5,6,123–125]. In this case the reduction of nitrogen is observed only in a highly alkaline medium (at pH ≥ 10.5). With increase of the concentration of alkali, the yield of hydrazine passes through a maximum. Without the addition of molybdenum compounds ($MoOCl_3$, MoO_4^{2-}), the reaction hardly occurs.

Small amounts of hydrazine were detected even at room temperature and atmospheric pressure. The yield of hydrazine increases with nitrogen pressure and temperature.

At 90–110°C and a nitrogen pressure of 100–150 atm the system is catalytic with respect to molybdenum: several tens of nitrogen molecules can be reduced to hydrazine and ammonia per molybdenum atom. The reduction of $^{15}N_2$ proved to be consistent with the results obtained using light nitrogen.

The increase of the yield following the addition of other metal (Mg, Ca, or Ba) salts proved to be extremely interesting. Magnesium salts (chloride or sulphate) have a particularly marked effect.

The addition of these salts retards the reaction of titanium(III) hydroxide with water (which results in the evolution of hydrogen) and there is a simultaneous increase of the yield of hydrazine. It proved to be a maximum for the ratio Mg : Ti = 1 : 2.

At low temperatures hydrazine is virtually the only nitrogen reduction product. Above 85°C ammonia appears, its relative yield increasing with temperature. A kinetic study showed [125] that ammonia is a secondary product and is formed on reduction of hydrazine. Carbon monoxide and acetylene inhibit the reaction. In the presence of carbon monoxide a yellow carbonyl compound of molybdenum, in which the oxidation state of molybdenum is three, passes into the solution. Under these conditions, acetylene is reduced to ethylene, the reaction occurring also without molybdenum compounds.

In the absence of nitrogen the system evolves hydrogen from water irreversibly. Under these conditions, hydrogen cannot, of course, reduce nitrogen to hydrazine in an alkaline medium. However, it has been shown [126] that in an acid medium hydrogen can be used as a reducing agent for titanium(IV) (in the presence of platinum) and, after increasing the alkalinity of the solution, the resulting titanium(III) can (in the presence of molybdenum) reduce nitrogen to hydrazine. Thus, under the conditions of alternate increase of the acidity and alkalinity of the solution, hydrogen can reduce nitrogen to hydrazine; the energy deficiency is then in fact made good by the energy of neutralisation of the acid by alkali.

The temperature variation of the rate yields an activation energy for the reduction of nitrogen to hydrazine of 13 kcal mole^{-1}. [125] The attempts to employ instead of molybdenum other transition elements combined with titanium(III) were unsuccessful. Only vanadium compounds (for example $VOCl_2$) proved to be capable of replacing molybdenum with partial retention of activity in relation to nitrogen.

The Cr^{2+} – Mo^{V} – N_2 system [6,126]. Nitrogen is reduced to hydrazine when an aqueous alcoholic suspension of chromium(II) hydroxide is mixed with an $MoOCl_3$ solution in an atmosphere of nitrogen. In this case the reaction proceeds at an appreciable rate even in room temperature and the minimal concentration of alkali at which nitrogen is reduced to hydrazine is appreciably less than in the presence of titanium(III). The catalytic yields in relation to molybdenum were not determined in this system.

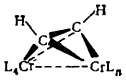
In such systems acetylene is also reduced in the absence of molybdenum, the reaction occurring in acid

solutions of chromium(II) salts as well. In this connection we may note that, in one of the earlier attempts to investigate the reduction of acetylene to ethylene from the standpoint of the simulation of the nitrogenase reaction, a study was made of the process [127]

$$C_2H_2 + 2Cr^{2+} + 2H^+ \rightarrow C_2H_4 + 2Cr^{3+} .$$

This reaction, discovered as early as 1916, [128] is interesting because, as in the case of nitrogenase, acetylene is quantitatively converted into ethylene without further reduction to ethane. The rate of reaction is proportional to the square of the concentration of chromium, which indicates the formation of a dinuclear complex of chromium ions and acetylene. Indeed, on cooling aqueous alcoholic solutions, the reversible formation of a relatively unstable dinuclear complex of acetylene and chromium, the heat of formation of which is only about 2 kcal mole^{-1}, was observed spectroscopically [129].

Further study of the analogous but more stable complex, which is formed in the presence of ammonia and can be isolated from the solution, showed [130] that its structure corresponds most closely to the formula



with a C–C bond close to a single bond and sp^3-hybridised C–H bonds. Thus acetylene in the complex is in fact reduced by a "four-electron" mechanism to an ethane derivative.

The reduction of acetylene in aqueous solution of chromium(II) salts is catalysed by acids and can be represented as follows:

$$2Cr^{2+} + C_2H_2 \rightleftharpoons [CrC_2H_2Cr]^{4+} \xrightarrow{H^+} [CrC_2H_3Cr]^{5+} \xrightarrow{H^+} 2Cr^{3+} + C_2H_4 .$$

Studies [131] on the reduction of other unsaturated compounds in a solution of chromium(II) salts showed that the mechanism involving two chromium ions is general. In acid media nitrogen is not reduced by Cr^{2+} ions, although the reduction potential of chromium(II) $E_0 = -0.40$ V is sufficient to form hydrazine from nitrogen. Admittedly it has been reported [132] that small amounts of ammonia are present in acid solutions in the reduction of nitrogen by zinc in the presence of chromium(VI) compounds, but these results were not confirmed by use of labelled nitrogen and are as usual doubtful.

The formation of small amounts of hydrazine in the electrochemical reduction of nitrogen in acid solutions in the presence of molybdenum complexes has been reported [133]. The yields did not exceed 1% with respect to molybdenum and varied appreciably from experiment to experiment.

The $V^{2+}-N_2$ system [6,124,134,135]. The formation of hydrazine was observed on mixing an aqueous alcoholic suspension, prepared beforehand, of a mixture of vanadium(II) and magnesium hydroxides with an $MoOCl_3$ solution in an atmosphere of nitrogen. In this case appreciable yields of hydrazine were observed at high temperatures and high concentrations of alkali (in excess of 1 M).

Hydrazine is also formed on reduction of nitrogen in aqueous solution by freshly precipitated vanadium(II) hydroxide produced in the presence of added magnesium salts. In this instance the presence of molybdenum compounds is not required.

This, the simplest of the known nitrogen-reducing systems, proved to be the most active. When the optimal conditions are selected, nitrogen is reduced at a high rate in aqueous solutions even at room temperature and under an atmospheric nitrogen pressure. Together with hydrazine, ammonia is formed even at room temperature. The reaction again proceeds only in strongly alkaline media.

In this case magnesium salts proved to be even more important than for other analogous systems: in their absence hydrazine is hardly formed. At room temperature and [atmospheric ?] nitrogen pressure the reaction ceases (the system loses activity) when the yield of reduction products reaches 8–20% relative to the reducing agent, but, on raising the nitrogen pressure to 20–40 atm, the overall yield of hydrazine and ammonia becomes nearly quantitative, i.e. the following reactions take place:

$$4V(OH)_2 + N_2 + 4H_2O \rightarrow 4V(OH)_3 + N_2H_4 ,$$
$$6V(OH)_2 + N_2 + 6H_2O \rightarrow 6V(OH)_3 + 2NH_3 .$$

Vanadium(II) is comparatively readily regenerated by the electrochemical reduction of the vanadium(III) formed. In this connection and bearing in mind that, by selecting appropriate conditions it is possible to drive the reaction solely to the formation of hydrazine, the reaction can be employed as a new method for the synthesis of hydrazine from molecular nitrogen [136].

Kinetic data again show that ammonia is a secondary product formed by the reduction of hydrazine.

The activation energy for the reduction of nitrogen to hydrazine is only 10 kcal mole^{-1}. The vanadium system is also active in the presence of inhibitors of nitrogen fixation [134]. Under these conditions, carbon monoxide hardly retards the reduction of nitrogen. Acetylene competes with nitrogen for active centres (being itself converted into ethylene). Under these conditions, acetylene is only three times more active than nitrogen.

Even the reactivity of oxygen is comparable to that of molecular nitrogen in the reaction in alkaline solutions containing a suspension of vanadium(II) hydroxide in the presence of magnesium hydroxide. Therefore such solutions are capable of fixing nitrogen directly from air. The yield of reduction products is smaller only by a factor of two compared with pure nitrogen [134].

The oxidation-reduction potential of the system was measured and its relation to activity with respect to nitrogen was investigated [137].

3. Reduction of Nitrogen in Homogeneous Solutions of Vanadium Complexes [138,139]

In the search for homogeneous systems capable of fixing N_2 in protic media, Nikonova et al. [138] observed that vanadium(II) complexes with phenols containing two hydroxy-groups in *ortho*-positions relative to one another (catechol, dihydroxynaphthalene, etc.) have this ability. In alcoholic, aqueous alcoholic, and aqueous media the complexes can rapidly reduce nitrogen to ammonia even at room temperature and atmospheric pressure; the yield of ammonia increases with pressure and temperature.

The reaction with nitrogen proceeds in a narrow pH range [139]. The maximum yield in water (about 60% at room temperature, $P_{N_2} \geq 70$ atm) is attained at pH ~ 10. In this case the intermediate formation of hydrazine is not observed, which may be related to its reduction under the experimental conditions. Indeed, it has been shown that hydrazine is rapidly reduced to ammonia by vanadium(II) complexes of catechol.

Simultaneously with the reduction of nitrogen, the complexes decompose water, hydrogen being evolved. Under these conditions acetylene is reduced to ethylene, *cis*-dideuterioethylene being formed from C_2D_2 in H_2O. [140]

4. The Reduction of Nitrogen in Molybdenum–Thiol Systems

Schrauzer and coworkers reported in 1970–1971 the reduction of nitrogen to ammonia by sodium tetrahydroborate in the presence of molybdate and compounds containing mercapto-groups (cysteine, thioglycerol, and glutathione)[141,142]. The authors regard this system as a close model of nitrogenase, although under the optimal conditions the yield of ammonia is extremely small, reaching 0.06–0.1% relative to the initial molybdenum compound after five days at a nitrogen pressure of 140 atm. In later communications[143,144] the authors reported that the results were confirmed with the aid of labelled nitrogen $^{15}N_2$.

Acetylene inhibits the reduction of nitrogen, while carbon monoxide does not affect the yield of ammonia appreciably. In order to account for the absence of the inhibiting capacity of CO (in contrast to the behaviour in the biological fixation of nitrogen), the authors suggest the existence of an additional coordination site at the molybdenum atom (which is occupied by the enzyme in the biological system). However, it is not clear why CO cannot occupy also the second coordination site at the molybdenum atom. It is likewise difficult to imagine that, after its addition to molybdenum, the reactivity of carbon monoxide with respect to N_2 remains unchanged (this is evidently postulated by the authors).

Much higher yields of ammonia (1.5 moles of ammonia per mole of molybdate) have been quoted[145] for the Na_2MoO_4–$FeSO_4$–$NaBH_4$–N_2 system in the presence of 2-aminoethanethiol. However, subsequently the authors[145] were unable to reproduce their results (see Chatt and Leigh[25]). It was found that the system incorporating the pure reactants is virtually inactive with respect to nitrogen and it has been tentatively suggested that the system can begin to reduce nitrogen only after undergoing changes under the influence of certain hitherto unknown factors.

The data reported by Schrauzer and coworkers concerning the activity of molybdenum–thiol systems with respect to nitrogen are also still very contradictory. Thus the role of the added iron salts is obscure. In the first report[141] the authors do not mention iron, while in the next[142] they note that an iron salt is a necessary cocatalyst. Finally, it was stated in a recent communication[144] that an iron salt increases the yield of ammonia only slightly. In the same report[144], it is unexpectedly stated that the primary reaction product is di-imide, which accumulates in the course of 40 min.

It has been reported[146] that nitrogen is not reduced at all by sodium tetrahydroborate in the presence of the molybdenum–glutathione complex. These contradictions are probably related to the low activity of the system with respect to nitrogen.

Much more definite results were obtained for the reduction of other compounds, which can serve as substrates of nitrogenase: acetylene, isonitriles, etc. In particular it has been shown that acetylene[147] yields ethane simultaneously with ethylene, the latter not being an intermediate in the formation of ethane. This distinguishes molybdenum–thiol systems from nitrogenase, in the presence of which the only reduction product is ethylene. The very fact of the formation of ethane in this case constitutes direct confirmation of the possibility of the "four-electron" reduction of acetylene without its emergence from the coordination sphere of the complex.

One of the characteristic features of molybdenum–thiol systems is the activating effect of ATP, which, as stated by Schrauzer et al.[147], simulates the action of ATP on the functioning of nitrogenase. However, it has been established[148,149] that hydrolysis of ATP hardly occurs under the conditions of the operation of molybdenum–thiol system and the accelerating effect of ATP as well as of ADP and other nucleoside phosphates is in fact related to a change in the pH of the medium. Other acids, for example, sulphuric acid, act no less effectively.

Molybdates are not unique catalysts in these systems. For example, in the reduction of isonitriles molybdate can be replaced by compounds of other transition metals (WO_4^{2-}, VO_3^-, Pd^{2+}, Rh^{3+}, Ru^{3+}, Co^{3+}, and Fe^{2+}), some of which are more effective than molybdenum compounds[143].

5. The Cobalt–Porphyrin System

A reduction system containing a soluble porphyrin derivative of cobalt—*meso*-tetra(*p*-phenylsulphonato)-porphinatocobalt(III) (CoTPPS) and sodium tetrahydroborate—was described in a recent study[150]. The authors reported the reduction of nitrogen "on passing pure dry air" through an aqueous solution containing CoTPPS and $NaBH_4$ at pH 10. When the reaction was carried out over a period of one week with a daily addition of sodium tetrahydroborate solution, the authors observed the formation of 0.8–1 mole of ammonia per mole of CoTPPS. However, when these results were tested with the aid of labelled nitrogen[151], it was observed that the entire ammonia detected[150] is not formed from molecular nitrogen but evidently originates from the nitrogen of the porphyrin rings, i.e. the system is not active with respect to N_2. On the other hand, according to these data[150], the system reduces acetylene catalytically to ethylene and partly to ethane. Other unsaturated compounds (azide, cyanide, and acetonitrile) are also reduced catalytically. It is suggested that, under the influence of sodium tetrahydroborate, $Co^{III}TPPS$ is reduced to a cobalt(I) derivative which is involved in the reduction of the substrates. It was established earlier that cobalt(I) derivatives readily reduce nitrous oxide to nitrogen[152,153].

6. Complexes of Iron Compounds

It has been shown[154] that certain nitrogenase substrates can be reduced catalytically in the presence of iron complexes. The reducing agents were sodium tetrahydroborate or sodium dithionite in alcohol, water, or buffer mixtures. In the presence of dichlorotetrapyridineiron(II) as a catalyst sodium azide is reduced by sodium tetrahydroborate to ammonia and nitrogen. Cyanide is reduced to methane and ammonia. On reduction, acetonitrile give rise to ethane and ammonia. Acetylene and methylacetylene are reduced slowly to ethylene and propene and ethylene is reduced fairly rapidly to ethane, the last reaction being strongly inhibited by acetylene, which indicates the formation of stable acetylene complexes. On the basis of their results, the authors conclude that at the present time model experiments do not demonstrate whether molybdenum, iron, or both metals activate nitrogen in the nitrogenase reaction.

It has been noted that low yields of ammonia are formed when molecular nitrogen is reduced by iron complexes. However, without a test using $^{15}N_2$ these results give rise to the usual doubts.

7. The Mechanism of the Reduction of Nitrogen in Protic Media

Since the discovery of systems reducing nitrogen in protic media, only a short time has as yet elapsed and many aspects of the mechanism of the action of these systems still remain obscure.

The isolation of the carbonyl derivative of molybdenum(III) in the Ti^{3+}–Mo^{V}-VI nitrogen-fixing system in the presence of CO permits the conclusion that nitrogen is also activated by species containing molybdenum(III) (d^3 electronic configuration). Vanadium in the bivalent state, i.e. also in the d^3 electronic configuration, is active in relation to nitrogen.

The high pH values at which hydroxides are active with respect to N_2 provide evidence that the transition metal atoms interacting with N_2 have an effective negative charge. This is evidently required primarily to create a higher reduction potential. In homogeneous vanadium systems phenols, which are powerful electron donors, also probably increase the reduction potential of the system and ensure the reduction of N_2.

However, the results show that a high reduction potential is by itself insufficient for the creation of active systems. Vanadium(II) and molybdenum(III) systems exhibit specific activity in relation to nitrogen and their presence is essential. Presumably the d^3 configuration of molybdenum(III) and vanadium(II) makes them fairly powerful one-electron reducing agents and ensures the stability of the intermediate complex of the type

$$M{=}{=}N{=}{=}N{=}{=}M$$

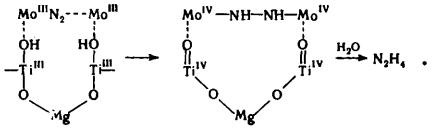
as a result of a dative interaction of the remaining electron pairs at the M atoms with the π-linkage of nitrogen.

The dinuclear structure is indicated particularly by the much higher activity of these systems in relation to acetylene molecules than in relation to ethylene [155]. The role of added metal salts, particularly of magnesium compounds, also confirms the necessity for a polynuclear structure. Data concerning the retardation of the formation of hydrazine in the vanadium system by vanadium(III) ions [156] led to the conclusion that a quartet of four vanadium(II) ions at a short distance from one another is necessary.

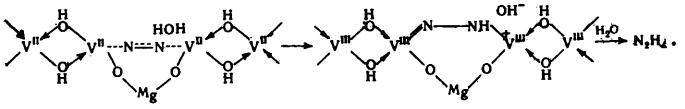
Apparently two vanadium ions form a dinuclear complex with N_2 and two other ions must transfer an additional two electrons to activated nitrogen in order to achieve the four-electron reduction to hydrazine. The magnesium ion (the efficiency of which is related to its small dimensions and the high concentration of charge) evidently forms a suitable structure, moving apart the atoms of the reducing agent to a specific distance with the aid of hydroxo- or oxo-bridging bonds.

These postulates are confirmed by measurements of the magnetic susceptibility of vanadium(II) hydroxide in the presence and absence of magnesium ions [157]. In the presence of magnesium ions the effective magnetic moment per vanadium atom increases, which indicates a decrease of electron exchange between the vanadium atoms.

The following mechanism for the formation of hydrazine in the Ti^{3+}–Mo^{V}-VI–Mg^{2+}–N_2 system has been suggested [124] (bearing in mind that molybdenum takes part in the reaction in the tervalent state):



A similar mechanism can be proposed for systems incorporating vanadium(II) hydroxide, but in this case vanadium ions play the role of all four atoms. One cannot rule out the possibility that a water molecule is involved in the reaction and that the mechanism is heterolytic. For example, the following mechanism can be proposed for the vanadium(II)–magnesium(II) hydroxide:



In homogeneous systems polyoxyaryl ligands also apparently give rise to dinuclear complexes. In all cases it is suggested that a dimolybdenum (or divanadium) structure is created in the intermediate complex and not one with two different metals, for example Mo^{III} and Cr^{II} or Mo^{III} and Ti^{III}.

There is as yet no direct proof of this hypothesis, although in dinuclear complexes in vanadium systems the second atom in the complex cannot of course be other than vanadium. However, bearing in mind that the reducing agent is not specific, it appears more likely that the reducing agents transfer electrons (and hydrogen atoms) to nitrogen activated in the complex containing two molybdenum atoms and in molybdenum systems.

V. COMPARISON OF NITROGENASE AND VARIOUS NITROGEN-FIXING SYSTEMS

The problem of which systems simulate the action of nitrogenase and which cannot be regarded as its models is to some extent academic. It appears that an absolute model cannot exist at all and that each reaction investigated from the standpoint of the simulation of nitrogenase simulates only a property or several properties of the enzyme. In the course of development of our knowledge of the mechanism of the action of nitrogenase, and following the discovery of new nitrogen-fixing systems, the models have improved to an increasing degree.

One can agree with the view of Newton et al. [154] that "the crucial test of a nitrogenase model is its ability to catalyse the reduction of molecular nitrogen at ambient temperature and pressure". However, the most general conclusions are apparently obtained not from a comparison of nitrogenase with any one nitrogen reduction reaction, but by examining the sum total of the information concerning both the reaction of nitrogen and systems which do not reduce nitrogen and can be regarded as models only by convention.

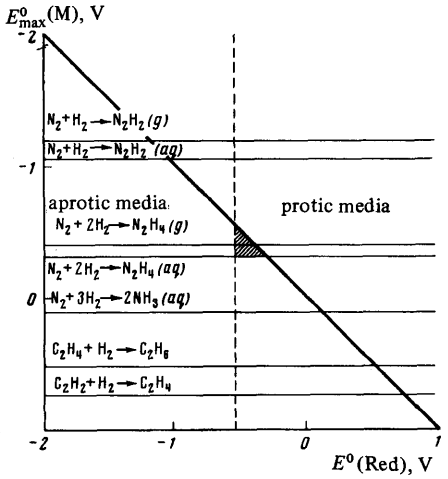
Moreover, the number of nitrogen reduction reactions under the conditions approaching those in which nitrogenase is active is so far small and it is therefore reasonable to consider also the reactions of other nitrogenase substrates. The available results permit the following generalisation. Many transition metals in low valent states can activate and reduce nitrogen to nitrides in aprotic media under the influence of powerful reducing agents. In protic media, including the aqueous medium, moderately strong reducing agents reduce acetylene and other nitrogenase substrates, also in the presence of a large number of various transition metal compounds.

The reduction of nitrogen in protic media (by moderately strong reducing agents) at a fairly high rate has so far been observed only for metals which are effective as part of the active centre of nitrogenase, namely molybdenum and vanadium. This agreement can hardly be fortuitous

and is evidently a consequence of a profound analogy between the mechanism of the action of nitrogenase and of systems reducing nitrogen in protic media.

There is no reason to suppose that in the future systems incorporating other metals in the active centre will not be discovered. However, there is no doubt that molybdenum and vanadium compounds in simple combinations form active nitrogen-fixing systems more readily than other metals.

The explanation of the comparative scarcity of nitrogen-reducing systems is probably related, to a first approximation, to the energetic difficulties which were considered in Section II of the present review.



Schematic representation of the free energy relations of nitrogen-fixing reactions.

The situation is illustrated schematically in the Figure, where the horizontal lines represent the free energies of the corresponding reactions referred to one electron and the inclined line corresponds to the maximum reduction potential of the catalyst M (which must not exceed the potential of the reducing agent Red participating in the reaction). At a given reduction potential, a particular reaction is possible if the corresponding horizontal line is located underneath the inclined straight line. Naturally, the greater the distance between the inclined and horizontal lines the greater the probability of finding a catalyst M for this reaction, other conditions being equal.

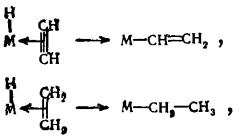
At very high reduction potentials there is a possibility of two-electron reduction of nitrogen. In such instances the rupture of the π-linkage can occur in the mononuclear complex with subsequent formation of the structure M–N=N–M', where M' is a non-transition metal, for example lithium. At even higher potentials there is a possibility of a one-electron mechanism and the transition metal ceases to be necessary for the reduction of nitrogen.

When E^0 is reduced, the formation of a dinuclear complex MN_2M with two transition metals, which is stabilised by the additional interaction of the *d* electrons with the π-linkages of nitrogen, becomes necessary. In this case there is a possibility of further reduction to a hydrazine derivative and then to the nitride with the maximum yield (in catalytic systems) of one nitride molecule per transition metal atom. The majority of the Vol'pin–Shur systems are of this kind. When the difference between E^0 and the value for hydrazine (or its derivative) is large, there is a high probability that the transition metal compound present in the system will be suitable for the activation and reduction of N_2.

On further decrease of E^0 and transition to protic media, the difference between the potentials of the reducing agent and hydrazine falls and the probability of catalytic action by the transition metal is sharply diminished. We have seen that in the presence of reducing agents sufficiently powerful to reduce nitrogen in protic media the transition metal must possess a comparatively rare combination of a specific set of properties. It is not surprising that such systems are encountered rarely and that in the course of evolution nature has chosen the metals which permit the most efficient reduction of nitrogen.

The difference between the potentials of the reducing agent and the acetylene–ethylene pair can remain considerable under these conditions also on further decrease of E^0. Naturally the probability that the transition metal compound will prove suitable is fairly high and many transition metals may be catalytically active.

Here a mononuclear structure of the complex is again possible. The weakness of the π-linkage in acetylene and ethylene permits the reactions



which take place in numerous known catalytic hydrogenation reactions of unsaturated molecules.

From the standpoint of this approach, the structure of the intermediate complex in nitrogenase as well as in nitrogen-fixing systems in protic media must be dinuclear.

Examination of model systems thus confirms the conclusions reached in studies on the mechanism of the activation of nitrogen by nitrogenase, where a dinuclear structure of the intermediate complex is adopted (see, for example, Refs. 19 and 120) and one of the atoms activating the N_2 molecule is definitely molybdenum. It has been by no means clearly shown whether two molybdenum atoms or one molybdenum atom and one iron atom, as suggested in some investigations [19,158], enter into the dinuclear structure of the nitrogenase complex.

As already stated, in model systems the activation of N_2 presumably takes place in dinuclear complexes involving only molybdenum atoms and the reducing agent transfers electrons to the activated nitrogen.

Thus the study of the fixation of nitrogen in model systems currently known suggests that it is more likely that the biological process also involves two molybdenum atoms rather than one molybdenum atom and one iron atom, although this conclusion cannot be regarded as unambiguous.

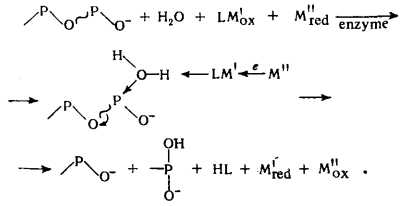
One may note yet another analogy between the nitrogenase and model systems involving hydroxides, which is probably not fortuitous. The metal atoms participating in electron transfer are linked in both cases (in nitrogenase iron ions are linked via bridging sulphide bonds [120] and in the hydroxides Ti^{III}, Cr^{II}, and V^{II} atoms are joined via hydroxo- and oxo-bridges). Presumably this ensures the possibility of many-electron processes involving the nitrogen bound in the complex.

An important characteristic of the biological fixation of nitrogen is the fact that it proceeds as a process coupled with the hydrolysis of ATP. The mechanism of the action of ATP is still obscure.

According to the hypothesis adopted at present[19], the hydrolysis of ATP tends to increase E^0 for the system. Parshall[159] suggests that the phosphorylation of the molybdenum complexes facilitates the formation of molybdenum hydride.

Studies on the changes in the ESR spectra under the influence of ATP have shown[160] that the ATP linked to Fe-protein in nitrogenase does in fact ensure electron transfer from Fe-protein to MoFe-protein. These results are consistent with those of Syrtsova et al.[161] who showed that ATP is not located unduly close to MoFe-protein of nitrogenase, where the nitrogen molecule is evidently activated by combining with the molybdenum atom.

Models of the action of ATP are so far unknown in the reduction of nitrogen in non-biological systems. On the other hand, in many of the examples quoted in the review involving the reduction of both nitrogen and other compounds, an acid which protonates the substrate and facilitates the reduction plays an activating role. In this connection it is possible to suggest[148,149] that an active proton is formed in the hydrolysis of ATP which ensures electron transfer (for example from the iron atom of Fe-protein of nitrogenase to the iron cluster of MoFe-protein). For example, the following chemical mechanism of this coupled process may be suggested:



As a result of the energy of the high-energy bond of ATP the potential of M' (for example of the iron cluster of MoFe-protein) may be sufficiently high to reduce the activated nitrogen molecule.

Naturally the suggested mechanism of the action of ATP requires a definite steric activation by the enzyme molecule, which has not so far been achieved in non-biological studies.

The alkaline medium in model systems creates an effective negative charge on the metal atoms activating molecular nitrogen and increases thereby the reduction potential of the system. In this case there is no need for additional activation by the proton arising in the hydrolysis of ATP and the water proton can prove to be a sufficiently powerful acceptor.

The determination of further details of the relation between the mechanism of the reduction of nitrogen in models systems and its enzymatic reduction would probably require the introduction of a large number of unjustified hypotheses and would not at present be useful for the determination of new and more specific data concerning the mechanism, particularly since the rapid development of this field will evidently make it possible in the near future to employ firmly established experimental facts as a basis.

---o0o---

During the decade which has elapsed since the discovery of the nitrogen reduction reactions in solutions of transition metal complexes, the chemistry of molecular nitrogen has already required serious revision and considerable expansion. There is no doubt that progress in this field will continue also in the future.

Processes of practical value should presumably be developed in parallel with the discovery of new reactions which are of fundamental interest, particularly reactions which are still closer models of the biological fixation of nitrogen. Although competition with the modern large-scale ammonia synthesis is hardly likely in the immediate future, one may hope that the syntheses of other nitrogen-containing substances will find applications in the laboratory or in industry.

Molecular nitrogen is becoming an increasingly common ligand and reagent in catalytic and non-catalytic reactions.

Hydrogen Transfer from Organic Compounds Catalysed by Transition Metal Complexes

I.S.Kolomnikov, V.P.Kukolev, and M.E.Vol'pin

The review deals with the new rapidly developing field of homogeneous catalysis and coordination chemistry, namely with reactions involving hydrogen transfer from organic compounds to transition metal complexes accompanied by the dissociation of a C-H bond and the formation of a metal-hydrogen bond. Particular attention has been devoted to catalytic reactions in which transition metal compounds serve as catalysts of hydrogen transfer and of the reduction of organic compounds by the C-H bonds of other organic molecules.
The bibliography includes 177 references.

CONTENTS

I. Introduction 399
II. Dissociation of the C-H bond and hydrogen transfer to the transition metal 399
III. Catalytic hydrogen transfer 405

I. INTRODUCTION

The homogeneous hydrogenation of organic compounds catalysed by transition metal complexes is one of the most thoroughly investigated fields of homogeneous coordination catalysis (see the relevant reviews[1-17]). The most important stage in the mechanism of homogeneous hydrogenation reactions is the activation of the H_2 molecule and the dissociation of the H-H bond. Recently we witnessed the growth of interest in extremely similar processes—the activation and dissociation of a C-H bond by transition metal compounds. Reactions of this kind are being increasingly used to transfer hydrogen and (or) an organic residue to different molecules.

This review deals with the part of the problem concerning hydrogen transfer from one organic molecule to another with the aid of transition metal compounds. These reactions have not so far been reviewed and are only mentioned in studies on homogeneous hydrogenation (see, for example, Ugo[13] and Kwiatek[14]).

Hydrogen transfer reactions are of significant interest both from the standpoint of the search for new methods of activating C-H bonds and in the preparative sense, since they lead to new ways of achieving hydrogenation and dehydrogenation reactions under mild conditions. It should also be noted that reactions of this type have attracted attention from the standpoint of the simulation of biochemical hydrogen and electron transfer processes (cf. Zelenin and Khidekel'[18]).

In the present review we consider only those catalytic hydrogen transfer reactions which are accompanied by the dissociation of C-H bonds. We are not concerned with the large field of reactions accompanied by the oxidation of C-H bonds, which results in electron transfer to a molecule of oxygen or another oxidant. Thus we are dealing primarily with processes where one can speak with greater or lesser certainty of hydrogen transfer from one organic molecule to another, catalysed by transition metal compounds.

Catalytic hydrogen transfer from organic compounds has much in common with homogeneous hydrogenation by molecular hydrogen. Like homogeneous hydrogenation, it includes two fundamental stages.

1. Dissociation of the C-H bond and hydrogen transfer to the metal (M):

$$R{-}H + M \rightarrow R{+}MH \quad \text{or} \quad R\!\!<\!\!\begin{matrix}H\\H\end{matrix} + M \rightarrow MH_2 + R\,.$$

2. Hydrogen transfer from the metal to an unsaturated substrate (S):

$$M{-}H + S \rightarrow S{-}H + M \quad \text{or} \quad MH_2 + S \rightarrow SH_2 + M\,.$$

The second stage is evidently the same as the analogous stage in homogeneous hydrogenation. Thus the specific features of hydrogen transfer processes are fundamentally related to the specific features of the first reaction stage. In this connection we shall consider separately the first, most important reaction stage and shall then return to the problem of the catalysis of hydrogen transfer, which includes the simultaneous occurrence of both processes.

II. DISSOCIATION OF THE C-H BOND AND HYDROGEN TRANSFER TO THE TRANSITION METAL

As in the dissociation of the H-H bond, the dissociation of the C-H bond with the aid of transition metal compounds can occur in principle via several different mechanisms (M is the transition metal atom in the complex).

1. With proton transfer:

$$R{:}H + M \longrightarrow R^- + (M{-}H)^+\,.$$

2. With hydride hydrogen transfer:

$$R{:}H + M \longrightarrow R^+ + (M{-}H)^-\,.$$

3. With homolytic dissociation of the C-H bond:

$$R{:}H + 2M \longrightarrow M{-}H + M{-}R\,.$$

4. Via reactions of the oxidative addition type:

$$R{-}H + M \rightarrow M\!\!<\!\!\begin{matrix}H\\R\end{matrix}\,.$$

The nature of the process occurring will of course depend not only on the transition metal compounds but to

no less an extent on the nature of the C–H bond in the reacting organic compounds, the properties of which can vary within extremely wide limits.

Reactions of Type (1)

These involve the acid dissociation of the C–H bond and protonation of the transition metal compounds. They are not of interest for the present problem, since such hydrogen transfer cannot lead to the reduction of the substrate. However, one should note that the analogous process—the dissociation of the C–H bond as a result of electrophilic substitution,

$$R{-}H + M^+ \longrightarrow RM + H^+ , \qquad (1a)$$

is the first stage of a number of important catalytic processes. The metal–carbon σ bond formed in this reaction can undergo further transformations and in the first place can give rise to oxidative dimerisation products[19]. A reaction of this type is, for example, the first stage of the conversion of benzene into biphenyl under the influence of palladium and platinum compounds[20–23]:

$$ArH + Pd^{2+} \rightarrow ArPd^+ + H^+ ,$$
$$2ArPd^+ \rightarrow ArAr + 2Pd^+ .$$

Possibly the oxidative dimerisation of olefins under the influence of palladium salts takes place analogously[24–27]:

$$2CH_2{=}CR_2 + Pd^{2+} \rightarrow R_2C{=}CHCH{=}CR_2 + 2H^+ + Pd^0 ,$$

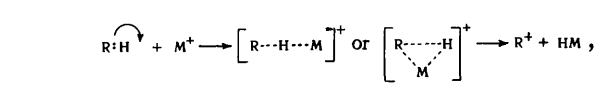
as well as the oxidative coupling of aromatic hydrocarbons to olefins[28]†:

$$ArH + Ar'CH{=}CH_2 + Pd^{2+} \rightarrow Ar'CH{=}CHAr + 2H^+ + Pd .$$

We shall examine in somewhat greater detail reactions of types (2), (3), and (4), which are of greatest interest from the standpoint of hydrogen transfer to unsaturated substrates.

Reaction (2)

This can be regarded as the transfer of the hydride ion H^- from carbon to the metal (the hydride shifts in organic chemistry have been reviewed[29]). Reactions of this type can occur either as a synchronous transfer of hydrogen and an electron pair via a transition state of a linear or π-type,



or as a result of a one-electron transfer followed by the transfer of hydrogen in the form of a proton (or radical):

$$R{:}H + M^+ \rightarrow \begin{matrix}[RH^{+\cdot} + \cdot M] \rightarrow R^+ + HM \\ \searrow [R^+ + H^+ + :M^-] \nearrow\end{matrix} .$$

However, regardless of the nature of these "intimate" mechanisms of the hydride shift, the latter should be favoured by factors such as a positive (not unduly large) charge at the metal atom and the presence of π-ligands, which stabilise the metal–hydrogen bond.

The hydride mobility of the C–H bond in the organic compound which behaves as the donor of the hydride ion is particularly important for the occurrence of such reactions. The ease of the elimination of the hydride ion is paralleled by the stability of the carbonium ion formed as a result—the more stable the carbonium ion under the given conditions the greater the ease with which the hydride ion is split off from the initial C–H bond. The stability of carbonium ions is known to be determined to a considerable degree by the nature of the substituents at the carbonium carbon atom.

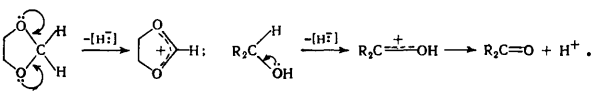
The resulting carbonium ions are stabilised and the hydride shifts via mechanism (2) are thus facilitated by electron-donating substituents of the following kinds.

a. Alkyl groups; the ease of elimination of hydride hydrogen increases in the sequence Me–H < Me_2CH–H < Me_3C–H.

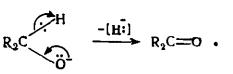
b. Substituents containing multiple bonds (in the first place carbon–carbon bonds) coupled with the carbonium centre and giving rise thereby to the possibility of the delocalisation of the positive charge. The accumulation of such aryl or vinyl substituents at the carbon atom significantly facilitates the elimination of the hydride ion from the latter; an example is provided by triphenylmethane, which is readily converted into the triphenylmethyl cation:

$$Ph_3CH \xrightarrow{-[H^-:]} Ph_3C^+ .$$

c. Substituents containing a free pair of *p* electrons ($-\ddot{N}R_2$, $\ddot{O}R$, $\ddot{S}R$, etc.). Such substituents stabilise the carbonium centre with formation of much more stable conjugate cations:

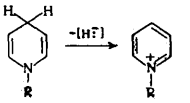


Groups bearing not only an electron pair but also a negative charge facilitate the elimination of the hydride ion even more. In particular this accounts for the high reducing capacity of alkoxides:



d. The hydride ion elimination reaction is significantly facilitated when it results in the formation of molecules with enhanced stability. This factor accounts for the particularly great ease of elimination of the hydride ion from cyclopropene and cycloheptatriene (including cases where the process takes place under the influence of transition metal compounds), leading to the formation of non-benzenoid aromatic cyclopropenylium and tropylium cations:

Another example is provided by the dihydropyridine-nucleotide coenzyme (reduced nicotinamide-adenine dinucleotide NADH), which is an active hydride ion donor (cf. Zelenin and Khidekel'[18]):



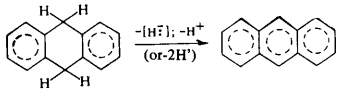
This reaction, which is biochemically important, is facilitated both by the presence of the free electron pair

† However, one cannot rule out the possibility that in the dimerisation of olefins the first stage is the dissociation of the C–H bond via mechanisms (2), (3), or (4). Thus reversible homolytic dissociation of the vinyl C–H bond has been suggested[27] for the oxidative coupling of acrylonitrile under the influence of ruthenium(III) salts:

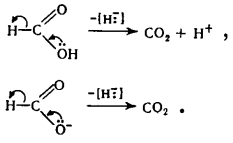
$$2L_nRu + 2CH_2{=}CHCN \rightleftarrows 2L_nRuH(CH{=}CHCN) \rightarrow NCCH{=}CH{-}CH{=}CHCN .$$

of nitrogen and by the formation of the aromatic pyridinium system.

In certain cases the stabilisation of the products of the hydride shift reaction is accompanied by rapid elimination of a proton. The elimination of the hydride ion from dihydroanthracene, which leads to the formation of the aromatic anthracene system, takes place in this way:



The ease of elimination of the hydride ion from formic acid and formates can be explained not only by the influence of the free electron pair of the adjacent oxygen atom but also by the considerable stability of the resulting carbon dioxide molecule:



Reaction (3)

We shall now turn to the mechanism of reactions (3), which involves the homolytic dissociation of the C–H bond. The energy of the homolytic dissociation of the C–H bond ($R-H \rightarrow R\cdot + H\cdot$) is 103 ± 2 kcal mole^{-1} (at 298°K) for the methane molecule and has similar values for other saturated hydrocarbons and for benzene. It differs very little from the dissociation energy of the H–H bond, which is 104.2 kcal mole^{-1} (at 298°K)‡. Thus comparison of reaction (3) with the analogous homolytic dissociation reaction of the H_2 molecule,

$$H_2 + 2M\cdot \rightarrow 2MH ,$$

shows that the differences between the free energies of these two reactions must be determined primarily by the differences between the stabilities of the metal–carbon and metal–hydrogen bonds.

Reaction (4)

The same considerations apply also to the occurrence of the oxidative addition reactions of type (4). As in the analogous reaction of H_2,[30] the energy of this reaction can be deduced from the following qualitative considerations. If in the course of the dissociation of the C–H bond the metal is oxidised as a result of oxidative addition via mechanism (4) and passes from the square d^8 configuration to the octahedral d^3 configuration [d^6 configuration (Ed. of Translation)], the energy of the reaction will be approximately described by the equation

$$\Delta E = E_{M-H} + E_{M-C} - (E_{C-H} + P) ,$$

where E_{M-H} is the energy of the hydrogen–metal bond, E_{M-C} the energy of the carbon–metal bond, E_{C-H} the dissociation energy of the C–H bond, and P the promotion energy of electron transfer in the ligand field to a higher orbital (for example from the $5d_{z^2}$ orbital to the $6p_z$ orbital). As stated above, E_{C-H} changes within fairly narrow limits and ΔE will thus depend primarily on P and E_{M-C}. P will decrease (and hence ΔE will increase) following the introduction of electron-donating ligands (promoting the transfer of non-bonding electrons to higher orbitals) and on passing to metals of the lower Periods. On the other hand, electron-accepting ligands should hinder the reaction. One should of course note that, for hydrogen transfer catalysts, P must not be very small either, since otherwise the hydride formed will be unduly stable and will be unable to give up its hydrogen to the substrate.

It is as yet not completely clear how the E_{M-C} depend on different factors. However, one should note that previous ideas concerning the low thermodynamic stability of the transition metal–carbon bond proved to be incorrect and that the role of the ligands in the stabilisation of these bonds is related in the first place to kinetic factors[31,32]. Electron-donating, strongly nucleophilic ligands should probably exhibit a powerful stabilising effect[31]. The available thermodynamic data are very scanty, but they do show that the transition metal–aryl bond is much more stable than the transition metal–alkyl bond. Thus the energy of the Pt–Ph bond in $(Et_3P)_2PtPh_2$ is approximately 250 kJ mole^{-1},[33] while the Pt–Me bond in $CpPtMe_3$ has an energy of only about 164 kJ mole^{-1}.[34] Similarly the energies of the Ti–Ph and Ti–Me bonds in Cp_2TiPh_2 and Cp_2TiMe_2 are respectively 350 and 250 kJ mole^{-1}.[35]

Thus, other conditions being equal, the reactions involving the oxidative addition of the C–H bond to a transition metal atom should occur much more readily for aromatic compounds than for aliphatic compounds. Indeed the experimental data quoted below confirm this conclusion.

Furthermore, in oxidative addition reactions occurring with the formation of a metal–carbon bond the entropy component will presumably make a large contribution to E_{M-C} (in contrast to the M–H bond). For this reason, such reactions should be favoured by a low coordination number of the initial complex (which is frequently associated also with a low oxidation state of the metal) and a small size of the ligands present and of the organic group R introduced.

It is noteworthy that reactions of type (3) and (4) give rise to the possibility not only of hydrogen transfer but also of the transfer of various organic groups R to substrates S with the aid of transition metal complexes, for example:

It has been shown recently that the dissociation of C–C bonds can sometimes take place analogously to the dissociation of C–H bonds with formation of products containing a metal–carbon σ bond[36–39]:

In certain cases these reactions, in which the metal is inserted into the C–C bond, constitute intermediate stages in skeletal rearrangements[40,41]. However, examination of these interesting reactions is outside the scope of the present review.

The data available at present by no means make it always possible to decide which of the mechanisms (1)–(4)

‡ In those cases where the radical R· is stabilised by conjugation, the dissociation energy is appreciably lower: 77 kcal mole^{-1} for the allyl–H bond and 78 kcal mole^{-1} for the benzyl–H bond. This accounts for the greater ease of dissociation of these bonds.

governs the activation of the C–H bond; usually this has to be inferred solely on the basis of the structure of the resulting transition metal hydride complexes.

Fairly extensive experimental data on the use of various organic hydrogen donors for the synthesis of hydride complexes have accumulated in the coordination chemistry of transition metals (see reviews [42-44]). We shall examine these experimental results from the standpoint of the ideas formulated above concerning the dissociation of C–H bonds. We shall consider first reactions where a hydride mechanism of type (2) can be postulated.

The formation of ruthenium, osmium, rhodium, and iridium hydride complexes using alcohols as hydrogen donors has been most widely investigated. This reaction is promoted by alkaline agents, i.e. the C–H bond in alcohols is activated as a result of the formation of the alkoxide ion and in the course of the reaction the alcohols themselves are converted into aldehydes and ketones; reactions of this type probably take place with a hydride ion shift via mechanism (2).

Thus, when the complex $PtCl_2(PEt_3)_2$ is refluxed in an ethanol solution of potassium hydroxide, the hydride complex of platinum and acetaldehyde are obtained [45,46]:

$$PtCl_2(PEt_3)_2 + KOH + EtOH \rightarrow PtHCl(PEt_3)_2 + Me-C\overset{O}{\underset{H}{<}} + KCl + H_2O ,$$

$$Ru_2Cl_5(PEt_2Ph)_6Cl + 2EtOH + 2KOH \rightarrow 2RuHCl(CO)(PEt_2Ph)_3 + 2CH_4 + 2KCl + 2H_2O .$$

The rhodium hydride complex $HRh(PPh_3)_4$ is formed when $(Ph_3P)_3RhCl$ interacts with triphenylphosphine in n-propyl alcohol in the presence of alkaline agents [47]. In certain cases hydride complexes can be obtained from alcohols also in the absence of alkalis. Thus, when $(Ph_3P)_3IrCl$ reacts with ethanol (in the absence of a base), the hydride complex $(Ph_3P)_3IrH_2Cl$ and acetaldehyde are obtained [48]. The question of which hydrogen atom in the alcohol passes to the metal was elucidated for the formation of iridium hydride complexes in the presence of deuteriated alcohols [49]:

$$K_2IrCl_6 + Ph_3P \begin{cases} + CH_3CH_2OH + H_2O \rightarrow IrHCl_2(Ph_3P)_3 , & (1) \\ + CH_3CH_2OH + D_2O \rightarrow IrHCl_2(Ph_3P)_3 , & (2) \\ + CH_3CH_2OD + D_2O \rightarrow IrHCl_2(Ph_3P)_3 , & (3) \\ + CH_3CD_2OH + H_2O \rightarrow IrDCl_2(Ph_3P)_3 . & (4) \end{cases}$$

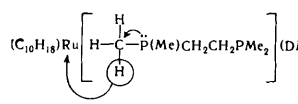
The mechanism shows that the interaction of the iridium salt and triphenylphosphine with both aqueous ethanol and with EtOD in the presence of D_2O [reactions (1)–(3)] leads to the formation of the iridium hydride complex $IrHCl_2(PPh_3)_3$, i.e. neither water nor the hydrogen atom of the alcoholic hydroxy-group behave as hydrogen donors in this reaction. On the other hand, the use of an alcohol with deuterium atoms at the 1-C atom [reaction (4)] leads to the formation of the deuteriated complex $IrDCl_2(Ph_3P)_3$. The experimental data show convincingly that the formation of hydride complexes from alcohols takes place as a result of the elimination of a hydrogen atom from the 1-C carbon atom of the alcohol, which exhibits the greatest hydride mobility. The fact that the addition of a base facilitates the removal of hydrogen from the alcohol as a result of the enhancement of the effect of p, σ conjugation in alkoxides becomes understandable from the same point of view.

One should note that alcohols can behave not only as hydrogen donors but also simultaneously as donors of the carbonyl group. For example, when triphenylphosphine is refluxed with $(NH_4)_2OsCl_6$ in the monomethyl ether of diethylene glycol, the mixed hydridocarbonyl complex $HOsCl(CO)(Ph_3P)_3$ is obtained [50]. When [^{14}C]ethylene glycol was used, it was shown that the glycol in fact behaves as the carbonylating agent in this reaction.

The formation of iridium, ruthenium, rhodium, and osmium hydride complexes in the reaction with alcohols has been described also in a number of other studies [51-58].

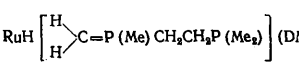
When transition metal complexes react with alcohols, it is not always possible to isolate and identify the hydride complex, although its formation is indirectly confirmed by the identification of the alcohol dehydrogenation products. For example, when allyl alcohol was refluxed with $RuCl_3 \cdot 3H_2O$, propene, acrolein, and propionaldehyde were found in the reaction products, although the hydride complex was not identified [59]. The study of the effect of phosphines on the capacity of rhodium complexes to eliminate hydride hydrogen from alcohols showed that the more basic the phosphine the greater the ease of this reaction [60].

It is noteworthy that the ligands coordinated to the metal atom can themselves behave as hydride donors in the formation of transition metal hydride complexes. In this case the hydride complex is formed as a result of hydrogen transfer from the organic component of the ligand molecule to the metal atom with dissociation of the C–H bond. Thus in the ruthenium complex $(C_{10}H_{18})Ru(DMPE)$, where DMPE = $Me_2P(CH_2)_2PMe_2$, hydrogen transfer from the methyl group of the phosphine ligand leads to the formation of a ruthenium hydride complex [61]:



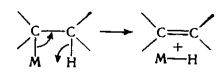
$$\rightarrow C_{10}H_{18} + RuH[CH_2{=}P(Me)CH_2CH_2PMe_2](DMPE) .$$

According to the authors' data, the hydride complex is in tautomeric equilibrium with a zerovalent ruthenium complex:



The dissociation of the C–H bond of the methyl group is observed also for the rhodium complex coordinated to the $(o\text{-tolyl})_3P$ ligand [62].

Reactions involving the intramolecular transfer of hydride hydrogen from the β-position of σ-alkyl ligands, leading to the formation of hydride complexes, are very common in the chemistry of organic derivatives of transition metals (they have been reviewed [63]):



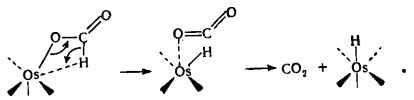
Reactions of this type take place readily when organolithium, organomagnesium, and organoaluminium compounds act on salts and complexes of transition metals. As an example of reactions involving individual σ-alkyl derivatives, we may quote the reaction of the platinum complex $PtCl(Et)(PEt_3)_2$, which eliminates ethylene on heating and forms a hydride complex via the mechanism [64,65]

That β-elimination does in fact take place has been demonstrated, in particular for the n-butylcopper complex [66]:

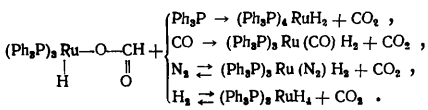
$$(Bu_3P)CuCH_2CD_2CH_2CH_3 \rightarrow (Bu_3P)CuD + CH_2{=}CDCH_2CH_3 .$$

Coordinated formate ligands can also readily give up hydrogen with formation of hydride complexes. For example, the osmium formate complex $Os(OOCH)_2(CO)_2 \cdot (PPh_3)_2$ is converted on refluxing in benzene into the

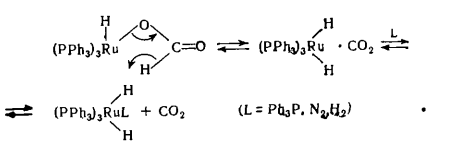
hydride $H_2Os(CO)_2(Ph_3P)_2$ with evolution of carbon dioxide via the mechanism [67]



The migration of hydrogen from carbon to the transition metal was observed very easily in the ruthenium formate complex $(Ph_3P)_3Ru(H)OOCH$. [68-70] This complex eliminates carbon dioxide unusually readily under the influence of various agents with formation of a hydride complex:



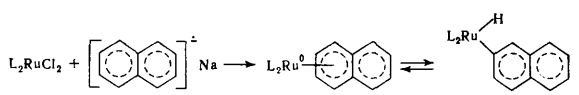
These unusual properties of the ruthenium formate complex can be accounted for by the exceptional ease of the migration of the hydride hydrogen of the formate group to the metal, accompanied by the formation of an unstable ruthenium hydride complex with carbon dioxide via the mechanism



All the examples described above concerned reactions leading to the formation of a metal–hydrogen bond via mechanism (2), i.e. with formal transfer of a hydride ion from the C–H bond. Reactions involving the dissociation of the C–H bond via mechanisms (3) and (4), accompanied by the simultaneous formation of metal–carbon and metal–hydrogen bonds, constitute another group.

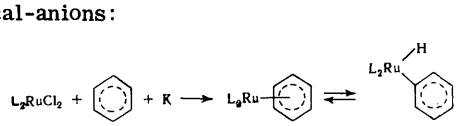
In contrast to hydride addition reactions, processes of this type are most typical for the dissociation of aromatic C–H bonds and the majority of examples known at present concern reactions of the type

These reactions, which occur under the influence of low-valence transition metal derivatives, are frequently accompanied by the intermediate formation of π-arene complexes and their isomerisation to σ-aryl derivatives. According to the data of Chatt and Davidson [71], dichlorodi-(1,2-bisdimethylphosphinoethane)ruthenium is converted on treatment with sodionaphthalene in tetrahydrofuran (THF) into a π-arene complex of ruthenium which is in equilibrium with the σ-naphthylruthenium hydride complex:

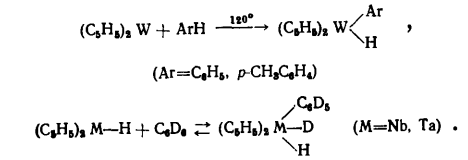


$(L = Me_2PCH_2CH_2PMe_2)$

The radical-anions of other aromatic hydrocarbons react similarly. In the case of benzene one can employ a mixture of benzene and metallic potassium instead of the radical-anions:



Similar reactions with aromatic radical-anions have been observed for cyclopentadienyl complexes of tungsten, tantalum, platinum, and other transition metals [72-75], for example:

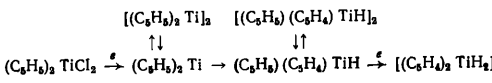


Titanium, vanadium, and chromium complexes give rise to reactions of the same type, with dissociation of the aromatic C–H bond [76,77].

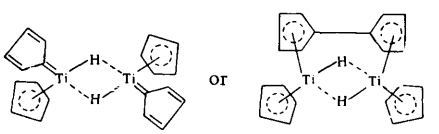
It has been shown by X-ray diffraction [78] that the product of the reaction of naphthalene with the 1,2-bisdimethylphosphinoethane complex of ruthenium is indeed a σ-naphthyl derivative of ruthenium.

It is noteworthy that hydrogen isotope exchange in benzene, catalysed by platinum salts, proceeds via an analogous mechanism with preliminary dissociation of the C–H bond [79,80].

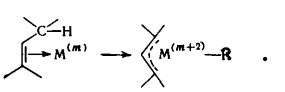
Not only aromatic hydrocarbons of the benzene type but also cyclopentadienyl ligands can serve as a source of hydrogen for the formation of the metal–hydrogen bond. Thus, in the reduction of titanocene derivatives by sodium, magnesium, sodionaphthalene, and other reducing agents, extremely ready migration of hydrogen from the ligand to the metal takes place [81-84]:



These reactions are also accompanied by the π, σ rearrangement of the ligand. Thus the following structural formulae have been proposed for the hydride form of titanocene $[(C_5H_5)(C_5H_4)TiH]_2$:

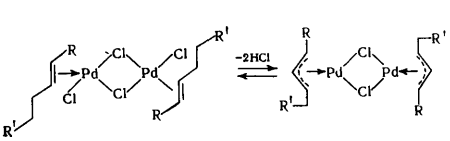


Finally the formation of hydride–allyl complexes from olefinic π complexes can be included among reactions of the type occurring with homolytic dissociation of the C–H bond via a mechanism close to oxidative addition:



(m = degree of oxidation)

Thus ruthenium hydride–allyl complexes $HRu(CO)_9(C_{12}H_{15})$, $HRu_3(CO)_9(C_{12}H_{17})$, and $HRu_3(CO)(C_{24}H_{33})$ are formed when cyclododecatriene reacts with ruthenium carbonyl $Ru_3(CO)_{12}$. [85] In the formation of π-allyl complexes of palladium, allyl hydrogen is also split off with intermediate formation of the Pd–H bond [86-91]:



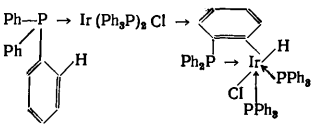
Dienes are formed in the decomposition of allyl complexes at an elevated temperature; a reaction of this

kind in the presence of oxidising agents (for example $CuCl_2$) can be achieved catalytically[92,93]:

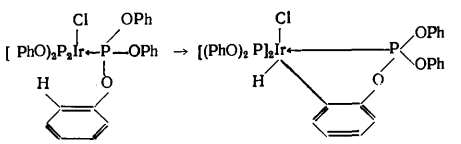
$$ROOCCH_2CH{=}CHCH_2COOR + 2CuCl_2 \xrightarrow{PdCl_2} \rightarrow ROOCCH{=}CHCH{=}CHCOOR + 2CuCl + 2HCl\ .$$

Another group of reactions occurring with insertion of the metal in an aromatic C–H bond comprises intramolecular hydrogen transfer from the *ortho*-position in the aromatic rings of phenylphosphine and phenyl phosphite ligands. Thus, on heating a solution of $(Ph_3P)_3IrCl$ in benzene, a hydride complex is formed[94]. The migration of the hydrogen atom from the phenyl ring was demonstrated using a fully deuteriated initial complex. On heating of $[P(C_6D_5)_3]_3IrCl$ in benzene, the product is a complex whose infrared spectrum indicates the presence of the Ir–D bond and the absence of the Ir–H bond.

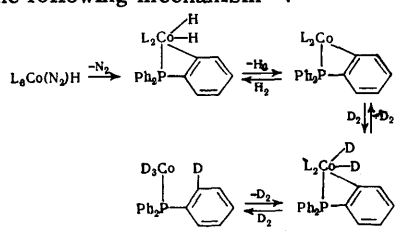
Evidently this reaction is a type of oxidative addition [reaction (4)]:



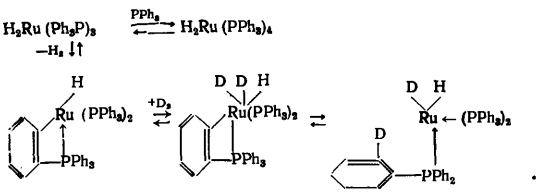
The interaction of IrCl(1,5-cyclo-octadiene) with triphenyl phosphite in acetone also leads to the formation of a hydride complex as a result of the migration of the *ortho*-hydrogen from the ligand[95]:



In many instances reactions of this kind are reversible and lead to the exchange of the *ortho*-hydrogen atoms of the benzene rings with the hydride hydrogen linked to the metal. For example, the exchange of hydrogen for deuterium in the *ortho*-positions of the benzene ring of the triphenylphosphine ligands in the cobalt complex proceeds via the following mechanism[96]:

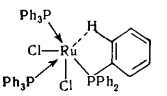


The deuterium exchange reactions take place similarly with the phosphine complexes of ruthenium[97–99]. For example, when the ruthenium complex $H_2Ru(Ph_3P)_4$ was allowed to react with D_2 in benzene and this was followed by the decomposition of the resulting complex with hydrogen peroxide, deuterium was identified in the benzene ring[99]. On the basis of these results, the authors concluded that in the course of the reaction there is a rapid reversible interaction of the ruthenium atom with the *o*-C–H bond:



A similar hydrogen transfer to the ruthenium atom with formation of a hydride complex occurs also in the case of the triphenyl phosphite ligand[100].

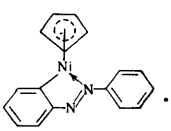
It is noteworthy that the ease of migration of hydrogen from the *ortho*-position of the benzene ring is probably related not only to the nature of the metal but also to the structure of the complex. X-Ray diffraction analysis of the triphenylphosphine complex of ruthenium $(Ph_3P)_3RuCl_2$ showed that the hydrogen atom in the *ortho*-position in the benzene ring is at a very short distance from the ruthenium atom[101]:



This accounts for the ease of migration of the hydrogen atom to ruthenium in such complexes.

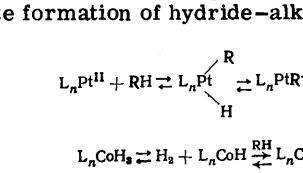
The formation of hydride complexes as a result of hydrogen transfer from the phenyl group and the coordinated phosphine ligand was also observed for cobalt and iron complexes. Thus the interaction of $HCo(N_2)[P(C_6D_5)_3]_3$ with bis-(1,2-diphenylphosphinoethane) results in the formation of a mixture of $HCo(DPPE)_2$ and $DCo(DPPE)_2$, where DPPE is diphenylphosphinoethane[102], while irradiation of $Fe(C_2H_4)(DPPE)_2$ in benzene solution leads to the formation of ethylene and the hydride complex $HFe(o\text{-}C_6H_4)(PC_6H_5)CH_2CH_2P(C_6H_5)_2(DPPE)$, the phosphine ligand behaving as the source of hydrogen in both instances[103,104]. A similar reaction has been observed also for ruthenium complexes with triphenylphosphine[105,106].

It is noteworthy that the cleavage of the *o*-C–H bonds of the benzene ring in the ligands proceeds so readily that in many cases they yield products with a stable transition metal–carbon bond. Certain transition metal complexes of azobenzene[107,108] and Schiff bases[109,110] have this structure, for example:



In the course of formation of such complexes the metal is apparently inserted in the *o*-C–H bond with subsequent elimination of hydrogen (as a proton or a hydrogen atom).

The examples examined above concern the insertion of the metal in an aromatic C–H bond. However, recent findings show that transition metal compounds are capable of being inserted also in an aliphatic C–H bond in saturated hydrocarbons. Shilov, Shteinman, and coworkers[111–113] and then also other workers[114,115] observed deuterium exchange involving methane, ethane, and other saturated hydrocarbons under the influence of platinum and cobalt. The results can be accounted for by reversible oxidative addition with dissociation of an aliphatic C–H bond and the intermediate formation of hydride–alkyl derivatives:



Analysis of kinetic data for deuterium exchange with water in aqueous acetic acid solutions of platinum(II) salts showed that the activity of the platinum compounds decreases in the sequence $PtX_2 > PtX_3^- > PtX_4^{2-}$ and in the

following sequence of the ligands X: Cl > Br > I. However, this reaction can occur also without the formation of a hydride via the elimination of a proton and the formation of an alkylplatinum derivative[116]:

$$PtCl_4^{2-} + RH \rightleftarrows PtCl_3R^{2-} + H^+ + Cl^- .$$

Thus fairly numerous organic substrates can behave as hydrogen donors in reactions with transition metal complexes leading to hydride complexes. However, the formation of hydride complexes alone is insufficient for the reduction of organic substrates. The hydrogen atom in the hydride complex must be sufficiently labile for the complex to be capable of participating in hydrogen transfer reactions. Moreover, as in homogeneous hydrogenation, the resulting hydride complex must be able to coordinate and activate the unsaturated substrate.

III. CATALYTIC HYDROGEN TRANSFER

The range of catalytic reactions involving hydrogen transfer from organic compounds to unsaturated substrates (olefins, aldehydes, ketones, etc.) known at present is much narrower than that of hydrogen reduction reactions. However, the number of known reactions of this kind is rapidly increasing and some of them have already assumed preparative importance.

1. Reduction by Alcohols, Alkoxides, and Ethers

Alcohols and alkoxides are most widely used as hydrogen donors. One of the first studies in this field was carried out by Italian workers[47,117], who found that unsaturated compounds can be reduced in the presence of rhodium, complexes using benzyl alcohol as the hydrogen donor. In the presence of rhodium complexes of the type $L_3Rh(CO)H$, where L = Et_3P, Bu_3P, Ph_2MeP, etc., the reduction of oct-1-ene by benzyl alcohol in the presence of potassium benzyloxide (with formation of PhCOOK) was observed. However, this reaction was fairly slow even at an elevated temperature (130°C), the maximum yield of the hydrogenation product (octane) amounting to only 35% after 4 h (Table 1).

Table 1. Catalytic activities of the phosphine complexes of rhodium in hydrogen transfer from benzyl alcohol to oct-1-ene (0.06 mole of benzyl alcohol, 0.035 mole of oct-1-ene, 0.006 mole of potassium benzyloxide, and 0.0003 mole of the catalyst, 130°C, time 4 h).

Catalyst	Conversion of benzyloxide into benzoate, %	Conversion of oct-1-ene into octane, %
$HRh(CO)(PEt_3)_3$	50	35
$HRh(CO)(PBu_3)_3$	25	6
$HRh(CO)(PEt_2Ph)_3$	15	3
$HRh(CO)(PMePh_2)_3$	2	traces
$HRh(CO)(PEt_3)_3$	4	6

The reduction of unsaturated compounds with hydrogen transfer from alcohols can occur also in the presence of certain transition metal salts[118]. Thus rhodium and ruthenium chlorides catalyse at 100°C the reduction by ethanol of hex-3-yne to hex-3-ene, of cyclopentadiene to cyclopentene, and of 5-vinylbicyclo[2,2,1]hept-2-ene to 2-vinylbicyclo[2,2,1]heptane, the ruthenium salt proving to be more active than the rhodium salt.

The authors of this investigation suggest that in the course of the reduction process an intermediate complex with an Rh–H bond is formed and is responsible for the reduction. The study[119] where it was shown that rhodium salts catalyse the dehydrogenation of 2-propanol is interesting in this connection. It is suggested that the dehydrogenation of the alcohol proceeds via an intermediate hydride according to the mechanism

$$Me_2CHOH + [Rh^{III} - Cl] \rightleftarrows Me_2CO + [Rh^{III} - H] + HCl ,$$

$$[Rh^{III}H] + HCl \rightarrow [Rh^{III}Cl] + H_2 .$$

The alcohol dehydrogenation reaction has also been described in the presence of cobalt carbonyl as a process which is the converse of the hydrogenation of aldehydes in the hydroformylation reaction[120–123].

There are literature data concerning the transfer of hydrogen from alcohols to unsaturated compounds under the influence of transition metal acetylacetonates (for example, nickel acetylacetonate)[124]. The reaction proceeds under fairly severe conditions at a temperature of 200–220°C. Methyl linoleate and methyl octadecadienoate, which have conjugated double bonds, were reduced under these conditions with the aid of different alcohols (isopropyl, n-propyl, ethyl, s-butyl, n-butyl, s-pentyl, and n-tentyl). In the hydrogenation of methyl linoleate the reaction products contain an appreciable proportion of *trans*-octadecenoate. The authors did not observe an appreciable difference between the rates of hydrogenation of *cis*-octadecenoate and its *trans*-isomer, but, owing to steric hindrance, *trans,trans*-octadecadienoate is reduced much more slowly than the *cis,trans*-isomer.

Other examples of hydrogen transfer from alcohols to the unsaturated soya-bean oil esters, to linoleic and linolenic acid esters, and to other polyenes have also been described[125,126]. The reactions proceed at 100°C and lead mainly to the formation of mono-olefins. Complexes of the type $Cl_2M(PPh_3)_2$, where M = Pt or Pd, in combination with $SnCl_2$ behave as catalysts of these hydrogen transfer reactions.

The double bonds activated by functional groups can be selectively reduced by alcohols. Thus a study has been made of the catalytic hydrogen transfer from 2-propanol to $\alpha\beta$-unsaturated ketones in the presence of iridium compounds[127,128]. The reduction of the double bond is catalysed by the complex $H[IrCl_4(Me_2SO)_2].2Me_2SO$, which on refluxing forms the hydride $HIrCl_2(Me_2SO)_3$.

The C=C double bond in benzylideneacetophenone and in other similar compounds has been reduced with the aid of the same catalytic system:

$$PhCOCH{=}CHPh \rightarrow PhCOCH_2CH_2Ph ,$$

$$Me_3CCOCH{=}CHPh \rightarrow Me_3CCOCH_2CH_2Ph ,$$

$$PhCO(CH{=}CH)_2Ph \rightarrow PhCO(CH_2CH_2)_2Ph .$$

The reduction of $\alpha\beta$-unsaturated ketones to saturated ketones by benzyl alcohol is catalysed effectively by the ruthenium complex $(Ph_3P)_3RuCl_2$.[129] For example, when 1-phenylbut-1-en-3-one is heated in benzyl alcohol in the presence of a catalytic amount of the ruthenium complex at 200°C, the product is 92% of 1-phenylbutan-3-one. Together with benzyl alcohol, other alcohols were also employed as hydrogen donors in this reaction: $PhCH_2CH_2OH$, $PhCH(OH)CH_3$, and $CH_3(CH_2)_6CH_2OH$ (Table 2). The same investigators showed that the aromatic aldehydes α-$C_{10}H_7CHO$, β-$C_{10}H_7CHO$, and others can also function as hydrogen donors[130] (Table 3).

Reports have been published recently concerning the reduction of the double bond in cyclo-olefins with the aid of dihydric phenols[131,132]§. Thus when cyclo-octa-1,3-diene and cyclo-octa-1,5-diene react with hydroquinone in dioxane in the presence of triphenylphosphine complexes of iron(II), cobalt(II), and nickel(II) at 200°C the cyclo-octadienes are reduced catalytically to cyclo-octene and cyclo-octane. According to the authors, these reactions take place as a result of an intramolecular hydrogen transfer, since the pressure in the reaction vessel remained unchanged in the course of the reactions, i.e. the evolution of molecular hydrogen was not observed. Apart from cyclo-octene and cyclo-octane, isomerisation products were detected at the end of the reaction: cyclo-octa-1,4-diene and cyclo-octa-1,3-diene. The efficiency of various compounds as reducing agents under the conditions investigated decreases in the sequence pyrogallol > catechol > hydroquinone > n-dodecanethiol > 1-octanol > cyclohexene > 2-octanol > 1-dodecanol > n-dodecylamine.

Table 2. Hydrogen transfer from alcohols to $\alpha\beta$-unsaturated carbonyl compounds in the presence of $(Ph_3P)_3RuCl_2$ (Sasson and Blum[129]).

Hydrogen donor (weight, g)	Hydrogen acceptor (weight, g)	Reaction temp., °C	Yield of saturated carbonyl compound after 4 h, %
$PhCH_2OH$ (1.08)	PhCH = CHCOMe (1.46)	200	94
$PhCH_2CH_2OH$ (1.22)	PhCH = CHCOMe (1.46)	200	94
PhCH(OH)Me (1.22)	PhCH = CHCOMe (1.46)	200	93
$Me(CH_2)_6CH_2OH$ (1.30)	PhCH = CHCOMe (1.46)	190	82
$PhCH_2OH$ (1.08)	PhCH = CHCOPh (2.08)	200	98
$PhCH_2OH$ (1.08)	$CH_2CMe_2CH_2CMe = CHCO$ (1.38)	200	41
$PhCH_2OH$ (1.08)	PhCH = $CHCOCMe_3$ (1.88)	200	89
$PhCH_2OH$ (1.08)	PhCH = CMeCHO (1.46)	200	61
$PhCH_2OH$ (1.08)	PhCH = CHCOOEt (1.76)	200	53

The reduction of the multiple bond in unsaturated compounds with the aid of dihydroxybenzene derivatives can occur also in aqueous solutions[133], for example in aqueous alkaline solutions of vanadium(III) in the presence of a number of di- and trihydroxy-derivatives of benzene and naphthalene (catechol, pyrogallol, and 2,3-dihydroxynaphthalene). Acetylene is reduced to ethylene at room temperature.

Together with alcohols, cyclic ethers can also be used as hydrogen donors for the reduction of unsaturated compounds. For example, when tetrahydrofuran is employed as the solvent in the presence of catalysts of the type $Cl_2M(PPh_3)_2$, where M = Ni, Pd, or Pt, the olefins are reduced[125,126,134]. It is interesting that the nickel catalyst is active also in a benzene medium, but it is not clear what the hydrogen source is in this case.

Japanese workers[135] described the reduction of olefins with the aid of dioxane in the presence of a rhodium catalyst. When cyclopentene is heated at 180°C in dioxane solution in the presence of $(Ph_3P)_3RhCl$, 0.43 mole of dioxene and 0.42 mole of cyclopentane are formed. After the reaction the individual complex $(Ph_3P)_2RhCl(C_4H_8O_2)$, formed as a result of the displacement of one phosphine group from the initial complex by dioxane, was isolated.

§ These reactions proceed with the dissociation of O–H bonds only. However, the similarity of the catalysts and conditions employed make it useful to examine them in this section.

By analogy with hydrogenation by molecular hydrogen and the isomerisation of olefins, the authors suggest the following reaction mechanism:

$$RhCl(PPh_3)_2(C_4H_8O_2) \rightleftarrows RhClH(C_4H_7O_2)(PPh_3)_2 \rightleftarrows RhClH_2(PPh_3)_2(C_4H_6O_2) \xrightleftharpoons{+olefin}$$

$$\rightleftarrows RhClH_2(PPh_3)_2(olefin) \rightleftarrows RhClH(alkyl)(PPh_3)_2 \xrightleftharpoons{+dioxane}$$

$$\rightleftarrows RhCl(PPh_3)_2(C_4H_8O_2) + paraffin$$

There is convincing evidence showing that rhodium monohydride complexes are formed via the oxidative addition of dioxane with dissociation of the C–H bond (kinetic data, isotope effect data, etc.). With the aid of organic hydrogen donors, primarily alcohols, it is possible to reduce not only carbon–carbon multiple bonds in unsaturated compounds but also functional groups such as the carbonyl and nitro-groups.

Table 3. Hydrogen transfer to $\alpha\beta$-unsaturated quitones in the presence of ruthenium, rhodium, and iridium complexes[130] (donor : acceptor : catalyst = 1 : [?] : 5×10^{-2} for Nos. 1–8 and 1 : 20 : 5×10^{-3} for Nos. 9–16).

Thus the reaction of substituted cyclic ketones with solutions of chloroiridic acid in aqueous isopropyl alcohol containing different ligands (dimethyl sulphoxide, trimethyl phosphite, or phosphorous acid) leads to the formation of axial alcohols in high yields[127]. For example, 4-t-butylcyclohexanol is formed from 4-t-butylcyclohexanone under these conditions. When the reaction was carried out in the presence of dimethyl sulphoxide, a number of iridium complexes, which catalyse hydrogen transfer reactions, were isolated[128].

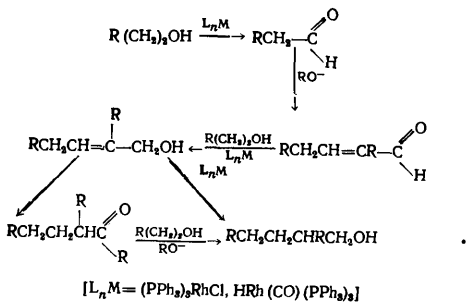
Hydrogen transfer and reduction of carbonyl group are observed also when isopropyl alcohol is refluxed with cyclohexanone in the presence of catalytic amounts of the complexes $IrH_3(PPh_3)_3$, $IrH_3(PPh_3)_2$, $ReH_7(Ph_3P)_2$, and $RuHBr(CO)(PEt_2Ph)_3$.[136] It is interesting that, when 4-substituted cyclohexanones are employed, equatorial alcohols are formed as the main reduction products[137].

An active ruthenium catalyst of hydrogen transfer from primary and secondary alcohols to ketones [$RuCl_2(PPh_3)_3$] was proposed by Freidlin and coworkers[138–141]. The addition of bases accelerates this reaction. The reaction rate depends on the structure of the alkyl substituents in the alcohol molecule and falls sharply following the introduction of bulky tertiary groups. Alkylphenylmethanols reduce ketones at a much higher rate than 2-alkanols. The structure of the ketone has also a significant influence

on the rate of reaction, which decreases in the sequence cyclohexanone > acetophenone > cyclopentanone > 2-hexanone > cycloheptanone > cyclo-octanone.

It is interesting that the univalent rhodium complex $(PPh_3)_3RhCl$, which is an active catalyst of homogeneous hydrogenation, is also active in hydrogen transfer from alcohols[138,139]. Its activity in this reaction is higher approximately by a power of ten than the activity of the ruthenium complex $(PPh_3)_3RhCl_2$ and depends little on the structure of the alcohol and ketone.

Catalytic reduction of aldehydes by alcohols was observed also in the course of the condensation of alcohols catalysed by rhodium compounds[142]. In this reaction the rhodium catalyst dehydrogenates the primary alcohol to the aldehyde with simultaneous formation of a carbonyl–phosphine–hydride complex (in this complex the carbonyl group of the aldehyde formed serves as a source of CO). In an alkaline medium two aldehyde molecules condense with formation of an $\alpha\beta$-unsaturated aldehyde, which is reduced by the rhodium hydride complex to a saturated aldehyde and to a higher alcohol:



$[L_nM = (PPh_3)_3RhCl,\ HRh(CO)(PPh_3)_3]$

Studies on the catalytic reduction of the carbonyl group in complex natural products are interesting. Thus steroid ketones can be reduced by isopropyl alcohol in the presence of tris(triphenylphosphine)rhodium chloride[143]. Under these conditions, the reduction of ketones to axial alcohols is to some extent stereospecific. The rate of reduction in the presence of the rhodium catalyst did not increase appreciably following the addition of alkali.

A study has also been made of the reduction by alcohols of a wide range of steroids in the presence of the $H_2IrCl[P(OMe)_3]_3$ catalyst[144]. This system is fully selective in the reduction of the 3-oxo-group in the presence of oxo-groups in other positions. Thus the oxo-groups in the 6-, 7-, 11-, 12-, 17-, 17α-, and 20-positions are hardly reduced (Table 4).

The reduction of other functional groups, in particular of the nitro-group, by alcohols in the presence of transition metal complexes has been described[145]. Thus a methanol solution of $Fe_3(CO)_{12}$ reduces specifically the aromatic nitro-group to a primary amino-group. The nitro-group is reduced with relatively high yields also in the presence of different substituents in the benzene ring (*p*-Cl, *o*-Cl, *o*-Me, *p*-OMe, *p*-OH, *p*-COOEt, *p*-COMe, *p*-HCOMe, *p*-CH=CH–CH=CH_2, *m*-NO_2, *p*-NH_2, and others).

It is noteworthy that the hydrogen transfer from alcohols to unsaturated substrates occurs under somewhat more severe conditions (temperature 80—130°C) than in homogeneous hydrogenation under the influence of analogous catalysts (usually at room temperature). This can be accounted for by the greater difficulty of the dissociation of the C–H bond compared with the H–H bond.

2. Reduction by Formic Acid and Formates

One of the interesting and extremely effective hydrogen donors for the reduction of organic compounds is formic acid and its derivatives. It is well known that formic acid and its salts are powerful reducing agents. This is usually attributed to the presence of the "aldehyde-like" hydrogen at the carbon atom which exhibits an appreciable hydride mobility (see above). In 1967 Coffey reported that, in the presence of phosphine complexes of platinum, ruthenium, and iridium, formic acid undergoes catalytic decomposition with formation of hydrogen and carbon dioxide[146]. He also stated that, following the introduction into this catalytic system [in the presence of the complex $H_3Ir(PPh_3)_3$] of butyraldehyde, the latter is reduced to the corresponding alcohol. Further results obtained in the reduction of the carbonyl group by formic acid were published by the same author in a patent[147].

* The reaction is carried out in boiling isopropyl alcohol.

It was found recently that formic acid can readily reduce carbon–carbon multiple bonds in the presence of various transition metal complexes as catalysts[148-151].

The study of a wide range of phosphine complexes in this reaction showed that the principal relations observed in hydrogenation by molecular hydrogen are retained also in the reduction of olefins by formic acid. The influence of ligands, the valence of the transition metal, the nature of the substrate, etc. is similar. However, in contrast to hydrogenation by hydrogen, the reduction of olefins by formic acid is significantly affected by the solvent. The reduction hardly occurs in non-polar solvents (benzene, toluene, etc.) even under severe conditions, but proceeds extremely readily in dimethylformamide (DMF) and

dimethylacetamide. It is extremely significant that molecular hydrogen does not hydrogenate olefins in these solvents and under these conditions, which is evidence of intramolecular hydrogen transfer from HCOOH. That the hydride hydrogen from formic acid is involved in the reduction of the olefins has been demonstrated by separate experiments with DCOOH.

Olefins are reduced by formic acid usually at a higher temperature (60–100 °C) than in the hydrogenation by molecular hydrogen in the presence of the same complexes. This is due in all probability to the greater difficulty of the dissociation of the C–H bond in formic acid. There are several ways of increasing the catalytic activity of the systems in which formic acid functions as a source of hydrogen.

1. By employing a combination of catalysts instead of individual complexes. Thus combination of the catalysts $(PPh_3)_2Rh(CO)Cl$ and $(PPh_3)_2Ir(CO)Cl$ is more active than each complex separately.

2. By employing a combination of transition metal complexes one of which is incapable of reducing the olefin but behaves under mild conditions as a catalyst of the decomposition of formic acid and the other can transfer hydrogen to the olefin. Such a system can be achieved, for example, by combining the complex $(Ph_3P)_3Co(N_2)H$, which can catalyse the decomposition of formic acid at room temperature, and any catalyst of homogeneous hydrogenation which can give rise to hydrogen transfer [for example, $(PPh_3)_3RhCl$].

3. By adding formate salts. In this case the formate anion presumably serves as an efficient donor of the hydride ion and formic acid behaves as a proton donor:

$$H\text{—}COO^- + M \longrightarrow (MH)^- + CO_2 ,$$

$$(MH)^- + HCOOH \longrightarrow MH_2 + HCOO^- ,$$

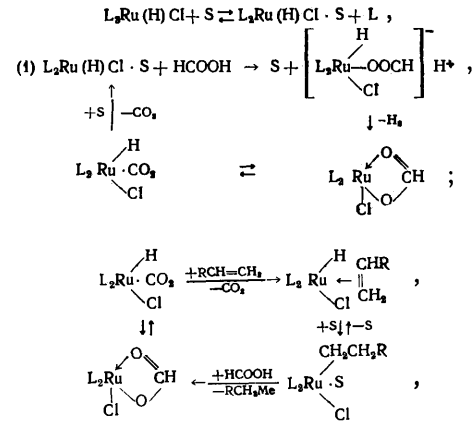
$$MH_2 + RCH{=}CH_2 \longrightarrow M + RCH_2CH_3 .$$

Indeed the employment of a mixture of formic acid and its salt made it possible in a number of cases to increase appreciably the degree of reduction and to lower the reaction temperature. For example, a mixture of formic acid with its salt in the presence of the complex $(Ph_3P)_3RhCl$ reduces quantitatively oct-1-ene and oct-4-ene, while the degree of their reduction by formic acid alone under the same conditions does not exceed 15%. In many instances a mixture of formates and formic acid reduces olefins even at room temperature.

It is interesting that formates themselves are also capable of reducing olefins and acetylenes in the presence of transition metals and in some cases the reduction by alkali metal formates proceeds more readily than by formic acid. Water behaves as the source of protons in such systems. The nature of the cation linked to the formate has hardly any effect on the activity of the reducing agent.

Comparison of the catalytic activities of various transition metal complexes in the reduction of olefins by formic acid showed that ruthenium complexes are the most active and among these the highest activity is shown by $(Ph_3P)_3Ru(H)Cl$. This complex catalyses the reduction of terminal olefins at room temperature in high yields. This behaviour of the ruthenium complex can be explained by the exceptional ease of the dissociation of the C–H bond of the formate group at the ruthenium atom with transfer of the hydride ion to ruthenium (see above). It is noteworthy that the ruthenium formate complex $(PPh_3)_3RuH(OOCH)$ is itself an effective catalyst of the decomposition of formic acid and of the reduction of olefins by formic acid at room temperature.

Kinetic studies and studies on model reactions suggest the following general mechanism of the decomposition of formic acid and the reduction of olefins [in the presence of the complex $(Ph_3P)_3Ru(H)Cl$]:



where S is a solvent molecule.

The decomposition of formic acid under the influence of transition metals can probably proceed not only via the formation of a formate complex with subsequent hydride transfer from the C–H bond to the metal in accordance with the mechanism

$$M + HCOOH \rightarrow HCOOM^- + H^+ \rightarrow HM^- + CO_2 + H^+ \rightarrow MH_2 + CO_2 ,$$

but also by the insertion of the metal in the carbon–hydrogen bond with the initial formation of the hydride of the metallocarboxylic acid:

$$M + HCOOH \rightarrow \overset{H}{\underset{COOH}{M}} \rightarrow MH_2 + CO_2 .$$

Indeed, when formic acid is refluxed with iridium complexes of the type L_3IrCl_3 (where L = Me_2PhP or Et_2PhP), the product is a complex, which has the structure $L_2Ir(CO)H(COOH)Cl$ according to infrared spectroscopic data and its chemical properties[152]. This reaction is of interest not only from the standpoint of the understanding of the mechanism of the decomposition of formic acid but also from the standpoint of the possible transfer of fragments of the metallocarboxylic acid to olefins via a mechanism involving a kind of reductive carboxylation[153]:

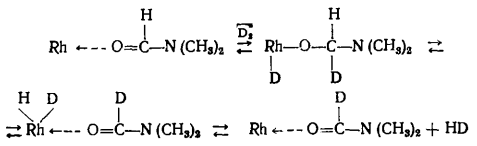
$$M + HCOOH \rightarrow \overset{H}{\underset{COOH}{M}} \xrightarrow{C=C} H\text{—}C\text{—}C\text{—}COOH .$$

The possibility of such addition of the elements of formic acid and also of its esters to cyclohexene and other olefins has been demonstrated in catalysis by rhodium, ruthenium, osmium, and platinum complexes[68]. The complexes $(PPh_3)_3RhCl$, $(PPh_2)_3RhCl$, $(PPh_3)_2Ir(CO)Cl$, and $(PPh_3)Rh(CO)_2Cl$ proved to be the most active catalysts. However, the yields of the carboxylic acid are low and do not exceed 40 mole per mole of the catalyst; the process is complicated by side reactions involving the decomposition of formic acid, the reduction of the olefin, etc.

This reaction is an example of an interesting type of C–H bond dissociation and of the transfer of both hydrogen and of an organic group to the substrate. Such reactions can in many instances lead to new ways of obtaining valuable substances.

In conclusion of the section devoted to formic acid as a reducing agent, mention should be made of the fact that in

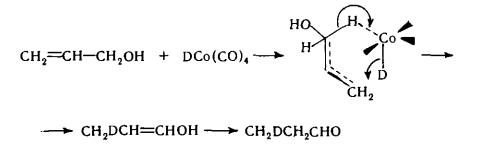
the presence of ruthenium and rhodium complexes the acid is capable of the selective reduction of $\alpha\beta$-unsaturated ketones to saturated ketones[130] (Table 3). It is interesting that, when the complex $(PPh_3)_3RuCl_2$ is used as a catalyst, not only formic acid but also DMF can serve as a source of hydride hydrogen. The study on the exchange of hydrogen in the C–H bond in DMF with molecular deuterium catalysed by rhodium complexes[154,155] is interesting in this connection. The authors propose the following possible mechanism for the exchange process:



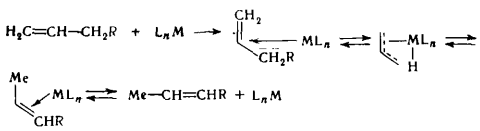
3. Disproportionation Reactions

Catalytic reactions where the same substrate molecule can behave both as a donor and as an acceptor of hydrogen are of great interest. This results either in the isomerisation of the initial molecule (with intramolecular hydrogen migration) or disproportionation (with intermolecular hydrogen migration).

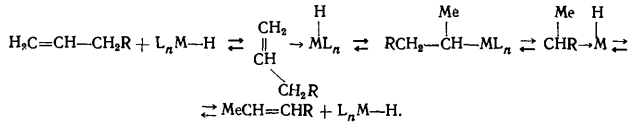
The isomerisation of allyl alcohol to propionaldehyde catalysed by cobalt hydrocarbonyl[156], iron[157], ruthenium[158], and palladium[159] complexes can serve as an example of such intramolecular hydrogen transfer. When allyl alcohol is acted upon by deuteriated cobalt hydrocarbonyl, the entire deuterium is bound in the methyl group of propionaldehyde, which suggests the following mechanism for this reaction[156]:



Numerous olefin isomerisation reactions under the influence of transition metal compounds also constitute essentially intramolecular hydrogen migrations. They occur either with activation of the allylic C–H bond of the olefin (which is most readily dissociated):



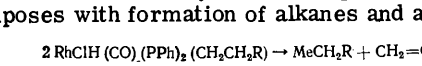
or they involve the metal–hydrogen hydridic bond already present via an intermediate σ-alkyl derivative:



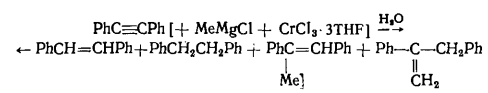
The isomerisation reactions have been discussed in greater detail in numerous reviews, for example that of Orchin[89].

σ-Alkyl derivatives of transition metals, which are in many instances intermediates in the catalytic migration of hydrogen in olefins, are also capable of undergoing very readily intermolecular hydrogen exchange in the course of the dissociation of the metal–carbon bond via the mechanism

For example, the decomposition of pentacyano(2-butenyl)-cobaltate(III) results in the formation of butenes and butadienes[160]. The alkylcarbonylrhodium hydride complex (formed in the decarbonylation of aliphatic aldehydes) decomposes with formation of alkanes and alkenes[161–163]:

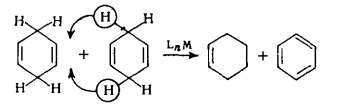


The number of examples of this kind could be greatly extended. It is noteworthy that σ-alkyl groups can behave also as reductants for an "external" substrate (an unsaturated compound), but this reaction does not have preparative value. For example, when tolane reacts at room temperature with σ-methyl derivatives of chromium, tolane reduction products were identified after hydrolysis[164]:

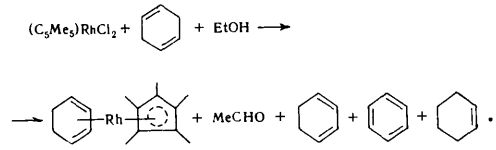


When a deuteriated Grignard reagent was employed it was shown that the methyl group is in fact the hydrogen donor[165].

The olefin disproportionation reactions in the presence of complex catalysts discovered recently are interesting. It was found that cyclohexe-1,4-diene can disproportionate in a homogeneous medium in the presence of $(Ph_3P)_2Ir(CO)Cl$ with formation of benzene and cyclohexane[166]. In this case, as in N.D. Zelinskii's classical irreversible catalysis, one cyclohexadiene molecule behaves as the donor and the other as the acceptor of hydrogen:



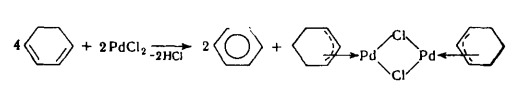
The complex $Ph(\pi\text{-}C_5Me_5)C_6H_8$ also catalyses the disproportionation of cyclohexa-1,3-diene and cyclohexa-1,4-diene to cyclohexene and benzene[167]. This involves the formation of a rhodium complex accompanied by the isomerisation of the 1,4-diene to the 1,3-diene with subsequent disproportionation:



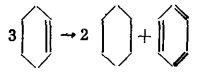
The formation of the rhodium complex from the 1,3-diene is accompanied only by disproportionation without isomerisation.

The reaction of cyclohexa-1,3-diene with $RuCl_3$ in ethanol results in the formation of a π-benzene complex of ruthenium[168]. This reaction probably proceeds via the catalytic disproportionation of cyclohexadiene.

In the presence of palladium salts cyclohexa-1,3-diene is converted into benzene and an allyl complex of palladium[169]:

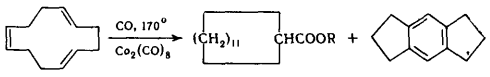


The disproportionation reactions of cyclohexene catalysed by palladium salts[170,171] probably belong to the same type. For example, on heating with $Pd(CN)_2$ at 130°C, cyclohexene gives rise to a mixture of cyclohexanes and benzene [yields of 479 and 212% relative to $Pd(CN)_2$][170]:



When acted upon by $PdCl_2$, 1-methylcyclohex-1-ene forms similarly methylcyclohexane and toluene even at room temperature[170]; this entails the simultaneous oxidation of the olefin and the formation of metallic palladium. However, the authors believe that palladium complexes and not metallic palladium catalyse this reaction.

An interesting disproportionation reaction was discovered by Rüll[172], who established that, in the presence of $Co_2(CO)_8$ under the conditions of the Reppe synthesis, cyclododeca-1,5,9-triene is converted into the methyl ester of cyclododecanecarboxylic acid. In addition it was found that the corresponding aldehyde is formed in the course of the reaction. Hydrogen required for this reaction is formed as a result of the conversion of cyclododeca-1,5,9-triene into the symmetrical hydrindacene, which was detected in the reaction products:



4. Direct Dehydrogenation Reactions

The problem of the possible occurrence of direct dehydrogenation reactions under the influence of complex catalysts, i.e. reactions which are the converse of hydrogenation, for example

has attracted particular attention. Such reactions could in principle be catalysed by the same complexes as hydrogenation and the reaction mechanism might include the activation of the C–H bond:

However, under mild conditions all these reactions are as a rule thermodynamically unfavourable and the equilibrium is displaced wholly towards the formation of the hydrogenation products.

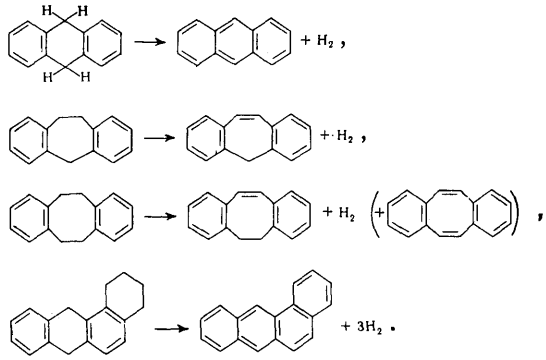
The few examples in which processes of this kind are known involve the formation of products which are thermodynamically the most stable. Thus, as already stated above, formic acid decomposes extremely readily when acted upon by various transition metal complexes via the mechanism

Here the "driving force" of the reaction, which is completely displaced to the right, is the high thermodynamic stability of the CO_2 molecule ($\Delta H_{298} \simeq 264$ kcal mole^{-1}).

Direct dehydrogenation with formation of a C=C double bond was observed in a few instances and only for compounds where the double bond is stabilised by conjugation. Thus it has been stated[173] that cyclohexane is dehydrogenated to benzene on interaction with $IrCl(PPh_3)_3$. However, the yield of benzene was small and it was not clear whether hydrogen was evolved or an iridium hydride complex was formed. (Experiments with a deuteriated substrate showed that hydrogen is transferred to iridium from the phosphine ligands and not from the substrate.) There are also data for the dehydrogenation of cyclohexane by palladium(II) salts[174].

Extremely interesting examples of catalytic dehydrogenation were observed by Blum and Biger[175] for compounds whose dehydrogenation results in the formation of a double bond between two benzene rings. For example, on heating with a catalytic amount of $(Ph_3P)_3RhCl$, $(AsPh_3)_3RhCl$, $(Ph_3P)_2Ir(CO)Cl$, or $(PPh_3)_3RuCl_2$ at 260°C, bibenzyl gives rise to *trans*-stilbene:

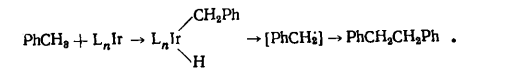
Other dehydrogenation reactions proceed similarly:



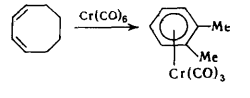
It is interesting that the rates of these reactions are close to those of dehydrogenation at a heterogeneous palladium catalyst, but the reactions in the presence of the complexes are more selective. Thus, on heating with $(Ph_3P)_3RhCl$ (at 225°C for 15 h), 9,10-dihydroanthracene gives a quantitative yield of anthracene (without the formation of tetrahydroanthracenes). Transition metal hydride complexes are probably formed as intermediates in this reaction. Indeed the hydride was isolated in the case of the ruthenium complex.

There has been a brief communication[176] concerning the catalytic dehydrogenation of toluene in the presence of $(PPh_3)_3IrCl$:

Presumably the occurrence of this reaction is related primarily to the great ease of the dissociation of the benzyl–hydrogen bond and subsequent dimerisation of the benzyl radicals:



Finally mention may be made of the reaction in the course of which cyclo-octa-1,3-diene is dehydrogenated under the influence of chromium carbonyl with simultaneous ring contraction and aromatisation. The chromium carbonyl complex of *o*-xylene was isolated in a low yield[177]:



---o0o---

The present review has dealt with a wide variety of reactions involving the dissociation of C–H bonds with subsequent hydrogen transfer to unsaturated compounds. Transition metal complexes are effective catalysts of these reactions and make it possible to carry them out under comparatively mild conditions and fairly selectively.

Alcohols, alkoxides, aldehydes, dihydric phenols, cyclic ethers, etc. can be used as hydrogen donors. Formic acid and formates are particularly convenient reducing agents.

Carbon–carbon double and triple bonds, the carbonyl group, and the nitro-group have been hydrogenated with the aid of these reducing agents. In many instances it proved possible to demonstrate the high selectivity of the reactions and their stereospecificity. It is noteworthy that the ease and selectivity of the hydrogen transfer processes and the availability of the reducing agents and catalysts used make the reactions very convenient in many instances on a preparative scale.

Cyclic Oxyphosphoranes

B.A.Arbuzov and N.A.Polezhaeva

The review deals with a new interesting field in the chemistry of organophosphorus compounds—cyclic derivatives of pentacoordinate phosphorus containing at least one endocyclic P-O bond and not containing halogens.
The principal types of cyclic oxyphosphoranes with four-, five-, and six-membered rings, spirophosphoranes, and phosphoranes of the condensed and prismatic types have been examined. The methods of synthesis and chemical reactions of cyclic phosphoranes are described: condensation with carbonyl compounds, hydrolysis, alcoholysis, thermal stability, etc. Physicochemical studies on phosphoranes have been undertaken to establish their structures and to investigate their stereochemistry. X-ray diffraction, infrared spectroscopy, ^{1}H NMR, and ^{31}P NMR have been used for these purposes. The groups linked to phosphorus are capable of permutational isomerisation which can occur via the mechanism of the Berry pseudorotation or via turnstile rotation.
The bibliography includes 264 references.

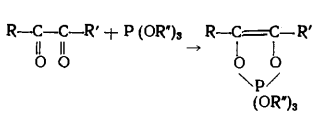
I. INTRODUCTION

Organic derivatives of the hypothetical phosphorus hydride PH_5 (phosphorane) are called phosphoranes. Derivatives of hydroxyl-containing substances with the general formula $R_nP(OH)_{5-n}$ ($n = 0-4$) are regarded as oxyphosphoranes; when $n = 0-3$, they can be treated as derivatives of the ortho-forms of the corresponding phosphoryl compounds $R_nP(O)(OH)_{3-n}$, where $n = 0-3$. The stability of phosphoranes increases on passing from a cyclic to monocyclic and bicyclic compounds.

The present review deals with cyclic phosphoranes containing at least one endocyclic P–O bond. Halogen-containing phosphoranes are excluded.

Cyclic phosphoranes have been vigorously investigated in the last 15 years. The formation of 1 : 1 adducts of α-dicarbonyl compounds with trialkyl phosphites was discovered independently in 1958–1960 by three groups of investigators: Kukhtin[1,2], Birum and Dever[3,4], and Ramirez and coworkers[5,6].



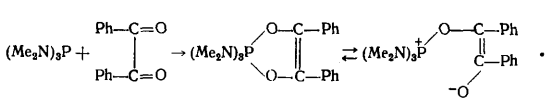
These adducts possess a set of interesting chemical and physical properties, lacked by the classes of organophosphorus compounds known previously, which led to their vigorous investigation by chemical and spectroscopic methods[7,8]. These studies showed that the adducts were unsaturated cyclic oxyphosphoranes. The relative ease of formation of such compounds and the wide variety of reactions which they undergo suggest that cyclic phosphoranes have a very promising future as chemical intermediates. Moreover, cyclic phosphoranes are ideal systems for the investigation of the stereochemistry of pentacoordinate phosphorus[9-13]

II. SYNTHESIS OF CYCLIC PHOSPHORANES

1. Synthesis of Phosphoranes by the Reaction of Phosphorus(III) Acid Derivatives with Carbonyl Compounds

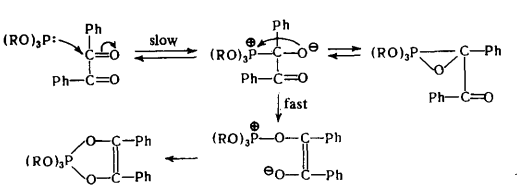
1,3,2-Dioxaphospholens are formed when trialkyl phosphites react with α-dicarbonyl compounds of the aliphatic[14-19], alicyclic[20,21], and aromatic[22-27] series. Phosphonites, phosphinites[19,28], dialkyl phosphoramidites[29-32], and dialkyl phosphonamidites[29,33,34] also form phosphoranes on interaction with α-dicarbonyl compounds. Cyclic phosphites and phosphoramidites react with α-diketones to form spirophosphoranes: 1,3,2-dioxaphospholen-spiro-1,3,2-dioxaphospholans[8,35,36], 1,3,2-dioxaphospholen-spiro-1,3,2-diazaphospholans[35,37], and 1,3,2-dioxaphospholen-spiro-1,3,2-dioxaphosphorinanes[36].

On reaction with certain α-dicarbonyl compounds tris(dimethylamino)phosphine gives rise to an equilibrium mixture of a phosphorane and a dipolar ion[9,37,38]:

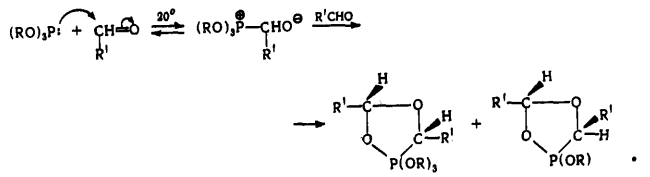


A similar equilibrium has been observed for the phenanthrenequinone–tertiary phosphine adduct[9,39].

The following mechanism has been proposed on the basis of a kinetic study of the reactions of trialkyl phosphites with benzil[40-42] and acyclic[43] and cyclic[21] α-diketones:

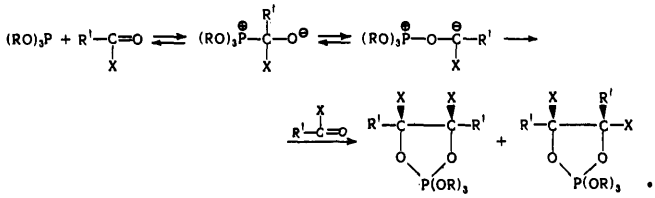


Under mild conditions, aliphatic aldehydes react with trialkyl phosphites to form diastereomeric 1,4,2-dioxaphospholans[44]:

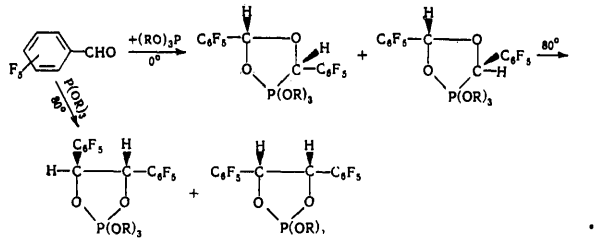


1,4,2-Dioxaphospholans are formed when dimethylketen[45] reacts with esters and ester-amides of tervalent phosphorus.

Aromatic aldehydes and ketones activated by electron-accepting groups[8,32,39,46-55], hexafluoroacetone[28,56,57], fluorenone[58,59], and indantrione[60] react with trialkyl phosphites to form 1,3,2-dioxaphospholans:

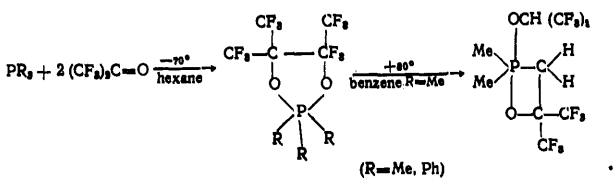


The rearrangement of the adduct with a P–C–O linkage formed initially into one with a P–O–C linkage was demonstrated for pentafluorobenzaldehyde[9,39]:



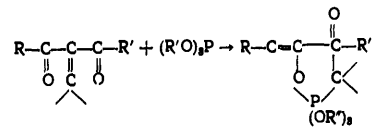
When cyclic phosphites and phosphorous triamides are employed, the products are 1,3,2-dioxaphospholan-spiro-1,3,2-dioxaphospholans[61] and 1,3,2-dioxaphospholan-spiro-1,3,2-diazaphospholans[62,63]. 1,3,2-Dioxaphospholans can also be obtained by the oxyphosphorane condensation of 1,3,2-dioxaphospholens with carbonyl compounds (see the Section on chemical properties).

Aromatic phosphines react with hexafluoroacetone to form 1,3,2-dioxaphospholans[39], while phosphines containing a fairly mobile hydrogen atom in the α-position relative to the phosphorus atom react with hexafluoroacetone to form 1,3,2-dioxaphospholans at −70° and 1,2-oxaphosphetans[64,65] at +80°C (see the Section on the thermal decomposition of phosphoranes):



(R=Me, Ph)

The reactions of trialkyl phosphites with certain $\alpha\beta$-unsaturated carbonyl compounds lead to the formation of 1,2-oxaphospholens; the reactions with methyl vinyl ketone[66], acrolein[67,68], and dibenzylidenecyclohexanone[69,70] take place in this way. Trialkyl phosphites react more readily with $\alpha\beta$-unsaturated carbonyl compounds in which the conjugated system is activated by electron-accepting groups. 1,2-Oxaphospholens have been obtained by the reaction of trialkyl phosphites with alkylidene derivatives of acetylacetone[66,71-73], acetoacetic[72-75] and benzoylacetic[76] esters, benzylidenephenylsulphonylacetophenone[77], and acetyl-*p*-quinone[78]:



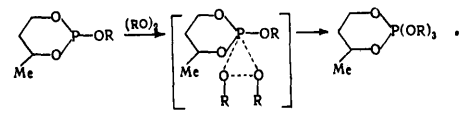
Stable 1,2-oxaphospholens are also obtained when phenylphosphonite and diphenylphosphinite are employed[66,79]. Allenic α-ketones[80] react with phosphites, phosphonites, and phosphinites and the products are also 1,2-oxaphospholens.

The $-N=N-\underset{|}{C}=O$, $-N=\underset{|}{C}-\underset{|}{C}=O$, and $\diagdown C=N-\underset{|}{C}=O$ conjugated systems can be involved in the formation of cyclic phosphoranes: phenylbenzoyldi-imide and azodiformic ester form 1,3,4,2-oxadiazaphospholens[81-83], α-ketoimine gives rise to 1,3,2-oxazaphospholen[84], and 1,1,1,3,3,3-hexafluoro-*N*-acyliminopropane yields 1,4,2-oxazaphospholen[85].

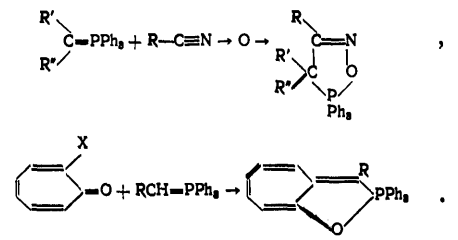
The synthesis of phosphoranes by the reaction of tervalent phosphorus acid derivatives with carbonyl compounds is described in greater detail in the literature[86,87].

2. Other Methods of the Synthesis of Phosphoranes

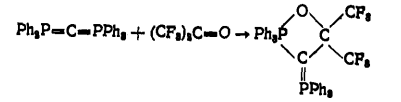
Cyclic phosphoranes of different types can be obtained with the aid of the so called peroxide method. It consists in the treatment of cyclic phosphites[88,89], phosphonites, phosphinites, and amidoesters[90] with alkyl peroxides. The method is general:



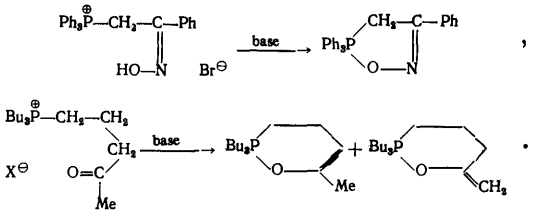
1,3-Dipolar addition to methylenephosphoranes leads to the formation of oxaphospholens. Such reactions take place with nitrones[91,92], nitrile oxides[93-96], epoxides[97], and 2-halogenotropones[98,99]:



In the reaction with phosphorus ylides, hexafluoroacetone yields 1,2-oxaphosphetan[100-103]:

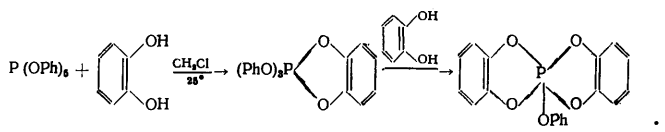


Phosphonium salts containing a hydroxy-group in the γ- or δ-position form phosphoranes on treatment with bases[104-109]:



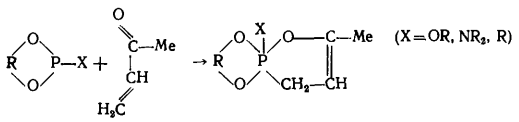
Oxazaphospholens have been obtained by the reaction of trialkyl phosphites with $\alpha\beta$-unsaturated β-nitroacid esters[110] and with 2,6-dimethylaryl 2-nitrophenyl ethers[111].

Cyclic phosphoranes can be obtained by an exchange reaction[112-115] from acyclic phosphoranes and bicyclic phosphoranes can be synthesised from monocyclic phosphoranes (see also the reactions of phosphoranes with glycols):

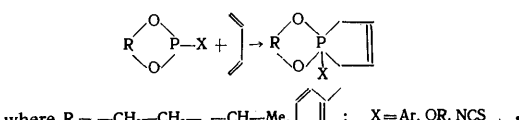


3. Synthesis of Spirophosphoranes and Phosphoranes of the Condensed and Cage Types

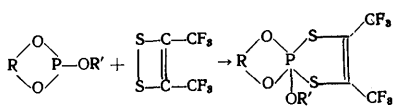
As already mentioned above, spirophosphoranes can be obtained by the interaction of five- and six-membered cyclic phosphites, phosphoramidites, and amides with α-dicarbonyl[8,35-37] and monocarbonyl[61-63] compounds. The reaction of cyclic derivatives of phosphorus(III) with $\alpha\beta$-unsaturated carbonyl compounds takes place similarly[84,116-120]:



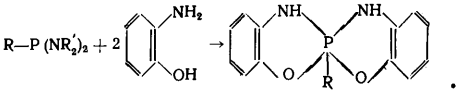
The condensation of the glycol and catechol esters of alkylphosphonous[121] and arylphosphonous acids[122-124] and of the methyl ether and isocyanate of catecholphosphorous [(*OO'*-phenylene)phosphorous] acid[125,126] with 1,3-diene hydrocarbons leads to 1,3,2-dioxaphospholan-spiro-2-phospholens:



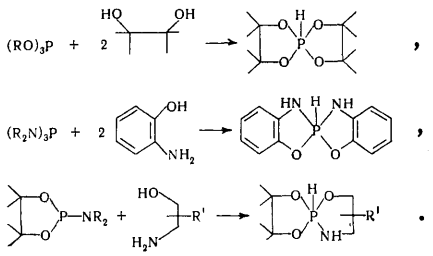
The condensation of cyclic phosphites with 3,4-bis(trifluoromethyl)-1,2-dithietans leads to stable phosphoranes containing sulphur[127]:



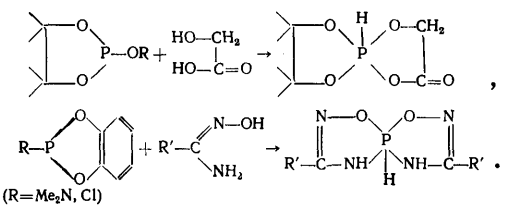
Certain derivatives of tervalent phosphorus form with *o*-aminophenols 1:2 adducts containing a pentacoordinate phosphorus atom[128]:



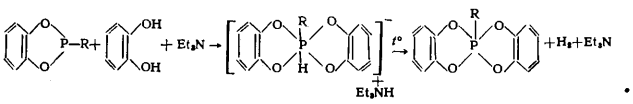
Spirophosphoranes with a P–H bond constitute an interesting group of compounds. They are formed when β-glycols and β-aminoalcohols react with phosphites[129-133] phosphorochloridites[129,134], phosphorus trichloride[129,135,136], tris(dimethylamino)phosphine[135,136,138-142], and cyclic phosphoramidites[143-145]:



Analogous spirophosphoranes are obtained from derivatives of cyclic phosphites and α-hydroxyacids[146] or amidoximes[147-149]:



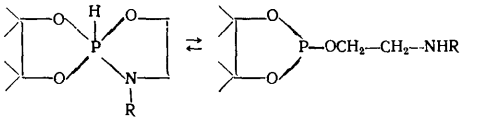
The reactions of cyclic phosphorus(III) derivatives with β-glycols and β-aminoalcohols, leading to the formation of spirophosphoranes, takes place only in a neutral or acid medium. In the presence of amines, ammonium salts with a hexacoordinate phosphorus atom are formed[148,150,151], from which spirophosphoranes can be obtained by treatment with acid or on heating:



A tautomeric phosphite $\rightleftharpoons$ spirophosphorane equilibrium is characteristic[137,152,155,156] of spirophosphoranes with a P–H bond derived from glycols[131,137,152] or aminoalcohols[140,153,154]:

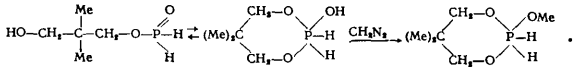
The equilibrium position depends on the temperature and the nature of the substituent in the ring and at the nitrogen atom. When X=Y=O, the equilibrium at room temperature is almost completely displaced towards spirophosphoranes[141,146]. The form with a pentacoordinate phosphorus atom is more characteristic of unsaturated or aromatic systems than of saturated rings or rings with alkyl substituents[154,157]. In asymmetric spirophosphoranes the less substituted ring is opened preferentially[157].

The dependence of the equilibrium position on the substituent at the nitrogen atom can be seen from the following example:

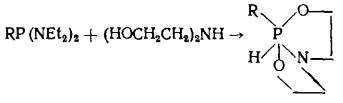


R	H	Me	Et	Ph
Spirophosphorane, %	90	25	3	0

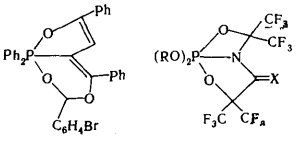
A report has been published[158] on the synthesis of a phosphorane with two P–H bonds:



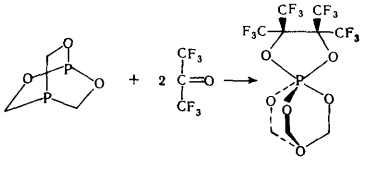
A phosphorane of the condensed type with a P–H bond is formed when aminophosphine reacts with diethanolamine[159]:



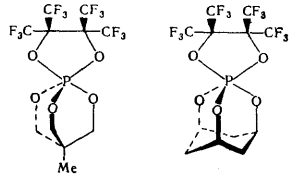
Condensed phosphoranes of the analogous type without P–H bonds have also been described[114,160,161]:



A cage phosphorane[12], which does not react further at the phosphine phosphorus atom, has been obtained by the reaction of a bicyclic phosphite–phosphine with hexafluoroacetone:



Another cage and adamantanoid phosphoranes have been obtained similarly[12,162].



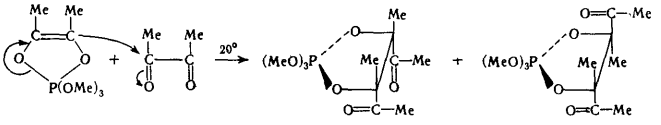
Cage phosphoranes are less stable owing to ring strain and intramolecular twisting in the trigonal bipyramid than the corresponding monocyclic and bicyclic phosphoranes. For this reason the above cage phosphoranes were obtained only with hexafluoroacetone and analogous compounds from, for example, diacetyl could not be synthesised.

III. CHEMICAL PROPERTIES

1. The Oxyphosphorane Condensation

1,3,2-Dioxaphospholens are very reactive. They can condense with carbonyl compounds to form 1,3,2-dioxaphospholans. This new method for the formation of carbon–carbon bonds has been called the oxyphosphorane condensation[7,8,46,163–166].

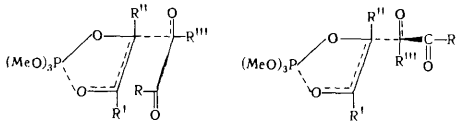
The reaction is nucleophilic addition of the unsaturated carbon atom to the carbonyl group. The condensation can proceed both stereoselectively (with formation of two isomers) and stereospecifically (with formation of one isomer only). For example, 2,2,2-trimethoxy-4,5-dimethyl-1,3,2-dioxaphospholen reacts smoothly with diacetyl to form two diastereomeric 1,3,2-dioxaphospholans[167]:



meso (80%) $\delta^{31}P = +54{,}8$ p.p.m. racemate (20%) $\delta^{31}P = +52{,}8$ p.p.m.

These two forms differ in their ^{31}P and ^{1}H spectra. The nucleus of the phosphorus atom is more effectively screened in the meso-form than in the racemate.

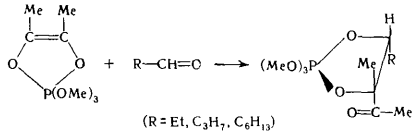
The reaction may proceed[23,168] via the transition states



in which the P–O bond of the phospholen is ruptured and new P–O and C–C bonds of the phospholan are formed.

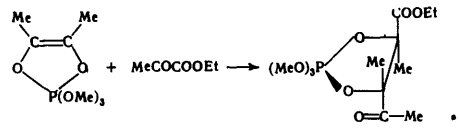
Two factors determine the proportions of the isomers formed: (1) the steric factor, according to which the least bulky groups are closest to one another and (2) the electronic factor associated with the favourable dipole–dipole interaction between the carbonyl groups when these are present.

The following compounds undergo the oxyphosphorane condensation with 1,3,2-dioxaphospholens: benzil, 1-phenylpropanedione (the benzoyl group is attacked exclusively), and phenylglyoxal (the reaction involves the aldehyde group)[168]. Propionaldehyde, butyraldehyde, and heptanal[7] react stereospecifically with formation of only one distereomer, in which the methyl and alkyl groups are in the *trans*-positions relative to one another, i.e. the stereochemistry of the products is determined by steric factors:



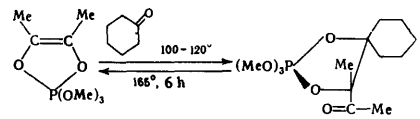
The following compounds undergo condensation with phospholens: benzaldehyde, phthalic and terephthalic aldehydes[169], and others[170,171]. Methyl pyruvate gives rise to two isomers, the product in which the two methyl groups are in the *trans*-positions relative to one another predominating, i.e. the steric repulsion between these two

groups exceeds the dipole–dipole attraction of the acetyl and methoxycarbonyl groups:

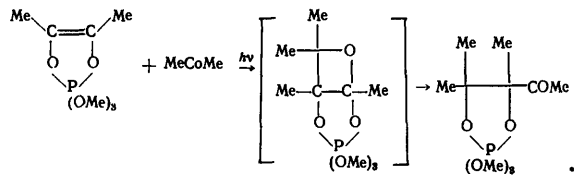


Acenaphthenequinone[7], *p*-benzoquinone[38,172,173], and hexafluoroacetone[174] readily condense with 1,3,2-dioxaphospholens.

Monoketones (cyclobutanone, cyclohexanone, acetophenone, *p*-nitroacetophenone, and $\alpha\alpha\alpha$-trifluoroacetophenone[174]) are less reactive than monoaldehydes and the reaction requires relatively high temperatures (100–120°C), which makes it unsuitable, since under these conditions the thermal decomposition of 1,3,2-dioxaphospholans begins:

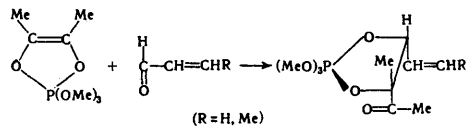


Cyclopentanone, acetone, butanone, 3-hexanone, and benzophenone do not enter into the oxyphosphorane condensation. Acetone can undergo photocondensation[175] with 1,3,2-dioxaphospholens. It has been established[176] that the reaction proceeds via the intermediate formation of oxetans:



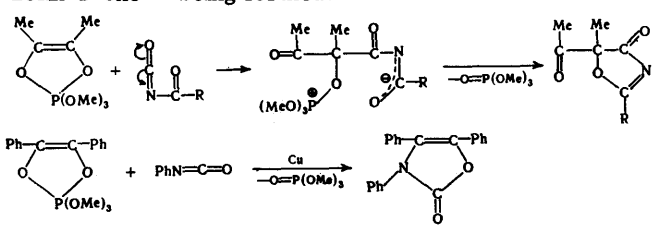
The reactivity of 1,3,2-dioxaphospholens in the oxyphosphorane condensation decreases on passing from dicarbonyl compounds to monoaldehydes and then to ketones. Electron-accepting substituents accelerate this reaction.

$\alpha\beta$-Unsaturated aldehydes[177,178] add to phospholens via the C=O group, and not in the 1,4-positions, with formation of only one stereoisomer:



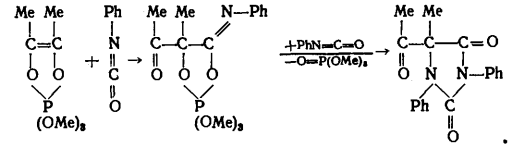
The attempts to condense a phospholen with $\alpha\beta$-unsaturated ketones were unsuccessful.

Systems with cumulative double bonds such as acyl or aryl isocyanates react with phospholenes, a trialkyl phosphate being eliminated and 2-oxazolin-4-one[179] or 4-oxazolin-2-one[180] being formed:

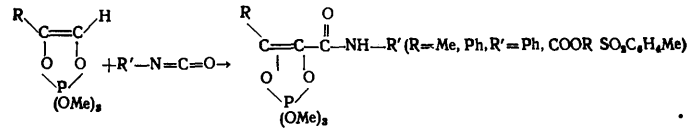


The latter reaction is catalysed by copper and probably proceeds via the intermediate formation of benzoylphenylcarbene, which reacts further with phenyl isocyanate.

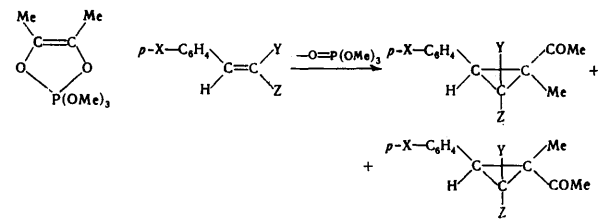
When aryl isocyanate adds to a phospholen without a catalyst, a dioxaphospholan is formed initially and then reacts further with a second molecule of phenyl isocyanate to form a hydantoin derivative[181,182]:



When there is a hydrogen atom at the double bond of the phospholen, the reaction with isocyanates takes place with retention of the phospholen ring[183]:



1,3,2-Dioxaphospholens can condense with olefins containing an electrophilic double bond. The reaction products are substituted cyclopropanes[184,185]:

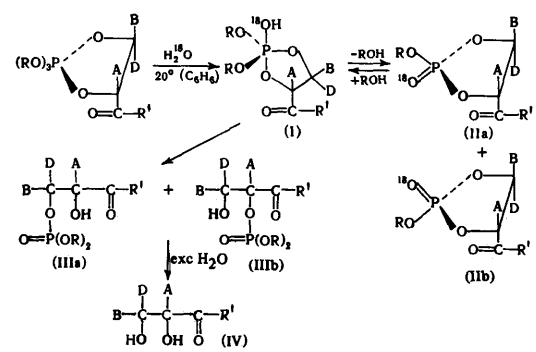


Keten[186] and carbon suboxide[187] react with phospholens at the C=O group. 1,2-Oxaphospholens do not undergo phosphorane condensation with carbonyl compounds[44].

The synthetic possibilities of the oxyphosphorane condensation are very great. Apart from the synthesis of new derivatives with a pentacoordinate phosphorus atom and certain cyclic compounds without a phosphorus atom (as stated above), this reaction leads to a series of new cyclic phosphates, open-chain phosphate esters, and hydroxycarbonyl compounds without phosphorus. All these compounds can be obtained from phosphoranes via hydrolysis.

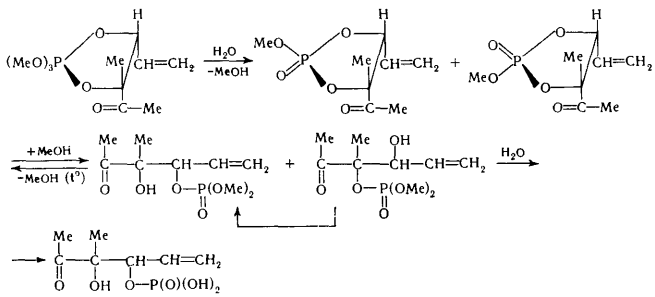
2. Hydrolysis of Phosphoranes

All 1,3,2-dioxaphospholans are extremely sensitive to hydrolysis. There is a possibility of the formation of three types of products: cyclic phosphates, open-chain phosphates, and diols without phosphorus:

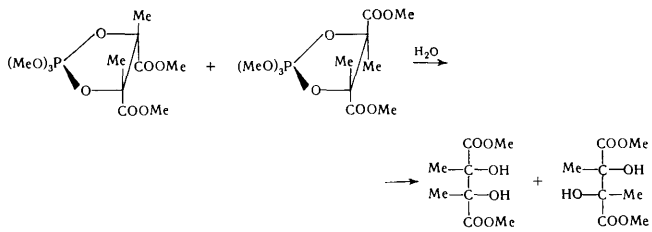


The first stage in the hydrolysis of 1,3,2-dioxaphospholans involves one equivalent of water and the nucleophilic substitution of a methoxy-group by a hydroxy-group[177]. The axial methoxy-group is apparently the first to be exchanged. The intermediate cyclic phosphorane (I) yields the cyclic phosphates (IIa) and (IIb)[165,170,188], which are diastereoisomers at the phosphorus atom. By employing heavy water, it has been shown that ^{18}O enters the phosphoryl group. The methanol formed in the hydrolysis reacts with the cyclic phosphates, yielding the acyclic phosphates (IIIa) and (IIIb) via the same intermediate (I). An excess of water leads to the formation of the corresponding diol (IV)[168,189,190]. The ease of removal of phosphorus from cyclic products depends on the nature of the groups linked to the five-membered ring.

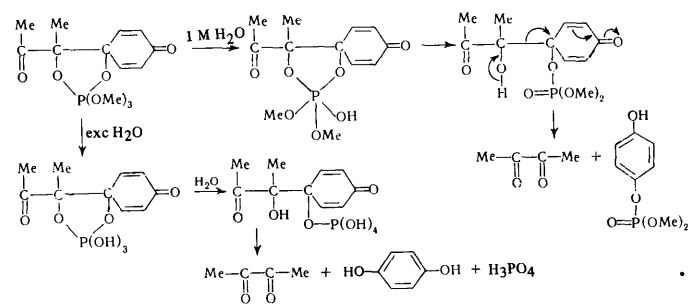
For example, the hydrolysis of 4α-acetyl-2,2,2-trimethoxy-4β-methyl-5α-vinyl-1,3,2-dioxaphospholan[177,178] leads to diastereomeric cyclic phosphates and further to acyclic phosphates. Phosphorus cannot be removed from the molecule even by an excess of water in the presence of an acid: the final hydrolysis product is a phosphate monoester:



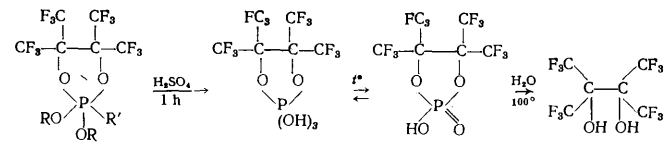
Diastereomeric 1,3,2-dioxaphospholans[46], obtained by the interaction of pyruvate ester with trimethyl phosphite, yield tartaric acid derivatives on hydrolysis[166]:



Thus hydrolysis of 1,3,2-dioxaphospholans makes it possible to obtain various polyhydroxycarbonyl compounds which are difficult to obtain by other procedures. In certain cases the hydrolysis of phospholans results in the cleavage of the C–C bond[172,173]:

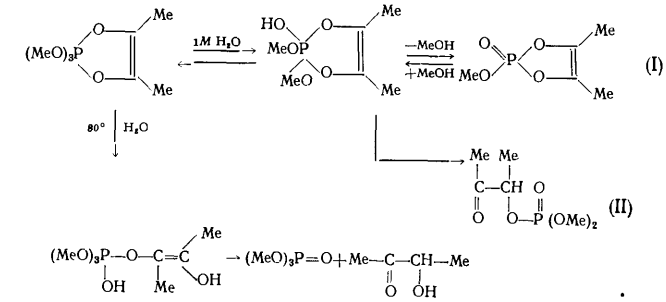


The mechanisms of the hydrolysis by 1 M water and an excess of water are different. The presence in the 1,3,2-dioxaphospholan ring of powerful electron-accepting substituents such as CF_3 makes them chemically inert and their hydrolysis proceeds only when they are acted upon by concentrated sulphuric acid[31,56]:



(R′=OR, NEt_2)

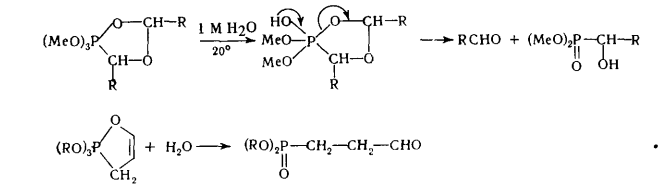
The hydrolysis of 1,3,2-dioxaphospholens proceeds similarly to that of 1,3,2-dioxaphospholans with formation of intermediates of the same type. For example, 2,2,2-trimethoxy-4,5-dimethyl-1,3,2-dioxaphospholen[191] is hydrolysed by one equivalent of water to a cyclic or acyclic phosphate (I or II):



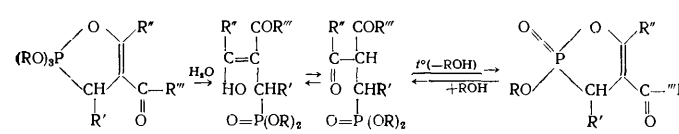
Trimethyl phosphate and acetoin are formed (at 80°C) via a different mechanism, since the phosphates (I) and (II) are not hydrolysed to acetoin under these conditions.

One of the most interesting aspects of the chemistry of cyclic oxyphosphoranes is their hydrolysis and alcoholysis. There is a striking similarity between these reactions and the analogous reactions of cyclic phosphates. The study of the hydrolysis of five-membered cyclic phosphates has shown[192,193] that compounds with a pentacoordinate phosphorus atom are involved in these reactions as intermediates. The hydrolysis of five-membered cyclic dioxyphosphoranes and the hydrolysis and alcoholysis of cyclic phosphates proceed via the formation of the same intermediates.

Phosphoranes containing a P–C bond in the ring are hydrolysed to the corresponding acyclic phosphonates[44,67,68]:

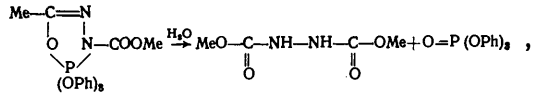


Certain 1,2-oxaphospholens undergo very rapid hydrolysis (sometimes even by atmospheric moisture) with formation of the corresponding ketophosphonates; in certain cases it is possible to isolate the labile enolic phosphonate[44,69,70]. When the products of the hydrolysis of 1,2-oxaphospholens are distilled, the alcohol is split off with formation of a cyclic phosphonate[73–75]:

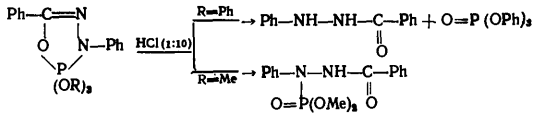


(R=Me, Et; R′, R″=Me, Ph; R‴=Me, OEt)

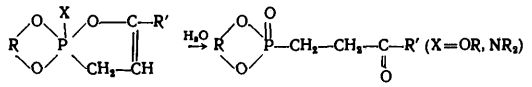
The sensitivity of 1,2-oxaphospholens to hydrolysis can vary within wide limits. While the adduct of triphenyl phosphite with azodiformic ester[83] is more hygroscopic than P_2O_5, the adducts of trialkyl phosphites with phenylbenzoyldi-imide[82,83] are hydrolysed,



only in the presence of hydrochloric acid:



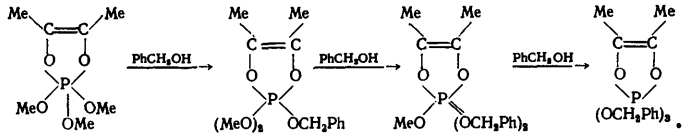
The 1,2-oxaphospholen ring is more sensitive to hydrolysis than the 1,3,2-dioxaphospholan or 1,3,2-dioxaphosphorinane rings. This is clearly seen for spirophosphoranes as an example[116,118]:



When spirophosphoranes obtained by the condensation of cyclic phosphonites with 1,3-dienes are hydrolysed, the ester linkage is broken[123,126].

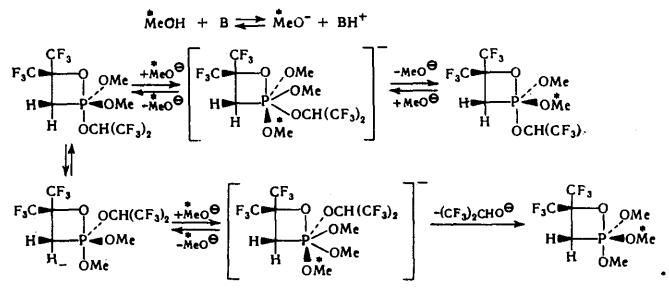
3. Alcoholysis of Phosphoranes

Phosphoranes are capable of undergoing nucleophilic substitution at the pentacoordinate phosphorus atom; the reaction proceeds with the retention of the phospholen ring. It is assumed that in a basic medium the process proceeds via a transition state with a hexacoordinate phosphorus atom[194,195]:



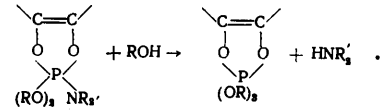
The reaction takes place in steps and the proportions of the products depend on the amount of the initial alcohol and the duration of heating. The rate of substitution depends on the concentration of the base.

The study of this substitution in 1,2-oxaphosphetans showed[115,198] that the nucleophilic RO^- species approaches the phosphorus atom from the equatorial side opposite the equatorial group being removed; the transition state has an octahedral symmetry with a linear distribution of the entering and leaving groups:

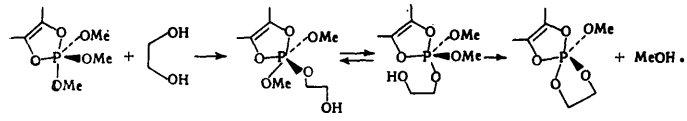


Hexafluoroisopropyl alcohol is more acid than methanol and therefore its anion is more suitable as the leaving group. The relative rates of substitution and of permutational isomerisation[10,12] of phosphoranes (see below) determine the course of this reaction.

When an alcohol is allowed to react with an aminophosphorane, the dialkylamine group is exchanged[30]:

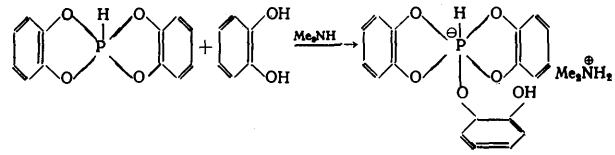


The reaction of ethylene glycol with phosphoranes is exothermic[115]. After the substitution of one equatorial group and subsequent permutation isomerisation, a second equatorial methoxy-group is substituted with formation of a spirophosphorane in which there is an axial-equatorial distribution of the two rings:

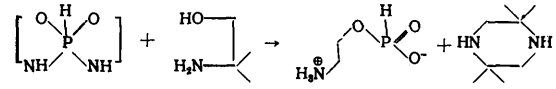


The driving force of this reaction is the appreciable increase of the stability of the resulting spirophosphorane (compared with 1,3,2-oxaphospholen) as a result of the decrease of intramolecular tension, which is smaller in bicyclic phosphoranes.

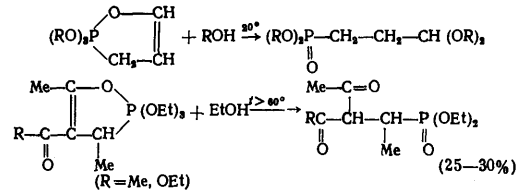
On reaction with β-aminoalcohols or β-glycols in the presence of bases, spirophosphoranes with a P–H bond form compounds with a hexacoordinate phosphorus atom[151]:



Salts of another type can be formed[197]:

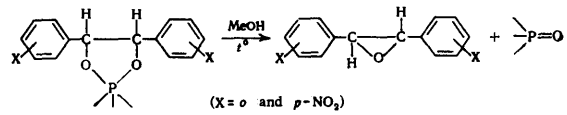


1,2-Oxaphospholen rings are opened by an alcohol[67,68,73]:

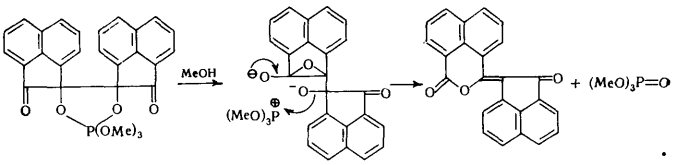


The thermal alcoholysis of 1,3,2-dioxaphospholans leads to the disruption of the phospholan ring. The reactions proceed with the formation of trialkyl phosphates and are frequently accompanied by molecular rearrangements.

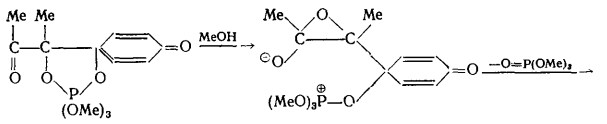
Methanolysis of phosphoranes with two hydrogen atoms and two phenyl groups in the phospholan ring leads to the formation of *trans*-epoxides[63,198]:



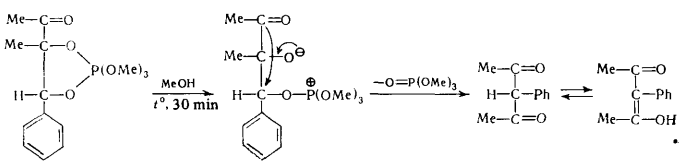
Methanolysis proceeds in a different manner when there are acyl substituents in the phospholan ring[163,164]:



The enol acetate formed on solvolysis can react with the alcohol[172]:



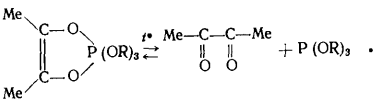
On treatment with hot methanol, 4-acetyl-2,2,2-trimethoxy-4-methyl-5-phenyl-1,3,2-dioxaphospholan loses trimethyl phosphate with a simultaneous skeletal carbon rearrangement, leading to a 1,2-shift of the acetyl group[169]:



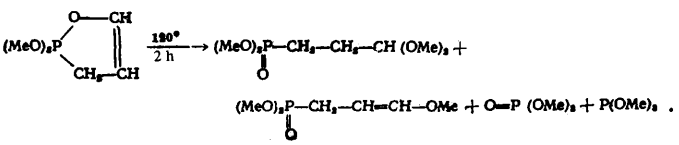
Possibly the high dielectric constant of the solvent (methanol) plays a decisive role in the thermal alcoholysis reactions.

4. Thermal and Photochemical Decomposition of Phosphoranes

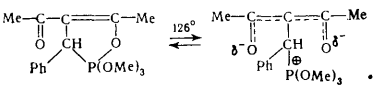
The majority of cyclic phosphoranes are thermally stable up to 100–120°C in an atmosphere of nitrogen[15] and many can be distilled *in vacuo*[5-7]. When certain 1,3,2-dioxaphospholens[14,77,199] and 1,2-oxaphospholens[73] are distilled, their partial dissociation into the initial compounds is observed:



When the simplest 1,2-oxaphospholen is heated, a complex mixture of substances is obtained[68], from which trimethyl phosphite, trimethyl phosphate, the dimethyl acetal of phosphonopropionaldehyde, and a small amount of an enol ether have been isolated; the latter is formed as a result of the thermal decomposition of the acetal[200] during distillation:

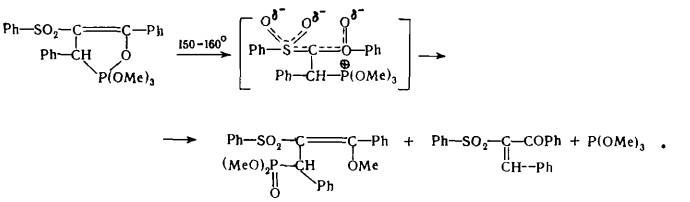


In the course of a study of the stereochemistry of cyclic phosphoranes in solution by ^{1}H NMR it was found[9,11,66] that above 110°C the ring P–O bond in 1,2-oxaphospholens is dissociated. The phosphorane ring is converted into a dipolar ion; the signals of the Me–C= and Me–C(O)– groups in the ^{1}H NMR spectrum merge at 126°C.

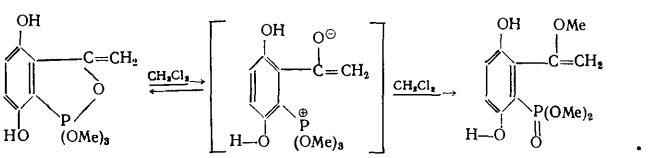


This process is reversible when it occurs below the decomposition and isomerisation temperatures. The temperature at which the Me–C= and Me–C(O)– peaks merge can serve as a measure of the stability of this phospholen system. In the spectrum of the analogous 1,2-oxaphospholen with ethoxy-groups at the phosphorus atom instead of the methoxy-groups the peaks merge at a temperature 15 deg lower. This can serve as an illustration of the importance of steric effects and intramolecular [packing? (Ed. of Translation)] density in the determination of the relative stabilities of compounds with pentacoordinate and tetracoordinate phosphorus. The adduct with EtO groups, which is more sterically strained, is less stable than the MeO adduct.

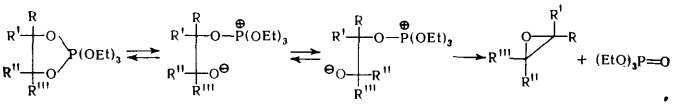
The dissociation of 1,2-oxaphospholen into a dipolar ion has been demonstrated by ^{31}P NMR spectroscopy[77]. The dipolar ion formed isomerises to an enol ether; the reaction is accompanied by the dissociation of the phosphorane (or the dipolar ion) into the initial compounds:



The isomerisation to an enol ether proceeds in the dipolar ion stage, while cyclic phosphoranes do not show a tendency to undergo this reaction; this has been demonstrated in a large number of instances[201]. Cases have been described where phosphoranes in polar solvents are in equilibrium with the dipolar form, the latter undergoing a rapid rearrangement as a result of dealkylation[58,78]:



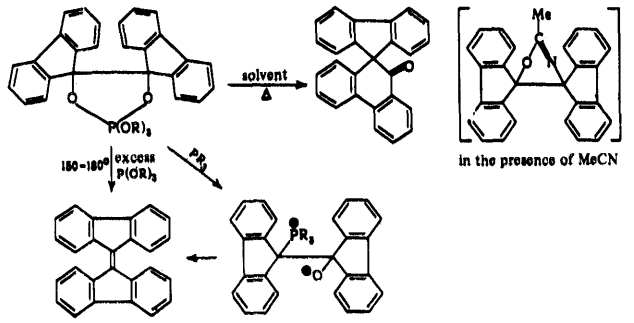
1,3,2-Dioxaphospholans undergo stereospecific thermolysis with formation of *trans*-epoxides. The temperature at which phospholans are decomposed depends on the ring substituents[49,54,89,169]:



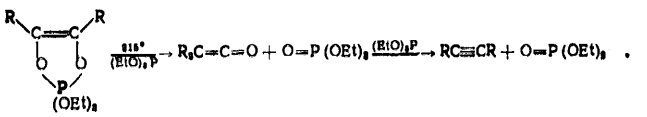
A similar course of the reaction, leading to the formation of epoxides, has been suggested for the highly exothermic interaction of tris(dimethylamino)phosphine with

aromatic aldehydes having electron-accepting substituents [83,203]. Such thermal decomposition of the phosphorane into an epoxide and a phosphate is analogous to the second stage of the Wittig reaction.

The 2 : 1 fluorenone–trialkyl phosphite adducts split off the trialkyl phosphate with a simultaneous rearrangement of the pinacol type on heating in different solvents [58,59,203-206]. The same rearrangement occurs when phospholan is dissolved in anhydrous acetonitrile with formation of an oxazoline in 17% yield [205]. On heating with an excess of the phosphite or phosphine, deoxygenation takes place [206]. The thermal stability of this 1,3,2-dioxaphospholan depends on the nature of the alkoxy-group linked to the phosphorus atom.

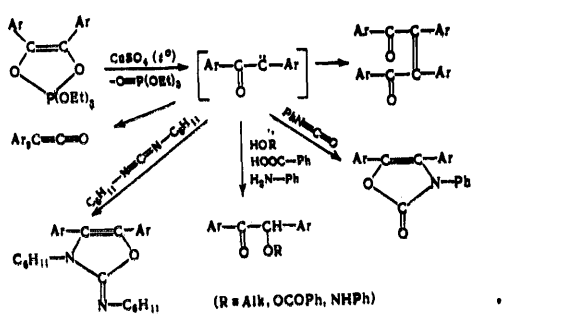


When 1,3,2-dioxaphospholens are heated in the presence of an excess of phosphite, deoxygenation with formation of a trialkyl phosphate and a diaryl- or alkylaryl-acetylene is also observed [207,208]. The intermediate formation of a disubstituted keten in this reaction has been demonstrated:

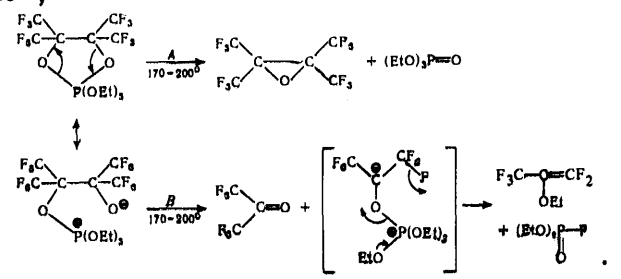


Dialkylacetylenes have not been obtained in the analogous reaction, although the corresponding phosphates are formed.

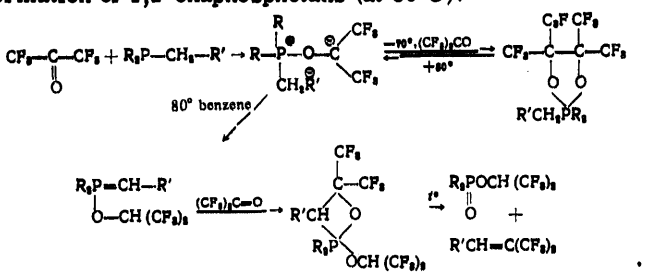
In the presence of copper or its salts 1,3,2-dioxaphospholen is decomposed at a lower temperature. The course of this reaction can be satisfactorily accounted for [180] on the assumption that a carbene is formed initially:



The thermal stability of the 2 : 1 adducts of hexafluoroacetone with various phosphorus(III) derivatives depends on the nature of the groups linked to the phosphorus atom. While 1,3,2-dioxaphospholans having alkoxy-groups at the phosphorus atom decompose at about 170°C into epoxyperfluorotetramethylethane and 2-ethoxyperfluoropropene [57],

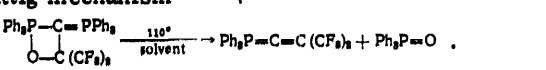


the adducts of hexafluoroacetone with phosphines containing active hydrogen in the α-position relative to the phosphorus atom undergo a rearrangement [64] with the formation of 1,2-oxaphosphetans (at 80°C):

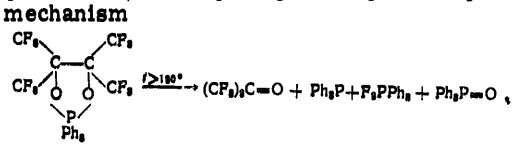


The process includes the cleavage of the 1,3,2-dioxaphospholan formed at a low temperature into a dipolar ion and hexafluoroacetone. The 1,2-oxaphosphetan formed decomposes at a higher temperature into an olefin and phosphinate in accordance with the second stage of the Wittig reaction.

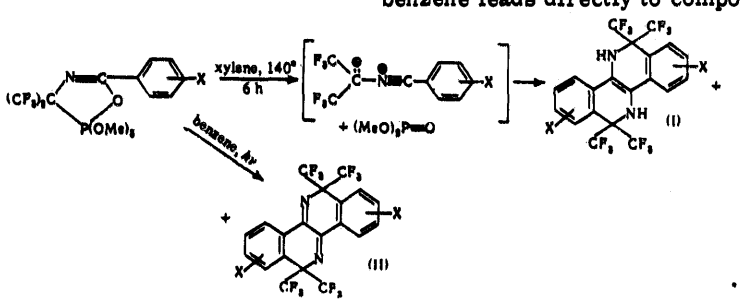
The decomposition of the 1,2-oxaphosphetan proceeds via the Wittig mechanism [101,102]:



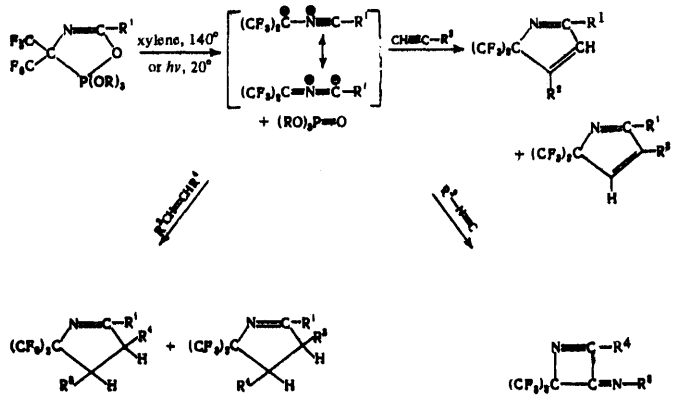
The adduct of hexafluoroacetone and triphenylphosphine is stable up to 120°C, decomposing at a higher temperature via the mechanism



The thermal elimination of phosphate is observed when 1,4,2-oxazaphospholen is refluxed in xylene [209]. The dimer (I) formed under these conditions is readily oxidised to compound (II). Photolysis of the oxazaphospholen in benzene leads directly to compound (II):

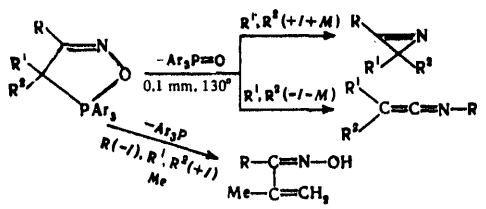


The nitrile imides formed on thermal and photochemical[210] decomposition of 1,4,2-oxazaphospholen can be detected with the aid of dipolarophiles; this results in the formation of products of 3 + 2 and 3 + 1 cycloadditions[210-215]:

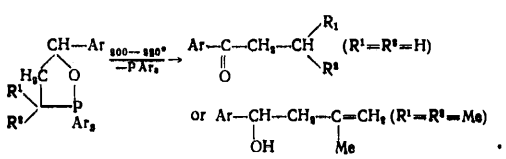


When asymmetric alkenes and alkynes were used, products with both orientations of the dipolarophile relative to the 1,3-dipole were obtained. Interaction with fumarate and maleate esters leads to identical products (epimerisation).

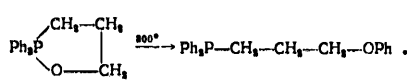
1,5,2-Oxazaphospholens having three phenyl substituents at the phosphorus atom undergo thermal decomposition with formation of either triphenylphosphine or its oxide[95]. The mode of reaction depends on the inductive ($\pm I$) and mesomeric ($\pm M$) effects of the substituents in the phospholen ring[95]:



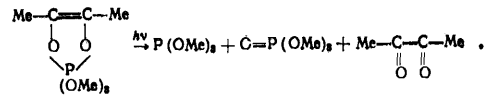
Pyrolysis of certain 1,2-oxaphospholans leads to the elimination of triphenylphosphine[97]:



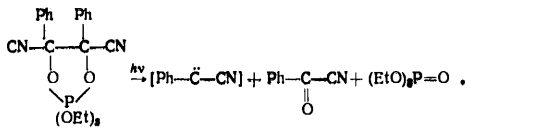
Phospholans of similar structure do not split off triphenylphosphine even at 300°C; a rearrangement, probably via an intramolecular mechanism, to 3-phenoxypropionyldiphenylphosphine takes place on heating[105]:



Photolysis of 1,3,2-dioxaphospholens leads to the formation of a trialkyl phosphite, a trialkyl phosphate, and an α-diketone. The phosphite/phosphate ratio depends on the wavelength of the irradiating light[216]:

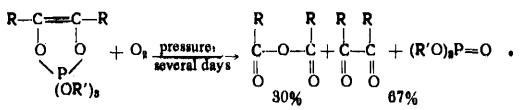


1,3,2-Dioxaphospholans can undergo photocycloelimination[54] (5 → 2 + 2 + 1):

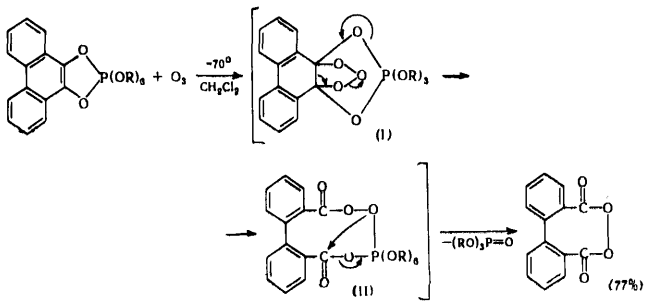


5. Oxidation of 1,3,2-Dioxaphospholens

When acted upon by molecular oxygen, the phospholen ring undergoes a rearrangement of its carbon skeleton with simultaneous dephosphorylation[5,217]:



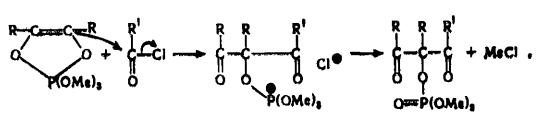
When a phospholen is treated with ozone at a low temperature, peroxide compounds are formed together with phosphates[217,218]:



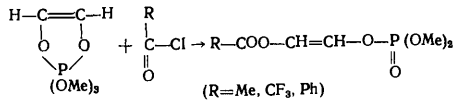
The authors believe that the process proceeds via the intermediate formation of an ozonide (I), which subsequently rearranges to the product (II); the latter splits off phosphate with formation of a peroxide.

6. Interaction of Phosphoranes with Electrophilic Reagents

The interaction of 1,3,2-dioxaphospholens with electrophilic reagents is one of the reactions leading to the opening of the phosphorane ring. The interaction of phospholens with carboxylic acid chlorides[189] can yield polyfunctional carbonyl-containing phosphates, which are of biological interest. Various α-hydroxy-β-dicarbonyl compounds can be obtained by the hydrolysis of the phosphates formed; this is the reason for the synthetic possibilities of the reaction:

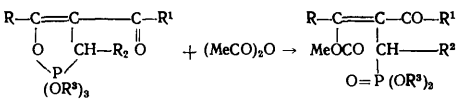


While phospholens with alkyl substituents at the unsaturated carbon atoms undergo *C*-acylation, phospholens with a labile hydrogen atom undergo *O*-acylation[219]:

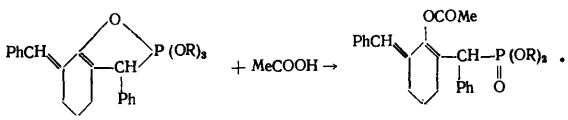


(R=Me, CF_3, Ph)

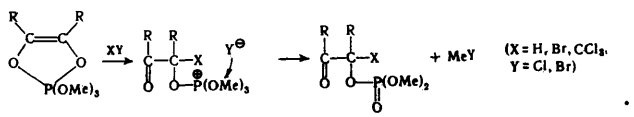
O-Acylation products are obtained when carboxylic acid anhydrides interact with 1,3,2-dioxaphospholens[220] and 1,2-oxaphospholens[68-70,73-76,118]:



The formation of an enol acetate when a 1,2-oxaphospholen was acted upon by acetic acid was noted in one instance[69,70]:

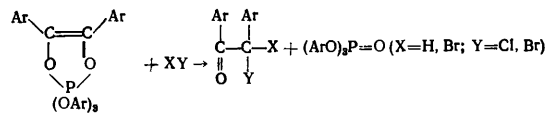


1,3,2-Dioxaphospholens interact with dry HCl,[6,26,186,219] with bromine[6,186,221], and with $CBrCl_3$ (photolysis in the presence of $CBrCl_3$).[222] Under these conditions, phosphates are formed when there are alkoxy-groups attached to the phosphorus atom:

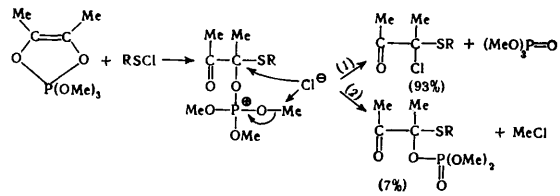


(X = H, Br, CCl_3, Y = Cl, Br)

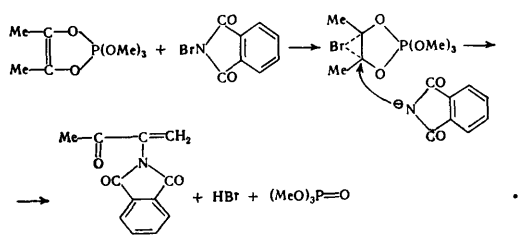
When phenoxy-groups, which are incapable of forming ArY are attached to the phosphorus atom, the intermediate phosphonium product decomposes with elimination of triphenyl phosphate:



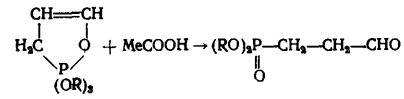
The interaction of phospholens with sulphenyl chloride takes place similarly[223-225], but the authors believe that an anionic attack is more likely:



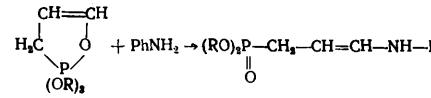
When 1,3,2-dioxaphospholen reacts with *N*-bromophthalimide, trimethyl phosphate is also split off[226]:



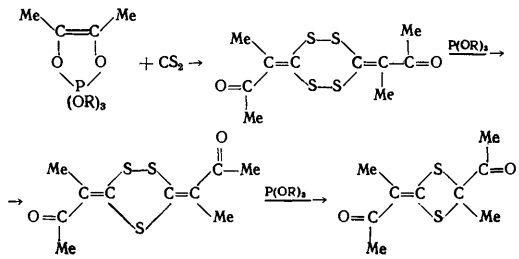
The interaction of certain 1,2-oxaphospholens with acetic acid has been investigated[68,77]:



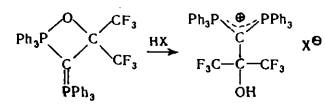
as well as the interaction with aniline[227]:



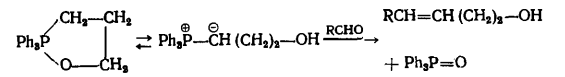
The phospholen ring is disrupted when acted upon by carbon disulphide[228]. The sulphur can be removed from the resulting tetrathi-ine by an excess of phosphite:



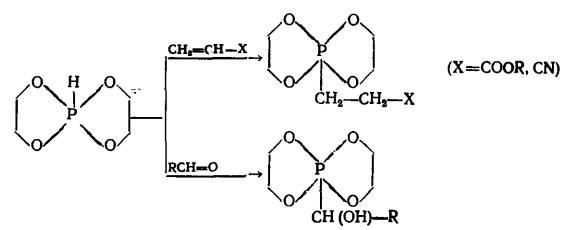
Phosphoranes with three phenyl substituents at the phosphorus atom differ in their chemical properties from phosphoranes with alkoxy-groups. For example, on interaction with HX, 1,2-oxaphosphetans give rise to salts[101]:



1,2-Oxaphospholans can react as ylides with aldehydes, yielding γδ-unsaturated alcohols[229]:

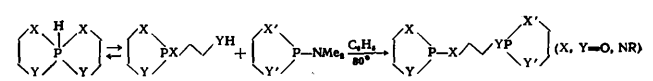


Spirophosphoranes with a P–H bond add to electrophilic multiple bonds[230] and interact with aldehydes[231] like dialkylphosphorous acids:



(X=COOR, CN)

The chemical properties of spirophosphoranes containing a P–H bond are in many ways determined by the phosphorane ⇌ phosphite equilibrium. Intermolecular isomerisation takes place when asymmetric phosphoranes are heated[131,132,143]. The formation of a diphosphite in the subsequent reaction constitutes chemical proof of the existence of the phosphite ⇌ phosphorane equilibrium[232]:



(X, Y=O, NR)

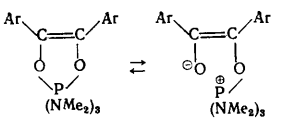
IV. PHYSICAL PROPERTIES. STEREOCHEMISTRY OF PENTACOORDINATE PHOSPHORUS COMPOUNDS

All the physicochemical studies on phosphoranes were undertaken to establish their structures and stereochemistry. Cyclic phosphoranes are ideal systems for the investigation of the stereochemistry of pentacoordinate phosphoranes. The problem of valence in compounds for which a phosphorane structure is proposed can be solved by combination of X-ray diffraction, ^{1}H and ^{31}P NMR, and infrared spectroscopic methods.

1. ^{31}P NMR Spectra

The principal argument in support of the pentacovalence of phosphorus is the high positive chemical shift ($\delta^{31}P$) of these compounds in ^{31}P NMR spectra relative to 85% orthophosphoric acid[7,15]. This implies that the phosphorus nucleus in phosphoranes is more screened than in the standard. In compounds with a dipolar structure and a positive charge on the phosphorus nucleus the phosphorus atom is highly descreened and $\delta^{31}P$ has a high negative value[233]. In those cases where phosphorane $\rightleftharpoons$ dipolar ion equilibrium obtains $\delta^{31}P$ has an intermediate value, since the equilibrium is attained rapidly relative to the NMR time scale. In such cases $\delta^{31}P$ depends on the polarity of the solvent: in non-polar solvents the equilibrium is displaced towards the phosphorane structure and $\delta^{31}P$ becomes more positive; in polar solvents the equilibrium is displaced towards the dipolar form and the chemical shift is displaced towards lower fields.

The benzil–tris(dimethylamino)phosphine adduct has been isolated in two crystalline forms[9,37,38], one of which corresponded to a phosphorane and the other to a dipolar ion. In solution the two forms exist in equilibrium:



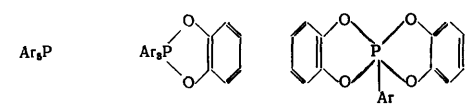
$\delta^{31}P$ = + 29.9 p.p.m. (1 M in hexane)
+13.1 p.p.m. (1 M in CH_2Cl_2)

A similar dependence of $\delta^{31}P$ on the solvent has been noted for adducts of phenanthrenequinone with diethylphenylphosphine and ethyldiphenylphosphine[9,39].

The ^{31}P NMR spectra of phosphoranes have fine structure owing to the interaction of phosphorus with adjacent protons: $^{3}J_{P\text{-}O\text{-}C\text{-}H} \simeq 10\text{–}13$ Hz and $^{2}J_{P\text{-}C\text{-}H} \simeq 20\text{–}24$ Hz.

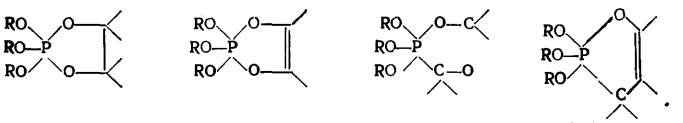
Most of the cyclic oxyphosphoranes have $\delta^{31}P$ in the range +50 ± 30 p.p.m. The dependence of this quantity on the structure of the ring and on the electronegativity of the substituents is not very pronounced. As a rule, the replacement of methoxy-groups at the phosphorus atoms by phenoxy-groups greatly increases $\delta^{31}P$.[36,83]

On passing from acyclic phosphoranes to monocyclic and bicyclic phosphoranes, $\delta^{31}P$ falls[9]:



+ 85.6 p.p.m. + 60.8 p.p.m. + 29.8 p.p.m.

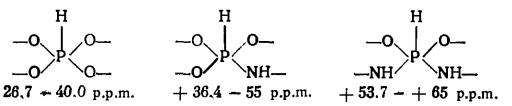
2,2,2-Trialkoxy-1,3,2-dioxaphospholans have $\delta^{31}P$ ranging from +44 to +62 p.p.m.[23] The replacement of one P–O bond in the phosphorane ring by P–C decreases $\delta^{31}P$.



+ 54.8 p.p.m. + 48.9 p.p.m. + 34.1 p.p.m. + 27.8 p.p.m.

The introduction of a second 1,3,2-dioxaphospholen or a 1,3,2-dioxaphospholan ring reduces $\delta^{31}P$, while the introduction of the 1,3,2-dioxaphosphorinane ring does not appreciably alter the chemical shift. The substitution of an endocyclic oxygen atom by nitrogen leads to a slight increase of $\delta^{31}P$ (about 5 p.p.m.), while the replacement of an exocyclic oxygen atom by nitrogen reduces $\delta^{31}P$ by 2–4 p.p.m.[36]

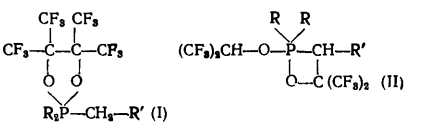
The majority of spirophosphoranes with a P–H bond have $\delta^{31}P$ = +26 – +55 p.p.m.; the values of $\delta^{31}P$ increase when O in the ring is replaced by N:



+ 26.7 – 40.0 p.p.m. + 36.4 – 55 p.p.m. + 53.7 – + 65 p.p.m.

If the molecule contains phenyl substituents, $\delta^{31}P$ decrease. In certain spirophosphoranes containing substituted nitrogen in the ring $\delta^{31}P$ may be between +60 and +100 p.p.m.[143,156] The differences between the chemical shifts of diastereomers are between 1 and 5 p.p.m.[7]

A high positive value of $\delta^{31}P$ constitutes important but not unique evidence of the pentacovalence of phosphorus in cyclic phosphoranes. The chemical shifts of certain phosphoranes are negative. For example $\delta^{31}P$ of 1,3,2-dioxaphospholans obtained by the condensation of hexafluoroacetone with tertiary phosphines[10,11,39,64] vary from −11.7 p.p.m. (for R = Et) to +53.2 p.p.m. (for R = OEt).



Chemical shifts for the phosphorus nucleus in 1,3,2-dioxaphospholans (I) and 1,2-oxaphosphetans (II).

R	$\delta^{31}P$ R_3P	$\delta^{31}P$ (I)	$\delta^{31}P$ (II)	R	$\delta^{31}P$ R_3P	$\delta^{31}P$(I)	$\delta^{31}P$ (II)
Me	+62	+3.2	+23.7	Ph	+5.7	+21.6	—
Et	+19.1	−11.7	+15.7	OEt	−138.5	+53.2	—
n-Bu	+32.6	−7.3	+17.2	OMe	−140.0	+50.1	—

The following observation has been made (see Table): if the signal of the initial phosphorus(III) compound is in the high field region, then $\delta^{31}P$ for the 1,3,2-dioxaphospholan (I) obtained from it is displaced towards lower fields and conversely[11]. In 1,2-oxaphosphetans (II) $\delta^{31}P$ are more positive than in the corresponding 1,3,2-dioxaphospholans (I). Low values of $\delta^{31}P$ have been reported for

certain spirophosphoranes obtained by the condensation of cyclic derivatives of tervalent phosphorus with acrolein[118] (+2 p.p.m.), methyl vinyl ketone[119] (+0.62 p.p.m.), and 3,4-bis(trifluoromethyl)-1,2-dithietan[127] (between −16.5 and −17.5 p.p.m.).

2. Infrared, Raman, and Ultraviolet Spectra

A characteristic feature of compounds with pentacoordinate phosphorus atom is a shift of the stretching vibration band of the P–O–R group towards higher wavenumbers (1090–1075 cm^{-1})[15] compared with the analogous band in compounds with a tetracoordinate phosphorus atom. In the spectra of phosphoranes with aryloxy-groups at the phosphorus atom the P–O–Ar stretching vibration bands are at 1215–1200 cm^{-1}.

The position of the olefin band in the spectra of phospholens depends strongly on the substituents at the double bond and varies from 1664–1645 cm^{-1} [23,27] to 1740 cm^{-1}.[15] In controversial cases the problem of whether or not the band belongs to the stretching vibrations of the double bond can be solved by Raman spectroscopy[15,73]. If a carbonyl group is present in the α-position relative to the double bond in phospholens, there is an interaction between the vibrations and the wave-numbers ν(C=O) and ν(C=C) are markedly distorted[71]. The infrared and Raman spectra indicate the presence of two forms of such phospholens with different mutual orientations of the  and C=O groups[73].

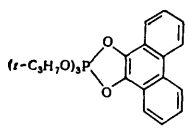
Spirophosphoranes with a P–H bond have a broad band at 2380 ± 30 cm^{-1}.[141,234,235]

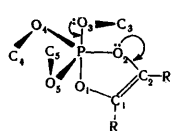
The ultraviolet spectra of 1,3,2-dioxaphospholens[23] and 1,2-oxaphospholens[73,74,76] with a carbonyl or alkoxycarbonyl group in the α-position relative to the double bond are characterised by an intense absorption over a broad section of the spectrum from 220 to 340 nm. The positions of the maxima depend on the substituent in the phospholen ring.

The dipole moments of oxaphospholens are 2–4 D.[6,14,67] The atomic refraction of the phosphorus in phospholen is 3.95.[236]

3. X-Ray Diffraction Analysis

The X-ray diffraction analysis of the two allotropic forms of the 1,3,2-dioxaphospholen obtained by the interaction of phenanthrenequinone with tri-isopropyl phosphite showed that the molecule has a slightly distorted trigonal bipyramidal structure with an axial-equatorial placement of the 1,3,2-dioxaphospholen ring[25,65,160,237,238]. The axial P–O bonds in the ring are longer by 0.1 Å than the equatorial P–O bonds. The exocyclic P–O bonds are somewhat shorter than the endocyclic bonds. This is related to the more intense $p_\pi - d_\pi$ interaction of phosphorus with the exocyclic oxygen atoms. The axial P–O bonds are weaker and more polarisable than the equatorial bonds and are therefore preferred by electronegative substituents.



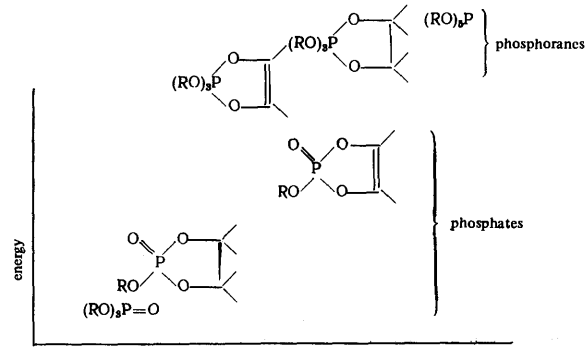


Certain bond lengths and angles in the phenanthrenequinone–tri-isopropyl phosphite adduct[9,11].

Bond length, Å		Angle in degrees			
$P-O_1$	1.753	O_1-P-O_2	89.3	$P-O_1-C_1$	111.9
$P-O_2$	1.649	O_2-P-O_3	88.6	$P-O_2-C_2$	114.2
$P-O_3$	1.641	O_3-P-O_4	91.3	$P-O_3-C_3$	121.8
$P-O_4$	1.601	O_4-P-O_5	93.1	$P-O_4-C_4$	129.8
$P-O_5$	1.586	O_5-P-O_1	117.2	$P-O_5-C_5$	127.5
O_1-C_1	1.347	O_4-P-O_1	117.2		
O_2-C_2	1.433	O_3-P-O_2	125.5		
C_1-C_2	1.333	$O_1-C_1-C_2$	113.9		
O_3-C_3	1.463	$O_2-C_2-C_1$	110.3		

The fact that α-dicarbonyl compounds form 1,3,2-dioxaphospholens with trialkyl phosphites but not with tris(dimethylamino)phosphine can be accounted for by the lower electronegativity of nitrogen (less favourable for the axial position) and the more stringent steric requirements of the dimethylamino-group compared with alkoxy-groups.

The O–P–O and P–O–C angles are capable of undergoing considerable distortion. The trigonal bipyramid is very tightly packed owing to the very short distances between certain non-bonded atoms (down to 2.63 Å). The contraction of the trigonal bipyramid can explain the higher stability of five-membered cyclic phosphoranes compared with acyclic phosphoranes, in contrast to the higher stability of acyclic phosphates compared with five-membered cyclic phosphates, although on the whole phosphoranes have a higher energy than the corresponding phosphates. This is clearly illustrated in the figure below[9,11].



This phenomenon plays a major role in the chemistry of biologically active compounds. Nucleophilic reagents (water, alcohol) add to the P=O group of five-membered cyclic phosphates (but not acyclic phosphates) with formation of intermediate unstable compounds containing a pentacoordinate phosphorus atom[177,178,188,191,192,239–245].

The existence of stable oxyphosphoranes supports the hypothesis that metastable oxyphosphoranes are intermediates in the reaction of tetracoordinate phosphorus[246]. The entering and leaving groups are then located in the axial positions.

4. Permutational Isomerisation

The ligands in the trigonal bipyramid can undergo intramolecular shifts (permutational isomerisation) more or less readily, which occur either via bond deformation (regular process) or via bond dissociation and recombination (irregular process)[162,247].

As a result of permutational isomerisation, the groups occupying the axial and equatorial positions change places, which leads to the formation of a new bipyramid. If all the five groups linked to the phosphorus atom are different, we have twenty chiral isomers, i.e. ten pairs of enantiomers in relation to the configuration at the phosphorus atom. If two ligands are equivalent, the number of isomers decreases to ten, namely six chiral and four achiral isomers. If three ligands are equivalent, we have four achiral isomers.

However, virtually all the ligands linked to the phosphorus atom occupy a definite position in the trigonal bipyramid, which is determined by the electronegativity, steric requirements, and the involvement of the *d* orbitals of phosphorus in the formation of the bonds. All this can be expressed in terms of the general polarity rule[162,247-250].

If any one group cannot occupy an axial position owing to steric or electronic factors, the number of isomers is reduced to twelve. A similar situation obtains if the substituent cannot occupy an equatorial position. Four- and five-membered rings occupy an axial-equatorial position in the trigonal bipyramid[9,25,65,160], while both axial-equatorial and diequatorial positions are possible for a six-membered ring.

Regular permutational isomerisation of acyclic phosphoranes can occur via six different mechanisms[250,251]. It has been shown theoretically[252] and by calculations based on infrared and Raman spectra[253] that the Berry pseudorotation mechanism is the most probable[254]. In a pseudorotation two pairs of axial and equatorial ligands change places via an intermolecular process consisting of the bending of the bonds with deformation of the angles at the central atom. This mechanism is consistent with the experimental data and has undoubted advantages over other mechanisms proposed as alternatives (pseudorotation is discussed in Refs. 248, 253, and 255).

In order to account for permutational isomerisation in cage phosphoranes, a new process called turnstile rotation has been proposed[256]. In turnstile rotation one axial and one equatorial ligand constitute a "pair" and the remaining ligands constitute a "trio". The process consists of a slight deformation of angles at the central atom and in the rotation of the "pair" in relation to the "trio" in opposite directions. On rotation by 60°, a single turnstile rotation (TR) is executed; it can be continued for a further 60° whereupon double turnstile rotation $(TR)^2$ takes place, etc. Ramirez and coworkers[13,246] give preference to this mechanism in the interpretation of the permutational isomerisation of all cyclic phosphoranes.

In turnstile rotation four- and five-membered rings play only the role of the "pair", the remaining ligands playing the role of the "trio", while six-membered rings can play the role of both the "pair" and the "trio". (Turnstile rotation is considered in greater detail in the literature[12,162,247].)

In both pseudorotation and turnstile rotation the axial and equatorial ligands are exchanged in pairs with retention of the position of the third. In turnstile rotation the ligand whose position is retained always forms part of the "trio". For each pseudorotation, there are four equivalent turnstile rotations. However, there are fundamental differences between these mechanisms. Only in turnstile rotation are all the ligands involved in internal motion about the axis passing through the central atom. The geometries, skeletal symmetries, and potential energies of these processes are different[162].

There is no unanimous view in the literature concerning the mechanism of permutational isomerisation in phosphoranes in general and in cyclic phosphoranes in particular. The pseudorotation and turnstile rotation mechanisms must be regarded as the most probable. It is impossible to give preference[257] to either on the basis of experimental data.

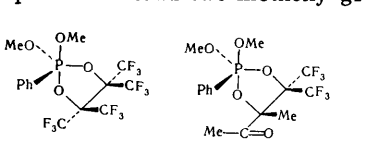
Both these processes presuppose a unimolecular mechanism. A bimolecular process including the formation of either the phosphorane dimer or a complex of the phosphorane with the solvent as the transition state or a metastable excited state has been proposed recently[258] for compounds of the type RPF_4.

5. ^{1}H NMR Spectra. Stereochemistry of Cyclic Phosphoranes

Much information about the structures of phosphoranes and their stereochemistry has been obtained from ^{1}H NMR spectra. The ^{1}H NMR spectra of many 2,2,2-trimethoxy-1,3,2-dioxaphospholens, investigated in the temperature range from +30° to −60°C, contain only one doublet due to the methoxy-groups linked to the phosphorus atoms with $^3J_{P\text{-}O\text{-}C\text{-}H} \simeq 10\text{–}13$ Hz. These results show that the methoxy-groups in the axial and equatorial positions change places, i.e. they are equivalent relative to the NMR time scale. This exchange of ligand positions cannot be inhibited even at fairly low temperatures (−90°C)[7-9,79].

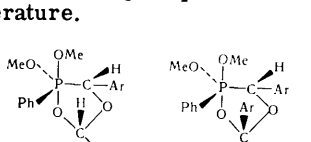
When there are different substituents at the phosphorus atom, the exchange of ligand position is retarded at a higher temperature, as demonstrated by ^{19}F NMR.[259]

A similar phenomenon occurs in 2,2,2-trimethoxy-1,3,2-dioxaphospholans, which give rise to only one doublet due to the methoxy-groups in the ^{1}H NMR spectra at all the temperatures investigated, regardless of molecular symmetry. When there are two methoxy-groups at the phosphorus atom, the ^{1}H NMR spectrum of the phospholan shows a single methoxy-group doublet, provided that the phospholan ring (but not the molecule as a whole) has a plane of symmetry. If there is no plane of symmetry, the ^{1}H NMR spectrum shows two methoxy-group doublets[11]:



one MeO group doublet — two MeO group doublets

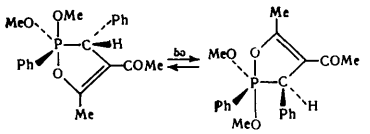
The exchange of ligand positions in 2,2,2-trimethoxy-1,4,2-dioxaphospholans is inhibited at −140°C. At this temperature three methoxy-group doublets appear in the ^{1}H NMR spectrum: the equatorial groups give rise to signals in a lower magnetic field than the axial groups; the $^3J_{PH}$ are higher for the equatorial groups than for the axial groups[44,260]. The *cis*-H/H isomers of 1,4,2-dioxaphospholans with two methoxy-groups at the phosphorus atom are "frozen" at a higher temperature (−42°C), while in the *trans*-H/H isomer the "freezing" occurs at −90°C,[10,11] i.e. the *cis*-isomer is more "rigid" in the sense that the exchange of ligand positions in it is inhibited at a higher temperature.



cis-H/H — *trans*-H/H

The ^{1}H NMR spectra of the diastereomeric 1,3,2-dioxaphospholans and 1,4,2-dioxaphospholans do not differ only in the region of the methoxy-groups. When the molecule contains phenyl substituents, the hydrogen or the methyl group in the *cis*-position relative to such a substituent absorbs in higher fields than the same groups in the *trans*-position[11,51,63,174].

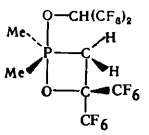
1,2-Oxaphospholens are frozen at −65°C[9-11,66,79,261,262]. 1,2-Oxaphospholens with two methoxy groups at the phosphorus atom exist in solution in the form of two diastereomers. They have different δ^{31}P values in solution at +30°C and for this reason do not undergo stereomutation under these conditions. Each of the two forms has two methoxy-group signals.



$\delta^{31}P = +16.7$ p.p.m. $\delta^{31}P = +13.3$ p.p.m.

The analogous 1,2-oxaphospholen with two phenyl groups at the phosphorus atom is "frozen" at +25°C. It exists in only one configuration[79].

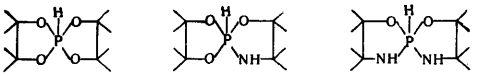
The relative rigidity of the 1,2-oxaphosphetan system was demonstrated by the fact that the ^{1}H NMR spectrum of this phosphorane does not change in the temperature range from −60° to +80°C.[10,39,64]



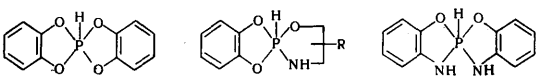
The isomer illustrated here is most stable, i.e. here the two oxygen atoms occupy the axial positions. The ^{19}F and ^{1}H NMR spectra are consistent with this structure: there is a singlet with $\delta^{19}F = +0.4$ p.p.m. relative to CF_3COOH and a doublet with $\delta^{19}F = -3.9$ p.p.m. and $I_{HF} = 5.8$ Hz. The two equatorial methyl groups give rise to a doublet with $\delta = 1.98$ p.p.m. and $^2J_{PH} = 15$ Hz and the protons of the phosphetan ring give rise to a doublet with $\delta = 4.04$ p.p.m. and $^2J_{PH} = 20.7$ Hz.

Spirophosphoranes obey the same rules as other cyclic phosphoranes. The rings assume the axial-equatorial position in the trigonal bipyramid[144,234]. Depending on the ring substituents, there are different numbers of diastereomers[153]. The diastereomers differ in their ^{31}P and ^{1}H NMR spectra at room temperature. At elevated temperatures the rate of interconversion of the diastereomeric forms increases and they cannot be distinguished on the basis of their NMR spectra[157]. The situation simplifies when there is nitrogen in the ring, since the more electronegative oxygen always occupies the axial position. Such molecules are "frozen" even at room temperature[234]. Spirophosphoranes with four oxygen atoms in the ring undergo permutational isomerisation even at −70°C.[263]

The ^{1}H NMR spectra of all spirophosphoranes with a P–H bond show the chemical shift of the P–H proton in the region 6.5–8.5 p.p.m. When the ring oxygen is replaced by the less electronegative nitrogen, the δH shift to higher fields; the position is reversed when there are benzene rings in the molecule[141,143,144,234,264]. J_{PH} increases when the ring is condensed with an aromatic nucleus[235]:



δ_H 7.1-6.8 p.p.m. 7.13-6.66 p.p.m. 6.76-6.4 p.p.m.
I_{PH} 830-802 Hz 800-760 Hz 770-730 Hz



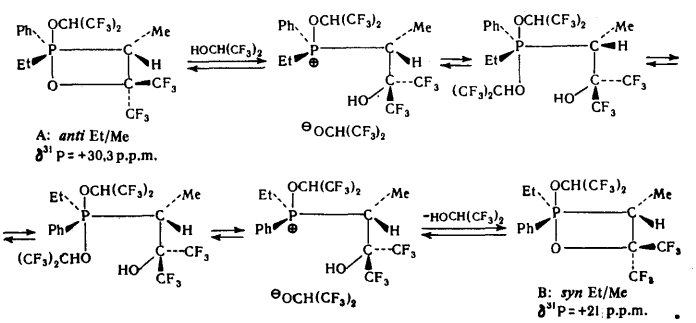
δ_H 8.6 p.p.m. 7.73-7.91 p.p.m. 8.62 p.p.m.
I_{PH} 918 Hz 826-839 Hz 835 Hz

It decreases when oxygen in the ring is replaced by nitrogen. The substitution of H at the nitrogen atom by Me increases I_{PH} and shifts δH to lower fields[154].

6. Irregular Permutational Isomerisation

The base-catalysed irregular permutational isomerisation of oxyphosphoranes can proceed via the intermediate formation of compounds with a hexacoordinate phosphorus atom (see the alcoholysis of phosphoranes described above). An acid-catalysed irregular permutational isomerisation process[12,162,247], proceeding via the formation of a tetracoordinate intermediate, was discovered recently.

The 1,2-Oxaphosphetans A and B are diastereomers differing in the configuration at the phosphorus atom. They are stable in the absence of moisture and are not interconverted at a temperature below that of the Wittig reaction. Their interconversion via the regular process is forbidden, since it requires either the placement of the four-membered ring in the diequatorial position or the location of the P–C bond in the axial position. In the presence of hexafluoroisopropyl alcohol as the catalyst they undergo stereomutation, which proceeds via an irregular process associated with ring opening.



A: *anti* Et/Me
$\delta^{31}P = +30,3$ p.p.m.

B: *syn* Et/Me
$\delta^{31}P = +21$ p.p.m.

The following general rules can be formulated on the basis of the stereochemical study of cyclic oxyphosphoranes: (1) the more electronegative substituents occupy axial positions in the trigonal bipyramid; (2) four- and five-membered rings occupy the axial-equatorial position.

When these requirements are met, phosphoranes are obtained in which there is fairly rapid exchange of ligand positions, provided that the above rules hold for all the intermediate positions in the trigonal bipyramid. The exchange of ligand positions in cyclic oxyphosphoranes can be "frozen" at certain temperatures; 1,2-oxaphospholens constitute a more rigid system than 1,3,2-dioxaphospholans and 1,4,2-dioxaphospholans. In the latter

case some of the diastereomers (*cis*-H/H conformation) are more rigid than others (*trans*-H/H conformation). Certain four-membered cyclic phosphoranes are more stable than the corresponding five-membered phosphoranes. The steric effects and the electronegativities constitute important factors in determining the relative stabilities of pentacoordinate and tetracoordinate phosphorus. The importance of the static and dynamic stereochemistry of phosphoranes is great, since the compounds with pentacoordinate phosphorus are intermediates in the reactions of many derivatives of tetracoordinate phosphorus and can be used in the interpretation of the biochemistry of phosphorus.

Specific Activity of Metallic Catalysts

V.A.Dzis'ko

This review deals with published work on the influence of chemical composition, degree of dispersion, and method of preparation on the specific activity of metallic catalysts. In most cases the specific activity is determined by the nature of the metal, and is independent of the degree of dispersion or other parameters. This behaviour is probably due to interaction between the catalyst surface and the surrounding medium, which converts the initial catalyst surface into a state which is relatively unaffected by variations introduced during the preparation of the catalyst. 131 references.

III.	Degree of dispersion of metallic catalysts, and their specific activity	440
IV.	Dependence of the specific activity of catalysts on the method of preparation	446

I. INTRODUCTION

The catalytic activity of unit surface area of solid catalysts, usually termed the "specific activity"†, is the most characteristic parameter of the catalytic properties of the material, and it can be used, together with a knowledge of the accessible surface area, to predict the activity of the catalyst.

The specific activity of a catalyst can be influenced by various factors: 1) the chemical composition; 2) the degree of dispersion of the active component, i.e. its crystallite size, which determines the relative proportions of atoms on the corners, edges, and faces of the crystallite; 3) the method of preparation, and some other factors. The relative importance of chemical composition and of the structural factors listed above in determining the specific activity is one of the most important problems facing the development of an effective theory of catalyst preparation.

During the first phase of the development of catalyst theory, before the advent of effective methods of measuring surface areas, most workers believed that catalytic activity was associated with non-equilibrium structures possessing a large amount of excess free energy, and therefore that the method of preparation of the catalyst could be the predominant factor in determining the specific activity[4-13]. These *a-priori* views were put to the test when methods of measuring surface areas were developed and generally adopted. The results of specific activity studies on one-component oxide catalysts have been discussed[14] by the present writer. The general conclusion was that the specific activity of catalysts of a given composition, measured in the activation-controlled regime

† Some ambiguity exists in the concept of "specific activity": some workers refer the term to the activity of 1 g of the catalyst[1], others to the activity of 1 m^2 of total surface area[2], yet others to the activity of unit "working" surface, by which they understand the "true" surface accessible to the catalytic reaction[3]. The most rational characterisation of the catalyst is to relate the activity to unit surface area of the active component.

with the catalyst and the reacting medium under steady state conditions, is approximately constant and independent of the method of preparation and of the thermal history of the catalyst.

The present review is concerned with the influence of chemical composition, degree of dispersion, and method of preparation on the specific activity of metallic catalysts‡. In Sections II–IV we shall discuss the results of experimental studies available at the time of writing. A discussion of the results obtained by different workers and of possible explanations of the discrepancies observed will be found in the concluding Section. The selection of publications relevant to the present review was limited by the following conditions: 1) we shall consider only those papers in which the reported activities can be compared with the surface area or the degree of dispersion of the active component; 2) we shall confine our discussion to gas-phase reactions, because reactions at a liquid–solid interface or in three-phase gas–liquid–solid systems often involve diffusional limitations which could obscure the effects of interest to us; 3) although the most precise characteristic of the specific catalytic activity is the rate constant of the reaction, related to unit surface area [18,19], we shall also include (for the sake of a balanced presentation of relevant work) those papers in which the activity is characterised by the extent of reaction.

II. EFFECT OF CHEMICAL COMPOSITION ON THE SPECIFIC ACTIVITY OF METALLIC CATALYSTS

The relationship between the specific catalytic activity and the nature of the non-reducible oxide support and the concentration of metal is an important aspect of the study of metal–oxide catalysts.

Table 1. Effect of chemical composition on the activity of cyclohexane dehydrogenation catalysts (Ref. 21).

Catalyst	Carrier	Concn. of metal in catalyst, %	Surface area of metal in catalyst, $m^2\ g^{-1}$	Specific activity (% conversion $m^{-2}\ h^{-1}$)
Pt	η-Al_2O_3	0.4	0.9	97.1
Pt	η-Al_2O_3	0.78	2.3	36.1
Pt	γ-Al_2O_3	0.4	1.1	74.5
Pt	γ-Al_2O_3	0.82	2.33	35.2
Ni	η-Al_2O_3	2.57	—	—
Ni	η-Al_2O_3	6.0	1.46	18.4
Ni	η-Al_2O_3	6.48	0.58	27.6
Ni	γ-Al_2O_3	2.56	—	—
Ni	γ-Al_2O_3	6.0	1.24	20.2–21.0
Ni	Al_2O_3-SiO_2	6.0	1.11	22.3
Ni	SiO_2	6.0	1.29	10.3

Platinum and the platinum metals. Cusumano and coworkers [20] studied the effect of the nature of the carrier on the specific activity of platinum towards the dehydrogenation of cyclohexane. Aluminium oxide and alumina–silicas were used as carriers; the Pt content of the catalysts was 2%. The size of the platinum crystallites, calculated from H_2 adsorption measurements, was less than 10 Å on alumina and 85 Å on Al_2O_3–SiO_2. Measurements in a flow reactor showed that Pt is approximately 6 times more active on Al_2O_3 than on alumina–silica gel, as a result of differences in surface area. The specific activity of the platinum, referred to 1 m^2 of Pt, was found to be independent of the nature of the carrier and of the degree of dispersion of the metal.

Swift and coworkers [21], who studied the same reaction on nickel and platinum supported on γ- and η-Al_2O_3, came to a similar conclusion. Table 1, which is a compilation of their results, shows that samples prepared from γ- and η-Al_2O_3 have practically the same specific activity for equal concentrations of Pt. When the Pt concentration in the catalyst is raised from 0.4 to 0.8% the specific activity falls by a factor of 2–2.5.

Hightower and Kemball [22] have compared the activity and selectivity of platinum catalysts supported on silica gel and on γ- and α-alumina with the activity of a platinum foil towards the more complex deuteration and H exchange reaction in *p*-xylene. No significant difference was found in the specific activity and selectivity of samples deposited on the same carrier and differing only in Pt concentration. Catalysts prepared by depositing Pt on different carriers, on the other hand, differed in selectivity among themselves as well as from the platinum foil. The authors suggest that the water adsorbed on the carrier may have a poisoning effect on the catalyst.

Table 2. Effect of carrier on the activity of Ru, Pt, Tc, Pd, and Re in the hydrogenation and hydrogenolysis of benzene (Ref. 23).

Catalyst composition*		Specific activity, mol. $cm^{-2}\ s^{-1}$, $\times 10^{-12}$		Catalyst composition*		Specific activity, mol. $cm^{-2}\ s^{-1}$, $\times 10^{-12}$	
metal	carrier	hydrogenation	hydrogenolysis	metal	carrier	hydrogenation	hydrogenolysis
Ru	SiO_2	395	300	Tc	γ-Al_2O_3	20	16
Ru	γ-Al_2O_3	350	390	Pd	SiO_2	16	—
Pt	SiO_2	175	—	Pd	γ-Al_2O_3	8.4	—
Pt	γ-Al_2O_3	142	—	Re	SiO_2	1.2	3.4
Tc	SiO_2	4.6	8.9	Re	γ-Al_2O_3	0.5	1.1

*The catalysts contained 1% of metal.

Kubicka showed [23] that the nature of the carrier does not significantly influence the specific activity of ruthenium, platinum, palladium, and rhenium supported on γ-Al_2O_3 and on silica gel (see Table 2) towards the hydrogenation and the hydrogenolysis of benzene. Differences in specific activity for any one metal were less than a factor of 2, and differences in activation energy less than 1 kcal $mole^{-1}$. Only technetium was exceptional its activity towards the hydrogenation of benzene being 4 times greater on Al_2O_3 than on SiO_2. Also rhenium was 3 times more active towards both reactions on SiO_2 than on Al_2O_3.

Witekowa and Matyjewski [24] studied the effect of the nature of the carrier on the specific activity of platinum (on metallic aluminium and on Al_2O_3) and of Pt black towards the oxidation of hydrogen, and found that the total activity is slightly increased, but the specific activity is greatly decreased, by increasing the coverage of aluminium by platinum.

‡ Recent publications by Boudart [15] and Slinkin [16,17] include brief reviews of the specific activity of metallic catalysts, but comprehensive coverage is not claimed.

Nickel and cobalt. The influence of chemical composition on the specific activity of nickel towards the hydrogenation of benzene was investigated [25-29] by examining a large number of catalysts with difference non-reducible components and covering a range of nickel concentrations. Chromium oxide, alumina, magnesia, silica gel, and carbon were used as carriers. The catalysts were prepared both by impregnation and by coprecipitation. Samples of nickel black, prepared by decomposing nickel salts, were also investigated. The catalytic activity was measured by circulating-flow [25-28] and by flow [29] methods. The results of this work are summarised in Tables 3 and 4 and in Fig. 1. It is evident that, in spite of the large difference in chemical composition, the activity of all the catalysts (except the Raney-nickel) is proportional to the surface area of Ni in the catalyst; the specific activity is constant and independent of the nature of the non-reducible oxide and of the Ni content.

Table 3. Effect of carrier on the specific activity of nickel in the hydrogenation of benzene (refs. 25-27).

Carrier and method of preparation	Ni content, wt.%	Area of metallic nickel, $m^2 g^{-1}$	Crystal size, A	Specific activity at 100°, mmole $h^{-1} m^{-2}$ Ni
Nickel black (decomposition of formate)	100	4	1250	0.46
Chromic oxide	50	60	94	0.58
Magnesium oxide	65	65	86	0.65
Carbon	9.4	203	28	0.58
Raney nickel	75	87	65	3.30

Table 4. Effect of Ni content on the activity of $Ni-Al_2O_3$ catalysts in the hydrogenation of benzene (Ref. 29).

Nickel concentration	%	5.4	16.9	29.5	53.0	75.0
Ni surface area	$m^2 g^{-1}$	1.3	14.3	24.5	51.7	43.0
Apparent activation energy	kcal $mole^{-1}$	41.03	39.77	39.35	41.03	37.26
Rate at 35°	mole $h^{-1} g^{-1} \times 10^5$	3.7	48	68.1	138	123
Specific activity at 35°	mol. $s^{-1} cm^{-2} \times 10^{-11}$	4.78	5.62	4.66	4.48	4.8

Taylor and Staffin [30], who studied the effect of carrier on the specific activity of dilute nickel catalysts in the same reaction, obtained rather different results. Their measurements were made under pulsed conditions, in 5-minute experiments. It can be seen from Table 5 that the specific activity increases as the amount of nickel in the catalyst is increased, the effect being slight on SiO_2 but very marked on alumina-silica gel. The nature of the carrier is significant only at low nickel concentrations, samples containing 10% Ni show only marginal differences in activity.

The role of nickel content in nickel-magnesia catalysts has been studied [31] in the particular case of the dehydration of cyclohexane (Fig. 2). The activity was measured in a flow apparatus at 250°, and it was found that the catalytic activity and the H_2 adsorption give similar plots at low nickel concentrations. The plots begin to diverge at Ni concentrations greater than 15%: the adsorption increases monotonically, but the catalytic activity goes through a maximum at 36.5 wt.% Ni. Hence, the specific activity (expressed in relative units) varies in the range 1 ± 0.5 as the nickel content of the catalyst is varied. The authors [31] explain this observation by assuming that the catalytic activity of the nickel is determined by the "coordination of the surface atoms", which is apparently an optimum at a Ni content of 36.5%.

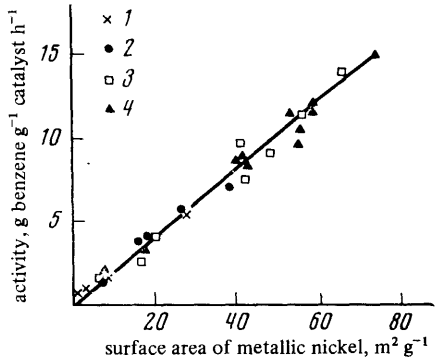

Figure 1. Surface area of nickel against activity of benzene dehydrogenation catalysts of different composition (Ref. 28): *1*) Ni black, *2*) $Ni-Cr_2O_3$, *3*) $Ni-Al_2O_3$, *4*) $Ni-Al_2O_3.Cr_2O_3$.

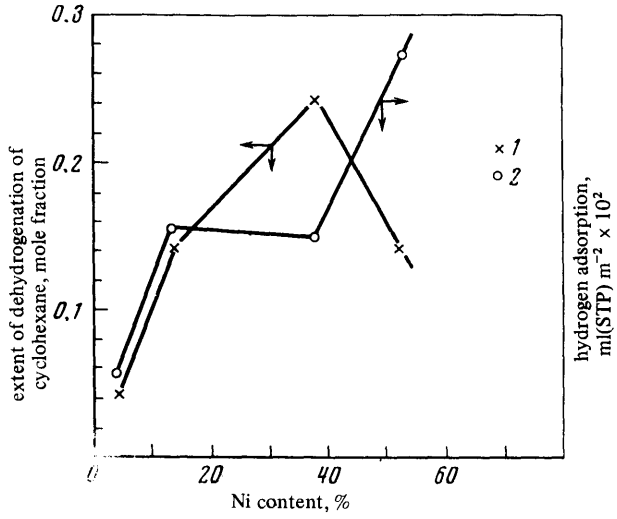

Figure 2. Effect of chemical composition on the activity of catalysts towards *1*) the dehydrogenation of cyclohexane and *2*) hydrogen adsorption (Ref. 31).

Swift and coworkers [21] also studied the effect of the nature of the carrier and of nickel content on the specific activity of nickel towards the dehydrogenation of cyclohexane. They found that samples containing ~2.5% of

nickel were catalytically inactive, and they suggested as an explanation that the nickel in these samples is chemically combined with the carrier and cannot be reduced. Samples containing 6–6.5% Ni on γ- and η-Al_2O_3 and on Al_2O_3–SiO_2 have almost identical specific activities (see Table 1), but the activity of nickel on silica gel is lower by about a factor of 2. The authors ascribe the enhanced activity of the catalysts containing Al_2O_3 to compound formation between the nickel and the aluminium oxide, the nickel being converted into an ionic form. The role of the nickel ions is to capture electrons and transfer them to the metallic nickel, thus modifying its catalytic activity.

Table 5. Effect of chemical composition of the catalyst on the specific activity of Ni in the hydrogenation of benzene (Ref. 30).

Carrier	SiO_2			$SiO_2 - Al_2O_3$		
Ni content, %	1	5	10	1	5	10
Ni crystallite size, Å	12	—	24	26	—	29
Ni surface area, $m^2 g^{-1}$	0.7	5.9	13.6	0.1	3.1	6.8
Specific activity, mole m^{-2} Ni $h^{-1} \times 10^4$	17.9	19.9	22.1	<1	3.84	17.2

Slinkin and coworkers [32] have reported an extensive investigation of the activity of Ni towards the dehydrogenation of cyclohexane as a function of the concentration of nickel in nickel–chromium catalysts. The reaction was studied in a flow reactor; it was found to follow the same kinetic law on all the samples examined. The surface area of metallic nickel was calculated from the concentration of metallic nickel and from its degree of dispersion, determined from X-ray diffraction and from magnetic measurements. The specific activity of the catalysts was found to vary by not more than a factor of 4 as the nickel content was varied from 2.4 to 34.8%: only the sample containing 70.5% Ni had an activity 46 times lower than the maximum. This behaviour is ascribed to incomplete removal of oxygen from the nickel surface.

An approximately constant specific activity was observed also in a study [33] of the influence of composition and degree of dispersion on the activity towards the hydrogenation and hydrogenolysis of cyclopropane of Ni catalysts deposited on kieselguhr, Al_2O_3, and alumina–silica gel.

It is evident from Table 6 that the hydrogenation rate constants for the various catalysts differ by not more than a factor of 2, and the hydrogenolysis rate constants by a factor of 4. According to a more recent study [34], the overall reaction rate varies only within the range ±25% (last column of Table 6).

Taylor and coworkers [35] also studied the hydrogenation and hydrogenolysis of cyclopropane on nickel catalysts, using pulsed conditions in 3-minute experiments. The nickel content of the catalysts was 10 wt.%. The nature of the carrier was found to have a marked influence, the specific activity of nickel being approximately 2 orders of magnitude higher on silica gel than on Al_2O_3–SiO_2.

The same group of workers [36–38] found that the nature of the carrier has a strong effect also on the specific activity of nickel and cobalt towards the hydrogenolysis of ethane: the specific activity of nickel on silica gel was higher than on Al_2O_3 by about a factor of 2, and almost 50 times higher than on Al_2O_3–SiO_2.

Similar results were obtained in the work on cobalt [37], samples based on silica gel and aluminium oxide having the highest activity, and samples based on Al_2O_3–SiO_2 and carbon the lowest. The specific activity of the former was about 20 times greater than the specific activity of the latter, even though the degree of dispersion of the catalysts differed only by a factor of 3.

Table 6. Specific activity of nickel in the hydrogenation and hydrogenolysis of cyclopropane at 60° (Refs. 33, 34).

Ni content, %	Carrier	Nickel surface, $m^2 g^{-1}$	Ni disperseness, (fraction of atoms on surface)	Specific activity, mole $h^{-1} m^{-2} \times 10^3$			
				hydrogenation k_1 (Ref.33)	hydrogenolysis k_2 (Ref.33)	total $k_1 + k_2$ (Ref.33)	total $k_1 + k_2$ (Ref.34)
58	Kieselguhr	63	0.163	5.8	1.28	7.0	7.9
5	$SiO_2 - Al_2O_3$	0.2	0.006	4.0	0.45	4.4	5.0
40	Al_2O_3	5.7	0.022	3.1	1.6	4.7	6.3
14	Al_2O_3	2.8	0.03	2.58	2.0	4.58	6.1

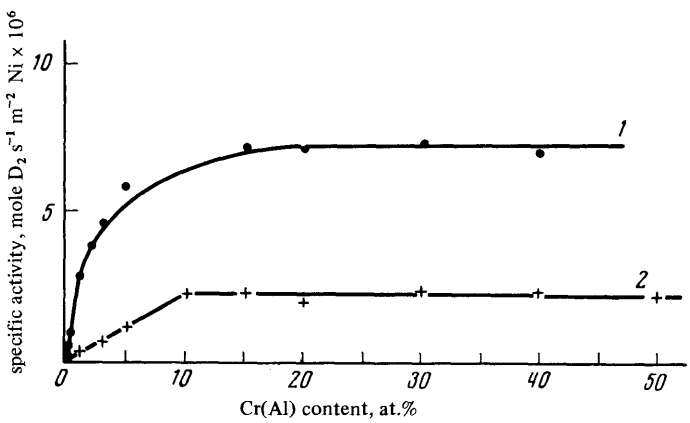

Figure 3. Effect of Cr_2O_3 and Al_2O_3 content on the specific activity of nickel catalysts in the reaction $HDO + H_2 \rightarrow H_2O + HD$: [39–41] *1*) Ni–$Cr_2O_3$; *2*) Ni–$Al_2O_3$.

When the nickel concentration in silica gel and alumina–silica catalysts was changed from 1 to 10% it was found [38] that the specific activity of the nickel varied in the same sense as the nickel content. This observation was explained by postulating an interaction between the nickel and the carrier, which can be expected to be stronger when the nickel content is low. However, the nature of this interaction is not clear.

Margineanu and Olariu [39,40], who studied the reaction $HDO + H_2 \rightarrow H_2O + HD$, found a relationship between the specific activity and the chemical composition of a nickel–chromium catalyst. The concentration of chromium oxide

in the binary system was varied from 0.1 to 40 mole %. With pure nickel, both the surface area and the specific activity were found to be very low. As the concentration of chromic oxide was increased to 5% the activity of the nickel increased 100-fold. However, at still higher concentration of chromium oxide the specific activity of the nickel remained approximately constant (curve *1* of Fig.3).

The authors explain these results by assuming that the "promotion" of the nickel catalyst involves an interaction with the chromium oxide, yielding a surface compound which has a very high activity towards the exchange reaction. As the concentration of chromium oxide in the catalyst is increased, the concentration of active surface centres increases at first and then reaches a constant level. As a result, the specific activity also rises to a constant level, independent of the concentration of Cr_2O_3. The decrease in specific activity with decrease in chromium oxide content could also be explained in terms of increasing crystallite size. The same authors[41] observed a similar relationship between the specific activity of nickel and the concentration of non-reducible oxide in nickel–alumina catalysts: as the concentration of Al was raised from 0 to 10 at.% the specific activity rose from 0.057 to 2.22 mole D_2 m^{-2} s^{-1}, and remained constant at still higher Al concentrations (curve *2* of Fig. 3).

Müller and coworkers[42] studied the effect of nickel content in nickel–chromium catalysts on the total and the specific activity towards the hydrogenation of CO_2 to CH_4. The activity was measured in a circulating flow apparatus in the presence of a large excess of hydrogen. As Table 7 shows, a change in nickel concentration alters the total activity by more than an order of magnitude without significantly affecting the specific activity.

Table 7. Effect of Ni : Cr_2O_3 ratio on the activity of nickel–chromia catalysts in the hydrogenation of CO_2 at 175° (Ref. 42).

Ni:Cr_2O_3	∞ (100% Ni)	21.6	9.03	4.37	1.96	0.925	0.25
Total activity, mole $CO_2^{0.5}$ litre$^{0.5}$ g^{-1} h^{-1}	0.047	0.463	0.490	0.530	0.381	0.043	0.046
Specific activity, mole $CO_2^{0.5}$ litre$^{0.5}$ m^{-2} Ni h^{-1}	0.67	0.721	0.716	0.731	0.839	0.906	—

Iron. Shcheglov and coworkers[43] studied the effect of catalyst promotion on the specific activity of the catalyst towards the dissociation of ammonia. The measurements were made in a circulating flow apparatus at atmospheric pressure.

Table 8 shows that catalyst promotion results in a 15-fold increase in the rate constant (referred to 1 g of catalyst), whereas the specific activity increases at most by 30%. The authors conclude that the role of the promoting agent is to increase and stabilise the iron surface.

Similar conclusions were reached in studies of the effect of alumina content on the activity of iron catalysts in the synthesis of ammonia[44]. There was no direct relationship between the catalytic activity and the total surface area. As the proportion of aluminium oxide in the catalyst increases, the fraction of the surface occupied by free iron decreases. However, since the total surface area is increased, the area of metallic iron goes through a maximum. The yield of ammonia goes through a similar maximum. The rate constant, calculated by the Temkin–Pyzhov equation, varies in direct proportion to the iron surface (Fig. 4), and therefore the specific activity is constant.

Table 8. Effect of catalysts composition on the activity of iron towards the decomposition of ammonia[43].

Catalyst	Rate constants x 10^2*			
	375°		400°	
	k_g	k_{sp}	k_g	k_{sp}
Armco-iron	11	9.9	65	59
Promoted Fe catalyst	171	12.9	943	69

*k_g is the rate constant per 1 g of catalyst, k_{sp} is the rate constant referred to 1 m^2 of metallic iron surface (cm^3 NH_3 m^{-2} Fe h^{-1}).

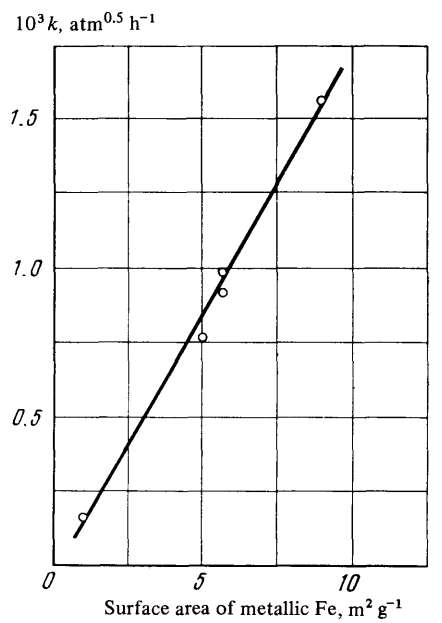

Figure 4. Metallic iron surface against rate constant calculated by the Temkin–Pyzhov equation[44].

The specific activity of iron towards the synthesis of ammonia was investigated by Lachinov and coworkers[45], who varied the composition of their catalysts over wide limits. It is clear from their experimental results, summarised in Table 9, that with the exception of sample 12a (which had a very small iron surface) the specific activity of the catalysts varies by no more than a factor of 2.7, which is probably within the limits of experimental error in this type of measurement.

In contrast to these results, the same group of workers[46] had previously found that the specific activity of iron increases from 30 to 1200 when the fractional occupancy of the surface by alkali is increased from 0.08 to 0.78. They had concluded that the active component in iron catalysts for ammonia synthesis is not elemental iron, but an iron compound formed on the catalyst surface during the reduction stage.

Table 9. Effect of Al_2O_3 content on the surface area and specific activity of Fe ammonia synthesis catalysts at 400° (Ref. 45).

Sample No.	Al_2O_3 content, wt.%	Surface area, $m^2 g^{-1}$		k_{sp}, $atm^{0.5} h^{-1} m^{-2}$ Fe
		total	metallic iron	
12a	0.0	1	1.0	0.75
8a	0.6	6	2.5	20.3
7a	1.1	8	3.4	15.5
6a	2.4	13	3.8	20.0
4a	5.4	24	7.7	11.7
3a	7.9	35	5.2	11.3
2a	13.4	91	4.1	16.3
1a	37.5	91	5.5	7.5

The effect of Al_2O_3 and K_2O additions on the specific activity in the synthesis of ammonia was investigated also with iron–cobalt catalysts containing 15% of cobalt. It was found that the additives have a significant effect on the surface area and on the total activity of the catalysts, but the rate constant (referred to 1 m^2 of metal surface) remains unchanged[47].

Table 10. Specific activity of silver catalysts for the oxidation of ethylene to ethylene oxide (Ref. 48).

Ag content of catalyst, $g l^{-1}$	17	33	43	73	10	23	53	83	50	1600 Ag pellets
Surface area of carrier, $m^2 g^{-1}$	5.0	5.0	5.0	5.0	2.8	2.8	2.8	2.8	0.5	—
Specific activity of silver, $10^5 k$, m^{-2}	2.8	5.1	4.7	2.8	5.9	5.6	4.2	3.1	3.1	2.8–4.2

Table 11. Specific activity of catalysts with different silver contents towards the oxidation of ethylene to ethylene oxide (Refs. 49, 50).

Silver content, wt.%	4.3	11.1	11.6	17.8	19.1	21.5	26.7
Specific activity, g ethylene oxide m^{-2} Ag $h^{-1} \times 10^2$	28	41	36	42	42	31	32

Silver. Soviet workers[48–50] have investigated the effect of method of preparation and of silver content on the activity of silver catalysts for the oxidation of ethylene to ethylene oxide. In the activation-controlled region the activity of the catalysts per 1 m^2 of silver surface was found to be approximately constant (Tables 10 and 11).

III. DEGREE OF DISPERSION OF METALLIC CATALYSTS AND THEIR SPECIFIC ACTIVITY

The dependence of the specific activity on the crystallite size of the active component has been actively investigated during the past 50 years. According to Taylor and others[4,7], who published their work in the 1920's, the catalytic activity resides mainly in the atoms which are weakly bound to the surface and therefore have an excess of free energy. Hence, the specific activity should increase on decreasing the size of the crystallites, thus increasing the proportion of atoms weakly bound to the surface. More recently, Bond has shown[51] from theoretical considerations that changes in crystallite size can influence the specific activity in different ways. 1) The specific activity may be independent of crystallite size. 2) Small crystals may be more active than large crystals: in this case the specific activity decreases if the crystal radius increases. Bond called this the "positive internal effect". 3) If the larger crystals are more active than the smaller crystals (negative internal effect) the specific activity increases with crystallite size. It is also possible for very small crystals to have a negative internal effect and larger crystals to have a positive internal effect: in this case the specific activity goes through a maximum. In the present section we shall discuss the results of experimental studies of the effect of degree of dispersion on the specific activity of catalyst particles. [Dispersion in this context is sometimes defined as the fraction of the total metal atoms which are the metal surface. (Ed. of Translation)].

Table 12. Specific activity of platinum towards the oxidation of sulphur dioxide and hydrogen (Refs. 53–55).

Catalyst	Surface of 1 g Pt, cm^2	Rate constants*			
		Oxidation of sulphur dioxide at 427°		Oxidation of hydrogen at 100°	
		k_g, $cm^3 s^{-1}$	k_{sp}, 10^2 cm s^{-1}	k_g, $cm^3 s^{-1}$	k_{sp}, cm s^{-1}
0.2% platinum on silica gel	$3 \cdot 10^5$	$1.1 \cdot 10^3$	0.37	$4.9 \cdot 10^8$	1400
0.5% platinum on silica gel	$7 \cdot 10^5$	$(0.7–2.8) \cdot 10^3$	0.1–0.40	—	—
Platinum sponge	$1.7 \cdot 10^3$	1.5–3.9	0.09–0.23	—	—
Wire 0.1 mm diameter	20.6	0.054	0.26	$1.1 \cdot 10^4$	535
Gauze	22.6	0.1	0.49	—	—
Foil	6.9	0.12	1.74	$6.2 \cdot 10^3$	900

*k_g is the rate constant per 1 g of catalyst, k_{sp} is the rate constant referred to 1 cm^2 of Pt surface.

Platinum, palladium, and rhodium. Boreskov and coworkers[52–56] made a comparative study of the activity of "massive" platinum samples (sponge, wire, gauze, foil) and of platinum deposited on silica gel towards the oxidation of sulphur dioxide and hydrogen, and towards the homomolecular $H_2–D_2$ exchange reaction. In the oxidation reactions (SO_2 and hydrogen) the activity was measured in the activation-controlled region by the circulating flow method, which ensures isothermal conditions in the catalyst bed. The surface area of metallic platinum was varied from 6.9 $cm^2 g^{-1}$ (foil) to 7×10^5

$cm^2\ g^{-1}$ (platinised silica gel containing 0.5% Pt), i.e. more than 100 000-fold. In spite of this enormous difference in the degree of dispersion of the catalysts, the specific activity towards the oxidation of SO_2 was found to vary only by a factor of 4 (excepting only the foil sample). The foil had an unexpectedly high specific activity, tentatively ascribed to the presence of impurities (Table 12).

The catalytic activity of the same samples towards the oxidation of hydrogen[55], referred to 1 g of platinum, was found to vary by 4 orders of magnitude, while the specific activity varied only by a factor of 2.5. The differences in specific activity of different samples were comparable to the differences in specific activity of a given sample in different experiments: this effect probably arises from the slow establishment of a steady state over the catalyst surface.

Similar values of the specific activities of massive platinum, platinum sponge, and platinum black were observed also in a study[56] of homomolecular exchange. In this case, the platinised silica gel samples had a substantially higher specific activity, which the authors ascribed to a significant catalytic activity of the silica gel itself (in the presence of platinum) towards the H_2 exchange reaction. More recent work[57] failed to confirm the higher specific activity of Pt deposited on silica gel, although the absolute values of specific activity observed were close to those reported by Boreskov and Avdeenko[56].

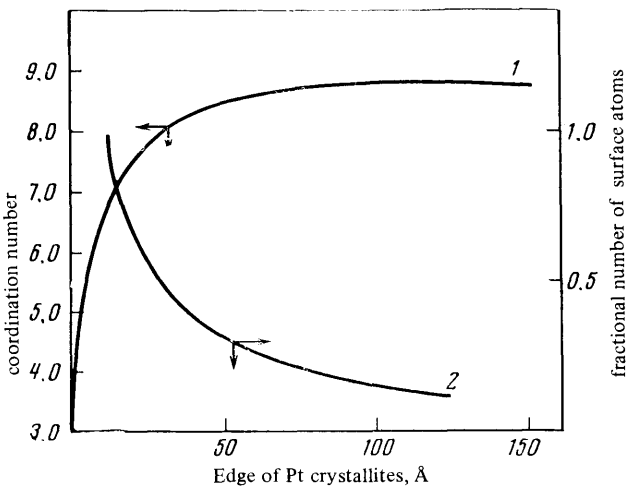

Figure 5. Coordination number (*1*) and fractional number of surface atoms (*2*) against platinum crystallite size (Ref. 58).

Poltorak and coworkers[57-62] published a series of papers on the effect of dispersion on the specific activity of platinum crystallites towards various reactions. The structural properties of the crystallites were evaluated from a theoretical treatment of the octahedral model. Plots of the coordination number (c.n.) and of the fractional number of surface atoms (γ) against the size of the platinum crystallites[58] are shown in Fig. 5. It is clear that the most important changes in structural properties occur when the edge length l is varied from 5 to 30–40 Å: further increase in crystallite size produces only minor changes in these parameters, and for crystals greater than 100 Å the changes are insignificant. These considerations lead to the conclusion that studies of the effect of dispersion on the activity of catalysts are not likely to be meaningful unless the catalyst is highly disperse. It is convenient to consider three cases: 1) crystallites containing less than 15 atoms, in which $\gamma \simeq 1$ and c.n. < 6, whose properties can be equated to those of micro-defects on crystal surfaces; 2) crystallites with $\gamma = 0.8-0.9$ ($l = 10-15$ Å), in which the properties of the atoms in the surface layer are similar to those of edge atoms in coarser crystal; 3) crystallites with $\gamma < 0.3$ and $l > 50$ Å, in which the properties of the surface atoms are no different from those of ideal crystal faces.

By applying these considerations, samples of platinised silica gel covering the appropriate range of crystallite size were prepared. The effect of platinum concentration on the catalytic activity towards the homomolecular H_2-D_2 exchange reaction was studied[57]; it was found that, in spite of the large difference in dispersion, samples in the first and second series had almost identical specific activities, and samples in the third series had a slightly lower specific activity (1.5–2-fold, almost within the limits of experimental error).

Table 13. Influence of dispersion on the specific activity of platinum (Refs. 60–62).

H/Pt	Average size of Pt crystallites, Å	Initial specific activity, mol. min^{-1} $atom^{-1}$ Pt

0.4	37	4.65	—	—
0.05	100	5.3	—	—

*From Ref. 62.

Mitrofanova and coworkers[60-62] studied the dehydrogenation of cyclohexane and isopropanol, and also the hydrogenolysis of cyclopentane. The catalytic activity was measured in a circulation apparatus. It is evident from the results (Table 13) that the specific activity of catalysts in the above reactions is not significantly influenced by the size of the crystallites, and hence that the ratio of surface to bulk platinum atoms does not play a major role. The authors conclude[58] that "in no single instance has the enhanced activity of crystal edges or structural defects, axiomatically assumed in theoretical discussions of heterogeneous catalysis, been experimentally confirmed for gas-phase reactions".

Constant specific activity of alumina–platinum catalysts towards the dehydrogenation of cyclohexane has been reported also by Zaidman and coworkers[63-65]. The dispersion of the catalysts was varied by varying the platinum content and the annealing temperature, and was

characterised by the H/Pt ratio. The activity was measured in a circulating flow system at low extents of reaction, for which the kinetic order is zero. It can be seen from Fig. 6 that the activity is proportional to H/Pt, and hence the specific activity of the platinum is constant within experimental error.

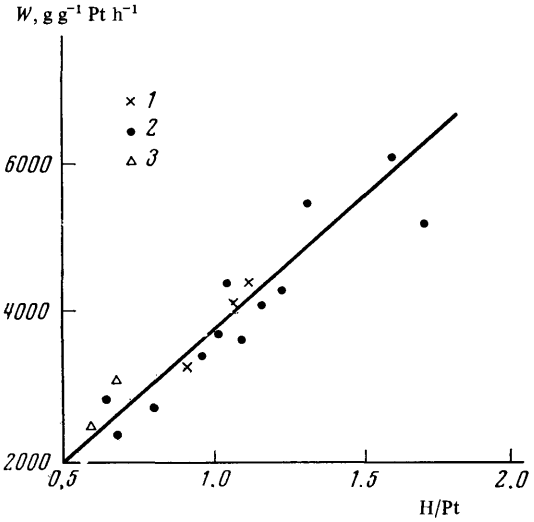

Figure 6. Activity of platinum in the dehydrogenation of cyclohexane against H/Pt (Refs. 63–65): *1*) 300°, *2*) 500°, *3*) 700°.

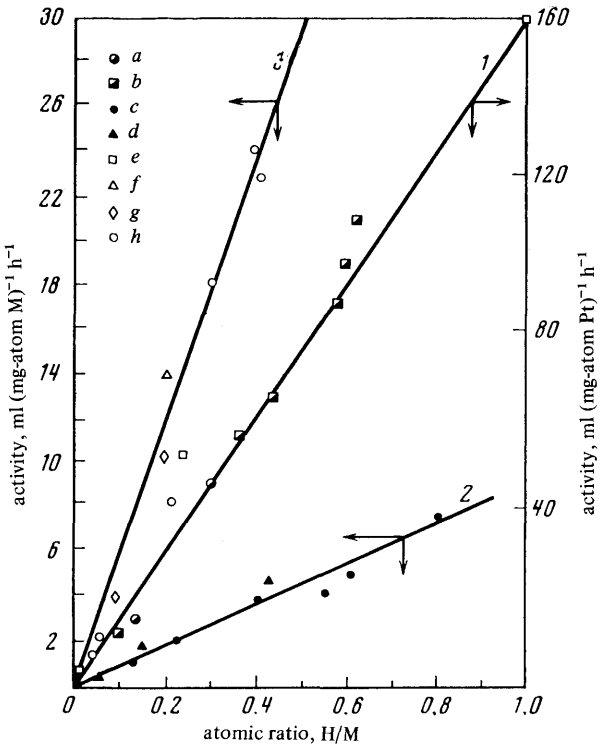

Figure 7. Benzene hydrogenation activity against fractional number of surface atoms (Refs. 66, 67): *1*) Pt, *2*) Pd, *3*) Ni; (*a*) Pt–SiO_2, (*b*) Pt–Al_2O_3, (*c*) Pd–SiO_2, (*d*) Pd–Al_2O_3, (*e*) Ni–Al_2O_3, (*f*) Ni–SiO_2.MgO, (*g*) Ni–SiO_2.Al_2O_3, (*h*) Ni–SiO_2.

Similar results were obtained in work [66,67] on the influence of the crystallite size of platinum and palladium on the specific activity of these metals towards the hydrogenation of benzene. The size of the crystallites was varied between 10 and 200 Å, and silica gel, alumina, SiO_2–MgO, and SiO_2–Al_2O_3 were used as carriers. The activity was found to be proportional to the degree of dispersion of the platinum (Fig. 7), showing that the specific activity is constant and independent of the degree of dispersion of the metal.

Dorling and Moss [68] also studied the relationship between the size of Pt crystallites deposited on silica gel, the surface area of the metal, and the activity of these catalysts towards the hydrogenation of benzene. The crystallite size was varied between 45 and 980 Å by varying the temperature of heat treatment. It can be seen from Table 14 that in spite of the large (15-fold) difference in crystallite size the specific activity of catalysts heated at 500° and below varies only by a factor of 2.

Larsen and coworkers [69] have studied the effect of dispersion on the activity of platinum towards the hydrogenation of aromatic compounds, using the extent of hydrogenation to characterise the activity. The reaction was found to proceed only to a maximum of 60% conversion, which was ascribed to achievement of equilibrium. It can be seen from Fig. 8 that for up to 30% reaction (i.e. 50% of the maximum) the relationship between percentage conversion and platinum surface area is approximately linear, but at higher extents of reaction the proportionality no longer holds.

Table 14. Influence of sintering temperature and dispersion on the specific activity of platinum towards the hydrogenation of benzene (Ref. 68).

Sintering temperature	120	250	300	400	500	600	800
Pt crystallite size, Å	45	220	210	360	640	980	890
Pt surface area, $m^2 g^{-1}$	2.0	1.32	1.52	3.0	1.53	0.2	0.04
Specific activity (molecules cm^{-2} Pt s^{-1}) × 10^{-13}	2.8	2.7	3.2	1.4	1.3	inactive	

Boudart and coworkers [70] studied the effect of crystallite size on the catalytic activity of platinum towards the hydrogenation of cyclopropane in order to account for the existence of an optimum particle size. Their measurements were made in a circulation system. The dispersion was varied by varying the platinum concentration and the temperature of heat treatment, and was characterised by the surface area as determined by H_2 adsorption, and also by the ratio of the number of surface atoms to the total number of atoms (%-age dispersion). For comparison, Pt foil 12.7 μm thick was also examined. It was found (Table 15) that the specific activity remained relatively constant (within a factor of 3) in spite of very large differences in dispersion (20 000-fold) and in the nature of the carrier.

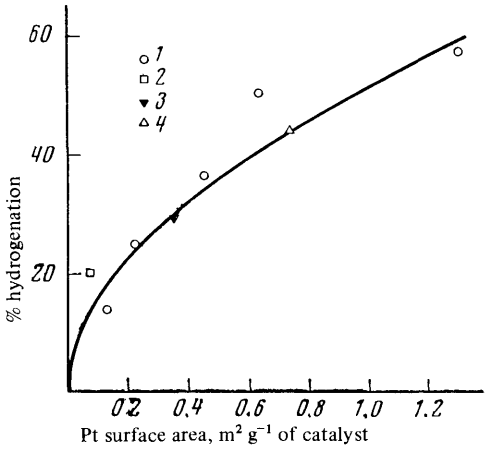

Figure 8. Influence of platinum surface area on the extent of hydrogenation of aromatic compounds in a petroleum fraction (Ref. 69): *1*) normal catalyst preparation, *2*) heated at 760°, *3*) heated in rotating furnace, *4*) impregnated 5 times.

Table 15. Effect of dispersion on the activity of platinum towards the hydrogenation of cyclopropane (Ref. 70).

Catalyst	Fraction of surface Pt atoms, %	Specific surface area of Pt, μmole H_2 g^{-1}	Activity at 0°	
			total mole C_3H_6 min^{-1} g^{-1}	specific mole C_3H_6* min^{-1} cm^{-2} Pt
0.3% Pt on η-Al_2O_3	44	10.2	82.4	8.2
0.3% Pt on γ-Al_2O_3	59	13.5	100	7.4
0.6% Pt on γ-Al_2O_3	73	33.5	186	5.4
1.96% Pt on η-Al_2O_3	64	97.0	637	6.5
ditto after sintering	7 6	11.5	44	3.8
4.3% Pt on silica gel	17	57.3	160	2.8
Foil (100% Pt)	0.0039	0.55	1.4	2.5

*Calculated from data in Table 1 of Ref. 70.

To explain these "strange" results the authors proposed the concept of "easy" and "difficult" catalytic reactions. In the former, most of the surface sites are active, and therefore the non-uniformity of the surface is immaterial. In the "difficult" reactions, on the other hand, surface non-uniformity can be expected to play an important role, and hence the reaction rate should be influenced by the dispersion of the metal, the method of preparation, and other factors. In a more recent paper by Boudart [71] a typical "difficult" reaction is discussed in detail (the isomerisation and hydrogenolysis of neopentane). The activity in this case was measured in a micro-reactor operating under pulsed conditions.

As Table 16 shows, changes in dispersion and in the method of preparation of the catalyst give rise to substantial differences in specific activity and selectivity for this system: the activity in the isomerisation reaction varied by a factor of 15 and the activity in the hydrogenolysis reaction varied by a factor of 300; the selectivity varied by a factor of 100. The large differences in activity were explained by the need for three-point adsorption of the neopentane molecule: "triplet" sites, able to adsorb the reacting molecule in the appropriate configuration, must be present on the surface. The concentration of triplets can be expected to depend on the dispersion and on the method of preparation of the catalyst.

Table 16. Specific activity and selectivity of platinum towards the isomerisation and hydrogenolysis of neopentane (Ref. 71).

Catalyst		Disperseness, %	Specific activity, (molecules Pt $atom^{-1}$ s^{-1}) × 10^3		Selectivity N_I/N_H
Pt content, wt.%	Carrier		isomerisation N_I	hydrogenolysis, N_H	
0.6	γ-Al_2O_3 [a]	73	2.6	4.7	0.55
1.96	η-Al_2O_3 [a]	64	5.3	13.0	0.41
0.60	γ-Al_2O_3 [b]	73	2.8	1.9	1.5
1.96	η-Al_2O_3 [b]	64	3.4	2.3	1.5
4.3	SiO_2	17	3.8	13	0.29
1.0	Spheron [c]	12	1.1	0.04	27
1.96	η-Al_2O_3 [d]	7.6	11	4.5	2.4
100	— [e]	0.028	0.73	0.08	9.1

Note. [a] reduced in H_2 at 425° for 10 h; [b] ditto, at 500°; [c] reduced at 500°, vacuum-baked at 900° for 16 h, stored in air, and reduced as for "b"; [d] heated in a stram of H_2 at 650° and reduced as for "b"; [e] heated in hydrogen and oxygen alternately, and finally reduced as for "b".

Boudart's hypothesis was put to the test by other workers. In one of the most interesting investigations of this topic, due to Dorling and coworkers [72], the activity of platinum towards the hydrogenation of ethylene was studied as a function of crystallite size and method of preparation. Catalysts were prepared by impregnating silica gel with a solution of H_2PtCl_6, and by adsorption of ammine. The platinum content, and the reduction conditions, were also varied. The catalytic activity was measured in a flow apparatus. Catalyst poisoning by the decomposition products of ethylene was observed in all cases (Table 17). The specific activity was found to vary by more than 2 orders of magnitude as a result of changes in Pt content and conditions of preparation. With the catalysts prepared by impregnation with H_2PtCl_6, samples containing less than 1% of Pt had the lowest activity. The highest activity was found in samples containing 1% Pt or more, and reduced at 80°. As the reduction temperature was raised, the activity fell to a limiting value of about 2×10^{12} molecules cm^{-2} Pt s^{-1}. Samples prepared from the ammine had an approximately constant specific activity of $2-3 \times 10^{12}$ molecules cm^{-2} Pt s^{-1}. From these results the authors concluded that the specific activity of platinum is constant ($2-3 \times 10^{12}$ molecules cm^{-2} Pt s^{-1}), and independent of the platinum crystallite size. The low specific activity of samples prepared by impregnation and containing less than 1% of platinum is due to poisoning effects, which can be very marked in catalysts with a low surface area. The enhanced activity of samples reduced at 80° is due to the promoting effect of traces of Cl, which are removed at higher reduction temperatures. Thus, the observed differences in specific activity are fortuitous.

Kraft and Spindler[73] studied the effect of dispersion on the activity of platinum (supported on Al_2O_3) towards the dehydrogenation of cyclohexane and the dehydrocyclisation of n-heptane. The activity was measured in a flow apparatus, and was characterised by the extent of reaction. The specific activity at low extents of reaction (23–31%) was found to be constant; at higher extents of reaction the specific activity fell by a factor of 3.5–4. This effect was ascribed to the approach to equilibrium. In the dehydrocyclisation of n-heptane no simple relationship between dispersion and specific activity was found.

Table 17. Effect of dispersion and preparative conditions on the specific activity of platinum towards the hydrogenation of ethylene (Ref. 72).

Catalyst	Average crystallite size, Å	Pt surface, $m^2 g^{-1}$	Reduction temp., °C	Specific activity at −80° (mol. cm^{-2} Pt s^{-1}) × 10^{-12}	Comments
Impregnated < 1% Pt	30—40	0.1—0.5	210	0.1—0.6	Low specific activity due to poisoning
Heated at 600°	200	0.2	80	3	
Impregnated 3.4% Pt	40	2	80	20	Specific activity decreasing due to loss of Cl_2 during reduction
			210	7	
			500	2	
Impregnated 9.8% Pt	50—75	3—5	80	15	
			210	8	
			500	2	
Impregnated 1-11.5% Pt	30—60	0.8—4.5	80	5—23	—
			210	2—8	
Ammine adsorption 2.45% Pt	13—30	3—4	300	2—3	Approximately constant specific activity

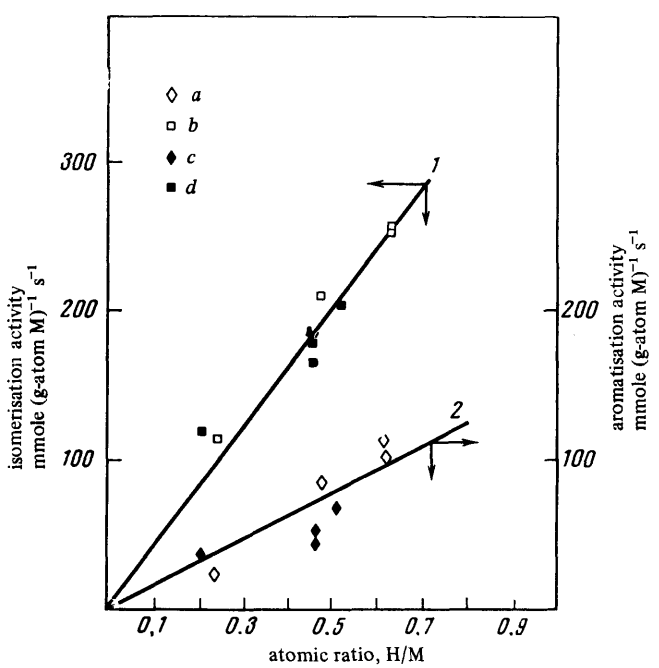

Figure 9. Effect of dispersion on the activity of platinum towards the isomerisation (*1*) and aromatisation (*2*) of hexane (Ref. 74): *a*) and *b*) 0.5% Pt; *c*) and *d*) 1.0% Pt.

Dautzenberg and Platteuw[74] studied the influence of dispersion on the activity of platinum towards the isomerisation and cyclisation of hexane. The measurements were made in the flow regime. Aluminium oxide, which is inert in isomerisation reactions, was chosen as the carrier. The platinum was deposited from $Pt(NH_3)_4(OH)_2$ solution in order to avoid the inclusion of acidic groups. It is evident from Fig. 9 that in both reactions the activity is directly proportional to the surface area of platinum. These results were confirmed by a subsequent observation[75] that the selectivity in the isomerisation of n-hexane is unaffected by changes in platinum particle size from <10 to ~80 Å.

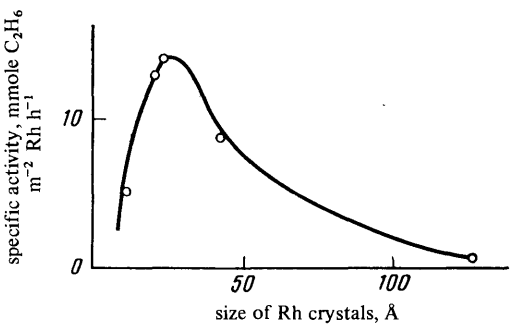

Figure 10. Length of crystallite edge against the specific activity of rhodium in the hydrogenolysis of ethane (Ref. 76).

The specific activity of rhodium towards the hydrogenolysis of ethane has been studied[76] as a function of particle size. The reaction rate was measured in a pulsed reactor. The specific activity was characterised by the number of millimoles of ethane reacting per hour on a square metre of rhodium surface at 253°. As Fig. 10 shows, samples in which the rhodium crystallites have a diameter of ~20 Å have the highest activity. When the crystallite size is decreased to 10 Å the specific activity falls by a factor of 3. The specific activity of coarsely gound samples of massive rhodium, and of samples deposited and heat treated at 800°, is 20–40 times lower than the maximum.

The effect of particle size on the activity of platinum in thin-film form towards the hydrogenolysis of n-hexane, 2- and 3-methylpentane, and methylcyclopentane has been studied[77] under static conditions. The reaction rate fell rapidly during the course of the reaction, reaching a steady value at an extent of conversion of 0.1–0.2%. This effect can be ascribed to "self-poisoning" of the catalyst. When the platinum crystallite size is increased from 15 to 58 Å both the initial and the steady-state specific activity decrease by an order of magnitude.

McKee[78] studied the effect of dispersion on the activity of platinum black towards the cracking of propane in a static apparatus with an initial propane pressure of 17.5 mmHg. The dispersion of the metal was varied by varying the sintering temperature between 150 and 220°, and it was characterised by the surface area measured by nitrogen adsorption. The particle size of the catalysts

was not stated. The activity fell during the reaction owing to the formation of a carbon deposit. The catalytic activity of the platinum (Fig. 11) decreases as the extent of sintering increases: in order to produce a measurable rate of reaction the surface area of the sample must be greater than some minimum value (depending on the reaction temperature). The dispersion also influences the activation energy of the reaction, which increases from 12 to 24 kcal mole^{-1} as the samples are more heavily sintered. These observations are explained by assuming that sintering causes a decrease not only in surface area but also in the concentration of surface defects which behave as active centres in the cracking reaction.

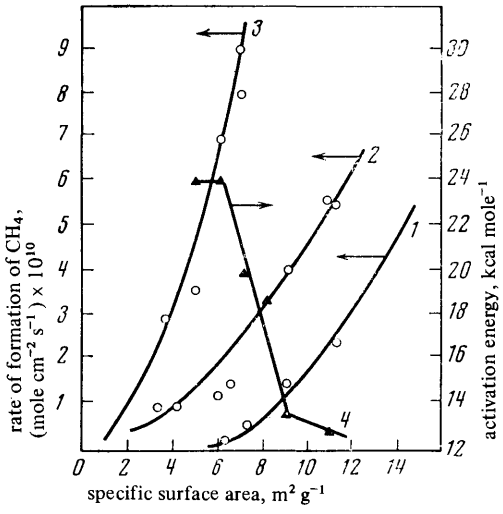

Figure 11. Effect of surface area on the activation energy and activity of platinum black towards propane cracking at different temperatures: *1*) 153°, *2*) 180°, *3*) 200°, *4*) activation energy (Ref. 78).

The specific activity of platinum samples of different degrees of dispersion towards the exchange reaction $HDO + H_2 \rightleftharpoons H_2O + HD$ has been studied [79] under flow conditions. The catalysts were prepared by three methods, and within each series the particle size was varied from 5 to 250 Å. The platinum surface area was measured by H_2 adsorption. The specific activity was characterised by the rate constant per unit surface area. By varying the sintering temperature the specific activity within each series could be varied by a factor of 3, reaching a maximum after sintering at 500°. Varying the crystallite size from 5 to 250 Å produced a change in the specific activity at 127° from 1.9×10^{-8} to 5×10^{-8} mole D_2 cm^{-2} s^{-1}.

Nickel. Rienäcker and coworkers [80] studied the activity of nickel powder and of heat-treated sheet nickel towards the decomposition of formic acid. In spite of the very large (more than an order of magnitude) difference in dispersion, the specific activity of the catalysts differed only by a factor of 1.5.

A group of Czech workers [81-83] has investigated the effect of dispersion on the activity of a nickel–magnesia catalyst towards the hydrogenation of benzene. The catalysts were prepared by thermal decomposition of the double oxalate of nickel and magnesium. Particle size was determined by X-ray diffraction and thermomagnetic methods.

Table 18. Effect of crystallite size on the specific activity of nickel in the hydrogenation of benzene at 40° (Ref. 81).

Sample No.	Prepared from	Metallic nickel content, wt %	Nickel surface m^2 g^{-1}	Crystallite size, Å	Specific activity, (mole min^{-1} m^{-2} Ni) × 10^7
7	Mixed Ni and Mg oxalates	32.3	97.0	22	4.9
11	ditto	86.6	52.0	148	4.9
3	Nickel oxalate	100	11.6	580	7.8
6	ditto	100	3.6	1870	5.25

Table 18 shows that the specific activity of nickel is constant within experimental error in spite of large differences in dispersion. The authors point out that their value of the specific activity is close to that reported [25] by Lyubarskii ($3-5\times10^{-7}$ mole min^{-1} m^{-2}).

Table 19. Effect of crystallite size on the specific activity of nickel in the dehydrogenation of benzene (Ref. 84).

Nickel content, %	4.26	10.2	28.9	52.5
Ni surface area, m^2 g^{-1}	12.86	26.2	56.6	43.1
Average crystallite size, Å	12.0	15.1	19.2	50.6
Specific activity, μmole min^{-1} m^{-2} Ni	6.2	4.2	3.6	3.8

Rijnten and coworkers [84] also failed to observe a significant effect of crystallite size on the specific activity of nickel towards the gas-phase hydrogenation of benzene (Table 19). It is evident from the Table that even in the region of large changes in the relative numbers of centres with different coordination (12–50 Å particle size) the changes in specific activity are only marginal.

In contrast to these findings, Sinfelt and coworkers [85] (who studied the effect of crystallite size of nickel deposited on $Al_2O_3-SiO_2$ on the rate of hydrogenolysis of ethane) observed a sharp decrease in the specific activity of nickel with increase of crystallite size (Fig. 12). The same workers [86] reported a 50-fold increase in the specific activity for the hydrogenolysis of ethane associated with an increase in crystal size from 12 to 24 Å, but in this case the situation was complicated by a simultaneous increase in nickel content from 1 to 10%. There is also a large difference in specific activity between nickel catalysts supported on Al_2O_3 and on $Al_2O_3-SiO_2$, in spite of the similarity in particle size (Table 20).

Van Hardeveld and Hartog [87] found that the specific activity of nickel catalysts towards the deuteriation of benzene remains approximately constant as the nickel particle size is varied from 20 to 185 Å, but the relative rates of deuteriation and exchange are significantly affected.

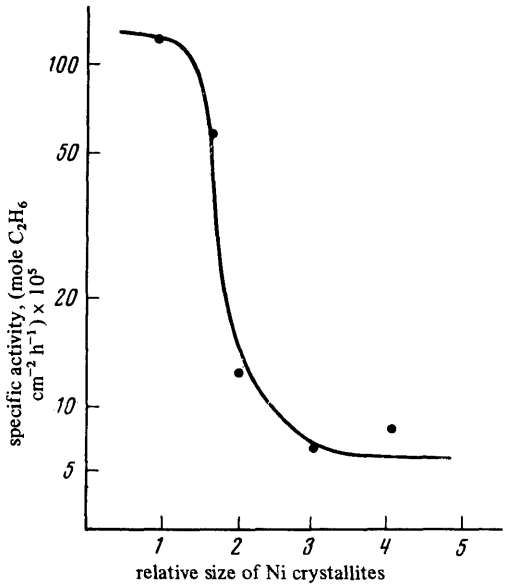

Figure 12. Specific activity of nickel in the hydrogenolysis of ethane at 267° against relative crystallite size. The size of the crystallites in the sample reduced at 370° is taken as unity (Ref. 85).

Table 20. Effect of crystallite size on the specific activity of nickel towards the hydrogenolysis of ethane (Ref. 86).

Ni content, wt.%	Carrier	Crystallite size, A	Specific activity, mole h^{-1} m^{-2} Ni
1	Silica gel	12	11
10	Silica gel	24	500
10	Al_2O_3	23	260
1	SiO_2 — Al_2O_3	26	0.08
10	SiO_2 — Al_2O_3	29	9.5

IV. DEPENDENCE OF THE SPECIFIC ACTIVITY OF CATALYSTS ON THE METHOD OF PREPARATION

Platinum and palladium. Schnabel and coworkers [88] studied the effect of the heat-treatment temperature of an activated charcoal on the specific activity of platinum (deposited on the charcoal) towards the dehydrogenation of cyclohexane, the C_5-dehydrocyclisation of iso-octane, and the hydrogenation of benzene. As the temperature was raised from 100 to 1070°, the specific activity of the platinum decreased by a factor of 2 for the first reaction and varied by not more than a factor of 4 for the second. The sample deposited on charcoal heat treated at 300° was inactive towards the hydrogenation of benzene. Samples prepared by depositing platinum on BAU charcoal heated at 1100° and treated by the Curtius method have a specific activity of 3.8×10^{-2} and 2.76×10^{-2} mole m^{-2} Pt respectively (i.e. practically identical). Another paper [89] from the same laboratory describes the changes in specific activity of platinum deposited on BAU charcoal heat treated at 300–2300° towards the C_5-dehydrocyclisation of iso-octane. It can be seen from Table 21 that the specific activity varies by less than a factor of 2.

Table 21. Specific activity of platinum on BAU activated charcoal towards the dehydrocyclisation of iso-octane (Ref. 89).

Carrier heat-treatment temperature, °C	300	1400	2000	2300	2800	1000 vacuum
Specific activity of Pt at 310° (mmole m^{-2} Pt h^{-1}) × 10^2	4.7	4.0	6.3	7.6	9.3	5.7

The specific activity of Pt and Pd catalysts prepared by different methods has been found [90,91] to be approximately constant also in respect of the hydrogenation of benzene.

Nickel. Tetenyi and coworkers [92] have studied the influence of method of preparation on the dispersion and specific activity of nickel black towards the dehydrogenation of cyclohexane and the decomposition of isopropanol and t-butanol. They were unable to establish any definite correlation between the activity and the dispersion of the nickel crystallites, the specific activity increasing more than 30-fold for relatively small changes in crystallite size. The conclusion from this work was that the specific activity depends on the method of preparation of the catalysts.

Crawford and coworkers [93], who studied the effect of sintering temperature on the specific activity of nickel black towards the hydrogenation of ethylene, disagree with this conclusion. They found that the specific activity varies only from 8.9 to 1.1 min^{-1} over a range of sintering temperatures between 25 and 400°, and they conclude that the loss of activity could be due to poisoning of the small catalyst surface by impurities evolved from the apparatus.

Catalysts prepared by reduction of NiO obtained by thermal decomposition of the hydroxide, basic carbonate, and acetate, and also by reduction of various mixtures of NiO, SiO_2, Al_2O_3, and Cr_2O_3 have been examined in the writer's laboratory [28]. Their catalytic activity towards the hydrogenation of benzene was found to be directly proportional to the surface area of metallic nickel and independent of the starting materials and of the method of preparation (Fig. 1).

Sinfelt and coworkers [94] studied the activity of nickel catalysts on silica gel towards the hydrogenolysis of ethane in a flow system. By varying the preparative conditions they were unable to vary the surface area by a factor of 3, but the specific activity varied only by a factor of 1.5.

Shephard [95] has described a detailed study of the effect of washing, and of heat treatment at 340–1160°, on the specific activity of an industrial nickel–alumina catalyst for the hydrogenolysis of propane. The catalytic activity was measured in a flow system. With the exception of one

sample, the catalytic activity before the leaching treatment was found to be proportional to the surface area of nickel. After being leached the catalysts contained a small amount of sodium, and their activity was somewhat higher. However, it is pointed out that these results could be due to insufficient precision in the measurement of surface area by hydrogen adsorption.

The specific activity of the nickel in nickel–chromia and nickel–magnesia catalysts for the hydrogenation of CO and CO_2 has been found to be independent of the temperature of heat treatment [96,97].

Vasserberg and coworkers [98] studied the effect of the preparation on the activity of nickel catalysts for the hydrogenation of CO_2. The catalysts were prepared by gas-phase deposition of carbonyl nickel on Al_2O_3 (series I) and by impregnation with a solution of $Ni(NO_3)_2$ (series II); three samples of industrial catalysts were also examined. Surface areas were measured by O_2 chemisorption. The activity was measured in a vacuum system with circulation, and characterised by the first-order rate constant of the reaction. It was found that samples of series I (containing less than 0.75% Ni) and of series II (containing 1.5% Ni or less) do not adsorb significant amounts of O_2 and have negligible catalytic activity. In samples with a higher nickel content the specific activity varies between 5.3 and 25.6×10^{-3} min^{-1} m^{-2} Ni.

Iron. Samchenko and coworkers [99,100] studied the effect of preparative conditions on the activity of doubly promoted iron catalysts in the synthesis of ammonia. The catalysts were characterised both in terms of total surface area and in terms of fractional occupancy of the surface by metallic iron, alkali, and aluminium oxide. The rate constants calculated for a unit area of alkali and Al_2O_3 were very variable, but the specific activity of the free iron surface was practically constant for all the samples, irrespectively of composition.

---o0o---

The experimental work discussed in this review justifies the following statements: 1) in spite of the widely held view that the specific activity of catalysts should be a function of dispersion, method of preparation, etc., in the vast majority of cases the specific activity is found to be approximately constant; 2) contradictory results are reported by different workers: some workers find a constant specific activity whilst others, working on the same system, find large changes in specific activity under the influence of various factors. The constancy or otherwise of the specific activity is unrelated to the nature of the catalyst or to the type of reaction under study. In this Section we shall attempt to analyse the possible causes of these discrepancies, and to clarify as far as possible the validity of "Boreskov's rule" [55], which predicts an approximately constant specific activity.

The discrepancy between the results of different workers may be due to the following causes: 1) inadequacy of the experimental procedures used to determine the surface area of metal on the carrier, and also incorrect characterisation of the catalytic activity; 2) neglect of heat and matter transport processes; 3) influence of uncontrolled impurities in the catalyst and in the reaction mixture; 4) blocking of the surface by reaction products, and 5) measurements of the activity before the catalyst surface has reached a steady state in the reaction mixture.

In order to measure the specific activity correctly, the following conditions must be satisfied: a) the catalytic surface area (in this case, the area of metal on the carrier) must be measured correctly, and b) the catalytic activity must be correctly characterised. The surface area of metals on carriers is usually measured [101,102] under conditions when gas adsorption occurs only on the metal. The shortcoming of this method is the possible dependence of the adsorption capacity per unit area of the metal upon the dispersion. For example, the H/Pt or O/Pt ratio can vary from 1 to 2 when the particle size of Pt on Al_2O_3 is varied [103,104]. Similar effects have been observed on nickel. Hence, even if the true specific activity is strictly constant it is possible for the apparent specific activity to vary by a factor of 2 unless due allowance is made for changes in the gas/metal ratio.

There is still no generally accepted method of measuring the activity of catalysts. The most satisfactory method [18,19] appears to be to characterise the activity in terms of the rate constant. If the kinetic equation is not known, the activity of the catalyst can be characterised by the reaction rate at a given extent of reaction. Consistent results are obtained if the extent of reaction is small, the kinetic order of the reaction is nearly zero, and the system is not allowed to approach equilibrium. On the other hand, serious discrepancies can result if the extent of reaction is large enough to bring the system near equilibrium. The changes in specific activity reported by Larsen and coworkers [69] are probably due to this effect.

The effect of diffusion on catalytic reactions has been investigated by Boreskov [105–107], Slin'ko [108–110], and their coworkers. Diffusional limitations can have a very marked effect on the observed reaction rate. Thus, on varying the size of Al_2O_3 granules from 0.10–0.15 to 2–3 mm the specific activity of a given catalyst towards the decomposition of ethanol decreases by more than an order of magnitude as a result of diffusional control [111]. The extent of diffusional control depends on the porosity of the catalyst structure: the smaller the typical pore radius, and the larger the grain size, the lower will be the temperature at which rate limitation by the diffusion of reactants will set in [112]. If the experimental catalysts have different pore structures, and the measurements are not made under activation-limited conditions, the observed activities can be in error through differences in the amount of diffusional limitation. Furthermore, the imposition of diffusional limitation influences the selectivity of the catalyst in the direction of smaller yields of intermediates and greater yields of final products [113]. Hence, one of the most important prerequisites to ensure reliable results is the adoption of activation-limited conditions. Unfortunately, only a minority of authors specifies whether their results were obtained under activational or diffusional control. Very probably, some of the faster reactions studied on relatively large-grained catalysts were taking place in the diffusion-limited region. This effect could explain the reported dependence [92] of catalytic activity on crystallite size, since that investigation of a very active catalyst (nickel black) was carried out without the necessary precautions.

Impurities, often uncontrolled, can contaminate the catalyst both at the preparation stage and during the investigation. The reaction can be inhibited or accelerated by impurities. Thus, small amounts of alkali metals are known to lower the activity of oxides towards reactions involving an acidic mechanism [114,115], and traces of Al_2O_3 (less than 0.1%) can increase very substantially the activity of silica gel [116,117]. Similar effects have been reported [118,119] for metallic catalysts. Dorling and coworkers [72] have shown that the large changes in the

specific activity of platinum towards the hydrogenation of ethylene brought about by changes in preparative conditions are due to traces of HCl, which is sorbed by the catalyst and has a promoting effect on the reaction. Higher heat-treatment temperatures decrease the surface area of platinum and at the same time remove the HCl, thus lowering the specific activity.

Changes in catalytic activity associated with the take-up of impurities from the reaction medium are due to the formation of surface compounds between the impurity and the catalyst. The mechanism of the poisoning effect, and its reversibility, are determined by the stability of this compound under the experimental conditions. If the compound is not very stable it can be dissociated by lowering the partial pressure of the impurity or raising the temperature, and the activity of the catalyst can be restored to its initial value [120]. If, on the other hand, a very stable surface compound is formed by adsorption, the poisoning effect is irreversible [120-122].

Quite small concentrations of impurities are usually sufficient to produce significant poisoning effects. For example, Lyubarskii found [26] that a sulphur concentration of 10 parts per million (p.p.m.) in benzene is sufficient to cause appreciable poisoning of a nickel–chromia catalyst. In another investigation [123], 5 p.p.m. of water were found to deactivate small quantities of catalyst completely towards the polymerisation of ethylene: to obtain a measurable reaction rate the amount of catalyst in the reactor had to be kept above some "threshold" level. A similar effect has been reported by Poltorak and coworkers [124] for the decomposition of H_2O_2.

The poisoning effect of impurities will be stronger, of course, the higher the impurity concentration and the smaller the surface area of the active component of the catalyst. This is the most likely explanation of the large differences in specific activity obtained from studies in different laboratories of the effect of dispersion and of the temperature of heat treatment. Thus, Dorling and Moss [68] observed an approximately constant specific activity with increasing heat-treatment temperature until the surface area of Pt had fallen to 0.2 $m^2 g^{-1}$, when the catalyst suddenly became inactive. Similarly, Crawford and coworkers [93] found that the specific activity of their nickel films fell by a factor of 3 when the annealing temperature was raised from 300 to 400°. It is quite possible, also, that the deactivation of nickel catalysts containing small amounts of nickel reported by Dergachev and coworkers [98] was due to poisoning by traces of mercury (present in the vacuum system as a manometric fluid).

The opposite effect, activation of the catalyst by impurities in the reacting system, is far less commonly observed [72].

It follows from these considerations that a correct judgement of the constancy or otherwise of the specific activity can be made only in the knowledge of the impurity content of the reacting system and of the type of interaction to be expected between the impurity and the catalyst.

In addition to the impurities introduced with the reactants, any relatively involatile reaction products retained on the catalyst surface can affect the reaction rate. Catalyst poisoning by "fragments" of organic molecules has been observed in many reactions, including simple reactions (like the hydrogenation of ethylene [72,126]) as well as reactions involving the decomposition of large organic molecules [125].

Carbonisation of the catalyst can affect the selectivity as well as the rate of the reaction. Thus, Panchenkov and coworkers [127] found that the selectivity of an industrial alumina–silica catalyst for the cracking of n-decane changes very significantly with increasing reaction time (and hence extent of carbonisation of the catalyst): the yield of intermediate products (olefins) goes through a maximum, and the yield of the final products increases continuously.

We may conclude from these observations that time-variations in the activity of the catalyst may be responsible for some of the erroneous results obtained in studies of the influence of various factors on the specific activity. McKee's results [78] for the cracking of propane on platinum black were very probably vitiated by the non-stationary activity of the catalyst.

Changes in catalytic activity due to changes in catalyst composition brought about by interactions with the reacting medium are less clearly recognised, but nonetheless very common. According to Boreskov [128], these interactions can lead to: 1) deep-seated changes in chemical composition, accompanied by phase transitions of the active component; 2) changes in chemical composition without phase transitions; 3) compositional changes in the surface layer of the catalyst. All these changes are accompanied by more or less pronounced changes in specific activity. A good example of this effect is Boreskov and Matveev's observation [129] of a 500-fold increase in the specific activity of zinc oxide due to partial reduction of the catalyst during the decomposition of methanol: a phase of metallic zinc is not formed, but the stoichiometric ratio of oxygen to zinc in the oxide phase is lowered by the reducing action of the medium. A similar effect takes place during the reaction between H_2 and O_2 on platinum [130]. Boreskov also showed that the interaction between the catalyst and the reacting system can produce changes in the kinetics of the reaction as well as in the specific activity of the catalyst [131].

The steady-state composition (and hence activity) of the catalyst depends on the composition of the reacting system and on temperature: sufficient time must be allowed for the catalyst to reach a steady state.

Different workers, investigating similar (or even identical) catalysts and reactions by flow and by pulsed methods, usually find that the specific activity is constant if they are using the flow method and variable if they are using pulsed methods. It seems likely that in the pulsed regime [36-38,85,86] the surface layer cannot reach steady state, and the observed specific activity is seriously in error. We may suggest that the large differences in specific activity observed in pulsed measurements [36-38,85,86] are not due to the "difficulty" of the reaction, or to the "need" for a special surface topography [71], since other workers [33,35,70,74,75] found no evidence of this type of specificity. The most likely reason for the discrepancy is the use of a pulsed method to measure the activity, since it is difficult to believe that steady state can have been achieved in the short time (3–5 min) allowed for each experiment.

Thus, this review of the published work leads us to conclude that in most cases the specific activity is found to be constant if the correct experimental procedure has been used. Large changes in dispersion, and in the method of preparation of the catalyst, yield only a 3-fold change in specific activity. This relative constancy may be due to interaction between the catalyst surface and the reaction medium, which converts the initial surface structure into a final state independent of the previous history of the catalyst. Lastly, we cannot exclude the possibility of genuine differences in specific activity arising from the

retention of a non-steady-state structure in low-temperature reactions, but we have not found any experimental evidence of this effect in the published literature. Significant differences in specific activity are not encountered under the normal conditions of the majority of industrial catalytic processes.

The Rate of Extraction Under Kinetic Conditions (Reaction in the Bulk Phase)

V.V.Fomin and G.A.Leman

Under kinetic conditions the rate of extraction depends on the rate of one or two slow reactions in the aqueous phase with the ion A^- or the molecule HA and also on the rate of reaction in the aqueous phase not involving the extractant. This has been examined for the extraction of trace amounts of bivalent and tervalent elements from aqueous solutions of their salts by solutions of an acid HA in organic solvents. The rate of extraction varies in a complex manner both with the rate constants for the corresponding reactions and with the stability constants of the complex ions formed; for this reason, studies on the mechanism of the reactions determining the rate of extraction in which no account was taken of complex formation in general give erroneous results. The possibility of using the proposed methods to determine the mechanism of the extraction of macroamounts of a univalent element has been demonstrated.
The bibliography includes 83 references.

I. INTRODUCTION

The study of the rate of extraction has significant practical interest, since the efficiency or size of extraction apparatus depends on the rate. The rate of extraction is also of theoretical interest, since it makes it possible to establish the mechanism of extraction, which cannot be done by studying extraction equilibria alone.

The extraction of inorganic compounds is usually accompanied by chemical processes: the formation of salts in extraction by acids and amines and of solvates in extraction by neutral extractants[1]. Apart from the reactions with extractants, other reactions may occur, for example complex formation and hydrolysis in the aqueous phase, which determine the rate of extraction. We refer to such processes not involving the extractant as "side" reactions[2]. There is no doubt that the slow shift of equilibrium in hydrolysis accounts for the time variation of the partition coefficients in the extraction of zirconium from nitric acid solutions by solutions of dicresylphosphoric acid in organic solvents[3].

Since the reactions can occur both in the bulk phases and at the interface, heterophase and heterogeneous reactions are distinguished[4].

The wide-scale and increasing application of extraction in technology increases interest in the question of the rate of extraction, which has been noted, for example, in a review published in 1964.[5] The number of studies on this topic has now greatly increased. However, in most of the published work the authors confine themselves to characterising the dependence of the degree of extraction or the partition coefficient on time without establishing the mechanism of the process determining the rate of extraction.

Extraction is always associated with the transfer of a substance from one phase to another (mass transfer) and therefore its rate can be determined by the rate of the reaction occurring, the rate of mass transfer, or the rates of both processes.

If the rate of extraction depends only on the rate of the chemical reaction, the process is said to occur under kinetic conditions, when the rate of extraction depends only on the rate of mass transfer, it is said to occur under diffusion-dependent conditions, and, when the rate of extraction depends on the rate of both the reaction and of mass transfer, the process is said to take place under mixed conditions.

Under kinetic conditions, the rate of mass transfer is so high that at any instant an equilibrium distribution between the phases of the compound passing from one phase to the other is virtually attained[6,7]; however, in extraction this is valid only for the given compound and not for all the compounds of the element being extracted which exist in the system investigated.

For example, when in the extraction of iron from aqueous solutions of inorganic acids by acetylacetone solutions FeA_3 (A is the acetylacetonate anion) is formed slowly in the aqueous phase and only this compound passes to the organic phase, then, under kinetic conditions, equilibrium in its distribution between the phases is established very rapidly ("instantaneously"), but a long time is needed to establish the equilibrium in the determination of analytical concentrations of iron.

Under diffusion-dependent conditions, the rates of the chemical reactions in the given system are so high that equilibrium between the compounds present is virtually attained in every phase but there is no equilibrium between the phases.

The rate of mass transfer depends on the rate of stirring of the phases, which determines the rate of transfer of material from the bulk of the phase to its surface and from the surface to the bulk and also on the area of the interface. Under kinetic conditions, the rate of mass transfer is so high that a change in the area of the interface and in the rate of stirring hardly disturbs the equilibrium distribution of the compound extracted and the change in its concentration is due solely to the rate of the chemical reaction; for this reason, the rate of extraction in

this region is independent of both the area of the interface and of the rate of stirring of the phases.

Under diffusion-dependent and mixed conditions, the rate of extraction depends on the rate of mass transfer and hence on the rate of stirring and the area of the interface. Only after having demonstrated that this type of dependence exists can one assert that the process takes place under one of the above conditions.

However, if the extraction is accompanied by a reaction at the interface, then under kinetic conditions the rate of extraction is independent of the rate of stirring for a constant area of the interface but varies with the area for a constant rate of stirring. This is in fact why in the determination of the conditions under which the process takes place it is necessary to determine the dependence of the rate both on the rate of stirring for a constant area of the interface and on the area of the interface for a constant rate of stirring.

Under mixed conditions as well as under diffusion-dependent conditions, the rate of extraction varies with the rate of stirring and with the area of the interface, which makes it difficult to solve the problem of the process conditions, but, as will be shown below, there are methods whereby one can deduce whether one process (diffusion-dependent conditions) or two processes with comparable rates take place.

With increased rate of mixing of the phases, there is usually an increase of the degree of comminution and hence of the area of the interface and therefore the absence of a dependence of the rate of extraction on the rate of stirring is frequently regarded as evidence that the process occurs under kinetic conditions. However, it has been noted in the literature that a constant rate of dissolution of a solid can be maintained by increasing the rate of rotation of the stirrer[8].

Since only the absence of a dependence of the rate of extraction both on the rate of stirring and on the area of the interface is convincing evidence for a transition of the process to kinetic conditions with the reaction in the bulk of one or both phases, in order to establish the extraction mechanism it is necessary to determine at least the relative surface areas of the phases. A number of methods have been proposed for this, among which the most convenient for extraction (in the case of dispersed phases) are the light scattering and photographic methods. The methods have been described and examples of their applications in studies on the rate of mass transfer have been given, for example, in Refs. 9–18.

When light passes through an emulsion, the specific surface S/V (S is the area of the emulsion and V its volume) is determined from the equation

$$\frac{I_0}{I} = 1 + \beta \frac{S}{V} \quad , \qquad (1)$$

where I_0 is the intensity of the light which has passed through the continuous phase (without emulsion), I the intensity of the light which has passed through the emulsion, and β a coefficient which depends on the refractive indices of the phases. This equation makes it possible to find the ratio of the surface areas of the emulsion in two experiments with different rates of stirring without knowing β and hence one can solve the problem of whether or not the change in the surface area affects the rate of the process. We may note that, in order to determine the degree of light scattering, one can employ a nephelometer using its cell as an extraction vessel[19].

The dimensions of drops and hence their surface areas can be determined by the sedimentation method[20], but the method suffers from the disadvantage that the process has to be interrupted and the surface areas must be determined in independent experiments.

Under diffusion-dependent conditions in a system with constant partition and mass transfer coefficients, the change in the concentration in the receiving phase over a time t, when the concentration is initially zero, is given by the equation

$$\ln \frac{C_{2p} - C_2}{C_2} = -\frac{K_2(q+1)}{V} S t \quad , \qquad (2)$$

where V is the phase volume ($V_1 = V_2$), S the area of the interface, $q = C_{2p}/C_{1p}$ the partition coefficient, and K_2 the mass transfer coefficient referred to the receiving phase.

Then, in the first experiment (area S_1) we have $\ln 2 = K_2(q+1)S_1 t/V$ after a time interval such that, for example, $C_2 = 0.5C_{2p}$, where C_{2p} is the equilibrium concentration in the given system. In another experiment (area S_2) the change in concentration during the same time interval can be found from the equation $\ln (C_{2p} - C_2)/C_{2p} = -\ln (2S_1/S_2)$. If $S_1/S_2 = 2$, then

$$\ln \frac{C_{2p} - C_2}{C_{2p}} = -\ln 4 \text{ and } C_2 = 0.75 C_{2p} \quad .$$

Thus, for constant mass-transfer and partition coefficients, the change in area by a factor of two leads to a change in concentration in the receiving phase (during the same period) by a factor of 1.5, which can be readily detected. If the increase in area has occurred as a result of an increase of the rate of stirring, then, under diffusion-dependent conditions, there is an increase of the mass-transfer coefficient and the change in concentration is even greater.

In the study of the rate of mass transfer one frequently employs apparatus with a constant area of the interface, for example that proposed by Lewis[21]. In such apparatus the phases are separated by a horizontal partition with an annular aperture in which the level of the interface is established and each phase is agitated by its own stirrer. However, in this system the thickness of the ring has some importance, since the conditions governing the stirring of the liquids in the gap may differ from those in the bulk of the phases, which may affect the process conditions.

In the study of the rate of mass transfer one frequently employs cylindrical vessels with vertical partitions. Their purpose is to prevent the breakdown of the surface during the stirring of the phases, i.e. to prevent the formation of waves[22–24].

However, apparatus with a constant area of the interface has a small specific surface and hence the rate of mass transfer is also low, as a result of which many processes which occur under kinetic conditions when the phases are dispersed can occur under mixed or diffusion-dependent conditions in apparatus with a constant area of the interface[19].

The employment of apparatus of the Lewis type with a variable width of the annular aperture can be useful in testing the hypothesis that the process occurs under kinetic conditions with a surface reaction, since in such apparatus one can vary the area of the interface keeping constant the rate of stirring or one can vary the rate of stirring keeping constant the area of the interface.

In studies on diffusion accompanied by a chemical reaction and on mass transfer with chemical reaction[25,26] it has been shown that, for a fairly high rate of reaction (for this reason it takes place in the diffusion film), the rate of the process under the conditions of a constant area

of the interface is independent of the rate of stirring. Such conditions are referred to as fast reaction conditions[27]. They resemble the kinetic conditions with a surface reaction. An example of mass transfer with a rapid or surface reaction is the interaction of certain organic [sic!] formates and acetates with aqueous solutions of alkalis accompanied by the transfer of the acid to the aqueous phase and its neutralisation. These reactions are used to determine the dependence of the surface area of the emulsion on the rate of stirring and on the design of the stirrers[28-31]. They can be used to test the constancy of the area of the interface when the rate of stirring is varied in apparatus of the Lewis type and particularly in cylindrical vessels with partitions.

If it has been shown that at a certain rate of stirring, the process proceeds under kinetic conditions, then, by changing the rate of stirring, it is impossible to increase the rate of extraction, since the latter is determined by the rate of the chemical reaction. In this case the rate of extraction can be increased only by increasing the rate of reaction (by increasing the concentration or temperature). Under diffusion-dependent or mixed conditions, the rate of extraction can be raised by increasing the area of the interface and the rate of stirring as long as the process does not pass to kinetic conditions.

The extraction mechanism and the rate of the reactions taking place can be determined most simply under kinetic conditions. As will be shown below, even in this case the problem is more difficult than the determination of the mechanism and of the rates of reactions in a homogeneous system, but the difficulty becomes even more marked under mixed conditions.

An important complication in the study of extraction kinetics is associated with the measurement of concentration when one of the phases is dispersed. The main method, in which the stirring of the phases is stopped and the latter are allowed to separate before removing the samples, distorts the results, since the hydrodynamic conditions and the area of the interface change during this period. This type of method can be used only for fairly slow processes. The effect of the interruptions on the results of the measurement of the rate can be tested by carrying out two experiments under the same conditions. In one experiment samples are removed twice or more frequently and in the other only one sample is removed after stirring for a period equal in duration to the overall time of stirring in the first experiment. Comparison of the results will then reveal the effect of the interruption of stirring.

A method has been proposed[14] for the measurement of concentration in a continuous aqueous phase in the presence of an emulsion on the basis of conductivity. The application of this method is restricted to systems with one electrolyte in the aqueous phase and does not allow the employment of trace amounts of radioactive elements, the use of which frequently simplifies the interpretation of the experimental data, because the concentrations of the other components, reacting with the given element, can be regarded as constant. It is much easier to measure the concentration in apparatus with a constant level of the interface. In this case one can measure the conductivity in the aqueous and sometimes in the organic phases[32,33], the radioactivity of the phase can be determined (for example on the basis of γ-radiation) when radioactive isotopes are employed[34-37], and removal of samples for analysis is simplified (samples can be removed without stopping the stirrer).

A significant defect of many studies on extraction kinetics is that the authors did not establish the conditions under which the process occurred, introducing thereby an uncertainty into their results.

In a number of studies[38-46] the authors assumed that the extraction proceeds under kinetic conditions (with the reaction in the aqueous phase) and described the rate of extraction by an equation of the type

$$-\frac{d[M]_w}{dt} = \varkappa [M]^m \ [A]^n , \qquad (3)$$

where [M] is the analytical concentration of the element being extracted, [A] the concentration of the extractant anions in the aqueous phase when the extractant is an acid HA, and κ the rate constant for the reaction determining the rate of extraction. Under these conditions, one frequently employs trace amounts of the compound (element) being extracted and for this reason [A] in a given experiment at constant pH is itself constant. Then Eqn. (3) can be put in the form

$$-\frac{d[M]_w}{dt} = \varkappa' [M]_w^m , \qquad (4a)$$

where $\kappa' = \kappa[A]^n$ and $[A] = K_{HA}[HA]_0/q_{HA}[H^+]$, $[HA]_0$ being the concentration of the acid HA in the organic phase, q_{HA} is the partition coefficient, and K_{HA} the dissociation constant. If $m = 1$, integration of Eqn. (4a) yields

$$\ln \frac{[M]_w}{[M]_w^0} = -\varkappa' t , \qquad (4b)$$

where $[M]_w^0$ is the initial concentration of M in the aqueous phase. If $m > 1$, then integration gives

$$\frac{1}{[M]_w^{m-1}} - \frac{1}{([M]_w^0)^{m-1}} = (m-1)\ \varkappa' t . \qquad (4c)$$

These equations make it possible to find m and κ' for the given value of [A] by varying t. Assuming that m is constant and having determined κ' for different concentrations of the extractant [A], it is possible to find κ and n. For example, it was established in this way that in the extraction of zinc from aqueous solutions of its salt by dithizone solutions in organic solvents, $m = 1$ and $n = 1$ and therefore the authors[38] suggest that the rate of extraction is determined by the rate of the reaction $Zn^{2+} + A^- \rightleftharpoons ZnA^+$, while the reaction $ZnA^+ + A^- \rightleftharpoons ZnA_2$ and mass transfer are rapid. The extraction mechanisms have been determined similarly also in other investigations[39-46]. However Eqns. (4a), (4b), and (4c) do not reflect the essential property of extraction—its reversibility. It follows from these equations that, when t tends to infinity, $[M]_w$ tends to zero and the plot of $\ln\{[M]_w/[M]_0\}$ as a function of t will be linear up to infinity, although it is evident that, under the specified conditions, $\ln\{[M]_w/[M]_w^0\}$ will approach a limit equal to $\ln\{[M]_{w,e}/[M]_w^0\}$, where $[M]_{w,e}$ is the equilibrium concentration.

In addition, the equations quoted above include the analytical concentration of the element M in the aqueous phase, although the latter contains its various species, namely complex ions and molecules. Thus in the example quoted the ions and the species ZnA^+ and ZnA_2 exist in the aqueous phase, which follows from the hypothesis, adopted in the study quoted, that the processes take place in steps. In the extraction of acids and salts from solutions, complexes with the corresponding ions are formed in the aqueous phase and for this reason the concentration of the cations of M or of any compounds involved in the reaction determining the rate of extraction can differ significantly from the analytical concentration of the element M. For example, in a study[47] of the rate of extraction of beryllium

by thenoyltrifluoroacetone (TTA) from a mixture of hydrochloric and perchloric acids (with a constant overall concentration) the equation for the rate of extraction was put in the form $-d[Be^{2+}]/dt = K^*[Be]^a[HA]_o^b[H^+]^c[ClO_4^-]^d$, where $[HA]_o$ is the concentration of TTA in the organic phase, $K^* = \kappa K_A/D$, K_A the dissociation constant of TTA, D its partition coefficient, and κ the reaction rate constant. The concentration of ClO_4^- ions has been included in the equation, since it has been established that the rate of extraction increases with increase in the concentration of perchloric acid (and with the corresponding decrease in hydrochloric acid concentration). To account for this dependence, the authors suggest that beryllium perchlorate passes to the organic phase where it is very rapidly converted into the thenoyltrifluoroacetonate and perchloric acid is also rapidly re-extracted. However, beryllium chloride complexes are formed in the aqueous solution (the authors quote the stability constants) and therefore the analytical concentration is not equal, for example, to the concentration of Be^{2+} ions and the rate equation must include the concentration of those beryllium cations or complex ions directly involved in the reaction determining the rate of extraction and not the analytical concentration of beryllium. In particular, when TTA reacts with Be^{2+} ions, the concentration of the latter must increase with increase of the concentration of perchloric acid, since the concentrations of chloride ions and beryllium chloride complexes then decrease.

It has been noted in the literature that complex formation can decrease the rate of extraction[40]†. In particular it has been shown[48] that, in the extraction of zinc by dithizone, the introduction of chloride ions into the aqueous phase reduces the rate of extraction and increases the rate of re-extraction. However, the introduction of certain substances to the aqueous phase sometimes increases the rate of extraction. For example, the extraction of iron by thenoyltrifluoroacetone is slow, but the introduction of ammonium thiocyanate into the aqueous phase increases its rate[49]. In the extraction of chromium by TTA or hydroxyquinoline, sodium acetate[50], ammonium fluoride, and other compounds[51-53] have a similar effect. These examples show that the rate of extraction is not determined by the analytical concentration of the element being extracted and the expression for the rate of extraction in terms of the latter constitutes only an empirical description of the process and does not yield information about the mechanism of extraction.

Finally, in the investigations quoted no account is taken of the fact that each phase is an open system and therefore a change in the concentrations of certain compounds is caused not only by a chemical reaction but also by the transfer of compounds from one phase to another. Problems associated with the rate of reactions in open systems have been considered in the literature[4,54], but usually for processes in flow-type apparatus of different kinds and not for extraction.

In this connection, the mechanism of extraction under kinetic conditions with complex formation in the aqueous phase has been examined in greater detail, in particular for complex formation involving the extractant or its ions. An acid HA was employed as the extractant and it was assumed for simplicity that complex anions involving A^- are not formed in the aqueous phase (this does not alter the general approach to the problem, but reduces the number of parameters introduced into the corresponding equations) and in the organic phase there are no solvates formed by the extractant with the salt being extracted. We shall restrict the treatment to reactions in the bulk of the aqueous phase and in the first place to the extraction of trace amounts of the corresponding substance; also we shall disregard the use of isotope exchange for this purpose, which has been briefly described already[55].

Some results of such analysis have already been published[56,57]; this review gives a systematic description of the problem and a number of possible mechanisms, which were not analysed previously, are discussed.

II. ONE SLOW REACTION WITH THE EXTRACTANT (AN ACID HA) IN THE AQUEOUS PHASE

We shall consider the determination of the rate of extraction under kinetic conditions in the case of one slow reaction of the metal being extracted, forming the ions M^{3+} in the aqueous phase, with the extractant (an acid HA) under conditions such that the rate of reaction is determined by the concentrations of the reactants (the activity coefficients are virtually unity). The molecules MA_3 formed in the aqueous phase pass to the organic phase. In the general case the flux of the molecules MA_3 from the aqueous to the organic phase is

$$j = K_w([MA_3]_w - [MA_3]_w^*) \quad , \qquad (5)$$

where $[MA_3]_w$ is the concentration of these molecules in the aqueous phase and $[MA_3]_w^*$ the concentration which must occur in this phase at a given instant to ensure its equilibrium with the organic phase. Then $[MA_3]_w^* = [MA_3]_o/q_{MA_3}$, where q_{MA_3} is the partition coefficient of the compound MA_3, $[MA_3]_o$ the concentration of MA_3 in the organic phase, and K_w the mass transfer coefficient referred to the aqueous phase‡. We believe that the mass-transfer coefficient of a specific compound as well as its partition coefficient are independent of phase composition (concentrations of the components) over a fairly wide concentration range; for this reason, the driving force of the mass-transfer process can be expressed in terms of the concentrations as $[MA_3]_w - [MA_3]_w^*$. This is confirmed by the determinations of a number of mass transfer coefficients for compounds which remain unchanged in extraction[58,59]. However, under kinetic conditions there is virtually an equilibrium between the phases with respect to the compound MA_3, so that the driving force of the process is extremely small, but the mass transfer coefficient is very high (in the limit the driving force is zero and the mass transfer coefficient is infinite). The flux is a finite quantity determined by the rate of reaction.

The necessity to determine the rate from the variation of the analytical concentration of the element extracted in one or both phases constitutes a difficulty in the employment of trace amounts of the element. In the extraction of macroamounts it is possible to determine the concentrations of individual compounds by physical methods, for example by spectrophotometry, NMR, etc., but we have been unable to find examples of such studies in relation to the rate of extraction. Moreover, when the concentrations of individual compounds cannot be determined in the

† The same investigation quotes a number of references to other publications where the effect of complex formation on the rate of extraction is also noted.

‡ Eqn. (5) is also used in the form $j = K_o\{[MA_3]_o^* - [MA_3]_o\}$, where $K_o = K_w/q_{MA_3}$ is the mass transfer coefficient referred to the organic phase.

extraction of macroamounts, the number of variables increases, which, as shown below, makes it difficult to interpret the experimental results.

We examined previously[56,57] the effect of the rate of complex formation on the rate of extraction of trace amounts of an element M^{3+} by an acid HA under kinetic conditions when the reactions occur in the aqueous phase and the rate of extraction is determined by the rate of one of three reactions:

$$M^{3+} + A^- \underset{\varkappa_2}{\overset{\varkappa_1}{\rightleftarrows}} MA^{2+} \quad , \tag{I}$$

$$MA^{2+} + A^- \underset{\varkappa_4}{\overset{\varkappa_3}{\rightleftarrows}} MA_2^+ \quad , \tag{II}$$

$$MA_2^+ + A^- \underset{\varkappa_6}{\overset{\varkappa_5}{\rightleftarrows}} MA_3 \quad . \tag{III}$$

The other two reactions and mass transfer are very rapid ("instantaneous"), so that they reach equilibrium at any instant. It is then assumed that the effect of the rate of mass transfer of the acid HA and of the rate of its dissociation is eliminated by the fact that the phases are equilibrated with respect to the macrocomponents, including the extractant, and the changes in their concentrations may be neglected when trace amounts of the element extracted are employed§.

The processes occurring in the system are described by the equations

$$-\frac{d[M^{3+}]}{dt} = \varkappa_1[M^{3+}][A^-] - \varkappa_2[MA^{2+}] \quad , \tag{6a}$$

$$\frac{d[MA^{2+}]}{dt} = \varkappa_1[M^{3+}][A^-] - \varkappa_2[MA^{2+}] - \varkappa_3[MA^{2+}][A^-] + \varkappa_4[MA_2^+] \quad , \tag{6b}$$

$$\frac{d[MA_2^+]}{dt} = \varkappa_3[MA^{2+}][A^-] - \varkappa_4[MA_2^+] - \varkappa_5[MA_2^+][A^-] + \varkappa_6[MA_3]_w \quad , \tag{6c}$$

$$\frac{d[MA_3]_w}{dt} = \varkappa_5[MA_2^+][A^-] - \varkappa_6[MA_3]_w - \frac{V_o}{V_w}\cdot\frac{d[MA_3]_w}{dt} \quad , \tag{6d}$$

where the last term on the right-hand side corresponds to the rapid transfer of part of MA_3 to the organic phase. We have

$$\frac{d[MA_3]_o}{dt} = q_{MA_3}\cdot\frac{d[MA_3]_w}{dt} \quad , \tag{7}$$

where V_W and V_O are the volumes of the aqueous and organic phases.

Since only one reaction is slow and the others are rapid, equilibrium is established in the latter. For example, when reaction (I) is slow, there is at any instant equilibrium in the formation of MA_2^+ from MA^{2+} and A^- and of MA_3 from MA_2^+ and A^-. This makes it possible on the basis of Eqns. (6) and (7) to express the time dependence of the analytical concentration of M in one of the phases (for example the aqueous phase) in terms of the rate constant for the reaction which determines the rate of the process, the equilibrium constants for the complex formation reaction and the dissociation of the acid, and also the partition coefficients of the acid and MA_3.

Several different methods for the investigation of extraction kinetics are possible. For example, an element M can be introduced in microamounts into the aqueous phase of specified composition in equilibrium with the organic phase. In this case the aqueous phase does not initially contain the compound extracted (MA_3).

§ For this reason the concentration of the anions A^- is $[A^-] = K_{HA}[HA]_o/q_{HA}[H^+]$, where K_{HA} is the dissociation constant of the acid, q_{HA} its partition coefficient, and $[H^+]$ the concentration of hydrogen ions (constant in each experiment).

If, for example, reaction (II) is slow and reactions (I) and (III) as well as the partition of MA_3 between the phases are rapid, then at any instant

$$[MA^{2+}] = K_1[M^{3+}][A^-] \quad , \tag{8a}$$

$$[MA_3]_w = K_3''[MA_2^+][A^-] \quad , \tag{8b}$$

$$[MA_3]_o = q_{MA_3}[MA_3]_w = q_{MA_3}[MA_2^+][A^-]\quad K_3'' \quad , \tag{8c}$$

where K_1 and K_3'' are the stability constants of the MA^{2+} ions and MA_3 molecules. Having determined $d[MA_3]_w/dt$ and $d[MA_3]_o/dt$ from these equations, we find

$$\left(1 + K_3''[A^-] + \frac{V_o}{V_w}q_{MA_3}K_3''[A^-]\right)\frac{d[MA_2^+]}{dt} = \varkappa_3[MA^{2+}][A^-] - \varkappa_4[MA_2^+] \quad , \tag{9}$$

since in the extraction of trace amounts of the element $[A^-]$ is constant.

The analytical concentration in the aqueous phase at any instant is

$$C_w = [M^{3+}] + [MA^{2+}] + [MA_2^+] + [MA_3]_w = \frac{[MA^{2+}]}{K_1[A^-]} + [MA_2^+] + [MA^{2+}] + K_3''[MA_2^+][A^-] \quad . \tag{10}$$

This equation makes it possible to express the concentration $[MA^{2+}]$ in terms of C_W and $[MA_2^+]$ and since

$$[MA_2^+] = \frac{[MA_3]_w}{K_3''[A^-]} = \frac{[MA_3]_o}{q_{MA_3}K_3''[A^-]} = \frac{V_w(C_w^0 - C_w)}{V_o q_{MA_3}\cdot K_3''[A^-]} \quad ,$$

where C_W^0 is the initial concentration of M^{3+} in the aqueous phase, it follows that, having determined $d[MA_2^+]$ from this equation and having substituted $[MA_2^+]$ and $d[MA_2^+]/dt$ in Eqn. (9), we find after appropriate rearrangements

$$-\frac{dC_w}{dt} = a_2C_w - b_2C_b^0 \quad , \tag{11}$$

where

$$a_2 = \frac{\varkappa_3[A^-]\left\{\frac{V_o}{V_w}K_3''[A^-]\,q_{MA_3} + K_3''[A^-] + 1 + \frac{\varkappa_4}{\varkappa_3[A^-]}\left(1 + \frac{1}{K_1\cdot[A^-]}\right)\right\}}{\left(1 + \frac{1}{K_1[A^-]}\right)\left(1 + K_3''[A^-] + \frac{V_o}{V_w}q_{MA_3}\,K_3''[A^-]\right)} \quad . \tag{12a}$$

since $\varkappa_4/\varkappa_3[A^-] = [MA^{2+}]_e/[MA_2^+]_e$, where the subscripts "e" denotes equilibrium concentrations, it follows that, having substituted this value in Eqn. (12a), having multiplied the numerator and denominator by $[MA_2^+]$, and having used Eqns. (8a), (8b), and (8c), we obtain

$$a_2 = \frac{\varkappa_3[A^-](V_o[MA_3]_{o,e} + V_w[MA_3]_{w,e} + V_w[MA_2^+]_e + V_w[MA^{2+}]_e + V_w[M^{3+}]_e}{\left(1 + \frac{1}{K_1[A]}\right)(V_w[MA_2^+]_e + V_w[MA_3]_{w,e} + V_o[MA_3]_{o,e})} = \frac{\varkappa_3K_1[A^-]^2\,C_w^0}{(K_1[A^-] + 1)\,(C_w^0 - [MA^{2+}]_e - [M^{3+}]_e)} \quad . \tag{12b}$$

The quantity b can be found similarly, but it is determined more simply from the condition that at equilibrium $dC_W/dt = 0$, so that

$$b_2 = \frac{a_2\ C_{w,e}}{C_w^0} \quad . \tag{13}$$

A similar derivation of the equations was made earlier[56,57] for a system with equal phase volumes. The same equation for the coefficient a was obtained when reaction (II) was slow. The rate of extraction is also described by Eqn. (11) when reaction (I) or (III) is slow, but the corresponding coefficients are

$$a_1 = \frac{\varkappa_1\ [A^-]\ C_w^0}{C_w^0 - [M^{3+}]_e} \tag{14}$$

for reaction (I) and

$$a_3 = \frac{\varkappa_3 K_2' K_2 [A^-]^3 C_w^0}{(K_2' + K_2[A^-] + K_2 K_2' [A^-]^2)(C_w^0 - [M^{3+}]_e - [MA^{2+}]_e - [MA_2^+]_e)} \quad (15)$$

for reaction (III).

In these equations

$$K_2 = \frac{[MA_2^+]}{[M^{3+}][A^-]}, \qquad K_2' = \frac{[MA_2^+]}{[MA^{2+}][A^-]} .$$

The volumes of the phases enter into equations in which the rate constant ratio has not been replaced by the ratio of the equilibrium concentrations [Eqn. (12a)]. In Eqns. (12b), (14), and (15) the change in phase volumes alters the equilibrium concentrations.

Integration of Eqn. (11) yields

$$\ln \frac{C_w - C_{w,e}}{C_w^0 - C_{w,e}} = -at , \quad (16)$$

where a is defined by one of the Eqns. (12b), (14), and (15) and $C_{w,e}$ is the analytical equilibrium concentration of M in the aqueous phase.

It follows from Eqn. (16) that, when $C_{w,e} \ll C_w$ and particularly when $C_{w,e} \ll C_w^0$, it is converted into Eqn. (4b) but the coefficient a is not equal to κ_1'. In particular, a more complex dependence of the rate of extraction on the anions A^- will be observed than would follow from the expression for κ'. For example, when the rate of extraction is determined by the rate of reaction (II), then a_2 will be proportional to $[A^-]^2$ only when $K_1[A^-] \ll 1$ and $\{[MA^{2+}]_e + [M^{3+}]_e\} \ll C_w^0$. If $K_1[A^-] \gg 1$ but the second of the above conditions holds, then a_2 will be proportional to $[A^-]$ and therefore one can reach the erroneous conclusion that the rate is determined by reaction (I).

It follows from Eqn. (11) that $-dC_w/dt = C_w - C_{w,e}$ and therefore in the general case the rate of extraction cannot be of first order with respect to C_w, must be of first order with respect to $C_w - C_{w,e}$, and the first order with respect to C_w, established in the studies quoted here and in others[60], will be observed only when $C_w \gg C_{w,e}$. The observed first order with respect to C_w can be explained by the fact that the authors of many investigations restricted their treatment to the linear part of the time variation of $\ln(C_w/C_w^0)$, which is insufficient to deduce the extraction mechanism.

If the rate of extraction is determined by the rate of the reaction

$$M^{3+} + 2A^- \underset{\varkappa_8}{\overset{\varkappa_7}{\rightleftarrows}} MA_2^+ ,$$

it is also described by Eqn. (16), but in this case

$$a' = \frac{\varkappa_7 [A^-]^3 C_w^0}{C_w^0 - [M^{3+}]_e} \quad (17)$$

and therefore, when $[M^{3+}] \ll C_w^0$, the same variation with the concentration of the anions A^- (derived from the acid HA) will be observed as for reaction (II) when $K_1[A^-] \ll 1$ [Eqn. (12b)].

Thus the observation that the reaction is of second order with respect to the extractant, in accordance with Eqns. (12b) and (17), as was done, for example, by McClellan and Freiser[41] and Bodnya and Alimarin[61], does not allow one to decide whether the slow reaction is the addition of a second ligand (a bimolecular reaction) or whether the metal ion combines immediately with two anions (a trimolecular reaction).

In those cases where the system contains a complex-forming agent X and the equilibria in the reactions $MX_i + X = MX_{i+1}$ are established very rapidly (they do not affect the rate of extraction) and there are no mixed complex ions or molecules MX_iA_j, the following expressions hold for reactions (I)–(III) when the phase volumes are equal:

$$a_1 = \frac{\varkappa_1 [A^-] C_w^0}{(1 + f_0)\{C_w^0 - [M^{3+}]_e (1 + f_0)\}} , \quad (18a)$$

$$a_2 = \frac{\varkappa_3 K_1 [A^-]^2 C_w^0}{(K_1[A^-] + f_0 + 1)\{C_w^0 - [M^{3+}]_e (1 + f_0) - [MA^{2+}]_e\}} , \quad (18b)$$

$$a_3 = \frac{\varkappa_3 K_2' K_2 [A^-]^3}{(K_2[A^-] + K_1[A^-] + f_0 + 1)\{C_w^0 - M^{3+}]_e (1 + f_0) - [MA^{2+}]_e - [MA_2^+]_w\}} , \quad (18c)$$

where $f_0 = \sum_1^i \beta_i [X]^i$ and $\beta_i = [MX_i]/[M][X]^i$ are the stability constants of the complexes MX_i.

In the extraction by an acid HA of a bivalent metal, with formation of MA^+ and MA_2 in the aqueous phase, the rate of extraction corresponding to the partition of the molecules MA_2 is also characterised by Eqn. (16). If the slow reaction is M + A = MA and the phase volumes are equal, then

$$a_1 = \frac{\varkappa_1 [A^-] C_w^0}{C_w^0 - [M^{3+}]_e} , \quad (19a)$$

On the other hand, if the slow reaction is MA + A = MA_2, then

$$a_2 = \frac{\varkappa_3 K_1 [A^-]^2 C_w^0}{(K_1[A^-] + 1)(C_w^0 - [MA^{2+}]_e - [M^{3+}]_e)} , \quad (19b)$$

where K_1 is the equilibrium constant for the reaction $M^{2+} + A^- = MA^+$. For a large partition coefficient, when $C_w^0 \gg C_{w,e}$ and $C_w^0 \ll [MA^+]_e + [M^{2+}]_e$ and especially $C_w^0 \gg [M^{2+}]_e$, the rate of extraction is in both cases described by the same equation $\ln(C_w/C_w^0) = -\kappa[A^-]$, where κ can be either κ_1 or κ_3, provided that the condition $K_1[A^-] \gg 1$ holds. Thus, in order to deduce the mechanism of the reaction determining the rate of extraction, it is necessary to know the composition of the compounds existing in each phase and also their stability constants. The knowledge of these constants is necessary also for the choice of conditions which allow one to distinguish the possible reactions. Thus, in the extraction of a bivalent metal under consideration, the determination of the nature of the reaction taking place requires a concentration of the anion A^- such that the condition $K_1[A^-] \ll 1$ hold but the concentration of the extractant greatly exceeds that of the element being extracted (to ensure the condition that only trace amounts of the latter are extracted). Such conditions in the extraction by an acid HA can be created by carrying out the extraction from a fairly acid solution, assuming that the concentration of the anions A^- is much higher than the analytical concentration of the element M or that the acid dissociates very rapidly.

Thus the conclusion[62] that extraction can serve as a method for the investigation of very rapid reactions is valid (a low concentration of the interacting components ensures a rate suitable for measurement), but the determination of the reaction mechanism from measurements of the rate of extraction is extremely difficult.

It follows from Eqn. (16) that, at a given concentration of HA in the case of a single slow reaction, the quantity $\ln[(C_w - C_{w,e})/(C_w^0 - C_{w,e})]$ is a linear function of time, as under diffusion-dependent conditions with constant partition and mass transfer coefficients. The difference between these processes is that a change in the rate of stirring and in the area of the interface does not alter the rate of extraction under kinetic conditions but does change it under diffusion-dependent or mixed conditions.

In the extraction of molybdenum in different valent states from a hydrochloric acid solution by solutions of oxine, acetylacetone, and other extractants in chloroform, the authors[63] assumed that it is possible to ignore the reversibility of the process and to characterise the rate of extraction by the degree reaction which they believe to be $F = q_t/q_p = 1 - e^{-\kappa_1' t}$, where $q_t = C_O/C_W$ is the ratio of the concentrations at any instant, q_p is the partition coefficient (the ratio of the equilibrium concentrations), and $\kappa_1' = \kappa_1[A^-]$, assuming that the rate of extraction is determined by the rate of formation of the ions MA^+. We believe that the degree of reaction must be characterised by the fraction of substance which has reacted relative to the overall amount which can react, for example by the quantity $F = C_O/C_{O,e} = (C_W^0 - C_W)/(C_W^0 - C_{W,e})$ (only then is the degree of reaction zero at the initial instant and unity at equilibrium). Indeed, it follows from Eqn. (16) that $F = 1 - e^{-at}$, but

$$F = \frac{C_o}{C_{o,e}} = \frac{q_t}{q_e} \cdot \frac{C_w}{C_{w,e}} \neq \frac{q_t}{q_e} \quad .$$

This can explain the authors' observation in a number of experiments of a discrepancy between the experimental results and the proposed equation.

In the study of the rate of extraction of trace amounts of the extractable compound the process can be achieved in another way: the phases must be equilibrated with the microcomponents, separated, and the aqueous phase must be brought into contact with the organic phase obtained in the same way but without the element to be extracted (extraction); the organic phase containing the extractable element is brought into contact with the aqueous phase without the compound (re-extraction). The same process can be carried out by equilibrating initially the phases without the extractable compound and separating them, after which, having introduced into the aqueous phase trace amounts of the element to be extracted without altering the composition of the phases with respect to the macrocomponents (a very small volume of the solution with the extractable element is employed), the phase is allowed to stand until equilibrium is reached, after which the phases are again brought into contact.

In contrast to the methods described previously, in this case all the compounds already exist in the aqueous phase at the instant of contact between the phases and are in equilibrium with the extractant. Therefore under kinetic conditions the quantity q_t will be non-zero at $t = 0$ and in the plot of its time variation will tend to a finite quantity when t tends to zero. A similar phenomenon was observed, for example, in a study[50] involving a "side" reaction in the course of the extraction of antimony from hydrochloric acid solutions by alcohols.

However, in certain investigations where the phases were initially equilibrated without the extractable element and the latter was then introduced into the aqueous phase[39,40], the authors state that the solution was adjusted to the required pH directly before extraction but they did not estimate the effect of the change in the hydrogen ion concentration on the partition coefficient of the extractant. When such an effect obtains, the concentration of the extractant can vary in the course of extraction, but this was disregarded in the experiments.

The introduction of the extractant, for example an acid HA, into the aqueous phase with subsequent extraction by the pure solvents constitutes a modification of the method described. Thus, it has been found[64] that in the extraction of indium by solutions of 1-(2-pyridylazo)-2-naphthol in chloroform, equilibrium is established in 45—50 min. When this extractant is added in the form of an alcoholic solution to the aqueous phase and the latter is then shaken with chloroform, a high initial degree of extraction is rapidly reached; however, it gradually diminishes and equilibrium is established in 30—35 min. In this case there is initially a partition of both the compound formed and of the extractant and the decrease of the concentration of the latter in the aqueous phase disturbs the equilibrium, which leads to the dissociation of the extractable compound in this phase and hence to its re-extraction from the organic phase. Such a process can be used to determine the rates of the reactions occurring, provided that it has been shown that kinetic conditions obtain.

In the case of extraction of a tervalent element by an acid HA in which the aqueous phase is equilibrated with the organic phase without the extractable element, the phases are separated, the extractable element is introduced into the aqueous phase, and the latter is allowed to stand until the attainment of equilibrium in it, the initial analytical concentration of the extractable element in the aqueous phase is

$$C_{w(init)} = [M^{3+}]_{int} + [MA^{2+}]_{int} + [MA_2^+]_{int} + [MA_3]_{int} \quad , \qquad (20)$$

where the subscript "init" shows that the concentrations refer to the initial aqueous solution in equilibrium with the organic phase used in the experiment with respect to the extractant (the acid HA).

As a result of the "instantaneous" distribution of the molecules MA_3 between the phases, in the initial instant of the extraction their concentration in the organic phase is $[MA_3]_O^0 = q_{MA_3}[MA_3]_W^0$, and for equal phase volumes we have

$$[MA_3]_{int} = [MA_3]_o^0 + [MA_3]_w^0 = [MA_3]_w^0(q_{MA_3} + 1) = \frac{[MA_3]_o^0(q_{MA_3} + 1)}{q_{MA_3}} \cdot \qquad (21)$$

Under these conditions, the rate of extraction is also characterised by Eqn. (11) but $C_{W(init)}$ enters into the coefficient a instead of C_W^0. The derivation of the equation for the rate of extraction in the system under consideration is similar to that quoted above.

Thus the linear time variation of $\ln[(C_W - C_{W,e})/(C_W^0 - C_{W,e})]$ under kinetic conditions and the experimental conditions adopted shows that the rate of extraction may be determined by one slow reaction (below it will be shown that, for two reactions at comparable rates, the corresponding relation is not linear). The coefficient a can be found from the slope of the resulting straight line, but, in order to deduce the mechanism of the reaction determining the rate of extraction and to determine its rate constant, it is necessary to know the stability constants of the compounds existing in the given system, which may make the solution of the problem significantly more difficult. For example, in the extraction of iron from perchloric acid solutions with acetylacetone, it is essential to know the stability constants of the complex ions and molecules FeA^{2+}, FeA_2^+, and FeA_3. However, the data published in different studies for these constants differ appreciably. Thus, according to Badoz-Lambling[65], at zero ionic strength the dissociation constants of these ions are $K_1 = 3 \times 10^{-12}$, $K_2 = 8 \times 10^{-23}$, and $K_3 = 2 \times 10^{-27}$; according to Izatz et al.[66], $K_1 = 1.6 \times 10^{-10}$, $K_2 = 1.6 \times 10^{-19}$, and $K_3 = 6.4 \times 10^{-27}$. Bearing in mind that the dissociation constant of acetylacetone is 1.12×10^{-9} litre mole^{-1}, the difference between the complex formation constants will lead to a considerable difference between the equilibrium concentrations entering into the equations

for a, which hinders the choice of the appropriate mechanism.

However, when the slow stage determining the rate of extraction is the formation of the extractable compound (MA_3 in the extraction of a tervalent element or MA_2 in the extraction of a bivalent element), the coefficient a can be calculated from the experimental equilibrium data without knowing the constants. Then

$$C_w^0 - [M^{3+}]_e - [MA^{2+}]_e - [MA_2^+] = C_w^0 - (C_{w,e} - [MA_3]_{w,e}) = C_{o,e} + \frac{C_{o,e}}{q_{MA_3}} = \frac{C_{o,e}(q_{MA_3}+1)}{q_{MA_3}}$$

$$K_3' K_2 [A^-]^3 + K_2 [A^-] + K_2^+ \left(K_2 [A^-]^2 + \frac{K_2 [A^-]}{K_3'} + 1 \right) =$$

$$= K_2' \left(\frac{[MA_2^+]_e}{[M^{3+}]_e} + \frac{[MA^{2+}]_e}{[M^{3+}]_e} + 1 \right) = \frac{K_2'}{[M^{3+}]_e} ([MA_2^+]_e + [MA^{2+}]_e + [M^{3+}]_e) =$$

$$= \frac{K_3'}{[M^{3+}]_e} (C_{w,e} - [MA_3]_{w,e}) = \frac{K_2'}{[M^{3+}]_e} \left(C_{w,e} - \frac{C_{o,e}}{q_{MA_3}} \right) = \frac{K_2' \cdot C_{w,e}}{[M^{3+}]_e} \left(1 - \frac{q_p}{q_{MA_3}} \right),$$

where $q_p = C_{o,e}/C_{w,e}$ is the partition coefficient and $C_{o,e}$ and $C_{w,e}$ are the analytical equilibrium concentrations.

On substituting these values in Eqn. (15) and on replacing C_w^0 by $C_{w,e}(q_p + 1)$, we obtain after rearrangement

$$a_3 = \frac{\varkappa_3 K_2 (q_p + 1)}{K_3 (q_{MA_3} + 1) \left(1 - \frac{q_p}{q_{MA_3}} \right)}, \qquad (22)$$

where

$$K_3 = \frac{[MA_3]_{w,e}}{[M^{3+}]_e [A^-]^3} = \frac{C_{o,e}}{q_{MA_3} [M^{3+}]_e [A^-]^3}. \qquad (23)$$

Assuming that the rate constants and the stability constants of the complex ions are constant, it is possible to find the ratio of the coefficients a_3 in two experiments at different concentrations of the acid HA. It follows from Eqn. (22) that this ratio is

$$\frac{a_3'}{a_3''} = \frac{(q_p' + 1)(1 - q_p''/q_{MA_3})}{(q_p'' + 1)(1 - q_p'/q_{MA_3})}. \qquad (23a)$$

Thus, when the partition coefficient of MA_3 molecules is known and the partition coefficient q_p has been found experimentally, it is possible to test whether the ratio of the coefficients a_3 is consistent with Eqn. (23a) and whether reaction (III) determines the rate of extraction. When the experiments are performed at a low concentration of the acid HA or at a fairly high acidity, $q_p \ll q_{MA_3}$ so that Eqn. (23a) assumes the form

$$\frac{a_3'}{a_3''} = \frac{q_p' + 1}{q_p'' + 1}. \qquad (23b)$$

For the extraction of a bivalent metal, we obtain similarly

$$a_2 = \frac{\varkappa_2 K_1}{K_2} \frac{(q_p + 1)}{(q_{MA_2} + 1)(1 - q_p/q_{MA_2})}, \qquad (24)$$

where K_1 is the stability constant of the ion MA^+ and K_2 is the overall stability constant of MA_2 molecules (dissociation into simple ions).

If reaction (I) or (II) is slow in the extraction of a tervalent metal or the former is slow in the extraction of a bivalent metal, it is necessary to know the stability constants of the compounds formed in order to deduce the mechanism.

The concentrations of the anions A^-, which are determined under the specified conditions (specified microconcentrations of the extractable element) from the equation $[A^-] = K_{HA}[HA]_o/[H^+]q_{HA}$, where $[HA]_o$ is the concentration of the acid in the organic phase, enter into the above equations for the coefficient a. The equation for $[A^-]$ can be used to determine the variation of the rate of extraction with hydrogen ion concentration for a constant value of $[HA]_o$. If the ionic strength hardly changes with hydrogen ion concentration and the degree of dissociation of the acid in the aqueous phase is very low, then its dissociation constant and the partition coefficient will not vary. Evidently, when there are no reactions in the system involving H^+ of OH^- ions (for example hydrolysis reactions), then, on applying Eqn. (4a), the rate constant κ_1 will include the hydrogen ion concentration raised to the power n, where n is the number of molecules of the acid HA or the ions A^- involved in the corresponding reaction. However, when Eqns. (12b), (14), and (15) are applied, the coefficients a will vary in a more complex manner with hydrogen ion concentration, since the latter determines not only the concentration of the anions A^- but also the equilibrium concentrations $[M^{3+}]_e$, $[MA^{2+}]_e$, etc.

A significant difference between the reaction orders with respect to the extractant and hydrogen ions has been noted, for example, in the extraction of nickel and cobalt by dithizone derivatives. It has been found[41] that, when Eqn. (4a) is employed, the order is 1.35 and 1.53 with respect to the extractant and 0.73 and 0.75 with respect to hydrogen. On the other hand, the corresponding values for zinc are 1.91 and 1.71.

The variation of the rate of extraction with hydrogen ion concentration is regarded[67] as evidence that the reaction determining the rate of extraction proceeds in the aqueous phase. This is true if the partition coefficient of the acid is independent of hydrogen ion concentration.

In the above scheme of reactions (I)—(III) occurring in extraction it was assumed that there is interaction with the anions of the acid HA, but one can also postulate the interaction with its molecules. For example, whereas it has been assumed in some studies[49,64,68,70] that in the interaction of Fe^{3+} ions with thenoyltrifluoroacetone there is a slow reaction of these ions with enolate ions, in the analogous reaction with acetylacetone the interaction with the molecules in the keto-form[71], and in another investigation[72] with both forms, was postulated.

Thus, in order to deduce the extraction mechanism, it is necessary to consider the possibility of, for example, the following reactions:

$$M^{3+} + HA \underset{\varkappa_2'}{\overset{\varkappa_1'}{\rightleftarrows}} MA^{2+} + H^+ \text{ (V)}, \quad MA^{2+} + HA \underset{\varkappa_4'}{\overset{\varkappa_3'}{\rightleftarrows}} MA_2^+, \qquad \text{(VI)}$$

$$MA_2^+ + HA \underset{\varkappa_6'}{\overset{\varkappa_5'}{\rightleftarrows}} MA_3 + H^+ \text{ (VII)}, \quad MA_{3_w} \rightleftarrows MA_{3_o}. \qquad \text{(VIII)}$$

Having expressed the equilibrium constants for the reactions in the form

$$K_1^* = \frac{[MA^{2+}][H^+]}{[M^{3+}][HA]_w}; \quad K_2^* = \frac{[MA_2^+][H^+]}{[MA^{2+}][HA]_w}; \quad K_3^* = \frac{[MA_2^+][H^+]^3}{[M^{3+}][HA]_w^3} \qquad \text{(25c)}$$

it is possible to show that the rate of extraction is also characterised by Eqn. (11), but the corresponding coefficients are given by

$$a_1^* = \frac{\varkappa_1'[HA]_w C_w^0}{C_w^0 - [M^{3+}]_e} , \quad (26a)$$

$$a_2^* = \frac{\varkappa_2' K_1^* [HA]_w^2 C_w^0}{(K_1^*[HA]_w + [H^+])(C_w^0 - [M^{3+}]_e - [MA^{2+}]_e)} , \quad (26b)$$

$$a_3^* = \frac{\varkappa_3' K_2'^* K_2^* [HA]_w^3 C_w^0}{(K_2'^*[H^+]^2 + K_2''[H^+][HA]_w + K_2'^* K_2^*[HA]_w^2)(C_w^0 - [M^{3+}]_e - [MA^{2+}]_e - [MA_2^+]_e)} . \quad (26c)$$

If $C_w^0 \gg [M^{3+}]_e$, which is possible when the partition coefficients and the equilibrium constants for the corresponding reactions are high, it follows from Eqns. (14) and (26a) that

$$a_1 = \frac{\varkappa_1 K_{HA}[HA]_o}{q_{HA}[H^+]} ; \quad (27a)$$

$$a_1^* = \frac{\varkappa_1'[HA]_o}{q_{HA}} . \quad (27b)$$

Consequently, at a constant concentration of the acid HA in the organic phase, the quantity a_1 will be inversely proportional to the hydrogen ion concentration. This type of relation has been observed in certain experiments when Eqn. (4a) was used; a_1^* is independent of this concentration if q_{HA} is independent of the composition of the solution. Thus, there is a possibility of distinguishing reactions (I) and (V). However, in reactions involving HA molecules, for example with acetylacetone, there arises the problem of determining the reactive species (the enol or keto-form). There is a significant difference (depending on the hydrogen ion concentration) between the coefficients a_2 and a_2^*, but it is more difficult to analyse.

If reaction (VII) is slow, then, as in the preceding case, it is possible to show that, subject to the conditions $q_{MA_3} \gg q_p$, we have, for two experiments at the same value of $[HA]_O$,

$$\frac{a_3^{*'}}{a_3^{*''}} = \frac{[H^+]'}{[H^+]''} \cdot \frac{(q_p' + 1)}{(q_p'' + 1)} , \quad (28)$$

which makes it possible to choose one of the reactions [(III) or (VII)].

The examples quoted naturally by no means exhaust completely all the possible reactions in extraction under kinetic conditions. Thus even reaction (V) can proceed in two stages

$$M(H_2O)_x^{3+} + HA \rightleftarrows M(H_2O)_{x-i} \cdot HA^{3+} + i H_2O;$$

$$M(H_2O)_{x-i}HA^{3+} \rightleftarrows M(H_2O)_j A^{2+} + H^+ H_2O + (x - i - j - 1) H_2O$$

It has been noted in a number of studies that the rate of reactions in the aqueous phase can be determined by the rate of loss of water molecules[73,74]. In particular, in a study of the rate of formation of nickel complexes of malonic and succinic acids (in the case of a homogeneous reaction) it was established[74] that the rate of the forward reaction is determined by the rate of loss of water molecules and therefore the rate constants for this reaction are independent of the nature of the ligand, while the rate constants for the reverse reaction differ appreciably.

It has also been suggested for the reactions of zinc with dithizone quoted previously[62] that the rate depends only on the rate of elimination of water from the hydration shell. However, here the rate constant for the elimination of water is a factor of ten higher than the constant found from extraction experiments. The conclusion that the rate of reaction is determined by the rate of loss of water must be based on a comparison of the rates of the given reaction and of the exchange of water, for example on the basis of Eigen's data[73]. Such a comparison and the absence of a dependence of the rate of reaction on the nature of the ligand are probably the only means of proving that the rate is determined by the rate of loss of water.

Thus, studies on the mechanism of extraction under kinetic conditions are difficult even in the case of one slow reaction. The investigation of the corresponding reactions in a homogeneous system using physical methods permitting the determination of the concentrations of the individual compounds is important for such studies. However, if it has been shown that the process occurs under kinetic conditions and is determined by the rate of one reaction, the use of Eqn. (16) and of the empirical dependence of the coefficients a on the extraction conditions can facilitate the choice of the optimal conditions for the extraction process.

III. TWO SLOW REACTIONS WITH THE EXTRACTANT IN THE AQUEOUS PHASE

If two consecutive reactions occur at comparable rates under kinetic conditions in the aqueous phase of the given system, for example in the extraction of a bivalent metal by an acid HA,

$$M_w^{2+} + A^- \underset{\varkappa_2}{\overset{\varkappa_1}{\rightleftarrows}} MA_w^+; \; MA^+ + A^- \underset{\varkappa_4}{\overset{\varkappa_3}{\rightleftarrows}} MA_2 ,$$

then, as shown before[75], the concentration in the aqueous phase for equal phase volumes is given by the equation

$$C_w = C_1 e^{z_1 t} + C_2 e^{z_2 t} + \frac{a_3}{a_2} , \quad (29)$$

where z_1 and z_2 are the roots of the characteristic equation $z^2 + a_1 z + a_2 = 0$;

$$a_1 = \varkappa_1[A^-]_w + \varkappa_2 + \varkappa_3 + [A^-]_w + \frac{\varkappa_4}{q_{MA_2} + 1} , \quad (30a)$$

$$a_2 = (q_{MA_2} \varkappa_1\varkappa_3[A^-]_w^2 + \varkappa_1\varkappa_3[A^-]_w^2 + \varkappa_1\varkappa_4[A^-]_w + \varkappa_2\varkappa_4)/(q_{MA_2} + 1) , \quad (30b)$$

$$a_3 = -(\varkappa_1\varkappa_3[A^-]_w^2 + \varkappa_1\varkappa_4[A^-]_w + \varkappa_2\varkappa_4) C_w^0/(q_{MA_2} + 1) , \quad (30c)$$

$$\frac{a_3}{a_2} = C_{w,e} , \quad (30d)$$

C_1 and C_2 are integration constants which, as required by Eqn. (29) satisfy the condition

$$C_w^0 = C_1 + C_2 + C_{w,e} . \quad (30e)$$

It follows from Eqns. (29) and (30d) that

$$\frac{C_w - C_{w,e}}{C_w^0 - C_{w,e}} = \frac{C_1 e^{z_1 t}}{C_w^0 - C_{w,e}} \left[1 - \frac{C_2}{C_1} e^{(z_2 - z_1)t}\right] , \quad (31)$$

and for this reason $\ln[(C_w - C_{w,e})/(C_w^0 - C_{w,e})]$ is not a linear function of time. We shall assume that $z_2 < z_1$, whereupon we have, for fairly high values of t when $(C_2/C_1)e^{(z_2 - z_1)t} \ll 1$,

$$\ln \frac{C_w - C_{w,e}}{C_w^0 - C_{w,e}} \approx z_1 t + A , \quad (32)$$

where $A = C_1(C_w^0 - C_{w,e})$. It is seen from Eqn. (32) that for high values of t the logarithmic term on the left-hand side is a linear function of time. For low values of t, the equation represents a curve whose slope diminishes with increase of t until a constant value is reached.

Thus the initial section of the relation between $\ln[(C_w - C_{w,e})/(C_w^0 - C_{w,e})]$ and time (t is small) shows whether one or more than one reaction determine the rate

of extraction in the given system under kinetic conditions.

From the linear part of the plot of $\ln[(C_W - C_{W,e})/(C_W^0 - C_{W,e})]$ as a function of t, it is possible to determine z and C_1. Knowing C_1, one can find C_2 from Eqn. (30e) and then z_2 from the curved part of the plot. The same quantities can be calculated with the aid of the coordinates of two points on the curved part of the plot by solving the resulting system of two equations.

Since $a_1 = -(z_1 + z_2)$, $a_2 = z_1 z_2$, and $a_3 = a_2 C_{W,e}$, it follows that, knowing the partition coefficient of MA_2 (q_{MA_2}) and the stability constants of the ions MA^+ and molecules MA_2,

$$K_1 = \frac{[MA^+]}{[M^{2+}][A^-]} = \frac{\varkappa_1}{\varkappa_2} \tag{33a}$$

and

$$K_2' = \frac{[MA_2]}{[MA^+][A^-]} = \frac{\varkappa_3}{\varkappa_4} , \tag{33b}$$

it is possible to find from the above equations all the rate constants (κ_1, κ_2, κ_3 and κ_4) by carrying out a series of experiments with different concentrations of the acid $[A^-]$. Since there are five equations relating the rate and equilibrium constants [Eqns. (30a), (30b), (30c), (33a), and (33b)], it is possible to determine one of the equilibrium constants (when it is unknown) from kinetic data.

Since $\ln[(C_W - C_{W,e})/(C_W^0 - C_{W,e})]$ is also a nonlinear function of time under mixed conditions, the conclusion that the deviation from linearity is due to two reactions with comparable rates requires evidence that in the given case kinetic conditions obtain.

This type of relation probably also obtains for a large number of consecutive reactions but analysis of the relevant cases is fairly difficult. A deviation from linearity will probably be observed for parallel reactions, for example for slow reactions with the extractant and a complex-forming agent present in the aqueous phase.

The rate of extraction under mixed conditions for a reaction in the bulk of one of the phases, for example the receiving phase[76], can be described similarly.

It has been found[60] for the extraction of chromium(III) from 1 N perchloric acid by acetylacetone solutions that $\ln(C_W/C_W^0)$ is a linear function of time if the latter is longer than 90 min at pH 4 and longer than 5 min at pH 7. This can be caused either by the occurrence of two reactions with the extractant (if the equilibrium concentration of chromium is much lower than its concentration at any instant whereupon the equation describes the corresponding process) or by a side reaction and a reaction with the extractant, since the specified pH was established by adding alkali directly before extraction whereby equilibrium might have been only slowly established, for example in a hydrolysis reaction. Evidently in this case the determination of the reaction order by the van't Hoff method with the aid of Eqn. (4a) employed by the authors is doubtful.

IV. EXTRACTION WITH A SIDE REACTION

The determination of the rate of extraction in the presence of a slow side reaction has been examined[77]. The following scheme was analysed: a slow reaction

$$A_w + D_w = AB_w + E_w \tag{IX}$$

takes place in the aqueous phase and only the compound A passes very rapidly to the organic phase, where it either does not change or a very rapid reaction takes place.

Microconcentrations of A are employed, while the concentrations of D and E are high and hardly change. For example, A = $HSbCl_6$, D = H_2O, AB = $HSb(OH)Cl_4$, E = HCl, the compound A being extracted by alcohols[78]. In this case the variation of the concentrations of A in the aqueous and organic phases, subject to the condition that the phase volumes are equal, is described by the equations

$$\frac{d[A^-]_w}{dt} = -\varkappa_1'[A]_w + \varkappa_2'[AB]_w - K'[A]_w + K'[A]_o , \tag{34a}$$

$$\frac{d[A]_o}{dt} = K'[A]_w - K''[A]_o , \tag{34b}$$

where $\kappa_1' = \kappa_1[D]_W$, $\kappa_2' = \kappa_2[E]_W$, κ_1 and κ_2 are the rate constants for the forward and reverse reactions, $K' = K_W S/V_W$, and S is the area of the interface.

Therefore $d[A]_W/dt + d[A]_O/dt = -\kappa_1'[A]_W + \kappa_2'[AB]_W$ and under kinetic conditions we have at any instant $[A]_O = q_A[A]_W$, where q_A is the partition coefficient of the compound A assumed to be constant.

It follows from the above equations that

$$\left(1 + \frac{1}{q_A}\right)\frac{d[A]_o}{dt} = -\varkappa_1'\frac{[A]_o}{q_A} + \varkappa_2'\left(C_w - \frac{[A]_o}{q_A}\right) , \tag{35a}$$

where $C_W = [A]_W + [AB]_W$ is the analytical concentration of A in the aqueous phase at any instant.

Since $C_W = C_{W(init)} - [A]_O$, where $[A]_O$ is the concentration of A in the organic phase, Eqn. (34a) can be put in the form

$$-\frac{dC_w}{dt} = aC_w - b , \tag{35b}$$

where

$$a = \frac{\varkappa_1' + (q_A + 1)\varkappa_2'}{q_A + 1} , \tag{36a}$$

$$b = \frac{(\varkappa_1' + \varkappa_2')C_{w(init)}}{q_A + 1} = aC_{w,e} . \tag{36b}$$

After integrating Eqn. (35b) and assuming that $C_W = C_W^0$ when $t = 0$, we obtain

$$\ln\frac{C_w - C_{w,e}}{C_w^0 - C_{w,e}} = -at . \tag{37}$$

However, under kinetic conditions when there is an equilibrium in the initial aqueous phase, $C_W^0 \neq C_{W(init)}$, where $C_{W(init)}$ is the initial concentration in the aqueous phase (concentration before contact between the phases)¶, since under these conditions part of A is very rapidly ("instantaneously") transferred to the organic phase when the phases come into contact. For this reason, in the initial instant of extraction the following condition holds: $C_{W(init)} = C_W^0 + [A]_O^0$, where $[A]_O^0$ is the concentration of A in the organic phase in the initial instant of the extraction process (at $t = 0$). Hence, when t tends to zero, $[A]_O$ does not tend to zero but to a value $[A]_O^0$.

C_W^0 and $[A]_O^0$ can be found from the conditions for equilibrium in the initial aqueous solution and for equilibrium in the partition of A at the starting point. Indeed at equilibrium in the initial aqueous solution $C_{W(init)} = [A]_{W(init)} + [AB]_{W(init)} = (1 + \tilde{K}')[A]_{W(init)}$, where $\tilde{K}' = \tilde{K}[D]_W/[E]_W$ and $\tilde{K}$ is the equilibrium constant for reaction

¶ In the paper by one of the present authors[77] $C_{W(init)}$ is designated by C_W^0 and the concentration at $t = 0$ (after the instantaneous distribution of the extractable species) by $C_{W(t=0)}$.

(IX) under consideration. When A is distributed between the phases, we have at the starting point

$$[A]_{w(init)} = [A]^0_w + [A]^0_o = \frac{[A]^0_o}{q_A} + [A]^0_o = \left(\frac{1}{q_A} + 1\right)[A]^0_o .$$

Therefore

$$[A]^0_o = \frac{[A]_{w(init)}}{\left(\frac{1}{q_A}+1\right)} = \frac{C_{w(init)}}{(1+\tilde{K}_1)\left(\frac{1}{q_A}+1\right)}; \quad C^0_w = C_{w(init)} - [A]^0_o = \frac{\left(\frac{1}{q_A} + \frac{\tilde{K}'}{q_A} + \tilde{K}'\right) C_{w(init)}}{\left(\frac{1}{q_A}+1\right)(1+\tilde{K}')} .$$

The analytical partition coefficient $q_p = [A]_{o,e}/C_{w,e}$, where $C_{w,e}$ is the analytical concentration of A in the equilibrium aqueous phase but $C_{w,e} = [AB]_{w,e} + [A]_{w,e} = (\tilde{K}' + 1)[A]_{w,e}$, so that

$$q_p = \frac{[A]_{o,e}}{(\tilde{K}'+1)[A]_{w,e}} = \frac{q_A}{\tilde{K}'+1}, \text{ a } C^0_w = \left(\tilde{K}' + \frac{1}{q_p}\right) q_p \quad C_{w,e} = \left(\tilde{K}' + \frac{1}{q_p}\right)[A]_{o,e} .$$

One must bear in mind that C^0_w can be found from experimental data (even if $\tilde{K}'$ and q_p are unknown) by extrapolating C_w or C_o as a function of t to $t = 0$. Knowing C^0_w and the equilibrium concentrations, it is possible to find K' and q_p.

In the given case the rate of extraction is characterised by the variation of the concentration in the aqueous phase, but it is not difficult to obtain the corresponding equation for the rate in terms of the variation of the concentration in the organic phase. Since for the reaction under consideration $C_w = C_{w(init)} - [A]_o$, $C^0_w = C_{w(init)} - [A]^0_o$, and $C_{w,e} = C_{w(init)} - [A]_{o,e}$, substitution of these values in Eqn. (31) yields $\ln \dfrac{[A]_{o,e} - [A]_o}{[A]_{o,e} - [A]^0_o} = -at$. Putting the last equation in the form $[A]_{o,e} - [A]_o = \{[A]_{o,e} - [A]^0_o\} e^{-at}$, we obtain $[A]_o = [A]_{o,e} - \{[A]_{o,e} - [A]^0_o\} e^{-at}$. It follows from this equation that

$$q_t = \frac{[A]_o}{C_w} = \frac{[A]_{o,e} - ([A]_{o,e} - [A]^0_o) e^{-at}}{C_{w(init)} - [A]_o} = \frac{[A]_{o,e} - ([A]_{o,e} - [A]^0_o) e^{-at}}{C_{w(init)} - [A]_{o,e} + ([A]_{o,e} - [A]^0_o) e^{-at}} = \frac{[A]_{o,e} - ([A]_{o,e} - [A]^0_o) e^{-at}}{C_{w,e} + ([A]_{o,e} - [A]^0_o) e^{-at}} .$$

When $t = 0$, we have $q_t = q_o = [A]^0_o / \{C_{w(init)} - [A]^0_o\}$ whence $[A]^0_o = C_{w(init)}/(1 + 1/q_o)$. Bearing in mind that $\tilde{K}' = \kappa'_1/\kappa'_2$, the equation for the coefficient a can be put in the form $a = \kappa'_1[1/(q_A + 1) + 1/\tilde{K}']$. If q_A and $\tilde{K}'$ are fairly large and κ'_1 is small because the corresponding reaction is slow, the case $a \ll 1$ is possible and therefore $e^{-at} \simeq 1 - at$. Only in this case will the equation for q_t not contain an exponential term.

Hydrolysis or dehydrolysis in the extraction of antimony chloride complexes from hydrochloric acid solutions by oxygen-containing solvents (for example alcohols), which has been investigated by Iofa[78], can serve as an example of side reactions of this kind. Iofa found that q_t expressed as a function of extraction time does indeed have a finite value at $t = 0$.

V. DETERMINATION OF THE PHASE IN WHICH THE REACTION TAKES PLACE

If it has been established that the extraction proceeds under kinetic conditions with the reaction in one of the bulk phases, the determination of the phase in which the reaction occurs is of significant interest. In the extraction of electrolytes from aqueous solutions by organic extractants dissolved in non-polar solvents under the conditions where the extractant (in the given case an acid HA) is fairly soluble in the aqueous phase and the initial salt is completely dissociated in the aqueous phase and therefore has extremely low solubility in the organic phase, one can suggest with a great deal of confidence that the reaction takes place in the aqueous phase. The hypothesis put forward by Sekine et al.[47] that in the extraction of beryllium from aqueous solutions containing hydrochloric and perchloric acids beryllium perchlorate passes to the organic phase is therefore unlikely. However, when the extractant exists in several forms in the organic phase, for example the enolic and keto-forms of acetylacetone or thenoyltrifluoroacetone, which reach equilibrium slowly, and the extractable element reacts rapidly with one of these forms, the rate of extraction of macroamounts of the element M can be determined by the rate of the keto–enol transformation.

Thus the low rate of extraction of the lanthanides by thenoyltrifluoroacetone observed by Healy[79] is accounted for by the low rate of the keto–enol transformation, since according to the author these elements react only with the enol form.

In a qualitative study[80] of the rate of extraction of zirconium by benzoylacetone and thenoyltrifluoroacetone in various solvents, it was concluded, from the dependence of the relative amount of the enol form on the polarity of the diluent and the solubility of the ketone in water, that the enol forms of the ketones react. In the extraction of trace amounts in the presence of a high concentration of the extractant the transformation of one form into another does not limit the rate of the process, provided that equilibrium in the distribution of the extractant has been attained (the phases have been "equilibrated" without the extractable element).

When the dissociation of the extractable salt in the aqueous phase is incomplete (complex formation with the anion of the initial salt), the molecular form (undissociated molecules), whose partition coefficient is possibly insignificant, may pass to the organic phase also when the solubility of the extractant in water is low and the rate of extraction is then determined by the rate of reaction in the organic phase. For example, the partition coefficient of $AuCl_4$ between xylene and 2 M HCl is 0.005, but increases significantly following the addition of tributyl phosphate (TBP) to the organic phase[81]. If the given reaction is not a surface process, then, bearing in mind the low solubility of TBP in water, one can suggest with some confidence that the formation of a solvate, which increases the partition coefficient, takes place in the organic phase, although this should of course be tested experimentally.

Above it was already noted that in the extraction by an acid HA the dependence of the rate of extraction on hydrogen ion concentration has been regarded as evidence that the reaction determining the rate of extraction occurs in the aqueous phase. However, this is true only under

certain conditions, in particular when the partition coefficient is independent of the acid on hydrogen ion concentration, which occurs, for example, in the partition of acetylacetone.

Comparison of the rates of extraction by solutions of a single extractant in different diluents, enabled a number of investigators[82,83] to find that the rate of extraction is higher the higher the concentration of the extractant in the aqueous phase for an equal concentration in the organic phase {the lower the partition coefficient $q = [HA]_o/[HA]_w$}. Hence it was concluded that the reaction determining the rate of extraction takes place in the aqueous phase. This conclusion would be correct if the rates of reactions were determined by the concentrations and not the activities. However, the different concentrations of the extractant in the aqueous phase for the same concentration in different organic phases imply that the activities of the extractant in the organic phases are different (they are higher the higher the solubility in the aqueous phase). The increase of activity may be caused, in particular, by a decrease in the degree of interaction with the diluent, an increase in the degree of dissociation of the polymer when the latter is formed in the organic phase, and other factors, let alone the change in the activity coefficient as a result of a change in the relative molecular dimensions and intermolecular interactions. Evidently an increase of the activity of the extractant in the organic phase would increase the rate of reaction in this phase if it occurred. When the concentration of the extractant in the same diluent is varied, its activity coefficients can change much less than on varying the diluent and therefore in a certain concentration range they may be regarded as constant and the kinetics may be interpreted on the basis of the concentrations. This yields "effective" rate constants and equilibrium constants, which include these constant activity coefficients. For this reason, the change in the rate constants when the concentration is altered appreciably may be related to a change in the activity coefficients and not in the reaction mechanism.

In a study[6] of heterophase processes under kinetic conditions accompanied by the reaction A + B = AB with known partition coefficients of all the substances, an equation was obtained for the amount of substance which has reacted (for example the amount of AB formed), whereby one can determine the phase in which the reaction takes place. The possibility of applying this type of equation to our systems is complicated by the existence of a number of compounds in the aqueous phase and the necessity to distinguish the analytical partition coefficient and the partition coefficient of the extractable compound. It is therefore necessary to analyse this equation and compare it with the equations for the rate of extraction determined by the rate of the reaction in the organic phase.

When different diluents and the same extractant are employed, the determination of the reaction rate constants is of significant interest, since this might constitute more reliable evidence for the occurrence of the reaction in one phase than a qualitative comparison of the rates.

VI. THE RATE OF EXTRACTION UNDER KINETIC CONDITIONS FOR MACROCONCENTRATIONS OF THE COMPONENTS

The extraction of microamounts of the extractable substance (element) for which the concentration of the extractant remains almost constant was examined previously. With a suitable preparation of the solutions for the experiment (equilibration of the phases with respect to the macrocomponents), this ruled out the influence of the rate of transformation of one form of the extractant into another when the extractant can exist in different forms. Equations for the rate of extraction under the conditions of comparable concentrations of the extractant and the extractable compound are derived in the present section for the extraction of a univalent element by an acid HA having only one form. In this case, assuming that the rate of extraction is determined solely by the rate of the reaction $M^+ + A^- = MA$ occurring in the aqueous phase, we have at any instant

$$[HA]_w = q_{HA}[HA]_w \quad , \tag{38a}$$

$$[MA]_o = q_{MA}\,[MA]_w \quad , \tag{38b}$$

$$[HA]_w = K_{HA}[H^+][A^-] \quad , \tag{39a}$$

$$[A^-] = \frac{[HA]_w}{K_{HA}[H^+]} = \frac{[HA]_o}{q_{HA}\ K_{HA}\ [H^+]} \quad . \tag{39b}$$

For equal phase volumes, we obtain, as in a system with microconcentrations of the extractable element,

$$\frac{d\,[MA]_w}{dt} + \frac{d\,[MA]_o}{dt} = \varkappa_1[M^+]_w[A^-]_w - \varkappa_2[MA]_w \quad . \tag{40}$$

Since the analytical concentration of M in the aqueous phase is $C_w = [M^+]_w + [MA]_w$, and in the organic phase $C_o = [MA]_o$, it follows that

$$[M^+]_w = C_w - [MA]_w = C_w^0 - C_o - \frac{C_o}{q_{MA}} = C_w^0 - \left(1 + \frac{1}{q_{MA}}\right) C_o \quad , \tag{41}$$

where C_w^0 is the concentration of M^+ in the initial aqueous solution.

We have from Eqns. (38b), (40), and (41)

$$\left(1 + \frac{1}{q_{MA}}\right)\frac{dC_o}{dt} = \varkappa_1[A^-]\left\{C_w^0 - \left(1 + \frac{1}{q_{MA}}\right) C_o\right\} - \frac{\varkappa_2\ C_o}{q_{MA}} \quad . \tag{42}$$

[A] is determined using the material balance equations

$$[HA]_o = [HA]_o^0 - [HA]_w - [A^-]_w - [MA]_o - [MA]_w \quad , \tag{43a}$$

$$[H^+]_w = [H^+]_w^0 + [A^-]_w + MA]_w + [MA]_o \quad , \tag{43b}$$

where $[HA]_o^0$ and $[H^+]^0$ are the initial concentrations of the acid HA in the organic phase and of hydrogen ions in the aqueous phase. Then

$$[A^-] = \frac{[HA]_w}{q_{HA}\ K_{HA}\left\{[H^+]_w^0 + [HA]_o^0 - [HA]\left(1 + \frac{1}{q_{HA}}\right)\right\}} \quad , \tag{44a}$$

$$[HA]_o = [HA]_o^0 - [HA]_w - \frac{[HA]_o}{q_{HA}\ K_{HA}\left\{[H^+]_w^0 + [HA]_o^0 - [HA]_o\left(1 + \frac{1}{q_{HA}}\right)\right\}} - [MA]_w - [MA]_o \quad . \tag{44b}$$

On replacing $[HA]_w$ by $[HA]_o/q_{HA}$, it is possible to find $[HA]_o$ from Eqn. (44b). When $[HA]_o^0$, $[H^+]_w^0$, C_o, and $[HA]_o$ are known, it is easy to determine $[H^+]$ and $[A^-]$. Evidently, under these conditions Eqn. (42) is converted into a complex expression. However, if the degree of dissociation of the acid is low and $[A^-]$ can be neglected in Eqns. (43a) and (43b), it follows from the latter that

$$[HA] = \frac{[HA]_o^0 + \left(1 + \frac{1}{q_{MA}}\right) C_o}{1 + \frac{1}{q_{HA}}} \quad , \tag{45a}$$

$$[H^+]_w = [H^+]_w^0 - \left(1 + \frac{1}{q_{MA}}\right) C_o \quad . \tag{45b}$$

Putting, for brevity, $1 + 1/q_{MA} = a$ and $1 + 1/q_{HA} = b$, we have

$$[HA]_o = \frac{[HA]_o^0 - aC_o}{b} \quad , \tag{46a}$$

$$[H^+]_w = [H^+]_w^0 + aC_o \quad , \tag{46b}$$

$$[A^-] = \frac{[HA]_w^0 - aC_o}{q_{HA} K_{HA} b ([HA]_o^0 + aC_o)} \quad . \tag{46c}$$

Having substituted the value of $[A^-]$ from Eqn. (46c) in Eqn. (42), we obtain after appropriate rearrangements

$$f\frac{dC_o}{dt} = \frac{(a' - C_o)(C' - C_o)}{b' - C_o} + gC_o \quad . \tag{47}$$

In this equation $f = bq_{HA}K_{HA}/\kappa_1$, $a' = [HA]_o^0/a$, $b' = [H^+]_w^0/a$, $C' = C_w^0/a$, and $g = \frac{\kappa_2 q_{HA} K_{HA} h}{a\kappa_1 q_{MA}} = \frac{K_{HA}(q_{HA}+1)}{K_{MA}(q_{MA}+1)}$.

After adjusting Eqn. (47) to a common denominator and rearrangement, we obtain

$$\frac{(b' - C_o)\,dC_o}{C_o^2 - pC_o + r} = \frac{1+g}{r}\,dt \, , \tag{48}$$

where

$$p = \frac{a' + b'g + C'}{1 - g} \quad .$$

Integration of this equation subject to the condition $C_O = 0$ when $t = 0$ leads to the expression

$$(b' - x_1)\lg\frac{x_1 - C_o}{x_1} - (b' - x_2)\lg\frac{x_2 - C_o}{x_2} = \frac{(1-g)(x_1 - x_2)}{2.303f}\,t, \tag{49}$$

where x_1 and x_2 are the roots of the equation $C_O^2 - pC_O + r = 0$.

The condition $C_O^2 - pC_O + r = 0$ corresponds to equilibrium and therefore one of the roots, for example x_2, is equal to $C_{O,e}$—the equilibrium concentration in the organic phase, which can be determined experimentally. In this case $x_1 = r/x_2 = r/C_{O,e}$. If q_{HA}, q_{MA}, K_{HA}, K_{MA}, a', b', C', and g are known, then there is only one unknown in Eqn. (44), namely f, which includes the rate constant κ_1. Thus, having determined experimentally C_O at a time t, it is possible to find f, and, knowing the equilibrium constant K_{MA} for the given reaction, κ_2 can be determined.

The above equations show that the determination of the rate constant for a comparatively simple reaction in extraction requires the knowledge of the stability constant of the compound formed and of its partition coefficient and the corresponding calculations involve a considerable error, since the equations include coefficients which are complex functions of the initial concentrations, the equilibrium constants, and partition coefficients.

Evidently, in extraction whose rate is determined by the rate of a chemical reaction accompanied by the formation of several compounds of the extractable element, the corresponding equations will be still more complex.

When the concentrations of the components are altered appreciably, there is a possibility of a considerable change in their activity coefficients, which complicates still further the study of the extraction mechanism. For this reason, the use of radioactive traces is extremely desirable in the study of the extraction mechanism.

Mass Spectrometry of Transition Metal π-Complexes

P.E.Gaivoronskii and N.V.Larin

The problems of the fragmentation of transition metal π-complexes under the influence of electron impact are examined. The mass spectra of this class of compounds reflect fairly well the differences in the nature and stability of the metal-ligand bond as well as structural and other differences. Together with the rupture of the metal-ligand bond, electron impact results in the partial fragmentation of the ligands linked to the metal atom by π-bonds, the nature and degree of fragmentation depending on the nature and molecular weight of the ligand.
The bibliography includes 131 references.

I. INTRODUCTION

Volatile transition metal compounds can be conventionally divided into the following groups in terms of the type of the metal–ligand bond.

A. Chelate complexes, for example acetylacetonates.

B. Complexes with ligands of the π-acceptor type (carbon monoxide, nitric oxide, phosphines, arsines, nitriles, etc.).

C. Complexes with ligands linked by π-bonds. The ligands in such complexes are organic substances with double, triple, and conjugated bonds.

Studies on the mass-spectrometry of organometallic alkyl and phenyl compounds and metal complexes with ligands such as carbon monoxide have been described fairly completely in recently published reviews [1,2] and other reviews [3-5] deal with the mass spectra of certain transition metal π-complexes.

The present review deals with studies on the mass-spectrometry of transition metal π-complexes. The problems of the fragmentation of π-complexes and the correlation between the fundamental characteristics of the mass-spectra and the metal–ligand bond energies are considered initially. The review is also concerned with problems relating to the identification of ions containing the atoms of polyisotopic elements and with the occurrence of ion–molecule reactions in the mass spectrometer. The problems associated with the measurement of appearance potentials and the calculations on their basis of the average metal–ligand bond dissociation energy are not discussed, since they have been dealt with in detail in other reviews [2,6]. The mass-spectra of the π-complexes have been classified in accordance with the nature of the ligands, since the latter are in fact responsible for the main characteristics of the mass-spectra of the π-complexes.

II. METAL π-COMPLEXES WITH AROMATIC LIGANDS

The mass-spectra of the π-complexes of transition metals having the general formula L_1ML_2 (L = C_7H_7, C_5H_5, or C_6H_6) reflect the differences between the electron-donating capacities of the ligands but at the same time have many features in common.

Dicyclopentadienyl Compounds

Compounds of this class have been frequently investigated mass-spectrometrically [7-11]. The molecular ion peaks in the mass spectra of such complexes are as a rule the most intense and successive dissociation of the cyclopentadienyl groups from the molecular ion leads to the formation of metal ions and the fragment $C_5H_5M^+$, the peaks of which are also fairly intense. The cyclopentadienyl groups are also to a considerable degree fragmented. The group C_3H_3 and ethylene and acetylene molecules are mainly split off. When hydrogen atoms and methyl or other radicals are split off from the molecular ion, a series of ions are formed whose peak intensities are low. On fragmentation of molecular ions, the charge as a rule remains on the metal-containing fragment. The majority of fragmentation processes are accompanied by metastable transitions, with intense and distinct peaks [9].

The ionisation potentials of dicyclopentadienyl complexes are lower or equal to those of the atoms of the complex-forming elements [8,9,12,13]. This permitted the conclusion [8,9] that, in the ionisation of compounds such as ferrocene, an electron is removed from a non-bonding orbital localised at the metal atom. This conclusion is satisfactorily consistent with data calculated for ferrocene by the molecular orbital method [14].

The intensity of the metal ion peaks in the mass-spectra of the isoelectronic dicyclopentadienyl complexes of iron, ruthenium, and osmium (Table 1) decreases on passing from ferrocene to osmocene. This indicates an increase in the strength of the metal–cyclopentadienyl bond with increase of the atomic number of the complex-forming element. The metal–ligand bond energies for ferrocene and ruthenocene quoted in Table 1, calculated from the appearance potentials of iron and ruthenium ions, confirm this. An analogous correlation between the mass spectra and the appearance potentials was observed for chromium, molybdenum, and tungsten hexacarbonyls [15-18].

The relative intensity of the metal ion peaks in the spectra of a series of dicyclopentadienyl compounds of vanadium, iron, nickel, and chromium increases, amounting respectively to 12.5, 16.1, 18.9, and 28.2% of the overall intensity of the peaks [8]. The increase is due to the decrease of the average metal–ligand bond dissociation energy, which is 88, [19] 74, [20] 62, [20] and 54 [21] kcal $mole^{-1}$ respectively.

The substitution of hydrogen atoms in the ligands can have a significant influence on the nature of the fragmentation. The study of the mass-spectra of substituted ferrocenes [22-28] showed that simple substituents (methyl and ethyl groups and halogen atoms) hardly affect the nature and degree of fragmentation. More complex substituents give rise to a number of characteristic features associated with the fragmentation of the substituent itself. In compounds containing alkyl and vinyl substituents in the same ring, cyclopentadienyl (Cp) groups without substituents are split off preferentially [25].

Table 1. Relative peak intensities of the principal ions in the mass-spectra and the metal–ligand bond dissociation energies in the dicyclopentadienyl complexes of iron, ruthenium, and osmium (%).

Ion	Fe	Ru	Os
$(C_5H_5)_2M^+$	100	100	100
$C_5H_5M^+$	36	21.7	2.7
M^+	27	2.8	0.5
D_{M-L}, kcal mole^{-1}	78	112	—

The mass-spectra of cyclopentadienyl compounds also reflect satisfactorily the degree of polarity of the metal–cyclopentadienyl bond. In order to demonstrate the influence of the nature of the metal–cyclopentadienyl bond on the characteristics of the fragmentation and the nature of the mass-spectrum, it is useful to compare the mass-spectra of dicyclopentadienyl π-complexes with those of ionic and σ-linked dicyclopentadienyl compounds. Thus the fragmentation of ionic dicyclopentadienyl magnesium and manganese compounds † [8,9] proceeds in the same way as in compounds of the ferrocene type. However, an increase in the amount of ionic character of the metal–cyclopentadienyl bond reduces the relative intensity of the molecular ion peaks and increases the intensity of the fragment ion peaks (Table 2).

Table 2. Relative peak intensities of the principal ions in the mass-spectra of the dicyclopentadienyl complexes of iron, magnesium, and manganese (%).

Ion	Fe	Mg	Mn
$(C_5H_5)_2M^+$	100	100	100
$C_5H_5M^+$	36	171	157
M^+	27	139	136

† In contrast to ferrocene and other dicyclopentadienyl transition metal compounds, Cp_2Mn is an ionic compound. Detailed information about studies dealing with the demonstration of the ionic character of the metal–cyclopentadienyl bonds in this compound can be found in other reviews [29,30].

Under the influence of electron impact, thallium cyclopentadienide splits off the cyclopentadienyl group, giving rise to a metal ion whose peak intensity is a maximum in the spectrum [31,32].

The mass-spectra of metal dicyclopentadienyl complexes with σ linkages (see, for example, the mass-spectrum of Cp_2Pb) [33] are close to the mass-spectra of ionic dicyclopentadienyl compounds.

Tricyclopentadienyl Compounds

Tricyclopentadienyl complexes of the lanthanides, which are partly ionic and partly of the π-complex type, constitute an extremely interesting class. The relative intensity of the molecular ion peaks in the mass-spectra of these compounds is fairly high [34-37]. The elimination of the first cyclopentadienyl group leads to the formation of the ions Cp_2M^+, the relative intensity of whose peaks is as a rule maximal in the spectrum. Further fragmentation leads to the pattern which is well known for ferrocene.

In contrast to the dicyclopentadienyl compounds of transition metals, the ionisation potentials of the tricyclopentadienyl complexes exceed by 1–2 eV the ionisation potentials of the lanthanide atoms, which can probably be accounted for by the removal on ionisation of an electron which is not localised at the atom of the complex-forming element but at the ligand, as in chelated chromium acetylacetonates [38].

Tetracyclopentadienyl Compounds

The mass-spectra of the tetracyclopentadienyl π-complexes of uranium and thorium [34,39] have intense peaks due to the molecular ion and the ions formed as a result of the elimination of cyclopentadienyl groups from the latter. The peaks due to the Cp_3M^+ ions are the most intense in the spectra. As for the di- and tricyclopentadienyl complexes, in the mass-spectra of the tetracyclopentadienyl complexes of uranium and thorium contain fairly intense peaks due to ions associated with the partial fragmentation of the ligands.

Table 3. Relative peak intensities of the principal ions in the mass-spectra of bisbenzenechromium and bisbenzenevanadium (%). [40]

Ion	Cr	V
$(C_6H_6)_2M^+$	28.5	85.6
$C_6H_6M^+$	37.6	83.5
M^+	100	100
$(C_6H_6)_2M^+$	6.2	18.0

Bisarene Compounds

The intensities of the molecular ion peaks in the mass-spectra of bisbenzenevanadium [40] and bisbenzenechromium [7,13,40,41] are much higher (Table 3), which is evidence for a fairly high stability of the metal–benzene bond. However, in contrast to the dicyclopentadienyl

compounds, in the mass spectra of the bisarene complexes the peaks due to the metal ions and not the molecular ions are the most intense. This difference is evidence that the stability of the metal–ligand bond in compounds of the type LML decreases following the replacement of cyclopentadienyl groups by benzene molecules. On the other hand, comparison of the relative intensities of the molecular ion peaks in the mass-spectra of bisbenzenechromium and bisbenzenevanadium leads to the conclusion that the benzene–vanadium bond is stronger than the benzene–chromium bond. These conclusions are satisfactorily consistent with thermochemical measurements[42].

The fragmentation of bisarene compounds is extremely simple and leads to the successive elimination of benzene molecules from the molecular ion with retention of the charge on the metal-containing fragments, which is confirmed by the presence in the mass-spectra of intense and distinct peaks due to metastable transitions.

The intensities of the peaks due to the $MC_5H_5^+$, $MC_4H_4^+$, $MC_3H_3^+$, MC_2H^+, and other ions in the mass-spectra of the bisarene compounds are extremely low. This shows that the fragmentation of the π-linked ligands in the bisarene compounds hardly occurs, in contrast to the cyclopentadienyl complexes, which is related to the greater stability of the benzene ring compared with other aromatic systems and the low metal–ligand bond energy.

The study of the mass-spectra of methyl, isopropyl, and phenyl derivatives of bisbenzenechromium [43–45] showed that the nature of the mass-spectra and the fragmentation of the molecular ions in these compounds and in bisbenzenechromium are similar. In the mass-spectra of the bisarene compounds of chromium with asymmetric ligands—benzenecumenechromium and diethylbenzeneethylbenzenechromium [44,45]—the relative intensities of the peaks due to the CrL_1^+ and CrL_2^+ ions differ appreciably, which is evidence for the preferential elimination of ligands containing a smaller number of alkyl substituents. A mass-spectrometric study of benzenehexamethylbenzenemanganese[46] also showed that benzene is split off from the molecular ion more readily than hexamethylbenzene.

The peaks due to molecular ions and not the metal ion, as for bisarenechromium compounds, are the most intense in the mass-spectra of bisbenzenemolybdenum and its ethyl derivatives[47]. The sharp increase of the relative intensity of the molecular ion peaks on passing from bisbenzenechromium to bisbenzenemolybdenum is evidence, as for cyclopentadienyl and carbonyl complexes, for an increase in the strength of the metal–ligand bond with increase of the atomic number of the complex-forming element.

The ionisation potentials of the bisarene compounds are somewhat lower, as for the dicyclopentadienyl complexes, than the ionisation potentials of the complex-forming elements. The introduction of methyl substituents into bisbenzenechromium reduces the ionisation potential, but the decrease is not quite so distinct as for the free ligands[43].

A characteristic feature of the bisarene compounds is the permanent presence in their mass-spectra of fairly intense peaks due to the hydrocarbon ions of the ligands. The complete agreement of the relative intensities of the peaks due to these ions with the relative intensities of the corresponding ions in the mass-spectra of the free ligands, the formation of metallic films on the components of the ion source, the increase of the intensity of the peaks of these ions with increase of the temperature of the ion source, and the equality of the appearance potentials of the corresponding hydrocarbon ions in the mass-spectra of the bisarene compounds and the free ligands led to the conclusion[40,44] that the formation of the hydrocarbon ions is associated with the presence of free ligands in the ion source of the mass-spectrometer. The latter are formed as a result of the partial thermal decomposition of the bisarene compounds in the ion source.

Transition Metal Complexes with Asymmetric Aromatic Ligands

The mass-spectra of compounds of the type $C_5H_5MC_7H_7$, where M = V, Cr, Mo, or W, and compounds of the type $C_5H_5MC_6H_6$, where M = Mn or Cr,[7,40,48–50] reflect satisfactorily the differences between the electron-donating capacities of the C_5H_5, C_7H_7, and C_6H_6 groups. The elimination of the cyclopentadienyl group from the molecular ions of these complexes takes place after the C_7H_7 and C_6H_6 groups have been split off.

A characteristic feature of the fragmentation of the complexes containing the C_7H_7 group is the elimination from the latter of an acetylene molecule with formation of the ion Cp_2M^+ via the mechanism

$$C_5H_5MC_7H_7^+ \rightarrow (C_5H_5)_2M^+ + C_2H_2 ,$$

and the ion in its turn splits off in succession cyclopentadienyl groups with formation of the $C_5H_5M^+$ fragment and metal ions, so that the fragmentation of the C_5H_5 and C_6H_6 groups joined by π-bonds to the complex-forming atom is analogous to that of the dicyclopentadienyl and bisarene compounds.

Thus, comparison of the mass-spectra of compounds of the type $(C_5H_5)_2M$, $C_5H_5MC_7H_7$, $C_5H_5MC_6H_6$, and $(C_6H_6)_2M$, for example the mass-spectra of the isoelectronic iron, chromium, and manganese compounds (Table 4), readily demonstrates the decrease of the relative intensity of the molecular ion peak on passing from ferrocene to bisbenzenechromium. This decrease is evidence for the weakening of the metal–ligand bond due to the decrease of the electron-donating activity of the ligands in the series $C_5H_5 > C_7H_7 > C_6H_6$.

Table 4. Relative peak intensities of the principal ions in the mass-spectra of the isoelectronic complexes of chromium, manganese, iron with aromatic ligands (%)*.

Ion	$(C_5H_5)_2Fe$	$C_7H_7CrC_5H_5$	$C_5H_5MnC_6H_6$	$(C_6H_6)_2Cr$
$L_1ML_2^+$	61.5	50.4	22.6	17.2
$MC_5H_5^+$	22.4	9.5	45.1	
$C_6H_6M^+$	—	—	—	22.6
M^+	16.1	40.1	32.3	60.2

*The overall intensity of the peaks due to the ions $L_1ML_2^+$, L_1M^+, L_2M^+, and M^+ was adopted as 100%.

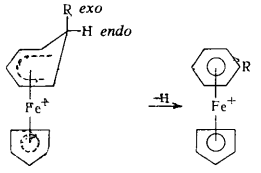
Complexes Containing Olefins Linked by π-bonds

The molecular ions of complexes containing, apart from the cyclopentadienyl group, π-linked olefins[50–53] split off the cyclopentadienyl group after the complete or

partial elimination of the olefin. Thus in the molecular ion of the $CpRh(C_2H_4)_2$ complex[50,52] the rupture of the metal–cyclopentadienyl bond is preceded by the stepwise elimination of the ethylene ligand species:

$$CpRh(C_2H_4)_2^+ \rightarrow CpRhC_2H_4^+ \rightarrow CpRh^+ \rightarrow Rh^+.$$

In complexes containing cyclo-olefins linked by π-bonds to the metal atom there is appreciable dehydrogenation of the olefin apart from the dissociation of the metal–ligand bond and partial fragmentation of the ligand species consisting in the elimination of the neutral C_2H_4, C_2H_2, and C_3H_3 groups. In a number of cases there is a stereoselective formation of aromatic fragments[54,69]:



The replacement of one cyclopentadienyl group in ferrocene by the indenyl ligand greatly complicates the nature of the fragmentation[51]. The molecular ion in the complex $CpFeC_9H_7$ loses the cyclopentadienyl group, simultaneously with the elimination of the indenyl ligand and the formation of the $CpFe^+$ ion, giving rise to the $C_9H_7Fe^+$ ion. In contrast to $CpFe^+$, the latter does not split off the indenyl ligand with formation of a metal ion but eliminates the iron atom, forming the ion $C_9H_7^+$, with a high intensity spectral peak.

The fragmentation mechanism becomes even more complicated when the indenyl group is replaced by its hydrogenation product C_9H_9 and C_9H_{11}. Dehydrogenation with formation of the $FeC_9H_8^+$ ion, which in turn loses the metal atom simultaneously with the elimination of the C_9H_8 group giving rise to the ion $C_9H_8^+$ and the products of its further fragmentation, is characteristic of these complexes. Fragmentation processes leading to the contraction of the ring with formation of the aromatic fragments $CpFeC_7H_7^+$, Cp_2Fe^+, and $CpFeC_6H_6^+$ are also characteristic of compounds containing the indenyl ligand and its hydrogenation products.

Table 5. The ionisation potentials of chromium, vanadium, manganese, and cobalt and of their complexes with benzene, the cyclopentadienyl group, and carbon monoxide.

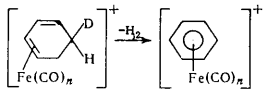
The olefin–metal complexes not containing the cyclopentadienyl group have been comparatively less well investigated by mass-spectrometry. The study of the mass-spectra of biscyclo-octa-1,5-dieneplatinum and biscyclo-octa-1,5-dienenickel[55], cycloheptadienylcycloheptatrienyltitanium[56], cyclo-octenylcyclo-octa-1,5-dienecobalt[57], and biscyclo-octatetraenethorium[58] showed that the fragmentation of complexes of this kind is analogous to that of the bisarene compounds, but the fragmentation of the π-linked hydrocarbon ligands takes place to a greater extent. The replacement of both cyclopentadienyl groups in ferrocene by indenyl groups leads to the elimination of the iron atoms from the molecular fragment ions $C_9H_7Fe^+$, which results in the presence in the mass spectrum of ions due to the indenyl ligand apart from the peaks due to metal-containing ions[51].

III. METAL π-COMPLEXES WITH AROMATIC AND π-ACCEPTOR LIGANDS

Mononuclear Complexes

The mass-spectra of the cyclopentadienyl complexes of cobalt[59], manganese[10,59–61], vanadium[59,61], rhenium[61], and iron[62] having the general formula $CpM(CO)_n$, cyclobutadienyltricarbonyliron[63], and benzenetricarbonylchromium[13,64,65] reflect satisfactorily the differences between the strengths of the metal–ligand bonds and the donor-acceptor properties of carbon monoxide, benzene, and the cyclopentadienyl group. The hydrocarbon ligands in these compounds are split off only after the complete loss of all the carbonyl groups from the molecular ion. Under these conditions, the CpM^+ ions also loses C_2H_2, C_2H_4, and other neutral groups, while there is hardly any fragmentation of the benzene ring with dissociation of carbon–carbon bonds.

The peaks due to the CpM^+ ion are the most intense in the mass-spectra of cyclopentadienyl derivatives of metal carbonyls, while the peaks of the metal ion are the most intense in the spectrum of benzenetricarbonylchromium. The carbonyl complexes with cyclic olefins behave similarly[60,62,66–69]. However, in this case the elimination of the carbonyl group and the olefin may prove to be equally probable, as has been observed for complexes of the type $C_5H_5M(CO)_2$(cyclo-olefin).[60] Moreover, dehydrogenation processes with subsequent aromatisation of the six-membered ring are characteristic of metal carbonyl complexes containing olefins, particularly those with adjacent CH_2 groups[54,69]:



The stereoselective formation of aromatic fragments proceeds in parallel with the decarbonylation of the molecular and fragment ions.

The fragmentation of substituted benzenetricarbonylchromium complexes $(CO)_3CrC_6H_5X$[64,70] depends significantly on the nature of the substituent X. The mass-spectra of the complexes with X = CH_3 and C_6H_5 hardly differ from the mass spectrum of benzenetricarbonylchromium. For electronegative substituents (Cl, F), the peaks of the rearranged ions CrX^+, the formation of which proceeds via the mechanism

$$CrC_6H_5X^+ \rightarrow CrX^+ + C_6H_5,$$

and is accompanied by a peak due to a metastable transition, exhibit an appreciable intensity in the mass spectra. The ions $CrC_6H_5X^+$ and $CrC_6H_4X^+$ lose an HX molecule with formation of the ions $CrC_6H_4^+$ and $CrC_6H_3^+$.

In the presence of more complex substituents (OCH_3, $COCH_3$, $OCOCH_3$, etc.) the peaks of the ions formed as a result of the fragmentation of the group X appear in the mass-spectra. The fragmentation of substituted cycloheptatriene and π-benzyl complexes of chromium tricarbonyl takes place similarly [71].

The ionisation potentials of benzenecarbonyl and cyclopentadienylcarbonyl complexes of transition metals (Table 5) are somewhat higher than those of the bisarene and dicyclopentadienyl compounds, but are lower than the ionisation potentials of the corresponding carbonyls.

The ionisation potential of benzenetricarbonylchromium decreases following the introduction of electron-donating substituents and increases following the introduction of electron-accepting substituents into the benzene ring [74]. However, a linear relation between the ionisation potentials of the arenetricarbonylchromium complexes and those of the free arenes, as in the case of the carbonylphosphine complexes of chromium, molybdenum, and tungsten[75], is not observed.

In cyclopentadienyl- and benzene-carbonylnitrosyl complexes of the type $CpM(NO)_x(CO)_y$ and $C_6H_6N(NO)_x(CO)_y$ [68, 76-78] nitric oxide and carbon monoxide are eliminated with equal probabilities. Fragmentation with dissociation of the Cp–M and C_6H_6–M bonds begins only after the complete elimination of the carbonyl and nitrosyl groups. A very unusual rearrangement has been observed by Müller [77] in the mass-spectrum of $CpV(NO)_2$. .CO. The ion $CpVNO^+$, formed after the elimination of the NO and CO groups, decomposes with formation of pyridine.

Whereas the loss of CO and NO groups from the carbonylnitrosyl complexes is equally probable, the mass-spectra of complexes with phosphines, arsines, and sulphur-containing and other ligands reflect the differences between the donor–acceptor capacities of carbon monoxide, nitric oxide, sulphur, and phosphines. Thus a study of the mass-spectrum of $CpMn(CO)_2N_2$ showed [79] that, for example, molecular nitrogen is a more powerful electron donor than carbon monoxide. The elimination of ligand species from the molecular ions derived from the carbonylphosphine complexes of the type $CpM(CO)_m(PX_3)_n$ and $C_6H_6M(CO)_m(PX)_n$ (X = H, Cl, Me, Et, etc.) [80-84] proceeds in the following sequence: the carbonyl groups are split off first, the phosphine molecules next, and only then does the elimination of the Cp and C_6H_6 groups begin. The elimination of the phosphine group is accompanied by its partial fragmentation, which leads to the presence in the mass-spectra of lines due to the ions $CpMPX_2^+$, $CpMPX^+$, and $CpMP^+$. The lines due to the CpM^+ ion in the spectra of the cyclopentadienyl complexes and due to the metal ion in the spectra of the benzene complexes show the greatest intensity. In the olefin complexes of manganese of the type $C_4H_4Mn(CO)_2EPh_3$ (E = P, As, or Sb) [85] the olefins are split off after the elimination of the CO and EPh_3 groups and there is a steady decrease of the strength of the bond between the metal and phosphine, arsine, and stibine.

The substitution of a hydrogen atom in the ligands PH_3, AsH_3, H_2S, H_2Se, etc. influences significantly the ionisation potential of the complex, the dependence of the latter on the ionisation potential of the corresponding ligand being linear [86].

Dinuclear and Polynuclear Complexes

Certain cyclopentadienyl complexes exist as dimers in the gas phase. Molecular ions and ions formed by their fragmentation have been detected in the mass-spectra of such compounds {see, for example, the mass-spectrum of $[PtCp]_2$}. [87] Simultaneously with the elimination of the cyclopentadienyl group and the formation of the M_2^+ cluster, the metal–metal bond is broken with formation of metal ions and the fragment CpM^+. Partial fragmentation of the π-linked cyclopentadienyl group is also observed.

In complexes containing ligands of the π-acceptor type apart from cyclopentadienyl groups the metal atoms can be joined both by a usual metal–metal bond and by bridge-type bonds:  Carbon monoxide, nitric oxide, phosphines, and other two- and three-electron ligands can serve as bridging groups.

Under the influence of electron impact, complexes with bridge-type bonds $CpMX_nMCp$ (where X = carbon monoxide, phosphines, and other ligands) [88-91] split off Cp groups forming the ions MX_nM^+ with fairly intense peaks. The removal of bridging groups leads to the breakdown of the cluster with formation of the ions M^+, CpM^+, $C_3H_3M^+$, etc. There are no peaks for M_2^+ ions in the mass-spectra of complexes of this kind. It is striking that the bridging ligands are linked to the metal atoms much more strongly than the same ligands occupying terminal positions.

In complexes with a usual metal–metal bond or with one such bond and several bridge-type bonds [90, 92-97] the successive removal of ligand species from the molecular ion leads to the formation of the ion M_2^+. There is a simultaneous rupture of the metal–metal bond with subsequent further fragmentation of the resulting fragments.

Structural differences are shown particularly clearly by the mass-spectra of $[CpFe(CO)_2]_2$ and $[CpMo(CO)_3]_2$. [90] Thus in the mass-spectrum of $[CpMo(CO)_3]_2$, which has a metal–metal bond, the peaks of the ion $CpMoMoCp^+$ have the maximum intensity, while in the mass-spectrum of $[CpFe(CO)_2]_2$, where the linkage between the iron atoms in the molecule is formed by CO bridging groups, the intensity of the peaks due to ions containing two iron atoms is low and the peak for the $CpFe^+$ ion is the most intense. A similar difference has been observed [98] for the molybdenum and chromium complexes $[CpM(CO)_3]_2$, although in this case the reason for the difference is in all probability the thermal instability of the chromium complex.

A similar behaviour has been observed for complexes containing different transition metal atoms [97, 99, 100].

IV. COMPLEX-CONTAINING GROUPS LINKED BY σ-BONDS

Certain transitions metals form complexes containing, apart from π-linked ligands and ligands of the π-acceptor type, also groups linked to the atom of the complex-forming element by σ-bonds, namely hydrogen and halogen atoms, organic groups, etc.

Dicyclopentadienylmetal Hydrides and Halides

Studies on the dicyclopentadienyl complexes of rhenium, tungsten, tantalum, and molybdenum hydrides showed [8, 9, 101, 102] that there are no significant differences between the mass-spectra of the dicyclopentadienyl complexes and the dicyclopentadienylmetal hydrides. After the elimination of hydrogen atoms from the molecular

ions, the Cp_2M^+ ions undergo fragmentation, which gives rise to the pattern well known for compounds of the ferrocene type.

In the cyclopentadienyl complexes of titanium, zirconium, hafnium, and niobium halides [11,103-105] the halogen atoms are retained somewhat more strongly by the molecular ions than are hydrogen atoms in the dicyclopentadienylmetal hydrides, but the type of fragmentation of both classes of compounds is similar. This can also be said of the uranium and thorium complexes Cp_3MF and Cp_3MI. [34,38]

Complexes with σ-Linked Organic Groups

The mass-spectra of cyclopentadienyl complexes with σ-linked organic groups are in many cases complicated by the fragmentation of the latter. The nature and degree of fragmentation of complexes of the type $CpM(CO)_xR_y$, [61,106-111] $Cp_2M(CO)_xR_y$, [11,112-115] and $CpMX_xR$ [116,117] (where X = fluorine, chlorine, bromine, or iodine atoms and R = organic or inorganic groups) are largely determined by the dimensions and stability of the organic groups linked by σ-bonds to the metal atom and also by the amount of ionic character of the metal–group and metal–halogen bonds [117]. The ion $CpMC_7H_7^+$, containing a π-linked tropylium cation, which is absent from the mass-spectrum of the corresponding fluorinated complex, has been detected in the mass-spectra of complexes containing the $CH_2C_6H_5$ group [110].

Heteronuclear Complexes

The so called heteronuclear metal complexes, namely compounds with σ-bonds between atoms of a transition metal and elements of the main Groups, exhibit somewhat unusual behaviour.

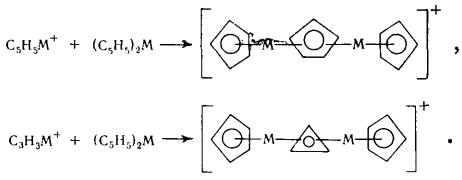
Under electron impact, extensive rupture of the metal–element bond takes place in such compounds simultaneously with the elimination of the ligand species. The charge is then retained preferentially by the fragment containing atoms of the elements of the main Groups. Thus in the mass-spectra of compounds of the type $CpM(CO)_mEX_n$ (where E = mercury, silicon, germanium, or tin; X = halogen atoms or organic groups) [62,90,118,119] and the compounds $CpRu(AsPh_3)_2SnCl_3$ [120] and $[HgM(CO)_nCp]_2$ [90,119] (M = Co or Fe) the peaks of ions containing a mercury, germanium, silicon, or tin atom are the most intense, while in the mass-spectra of the molybdenum and tungsten complexes $Et_2GeM(CO)_3Cp$ [121] the peaks of ions containing the M–Ge groups have the highest intensity.

Thus the mass-spectra of the metal complexes reflect the differences in the strength and nature of the metal–ligand and metal–metal bonds as well as structural and other differences. The principal characteristics of the mass-spectra of compounds of this class are a function of the electron-donating activity of the ligand and the atomic number of the complex-forming element. On the other hand, compounds of this type have features which will be discussed in the next section.

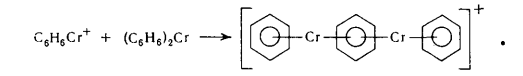
V. CHARACTERISTICS OF THE MASS-SPECTRA OF METAL π-COMPLEXES AND PROBLEMS OF THE ISOTOPIC ANALYSIS OF ELEMENTS IN THE FORM OF THEIR π-COMPLEXES

Ion–Molecule Reactions

One of the distinctive features of the complexes under consideration is their capacity to enter into ion–molecule reactions. At a pressure in the region of the ion source of $10^{-5}-10^{-6}$ mmHg, the mass-spectra of metal π-complexes can show peaks due to ions with a mass number exceeding the molecular weight of the complex. Thus, in a study of the mass-spectra of ferrocene and a mixture of ferrocene and nickelocene peaks due to the ions $Cp_3Fe_2^+$ and Cp_3FeNi^+ as well as peaks due to ions formed on their fragmentation with ejection of the cyclopentadienyl group were observed [122]. These ions, for which a double sandwich structure was suggested, are formed in the ion source of the mass-spectrometer as a result of the ion–molecule reactions



Similar reactions are characteristic also of other dicyclopentadienyl compounds, in particular of dicyclopentadienylchromium [123]. Bisbenzenechromium is also capable of forming ion–molecule association complexes [123]:



Both consecutive loss of ligand species and partial fragmentation of the cyclopentadienyl groups, mainly the elimination of ethylene and acetylene molecules with formation of the fragments $Cp_2C_3H_3M^+$, $CpC_3H_3M^+$, etc., are characteristic of the secondary ions Cp_3M^+, while the ion $(C_6H_6)_3Cr_2^+$ splits off only benzene molecules and there is virtually no partial fragmentation of the ligand species.

The mass-spectra of $CpM(CO)_n$ (M = V, Mn, or Co) [124] and $CpCr(NO)(CO)_2$ [123] contain peaks due to the ions $Cp_2M_2(CO)_n^+$ and $Cp_2M_2(CO)_n(NO)^+$ (formed as a result of reactions between ions and neutral molecules), which successively lose CO, NO, and cyclopentadienyl groups. As for the ions Cp_3M^+, a characteristic feature of these ions is the fragmentation of the cyclopentadienyl ligand species π-linked to the metal atom. The secondary ion $(C_6H_6)_2Cr(CO)_3^+$ behaves similarly in the mass-spectrum of benzenetricarbonylchromium [123], but there is no partial fragmentation of the C_6H_6 groups. Clusters containing three and more metal atoms are observed. Ion–molecule association complexes of this kind are characteristic also of trinuclear complexes [125].

Ion–molecule reactions of another type involve the addition of fluorides (PF_3, AsF_3, SbF_3, SF_4, and NF_4) to the metal-containing ions in the mass-spectrum of $CpMn(CO)_3$. [126]

Rearranged and Metastable Ions

Another characteristic feature of metal π-complexes is their capacity to form rearranged ions with fairly intense mass-spectral peaks.

Thus the rearranged ions MH^+ are as a rule absent from the mass-spectra of metal complexes with aromatic and π-acceptor ligands. However, in the mass-spectra of complexes containing σ-linked organic groups the intensity of peaks of ions of this kind is high, particularly in the case of fluorinated groups [91,109]. This can be explained by the higher strength of the metal–fluorine bond compared with the metal–hydrogen bond.

Another type of rearrangement processes characteristic of metal π-complexes are those involving the migration of cyclopentadienyl groups. In the mass-spectra of dinuclear compounds with one cyclopentadienyl group at each metal atom there are peaks due to the Cp_2M^+ ions [94,127]:

$$CpCr_2S_2Cp^+ \rightarrow Cr_2Cp^+ .$$

The cyclopentadienyl group can migrate also to a heteroatom σ-linked to the atom of the complex-forming element. Thus in the mass spectrum of $Cp(CO)_2FeSn.Cl_2Fe(CO)_2Cp$ the intensity of the peaks of the rearranged ion $CpSnCl^+$ is maximal [90]. Trialkylgermylmolybdenum and trialkylgermyltungsten complexes $Cp(CO)_3MGePh_3$, the mass-spectra of which show the presence of the $CpGe^+$ ion, behave analogously.

In many instances rearrangement processes lead to the formation of ions containing a metal–metal bond [128,129]:

$$Cp(CO)Fe(CO)_2Fe(CO)Cp^+ \rightarrow Cp_2Fe_2^+ ,$$
$$(CO)_5MnHgMn(CO)_5^+ \rightarrow Mn_2(CO)_n^+ .$$

A characteristic feature of the mass-spectra of π-complexes is also the unusually great abundance of peaks due to metastable transitions. Intense, distinct peaks accompany processes involving the abstraction from the molecular ions of cyclopentadienyl and carbonyl groups and benzene molecules:

$$CpM(CO)_n^+ \rightarrow CpM(CO)_{n-1}^+ + CO ,$$
$$C_6H_6M(CO)_n^+ \rightarrow C_6H_6M(CO)_{n-1}^+ + CO ,$$
$$Cp_2M^+ \rightarrow CpM^+ + Cp ,$$
$$(C_6H_6)_2M^+ \rightarrow C_6H_6M^+ + C_6H_6 .$$

Very intense peaks are observed also for metastable transitions accompanying the fragmentation of the cyclopentadienyl groups:

$$Cp_2M^+ \rightarrow CpMC_3H_3^+ + C_2H_2 ,$$
$$CpM^+ \rightarrow C_3H_3M^+ + C_2H_2 .$$

Still more intense metastable transition peaks accompany the decomposition of the fragment ions:

$$C_6H_6M^+ \rightarrow M^+ + C_6H_6 ,$$
$$C_5H_5M^+ \rightarrow M^+ + C_5H_5 .$$

The metastable transition peaks are diffuse and the corresponding apparent mass is determined from the relation [6]

$$m^* = \frac{m_2^2}{m_1} ,$$
$$m_1^+ = m_2^+ + (m_1 - m_2) .$$

Characteristics of the Mass-spectra of Polyisotopic Metal Complexes

Acton was the first to employ volatile metal carbonyls and their derivatives to investigate the natural abundance of metal isotopes [130]. (Acton's studies have been reviewed in detail by Bruce [1].) Transition metal π-complexes also constitute a convenient means for the investigation of isotope composition. Using cyclopentadienyl compounds, the natural abundance of ruthenium isotopes was investigated [131] and the relative amounts of vanadium and rhenium isotopes were checked. The presence in the mass-spectra of π-complexes of intense peaks due to the metal ion and the satisfactory agreement of these peaks with the isotope ratio make it possible to employ π-complexes for the isotopic analysis of metals.

No less important is the problem of the identification of ions in the mass-spectra of π-complexes. The identification of ions in the mass-spectra obtained on low-resolution apparatus is frequently extremely difficult. Such difficulties are somewhat diminished in the case of organometallic compounds. The differences between the relative concentrations of isotopes in the π-complexes of polyisotopic transition metals lead to the formation of different characteristic molecular and fragment ions, represented by a group of peaks the intensities of which agree satisfactorily with the isotope ratio. This greatly facilitates the identification of the metal-containing ions in low-resolution mass-spectra.

Catalysts for the Oxidative Ammoniolysis of Propene

I.K.Kolchin

The effect of the electronic structure of the lattice cations, of the environment of the adsorption centres, of the relative positions of the propene and oxygen adsorption centres, of the electronic work function of the solid, and of the acidity of its surface on the activity of catalysts for the oxidative ammoniolysis of propene is examined on the basis of the literature data. The bibliography includes 185 references.

I. INTRODUCTION

The development of the manufacture of polymeric materials, synthetic fibres, synthetic rubber, dyes, physiologically active substances, and other products of organic synthesis has led to the appearance of new effective methods for the conversion of petrochemical and coke-chemical raw materials into valuable polyfunctional organic compounds. These include oxidative ammoniolysis—an effective method for the synthesis of nitrogen-containing compounds developed recently [1-3].

The high selectivity, universality, and low cost of oxidative ammoniolysis make it one of the most promising new large-scale chemical processes. The list of nitrogen-containing substances obtained with the aid of oxidative ammoniolysis already includes several tens of names and processes such as oxidative ammoniolysis of methane [1], propene [2-4], isobutene [5], and aromatic compounds (toluene, xylene) [3,6-8] are now employed on an industrial scale.

The oxidative ammoniolysis of olefins has acquired particularly great industrial importance. It is sufficient to point out that acrylonitrile is nowadays manufactured from propene in about 30 plants with an overall output of more than 1.5 million tonnes per year in countries including the USA (in seven plants with an output of 616 000 tonnes) [8] and Japan (in nine industrial combines with an output of 670 000 tonnes per year) [9].

The studies published in recent years [1,2,10,11,12] reflect fairly completely the bulk of patent information concerning the catalysts for the oxidative ammoniolysis of propene. In Table 1 this compilation is supplemented by data from patents and the periodical literature published during 1968–1972.

Judging from the literature data, among the large number of a wide variety of compounds employed as catalysts for the synthesis of acrylonitrile only the bismuth phosphomolybdate catalyst [4,12], the uranium–antimony catalyst, (the so called catalyst-21), [52] and the iron–antimony catalyst [89] have found industrial applications. All these catalysts are made from metasilicic acid gel. The ASAHI Company improved the bismuth phosphomolybdate catalyst by incorporating iron compounds in its composition, thereby increasing the yield of acrylonitrile obtained to 72–76%. [27]

Societa Edison S.p.A. (Italy) employs the catalyst prepared from the highest oxides of tellurium, cerium, and molybdenum on silica gel [73] and SNAM Progetti S.p.A. employs vanadium and bismuth molybdates [90]. A catalyst in the presence of which the yield of acrylonitrile increases to 80–82% was developed recently by the Sohayo Company [sic], [91] but its composition was not disclosed.

Despite many studies on the preparation and properties of catalysts for the oxidative ammoniolysis of propene, the search for new effective catalysts for this process as well as for the mild selective oxidation of hydrocarbons is still continuing, largely by empirical procedures. There have been only a few studies in which relations were discovered whereby it is possible to regulate the catalytic properties of substances in these processes.

According to Lazukin et al. [92], the oxide catalyst "inherits" the activities and selectivities of its components. In order to obtain an effective catalyst, it is necessary to combine a highly active but relatively unselective metal oxide with a relatively inactive but highly selective oxide.

Alkhazov [93] believes that catalysts for the oxidative dehydrogenation of olefins can be formed only by combining in pairs oxides in the "highly isomerising and moderately oxidising" group.

According to the data of Kolovertnov and Boreskov [94], the catalytic activity of binary oxide catalysts for the oxidation of methanol to formaldehyde is a function of the amount of ionic character of the M–O bond determined from the ionisation constants of metal hydroxide compounds. The activity and selectivity of individual molybdates and vanadates are determined mainly by molybdenum and vanadium, which form part of the salt anion. The cation, stabilising the hexavalent or quinquevalent state of molybdenum or vanadium, regulates the activity.

A similar view has been expressed by Sachtler and Dorgelo [95], who investigated the oxidation of benzaldehyde to benzoic acid in the presence of the SnO_2–V_2O_5 catalyst. The authors believe that tin dioxide promotes the stability of the quinquevalent state of vanadium.

It has been suggested [96,97] that the catalytic properties of effective catalysts for the oxidation and oxidative ammoniolysis of olefins are due to the presence in their composition of doublets comprising different or identical cations. Batiste et al. [98] believe that, for mild oxidation

Table 1. Catalysts for the oxidative ammoniolysis of propene.

Catalyst	Carrier	Conditions governing the preparation of catalyst	Reaction conditions	Process parameters	References
Bismuth phosphomolybdate Bi:Mo:P = 9:1 2:1	Metasilicic acid gel	Joint precipitation and pelleting with formation of the compound $(Bi_9PMo_{12}O_{52})_x(SiO_2)_y.SiO_2$ content 50%	420-550°, $C_3H_6:NH_3:O_2:H_2O$(vapour) = 1.0:1.0:1.8:3.5, fluidised bed	Conversion 80%. Selectivity 65%	12,13
Bismuth phosphomolybdate with added cobalt and nickel oxides		Mixing of solns. of bismuth and cobalt (nickel) nitrates, ammonium paramolybdate, and phosphoric acid. Heat treatment for 12 h at 550°	$C_3H_6:NH_3$:air = 10:11:110, contact time 1-20 s	Yield of acrylonitrile 62%	14-16
Bismuth phosphomolybdate	Silica gel	Impregnation of silica gel with soln. containing the active components	$C_3H_6:NH_3:O_2:H_2O$(vapour) = 1.0:1.1:1.2-1.8:1.0-4.0, stationary bed, 480°, contact time 1.5-5.0 s	Conversion 70% Selectivity 60%	17,18
	Modified silica gel	Deposition of components from the same nitrate soln. Content of active components 12-14 wt.%	Fluidised bed, contact time 6 s	Conversion 85% Selectivity 60%	19
Bismuth phosphomolybdate	Corundum, porosity 32%	Impregnation of corundum with a soln. containing the active components	$C_3H_6:NH_3:O_2:H_2O$(vapour) = 1.0:1.0:1.9:6.2, 450-500°	Conversion 60% Selectivity up to 80%	20,21,22
	Corundum	Heat treatment of alumina at 1750°. Joint pelleting with bismuth phosphomolybdate in the presence of a carrier content of 85%	Data not available		23
Iron-modified bismuth phosphomolybdate (A-112 catalyst, Japan)	Metasilicic acid gel	Joint precipitation of active compound having the atomic ratio Bi:Fe = 1:12:3:5 with metasilicic acid gel	450-500°, fluidised bed	Conversion up to 92% Selectivity 68%	23-27
Iron-modified bismuth phosphomolybdate with added lead	Metasilicic acid gel	Joint precipitation of active compound $Pb_2Bi_4Mo_{12}Fe_9P$ with metasilicic acid gel	450°, contact time 1.2 s	Yield up to 52%	28
Bismuth antimonate		Preparation of bismuth antimonate $Bi_2O_3.Sb_2O_5$	450°	Conversion 10% Selectivity 10%	29
Mixture of bismuth antimonate and molybdate		Preparation of catalyst containing 65% of bismuth molybdate and 35% of bismuth antimonate	470°	Conversion 58% Selectivity 90%	29-31
Mixture of bismuth antimonate and molybdate		Preparation of catalyst by mixing soln. of bismuth nitrate, ammonium paramolybdate, and antimony perchlorate	450-470° $C_3H_6:NH_3$:air:H_2O(vapour) = 1.0:1.0:7.0:1.0	Conversion 60% Selectivity 85%	32-36
Mixture of bismuth antimonate and molybdate	Alumina	Impregnation of carrier with soln. containing the active components. Carrier content 50-80%	Data not available		37
Mixture of bismuth antimonate and molybdate with added tin dioxide	Silica gel, 10-60%	Precipitation of bismuth antimonate on mixing $Bi(NO_3)_3$ and Sb_2O_3 solns. in HNO_3 Bismuth antimonate mixed with bismuth molybdate: SnO_2, SiO_2. $BiSbO_4:SnO_2:Bi_2(MoO_4)_3$ = 60:40:5-50	$C_3H_6:NH_3:O_2:H_2O$ = 1.0:1.0:1.4:1.0, contact time 11.2 s	Conversion 60% Selectivity 91%	38-40
Mixture of As, Mo, and W oxides		Mechanical mixture (0.1-20 wt.% As_2O_5, 1.50 wt.% WO_3, 1-50 wt.% MoO_3)	$C_3H_6:NH_3:O_2$ = 1.0:1.2:1.5-5.0, 450-500°, 480°, contact time 10-40 s, fluidised bed	Yield of acrylonitrile 58% and 60-62%	40 41-44
Mixture of As, Mo, and W oxides	Silica gel, alumina	Impregnation of carrier by aqueous soln. of Mo, As, and W compounds. Drying at 100-200° and heat treatment at 400-450°	480°, As_2O_5 introduced into gaseous mixture	Yield up to 72%	45-46
Mixture of bismuth or antimony compounds		Mixing of the compounds $Sb(VO_3)_3$ and $SbPO_4$ or $Bi(VO_3)_3$ and $BiPO_4$, treatment of mixture at 500°	450-480°	Yield 45%	47-48
Uranium-antimony catalyst		Mixing of uranyl nitrate and antimony perchlorate solns., ratio in precipitate Sb:U = 1-50:2-100	480°, contact time 5-10 s, fluidised bed	Yield 62-64%	49-51
Mixture of spent uranium oxide with antimony oxide		Catalyst 21		Yield 62%	52
Uranium-antimony catalyst	Alumina	Impregnation of carrier by soln. containing uranium and antimony salts	480°	Yield 60%	53
Antimony-tin catalysts with atomic ratio Sn:Sb = 0.1-10:1.0-20.0		Mixing of solns. of antimony and tin chloride pptn. with ammonia, heat treatment of ppt. at 500-700°	470°, contact time 4 s, $C_3H_6:NH_3:O_2:H_2O$(vapour)= 1.0:1.0:1.2:6.0	Selectivity 65% Yield 51-52%	54,55
Solid soln. of tin(IV) oxide in antimony oxide with atomic ratios Sn:Sb = 1.0:1.0 and Sn:Sb = 0.25:1.0		Mixing of solns. of antimony and tin chlorides drying at 140°, and heat treatment at 800°	480°, contact time 0.8-1.5 s, $C_3H_6:NH_3:O_2:H_2O$(vapour) = 1.0:1.0:1.5:2.0	Yield 41-42%	56,57
Iron-antimony catalyst		Preparation of iron antimonate containing 55 at.% of antimony	480°, $C_3H_6:O_2$ = 1:6	Selectivity 80-82%	58,59

Table 1 (contd.)

Catalyst	Carrier	Conditions governing the preparation of catalyst	Reaction conditions	Process parameters	References
Iron-antimony catalyst		Mixing of solns. of antimony and iron chlorides. Heat treatment of ppt. for 16 h at 650°. Atomic ratio Sb:Fe from 1:50 to 99:1	480-500°, contact time 0.5-10 s, $C_3H_6:NH_3:O_2:H_2O$(vapour) = 1.0:1.2:1.5:1.2	Conversion 74% Selectivity 70%	60,61
Iron-antimony catalyst	Metasilicic acid gel	Joint precipitation of iron nitrate and antimony chloride with silica soln. Drying at 120° and heat treatment at 750°	450-550°, $C_3H_6:NH_3:O_2$ = 1:1.2:1.2-5.0	Selectivity 70%	60-62,68
Iron-antimony catalyst	Pumice	Impregnation of pumice by solns. containing iron and antimony compounds	$C_3H_6:NH_3$:air:H_2O(vapour) = 1.0:1.1:7.5:1.0	Selectivity 80%	63
Iron-antimony catalyst with added Mo(W) and B(P)		Preparation of compound by precipitation on mixing solns. of $Fe_aSb_bMo_c.X_dO_e$, where X = P or B, a = 10, b = 5-60, c = 0.5-1, and d = 0.005-1.0	$C_3H_6:NH_3:O_2$ = 1:0.5:0.5-5.0 480°	Selectivity 80%	64-67
Iron-antimony catalyst with added vanadium		Preparation of compound with the conventional formula $Fe_aSb_bV_cX_dO_e$, where X = P or B, a = 10, b = 5-80, c = 0.01-2, and d = 0-2. Catalyst activated by heating for 2-24 h at 600° and for 20 h at 700-1000°	480-500°	Yield 60%	69-70
Tin molybdate with atomic ratio Sn:Mo = 9:1		Mixing of ammonium molybdate and tin(II) chloride soln., heat treatment of ppt. at 500°	Contact time 7 s, $C_3H_6:NH_3:O_2:H_2O$(vapour) = 1.0:1.0:1.2:1.0	Conversion 75% Selectivity 65%	71
Bismuth molybdate + TeO_2	Silica gel	Joint pelleting of bismuth molybdate and tellurium oxide with silica gel	400-500°, contact time 0.5-15 s $C_3H_6:NH_3$ = 2.0-1.0:0.6-1.0	Selectivity 85%	73
Mixture of tellurium, lanthanum (cerium), and molybdenum oxides		Mixing of lanthanum nitrate with telluric acid, heat treatment at 500°		Selectivity 70%	73
Mixture of tellurium and molybdenum oxides	Silica gel	Deposition from soln. containing active components. Drying at 120° and heat treatment at 450°	$C_3H_6:NH_3:O_2:H_2O$(vapour) = 1.0:1.0:2.0:2.5, contact time 6 s	Yield 32%	74-76
Mixture of tellurium and molybdenum oxides with added phosphorus		Mixing and evaporation of aqueous solns. of ammonium molybdate, phosphoric acid, and telluric acid. Heat treatment at 420°	480°, contact time 3 s	Selectivity 80% Conversion 70%	77-80
Vanadium molybdate	Metasilicic acid gel	Joint deposition of silica soln. with molybdenum and vanadium oxides. Heat treatment at 400-500°	$C_3H_6:NH_3:O_2:H_2O$(vapour) = 1.0:1.0:1.5:1.2, fluidised bed, 400-500°	Conversion 71% Selectivity 80%	81-83
Copper phosphate	Silica gel	Impregnation of silica gel by copper pyrophosphate or triphosphate solns.	450-480°	Conversion 40%	84
Iron and bismuth phosphates			$C_3H_6:NH_3:O_2:H_2O$(vapour) = 1.0:1.2:2.0:2.0, 480°	Conversion 70% Selectivity 68%	85
Solid phosphoric acid		Mixture of titanium, molybdenum, iron, cobalt, vanadium, bismuth, etc. phosphates	500°	Conversion 30%	86
Copper phosphate	Borophosphate	Impregnation by soln. of copper nitrate and phosphoric acid		Selectivity 67%	87
Iron-containing zeolite	NaX	Ion exchange between NaX zeolite and iron thiocyanate soln.. Degree of exchange 50%	480°	Conversion 40%	88

of hydrocarbons on the surface of the catalyst, the formation of two kinds of anionic vacancies linked to the doublet centre is necessary. Unfortunately the hypothesis of the existence of doublet centres, responsible for the selective oxidation of olefins, is based only on the chemical composition and the determination of catalytic activity and requires additional evidence.

The molybdenum–oxygen plays a major role in catalytic oxidation reactions. The Mo=O bond in various metal molybdates is more reactive than other bonds [99,100]. A similar view was expressed earlier in a study of the catalytic activity of vanadium catalyst by Tarama and Teranishi [101], who observed that catalysts containing the V=O double bond exhibit the highest activity in the oxidation of benzene.

Many investigators are now seeking various correlations between particular properties of catalysts and their relative activities with respect to a specific reaction or group of reactions. Correlations have been observed between catalytic activity and properties such as the electronic work function, electrical conductivity, the width of the forbidden gap in semiconductors, etc. However, each correlation embraces a very limited range of catalysts for which the chosen property is for some reason dominant. Moreover, this property reflects only partly the characteristics of the chemical interactions of the reactant molecules with the catalyst and with one another, which determine the catalytic effect. The most reasonable are attempts to relate catalytic activity to thermodynamic characteristics—the energies of the bonds broken and formed on formation of the activated complex in the rate-determining step [102].

However, none of these hypotheses can explain fully the mechanism of the action of complex catalysts for the oxidation of hydrocarbons. From this standpoint, it is interesting to analyse the extensive literature data on catalysts for the oxidative ammoniolysis of propene in order to elucidate the nature of the active surface and its role in the selectivity of the process.

II. SOME PROBLEMS OF THE MECHANISM OF THE OXIDATIVE AMMONIOLYSIS OF PROPENE

Several communications dealing with the mechanism of the oxidation and oxidative ammoniolysis of propene in the presence of mixed catalysts were published recently[2,3,12,103,104]. According to their results, the only rigorously proved fact is that the oxidative ammoniolysis of propene as well as its oxidation proceed via the formation of an allyl complex. The constancy of the isotope effect in the formation of acrolein and acrylonitrile[105] and also the identical reaction kinetics[106] enabled many investigators[103,105,106] to suggest that the rate-limiting stages in these two processes are the same.

The discovery of the relations governing the formation of the CN group in the oxidative ammoniolysis of various compounds enabled Rafikov and Suvorov[3,107,108] to put forward the hypothesis that in the case of organic compounds of the type RCH_3 nitriles and their amide precursors are formed mainly from aldehydes. The authors believe that nitriles can be formed also via an "amine" reaction pathway. The hypothesis concerning the role of aldehydes in the oxidative ammoniolysis of hydrocarbons has found confirmation in studies by other investigators[109-112], although some of them suggest that ammonia interacts with the carbonyl group via an aldimine mechanism[111].

On the basis of kinetic data for the individual stages in the oxidative ammoniolysis of propene, Germain and coworkers[103,104] and Callahan and coworkers[4] believe that acrylonitrile is only partly formed via acrolein, while the contributions of the "amine" and "aldehyde" pathways to the formation of nitriles as well as the escape of acrolein to the gas phase apparently depend markedly on the concentration of oxygen and ammonia in the catalyst zone and on the structure of the initial hydrocarbon. On the basis of his data obtained under the condition of a low oxygen concentration and a high water concentration, Germain suggested that acrylonitrile may be formed via a stage involving the formation of an adsorbed carbene having the structure $CH_2{=}CH{-}\ddot{C}H$.

However, the mechanism proposed by the author for this reaction was not proved unambiguously and is extremely hypothetical. Gorshkov and coworkers undertook a detailed study of the mechanism of the formation and further reaction of the intermediate and side products of the joint oxidation of propene and ammonia using the kinetic isotopic method[113], with a complete computer calculation of the mechanism of the oxidation of propene[114] and the individual carbonyl compounds[115] with simultaneous evaluation of the rate constants for the individual stages. The experimental results suggested a possible process mechanism involving a number of stages[116], according to which a major role is played by the successive reaction of certain oxygen-containing compounds formed in the interaction between adsorbed oxygen and the hydrocarbon, which are desorbed from the surface in the form of aldehydes. According to a study[117] on the adsorption of propene and acrolein at 200° and 300°C on the surface of molybdenum catalysts using infrared spectroscopy, such oxygen-containing compounds are carbonyl-containing complexes coordinated to the surface via the double bond and via the carbon atom of the aldehyde group.

A significant distinctive feature of the proposed mechanism is also the demonstration of the formation of acetaldehyde and formaldehyde, like acrolein, via an allylic compound. Since it has been shown by the kinetic isotope method[113] that the intermediate in the formation of these compounds is the same, they are probably produced on the same active centres of the catalyst surface. The different modes of reaction of the intermediate are probably determined by the different energies of the bond between oxygen and the surface of the catalyst and the number of oxygen atoms involved in the formation of the surface carbonyl-containing compound. It has also been established[114-116] that carbon oxides are formed by the subsequent oxidation partly of the surface carbonyl-containing compounds and partly of the desired nitrogen-containing products via a parallel-consecutive mechanism, with the successive pathway predominating.

Infrared spectroscopic data on the oxidation of ammonia in the presence of certain metal oxides[118] and also for its adsorption on the oxidised surface of molybdenum catalysts[119] suggest that an oxygen containing complex of the type $H_2N{-}O{-}M$, adsorbed on the surface, is the most reactive. This complex probably plays a major role in the oxidation [of ammonia ?] and possibly in the oxidative ammoniolysis of propene. Similar ideas concerning the formation of NH_2 radicals bound to the surface in the presence of molecular oxygen have been put forward in other investigations[120-122].

The study of the adsorption of propene–ammonia–oxygen and acrolein–ammonia–oxygen mixtures in different sequences on the surface of molybdenum catalysts using infrared spectroscopy and a comparison of the resulting spectra with those of allylamine and acrylonitrile adsorbed under analogous conditions was undertaken[123]. The similarity of these spectra apparently confirms the hypothesis that acrylonitrile may be formed in the oxidative ammoniolysis of propene either via an intermediate surface amine compound, produced when the adsorbed propene interacts with ammonia adsorbed on top of oxygen, or via an oxygen-containing surface complex of the carbonyl type with subsequent addition to the latter of an oxygen-containing complex of ammonia and the formation of an amide.

The results are satisfactorily consistent with the calculations[124] by the LCAO-MO method of the energy scheme for the elimination of individual hydrogen atoms and the addition of oxygen and nitrogen atoms to the hydrocarbon residues in the formation of acrylonitrile on the surface of molybdenum trioxide. It was found that the pathways leading to the formation of acrylonitrile via the intermediate formation of compounds of the carbonyl or amine type are energetically equivalent.

Thus in the interaction of propene, oxygen, and ammonia with the catalyst surface dissociative adsorption of the olefin takes place with formation of an allylic surface compound[125-127] and probably of an oxygen-containing ammonia complex[119]. The allylic surface compound can be subsequently converted into an oxygen-containing surface complex of the carbonyl type, which can be desorbed into the gas phase in the form of the aldehyde or can react further with the oxygen-containing ammonia complex to form a surface amide. Moreover, the allylic surface compound can itself react with ammonia adsorbed on top of the surface oxygen with formation of an amine surface compound.

III. THE EFFECT OF THE ELECTRONIC STRUCTURE OF LATTICE CATIONS ON THE ACTIVITY OF THE CATALYSTS

It is believed[128] that the metal ions in the crystal lattice behave as hydrocarbon adsorption centres. In connection with the hypothesis that the dissociative chemisorption of propene entails the formation of a π-complex

which is subsequently converted into a π-allyl complex[125], it is necessary to examine the effect of various metal ions on the formation of complexes with olefins and to elucidate the relation between the stability of these complexes and catalytic activity.

Olefins are known to form π-complexes with vanadium, chromium, molybdenum, and cobalt[129] and π-allyl complexes with molybdenum, tungsten, cobalt, and iron[130].

Indeed, it has been shown for iron-containing zeolites[88] that iron ions can catalyse the oxidation and oxidative ammoniolysis of propene, the selectivity of these reactions depending on the distribution of the ions in the matrix and on their oxygen environment[131,132]. Presumably propene is capable of forming π-allyl complexes with iron ions like ethylene in its adsorption on silver ions in silver-zeolites[133]. If the oxygen adsorbed on the surface of the zeolite is sufficiently mobile, as happens on alumina[134], the oxidation and oxidative ammoniolysis of propene are possible.

It has been suggested[135] that the chemisorption of propene is determined by the formation of a donor-acceptor bond with a catalyst lattice cation as a result of the withdrawal of the double bond π electrons into the vacant d orbitals of the transition metal atoms. The adsorbed molecules are then positively charged.

On the other hand, the symmetry of the antibonding olefin orbital and the transition metal d orbitals promotes their interaction[136], as a result of which the positive charge produced is partly compensated by the withdrawal of the catalyst electrons into the π orbital. On this basis, it is suggested[135,136] that the electronic structure of the metal ions determines the bonding energy of the olefin in the complex.

Application of crystal field theory to the study of the catalytic activity of transition metal oxides in various reactions[136,137] led to the observation that maximum catalytic activity corresponds to the maximum stabilisation by the crystal field with increase of the coordination number, the maximum rate of catalysis corresponding to the following elements: Cr(d^3), Co(d^7), and Cu(d^9).

Data for the extensive oxidation of propene also show that metal oxides containing chromium, cobalt, and copper exhibit the highest activity[138], i.e. there is some correlation between the rate of the catalytic reaction and complex formation.

Data have been published[71,139] concerning the change of catalytic activity in the oxidative ammoniolysis of propene in relation to the formation of acrylonitrile, carbon dioxide, and the molybdates[71] and phosphates[139] of various metals in the Fourth Period as a function of the number of unfilled d levels. Fig. 1 shows that the catalytic activity of the molybdates falls on passing from the first to the last element of the Fourth Period. The maximum rates of formation of acrylonitrile and carbon dioxide are observed in the presence of iron phosphate; the activities of cobalt, nickel, and manganese phosphates are low. The data presented in Fig. 1 evidently demonstrate that there is no correlation between the catalytic activity in the oxidative ammoniolysis of propene and the maximum stabilisation of the complexes by the crystal field. The difference between the activities and selectivities of the compounds investigated in this reaction cannot be accounted for by the presence of a number of unfilled metal d orbitals.

Moreover, the experimental data obtained under analogous conditions for the catalytic activities of various mixed oxide systems showed that the compounds formed when tin ($5s^25p^2$) and lead ($6s^26p^2$) oxides are mixed with bismuth ($6s^26p^3$) oxide do not catalyse the oxidative ammoniolysis of propene[140]. It was natural to conclude that none of the above metals are active catalysts of this process, because their cations do not contain vacant d levels. However, solid solutions of tin and antimony ($5s^25p^3$) oxides proved to be extremely active and selective catalysts of the oxidative ammoniolysis although tin and antimony atoms do not contain unfilled d orbitals either.

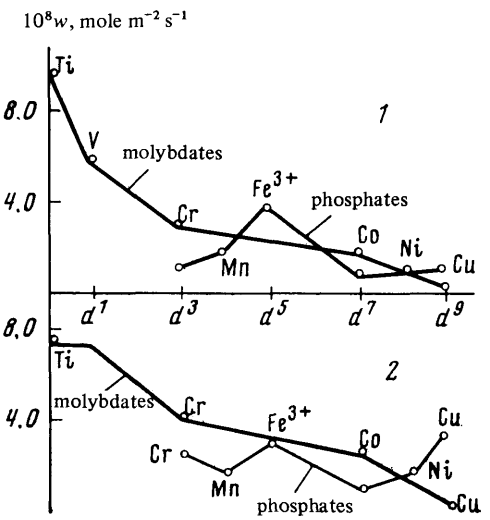

Figure 1. Dependence of the catalytic activity of molybdates[71] and phosphates[139] in the formation of acrylonitrile (1) and carbon dioxide (2) in the oxidative ammoniolysis of propene on the number of unfilled d levels in the lattice cations.

The possibility of the formation of unfilled d levels in the adsorption of oxygen on non-transition metals has been discussed in the literature[141]. For example, in the presence of oxygen silver behaves as a transition metal with this type of structure, acquiring the ability to chemisorb ethylene[142]. Oxygen binds the s electrons of silver and enables some of the d electrons to pass to the s and p levels. In this case catalysts containing, tin, antimony, and copper should be active and selective. However, it has been shown[140] that in the presence of stannates only extensive oxidation of propene takes place, while in the presence of bismuth antimonate the rate of formation of acrylonitrile is low.

Nor does the presence of cations with unfilled d levels influence the oxidation of ammonia under the conditions of the oxidative ammoniolysis of propene. The catalytic activities of various metal oxides in the oxidation of ammonia under the conditions of the oxidative ammoniolysis of hydrocarbons have been determined[143]. The maximum catalytic activity was observed in the presence of the oxides of cobalt (d^7), manganese (d^5), chromium (d^3), and copper (d^{10}), but complex catalysts containing these oxides do not exhibit an appreciable activity in the joint oxidation of propene and ammonia[140].

Thus the formation of a complex of the catalyst and the olefin requires that the catalyst contain a metal ion with a specific electronic structure. However, in the oxidative ammoniolysis of propene as well as in its oxidation[144] a correlation between the reaction rate and the stability of the metal–olefin complexes has not been observed. Such complexes are probably not the controlling intermediates in this process, oxygen being involved in its rate-limiting stage with formation of oxygen–hydrocarbon complexes.

Indeed, a Mössbauer study of the formation of a surface compound in the adsorption of propene and acrolein on the surface of an Sn–Mo–O catalyst showed[145] that the linkage between the chemisorbed organic molecule and the ion is formed via oxygen.

Moreover, as stated above, a study of the adsorption of propene on the oxidised surface of molybdenum catalysts for the oxidative ammoniolysis of propene revealed the presence of oxygen-containing complexes of the carbonyl type[117]. Oxygen also takes part in the formation of a reactive oxygen-containing ammonia surface complex.

For this reason, in the analysis of the nature of the active surface of catalysts for the oxidative ammoniolysis of propene particular attention must be paid to the type of bond between oxygen and the catalyst and to its reactivity.

IV. THE EFFECT OF THE ENVIRONMENT OF THE CATIONS IN THE CRYSTAL LATTICE ON CATALYTIC ACTIVITY

Many investigators[102,146,147] believe that the differences between the catalytic activities of oxides in oxidation reactions can be explained by the differences between the oxygen binding strengths in these oxides. The rate of oxygen isotope exchange between the gas phase and the oxide can serve as a measure of the reactivity of the oxygen in the surface layer of oxides. The mobility of oxygen in transition metal oxides frequently increases when they are mixed with oxygen derivatives of other elements. For examples, Boreskov and coworkers[148] established that potassium sulphate increases sharply the mobility of oxygen in vanadium pentoxide.

Skalkina[150] and Gel'bshtein and coworkers[151] compared the activation energies for the isotope exchange of the lattice oxygen determined for iron[149], cobalt[152], and bismuth[153] molybdates, iron and tin[154] antimonates, and molybdenum oxide[153] with the catalytic activities of these compounds in the formation of acrylonitrile by the oxidative ammoniolysis of propene. They concluded that the optimal M–O bond energy is 80–90 kcal mole^{-1}.

Such high M–O bond energies probably indicate that the lattice oxygen has a low probability of being involved in the rate-limiting reaction step, since the activation energy for the reaction does not exceed 20 kcal mole^{-1}. However, this oxygen can serve as a centre for the adsorption of the hydrogen split off in the dissociative adsorption of propene or can participate in the formation of certain other intermediates in the oxidation of propene.

Sachtler and De Boer[125] chose the rate of the partial reduction by hydrogen of various mixed catalysts as a criterion for the assessment of the lattice oxygen binding strength (ΔHM-O) in mixed oxide catalysts for the oxidation of propene, since ΔHM-O is proportional to the activation energy for the reduction reaction (Fig. 2). They estimated the rate of reduction from the quantity $10^3/T_\tau$, where T_τ is the temperature at which identical degrees of reduction are attained. Fig. 2 shows that the higher the capacity of the catalyst for reduction, i.e. the lower the metal–oxygen bond strength, the higher the degree of conversion of the hydrocarbon and the lower the process selectivity. Gel'bshtein and coworkers[155] measured the initial rate of reduction by propene of bismuth–molybdenum catalysts for the oxidative ammoniolysis of propene at 450°C and a pressure of 80 mmHg and showed that the maximum rate is observed for molybdenum oxide and the minimum for bismuth oxide. Bismuth molybdates of different compositions are reduced by the olefin at rates lower than the rate of reduction of molybdenum oxide.

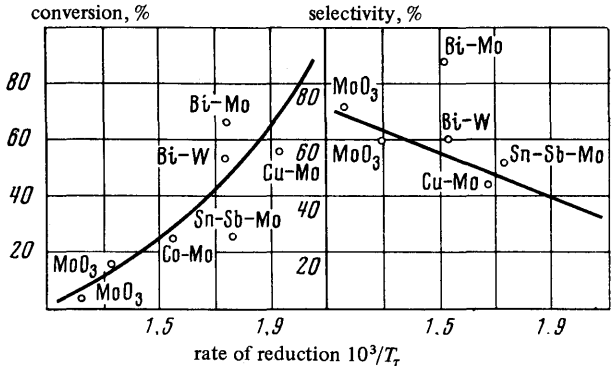

Figure 2. Dependence of the activity and selectivity of complex oxide catalysts in the oxidation of propene on their degree of reduction (T_τ is the temperature at which equal degrees of conversion are attained)[125].

Kolchin[11] also investigated this type of relation for various catalysts of the oxidative ammoniolysis of propene. Fig. 3 shows the variation of the degree of conversion and process selectivity with the rate of reduction of various complex oxide catalysts. Different relations between the rate of reduction and composition were obtained for molybdates and tungstates. Moreover, it is noteworthy that, according to Sachtler and De Boer's data[125] (Fig. 2), the activity and selectivity vary in opposition, while in another study[11] (Fig. 3) it was shown that they vary in parallel, albeit for a narrower range of catalysts. Evidently comparison of the catalytic properties of the substances for incomplete oxidation reactions with the values of ΔH_{M-O} is possible only within the limits of fairly small groups of selective oxidation catalysts and the optimal energy of the oxygen-catalyst bond is not the only factor responsible for the high activity and selectivity of the catalyst in the oxidative ammoniolysis of propene.

The energy of the bond between the metal ions forming part of the catalyst and oxygen varies as a function of the electronic structure of the ions. Mössbauer spectroscopy has shown[157] that, when the catalyst contains atoms of two different metals, the latter interact via oxygen: $M^I–O–M^{II}$. The effective charge of oxygen, i.e. the real charge within the space surrounding the oxygen atom, will depend on the difference between the electronegativities of these metals[158].

The catalytic activity of various compounds in the oxidative ammoniolysis of propene is determined by active centres of the same type and consequently is influenced

not by the bulk-phase charges but by the effective surface charges of oxygen, which depend on the difference between the electronegativities of the metal ions.

It has been shown for the oxidative ammoniolysis of propene [71] that the addition to the main oxide (of tin or iron) of another oxide containing a metal having a higher electronegativity (molybdenum or antimony) than that of the cation in the basic matrix alters the reaction pathway in the oxidative ammoniolysis of propene. Only carbon dioxide is formed in the presence of iron and tin oxides, while in the presence of solid solutions based on these oxide lattices acrylonitrile is obtained and the proportion of extensive oxidation falls. The authors conclude that the environment of the metal ion and the effective charge on the oxygen both change on formation of the solid solutions.

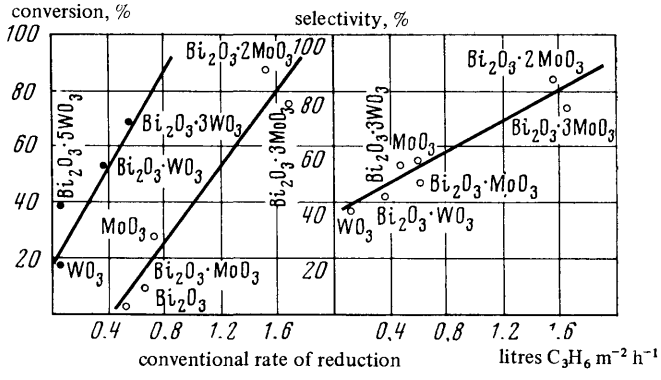

Figure 3. Dependence of the activity and selectivity of bismuth molybdates and tungstates in the oxidative ammoniolysis of propene on the rate of reduction of the catalyst [10].

In the determination of the catalytic activities of a large series of mixed oxide catalysts, Dalin et al. [159] drew attention to the fact that the highest selectivity is shown by catalysts in which there is a small difference between the ionisation potentials of the cation and the central atom of the anion. Evidently the difference between the ionisation potentials determines to some extent the amount of ionic character of the bond between the metal ion and oxygen. The isomeric shift δE of the Mössbauer spectrum, which is due to the change of the s electron density near the nucleus of the cation, can serve as a measure of the amount of ionic character of the bond.

Table 2 presents parameters of the Mössbauer spectra taken from the literature [160–162] (the isomeric shifts and the quadrupole splittings) for certain iron-containing compounds and the selectivities of the oxidative ammoniolysis of propene in the presence of such compounds. These data show that the dependence of the selectivity of the oxidative ammoniolysis on the amount of ionic character of the bond passes through a maximum. The highest selectivity is observed in the presence of iron phosphate and arsenate. A decrease and an increase of the number of s electrons in the Fe^{3+} ion both reduce the yield of acrylonitrile.

Another parameter of Mössbauer spectra, namely quadrupole splitting ΔEa, characterises the electric field gradient around the cation due to the distortion of the symmetry of the charge distribution within the crystal lattice. The electric field gradient depends on various factors, primarily on the type of bond, the crystal structure of the compound, and the electronegativity of the adjacent atoms.

Table 2. The isomeric shifts δE and the quadrupole splittings ΔEQ in the Mössbauer spectra of certain iron-containing compounds and the selectivity of oxidative ammoniolysis on their presence.

Compound	δE, mm s^{-1}	ΔE_Q, mm s^{-1}	Selectivity, %	References
$Fe_2(SO_4)_3$	1.42	0.0	9	139
Fe_2O_3	0.57	0.2	0	71
$FePO_4$	0.43	0.15	56	139
$Fe_2(CrO_4)_3$	0.34	0.38	0	71
$FeAsO_4$	0.49	0.2	50	163

Skalkina et al. [163] obtained the Mössbauer spectra of various complex oxide catalysts for the oxidative ammoniolysis of propene incorporating Fe^{3+} and Sn^{4+} ions and compared the quadrupole splitting with the activity and selectivity of the catalyst. Fig. 4 shows that the rate of extensive oxidation decreases monotonically with increase of ΔEQ, while in the mild oxidation reaction (the formation of acrylonitrile?) the rate passes through a maximum.

Since the iron(III) ion has the symmetrical electronic configuration $3d^5$, the electric field gradient at the nucleus is due solely to the external charges and is determined by the distortion of the lattice. Quadrivalent tin also has a symmetrical electronic configuration ($4d^{10}$). Thus in the given case ΔEQ characterises directly the charge distribution around the iron and tin atoms and affects the rate of reaction. For low values of ΔEQ, i.e. for slight distortions of the charge symmetry, carbon dioxide is is formed around the cation in the course of the oxidation of propene and, on further increase of ΔEQ, the formation of acrylonitrile begins. Since EM-O and qs increase with increase of ΔEQ, this can evidently be explained as follows. For low values of ΔEQ (E_{M-O} is small), a larger number of oxygen atoms enter into the reaction and extensive oxidation is observed, whereas on increase of ΔEQ a smaller number of oxygen atoms participate in the process and mild oxidation of the olefin begins. However, on further increase of ΔEQ, there is a rise in q_s also and the catalytic activity falls; the activation energy increases appreciably for these values of ΔE_q.

Evidently the differences between the ionisation potentials and quadrupole splitting both characterise the charge distribution around the cation and are probably related also to the M–O bond strength.

Apart from the oxygen adsorbed at the lattice ions, the oxygen surrounding the cation is probably also important in the oxidative ammoniolysis of propene; thus the replacement of oxygen in iron and copper oxides by sulphur and also the replacement of oxygen in vanadium pentoxide by boron, nitrogen, and carbon lead to the complete disappearance of catalytic activity in this reaction [139].

V. RELATIVE POSITIONS OF THE HYDROCARBON AND OXYGEN ADSORPTION CENTRES

According to the hypothesis of Callahan and Graselli[164], not only the electronic structure of the adsorption centres but also their number and relative positions are important for the selective oxidation of hydrocarbons. On the surfact of polycrystalline catalysts, there are planes with different indexes in which the elements entering into the composition of the catalyst are distributed with different separations.

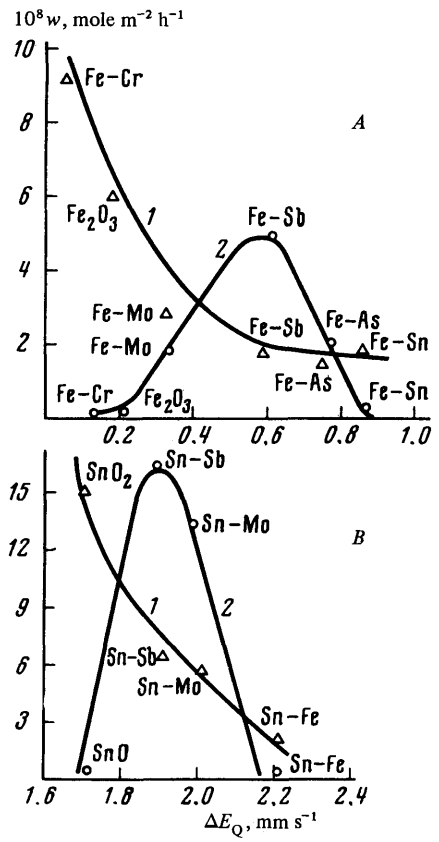

Figure 4. Dependence of the rate of formation of carbon dioxide (1) and acrylonitrile (2) in the presence of oxide catalysts containing iron (*A*) and tin (*B*) on the quadrupole splitting *E*Q (Skalkina et al.[163]).

Data are now available showing which lattice planes of the mixed oxide systems now preferentially exposed on the surface of the catalyst. These data are insufficient to analyse completely the results from the standpoint of the geometrical correspondence between the propene molecules and the atoms of the solid. However, the literature data lead to definite conclusions concerning the influence of the geometry of the active adsorption centres of the oxidative ammoniolysis of propene. Indeed, Kolchin and Gel'bshtein and coworkers showed that the most active catalysts in the Bi_2O_3–MoO_3 system usually contain compounds with the compositions $Bi_2O_3.2MoO_3$ and $Bi_2O_3.3MoO_3$ having the structures of the α- and β-phases[96,165] and that the catalytic activity of bismuth molybdate $Bi_2O_3.MoO_3$ depends on the presence of the γ''-phase structure in the crystal lattice of this catalyst[165].

It has been shown[11,165], on the basis of published data[166–168], that, on passing from molybdenum oxide to bismuth oxide and on formation of various bismuth molybdates, the distances between oxygen and bismuth and molybdenum cations are altered. For example, the distance between Mo and O in MoO_3 varies in the range 1.67–2.25 Å, depending on the position of the MoO_6 octahedra in the layer structure[167], in the bismuth molybdate $Bi_2O_3.3MoO_3$ the Mo–O distance in the tetrahedron is 1.75–1.95 Å and the Bi–O distance is 2.30–2.50 Å,[166] in the bismuth molybdate $Bi_2O_3.MoO_3$ the (Bi, Mo)–O interatomic distance is 2.35 Å, while in $2Bi_2O_3.MoO_3$ the interatomic distance is 2.45 Å.[168]

The distances between the Bi and Mo cations also change on passing from one compound to another, but in all cases are not less than the distances between the carbon atoms in the propene molecule; for this reason, the authors[11,165] conclude that the employment of a simple doublet scheme for the oxidative ammoniolysis of propene[96] on an ideal crystal is hardly valid in view of the defective structure of the catalyst surfaces.

It has been suggested[156] that the catalytic activity of compounds having the structure of the bismuth molybdates $Bi_2O_3.MoO_3$ (γ-phase) and $Bi_2O_3.2MoO_3$ (β-phase) in the oxidative dehydrogenation of n-butenes is due to the presence of Mo–O octahedra linked via their vertices within the bulk of the crystals. According to the authors, this crystal lattice structure allows the emergence onto the surface of the lateral planes of tetragonal pyramids, which leads to the occurrence of anionic vacancies associated with the molybdenum ion and these serve as the olefin adsorption centres[98].

On the other hand, in bismuth molybdates with a high bismuth content, there are vacancies on the lateral edges associated with the bismuth ion, which leads to complete oxidation. In the compound $Bi_2O_3.3MoO_3$ the Mo–O octahedra are joined via their edges and anionic vacancies associated with the molybdenum ion do not arise.

Indeed the γ-phase consists of layers of octahedra comprising molybdenum surrounded by oxygen and alternating with bismuth layers between which there is an oxygen layer[97]. Moreover, the existence of Mo–O octahedra in the structure of keochlinite has been confirmed by spectroscopic data[156].

According to crystal field theory[158], octahedral coordination leads to a greater stabilisation by the crystal field than tetrahedral coordination and for this reason compounds in which the cation is in the centre of a more or less regular octahedron catalyse many reactions.

The loss of catalytic activity by bismuth molybdates in the $\gamma \rightarrow \gamma'$ transition can be attributed to a change in the coordination polyhedron from an octahedron to a tetrahedron.

Recent structural studies[169] on individual bismuth molybdates showed that these phases are based on a face-centred pseudocubic subcell of the CaF_2 type with repeat periods of 5.4–5.8 Å, containing from MoO_2 groups, where M = W, Mo, or Bi. Since the scattering capacity of Bi and Mo atoms is much higher than that of O atoms, the above subcell should characterise primarily the distribution of the heavy atoms in the structure. Indeed, in the mineral koechlinite[167] the bismuth and molybdenum

atoms form a distorted face-centred cubic subcell in which there are four bismuth and molybdenum atoms and eight oxygen atoms.

In the range of catalyst compositions where the Bi_2O_3 content is between 0 and 50%, the subcell has vacancies corresponding to the positions of the metal atoms, when the ratio $Bi_2O_3 : MoO_3 = 1 : 1$ holds, the subcell has no vacancies, and finally in the range of compositions where the Bi_2O_3 content is between 50 and 100% the subcell has vacancies in the positions of the oxygen atoms.

Fig. 5 presents different versions of the structure, based on the data of Gal'perin and Erman [169,171], of the largest crystal faces of compounds in the Bi_2O_3–MoO_3 system. The positions of the vacancies in the distribution of bismuth atoms are indicated on the (010) face of the bismuth molybdate $Bi_2O_3.3MoO_3$ (part *a*). On the crystal faces of the compound $Bi_2O_3.MoO_3$, the vacancies are not indicated since their coordinates have not been determined. Fig. 5 shows that the structures of the largest faces of the α-, β-, and γ-phases are different and that the bismuth : molybdenum ratios also differ.

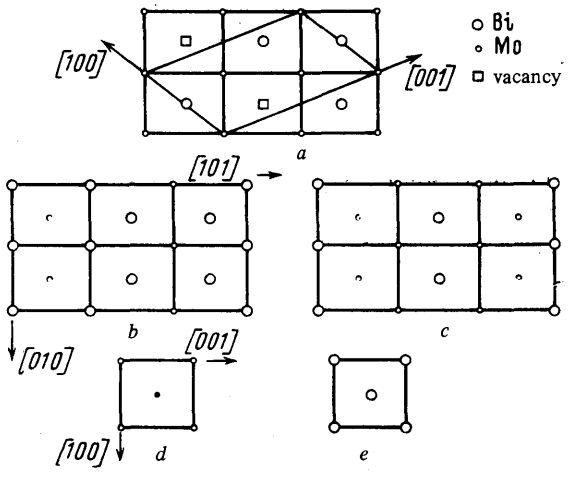

Figure 5. Distribution of metal atoms on the largest faces [144,169]: *a*) $Bi_2O_3.3MoO_3$; *b*) and *c*) $Bi_2O_3.2MoO_3$; *d*) and *e*) $Bi_2O_3.MoO_3$.

On the large (010) face of the α-phase, the presence of vacancies in the positions of the bismuth atoms increases the Bi : Mo ratio in favour of molybdenum (Mo : Bi = 1.5). On the surface of the β-phase crystals, either bismuth (1.6 : 1) or molybdenum (2.5 : 1) atoms predominate. In the γ''-phase, into which the γ-structure is converted under the conditions of the oxidative ammoniolysis of propene [11,165,170], the atoms are distributed in the same way as on the largest faces of the γ-phase (only molybdenum atoms on one face and only bismuth atoms on the other), since the expansion of the unit cell of the γ-form takes place mainly in the (100) and (001) directions, while the distances between the Bi_2O_3 and MoO_4 layers do not change significantly. Even if Bi : Mo ratios analogous to those on the faces of the α-, β-, and γ-phases hold on the surface of some of the faces of the γ'-phase, the fraction of these faces in the overall structure is small, because the γ'-phase, which exhibits the lowest catalytic activity, crystallises in the form of needles extended along the (001) axis. In the vertical band around these crystals, there are 16 faces of equal size in which both cations (Bi and Mo) are located. It is noteworthy that the presence of vacancies in the distribution of metal atoms is probably not an essential property of catalytically active phases, since they are absent from the structure of the bismuth molybdate $Bi_2O_3.MoO_3$. It is also evident that the existence of doublet centres does not play a dominant role in the activity of bismuth molybdates, because on the large faces of the catalytically active γ''-phase only Mo or Bi atoms are present.

Moreover the structural studies of Erman and Gal'perin [169,170] revealed that the length of the propene molecule and the repeat period of the sublattices of phases active in the oxidative ammoniolysis of propene are comparable. The formation of carbon–oxygen complexes probably requires the presence of a pair of identical atoms M–M with octahedral coordination and at a distance of 5.5–5.6 Å.

Comparison of the results of studies on the catalytic activities of various tin–molybdenum catalysts with the results of the phase analysis of the latter has shown [71] that, in contrast to bismuth–molybdenum catalysts, in this system catalytic activity is shown by solid solutions obtained by the substitution of both molybdenum ions in the lattice of molybdenum trioxide by tin ions and of tin ions in the lattice of tin dioxide by molybdenum ions. The solid solution based on the tin dioxide lattice with the atomic ratio Sn : Mo = 9 : 1 has the highest activity and selectivity in the oxidative ammoniolysis of propene.

Tin(IV) oxide has the rutile structure in which the cations are located at centres with octahedral coordination [172]. The replacement of a small proportion of the cations by Mo^{6+} yields a catalyst for the selective oxidation of propene. It is therefore possible that in this case, as in bismuth–molybdenum catalysts, the active centres are Mo^{6+} ions surrounded by oxygen ions with octahedral coordination.

However, in contrast to the bismuth–molybdenum catalysts, the active structure in this case is not a definite chemical compound but a solid solution obtained by the substitution of one ion by another.

In recently published detailed studies of the catalytic activity of the Fe_2O_3–Sb_2O_4 (Boreskov et al. [58]) and U_3O_8–Sb_2O_4 (Graselli and Callahan [173]) systems in the oxidative ammoniolysis of propene and the SnO_2–Sb_2O_4 system [174] in the oxidation of propene it is also emphasised that the highest catalytic activity and process selectivity are associated with the presence in the catalyst lattice of a compound having a definite structure: of iron antimonate in the Fe_2O_3–Sb_2O_4 system and of uranyl antimonate (UO_2) Sb_3O_7 in the U_3O_8–Sb_2O_4 system. In contrast to the latter, in the SnO_2–Sb_2O_4 system as for tin–molybdenum catalysts the highest activity and selectivity is shown, with a structure comprising a solid solution of antimony oxide in tin(IV) oxide. All these compounds contain Sb^{5+} ions in centres surrounded by oxygen ions with octahedral coordination [174,175].

The low activity of iron and manganese molybdates, the lattice cells of which contain, in contrast to active bismuth molybdates, MoO_4 tetrahedra between which Fe and Mn cations are distributed, can probably be explained from the same standpoint [176].

All these data show that the selectivity in the oxidative ammoniolysis of propene in the presence of various mixed oxide catalysts depends on the structure of the crystal lattice of the catalyst, which contains ions distributed at a

specific distance from one another and surrounded by oxygen ions with octahedral coordination. The accessibility of particular adsorption centres on the solid should play a major role in determining the nature of the active centres on the surface of oxidation catalysts. For example, Stone[177] believes that copper(I) oxide is more active in oxidative catalysis owing to the unusual distribution of oxygen on the faces which are preferentially exposed on the surfaces of these structures.

The low activity of iron-containing type A zeolites in relation to type X and Y zeolites, observed[131,132] in the oxidative ammoniolysis of propene, is evidently associated with the accessibility of the adsorption centres (iron ions) to the reacting molecules. In type A zeolites the size of the inlet into the large cavities is 4.2 Å, which hinders their penetration by propene molecules and hence their adsorption in the primary porous structure of this zeolite. With increase of the degree of substitution of sodium ions by iron ions, the dimensions of the octagonal oxygen inlets leading into the large cavities of the type A zeolite are somewhat altered[178] and the authors therefore believe that this makes the adsorption centre more accessible, which is probably the reason for the increased catalytic activity of the iron-containing zeolite.

VI. EFFECT OF THE ELECTRONIC WORK FUNCTION ON CATALYTIC ACTIVITY

It has been suggested[3,11,96] that in the heterogeneous oxidation of hydrocarbons the catalyst must be capable of forming a donor–acceptor bond with the organic reactant and with oxygen and also be able to transmit electrons from one molecule involved in the process to another. Depending on the mechanism of electron transfer in the solid, either the delocalised electrons of the solid or the electrons localised at the lattice cations take part in the electron exchange with the adsorbed species. As already mentioned above, in the adsorption of the reactants in the oxidative ammoniolysis of propene on the surfaces of oxide catalysts, charged oxygen-containing complexes of propene[117,135,145] and ammonia[118,119] are probably formed and therefore the rate of the process depends on their surface concentrations and the magnitude of their charges. The electron work functions of the crystals then regulate the filling of the catalyst surface by the charged intermediate species propagating the oxidation process.

It has been demonstrated in detail in a monograph[11] that, in cases where a relation is observed between the process selectivity and the electronic work function φ of the catalyst (the main characteristic of the electronic properties of the surface), it is possible to drive the oxidation of hydrocarbons in the presence of such catalysts towards partial or extensive oxidation by controlling the electronic work function of the solid. However, it has been established[179] from measurements of the conductivities of individual bismuth molybdates, which are the most active catalysts in the oxidative ammoniolysis of propene, that electrons are appreciably localised at individual lattice ions, i.e. in this case the electronic work function of the solid may play a subsidiary role in the catalytic process.

Indeed it has been shown[180,181] that, when bismuth molybdate is modified by the introduction of various additives, the electronic work functions of such catalysts hardly change. However, under these conditions their crystal lattices undergo a rearrangement, which affects the kinetic characteristics of the joint oxidation of propene and ammonia.

VII. ACIDITY OF THE CATALYST SURFACE

From an analysis of extensive experimental data for the activities of mixed oxide catalysts for partial oxidation, Roiter and Golodets[182] suggested that the stability of the activated surface complexes in the oxidation of hydrocarbons, which probably resemble salt-like formations, depends on the acid–base properties of the surface. Anphoteric properties of the catalyst surface, which ensure the ease of formation and decomposition of the salt-like complex, are particularly favourable for oxidative catalysis.

The low catalytic activity of salts of strong acids in the oxidative ammoniolysis of propene[139] compared with oxide catalysts due to the existence on their surface of mobile hydrogen atoms can probably be explained from this standpoint. The number of acid centres on the surface of these catalysts, determined by titrating them with weak bases in non-aqueous media in the presence of indicators[183,184], proved to be close to the number of acid centres on aluminosilicates (about 20 mequiv. m^{-2}, $pK \leqslant -3$).

According to Skalkina et al.[139], the presence of mobile hydrogen atoms on the surface of strong acid salts may alter the mechanism of the extensive oxidation of propene, i.e. an isopropyl carbonium ion is formed and can accelerate the subsequent conversion of the olefin molecule into final products.

In conclusion of our analysis of the published data, we may suggest that the activity and selectivity of the catalysts for the oxidative ammoniolysis of propene are determined by the structure of the oxygen-containing surface complexes of the hydrocarbon and ammonia. The active surface of the catalysts for the joint oxidation of propene and ammonia must contain active centres of the same type, the reactivity and oxygen mobility of which depend on the nature of the metal and its environment in the crystal lattice of the catalyst. Apart from the energy structure of the solid, the structure of the catalyst surface plays an important role in this reaction.

Changes in the conditions of preparation and also in the nature of the starting materials (salts, acids), which have been followed for bismuth–molybdenum[165,185], tin–molybdenum[150], and tin–antimony[174] catalysts, hardly influence the selectivity of the propene oxidation reactions.

The Chemistry of Myoinositol

V.I.Shvets

The present state of the chemistry of myoinositol, a naturally occurring cyclitol, is discussed, with information on its stereochemistry, its physical and chemical properties, and the reactivity of the hydroxy-groups. The principal methods of preparation of various derivatives, in which the cyclitol structure is unaffected, are considered. Special attention is paid to phosphoric esters of myoinositol, which are structural units of inositol phosphatides, a most important class of naturally occurring phospholipids. Specific properties of the phosphoric esters are examined, together with problems of their stability and synthesis. A list of 169 references is included.

CONTENTS

IV. Pentasubstituted derivatives of myoinositol 490
V. Phosphoric esters of myoinositol 494

I. INTRODUCTION

Myoinositol is the most widely occurring of the cyclitols (inositols, cyclohexanehexaols). Nine stereoisomeric inositols—neoinositol, *cis*-inositol, scylloinositol, myo-(*meso*-)inositol, (+)- and (−)-inositols, epi-inositol, mucoinositol, and alloinositol—are known[1]. All forms of inositols, with the exception of the (+)- and (−)-inositols, are *meso*-forms, but many of their derivatives may possess molecular asymmetry and hence exhibit optical activity. Naturally occurring optically active derivatives of myoinositol are known: (−)- and (+)-bornesitols (1- and 3-*O*-methyl-*sn*-myoinositols)†, (+)-ononitol (4-*O*-methyl-*sn*-myoinositol), (−)-liriodendritol (1,5-di-*O*-methyl-*sn*-myoinositol), galactin (3-*O*-α-D-galactopyranosyl-*sn*-myoinositol), phosphoinositides, and several other compounds have been isolated from bacterial, vegetable, and animal sources[1]. Myoinositol occurs widely in the vegetable kingdom as calcium salts of the hexaphosphoric ester (phytin)[1].

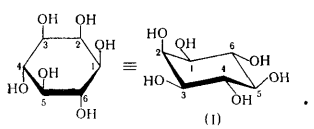
Inositols, in particular myoinositol, are suitable model compounds for the study of stereochemistry and conformational effects. Development of the chemistry of myoinositol has been stimulated also by its occurrence, as well as that of such derivatives as inosamines, in natural compounds—phospholipids, antibiotics, and several others.

Our interest in the chemistry of myoinositol arises from our prolonged concern with aspects of the synthesis of phosphoinositides and phosphoric derivatives of myoinositol, which raises the problem of the availability of definitely substituted derivatives of the latter. Each class of phosphoinositides—mono-, di-, and tri-phosphoinositides—requires its own methods of synthesis. Processes for obtaining triphosphoinositides are especially laborious, for no practicable routes are yet available; this contrasts with mono- and di-phosphoinositides, to whose synthesis definite approaches can be made.

Individual aspects of the chemistry and the biochemistry of myoinositol and its derivatives have been covered in several reviews and books[1,5-14]. The present Review does not deal with synthesis of the cyclitol structure of myoinositol, since this is an independent problem of intrinsic interest. Examples are the syntheses of derivatives of myoinositol and other cyclitols by the intramolecular aldol reaction of various compounds of D-glucose[15-21], by diene synthesis[22], by the hydroxylation of conduritols[23], etc. Research on the conversion of myoinositol derivatives into inosamines constitutes a separate field of investigation[24].

II. STEREOCHEMISTRY OF DERIVATIVES OF MYOINOSITOL AND THEIR REACTIVITY

Myoinositol (I) contains six hydroxy-groups—five equatorial and one axial[1]:



(I)

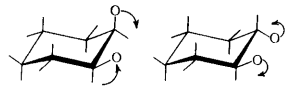
It is easy to predict by conformational analysis that the most stable conformation of myoinositol is the chair form (I), which possesses the smallest number of axial hydroxyls[25]. The chair conformation is consistent with such reactions of myoinositol and its derivatives as dehydrogenation, the formation of borate complexes, and acylation[25]. Physical data also support this conformation: derivatives exhibited an infrared absorption band at 873 ± 11 cm^{-1}, due to vibrations of equatorial C–H bonds[26]. The nuclear magnetic resonance spectra of myoinositol and its acetates[27] were also interpreted in terms of a chair conformation, and were fully consistent with the n.m.r. spectra of the corresponding hexachlorocyclohexanes[28]‡. The suggested conformation was supported also by X-ray diffraction[35] and by electron microscopy[36-38].

†A stereospecific nomenclature[2-4] is used in the Review for racemic and optically active asymmetrically substituted derivatives of myoinositol.

‡Several studies have recently been published[21,24,29-34] on the application of n.m.r. spectroscopy to the structural analysis of myoinositol and its derivatives.

Myoinositol is thermodynamically the most stable cyclitol, as is suggested by the calculated relative free energies (in kcal mole^{-1} at 25°C): myo 3.0, scyllo 3.2, (±) 3.55, (+) 4, neo 4.3, epi 4.9, allo 5.05, muco 5.1, and *cis* 8.05.[39] These values agree well with those determined from the equilibrium constants of the acid-catalysed epimerisation of isomeric inositols[40]. The possibility of the interconversion of myoinositol into other stereoisomers should always be taken into account in the preparation of various derivatives. These problems have been discussed in detail in reviews[1,14]. An example of the partial transition of myoinositol into scylloinositol is provided by the reduction of 2-myoinosose, obtained by oxidation of the axial hydroxyl[1]. Myoinositol hexa-acetate undergoes almost complete isomerisation into mucoinositol hexa-acetate when treated with liquid hydrogen fluoride[41], probably owing to the enhanced stability of intermediate acetyl-oxonium derivatives of the muco-form.

The reactivity of the hydroxyls in myoinositol is strongly dependent on the stereochemistry of the molecule, and is affected by steric hindrance. In this connection equatorial and axial substituents exhibit a difference in chemical behaviour, although the equatorial hydroxyls in myoinositol are not equivalent. But whereas differences between axial and equatorial groups in myoinositol[42] are well explained by conformational analysis and have been confirmed by numerous studies, the non-equivalence of the equatorial hydroxyls is not so usual, and each fact requires separate consideration. Attempts at such an approach have been made in reporting the chemistry of myoinositol. Many synthetic procedures, especially in the chemistry of phosphoinositides, have been based on these rules.



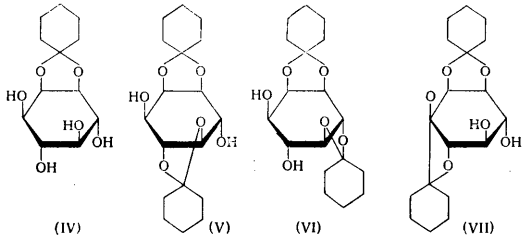
cis (II) *trans* (III)

The hydroxyls in myoinositol differ in reactivity also according as they are in *cis*- or *trans*-positions. In the undistorted chair form the distance between vicinal equatorial groups is the same as that between axial and equatorial *cis*-hydroxyls. It might have been expected, therefore, that the formation of cyclic acetals would occur equally readily with *cis*- and *trans*-hydroxyls. However, cyclisation involves formation of a new ring containing five coplanar atoms, and consequently the molecule is distorted in such a way that the two vicinal substitutents become quasi-coplanar. In all reactions requiring an approximately coplanar transition state, and not accompanied by migration of substituents, *cis* (*eq*, *ax*)-compounds react more rapidly than do *trans* (*eq*, *eq*)-compounds[43]. The chair conformation of the ring exhibits different relations towards the two types of distortion caused by bringing *cis* (*eq*, *ax*)- or *trans* (*eq*, *eq*)-substituents almost into coplanarity[36]. The former (II) is accompanied by levelling of the ring and increase in the endocyclic bond angles. Such distortion resembles incipient conformational inversion and requires no large consumption of energy. Formation of a new ring involving *trans*-hydroxyls is best explained in terms of a distorted conformation. Thus examination of hydrogen bonds has shown[44-46] that the effort to bring the two equatorial bonds (III) into the same plane entails a shortening of the interatomic distances, which distorts the chair form and therefore requires a large quantity of energy[47]. As a consequence, cyclisation takes place initially at the *cis*-hydroxyls (*ax*, *eq*), and then at the *trans*-hydroxyls (*eq*, *eq*) under more severe conditions[48]. These observations are confirmed by the formation of cyclic acetals of myoinositol.

III. ACETAL DERIVATIVES OF MYOINOSITOL AND REACTIONS BASED ON 1(3), 2-*O*-CYCLOHEXYLIDENE-*sn*-MYOINOSITOL

Studies of cyclic acetals of myoinositol are of interest for synthetic chemistry, besides the solution of stereochemical problems. Acetals have proved convenient protective groups in the chemistry of myoinositol. Originally an isopropylidene group was used to protect vicinal hydroxy-groups[43,49-55]. Myoinositol reacts with acetone in the presence of zinc chloride, and with 2,2-di(m)ethoxypropanes in the presence of toluene-*p*-sulphonic acid in dimethyl sulphoxide, to form isopropylidene derivatives. *cis*-Acetals are formed first[43,51], since they correspond more closely to coplanarity. The formation of acetals with a ketone requires that water be removed from the reaction medium. Acetone hinders the azeotropic removal of water, is unstable towards dehydrating agents, and causes side-reactions[48].

Cyclohexylidene derivatives were subsequently recommended for sugars and polyols, since they are obtained more simply than the corresponding acetonides, and moreover in the crystalline state[56]. Myoinositol is dissolved in a boiling mixture of cyclohexanone and benzene containing catalytic quantities of toluene-*p*-sulphonic acid, and water is removed by azeotropic distillation. The resulting formation of *O*-cyclohexylidene-*sn*-myoinositol derivatives —1(3), 2 (IV), 1(3), 2:4(6)5 (V), 1(3), 2:5, 6(4) (VI), and 1(3).2:3(1), 4(6) (VII)[48,57]



(IV) (V) (VI) (VII)

involved firstly the *cis*-hydroxyls (*ax*, *eq*) and then *trans*-hydroxyls (*eq*, *eq*).[48] Angyal showed[48] that a triacetal of myoinositol was formed, but this compound was not isolated.

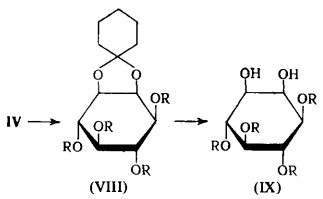
Cyclohexylidene derivatives of myoinositol are starting compounds for the preparation of phosphoinositides. A diphosphoinositide has been obtained from the diacetal (V).[58-60] Several syntheses of monophosphoinositides[61-65] have involved the use of 1(3), 4(6), 5, 6(4)-tetra-*O*-substituted derivatives of myoinositol obtained from the monoacetal (IV). Examples are the tetrabenzyl and tetra-acetyl compounds (IX: R = $C_6H_5CH_2$, CH_3CO) obtained by the benzylation or acetylation of (IV) followed by acid hydrolysis of the acetal protection (Scheme 1).[48,66] Other groups (toluene-*p*-sulphonyl (tosyl), methyl, allyl, etc.) are less suitable for these purposes, mainly because of the difficulty of their removal. Acetylation and benzylation of the acetal (IV) go to completion, so that differences in reactivity between the hydroxy-groups cannot be detected, although such conclusions may prove useful in the synthesis of polyphosphoinositides.

In this connection interesting results have been obtained for the tosylation of various derivatives of myoinositol. The action of tosyl chloride in pyridine on the mono-, di-, tri-, and tetra-tosylates (X–XVII, XIX, and XX) is represented by Scheme 2.[29] The degree of tosylation is determined by the quantity of the reagent: a large excess of tosyl chloride is required to obtain polytosyl derivatives of myoinositol. Gravimetric analysis of the tosylates obtained in various reactions leads to the reactivity sequence

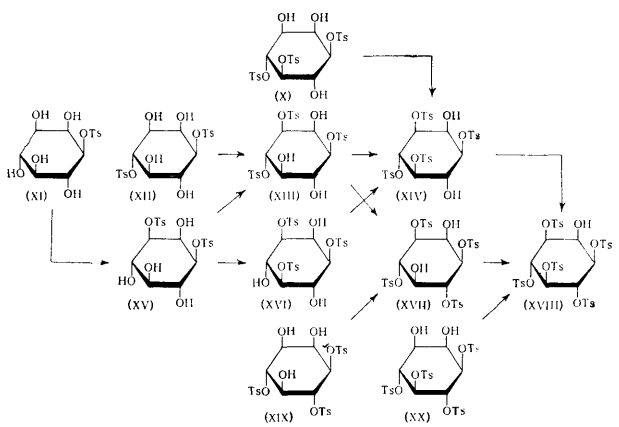
1(3)-OH>4(6)-OH>5-OH>2-OH

for the hydroxy-groups in this case.

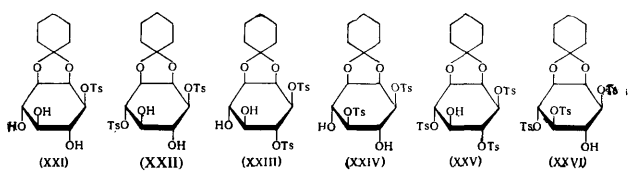
Scheme 1



Scheme 2



Similar results have been obtained for corresponding reactions with the monoacetal (IV):[30] several tosyl derivatives

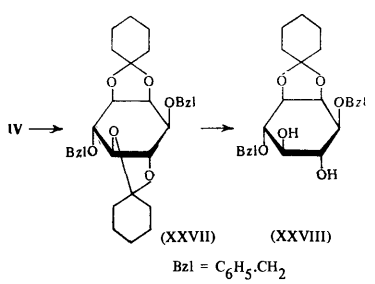


were prepared and used, after removal of the cyclohexylidene protection[31], to obtain polytosylates of myoinositol[29]. Similar reactivity of the hydroxy-groups in the monoacetal (IV) has been observed in benzoylation[33]. The derivatives (X), (XII), (XIII), (XXII), and (XXVI) are worthy of attention as starting materials for the preparation of di- and tri-phosphoinositides. However, the low yields of myoinositol tosylates, the difficulty of their isolation, and also the possibility of various transformations in work with tosyl groups[66,67] restrict the use of tosylation in the synthesis of polyphosphoinositides.

Several conclusions of the relative reactivity of the equatorial hydroxyls were drawn from an investigation of substitutions (S_N1 and S_N2) of the diacetals (V) and (VI) and their derivatives. Thus the benzylation[63,68,69], benzoylation[70], and phosphorylation[71] (S_N2) of (V) suggest that the 3(1)-hydroxyl is more reactive than the 6(4)-hydroxyl, despite the unfavourable conformational factors that the former is adjacent to a *cis*- and *trans*-acetal group, and the latter to a *trans*-group. The selectivity is due to the more strongly nucleophilic character of the 3(1)-hydroxyl. A similar phenomenon has been observed in the benzylation of (VI).[69] Selective benzoylation of the diacetal (V) formed the basis for a synthesis of a diphosphoinositide[60]. Nevertheless, these hydroxy-groups exhibit closely similar reactivity towards transesterification (S_N1).

With the diacetal (VI) this reaction showed that the 4(6)-hydroxy-group is more reactive than the 3(1)-hydroxyl, while 4 is the more active of the enantiotopic positions 4 and 6.[72,73] These hydroxyls behave similarly towards methylation[72,73]. The explanation is that position 4(6) is sterically more favourable (*trans*-OH, *trans*-acetal) than position 3(1) (*trans*-OH, *cis*-acetal).

Scheme 3



Transesterification of 1(3), 4(6)-di-*O*-cyclohexylidene-*sn*-myoinositol (XXVIII) by the ethyl chloroacetate of D-mannose indicates that the 5-hydroxyl is more reactive than the 6(4)-group. Of the two most probable diastereomers the compound with a free 4-hydroxyl is formed preferentially[63]. Examination of the stability of the *cis*- and *trans*-cyclohexylidene groups in the diacetals (V)–(VII) revealed the possibility of selective removal of the *trans*-acetal protection as sterically the less favourable[57,33,68]. This provided a method for preparing (XXVIII)[63] (Scheme 3), from which compound the preparation of triphosphoinositides can be planned.

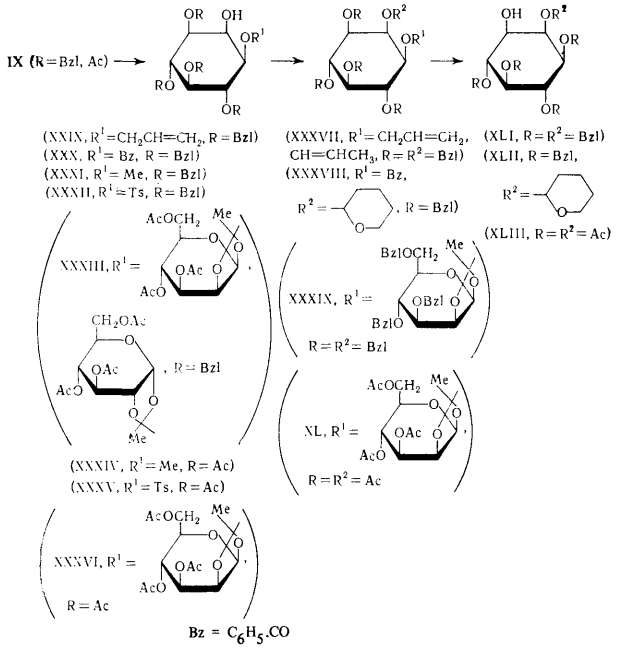
IV. PENTASUBSTITUTED DERIVATIVES OF MYOINOSITOL

A general method for obtaining monophosphoinositides is based on pentasubstituted derivatives of myoinositol having the free hydroxyl at the 3(1) position. It would therefore have been tempting to seek a selective protection for the axial hydroxyl in 1(3), 4(6), 5,6(4)-tetra-*O*-substituted derivatives. Unfortunately, it is impossible to

suggest such a group: substitution of 1(3), 4(6), 5,6(4)-tetra-*O*-substituted derivatives takes place predominantly at the 3(1) position. Benzylation[66], methylation[66], tosylation[31,74,75], acetylation[66], benzoylation[76], phosphorylation[62], and allylation[52] occur in this way. On the other hand, 2,3-dihydropyran and benzyloxymethyl chloride do not exhibit selectivity[77].

Reactions exhibiting selectivity towards an equatorial hydroxy-group can be assumed to depend on steric hindrance and to involve a transition state by an S_N2 substitution mechanism. If an ion is formed in the initial stage, on the other hand, the subsequent rapid interaction is less sensitive to steric hindrance, and such reactions (S_N1) therefore occur non-selectively. Results obtained for the transesterification of orthoacetates of D-mannose and D-glucose with 1(3), 4(6), 5,6(4)-tetra-*O*-benzyl-*sn*-myoinositol (IX: R = $C_6H_5CH_2$),[78,79] in which orthoesters of myoinositol isomeric with respect to the axial groups were isolated in considerable quantities, are significant in this connection. The absence of selectivity, despite steric hindrance to the introduction of an orthoester group at the 2-hydroxyl, becomes clear from an examination of the suggested S_N1 mechanism of transesterification[80], which is analogous to reactions with 2,3-dihydropyran and with benzyloxymethyl chloride[77].

Scheme 4

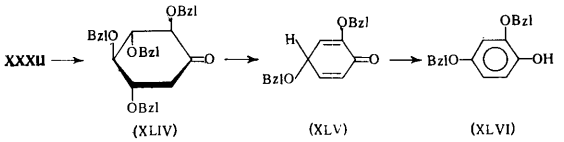


After the 3(1)-hydroxyl has been replaced, the problem is to protect the axial hydroxy-group and remove the protection from the 1(3)-hydroxyl (Scheme 4). The hydroxy-group attached to $C_{(2)}$ has been substituted by benzyl[52,61,62], acetyl[81], and tetrahydropyranyl[76] groups. 1(3), 4(6), 5,6(4)-Tetra-*O*-acetyl-*sn*-myoinositol (IX: R = CH_3CO) has not usually been employed in these syntheses, since the removal of methyl, acetyl, allyl, and tosyl groups entails deacetylation, although individual reactions[82] have been examined on this tetra-acetate. An exception is the orthoester carbohydrate protection, which makes it possible to acetylate completely the orthoester (XXXVI), and then remove the protective orthoester group without affecting the acetate groups[81]. Another factor restricting use of the tetra-acetate (IX), as well as the benzoyl derivatives to some extent, is acyl migration[83-85]. 1(3), 2,4(6), 5,6(4)-Penta-*O*-substituted derivatives of myoinositol have therefore been obtained mainly from the tetrabenzyl ether (IX: R = $C_6H_5CH_2$), from which the penta-acetate (XLIII) has also been prepared[86].

1. Tosylation–Detosylation Reactions

Tosylation of the compounds (IX: R = $C_6H_5CH_2$, CH_3CO) occurs selectively at the 3(1)-hydroxyl: tosyl chloride does not react with the sterically hindered 2-hydroxy-group[66,75]. Acetylation and benzylation of tosyl derivatives at the 2-hydroxyl (Scheme 4) followed by removal of the tosyl group might have given pentasubstituted derivatives of myoinositol with a free 1(3)-hydroxyl, but difficulties arise in such removal. Detosylation is effected with sodium amalgam in aqueous methanol at pH 5 to prevent side-reactions (deacetylation, acetyl migration, and formation of epoxides). The process takes place slowly, but varying the conditions leads to concurrent deacetylation[75].

Scheme 5



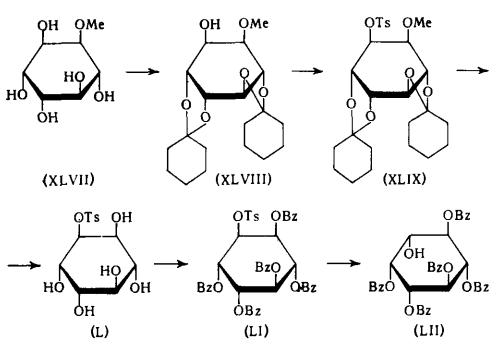
Attempts to benzylate 3(1), 4(6), 5,6(4)-tetra-*O*-benzyl-1(3)-*O*-tosyl-*sn*-myoinositol (XXXII) with benzyl chloride in the presence of alkali result in loss of the tosyl group with aromatisation of the ring. It was postulated that the reaction mechanism involved (Scheme 5) elimination of the tosyl group to give an unsaturated ketone (XLV), followed by aromatisation of the ring with formation of 2,4-dibenzyloxyphenol (XLVI).[66]

2. Methylation and Demethylation

Methyl ethers of cyclitols are of intrinsic interest, since they are widely represented in Nature[1]. They are used in the chemistry of myoinositol to establish the structure of its derivatives[71-73,78,79]. Methods of methylation are distinguished by standardisation of the conditions (methyl iodide and silver oxide) and are suitable for various derivatives of myoinositol[49,87], in which the 3(1)-hydroxyl is methylated first[66,74]. Other methods for methylating such compounds are also known (diazomethane and boron trifluoride)[88], when the 1(3)-hydroxyl is methylated more slowly than the 4(6)- and 5-groups, and the axial 2-hydroxyl does not react at all.[84]

Methyl ethers are little used as protection because of the severe conditions for demethylation by hydriodic and hydrobromic acids. Carbohydrate chemistry has recently seen the development of demethylation by means of boron trihalides (fluoride, chloride, and bromide), which form complexes with the ethereal oxygen, permitting nucleophilic cleavage of the O–CH_3 bond [89]. This method was first used in the chemistry of cyclitols by Gero [90] to prepare 1,2,4,5,6-penta-*O*-benzoyl-*sn*-myoinositol (LII) from natural quebrachitol, 2-*O*-methyl-(—)-inositol (XLVII) (Scheme 6). Cyclohexylidene and tosyl protective groups were employed in this preparation. Demethylation by boron trichloride was accompanied by removal of cyclohexylidene groups (XLIX → L). The tosylate (L) was benzoylated under the usual conditions, and the tosyl group was removed from (LI) by the action of sodium fluoride in dimethylformamide with inversion of the previously tosylated hydroxy-group.

Scheme 6



Since the initial quebrachitol (XLVII) is optically active, the pentabenzoate (LII) possesses the same property, but unfortunately only unnatural phosphoinositides, with the phosphoric residue at position 3, can be obtained from it. Another defect of the scheme is the relative unavailability of quebrachitol (XLVII). Boron tribromide has been used to remove methyl groups from pentatosylates of (–)-bornesitol (1-*O*-methyl-*sn*-myoinositol) and (+)-bornesitol (3-*O*-methyl-*sn*-myoinositol) [74,91].

3. Preparation of Penta-acyl Derivatives of Myoinositol. Acetyl Migration. Tetrahydropyranyl Protection. Acetolysis of Benzyl Ethers of Myoinositol

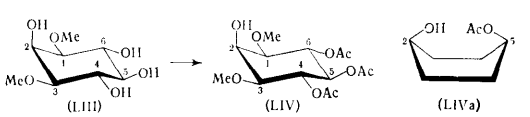
Acyl derivatives of myoinositol (acetates and benzoates) are well known. These groups are used to protect hydroxy-groups and also for the identification of derivatives. The simplicity with which acyl groups can be introduced and the great selectivity of the acylation of the 3(1)-hydroxyl attracted the attention of research workers, but these protections were then found to have substantial defects, so that they did not acquire general importance. Firstly, the ester link in derivatives of myoinositol is cleaved under conditions of hydrolysis and alcoholysis, so that it cannot be preserved during the removal of many other groups. Another disadvantage of acyl and especially acetyl groups is a tendency to migrate in the presence of bases [75,83,84].

Migration of acetyl groups in acetylated polyols has been observed previously [92–95]. In the chemistry of myoinositol attention was directed to this phenomenon in the methylation and tosylation of acetylated derivatives [49,85,96]. It is noteworthy that migration occurs when methyl iodide and silver oxide are used, but not when methylation is effected with diazomethane and boron trifluoride [83,84]. Migration is almost equally probable in *trans*- and *cis*-directions. The conformational factors responsible for the direction of these processes have not yet been determined [83,84].

The conditions governing acetyl migration have been studied in the methylation of 1(3), 4(6), 5,6(4)-tetra-*O*-acetyl-*sn*-myoinositol (IX: R = CH_3CO) and the 1(3), 3(1), 4(6), 5,6(4)-penta-*O*-acetyl derivative by the action of methyl iodide in the presence of silver oxide [83,84]. The presence of water is found to accelerate migration, which can be diminished to 25% by the addition of an anhydrous calcium sulphate, but cannot be completely suppressed because of the water produced in this method of methylation. The polarity of the solvent also influences the rate of the process: replacing dimethylformamide by chloroform in the methylation of the tetra-acetate (IX: R = CH_3CO) diminishes migration, but also lowers the yield of the methylated product. Raising the temperature accelerates methylation of the equatorial hydroxy-groups, but also increases *trans*-migration and methylation of the axial hydroxyl.

In order to avoid *trans*-migration and limit *cis*-migration in the methylation of 1(3), 4(6), 5,6(4)-tetra-*O*-acetyl-*sn*-myoinositol (IX: R = CH_3CO) it is advisable to use neutral silver oxide, a solvent of low polarity, a small content of methyl iodide, and a low temperature. However, methylation is incomplete under these conditions, and affects predominantly the equatorial position. Changing the reaction conditions in order to increase the yield entails increased migration.

Scheme 7



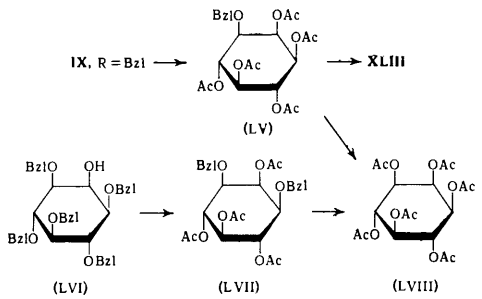
In view of possible transfers of acetyl groups round the ring, it was of interest to examine whether *trans*-ring migration—through adjacent *trans*-groups—will occur. To settle this question Angyal chose as model compound 1(3), 3(1)-di-*O*-methyl-*sn*-myoinositol (LIII, Scheme 7). [49] The axial hydroxyl remained free when this compound was acetylated, as the nuclear magnetic resonance spectra indicated that the main product was 4(6), 5,6(4)-tri-*O*-acetyl-1(3),3(1)-di-*O*-methyl-*sn*-myoinositol (LIV). The stability of the compound (LIV) in aqueous pyridine solution indicates that *trans*-ring migration is absent. These results also confirmed that myoinositol derivatives, in the present case (LIV), exist in the chair form, since in the boat form (LIVa) the 5-acetyl group is situated in a favourable position for migration to the $C_{(2)}$ atom.

Less study has been made of the behaviour of other ester derivatives of myoinositol. A benzoyl group has

been introduced at the equatorial group in 1(3), 4(6), 5,6(4)-tetra-*O*-benzyl- and -acetyl-*sn*-myoinositols (IX: R = $C_6H_5CH_2$ and CH_3CO respectively)[76,70,97] (Scheme 4). The product (XXX) was then used to obtain the 1(3), 2,4(6), 5,6(4)-penta-*O*-substituted derivative (XLII). The tetrahydropyranyl group was suggested for protecting the 2-hydroxyl in (XXX)[76]. This group had previously been used to protect primary, secondary, and tertiary alcohols[98], and several examples of its application in carbohydrate chemistry are known[99-101]. Having been the first to use it in the chemistry of myoinositol, Angyal[77] discovered the possibility of its selective removal by acid methanolysis in the presence of isopropylidene groups[102]. Unfortunately, the action of 2,3-dihydropyran is not distinguished by selectivity towards the 1(3)-hydroxyl[77]. A favourable aspect of this protection is the absence of acetyl migration when it is removed.

In spite of the difficulties caused by acetyl migration, the search for convenient synthetic methods of obtaining myoinositol penta-acetate (XLIII) was continued, since this compound forms a convenient starting point for the synthesis of an unsaturated monophosphoinositide. This problem was solved by the acetolysis of polybenzyl ethers of myoinositol[63,86,103]. Acetolysis of the tetrabenzyl ether (IX: R = $C_6H_5CH_2$) by acetic anhydride in the presence of perchloric acid at 18–20°C gives 1(3), 2,4(6), 5,6(4)-penta-*O*-acetyl-3(1)-*O*-benzylmyoinositol (LV) in 57% yield, which increases to 83% when the reaction is conducted at 0°C (Scheme 8). Acetolysis of the pentabenzyl derivative (LVI) involves formation of 2,4(6), 5,6(4)-tetra-*O*-acetyl-1(3),3(1)-di-*O*-benzyl-*sn*-myoinositol (LVII)[86].

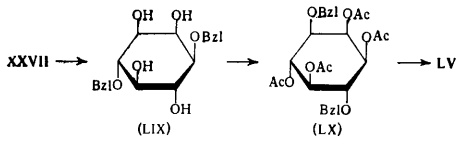
Scheme 8



The acetolysis of benzyl ethers of myoinositol (IX: R = $C_6H_5CH_2$) and (LVI) depends on steric factors. The 1(3)- and 2-benzyl groups are acetolysed more slowly than the corresponding 4(6)- and 5-groups, but this difference disappears with rise in temperature, and all benzyl groups are removed with formation of the hexa-acetate (LVIII). Acetolysis involves addition of an acetyl ion to the ethereal oxygen atom, and its rate depends on the nature and the configuration of neighbouring groups[86]: the acetoxy-group exerts greater steric hindrance than does the benzyloxy-group, and *trans*-groups impede acetolysis to a smaller extent than do *cis*-groups. It becomes clear why benzyl groups at positions 1(3) and 3(1) in the compounds (IX: R = $C_6H_5CH_2$) and (LVI) having *cis*-acetyl groups undergo acetolysis slowly. Acetolysis of the hexabenzyl ether is less selective and gives several products, among which the 1(3)-monobenzyl and 1(3),3(1)-dibenzyl derivatives (LV) and (LVII) predominate[86], which confirms the suggested reaction mechanism.

A similar process occurs in the acetolysis of 1(3), 4(6)-di-*O*-benzyl-*sn*-myoinositol (LIX), obtained from the diacetal (IV) by benzylation (XXVII) followed by removal of the protective cyclohexylidene groups (Scheme 9)[83].

Scheme 9



Hydrogenolysis of (LV) yields 1(3), 2,4(6), 5,6(4)-penta-*O*-acetyl-*sn*-myoinositol (XLIII), whose isolation may entail acetyl migration. Thus even crystallisation of the penta-acetate (XLIII) may be accompanied by migration owing to contamination with bases, and is therefore conducted in the presence of traces of acid[83,86].

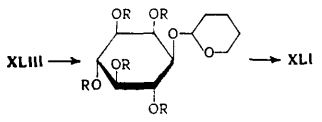
4. Pentabenzyl Ethers of Myoinositol. Allyl Protective Grouping

Benzyl ethers have found application as protective groups in the chemistry of cyclitols, in particular myoinositol, because they are stable in alkaline and acid media. They are obtained in good yields by the action of benzyl chloride or bromide in the presence of alkali[104], benzyl bromide in dimethylformamide in the presence of silver or barium oxide, and benzyl chloride in the presence of sodium hydride[105]. The benzyl group can be removed not only by catalytic hydrogenation but also by boiling with Raney nickel or reducing with metallic sodium in alcohol[86,106]. This makes the benzyl ethers convenient starting materials for obtaining monophosphoinositides. Their only disadvantage is that they cannot be used to obtain monophosphoinositides with unsaturated aliphatic acid residues.

The requirements for obtaining 1(3), 2,4(6), 5,6(4)-penta-*O*-benzyl-*sn*-myoinositol (XLI) are not satisfied by methyl, tosyl, or any ester group selectively introduced at the 3(1)-hydroxyl in the tetrabenzyl derivative (IX: R = $C_6H_6CH_2$). Allyl protection has since been successfully used for these purposes[52]. Allyl bromide, reacting mainly with the equatorial hydroxyl in the above compound (IX), gives a derivative (XXIX), which is benzylated to (XXXVII: $R^1 = CH_2.CH:CH_2$) and, after alkaline isomerisation of the allyl into the propenyl group and hydrolysis in an acid medium, is converted into (XLI)[52]. In the case of myoinositol derivatives containing acid-labile groups it has been suggested that the propenyl protection should be removed by (i) ozonolysis followed by alkaline hydrolysis, (ii) oxidation with alkaline permanganate, or (iii) the action of mercury(II) chloride in the presence of mercury[107-110]. A disadvantage of the allyl group is that it cannot be used in the presence of groups that are unstable to alkaline conditions, which applies in

particular to myoinositol derivatives with ester protecting groups. Furthermore, the conditions for isomerisation of the allyl into a propenyl group may cause aromatisation of the myoinositol ring[111].

Scheme 10



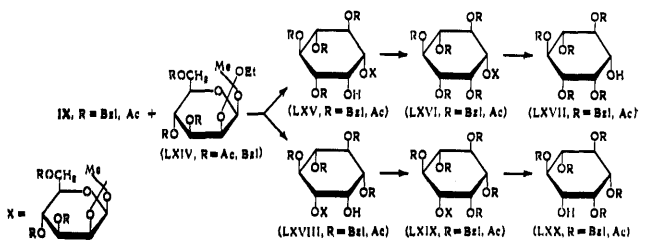
(LXI, R = Ac; LXII, R = H; LXIII, R = BzI)

Another route has recently been found[112] from the penta-acetate (XLIII) to the pentabenzyl ether (XLI). Reaction of the former with 2,3-dihydropyran gives 1(3), 2,4(6), 5,6(4)-penta-*O*-acetyl-3-*O*-tetrahydropyranyl-*sn*-myoinositol (LXI, Scheme 10), treatment of which with methanolic ammonia yields 1-*O*-tetrahydropyranyl-*sn*-myoinositol (LXII). Treatment of the latter with benzyl chloride in the presence of alkali converts it into the pentabenzyl derivative (LXIII), and removal of the oxanyl group by acid hydrolysis gives (XLI).

5. Orthoester Protective Group

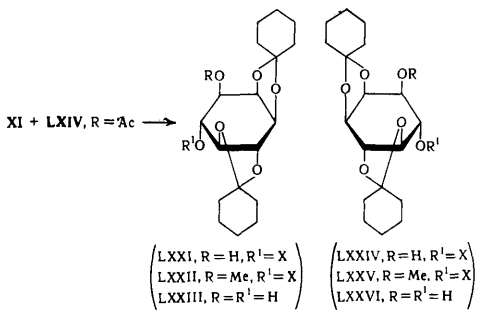
The carbohydrate orthoester group is beginning to find use in myoinositol chemistry[61,62,71-73,78,79,81,112-114]. Hitherto the main use of orthoesters has been based on their rearrangement into isomeric glycosides in the preparation of oligosaccharides[80]. The chief virtues of the orthoester group lie in the mild conditions of its introduction (transesterification with lower orthoacetates) and removal (acid hydrolysis)[80], which leave other groups unaffected. Furthermore, the diastereomeric orthoacetates of D-mannose and of myoinositol obtained from racemates of the latter differ in properties, and hence can be used to obtain optically active derivatives of an asymmetrically substituted myoinositol.

Scheme 11



D-Mannose orthoacetate (LXIV: R = CH_3CO, $C_6H_5CH_2$) has been used to prepare optically active pentabenzyl ethers and penta-acetates of myoinositol (LXVII, LXX: R = $C_6H_5CH_2$, CH_3CO—Scheme 11), which are initial compounds in the preparation of saturated and unsaturated monophosphoinositides[61,62,81,112,114]. A peculiarity of this reaction is that the 1-hydroxyl is more reactive than the 3-hydroxyl[78,81].

Scheme 12



D-Mannose orthoacetate (LXIV: R = CH_3CO) reacts with the diacetal (VI) to give the compounds (LXXI)–(LXXVI) (Scheme 12)[72,73], which, containing labile orthoester and *cis*- and *trans*-acetal groups, can be the starting points for the preparation not only of monophosphoinositides but also of di- and tri-phosphoinositides.

The orthoester protective group shows great promise in the chemistry of myoinositol, because of the simplicity of its introduction, the mild conditions of removal, and also the possibility of its use to obtain optically active derivatives of an asymmetrically substituted myoinositol.

V. PHOSPHORIC ESTERS OF MYOINOSITOL

1. Properties of Phosphoric Derivatives of Myoinositol

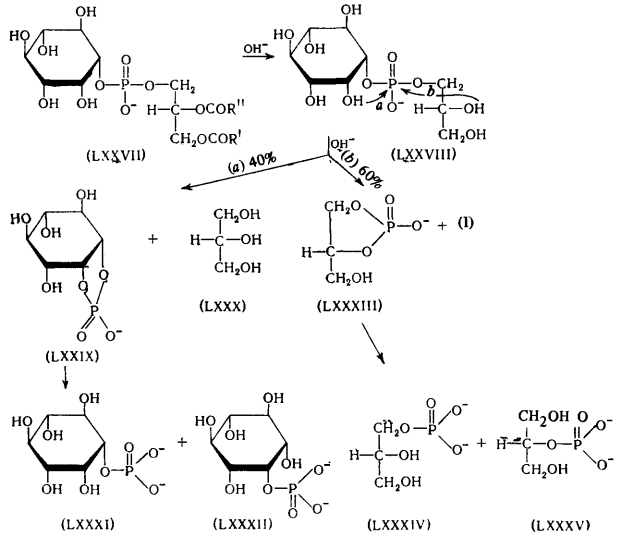
Phosphoric esters of myoinositol are polyfunctional compounds. The phosphoric groups in phosphoinositides are present in both monoesterified and diesterified forms; a triesterified form appears in the chemical reactions during preparation. Phosphoric esters of myoinositol are distinguished by lability depending on the presence of neighbouring groups. Study of the behaviour of these esters must take into account their capacity for various migrations[115-120], and therefore these properties should be allowed for in the preparation of phosphoinositides (phosphorylation, removal of protective groups).

Hydrolysis of Phosphoinositides

Diesterified phosphates of myoinositol are hydrolysed by acids and bases, the phosphates showing an appreciable tendency to cyclisation when vicinal hydroxyls are present (Scheme 13).[120-122] Such hydroxyls increase the rate of hydrolysis of phosphoric groups both in acid and in alkaline media, with formation of cyclic phosphates (LXXIX) and (LXXXIII) in the first stage. These reactions obviously involve transesterification, the cyclic phosphates being readily hydrolysed and forming the isomeric phosphates (LXXXI), (LXXXII), and (LXXXIV), (LXXXV). This is

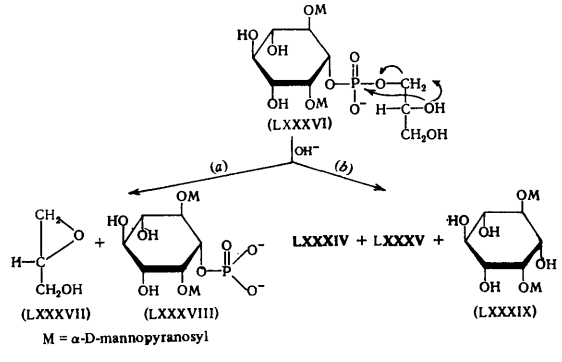
supported by results for the alkaline hydrolysis of the cyclic phosphate (LXXIX), when myoinositol 1-phosphate (LXXXI) and 2-phosphate (LXXXII) are formed to the extents of about 80–90% and 20–10% respectively, i.e. in the same proportions as in the alkaline hydrolysis of soya-bean phosphoinositides [122]. The ratio of these two phosphates shows that the bond at $C_{(2)}$ in the 1,2-cyclophosphate (LXXIX) is the more readily cleaved [122].

Scheme 13



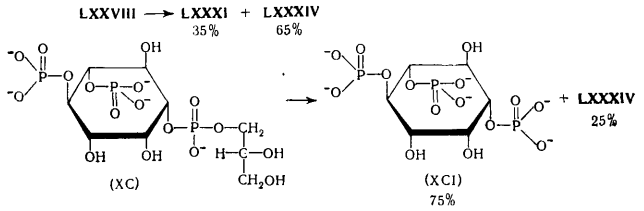
Cyclisation accompanying hydrolysis may involve functional groups both in *cis*(*ax*, *eq*) and in *trans*(*eq*, *eq*) positions. Stereochemical considerations indicate that a *cis*-diol cyclophosphate should be more stable than the *trans*-isomer, which was confirmed by Pizer and Ballou [122]. The action of dicyclohexylcarbodi-imide on *sn*-myoinositol 5-phosphate, in which the phosphate group is adjoined only by *trans*-hydroxyls, gives a series of unstable cyclophosphates, which then undergo several successive ring-openings and cyclisations, with the 1,2-cyclophosphate (LXXIX) as sole product of the reaction.

Scheme 14



The stability of deacylated dimannophosphoinositides (LXXXVI) to alkaline hydrolysis is somewhat puzzling [115–120]. The hydrolysis of these compounds is of considerable interest, since the vicinal hydroxyls attached to $C_{(2)}$ and $C_{(6)}$ are bound by a glycosidic bond with D-mannose and should not form cyclic phosphates. It might therefore have been expected that the only products of hydrolysis would be glycerophosphates, but a dimannoinositol phosphate (LXXXVIII) was also isolated on hydrolysis (Scheme 14). This fact can be explained by a different mode of degradation of the diesterified phosphate (LXXXVI), involving formation of epoxides (LXXXVII) (route *a*), which may compete with hydrolysis via intermediate formation of cyclic esters, which ultimately yield glycerophosphates (LXXXIV) and (LXXXV)—route (*b*).

Scheme 15



*Weights of hydrolysis products based on a mixture of isomers. *sn*-Myoinositol 2-phosphate and 2,4,5-triphosphate, as well as the 2-glycerophosphate, have been omitted from Scheme 15.

The ease of formation of cyclic phosphates depends very strongly on the degree of phosphorylation of the phosphoinositides [116–119]. In this connection it is interesting to compare the hydrolysis of mono- and tri-phosphoinositides (Scheme 15) [115–119,123]. Differences in the proportions of the corresponding hydrolysis products (LXXVIII) and (XC) may result from ionisation of the monoesterified phosphate groups in the triphosphoinositides, leading to distortion of the conformation of the myoinositol ring [124]. The 2-hydroxyl is then in a more favourable orientation for attack on the phosphorus, which is responsible for hydrolysis (route *a* in Scheme 13) with the formation of myoinositol triphosphate (XCI).

Migration of phosphate groups

Such migration was noticed in the isolation of glycerophosphates from lecithin and cephalin [125,126]. Hawthorne and Chargaff considered this process to be improbable in the myoinositol series in view of the large distance separating neighbouring hydroxy-groups in the chair conformation [127]. Migration of phosphate groups between vicinal hydroxy-groups in myoinositol phosphates was first observed by Posternak [128]. This phenomenon becomes appreciable at moderately low pH values [129]. The mechanism of such processes is analogous to migrations via cyclophosphates investigated in the alkaline hydrolysis of phosphoinositides (Scheme 13, route *a*) [121]. In myoinositol phosphates transfer of phosphate groups takes place when two vicinal *cis*-hydroxyls are present, whereas *trans*-migration is atypical [130].

Ballou et al.[122,131] investigated the migration of the phosphate group in *sn*-myoinositol 1-, 2-, and 5-phosphates, (−)-inositol 3-phosphate, and pinitol 4-phosphate in acid media. When 0.1 M solutions of the acid forms of myoinositol phosphates are heated to 90°C, interconversion of *sn*-myoinositol 1- and 2-phosphates is observed. The other compounds do not exhibit such properties, which indicates that autocatalytic migration of the phosphate group between *trans*-hydroxyls in hindered. It also appears possible[132] to hydrolyse monophosphoric esters of myoinositol at pH 4. Nevertheless, boiling 80% acetic acid leads to migration between the carbon atoms in positions 1(3) and 2, but not *trans*-migration; yet 1 *N* hydrochloric acid at 80–85°C causes both types of process. Under these conditions equilibrium is established between *sn*-myoinositol 1(3)- and 2-phosphates in 30 min, *trans*-migration is observed after 1 h, and all isomeric phosphates of myoinositol are detected after 8 h.[120,130,133] Thus under acid conditions transfers of phosphate groups took place between *cis*- and *trans*-positions, which governed migration round the ring.

Interconversions of myoinositol phosphates under alkaline conditions involve formation of an intermediate cyclic phosphate[134], as shown earlier. Absence of vicinal hydroxyls makes these processes more difficult owing to the low probability of formation of cyclophosphates through well separated hydroxyls, and also because of the stability of these cyclophosphates. Thus the cyclophosphate

obtained by phosphorylating *cis*-cyclohexane-1,3-diol, is not decomposed by 30% caustic soda at 100°C; ready degradation with the formation of phosphoric acid was appreciable only on treatment with 3 *N* hydrochloric acid at this temperature[134].

2. Synthetic Routes to Phosphoric Derivatives of Myoinositol

Preparation of monoesterified myoinositol phosphates

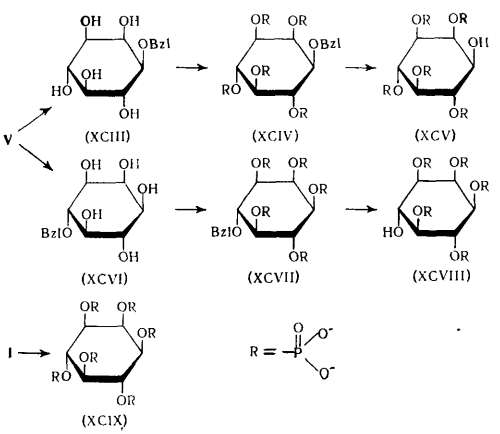
The phosphorylating agent most often used in the chemistry of monoesterified myoinositol phosphates is diphenyl phosphorochloridate, which is used at 0°C or in pyridine at 18–20°C. It is a strong phosphorylating agent, giving good yields of readily crystallisable triesterified phosphates. The phenyl groups are removed by hydrogenolysis in the presence of platinum catalysts. Phosphate migrations caused by the intrinsic acidity are avoided by isolating the myoinositol phosphates, obtained after removal of the protective groups, as their triethylammonium, cyclohexylammonium, and other salts. With as initial compounds myoinositol derivatives containing free hydroxyls at the positions to be phosphorylated, diphenyl phosphorochloridate has been successfully applied to the preparation of *sn*-myoinositol 2-phosphate[135], 1(3)-phosphate[49,52,71,112,131,136–138], 4(6)- and 5-phosphates[71,130] and 1(3), 4(6)-, 1(3),6(4)-, and 4(6),5-diphosphates[71,130]. It is interesting that, when this agent acts on D-mannose mono- and di-orthoacetates and on the diacetal (V) at 80–90°C, phosphorylation is accompanied[71] by replacement of orthoester by diphenyl phosphate groups (only phosphorylation takes place at 18–20°C), probably owing to nucleophilic attack on an orthoester oxygen atom by the activated phosphorus atom of the diphenyl phosphorochloridate with formation of a C–O–P bond. The phenomenon of removal of an orthoester group with simultaneous phosphorylation and probably acylation may find use in the synthesis of phosphoinositides.

Myoinositol monophosphates can be obtained also by the alkaline[139], acid[140], and enzymic[141–143] hydrolysis of phytin, and by the acid and alkaline hydrolysis of phosphoinositides[144,145].

The presence of a hydroxyl adjacent to the diphenoxyphosphinyloxy-group may lead to elimination of a phenyl group and migration of the phosphoric group with intermediate formation of a cyclic phosphate[118]. When the orientation of the vicinal hydroxyl is unfavourable to intramolecular phosphorylation, a bimolecular pyrophosphate may be formed. Hence the use of diphenyl phosphorochloridate for phosphorylating vicinal hydroxy-groups is not always justified.

A similar phosphorylating agent—bis-2,2,2-trichloroethyl phosphorochloridate—has recently been used to obtain monoesterified myoinositol phosphates[52]. Unlike a phenyl group, 2,2,2-trichloroethyl can be removed by the action of zinc in methyl alcohol[52]. This reagent has the same disadvantages as the diphenyl ester for obtaining polyphosphate derivatives. Dibenzyl and di-*p*-nitrobenzyl phosphorochloridates exerted a weak phosphorylating action on a secondary hydroxy-group in myoinositol[12].

Scheme 16

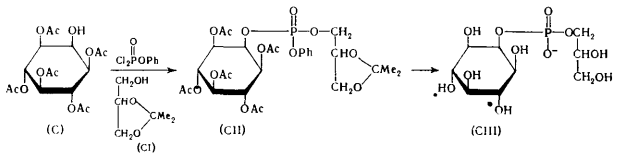


Angyal turned to polyphosphoric acid in the search for an agent for the polyphosphorylation of myoinositol derivatives[68]. However, application of this reagent to myoinositol compounds containing a benzyl, tosyl, or methyl protective group at position 1(3) results in the loss of such group with exhaustive phosphorylation. A convenient agent for these purposes was triethylammonium *N*-benzoylphosphoramidate[68], whose use completely eliminates the formation of cyclic phosphates, but involves experimental difficulties. Phytin (XCIX) and myoinositol pentaphosphates (XCV) and (XCVIII)—which may be products of the biosynthesis or decomposition of phytin—have been obtained by this method[146] (Scheme 16).

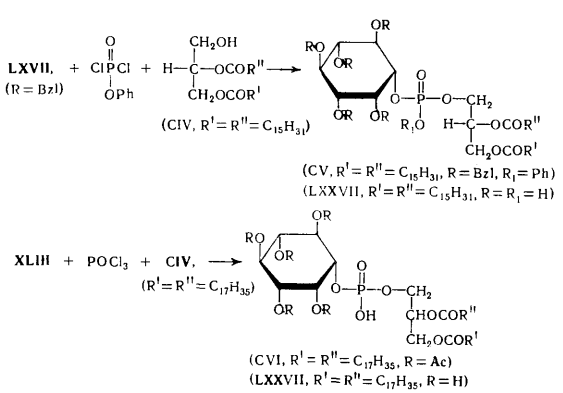
Preparation of diesterified myoinositol phosphates

Known methods of phosphorylation are used in myoinositol chemistry to form diesterified phosphate bonds[12]. Phosphorylation by means of polyfunctional chlorides of phosphoric acid presupposes the interaction of two different hydroxylated compounds followed by removal of protective groups. Thus Davies and Malkin[147] employed this method to prepare *sn*-myoinositol 2-*O*-glycerophosphate (CIII) by the interaction of *sn*-myoinositol 1(3),3(1),-4(6),5,6(4)-penta-acetate (C), phenyl phosphorodichloridate, and 1,2-*O*-isopropylideneglycerol (CI) (Scheme 17). A similar process was used to obtain the optically active monophosphoinositide (LXXVII) from the pentabenzyl derivative (LXVII: R = $C_6H_5CH_2$), phenyl phosphorodichloridate, and *sn*-glycerol 1,2-dipalmitate (CIV: R' = R" = $C_{15}H_{31}$) (Scheme 18)[61,62].

Scheme 17



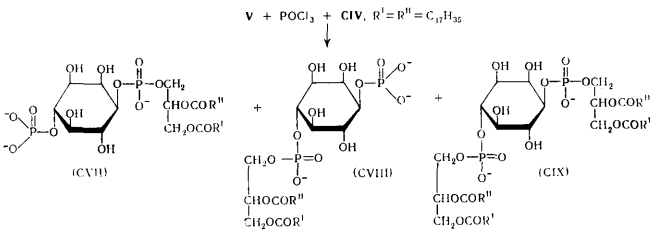
Scheme 18



Lyutik et al.[63] used phosphoryl chloride as phosphorylating agent (Scheme 18). This reacted with the 1,2-diglyceride (CIV: R' = R" = $C_{17}H_{35}$), and, without being isolated, the intermediate phosphorochloridate reacted further with myoinositol penta-acetate (XLIII). This method, unlike the previous method, can be used to obtain unsaturated monophosphoinositides. Another advantage is that the monophosphoinositide structure (CVI) is obtained as a diesterified phosphate—not the triesterified phosphate (CV)—which diminishes the number of stages in the synthesis.

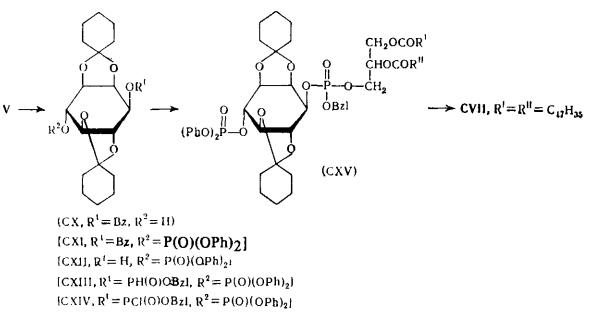
Phosphoryl chloride possesses not only advantages but also several disadvantages, which often prevent its use. Because of its polyfunctionality the phosphorylation of two hydroxylated compounds gives a large number of phosphorylated and also chlorinated products, which considerably lowers the yield of the required compound, and complicates its isolation[12].

Scheme 19



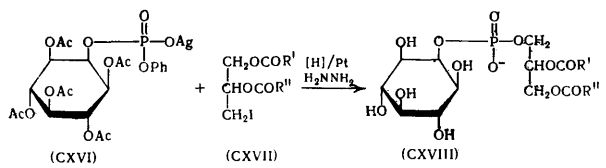
Phosphoryl chloride has been used also to produce the diesterified phosphate structure of more complicated phosphoinositides (Scheme 19)[58,59]. The above synthesis yielded not only the diphosphatidyl derivative (CIX) but also the diphosphoinositide positional isomers (CVII) and (CVIII), the latter (CVIII) having an unnatural structure. These isomers could not be separated.

Scheme 20



The above defect was overcome by using as starting material the diacetal benzoate (CX)[60], obtained by selective benzoylation of the diacetal (V) (Scheme 30)[70]. The compound (CX) was phosphorylated by means of diphenyl phosphorochloridate to form a monoesterified 4(6)-phosphate bond, and the benzoyl group was removed by the action of hydrazine hydrate (CX → CXI → CXII). A diesterified 1(3)-phosphate structure was formed by adding a phosphatidyl group by the method of mixed phosphoric anhydrides[12]: the phosphite (CXIII) was obtained by the action of the mixed anhydride of benzyl dihydrogen phosphite and diphenyl hydrogen phosphate on the derivative (CXII). The product was converted into the acid chloride (CXIV) by means of *N*-chlorosuccinimide, a new mixed anhydride was formed by the reaction of (CXIV) with diphenyl hydrogen phosphate, and this was condensed with the 1,2-diglyceride (CIV: R' = R" = $C_{17}H_{35}$) to obtain the protected diphosphoinositide (CXV), removal of the protective groups from which in the usual way gave the diphosphoinositide (CVII)[60].

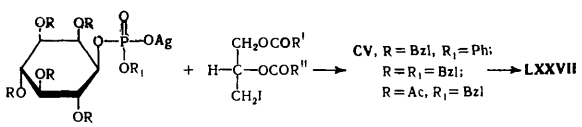
Scheme 21



(CXVI) (CXVII) (CXVIII)

The use of silver salts of substituted phosphoric acids for phosphorylation in the preparation of diesterified phosphates involves their reaction with halogen derivatives of the corresponding hydroxylated compounds. This method was first employed to obtain the unnatural monophosphoinositide (CXVIII) [148], by the action of 3-iodopropane-1,2-diyl distearate (CXVII) on the silver *sn*-myoinositol phosphate (CXVI)§ followed by removal of the protective groups (Scheme 21).

Scheme 22



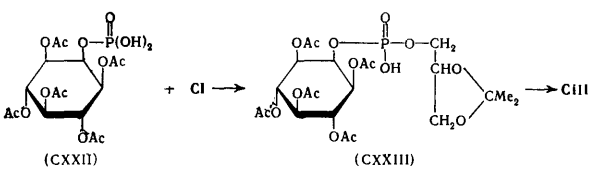
(CXIX, R = Bzl, R_1 = Ph) (CXVII, R' = R'' = $C_{15}H_{31}$;
(CXX, R = R_1 = Bzl) R' = $C_{11}H_{23}$, R'' = $C_{17}H_{33}$;
(CXXI, R = Ac, R_1 = Bzl) R' = $C_{15}H_{31}$, R'' = $C_{17}H_{33}$

The same method has been used to synthesise a natural monophosphoinositide [64,65,149] (Scheme 22), by treating the silver salts (CXIX)–(CXXI) with (CXVII). The silver salt (CXIX) was prepared by phosphorylating the pentabenzyl ether of myoinositol (XLI) with phenyl phosphorodichloridate, hydrolysing the product, and converting it into the potassium and then into the silver salt (CXIX) [52]. The silver salt (CXX) was synthesised by treating (XLI) with bis-2,2,2-trichloroethyl phosphorochloridate, removing the protective group, obtaining the dibenzyl ester by reaction with phenyldiazomethane, transforming to the sodium salt by anionic monodebenzylation, and converting to the silver salt (CXX) [149]. The silver salt (CXXI) was obtained similarly, except that myoinositol penta-acetate (XLIII) was phosphorylated with diphenyl phosphorochloridate, and the phenyl groups were then removed by hydrogenolysis [65]. This last salt (CXXI) was also prepared by treating (XLIII) with phosphoryl chloride and then with benzyl alcohol, subjecting the resulting triesterified phosphate to anionic monodebenzylation, and converting into (CXXI) [64]. The monophosphoinositide (LXXVII) containing unsaturated acid residues was obtained from (CXXI) [64,65].

The preparation of phosphoinositides by double decomposition between glycerol halogenohydrins and silver salts of phosphoric acids is distinguished by its selectivity and the high phosphorylation yields. However, it also involves many stages, as well as experimental difficulties in obtaining the starting materials, which often make it uncompetitive with other methods [12].

The reactions of monoesterified phosphates with hydroxylated compounds in the presence of condensing agents are also used to produce diesterified phosphate structures. The condensing agents act by preliminary activation of the monoesterified phosphate group [12]. Several of them are beginning to be used to obtain diesterified phosphate structures in the myoinositol series. Thus Ellis and Hawthorne synthesised the 2', 3'-dihydroxypropyl *sn*-myoinositol 1-phosphate (CIII) by condensing the phosphate (CXXII)¶ with 1,2-*O*-isopropylideneglycerol (CI) in the presence of dicyclohexylcarbodi-imide (Scheme 23) [150].

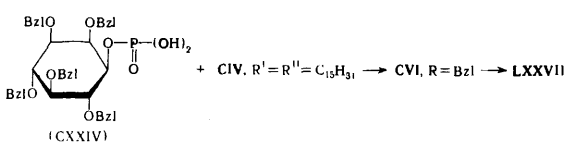
Scheme 23



(CXXII) (CXXIII)

2,4,6-Tri-isopropylbenzenesulphonyl chloride has been used to obtain the monophosphoinositide (LXXVII) from the phosphate (CXXIV) and the 1,2-diglyceride (CIV: R' = R'' = $C_{15}H_{31}$) (Scheme 24) [149]. The conversion of monoesterified into diesterified phosphates in the presence of condensing agents requires that excess of the hydroxylated compounds should be present: the use of stoichiometric quantities leads to the formation of pyrophosphate derivatives and hence a diminished yield of diesterified phosphates [150–159].

Scheme 24



(CXXIV)

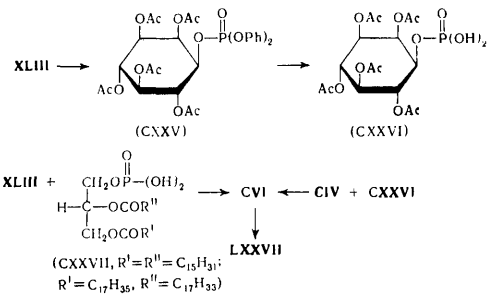
2,4,6-Trimethylbenzenesulphonyl chloride has been used in our laboratory to obtain mono- and di-phosphoinositides as optically active derivatives of natural structure or as diastereomeric mixtures (Scheme 25) [160]. Monophosphoinositides (LXXVII) have been obtained by the reaction of phosphatidic acids (CXXVII) with myoinositol penta-acetate (XLIII) or of the 1-phosphate of the penta-acetate

§The silver salt (CXVI) was prepared by phosphorylating the penta-acetate (C) with phenyl phosphorodichloridate, hydrolysing the product, isolating the potassium salt, and converting the latter into the silver salt (CXVI).

¶Compound (CXXII) was prepared by phosphorylating the myoinositol penta-acetate (C) with diphenyl phosphorochloridate and then removing the phenyl groups.

(CXXVI) with 1,2-diglycerides (CIV). A similar reaction was conducted with the phosphatidic acid (CXXVII) and the diacetal derivative (CXII) to obtain the diphosphoinositide (CVII: R' = R" = $C_{15}H_{31}$). This method is most promising for producing diesterified phosphate structures in the myoinositol series. Its virtue is that high yields of the products are obtained (almost uncontaminated with by-products) from readily available starting materials.

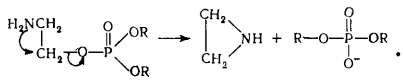
Scheme 25



Preparation of triesterified myoinositol phosphates

Various types of triesterified phosphates have already been mentioned as intermediates in the preparation of mono- and di-esterified structures. But their main interest lies in the hypothetical existence of triesterified glycerol phosphatides. It has been suggested that diesterified di- and tri-phosphoinositides are fragments of complicated lipid complexes, present in the animal brain, which may have the structure of triesters of phosphoric acid [161-165]. This hypothesis was first put forward by Collins [163]. Several hypothetical structures were suggested by Galanos and Kapoulos [164], who developed a technique for isolating lipid complexes from natural sources. According to the latter workers [164] myoinositol plays an important part in stabilising such complexes.

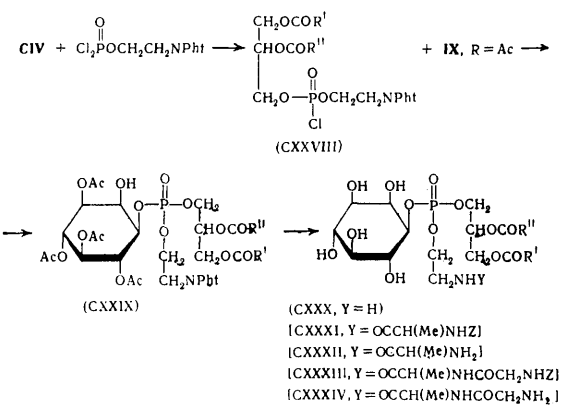
Nevertheless, other investigators [118] dispute the presence of phosphoric triesters in lipids because of instability. Reasons for the lability of triesterified myoinositol phosphates containing a vicinal hydroxyl have been discussed above. From theoretical considerations the corresponding triesters containing a neighbouring amino-group should also undergo hydrolysis with the formation of diesterified phosphate derivatives [118]:



Thus information on lipid complexes, as on triesterified phosphate structures, is inconsistent with theoretical views on the stability of such compounds studied on simple models. This problem requires further investigation, and one method may be to synthesise triesterified phosphate lipids.

Synthetic work has been done to obtain triesterified-phosphate glycerol phosphatides containing myoinositol (Scheme 26) [58,166-168]. The derivative (CXXVIII) was obtained by the action of 2-phthalimidoethyl phosphorodichloridate on the 1,2-diglyceride (CIV: R' = R" = $C_{17}H_{35}$) followed by condensation, without isolation, with the tetra-acetate (IX: R = CH_3CO), reaction occurring mainly at the equatorial hydroxyl in myoinositol [58,166]. Acetyl and phthaloyl groups were removed from the product (CXXIX) by hydrazinolysis. The resulting triesterified phosphate (CXXX) was used to synthesise phosphatido-peptides (CXXXII) and (CXXXIV) [58,167,168]—structural units in the hypothetical liquid complex of the bovine brain [164]—by condensation of the amino-group of the triesterified phosphate (CXXX) with *N*-benzyloxycarbonylalanine and *N*-benzyloxycarbonylglycylalanine followed by removal of the protective groups.

Scheme 26



The triesterified phosphate lipids—(CXXX), (CXXXII), and (CXXXIV)—are more labile than the corresponding diesterified-phosphate glycerol phosphatides [58,166-169], but their synthesis suggests that structures of this type may exist both in the free state and in natural lipids. Complexing with other natural compounds may restrict the degradation processes in triesterified phosphates studied on simple models. Final conclusions can be reached only after detailed investigation of this question.

Formation, Structure, and Properties of Polymer Gels

L.Z.Rogovina and G.L.Slonimskii

A gel is taken to be a polymer-solvent system in which the polymer, present at very low concentration, forms a quite stable three-dimensional network in the solvent. Consideration is given to the properties of gels in which the network is formed both by chemical and by physical bonds; attention is paid mainly to the second group of gels, in which variation in temperature produces a reversible transition between gel and solution. Existing views on the thermodynamic nature and structure of gels are subjected to critical analysis, and specific gel-forming systems are examined. A detailed analysis is made of the macroscopic phenomena accompanying the reversible solution-gel transition, as well as the strength, rubber-elastic, plastic, and relaxation properties of gels. A list of 399 references is included.

I. INTRODUCTION

Many, often controversial papers have now been published on the nature and structure of gels, the laws of the transition from solution to gel-like state and the mechanism of gelation, the peculiarities of the physical and mechanical properties of gels, and also specific features of gels of polymeric and non-polymeric substances. The reasons for the appearance of different views on the nature and the sturcture of gels are firstly the disconnectedness of independently developed colloid-chemical, thermodynamic, structure–kinetic, and rheological approaches to the process of gelation, and secondly the substantial differences among the gel-forming systems themselves, from whose study various investigators have drawn their own conclusions. The Reviewers will endeavour to define what systems must be regarded as gels and what differentiates polymer gels from disperse colloidal systems and from concentrated solutions of polymers, as well as which thermodynamic, structural, and rheological changes in a coagulating system are inherent in gelation and which are characteristic only of certain classes of gelling systems.

The concept of a gel first arose in colloid chemistry[1-20]. It implied a disperse two-phase system in which particles of the disperse phase, mostly of elongated form and present in very low concentration, from a three-dimensional framework filled with a very large quantity of the dispersion medium. The framework in such systems was formed by various relatively simple compounds, crystalline or amorphous, mostly inorganic. From the start of the investigation of gels formed by compounds of high molecular weight, however, many specific features due to the nature of the polymers themselves were observed, together with the properties common to all systems of this class. The term "studen' [jelly]" appeared in the Russian scientific literature at this time. Several investigators attempted to separate the concepts of "jelly" and "gel", using various criteria. Thus systems possessing rubberlike elasticity were termed "jellies", and brittle systems were "gels"[21,22]; sometimes systems which were incapable of swelling after removal of the solvent were regarded as gels, and strongly swelling systems as jellies[21]. In other cases gels were two-phase disperse systems, while jellies were single-phase systems constituting true solutions of polymers, in which a three-dimensional network of intermolecular bonds was present between individual macromolecules[23]. However, such separation of these concepts merely introduces confusion, since, for example, systems formed by polymerisation or polycondensation in solution, in which a molecular network is certainly present, are usually termed, not "jellies", but *gels* (they are formed at a characteristic "gel" point[24]); on the other hand, jellies, formed from true solutions of polymers, may be either single-phase or two-phase systems, as we shall show below. It therefore appears to the Reviewers that, as in Ref. 25, the concepts "gel" and "jelly" must be regarded as identical, referring to the same broad range of systems, which in turn can be subdivided according to various criteria. We shall use the single term "studen'"†.

A gel is a polymer–solvent system containing a three-dimensional network of quite stable bonds of non-fluctuating character (i.e. almost unbroken by thermal motion). If such a polymer network is surrounded by the solvent (as a result of swelling of the solid polymer or diminution of the solubility of the polymer in the solution), the system is a gel independently of whether this three-dimensional framework is formed by chemical bonds or intermolecular bonds of physical nature, whether the system has been obtained without phase separation of a true solution or as a result of such separation. A gel may be either a two-component or a multicomponent system.

When gels are formed from solutions, each system is characterised by a critical concentration of gelation, below which a gel is not formed. This concentration is determined by the amphiphilicity of the macromolecules and the degree of regularity of the chemical structure of the polymer, the form of the macromolecule, the interaction between polymer and solvent, the molecular weight, and the flexibility of the polymer chain (the more flexible

† Since the above distinctions do not appear to have been made in the English language literature, "studen'" will henceforward be translated throughout as *gel* (Ed. of Translation).

the higher the critical concentration)[26]. We shall examine in greater detail below the action of all these factors on the process of gelation.

The formation of branch points in the network is accompanied by a considerable increase in viscosity, the appearance of rubberlike elasticity, and at a high polymer concentration by normal elasticity, a yield-point stress, and the capacity for retention of shape and loss of fluidity under the influence of its own weight and small stresses (as we shall see later, considerable irreversible deformations appear in gels under higher stresses). Another characteristic feature of a gel is its inability under isothermal conditions to dissolve in the solvent from which it has been formed, whatever quantity of this solvent is added[27]. Gels can be divided into two large groups depending on the nature of the bonds forming the three-dimensional network[28-30].

Gels of type I are irreversible systems with a three-dimensional network formed by chemical bonds between macromolecules, incapable of reversible fusion and coagulation, and breaking down only on degradation of the polymer itself. They include swollen three-dimensional polymers (e.g. swollen vulcanised rubbers, tanned gelatin, etc.), systems whose network has been formed by polymerisation of a monomer in solution in the presence of very small quantities of a cross-linking agent, and spatially cross-linked systems obtained in a solvent by the polymerisation or polycondensation of monomers having three or more functional groups.

Gels of type II are heat-reversible systems whose network is formed by various kinds of intermolecular bonds, obtained either by the limited swelling of solid linear polymers or from solutions of polymers by appropriate variation of the thermodynamic conditions.

II. GELS INCAPABLE OF MELTING (IRREVERSIBLE GELS)

Gels of type I containing the equilibrium concentration of solvent are equilibrium single-phase systems[31,32]; their three-dimensional network is usually regarded as macromolecular. Studies of such gels have been concentrated mainly on the thermodynamics of the swelling of cross-linked polymers in various solvents, which enables the interaction between polymer and solvent to be assessed[30,33-36]; the dependence of the swelling and the thermoelasticity of the systems on the degree of cross-linking[24] and on the polymer concentration[37-49] has also been investigated. The properties of such gels are significantly affected by whether they have been formed directly by the cross-linking of a polymer in a solvent or by the swelling of a three-dimensional system obtained with a specified degree of cross-linking in the absence of solvent[37,40,50]. On the formation of a network in solution, when the solvent concentration considerably exceeds the equilibrium value corresponding to the given degree of cross-linking, the gel is a non-equilibrium two-phase system, in which syneresis‡ takes place until the solvent has the same chemical potential within the gel and in the fluid liquid phase[31,32,51,55]. The phase ratio and the size of the structural units in gels of this type have been studied by various optical methods[37,55-58]. One of the main factors determining the properties of gels whose network has been formed in a solvent is the concentration of polymer in the system. Another important factor is the nature of the solvent, which determines both the ability of the polymer to form a supermolecular structure in solution[59,60] (in the case of poor solvents; the three-dimensional network is then also supermolecular—not molecular—in character) and the rubberlike elasticity of the resulting networks, which governs the subsequent shrinkage of the gel[61]. Both these properties play a decisive part in the forming of a polymeric solid via a stage of gelation with subsequent removal of solvent, i.e. in the so called xerogel state[62], whose structure (porosity) is completely determined by the structure of the original gel and the mode of solvent removal. The porosity of xerogels plays a very important part in their use as ion exchangers[63], and in recent years as carriers in the vigorously developing gel chromatography[59,64]. The preparation of gels having various specified porosities[65-67] requires the study of a wide range of novel gel-forming systems, solvents, and methods of cross-linking: research in this field is growing vigorously at the present time[68-70]. Such porous structures can be obtained also be evaporating the solvent from gels whose networks are formed by bonds that are physical—not chemical—in nature; the properties of such systems have been described for agar-agar[71], poly(vinyl) acetals[72], and cellulose acetate[73].

‡Syneresis is the expulsion of solvent during the compaction of particles of the disperse phase in the case of a colloidal system or during the establishment of thermodynamic equilibrium in a polymer–solvent system[51-54].

III. HEAT-REVERSIBLE GELS

We have been concerned mainly with gels in which the reversible solution–gel transition is of the greatest interest, occurring usually with change either in temperature, pressure[74], or solvent composition (addition of a precipitant, change in pH, introduction of various additives, etc.).

The properties of heat-reversible gels can be approached in various ways. Most authors consider that a gel is always a non-equilibrium heterogeneous two-phase system, since formation of a three-dimensional gel network is possible, in their opinion, only on phase separation of a single-phase solution[29,75,76]. Several authors hold the view that gels are formed without phase separation, as a result of formation of local intermolecular bonds between individual macromolecules present in true solution: gels are thus regarded as homogeneous, one-phase systems[77-79]. A number of authors think that gels may be either single phases or two-phase systems, structurally either homogeneous or heterogeneous[80-83]. It is noteworthy in this connection that the question of the phase constitution of polymeric gels is almost completely ignored in the foreign literature, where interest is concentrated mainly on the change in properties of the system with the formation of branch points of the three-dimensional network. Soviet investigators, however, pay great attention to the phase constitution of gels, and we shall examine in greater detail existing approaches to this problem.

1. Formation of Two-phase Gels with Phase Separation of a Solution

Gels of compounds of high molecular weight are regarded in colloid chemistry, by analogy with those of low molecular weight, as disperse two-phase systems, in

which particles of the solid disperse phase form a framework. Such an approach has been widely developed by the Rebinder school[84], who have worked out a detailed theory of structure formation in colloidal systems, applying generally to such diverse compounds as clays, concretes, and supersaturated solutions of synthetic and even natural polymers. A distinction is made between structure formation by coagulation and by condensation[23,84-87]: in a coagulated structure contact between the particles is effected by weak van der Waals forces, so that the system is characterised by low strength, plasticity with slight elasticity, and thixotropy; in a condensed structure strong cohesive or adhesive contacts are established between the particles, which confer durability and elasticity on the system. According to the ideas of the Rebinder school, the formation of a three-dimensional structure by means of such strong contacts between coalescing particles of a new polymer phase separating from a true solution with spontaneous formation of a colloidal system below the consolute temperature is the cause of gelation and the strengthening of the gel. Results obtained on gelation in aqueous gels of gelatin[88,89], polyvinyl alcohol[90,91], and cellulose acetate[92,93] have been interpreted in terms of the above concepts. These ideas, which are not open to doubt for gels that are typical lyophobic colloidal systems (they may also be polymer—non-solvent systems), obviously cannot be true in other extreme cases, when phase separation of the solution involves formation of two liquid phases, or when gelation is unaccompanied by phase separation. Because of the high viscosity of polymer systems, of course, and also at low interfacial energies, gels of both types can be formed, differing as little as we please. For these transition systems the actual difference between them, of course, is devoid of meaning.

It is noteworthy also that the transition from typical polymer gels (formed with liquid phase separation or without phase separation at all) to typical colloidal gels is determined by the nature of the solvent, which has a significant influence also on the flexibility of the polymer chain: as the solvent becomes poorer and the rigidity of the polymer chain increases, its ability to swell diminishes (without which a polymeric type of gel cannot be formed), and the gel becomes increasingly colloidal in nature, i.e. it becomes a two-phase system with a three-dimensional framework formed by rigid macromolecules or their aggregates, which do not swell in the solvent. The above views on the formation of a solid polymer phase may therefore apply mainly to gels of rigid-chain polymers.

According to modern views, which originated in the work of Kargin, Papkov, and Rogovin[94-96], polymers form true solutions[28], interaction between polymer and solvent being regarded as the mixing of two liquid phases[97-99]. The concept of liquid phase separation underlies Papkov's concept of gelation[29,97]§, the theoretical principles of which will be briefly considered.

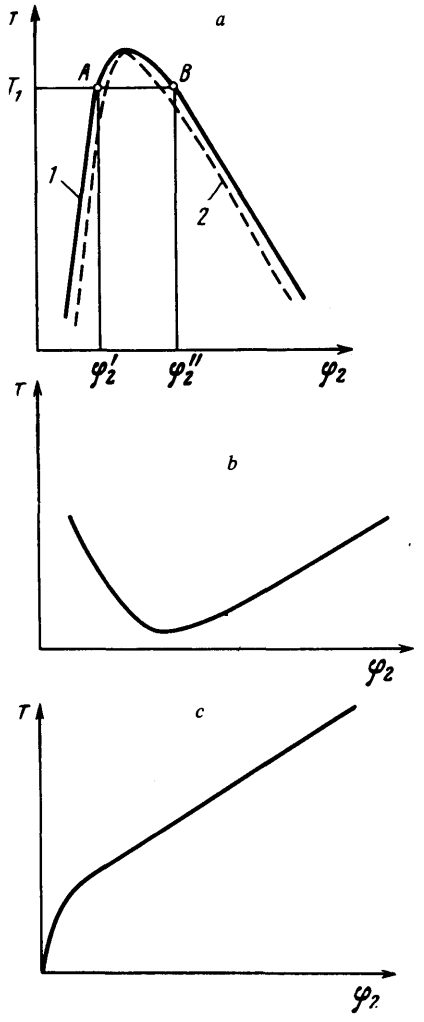

Figure 1. Equilibrium diagrams for systems with: *a*) an upper consolute temperature; *b*) a lower consolute temperature; *c*) a polymer crystallisable from solution, where T is the phase-separation temperature, φ_2 is the polymer concentration, and φ_2' and φ_2'' are the polymer concentrations in the equilibrium phases: 1) binoidal; 2) spinodal.

Gelation can occur either with a fall or a rise in the temperature depending on the type of temperature variation of solvent power[28]: gels are formed on cooling or on heating according as the systems have upper or lower consolute temperatures. Fig. 1 illustrates phase diagrams for various systems. The curve separating the regions of existence of stable single-phase and of metastable solutions is termed a binoidal (curve *1*), and that separating the regions of existence of metastable and unstable solutions is a spinodal (curve *2*). The temperatures and concentrations corresponding to the binoidal represent the conditions under which the thermodynamically stable true solution of a polymer passes into the metastable state and forms a colloidal solution containing the nascent new phase. The existence of a diagram having a consolute temperature suggests the existence of a region of phase separation of the polymer into two new, liquid phases.

§ The possibility of liquid phase separation in the formation of gels was mentioned long ago by Hardy[7,9,10], who investigated the gelatin—water—ethanol system, and showed that the single-phase solution separates into two liquid phases below a certain temperature. As these phases set further, the three-dimensional skeleton of the gel is produced by one or the other phase depending on the concentration of gelatin in the system and on its rate of cooling, which leads to a significant difference between the mechanical properties of the gels.

The diagrams are quite different in form (Fig. 1*c*) when a new solid crystalline polymeric phase separates from solution. The type of phase diagram may therefore indicate whether phase separation involves nucleation of a new polymeric solid phase or formation of two liquid phases, one of which is strongly enriched with the polymer.

According to Papkov[100] a gel is formed only in the region of phase separation if the viscosity of the concentrated polymer phase is very high, which prevents complete spatial separation of the system into two liquid phases. He therefore regards a gel as a non-equilibrium two-phase system with incomplete separation of the phases, which, in contrast to the above colloidal views on gel structure, comprise a swollen polymer forming a cellular framework with the almost pure solvent distributed in it as drops. The existence of these two phases is responsible for the presence of a gel. On Papkov's view a gel does not exist outside the region of phase separation, but a concentrated solution is present, possessing different properties—unlimited fluidity, low elasticity, etc.

Fig. 1 shows that at temperature T_1 the equilibrium state of the system corresponds to separation into two phases having concentrations φ_2' and φ_2''. Any gel of concentration below φ_2'' will therefore be a non-equilibrium system, and solvent will separate with time until the chemical potentials in the two phases become equal. Syneresis in these systems is completely analogous to that in gels which have been chemically cross-linked within the solvent (Section II). Its progress is more intense the lower the concentration of polymer in the gel, which undergoes considerable shrinkage.

Since at a given temperature the system undergoes phase separation until the concentration φ_2'' is reached, the gel obtained directly from a solution of this concentration is a thermodynamically equilibrium system[101], which means that its composition should be the same independently of the route—from the solution or by swelling of the solid polymer—by which it has been obtained. Such independence forms the basis of the plotting of phase diagrams for gelling systems: owing to the impossibility of determining the composition of a concentrated polymer phase during phase separation, points on the right-hand portion of the binoidal are determined experimentally from the equilibrium swelling of the dry polymer[89]; the left-hand portion is plotted as usual from the cloud points of the solutions[28].

Only a few experimental phase diagrams of gelling systems have been published (Fig. 2).[90,92,102,103] In most cases they are similar in shape to miscibility diagrams for partly miscible liquids. Right-hand portions of phase diagrams have been obtained experimentally from the swelling of solid films, i.e. from the view that a mixture of polymer and solvent comprises two liquid phases. However, gelation in the region of phase separation is then interpreted as emergence of the solid polymer as a new phase. As we have mentioned above, these two approaches are incompatible.

Nevertheless, the complexity of obtaining phase diagrams for gelling systems and the limited possibility of using them result from the fact that structure formation in complicated polymer systems leads to a dependence of the state of the system on the approach to it and to irreversibility of several processes. These features of polymer systems have been discussed theoretically[104,105]. It has been shown during recent years that the swelling of a polymer film also depends on the previous history, i.e. on the character of the solvent from which the film has been obtained and on its thermodynamic affinity for the polymer[60,63], on the temperature to which the solution has been preheated and on the rate of cooling, which govern the presence and character of a supermolecular structure in the film[106-109], on the concentration of the solution, which determines the proportions of intra- and inter-molecular bonds in the system and also the conformation of the polymer macromolecule[110-113], and on the temperature at which the solvent had been evaporated to obtain the film.

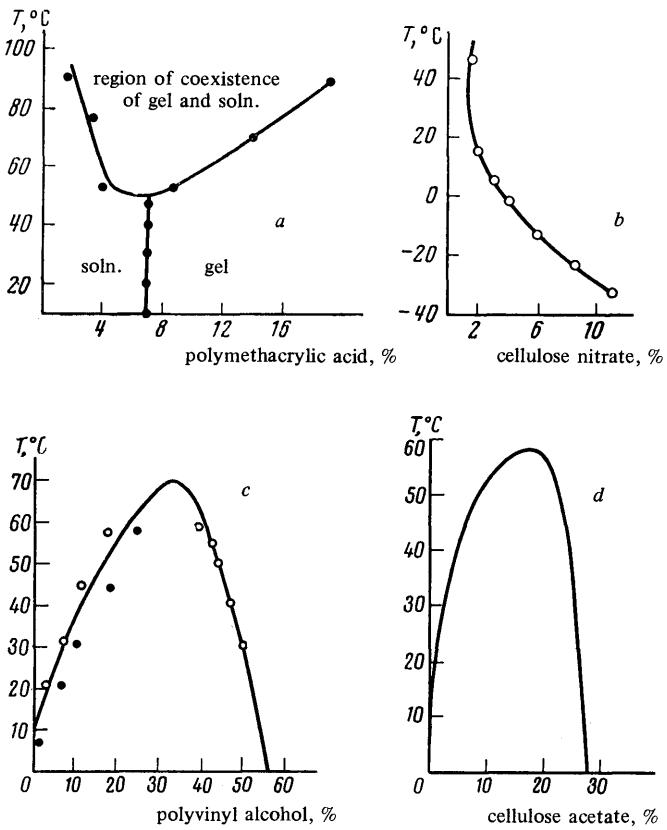

Figure 2. Experimental equilibrium diagrams for the gelling systems: *a*) aqueous polymethyacrylic acid[102]; *b*) ethanolic cellulose nitrate[103]; *c*) aqueous polyvinyl alcohol[90]; *d*) cellulose acetate—3,6-dioxaoctanol[92].

This last fact is well known for gelatin. If the solvent is evaporated at a temperature above the helix–coil transition point (considered in greater detail below), macromolecules are preserved in the loop conformation in the film; when evaporation occurs below the transition point, the macromolecules are preserved in the spiral state[114]. Furthermore, vaporisation of the solvent below the gel point of the system yields a film via a gel stage. Both these factors effect significantly the ability of the films to swell[29,115,116]. The degree of swelling of a film obtained from an aqueous gelatin gel depends very considerably on the concentration of the gel: the lower the concentration, the larger the number of cavities filled

with solvent, and the greater the swelling of the film, obtained by evaporation of this solvent, when replaced in the solvent (Fig. 3).[117]

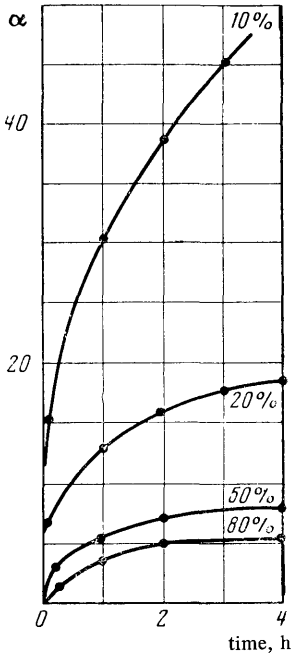

Figure 3. Dependence of swelling of film α on polymer concentration (indicated on curves) in gel from which it has been obtained[117].

For the above reasons the swelling of a film in fact depends on its previous history, and the right-hand branch of the phase diagram plotted from these values is displaced along the concentration axis (by 15–20%) depending on the various factors enumerated above[109]. As a consequence the region of phase separation in gelling systems can be determined only very roughly, and the characterisation of specific gelling systems by the temperature–concentration phase diagram is largely devoid of meaning unless the precise conditions under which it was obtained are indicated.

Two-dimensional phase diagrams are applicable only to binary systems, so that they can be used to characterise gelation only with a narrow molecular-weight distribution, when the polymer can be regarded as a single component. In this connection we must again mention the necessity of cautious use of the concept "component" in such multimolecular systems as polymers[118]. In real gel-forming systems—which are, of course, polydisperse—change in temperature is accompanied by loss of solubility initially of the higher fractions and then of the lower fractions. Gelling is therefore a multistage process[75] occurring in a multicomponent system[119], which it is illegitimate to characterise by a binary phase diagram[28,97]. The practical possibility of using such diagrams to represent gelation in polydisperse systems is due to the experimental fact that the position of the right-hand portion of the binoidal varies very little with molecular weight[120].

The investigation of gelation on narrow fractions[121-123] showed that the lower fractions play no specific part in gel formation, since it obeys the same laws in unfractionated and fractionated polymers. Fig. 4 illustrates the molecular-weight dependence of several parameters of gelation, and shows that the rigidity of the gel, as well as the melting point[124] and the "aggregation" temperature (i.e. the temperature at which viscosity begins to vary with time[125]), increases with molecular weight (in several cases only to a certain value).

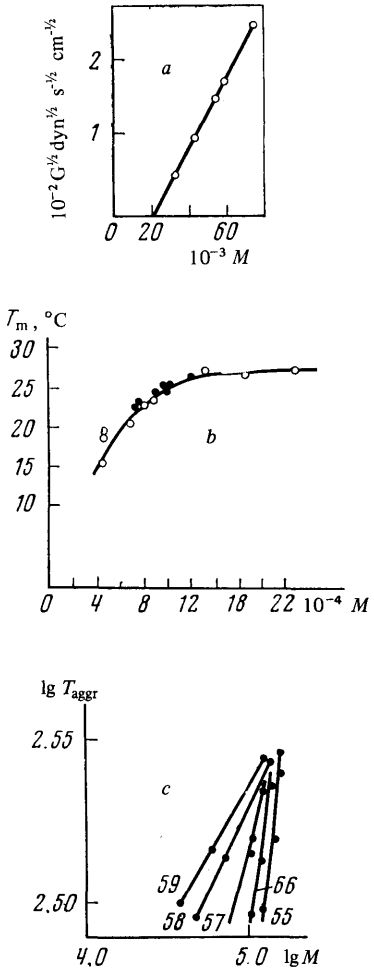

Figure 4. Influence of molecular weight of polymer on the properties of gels: *a*) modulus of elasticity G; *b*) melting point (for aqueous gelatin gels)[121]; *c*) "aggregation" temperature (for gels of cellulose acetate of varying degrees of substitution in benzyl alcohol)[125].

The above concepts on gel formation with phase separation are applicable also when the solubility of the polymer is diminished, with change not only of temperature but also of solution pH (ion-reversible gels)[112,126] and especially on introduction of a precipitant[29,127-130] (which is often encountered in the fractionation of polymers).

Under these conditions the range of existence of a gel can sometimes be determined by means of ternary diagrams[28]. In some cases not only two-phase but also multiphase systems are formed depending on the interactions of all the components[129,131,132].

2. Single-phase Gels obtained without Phase Separation

At polymer concentrations above the equilibrium value φ_2'' (Fig. 1), i.e. to the right of the binoidal, single-phase gels are formed without phase separation (Fig. 2*a*) either as the solubility of the polymer in the solution decreases or with limited swelling of linear polymers. Similarly to the swelling of network polymers, gel formation here is due to the existence of branch points in a three-dimensional network resulting from local interactions of macromolecules. Since gels are usually formed by polymers, amphiphilic in nature, in thermodynamically poor solvents, limited swelling of the polymers is evident under thermodynamic conditions such that the polymer–solvent interaction is sufficient to overcome some polymer–polymer contacts but insufficient to overcome other, stronger contacts, which form a three-dimensional network within the solvent.

Addition of excess of a lower component to an equilibrium gel cannot produce any change until the thermodynamic conditions change[27]. With rise in temperature, and also with improvement in the solvent power of the medium surrounding the gel, the number of branch points may decrease, ultimately with destruction of the gel. If the lifetime of the branch points becomes so short (owing to heating or change of medium) that the movement of macromolecules is virtually unrestricted by existing short-lived bonds, a transition will occur from the "stable" gel network to a purely fluctuational network, i.e. to a flowing liquid.

Transitions due merely to the kinetics of the formation of branch points, unaccompanied by change in the thermodynamic state of the system, are not associated with the presence of different phases, and such gels may therefore be single-phase systems. Gels comprising a single phase can be produced not only by variation of the temperature but even under isothermal conditions, with variation of the concentration during transition from the solid polymer to its dilute solution. Results obtained for such an isothermal transition in the poly(vinyl chloride)–dibutyl phthalate[133] and gelatin–glycerol[134] systems show (Fig. 5) a successive transition from vitreous to rubber-elastic state and to viscous fluid.

Rubberlike elasticity can appear only in solids possessing a three-dimensional network with sufficiently large distances between branch points, which is a necessary condition for the development of flexibility in the macromolecular segments forming the network. If the rubber-elastic state arises in solution owing to strong intermolecular bonds, i.e. because of formation of a stable three-dimensional network, the range of existence of the solution coincides with that of the gel. In solutions in which such strong bonds are not present, the rubber-elastic state is largely masked by fluidity, and the system passes from the solid polymer to a dilute solution via a concentrated-solution stage, not via a gel stage. There are then no grounds for assuming that the appearance of a rubber-elastic state as the polymer swells coincides with intersection of the binoidal, as is stated by Frenkel'[105]: i.e. rubberlike elasticity may appear equally in the one-phase and two-phase states of gels. Characterisation

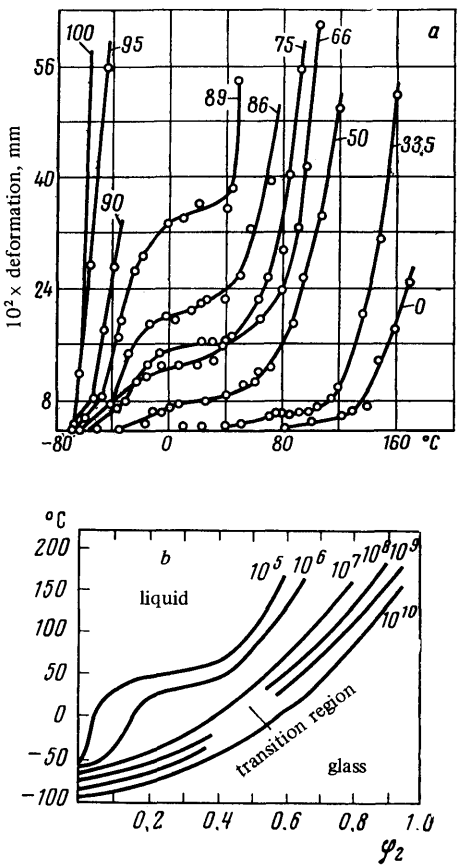

Figure 5. Isothermal transition from dilute solution to solid polymer via gelation stage: *a*) thermomechanical curves for the poly(vinyl chloride)–dibutyl phthalate system (numerals on curves denote concentrations of dibutyl phthalate)[133]; *b*) variation of modulus of elasticity of gelatin–glycerol system with temperature and concentration φ_2 (numerals on curves denote moduli of elasticity; a gel is present in the range $G = 10^5$–10^7 dyn cm^{-2}).[134]

of the gel-like state of polymers therefore requires, as stated by Papkov[29] and shown experimentally by Meerson[135], examination both of phase diagrams (which have limited applicability, as we have noted) and the concentration dependence of glass and yield points (for amorphous systems) or melting points (for crystalline systems) (Fig. 6).

The mechanism of the formation of single-phase gels of uncrystallisable polymers is analogous to vitrification of the polymers themselves[78], except that in the vitreous state bonds are formed between a considerable number of repeating units, whereas a kind of partial vitrification, i.e. formation of a small number of the strongest bonds, occurs in gels, leading to a stable network structure¶.

¶ Thus in the case of amorphous polymers gels, being systems intermediate between liquid and solid, are also intermediate between solutions and condensed systems in the vitreous state[79].

The presence of two types of intermolecular interactions—strong and weak[79]—causing the appearance of a three-dimensional network forms the basis of the gel-like state, independently of the phase state of the polymer in which it develops.

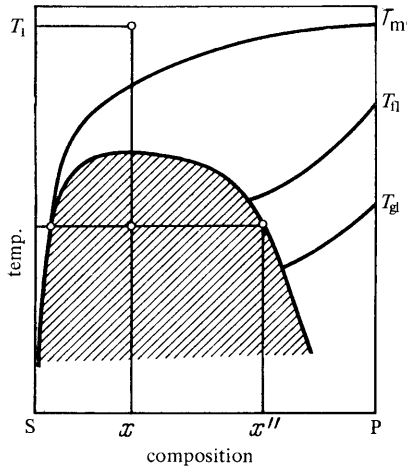

Figure 6. Concentration dependence of glass point T_{gl}, flow point T_{fl}, and melting point (S = 100% solvent; P = 100% polymer).[29]

3. Role of Crystallisation in Gelation

In contrast to the above discussion, most investigators consider that gelation is inseparably associated with crystallisation of the polymer within the solvent. This view is based firstly on the Herrmann—Gerngross micellar model[136], according to which crystalline regions (regions of parallel packing of segments of many macromolecules) form the branch points of the three-dimensional network, independently of whether the chemical structure of the polymer permits its crystallisation. It is based secondly on the fact that gelation is characteristic only of polymers whose macromolecule contains strongly interacting polar groups; such a structure leads to chain rigidity, which in the opinion of several investigators, increases the tendency to crystallisation[119,137-139]. On this hypothesis many authors assume that crystallisation accompanies gelation in polyacrylonitrile[140-142], poly(vinyl chloride)[143,144], and even random copolymers[138,145,146]. Sufficient regularity of the chain, in most cases a necessary condition for crystallisation, can hardly be achieved in ordinary statistical copolymers. In polymers and copolymers containing sufficiently extended blocks of uniform structure, however, local crystallisation is possible in solution[147], with the formation of more stable "branch points" of the gel network.

Crystallisation in solution is characterised thermodynamically by the phase diagram illustrated in Fig. 1*c*, representing the equilibrium between the pure crystalline polymer and its saturated solution. However, hardly any such diagrams have been published for specific gel-forming systems. Phase diagrams of crystallisable polymers were first obtained, for polyethylene in various solvents, by Richards[148], who showed also that, after the crystalline phase has melted completely, the system may separate into immiscible liquid phases, possibly accompanied by gelation. Thus crystalline and amorphous phase separations are independent processes, as is emphasised by Papkov[29].

The presence or absence of crystallisation is indicated also by the thermal effects and volume changes accompanying gelation[149-151] (see below) and by direct structural methods[150,152-154]. The concentration dependence of the melting points of crystallisable gels, in contrast to the corresponding relation for amorphous gels, follows Flory's equation

$$\frac{1}{T_m} - \frac{1}{T_{m_0}} = (R/\Delta H_u^1)(V_1 - \chi_1 v_1^2)(V_u/V_1) \qquad (1)$$

for mixtures of a crystalline polymer and a component of low molecular weight, in which T_{m_0} and T_m are the melting points of the polymer in the absence and in the presence of solvent, χ_1 is an interaction parameter, V_1 the molar volume of the solvent, ΔH_u the heat of fusion, v_1 the volume fraction of the solvent, and V_u the volume of the repeating unit of the polymer.

The combined application of these methods suggests that completely amorphous gels are obtained in several systems (polyacryloglycinamide in water[150,155-160], copolymers of acrylic acid, acrylamide, and acrylonitrile in water[161-163], poly(vinyl chloride) in dibutyl phthalate[143], and copolymers of methyl acrylate and methacrylic acid[164]). Nevertheless, amorphous (atactic) poly(methyl methacrylate) does not form gels in any solvent, whereas the crystalline stereoregular poly(methyl acrylate) exhibits a strong tendency to gelation because of the formation of complexes between iso-segments and syndio-segments[165-169]. The same effect is observed with polyacrylic acid[170], which forms gels only when in the isotactic form, whereas polymethacrylic acid forms gels in the amorphous (atactic) state[102,112,171-173]. The ability of several polymers to crystallise depends so strongly on the composition of the solvent that, as has been shown with polyacrylonitrile[142,174] and polyvinyl alcohol[175], they are able to give amorphous gels in some solvents, and crystalline gels in others.

When a polymer shows a strong tendency to crystallise in a solvent medium, the gels may have the character of crystalline solvates[176,177]. With intense crystallisation of the polymer the gels are devoid of the typical properties of gels, notably elastic and rubber-elastic properties: i.e. they are, rather, pastes[178] (polyvinyl alcohol in aqueous acetone[29], methanol[29], and glycerol[175], polycaproamide—formamide systems[29], and poly(alkyl acrylates) with straight-chain alcohols[176]). The other systems in which reversible gelation has been observed comprise polyvinyl alcohol in water (in the absence[179-183] and in the presence[184-186] of complexing agents) and in aqueous glycerol, diethylene glycol[124,149,187], methanol, and acetone[29], as well as in anhydrous solvents (formamide, *N*-methylpyrrolidone, and dimethyl sulphoxide[175]); poly(vinyl chloride) in dibutyl phthalate[143] and in dimethylformamide[144]; polysaccharides[188,189], alginates[190,191], pectins[192], and agaroid[193] in water; cellulose and its ethers in organic solvents[194-196]; polyacrylamide in water[197]; copolymers of vinyl chloride and methacrylic acid, acrylic acid and ethyl acrylate[198], styrene and caprolactam[199], styrene and oxiran[200], and styrene and isoprene[201] (so called "mesomorphic gels"); and gels of

cellulose and other polymers in water, obtained in a special way and containing large regions of the crystalline phase[202-205].

It is thus clear from the above account that both amorphous and crystalline gels exist: i.e. gelation often involves crystallisation, but the latter is not an inherent part of the process[163,175]. The tendency to associate gelation with crystallisation often arises from the well defined structure formation in solutions and gels of polymers, which we shall very briefly examine.

IV. STRUCTURE OF GELS

It was considered for a long time that formation of a single-phase gel involves merely the formation of a three-dimensional network of separate macromolecules[23,77,79]. However, true solutions of polymers, like solutions of liquids of low molecular weight, are inhomogeneous[28], strongly characterised by association. The presence of fluctuating association complexes is evident even in very dilute solutions and in good solvents[206-220] long before the consolute temperature. Great interest is aroused by the variation in the conformation of macromolecules during association with increase in concentration and by the dependence of this process on the flexibility of the polymer chain[221-228]. Which conformation is most favourable for gelation is also of interest[169,229].

The influence of macromolecular conformation on gelation has been studied in greatest detail on gelatin, the most widely distributed gel-forming compound. The helix—coil conformational transition, which is typical of many polypeptides and biological macromolecules, occurs in gelatin at 35°C. Gelation takes place only below this temperature, i.e. with the helical conformation of the macromolecule. When a dilute solution undergoes concentration above 35°C, with the macromolecules remaining in the coiled state, only a significant increase in viscosity occurs up to very high concentrations, with complete absence of gelation. Thus formation of the helical conformation of macromolecules and gelation are interlinked processes: i.e. the formation of intramolecular aggregates during helix formation and the formation of intermolecular bonds (branch points of the three-dimensional network) leading to gelation are due to interactions of the same nature. As we shall see below, the energy and other parameters of the gelation of gelatin are largely determined by the characteristics of the above conformational transition in the macromolecule (Section V, 1). Most other biological macromolecules do not form gels in the native state, and several of them are capable of gelation only when denatured. A favourable conformation of the macromolecule, with a considerable number of groups capable of forming intermolecular bonds facing outwards, obviously plays an important part here as well. Determination of the conformations of macromolecules in synthetic polymers involves great experimental difficulties, and therefore available data are ambiguous.

Processes preceding phase separation—aggregation and nucleation of a new phase, which appears near the consolute temperature—take place with change in temperature. However, if gelation occurs as a consequence of the formation of branch points of a three-dimensional network with change of thermodynamic conditions without phase separation, the system loses solubility and fluidity, with of course, the fixation of association complexes present at the instant of loss of fluidity. Thus, as stated by Glikman[76] for the separation of a new phase, structure formation unaccompanied by phase transition converts fluctuating association complexes present in solution into aggregates[174], i.e. into quite stable structures, the three-dimensional network within and between which is no longer fluctuating but stable in character. The viscosity of an associated true solution does not vary with time, whereas that of a solution undergoing cross-linking (a so called "gel-solution"), in which the structure of association complexes become fixed, varies considerably with time[21,75]. It appears to the Reviewers that a sharply defined transition from a solution of invariable viscosity to a solution whose viscosity varies with time does not necessarily indicate the start of separation of a new phase, as certain authors assert[33,75,88,89]. This is often evidence of the appearance of individual stable branch points of a three-dimensional network, whose formation takes a long time[21] and results ultimately either in a single-phase gel or in phase separation. Many investigators have pointed out the two-stage character of gelation (aggregation and formation of individual branch points leading to a diminution of fluidity, followed by formation of a continuous network leading to a complete loss of fluidity)[81,82,230]. The gel network would obviously be formed both inside aggregates (between separate macromolecules) and between aggregates (supermolecular structures). Theoretical aspects of the production of gels from aggregated particles have been discussed by Joly[231-233].

It may be supposed that a truly molecular network is very rarely formed in gels. It may appear either in very dilute systems or in solvents in which formation of a polymer structure is feebly developed (but these are usually thermodynamically good solvents, in which gels are seldom formed). A special case of the formation of a macromolecular network is possible in solvents possessing good affinity for the polymer but whose molecules each contain two functional groups, and can therefore act, as it were, as cross-linking agents, forming hydrogen or other intermolecular bonds between the polymer macromolecules[175].

The possibility of the formation of macromolecular and supermolecular networks in gels had already been considered by Ferry in his early papers[234,235], in which he distinguished between "coarse" and "fine" networks. He linked the different network structures with the conditions of production of the gels: the lower the temperature the less favourable the conditions for aggregation and the "finer" the networks formed. Heating the gel to near the melting point causes reorganisation with the formation of "coarser" networks. The same feature was found by Stainsby[236] from a study of the mechanical properties of gels. He stated that at low temperatures many bonds are formed of poor stability but preventing further ordering of the network, whereas near the melting point few but very stable bonds are formed, so that ordering is possible. The dependence of the structure of a gel on the temperature conditions of its formation has been confirmed also by sedimentation in an ultracentrifuge[237,238], as well as by a thermodynamic method[239], but the correctness of the latter is open to doubt.

The above considerations show that the majority of gels, including single phases, are structurally microheterogeneous systems. This is well supported by direct structural methods of investigating gels, primarily electron microscopy (with special procedures to ensure high resolution[240,241]). Results illustrated by Fig. 7 indicate that the gel networks of gelatin in water[240,242,243], as well as of cellulose diacetate in aqueous acetic acid[244] and of

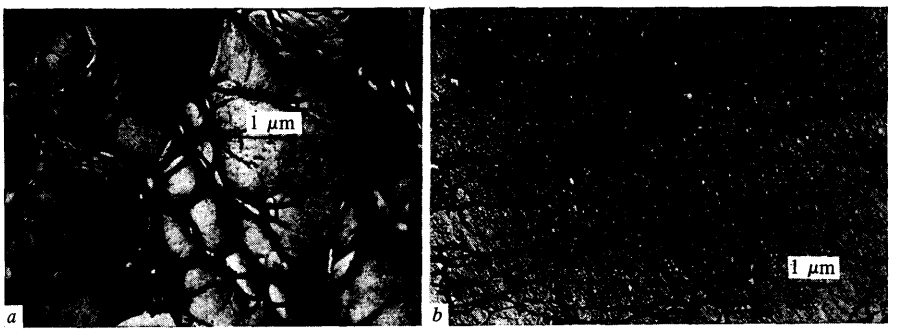

Figure 7. Electron micrographs (×8400) of gels of: *a*) gelatin in water (20% concentration);[243] *b*) cellulose diacetate in 35% aqueous acetic acid[244].

polystyrene in decalin[245], are made up of fibrillar structural units (of diameter ~1000 Å), whereas aqueous polyvinyl alcohol gels comprise globular units (diameter of globules ~1000 Å).[246-249] The electron micrographs cannot indicate, however, whether the observed structural units are at equilibrium or fluctuating in character; it must also be remembered that the presence of coarse particles in the case of polymers, *pace* Ref. 70, are quite unable to determine the phase state.

Another direct method for examining the structure of polymer solutions and gels is the scattering of light[250]. Application to concentrated solutions of polymers[251] reveals an extremal concentration dependence of scattering, which indicates that the association complexes increase in size until a fluctuating network appears in the solution, after which the scattering begins to diminish owing to the ordering of the network[252]. A similar variation is observed in coagulating systems[253,254]: the turbidity increases with aggregation, to reach a maximum on formation of the first branch points; with further increase in the latter the network becomes increasingly ordered, and the scattering of light diminishes to become independent of the number of branch points in the gel network[83,255]. The coarser scattering particles in polymer solutions and gels are therefore determined from the turbidity spectrum[56,256-259], obtained by measuring the optical density at various wavelengths of the incident light and processing the experimental results on the basis of Mie's theory[260-263]. During recent years a laser technique of measuring anisotropic small-angle scattering of polarised light has been successfully used to determine the size of the structural units of a gel[57,58,264-266]. Prins and Bueche have shown[267,268] that a random distribution of gel branch points is present over a certain concentration range and in certain solvents, but in most cases the branch points are formed by supermolecular structural units whose size varies with the temperature and with the nature of the solvent. According to this method the structural units of aqueous gels of gelatin and of polyvinyl alcohol have diameters of 3000–6000 Å, in good agreement with results obtained by electron microscopy.

The distinction between the hypothetical network and cellular structures of gels, which for a long time attracted great attention[33,269,270], disappears in considerable measure when the structural units are large. If the particles that are growing together into a network occupy a considerable volume, the space between them, filled with solvent, resembles a cell: i.e. the gel has a peculiar network–cellular structure, as is readily seen from Fig. 7. The predominance of one or other type of structure depends on the polymer–solvent system and on the concentration of the polymer. Transitions from open to closed gel structures have repeatedly been observed experimentally[93,271].

V. MACROSCOPIC PROPERTIES OF GELS DUE TO THEIR NATURE AND STRUCTURE

1. Properties characterising a Reversible Solution–Gel Transition

The temperature at which a gel passes from the rubber-elastic to a fluid state with destruction of the three-dimensional framework is termed the melting point of the gel. As this transition is somewhat diffuse, no absolute methods are available for determining the melting point; various research methods for detecting the melting of gels have been described[272-274], among which the most widely used is to measure the movement of a sphere, placed below the surface of the gel, when the temperature is slowly varied at a constant rate[275].

The gel point, i.e. the temperature at which formation of a gel first becomes possible, is usually determined as the temperature at which the viscosity of the system begins to increase rapidly (when each temperature is maintained for a given time). In all gel-forming systems the melting point is higher than the gel point. The magnitude of the difference, i.e. the hysteresis of fusion and gelation, varies within very wide limits for different gels: thus in 5% aqueous gels of gelatin the melting point is only 3 deg above the gel point[235], but in certain other gels the difference amounts to tens of and even a hundred degrees (e.g. the gel and melting points for a 5% gel of poly(vinyl chloride) in diethyl hexyl phosphate, a gel of cellulose triacetate in trischloroethyl phosphate, and a gel of polyvinyl alcohol in a 60 : 40 mixture of water and glycerol are respectively 36° and 108°C,[144] 3° and 120°C,[144] and −20° and 90°C, etc.). The hysteresis is probably due to a significant difference between the mechanisms of the formation and the fusion of a gel[114]. Formation involves a succession of many stages requiring a certain degree of supercooling and a long time, which results in a wide set of branch points in the three-dimensional network. Yet the melting of a gel has all the signs of a concerted transition, requiring the simultaneous rupture of several weak bonds followed by a rapid disordering of the chain units.

Even with infinitely slow cooling, therefore, the gel point will evidently not coincide with the melting point, as is supposed by certain authors[276], although some approach of these temperatures does occur. The difference in mechanism between formation and fusion of a gel is evident also in a difference between the energies of formation and rupture of the bonds in the network: gels of polyvinyl alcohol in various solvents show that the energy of destruction of the branch points always exceeds the energy of their formation[187,277] (since the latter corresponds experimentally to only one of the stages of gelation, whereas the former corresponds to the completely formed gel structure).

The hysteresis of melting and gel points is associated also with the often described Arisz effect[29,116,117], consisting in the dependence of the melting point of a gel on its previous history with respect to temperature. The melting point of a gel depends in several cases on the time and especially the temperature of its formation. This variation is connected firstly with different forms of cross-linking of the system at different temperatures, these determining the types and stability of the branch points formed (Section IV). The melting points of gels formed by cooling rise as the temperature of formation falls[122], but at very low temperatures of gelation (e.g. near 0°C with an aqueous gelatin gel[121]) the melting point becomes lower owing to inadequate mobility of the macromolecules involved in forming the network. Secondly, the dependence of the melting point of a gel on the conditions of its formation is determined by the completeness of the stress-relaxation processes following formation of the network[77,78].

Several quantitative approaches to the investigation of gels are based on the applicability of the theory of rubberlike elasticity and other statistical methods of polymer chemistry to the formation and properties of gels. From the analogy between the formation of a three-dimensional physical network and a network of chemical bonds within a solvent, Ferry applied to heat-reversible gels the Flory–Stockmayer theory[278], according to which a condition for formation of an infinite three-dimensional network is the relation

$$P_c = \frac{1}{\rho(\lambda_\omega - 1)} \qquad (2)$$

where λ_ω is the weight-average number of residues in the macromolecule, ρ the proportion of groups capable of forming cross-links, and P_c the proportion of these groups which actually form intermolecular bonds, i.e. the probability of cross-linking. If $\lambda_\omega \gg 1$, we have $P_c = 1/\rho\lambda_\omega$, which can be rewritten[239,279]

$$f m_{cl} = C/2M_\omega \qquad (3)$$

where m_{cl} is the molarity of cross-links (allowing for the fact that formation of a bond involves two groups) at the gel point, M_ω the weight-average molecular weight, C the concentration (g litre^{-1}) of macromolecules, and f a coefficient representing the proportion of groups capable of forming branch points that are involved, not in intermolecular, but in cyclic intramolecular bonds. Assuming that 1–2 bonds per macromolecule are required for formation of an infinite network, Ferry showed[235] that the critical concentration of gel formation by gelatin was 1%, in good agreement with experiment.

Experimental determination of the number of cross-links in the gel network and the number of groups involved in forming one cross-link is based on the equation of state

$$\tau = \alpha(d/M_0)RT\left[\left(\frac{l}{l_0}\right) - \left(\frac{l_0}{l}\right)^2\right] \qquad (4)$$

representing the relation between the stress τ and the elongation (in which $\alpha(d/M_0)RT = G$ is the modulus of rubberlike elasticity, l_0 and l are the initial and final lengths of the specimen, d is the density of the gel, M_0 is the molecular weight of the repeating unit, and α is the proportion of groups in the chain that form cross-links), deduced for three-dimensional networks from the theory of rubberlike elasticity, and the equation of swelling

$$\mu v_2 = -\ln(1 - v_2) - v_2 - \rho_2 \bar{V}_1 v_2^{1/3}/\bar{M}_c \qquad (5)$$

where μ is a polymer–solvent interaction parameter, v_2 the concentration by volume of the polymer, ρ_2 the density of the polymer, $\bar{V}_1$ the molar volume of the solvent, and $\bar{M}_c$ the molecular weight of the chain segment between branch points. It is then necessary to examine the swelling of films obtained by drying the gel (not by evaporating the solvent from a solution—Section III, 1), in which films the structure (i.e. the number and nature of the branch points) is fixed.

Most of the results calculated by using the above approach[279–284] lead to the conclusion that one cross-link is formed by many (20–30) groups, which is regarded as evidence that branch points in the gel network are formed by crystallites comprising many macromolecules. Sometimes, however, calculation shows that branch points are formed between two active groups, i.e. that association complexes are absent[155,156].

Although reasonable values are obtained in several cases for the number of branch points by transferring to cross-linked systems the theory of rubberlike elasticity developed for a macromolecular network, this theory is in large degree arbitrary and gives an idea, not of the number of real branch points in the system, but of the equivalent number in an ideal molecular network possessing the same properties as the test system†. We would like to lay special stress on this aspect, which is often overlooked.

From Eqn. (3) and the van't Hoff equation for the equilibrium formation of cross-links, Eldridge and Ferry[292] obtained the concentration dependence of the melting point T of a gel as

$$\ln C = -\frac{\Delta H}{RT} + \text{const} \qquad (6)$$

where ΔH is the energy of formation of a bond in a gel network. Pouradier established the relation

$$\frac{\Delta H}{RT^2} = \frac{1}{T} - \frac{d \lg G}{dT} \qquad (7)$$

between this energy and the temperature dependence of the modulus of elasticity of the gel[239,293]. Equations (6) and (7) enable us to determine the energy of formation (more correctly, of destruction) of branch points in a gel network. The same quantity can be determined by other methods not involving the premises of the theory of rubberlike elasticity. Firstly, it is determined as the apparent activation energy of flow (which is necessarily

† The same considerations apply also to investigation of the birefringence of gels, when the optical stress coefficient characterises the system[285–287], whereas the difference between the refractive indices, according to the theory of rubberlike elasticity, is related to the structural characteristics of the gel network[288–291].

connected with rupture of the cross-links of the gel network) from the temperature dependence of viscosity in the region of irreversible deformation of the gel (see below)[293]. Secondly, the bond energy ΔH or heat of gelation is measured by a direct thermographic or calorimetric method[294-303]. The examples of gels of gelatin, polyvinyl alcohol, and other polymers show good agreement among values of bond energies obtained by all these methods[157,175,187,299,301].

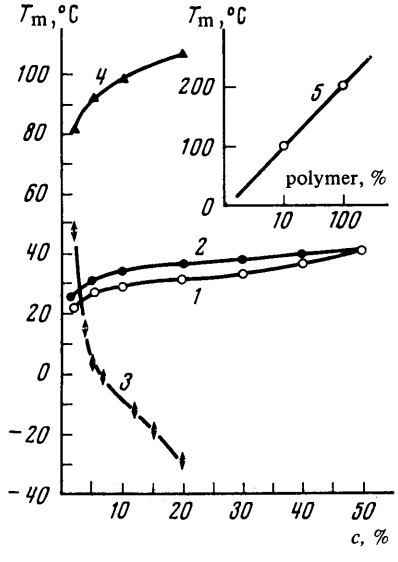

Figure 8. Concentration dependence of melting points of gels of: 1) aqueous gelatin[303]; 2) as (1) from Ref.88; 3) ethanolic cellulose nitrate[103]; 5) poly(vinyl chloride) in dibutyl phthalate[143]; 4) polyvinyl alcohol in 60% aqueous glycerol[175].

Because of the experimental simplicity ΔH is most often determined from Eqn.(6). Most of the gels investigated (gelatin, polyvinyl alcohol, poly(vinyl chloride), polyacryloglycinamide, polyacrylonitrile, etc.) exhibit proportionality between the melting point and the logarithm of the concentration. In several gels of well crystallisable polymers the melting point is proportional to the concentration (not its logarithm) in conformity with the Flory equation (Section III, 3). Equation (6) shows that the sharp concentration dependence of melting point, illustrated in Fig. 8 (curves *3–5*) for gels of poly(vinyl chloride), polyvinyl alcohol, and cellulose nitrate, and typical of the gels of most synthetic polymers, corresponds to a small energy of bonding.. Gelatin gels exhibit a quite different type of dependence (curves *1* and *2*)[303-305]: the melting point changes so little with concentration over the range 5–40% that it is often regarded as constant; the energy of formation of a bond in this region is very large, amounting to 50–200 kcal mole^{-1} depending on the conditions of preparation of the gel. The high heats of gelation and fusion of gelatin[294-303] were regarded for a long time as evidence that gelation is a phase transition of the first kind. Examination of gels of synthetic polymers of various types showed, however, that the energy of formation of a bond does not exceed 5–12 kcal mole^{-1} with amorphous polymers (which corresponds to 1–3 hydrogen bonds)[151,156,300] and 18 kcal mole^{-1} with crystallisable polymers[151,175,187]. The high heats of fusion and gelation of gelatin are due to the large helix–coil transition energy, which, as mentioned above, makes a most significant contribution to the formation and destruction of the gel. Thermogravimetric analysis with very slow stepwise heating reveals two fusion peaks, one attributed to the helix–coil transition, and the other to destruction of cross-links[302]. These peaks are preceded by an exothermic effect due to the formation of more stable bonds in the network when the gel is heated near the melting point. Calorimetric experiments show only one fusion peak[298].

The heat of the helix–coil transition has closely similar values in other proteins and polypeptides[306-309]. In cases in which these compounds form gels, e.g. with poly-(γ-benzyl L-glutamate), the heat of melting of the gels is of the same order as with gelatin[157], although slightly smaller in magnitude.

It must be remembered that heat effects in calorimetric experiments are expressed in calories per gram of the dry material, whereas energies of bonding determined by means of the Ferry–Eldridge equation are obtained in kilocalories per mole. Comparison of these quantities is difficult, since the number of bonds in a gram of the dry material is unknown.

The above considerations show that the magnitude of the heat of gelation cannot indicate that a phase transition is necessarily involved. The large heats of gelation found with gelatin and other natural polymers are explained by the large thermal effect of the intramolecular helix–coil phase transition, which cannot be separated from the heat of gelation itself. In all other gels the thermal effect is significantly lower and corresponds to the energy of formation of a few (with crystallisable polymers) or one or two (with amorphous polymers) intermolecular bonds. This can be regarded as an indication that gelation always involves structural conversion with the appearance of new branch points, the nature of which influences variation of the thermal effect within narrow limits.

The heat evolved on the formation of a small number of relatively weak bonds can be determined only in very high-sensitivity calorimeters. Hence the heat of gelation in such systems often could not be detected in the early work. In thixotropic colloidal systems formed by relatively weak van der Waals forces, in particular, the sol–gel transition occurs without a measurable thermal effect.

Analysis of the literature shows that the change in volume accompanying formation of a gel may vary. An increase occurs only when the gel is formed as a result of a chemical reaction with production of a new substance which remains in the system (e.g. the generation of hydrogen chloride in the formation of silicic acid gel)[21]. A decrease in volume on gelation has been observed with methylcellulose in water[310] and in several systems in which gelation is accompanied by crystallisation of the polymer, in particular on the gelation of polyvinyl alcohol in aqueous glycerol[149]. For a long time the volume change accompanying the gelation of gelatin was a matter of controversy[311-316]. Thus Neiman[313] assumed that the apparent change was due solely to volume relaxation (of both solution and gel) on variation of the temperature: when these factors are assessed correctly, no change in volume is detected. This view can hardly be correct, since the change in volume accompanying the helix–coil transition

and subsequent crystallisation makes a significant contribution to the gelation, and has been subjected to detailed dilatometric investigation by Flory and Garrett[317]. They discovered an appreciable, abrupt change in volume accompanying the gelation of collagen in ethylene glycol. The volume change, like other properties of a gelling system, probably depends significantly on the polymer concentration; in dilute gels and also in gels having weak intermolecular bonds, therefore, gelation takes place without a measurable change of volume. An abrupt change is evidently observed only when gelation is accompanied by rapid crystallisation of the polymer: in the absence of crystallisation, only a slight and gradual volume change takes place.

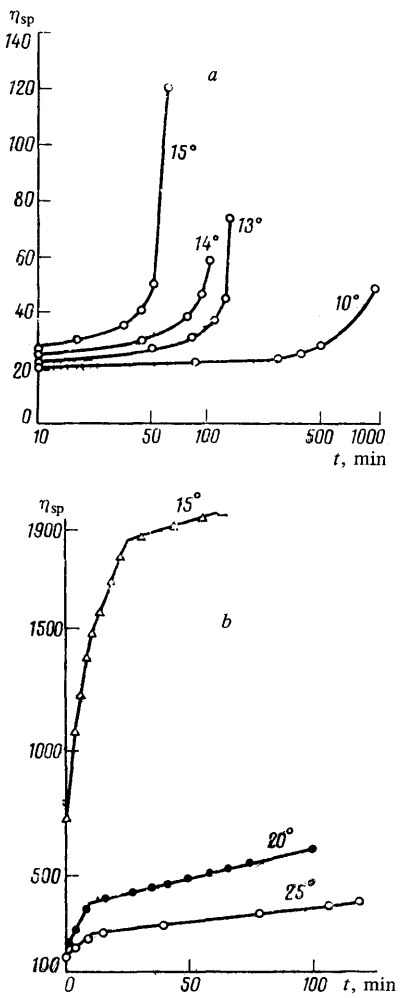

Figure 9. Variation of viscosity on gelation: *a*) cellulose nitrate in ethanol[103]; *b*) copolymer of acrylic acid and acrylonitrile in water[162].

The formation of stable branch points is most clearly evident in a change in the rheological properties of a gelling system. These properties may vary with temperature and concentration, but variation with time at constant concentration and temperature is most characteristic of gelation. Change in viscosity was for many years regarded as the most characteristic parameter of the solution–gel transition, and was studied intensively[317-324]. In several cases the viscosity isotherms have the typical shape (Fig. 9*a*) of the crystallisation isotherms of polymers[103]‡; this was used as an argument in support of the identity of gelation and crystallisation. In other cases the viscosity–time curves show several inflexions (Fig. 9*b*), which were attributed[81,180] to various cross-linking stages preceding formation of the gel.

However, the solution–gel transition is characterised not only by an increase in viscosity but also by the emergence of elastic properties in the system[11,325,326] (a reversible proportion of the deformation, a modulus of elasticity, i.e. rigidity) and a limiting shear stress[75], which increase with time§, as well as a change in the spectrum of relaxation times[327,328].

As Schwedoff emphasised, the elasticity and the viscosity of a system are not interrelated unambiguously: a system may be highly viscous and possess no shear elasticity; and conversely, the latter may be significant while the viscosity is very low. The second case is typical of dilute gels of gelatin, whose elasticity vanishes when they pass into the state of a dilute solution (melt). In contrast to dilute solutions, sufficiently concentrated solutions of polymers also exhibit elasticity, which is due to the presence of a fluctuating network (when sparse branch points are linked by flexible chain segments this is apparent as the rubberlike elasticity of solutions)[338-341]. In the gelling of a sufficiently dilute solution the increase in number and change in character of cross-links in the network lead to an increase in the rubberlike elasticity of the system; when a too dense network is present, however, the rubberlike elasticity diminishes, so that rubber-elastic deformation of a gel becomes less with increase in its concentration[342]. In concentrated solutions rubberlike elasticity is masked by flow, and adequate separation of reversible and irreversible portions of the deformation is important for a correct description of the rubberlike elasticity of solutions (as with gels and with the polymers themselves)[339,343,344]. Concentrated solutions, gels, and rubberlike polymers then exhibit closely similar moduli of rubberlike elasticity[134,339,344,345] at 10^4–10^6 dyn cm^{-2}.

Thus the rheological distinction between gels and concentrated solutions lies not in the elasticity of the former but in their yield stress[346]. Gels, like other bodies possessing a spatial framework (e.g. many disperse colloidal systems), are "quasi-Bingham" plastic solids[62]: i.e. they are characterised by a yield stress, below which they behave as solids (i.e. exhibit only elastic properties), but above as viscoelastic or viscous liquids (i.e. capable of irreversible deformation). This is evidently the decisive rheological property of gels[277,347-349], so that the long held view of gels as non-fluid systems must be regarded as incorrect. Such extremely low yield stresses were observed by Mishod in simple experiments[349] even for very

‡ A close similarity is observed also in the temperature variation of the rates of growth of cross-links and of crystal nuclei.

§ This time variation of properties, which is characteristic of a gelling system, demands that the system be brought to equilibrium—if at all possible—in order that the concentration or temperature dependence of these properties may be studied, or else that the rate of change of the properties should be taken into account.

dilute (0.2%) agar-agar gels. Later work showed that a limiting stress was absent from non-gelling concentrated solutions[345,350,351], but it also appears in filled solutions (e.g. a solution of polyisobutylene containing added particles of carbon black), in which a three-dimensional framework is formed[352].

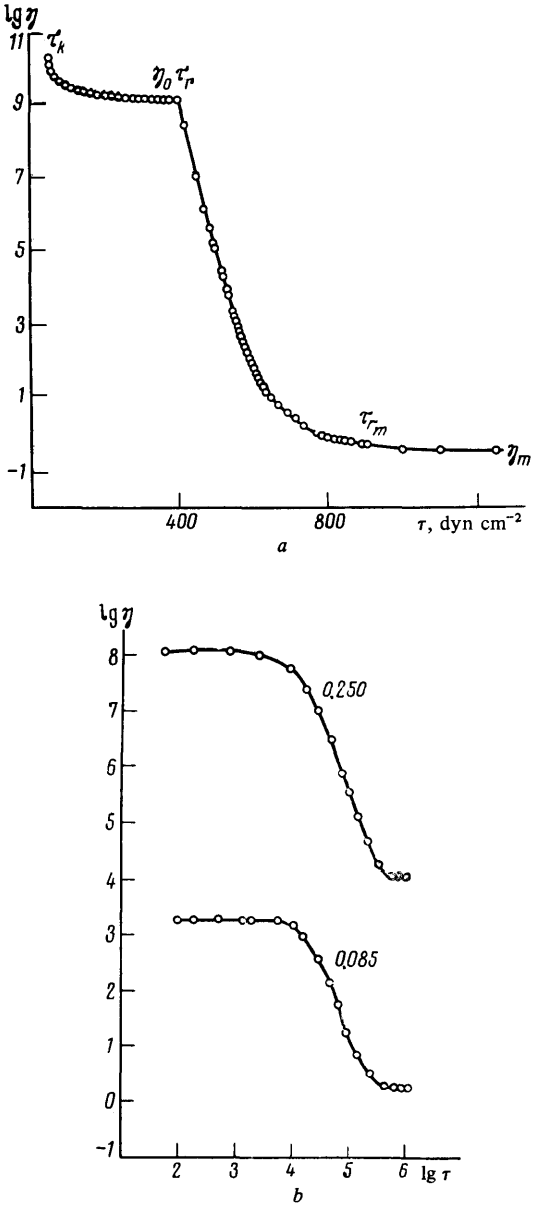

Figure 10. Variation of viscosity with shear stress in: *a*) a disperse colloidal system—an aqueous suspension of bentonite[357] (where τ_k is the limiting shear stress, τ_r the stress corresponding to the start of breakdown of the structure, τ_{r_m} the stress corresponding to complete breakdown of the structure, η_0 the maximum Newtonian viscosity, and η_m the minimum Newtonian viscosity); *b*) solutions of cellulose acetate in cyclohexane (concentrations denoted on the curves)[357].

During recent years it has become obvious that absolute limiting values do not in fact exist. According to Shurkov's theory of durability[353-355] the framework of a gel can be broken down by a sufficiently long-acting stress, even if considerably lower than the usually determined limiting shear stress. This, of course, is indissolubly connected with the development of irreversible deformations of the gel. A similar view was expressed by Trapeznikov, who considered that irreversible deformations, even in gels, could develop at any stress, and regarded the limiting shear stress as corresponding to a change in the character of the flow—Newtonian with unresolved structure below this limit, and plastic flow with resolution of the gel structure above it[356]. Shear at sufficiently high rates and stresses resolves the whole structure, and the flow again becomes Newtonian in character. Fig. 10 illustrates examples of complete rheological curves obtained both for plastic colloidal systems[357] and for concentrated solutions of macromolecular compounds[358,359]. Curves of the same type have recently been obtained also for dilute polymer gels[360] (since the limiting stress increases so much with gel concentration that it is almost impossible to realise a "quasi-Bingham" flow of gels).

Destruction of the gel structure on application of an external stress is a particular aspect of the thixotropic properties of gels[14,361,362]. In the initial stage of gel formation, when the spatial bonds have not yet become stable, thixotropy is apparent in the reversible transition of the gel into a solution under the action of external stress (and regelation after removal of the latter)[14]. Several gelling systems, however, possess dilatant properties, evident in enhanced viscosity and gelling on application of external stress, and reversible melting with decrease in viscosity after removal of the stress[363-366], which is attributed to the ordering of the structure under the influence of a mechanical field[18,347]. Among such systems are aqueous polymethacrylic acid[347], poly(methyl methacrylate) in dimethyl phthalate[366], etc. The phenomenon of rheopexy—acceleration of gelation as the external stress is increased—is often observed in such systems.

The transition from solution to gel involves a broadening of the whole relaxation spectrum[327,328,347,366]. The system retains its shape if the lifetime of the cross-links exceeds the duration of the experiment[347]. Trapeznikov therefore proposed the presence of relaxation times of 10^4—10^6 s in a polymer—solvent system, corresponding to the observation times employed in practice, as a rheological criterion of a gel, enabling it to be distinguished from a solution[367].

2. Elastic, Strength, and Relaxation Properties of Gels

The principal rheological investigations of already formed gels, like those of the polymers themselves and their concentrated solutions, reduce to the study of the static and dynamic moduli of elasticity, the dependence of stress on deformation at a constant rate of shear, creep (i.e. the development of deformation with time at a constant stress followed by relaxation of the deformation), and relaxation of stress at constant deformation, enabling relaxation times and the relaxation spectrum of the system to be estimated.

The modulus of elasticity of a gel can be determined either by static methods (under tension[368], compression[368], or shear[325,326,331,332], on change in the dimensions of the specimen in a tube[369]) or by dynamic methods (from the rate of propagation of sound waves)[370]. Good agreement

between static and dynamic shear moduli indicates the absence from the gels of relaxation times of 0.001–100 s[371]. The modulus of elasticity either increases continuously with the duration of gelation (poly(vinyl chloride)[143], polyacrylonitrile[328]) or reaches a limiting value after a very long time[88]¶. The shear modulus is proportional to the square[235] or higher powers[143,145] of the concentration of polymer in the gel, but in several cases this relation is observed only up to a certain concentration[373], above which the concentration dependence of the modulus changes. This may correspond to a change in the gel structure with increasing concentration (Section IV). With small deformations and stresses the behaviour of gels obeys Hooke's law: i.e. the modulus of elasticity is constant[374]. Under higher stresses it increases with the stress[373].

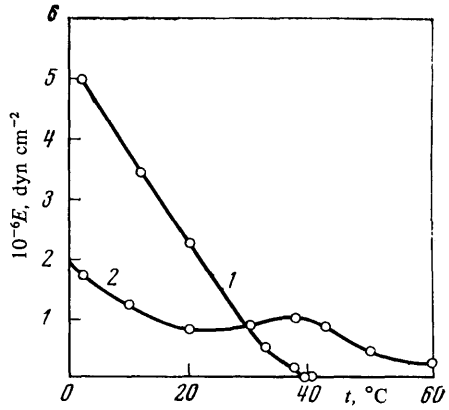

Figure 11. Temperature dependence of modulus of elasticity of gels of: 1) gelatin in water (φ_2 = 20%);[235] 2) polyvinyl alcohol in a mixture of water and glycerol (φ_2 = 10%).[373]

The temperature dependence of the shear modulus of gels indicates that in several cases their behaviour does not correspond to an entropy mechanism of elasticity. Fig. 11 shows that the shear modulus in gels of polyvinyl alcohol in aqueous glycerol increases with temperature over a considerable range (in conformity with the statistical theory of rubberlike elasticity), and only then does it decrease; whereas in gelatin gels the modulus of elasticity decreases with rise in temperature throughout the range investigated[235]. This decrease is due to the increasing rupture of cross-links with rise of temperature near the melting point of the gel, which is especially appreciable with gelatin, as the temperature range of the measurements is very limited. When a small number of chemical cross-links are introduced into a gelatin gel[375] or experiments are made under special conditions, such that the entropy mechanism of elasticity is not masked by the destruction of bonds[376-378], the shear modulus increases only slightly with rise in temperature.

¶ The modulus of elasticity, as well as other mechanical properties of gels, is determined by various aspects of their previous history: these properties differ for gels of the same concentration according as they have been obtained directly by cooling a solution or by concentrating a more dilute solution[372].

The strength properties of gels are most conveniently characterised by the limiting shearing strength[329,379], characterising the strength of the bonds forming the three-dimensional framework; rupture of these bonds precedes steady-state flow. The investigation of non-stationary régimes in concentrated solutions of polymers and gels of aluminium naphthenate has established several important laws governing these processes[379-381]. However, such a purely rheological approach is only beginning to be applied to polymer gels.

The creep of gels[382] under the influence of small shearing stresses was investigated by Rebinder and Ivanova-Chumakova, who proposed a simple method for determining the viscoelastic characteristics of gels[344,383,384].

In most gels part of the deformation is irreversible, with Newtonian flow (the viscosity of 10^6–10^9 P is independent of the applied stress). This means that gels are investigated under stresses exceeding the elastic limit, and that the flow involved in creep takes place with the structure unresolved. As the system cannot flow without the breakage of bonds forming the gel framework, however, a mechanism of chemical flow, i.e. with reorganisation of bonds under the influence of the load, must be envisaged for gels under these conditions[385,386]. Reorganisation and partial destruction of bonds in gels with rise in temperature and increase in stress also make it impossible to use reduced variable analysis in describing the creep of gels[387,388]: it is necessary to allow for reorganisation of the structure with variation in temperature, i.e. to displace the curves along not only the horizontal but also the vertical axis[389-391].

Investigations of the relaxation properties of gels by different workers have led to contradictory results. Deformation was found to be independent of frequency (between 1 and 1000 Hz) in dilute gels of gelatin (up to 20% concentration), but a frequency dependence appeared in concentrated gels[78]. The absence of long relaxation times in dilute gels was attributed to the presence of sparse local cross-links, which prevented displacement of the chains but did not ensure considerable intermolecular interaction. However, earlier[392-394] and later[395-399] investigations showed that stress relaxation occurs in extremely dilute gels (from 1% concentration) to a greater extent the higher the rate of the external constraint, and is described by the same equations as is stress relaxation in polymers and their concentrated solutions. Relaxation processes take place in gels not only by the reorganisation and interaction of chains but evidently mainly by a mechanism of destruction of old cross-links and formation of new ones under the influence of the applied stress[398]. The above discussion shows that the reorganisation of cross-links, i.e. of the gel structure, under the influence of an applied stress plays a decisive part in all mechanical properties of gels, which permits close connections to be established between such properties and the gel structure. Study of the general features of the reorganisation of the framework of gels and the mechanisms of such reorganisation is only beginning, and is extremely important for developing a theory of the deformation of all types of gels.

---o0o---

Scientific views have developed appreciably since publication of the previous review on polymer gels in 1961,[26] as a consequence of the considerable progress made in investigating proteins and other natural polymers, as well as in the whole field of the physical chemistry of polymers. A deeper understanding of the properties of

gels has been gained primarily from the development of the supermolecular physics of polymers in all their states, as well as ideas on the structural reorganisation of a polymer under the influence of mechanical stress. The combination of molecular and colloid-chemical approaches has been another very characteristic feature of recent polymer chemistry and physics. In many cases the latter leads to a reinterpretation of concepts that have already become traditional, and also removes many of the contradictions which have accumulated in the investigation of gels, permitting an understanding of the occurrence of gels of different types. An important part has been played also by a deepening of our knowledge of the structure of the solvent present in a gel, and of the changes which it undergoes on the introduction of various types of additives. The general advances made in polymer science enable us to predict a rapid future development of our knowledge of the structure, properties, and possible applications of polymer gels.

Structural Principles in the Chemistry of Heteropolycompounds

L.P.Kazanskii, E.A.Torchenkova, and V.I.Spitsyn

Different types of heteropolycompounds, which are formed in solutions and can be isolated from the latter in a crystalline state, have been analysed and classified on the basis of the results of latest X-ray diffraction studies. The physicochemical and research techniques which have led to the current views on the structures of heteropolycompounds (a large class of complexes) are briefly considered. The possibilities which arise on substitution of one or several metal atoms in the coordination sphere of the heteropolycompound are examined on the basis of structural considerations. The principal trends and problems in the chemistry of heteropolycompounds are discussed. The bibliography includes 191 references.

CONTENTS

I Introduction	525

III. Methods for the investigation of heteropolycompounds	530
IV. Principal trends in the chemistry of heteropolycompounds	534

I. INTRODUCTION

Various views concerning the structures and nature of heteropolycompounds which have been held until recently are described fairly completely in monographs and other publications [1-4]. The present review considers the current state of the chemistry of heteropolycompounds—a large class of complexes which are formed in solution from whence they can be isolated in the solid state. The physicochemical methods and also certain problems and the principal trends in the chemistry of compounds of this class will be briefly considered.

All the heteropolycompounds examined obey the well known Pauling rules [5], which explain the properties of stable oxide structures. In all cases the fundamental unit of isopolycompounds and heteropolycompounds is the MO_6 octahedron. The octahedra are joined to one another by their vertices, edges, or faces, forming the coordination sphere around the central atom. The outer octahedra of the coordination sphere are distorted, the displacement of the metal atom leading to the formation of shortened (multiple) bonds with the non-delocalised oxygen atoms. The M–O distances are about 1.7 Å for the terminal M=O bonds, 2.0 Å for the M–O–M bridge bonds, and 2.2–2.3 Å for the M–O–X bonds, where X is the central atom; the shortest M=O bond is always in the *trans*-position to the longest bond. We may note that in all the isopolycompounds and heteropolycompounds investigated the number of such non-delocalised atoms does not exceed two [6].

The large number of physicochemical studies on aqueous solutions of these compounds has not unfortunately yielded a corresponding amount of valuable information concerning the forms in which heteropolycompounds exist.

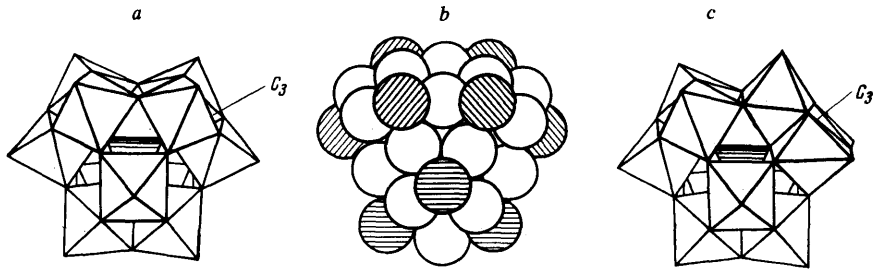

Figure 1. The structure of the anions:
a) α-$X^{x+}M_{12}O_{40}^{x-8}$; *b*) ditto in the form of close-packed spheres; *c*) β-$X^{x+}M_{12}O_{40}^{x-8}$.

Very often investigators make no assumption concerning the form with which they are dealing in solution. Although the compounds can be isolated in a crystalline form, the number of X-ray diffraction studies is fairly limited, since the large unit cell involves the determination of a large number of parameters. For this reason, work on the complete analysis of the structures of such compounds was not started unil the beginning of the 1960s.

II. STRUCTURAL TYPES OF HETEROPOLYCOMPOUNDS

Heteropolycompounds differ from the usual coordination compounds because they do not contain discrete ligands coordinated to the central atom, since the discrete MO_6^{n-} ion does not exist. Therefore one can regard the coordination sphere as one large ligand [7].

The structure of heteropolycomplexes is represented by an ideal octahedron whose vertices are occupied by oxygen atoms. Molybdenum or tungsten atoms are placed within the octahedron. The ionic radii of molybdenum(VI) and tungsten(VI) are 0.62 and 0.65 Å respectively and the ionic radius of O^{2-} is assumed to be 1.40 Å. [8]

The classification of heteropolycompounds generally adopted at present is based on the coordination number of the central atom and the number of metal atoms forming the coordination sphere [9]; attempts are being made to employ the IUPAC nomenclature for this purpose and this is the nomenclature which we shall adhere to in the present review. The overall formula, for example $H_3PMO_{12}O_{42}.nH_2O$, is usually employed to designate heteropolycompounds, because, as already stated, it is impossible to isolate an individual ligand. Sometimes formulae of the type $SiO_4W_{12}O_{36}^{4-}$ or $AlO_6Mo_6O_{18}^{9-}$ are used to indicate the coordination number of the central atom.

1. The Structure of the Anion $X^{x+}M_{12}O_{40}^{x-8}$ and Its Derivatives

The most familiar and widely investigated structure is the so-called Keggin structure [10]. The anion consists of four M_3O_{13} triplet† forming a tetrahedral cavity in which the central atom is placed (Fig. 1*a*). The general formula of the anion can be written in the form (for the 12 : 1 ratio)

$$X^{x+}M_{12}O_{40}^{x-8} ,$$

where X is the tetrahedrally coordinated central atom, which can be B, Si, P, As, Cr, Mn, Fe, Co, Cu, Zn, Ti, Zr, Ga, or H_2^{2+}. [12] The overall symmetry of the anion is T_d. X-Ray diffraction studies have been made on P^{5+}, As^{5+}, Si^{4+}, Ti^{4+}, and Zr^{4+} dodecamolybdates [8,13-20] and P^{5+}, B^{3+}, Ge^{4+}, Fe^{3+}, Zn^{2+}, Cu^{2+}, and Co^{3+} dodecatungstates [8,13,14,19-25], where the anion is claimed to have the T_d symmetry. We emphasise that the representation of the anion in the form of ideal octahedra does not take into account the fact that the oxygen atoms must be represented by large spheres. For this reason, the representation of the structure in this form (Fig. 1*a*) can create the incorrect impression that there are large open spaces within the anion. In Fig. 1*b* the anion is represented by close-packed spheres (the shaded circles represent terminal oxygen atoms). The structure is characterised by the presence of 12 M=O bonds and 24 M−O−M bridge bonds, twelve of which are almost linear and twelve are angular. The maximum M−O distance is that between the metal atom and the oxygen atom which links three metal atoms to the central atom (sp^3 hybridisation). The length of this bond depends on the size of the central atom. For central atoms of metallic type (for example Co^{III}, d^6), the tetrahedron is appreciably distorted (extended along the C_2 axis) in consequence of the Jahn−Teller effect, although the external coordination shell does not undergo appreciable changes [7]. Incidentally the Co^{3+} ion in $CoW_{12}O_{40}^{5-}$ is atypically in a tetrahedral environment.

Heteropolycompounds are formed immediately at an appreciable rate (faster on heating) in acid solutions on mixing molybdates or tungstates with the salt of the corresponding heteroelement. The acids can be isolated in a free state from highly acidified solutions by extraction with ether and also by ion exchange [1,4]. Certain metal heteropolycompounds are formed with much difficulty, since octahedral coordination is usually characteristic of the metals and the transition to tetrahedral coordination requires additional energy [26].

The large number of different hydrates of the same compound gives rise to difficulties in the preparation of truly homogeneous phases for chemical analysis and physicochemical studies. The exact amount of water is frequently fairly difficult to determine, because it can be zeolitic and is only gradually removed on dehydration [27]. The crystal structures of different hydrates of heteropolycompounds have been examined [2,28].

† The M_3O_{13} triplet, which is found in almost all the known structures of heteropolyanions, is made up of three MO_6 edge-sharing octahedra. It has been detected as a discrete unit in cluster type compounds $M_2^{II}Mo_3O_8$ in which a metal−metal bond is postulated [11]. In the heteropolyanion the M−M distance is about 3.3 Å, which rules out direct d−d interaction. However, it is quite possible in highly reduced forms of heteropolyanions.

In the crystalline state there is no direct linkage between the anions. Their packing is achieved via hydrogen bonds or via cations. Water can be completely removed by thermal dehydration (at about 300–400°C), whereupon the structure of the anion is fully retained, its stability increasing with increase of the ionic radius of the central ion [29]. All the heteropolyacids and some of their salts are very soluble in water and in oxygen-containing solvents, which can be explained [7] by the very low crystal lattice energy and by the solvation of the cations. Although the crystal lattice energies of heteropolycompounds are unknown, to a first approximation the lattice energy can be estimated as about 800 kcal mole^{-1} for $K_4SiW_{12}O_{40}$. [29]

There is no reason to doubt at present that the anion with Keggin's structure retains its high symmetry (T_d) in aqueous solutions. An X-ray diffraction study of the heteropolycompounds $H_4SiW_{12}O_{40}$ and $H_3PW_{12}O_{40}$ in aqueous solution [30,31] showed that the results agree with the existence of one form containing twelve tungsten atoms, forming a cubo-octahedron, i.e. the structure which was discovered by Keggin. Similar results were obtained for the dodecamolybdophosphate anion [30].

The determination of the diffusion coefficients of the heteropolyanions $XM_{12}O_{12}^{X-8}$ in solution showed that the anions are almost spherical, their radii are the same, and that the hydrodynamic radius of the anion is equal to the crystallographic radius of the non-solvated anion [7]. This indicates a very low degree of solvation. The addition of alkali to solutions of heteropolyacids leads to the decomposition of the anion and a slight increase of alkalinity leads to the formation of compounds with the ratio M : X = 11 : 1. [4] The formation of 11 : 1 complexes can be regarded as involving a simple elimination of one octahedron (i.e. an M=O group) from the structure of $X^{X+}M_{12}O_{40}^{X-8}$ and the charge of the anion always increases by four units. An X-ray diffraction study [28] of the salt $(NH_4)_7Na_2[GaW_{11}O_{39}(H_2O)].15H_2O$ showed that the Keggin structure persists and that gallium is in the centre of the tetrahedral cavity. The site of one octahedron is occupied by the water molecule. The formation of 11 : 1 compounds probably accounts for the hypothesis of an unjustifiably large number of dissociable protons in the Keggin structure, for example eight in molybdosilicic acid [1]. We shall not consider here the problem of the number of dissociable protons in heteropolyacids and no conclusions will be reached concerning the structure of the anion on the basis of determinations of the number of dissociable protons or the isolation of salts substituted to a high degree. In the light of structural concepts, any departure of the number of dissociable protons in an acid whose anions have the Keggin structure from the value $x - 8$, where x is the positive charge of the central atom, is caused either by the degradation of the anion or by the presence of non-salt-forming hydrogen atoms.

A greater increase in alkalinity leads to other forms with different M : X ratios. Salts containing the pentamolybdophosphate anion have been isolated [32]. The same anion was obtained in a study of multicomponent $PO_4 : MoO_4$ mixture [33], where the sodium salt was isolated and studied by X-ray diffraction [34]. The salt $Na_2H_2Mo_5.P_2O_{39}.10H_2O$ no longer belongs to heteropolycompounds, since in its anion there is no central atom, although its structure consists of five MoO_6 octahedra and two PO_4 tetrahedra. The addition of an excess of alkali (20–28 moles per mole of the anion) leads to the decomposition of the anion into simple MO_4^{2-} and XO_4^{X-8} anions. The stability of the molybdate anions varies in the series Si > (Zr,Ti) > Ge > P > As.

As early as 1941 Jahr [35] and later Chalmers and Sinclair [36] pointed out the possibility that different anions with a tetrahedral arrangement around the central atom can be formed by a simple rotation of one or several M_3O_{13} triplets by 60°, which reduces the T_d symmetry of the anion to C_{3v} or C_{2v}. Recently Yamamura and Sasaki [37] confirmed the possibility of geometrical isomerism for β-$Ba_2SiW_{12}O_{40}$ in the anion of which one W_3O_{13} triplet is rotated by 60° about the C_3 axis (Fig. 1*c*).

Heteropolycompounds with the ratio M : X = 9 : 1 or 18 : 2 have properties close to those of the 12 : 1 compounds. This series of complexes is known only with phosphorous and arsenic central atoms and they are obtained after prolonged boiling from solutions with a high excess PO_4^{3-} or AsO_4^{3-} concentration and a low acidity. An X-ray diffraction study [38] of compounds with the ratio W : P = 9 : 1 showed that the complex is made up of two fragments of the Keggin anion from the structure of which three WO_6 octahedra have been eliminated. The two 9 : 1 fragments share the resulting free vertices of the octahedra, leading to the 18 : 2 structure, which belongs to the point group D_{3h} (Fig. 2*a*). Two XO_4 tetrahedra remain separate. It is easy to imagine the formation of geometrical isomers of $X_2M_{18}O_{62}^{2X-16}$ by a simple rotation of one 9 : 1 fragment by 60°, which leads to the D_{3d} symmetry,

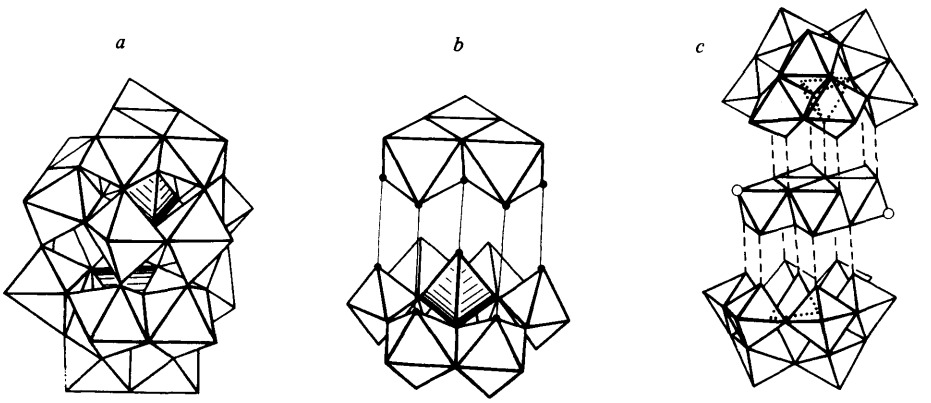

Figure 2. The structure of the anions:
a) $X_2^{X+}M_{18}O_{62}^{2X-16}$; *b*) $H_6PMo_9O_{34}^{3-}$; *c*) $P_2Co_4(H_2O)_2W_{18}O_{68}^{10-}$.

or by a rotation of W_3O_{13} triplets [39]. However, there is yet another possibility of the formation of isomers. The two fragments of the Keggin anion, each of which has lost one M_3O_{13} triplet, can share the free vertices but the two inner XO_4 tetrahedra then have a common oxygen atom (i.e. the X_2O_7 group is present) and the general formula of the anion should be written $X_2M_{18}O_{61}^{2X-14}$. There is no doubt that these geometrical isomers are possible for the molybdenum analogues.

The preparation of salts of octadecatungstodiberyllic acid, the anion of which belongs to the M : X = 18 : 2 series and has the formula $Be_2W_{18}O_{62}^{12-}$, has been described [40]. Goldman and Hargis [41], who studied the kinetics of the reduction of molybdophosphoric acid in the presence of bismuth(III), suggested the formation of a diheteropolycompound with the ratio P : Bi : Mo = 1 : 1 : 18. If this is confirmed by structural studies, the complex will be the first example of diheteropolycompounds with two different heteroelements.

It is interesting to note that a fragment of the Keggin structure was obtained recently for the first time. The anion $PMo_9O_{34}^{9-}$ (C_{3v} symmetry) was detected in the $xPO_4 : yMoO_4$ multicomponent system [33]. The sodium salt was crystallised and investigated by X-ray diffraction [42]. The structure of the anion is illustrated in Fig. 2*b*. It was also shown to persist in aqueous solutions [33].

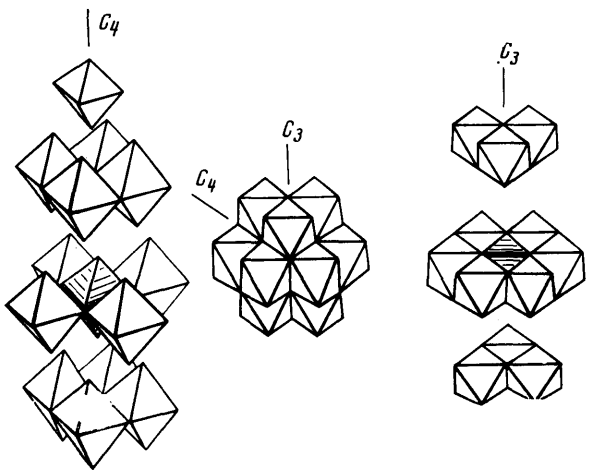

Figure 3. The structure of the $X^{X+}M_{12}O_{38}^{X-4}$ anion and its resolution along the C_4 and C_3 axes.

Another complex in which there is a fragment of the Keggin anion is $P_2Co_4(H_2O)_2W_{18}O_{68}^{10-}$ (point group C_{2h}), which has unique characteristics and whose structure has been determined [43] (Fig. 2*c*). The nickel and copper complexes belong to the same type and phosphorus can be replaced by arsenic(V). The characteristic features are the high molecular weight (4729) and the presence of the planar Co_4 group which is made up of CoO_6 octahedra in one plane; the two water molecules (represented by circles) cannot be replaced by other ligands, since they are thoroughly screened by the oxygen atoms of the neighbouring WO_6 groups. The Co_4 plane separates the two fragments of the Keggin anion from the structure of which a W_3O_{13} triplet has been eliminated. The anion may be of interest for the investigation of magnetic interactions since similar tetranuclear manganese(II), cobalt(II), nickel(II), and copper(II) complexes are unknown.

2. The Structure of the Anion $X^{X+}M_{12}O_{38}^{X-4}$ and Its Derivatives

The next group of heteropolycompounds comprises complexes whose structures are based on an octahedral arrangement around the central atom. Any of these structures can be represented as a fragment of the highly symmetrical (O_h symmetry) heteropolyanion (12 : 1) $X^{X+}M_{12}O_{38}^{X-4}$ (Fig. 3) formed by the addition of twelve MO_6 octahedra to all twelve edges of the central XO_6 octahedron [9]. This hypothetical ion would have a very low negative charge and for a high-valent central atom such as either Mo^{VI} or W^{VI} would have a zero or positive charge. However, in the case of vanadium the overall charge of the anion becomes $x - 16$; this structure has been proposed [44] for the anion $MnV_{13}O_{39}^{9-}$, the thirteenth VO_6 octahedron occupying the site between the four VO_6 octahedra on the C_4 axis (Fig. 3*a*). A preliminary X-ray diffraction study showed that the structure has tetragonal symmetry. The structure of the compound $MnV_{14}O_{40}^{8-}$ (D_{4h} symmetry), in which the fourteenth vanadium atom is in the *trans*-position relative to the thirteenth vanadium atom, was determined recently [45].

A known group of heteropolycompounds with an octahedral arrangement around the central atom comprises hexamolybdenum and hexatungsten compounds [12] (M : X = 6 : 1) with the general formula $X^{X+}M_6O_{24}^{X-12}$, where X^{X+} = Te^{6+}, I^{7+}, Al^{3+}, Cr^{3+}, Fe^{3+}, Co^{3+}, Rh^{3+}, Ga^{3+}, or Ni^{2+}. The structures of tellurium(IV) and chromium(III) hexamolybdates, which belong to this class, have been determined by Evans [46] and Perloff [47]. An incomplete X-ray diffraction study [25] confirmed this structure for the $NiW_6O_{24}^{10-}$ anion. The elimination of two M_3O_{13} triplets from the hypothetical ion on the C_3 axis (Fig. 3) leads to a structure consisting of seven octahedra, one of which is the central XO_6 octahedron. All the octahedra share their edges and are located in the same plane. The structure has the D_{3d} symmetry (Fig. 4*a*). The central XO_6 octahedron undergoes a slight trigonal distortion. The heteropolycompounds of triply-charged ions contain six protons firmly linked to the oxygen atoms of the central XO_6 octahedron. For this reason, the formula of the anion can be written as $X(OH)_6M_6O_{18}^{X-6}$.

The inclusion of six protons in the formula of the anions aroused a majory controversy, because these are non-salt-forming protons. Baker and coworkers [48,49] and then Rollins and Earley [50] had to resort to the hypothesis that dimeric forms of the anion exist in order to reduce the number of oxygen atoms and hence diminish the atomic charge of six units. However, in hexamolybdogallate(III) three water molecules are removed at a fairly high temperature, which indicates their unusual situation [51]. Subsequently Baker and coworkers [25] had to abandon these views, particularly since the ^1H NMR spectra of salts of 6 : 1 heteropolycompounds revealed the presence of six hydroxy-groups [52]. On the basis of this example, we should like to emphasise yet again the necessity for a critical approach to the interpretation of the results and also the desirability of employing several physicochemical methods to confirm one's conclusions.

Fig. 4*b* illustrates the structure of $CrMo_6O_{24}^{9-}$ with close-packed oxygen atoms (the terminal atoms are represented

by shaded circles), the metal ions being distributed within the octahedral cavities formed. The $Co_2Mo_{10}O_{38}^{8-}$ ion, whose structure has been determined by Evans and Showell[53], is related to these 6:1 complexes. The anion is formed from two $CoMo_6O_{24}^{9-}$ groups after two MoO_6 octahedra have been removed. By combining two 5:1 fragments and rotating one of them through 180° in relation to the other about the edges of the central octahedron (Fig. 5*a*), one obtains an anion with D_2 symmetry, which is consequently capable of having optical isomers. Quite recently these two isomers were isolated with the aid of the tristetramminecobalt ion[54]. In all probability this anion as well as the anions with the 2:18 ratio (Fig. 2*a*) are the only examples of true diheteropolycompounds.

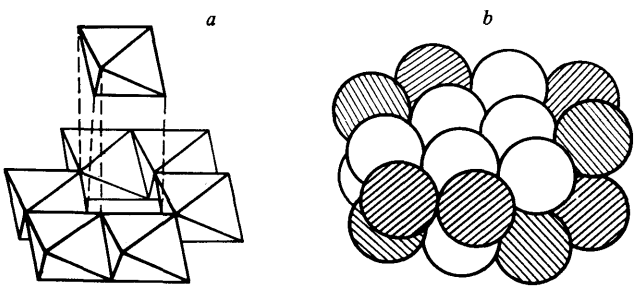

Figure 4. The structure of the anions: *a*) $X^{X+}M_6O_{24}^{X-12}$; *b*) ditto in the form of close-packed spheres.

Other examples of an octahedral arrangement about the central atom are provided by the manganese(IV) and nickel (IV) 9:1 complexes[55] whose structures are obtained by the removal of three octahedra from the six octahedra located in a plane perpendicular to the C_3 axis of the hypothetical anion $XM_{12}O_{38}$ (Fig. 3), which leads to the D_3 symmetry of the anion (Fig. 5*b*). Baker and Weakley[56] showed by cryoscopic measurements in Na_2SO_4 that the anion is monomeric. The acid prepared by ion exchange proved to be fairly unstable, but the number of its dissociable protons was found to be close to the calculated value.

3. The anions $X^{X+}W_{10}O_{36}H_2^{X-10}$

Peacock and Weakley[57] obtained a series of lanthanide heteropolytungstates with the ratio W:Ln = 10:1. It is interesting that all the lanthanides have the same coordination number, which is fairly unusual for this series of elements. The structure of decatungstocerate(IV) was determined[58] (Fig. 6). It contains the residues of two $W_6O_{19}^{2-}$ anions[59] and resembles the $W_{10}O_{32}^{4-}$ anion[60] (Fig. 7), the two halves of which make an angle of 45°. The heteropolycompounds XW_8O_{28}, where X = Ce^{IV}, Th^{IV}, or U^{IV}, have been isolated for elements with high coordination numbers[61,62], but subsequently their formulae were written as $XW_{10}O_{36}$,[63] and they probably belong to the same structural type.

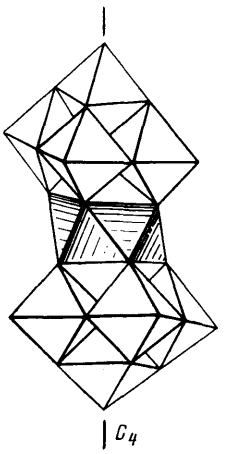

Figure 6. The structure of the $X^{X+}W_{10}O_{36}^{X-12}$ anion.

4. The Structure of the $X^{4+}Mo_{12}O_{42}^{8-}$ Anion

The anion of the 12:1 molybdoceric acid $CeMo_{12}O_{42}^{8-}$ belongs to the last known type of heteropolycomplexes. On the basis of the undoubtedly high number of dissociable protons and the high ionic radius of Ce^{4+}, Baker et al.[64] suggested that the structure of the anion should differ

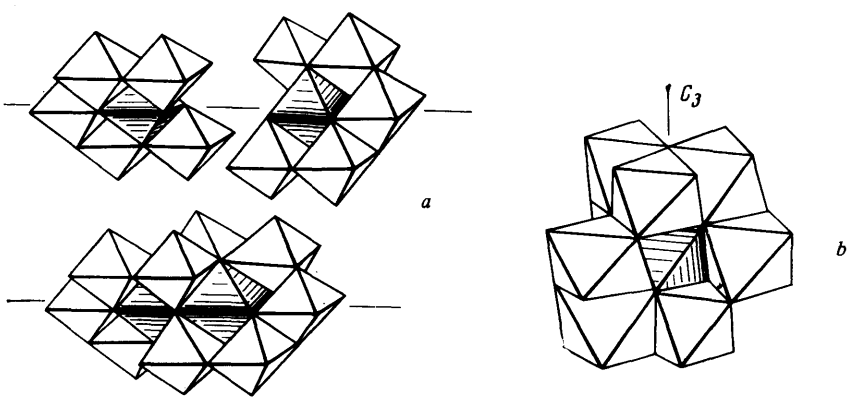

Figure 5. The structures of the anions: *a*) $Co_2Mo_{10}O_{38}^{8-}$; *b*) $X^{4+}Mo_9O_{32}^{6-}$.

significantly from the Keggin structure. A preliminary X-ray diffraction study[65] revealed two characteristic features of this anion: an eicosahedral arrangement about the central atom and face-sharing of pairs of MO_6 octahedra (Fig. 8) (T_i symmetry), observed for the first time in the structures of isopolycompounds and heteropolycompounds. The similarity of the properties[66] and X-ray diffraction data[67] show that the individual heteropolymolybdenum acids of quadrivalent cerium, thorium, uranium, and neptunium[68] have the same structures.

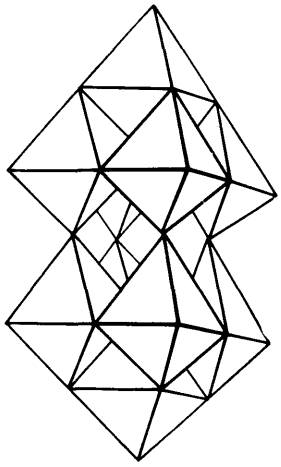

Figure 7. The structure of the $W_{10}O_{32}^{4-}$ anion.

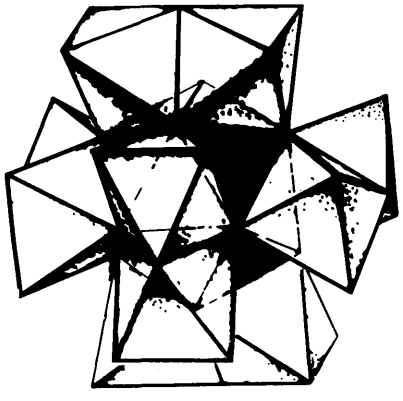

Figure 8. The structure of the $X^{4+}Mo_{12}O_{42}^{8-}$ anion.

5. Other Anions

Flynn and Stucky[69] made an X-ray diffraction study of the salt $Na_{12}[Mn(Nb_6O_{19})_2].5H_2O$. The anion consists of two isopolyanions $Nb_6O_{19}^{8-}$ coordinated to the Mn^{4+} ion (Fig. 9), so that the oxygen atoms form an octahedron about the Mn^{4+} ion and the overall symmetry of the anion becomes D_{3d}. However, in this case not all the Nb atoms are joined to the Mn^{4+} ion, and although its structure resembles $CeW_{10}O_{36}$ (Fig. 6), the complex is not intermediate between isopolycompounds and heteropolycompounds.

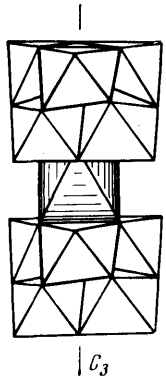

Figure 9. The structure of the $Mn^{4+}(Nb_6O_{19})_2^{12-}$ anion.

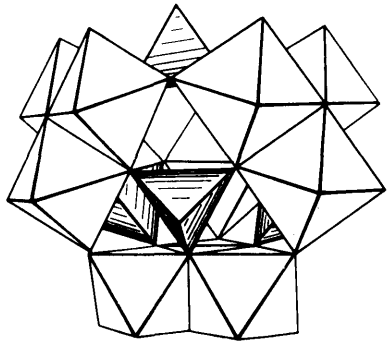

Figure 10. The structure of the $As_4Mo_{12}O_{50}^{8-}$ anion.

In 1973 Nishikawa and Sasaki[70] determined the crystal structure of $(NH_4)_4H_4As_4Mo_{12}O_{50}.4H_2O$ (Fig. 10). The anion has the T_d symmetry and resembles the Keggin structure turned inside out. The four Mo_3O_{13} triplets are joined via their vertices, forming the anion $Mo_{12}O_{46}^{20-}$ to which four AsO_4 tetrahedra are linked. At the centre of the anion there is a cavity (radius 1.43 Å) formed by eighteen oxygen atoms.

III. METHODS FOR THE INVESTIGATION OF HETEROPOLYCOMPOUNDS

There is at present no well founded theory which would account for the mechanism of the formation of heteropolycompounds, apart from a few hypotheses[71]. It is very difficult even to determine whether the process takes place in stages, the intermediate forms being fairly stable and long lived, or whether the intermediate compounds are unstable and the process can have a chain mechanism.

At any rate the intermediate compounds have not been isolated and characterised in the case of heteropolycompounds unless of course one formally includes among these the 6 : 1 compound (Fig. 4) as an intermediate before the formation of the 9 : 1 complex (Fig. 5*b*) with an octahedral arrangement about the central atom.

Moreover even for isopolycompounds it is not evident how the complex structure is produced by a simple addition of MoO_6 octahedra to the pre-existing framework. For example, it is regarded as fully proved that acidification of the MoO_4^{2-} ion [72] does not lead to the formation of intermediate species (the heptamolybdate anion [73] $Mo_7O_{24}^{6-}$ is formed at once and only then the octamolybdate anion [74] $Mo_8O_{26}^{4-}$ and the structure of the latter is not obtained by the simple addition of a single MoO_6 octahedron to the heptamolybdate framework but involves a rearrangement of the anion), but the causes of this are unknown.

In studies on the relaxation of isopolymolybdate solutions [75,76] it has been suggested that acidification of MoO_4^{2-} results in a rapid transition of molybdenum from tetrahedral configuration to an octahedral configuration with subsequent condensation of the octahedra.

In all probability the tendency of molybdenum, tungsten, and vanadium to form shortened M=O bonds, leading to a weakening of the M–O bonds in the *trans*-position, is responsible for the interaction of several octahedra. The formation of these double bonds leads to certain differences in the structures. A structure of the type XMo_6O_{24} has been suggested for the heptamolybdate (Fig. 4), but the structure of the isopolymolybdate is such (C_{2v} symmetry) that all the molybdenum atoms in it are equivalent, i.e. all the MoO_6 octahedra undergo identical distortions, whereas in the XMo_6O_{24} structure all the bonds in the XO_6 octahedron are equivalent and in MoO_6 they are different.

Furthermore, in many instances the molybdenum analogues of $XO_4W_{12}O_{36}^{x-8}$ do not exist, because the Mo–O bonds are weaker than the W–O bonds, and the $Mo_{12}O_{36}$ framework cannot maintain the X^{x+} ion in a tetrahedral arrangement. Although many examples of anions with the same structures have been observed in the chemistry of molybdenum and tungsten, in certain cases the heteropolyanions are different, for example the structure of cerium heteropolytungstate differs appreciably from that of the dodecamolybdocerate ion (Figs. 6 and 8).

The formation of heteropolycompounds is largely determined by the ability of the metal ions, comprising the coordination sphere, to polymerise and the structure of the complex depends on the nature of the central atom. However, cases are known where the conditions of the synthesis determine the coordination number of the central atom. For example, depending on the proportions of the initial reactants, the acidity of the solution, and time, it is possible to obtain complexes with the ratios M : GaIII = 6 : 1 (D_{3d} symmetry of the anion) and 12 : 1 (T_d symmetry) having octahedral and tetrahedral arrangements about the central atom [77].

The thermodynamics of the formation of polynuclear species having different shapes (the compact hexaniobate [78] $Nb_6O_{19}^{8-}$, the swollen heptamolybdate [73,79] $Mo_7O_{24}^{6-}$, or the loose bulky paratungstate [80] $W_{12}O_{42}^{12-}$) is virtually unknown. For this reason, studies [81–83] undertaken to determine the activity and osmotic coefficients of anions belonging to the 6 : 1 and 12 : 1 series merit attention.

There are many equilibrium states in the chemistry of solutions, which involves a time factor since equilibrium is very frequently established slowly, particularly in the case of molybdenum. It is sometimes impossible to compare the results of different studies, since the experiments were carried out under different conditions which are difficult to compare. Moreover it has been shown that the concentration and composition of the supporting electrolyte are very important and that the electrolyte can in turn influence the charge and dimensions of the anion. Therefore the results of studies in which the concentration of the supporting electrolyte did not exceed 3 M proved to be promising.

The existence of heteropolycompounds with the Keggin structure in different forms in equilibrium with one another, one of which (the metastable form) is converted into the other (the stable form), is well known. This equilibrium is influenced by the state of the initial tungsten and molybdenum ions, as shown clearly for dodecatungstosilicic and dodecatungstogermanic acids [84]. Depending on the sequence in which the solutions of the initial reactants are mixed, different forms are obtained:

$$\mathrm{Si(Ge)} + \mathrm{WO_4^{2-}} \xrightarrow{(H^+)} \alpha\text{-isomer (11 : 1 or 12 : 1)},$$

$$\mathrm{WO_4^{2-}} + \mathrm{H^+} \rightarrow \mathrm{HW_6O_{21}^{5-}} \xrightarrow{\mathrm{Si(Ge)}} \beta\text{-isomer (11 : 1 or 12 : 1)},$$

and in the case of silicon the conversion of the β-form into the α-form is very slow even on heating.

Much importance was attributed earlier to results obtained by certain methods which are not theoretically well founded. For example, diffusion coefficients were measured for many years [85] and then linked to the ionic weight of the polymeric form on the basis of the familiar Riecke relation. It was not until 1960 that Baker and Pope [86] published the results of a fairly simple but clear-cut experiment in which it was shown that the diffusion coefficients of the isomorphous anions $SiW_{12}O_{40}^{4-}$ (ionic weight 2875) and $SiMo_{12}O_{40}^{4-}$ (ionic weight 1820) are equal. This of course led to the conclusion (which was apparent previously) that the diffusion coefficients depend only on the ionic radius but not on the ionic weight.

Arbitrary interpretation of the results of thermogravimetric analysis and of other methods led to the assertion that heteropolyacids with the Keggin structure have a large number of dissociable protons [1] and doubts were actually cast on the results of X-ray diffraction analysis. In this connection it is useful to consider briefly the methods used to investigate heteropolycompounds. Evidently none of the individual methods can provide an unambiguous answer as to the nature of the existing forms of heteropolycompounds.

The first method used to determine the stoichiometric coefficients of the complex formation reaction products was quantitative analysis. More than 100 year ago, Marignac [87] carried out a major crystallographic and quantitative analytical study of complex compounds which were subsequently called heteropolycompounds. Here we must emphasise the importance of chemical analysis in relation to compounds where one of the metal atoms forming the coordination sphere is substituted by another metal atom, since in this case incorrect conclusions have been reached concerning the structures of the resulting compounds. For example, Baker and McCutcheon [88] reported the discovery of a new class of compounds, which they called diheteropolycomplexes, with the ratios M : X : Y = 12 : 1 : 1, where Y is a transition metal. Subsequently other studies were published [89], where the preparation of similar compounds was claimed. However, later these views were revised [28,90] and evidence was obtained showing that the second heteroatom substitutes one tungsten (or molybdenum) atom in the coordination sphere, the Keggin structure remaining unchanged. The discrepancy between the analytical results for the 11 : 1 and 12 : 1 compounds is

very small (11 : 1 = 12 : 1.09) and therefore the results of chemical analysis alone may prove to be unreliable.

In the potentiometric determination of the number of dissociable protons in heteropolyacids it is always necessary to take into account the possibility of the decomposition of the anion on increase of pH. Souchay [3] was able to show that a slight increase of the alkalinity of a solution of heteropolyacids leads to the formation of the anions of unsaturated heteropolyacids:

$$PMo_{12}O_{40}^{3-} + OH^- \rightarrow PMo_{11}O_{39}^{7-} + MoO_4^{2-} \text{ (or } Mo_6O_{24}^{6-}).$$

Therefore, in order to avoid the decomposition of the anion, Keller et al. [91] determined spectrophotometrically the degree of ionisation of heteropolyacids. These results show that the number of dissociable protons in heteropolyacids with the Keggin structure is small.

The spectrophotometric method (the molar ratio and isomolar series procedures) and also the method based on the variation of the pH of solutions as a function of the amount of heteroatoms introduced are widely used to determine the stoichiometric coefficients in complex formation reactions [92]. However, the interpretation of the results is fairly difficult and frequently indefinite so that it is difficult to determine reliably the equivalence point for high ratios such as 12 : 1. For this reason, the conclusions based on these data must be approached with much caution.

The method of salt cryoscopy, based on the decrease of the $Na_2SO_4.10H_2O \rightarrow Na_2SO_4 + 10H_2O$ transition temperature in the presence of various ions, is frequently used to determine the degree of condensation [56,77,93-95]. It was shown with the aid of this method that the hexamolybdochromate, hexamolybdoaluminate, and hexamolybdogallate ions as well as the 11 : 1 : 1 complexes (Co–Ga, Mn–Ga, Cr–Ga) are monomeric and that decomposition products are absent. A recent thermodynamic examination of this method [96] showed that it has a reasonable theoretical basis. The method involves a number of difficulties: (1) the necessity to know the exact H^+ and HSO_4^- concentrations, since they contribute to Δt and (2) the impossibility of extrapolation to infinite dilution when Δt varies with concentration. The application of certain methods requires extrapolation to infinite dilution in order to create nearly ideal conditions. Analysis of light scattering and ultracentrifugation data showed [97-99] that large anions bind the counterions from the salt medium to a considerable extent. In solutions where concentration influences the position of equilibrium, such extrapolation is impossible. Light scattering and equilibrium ultracentrifugation as well as sedimentation (methods which supplement one another) make it possible to establish the effective ionic weight of the anion in solution, usually the dominant ion, provided that the solutions are monodisperse and provided that the degree of polymerisation of the solutes is not influenced by dilution. Light scattering data [97] showed that, in solutions with the W : P = 12 : 1 and 9 : 1 ratios, there are monomeric and dimeric species respectively, i.e. W : P = 18 : 2. The results of sedimentation [100] and ultracentrifugation [101] studies on dodecamolybdophosphoric acid showed that it is fairly unstable and forms an anion with the ratio Mo : P = 11 : 1.

Ion exchange is used not only for preparative purposes (for the synthesis of heteropolyacids in a free state) but also permits an indirect determination of the ionic charge and also the stability of heteropolyanions. However, the determination of the charge of the anion yields no information about its structure, since the anion, which can formally have a large charge, frequently binds counterions from the supporting electrolyte and its overall effective charge does not exceed −6.

The origin of the absorption bands in the ultraviolet spectra of heteropolycompounds has been hardly considered [102-108]. There is no doubt that the absorption bands with extinction coefficients of the order of 10^4-10^5 are due to electron transfer from orbitals localised mainly at oxygen atoms to orbitals localised at the metal atoms forming the coordination sphere. The nature of the ultraviolet spectrum changes appreciably as a function of the structure of the anion and its symmetry [107]. A decrease of symmetry leads to the splitting of the absorption bands [104]. The similarity of the ultraviolet spectra constitutes satisfactory confirmation that the structures of the anions are the same [105]. A purely qualitative employment of ultraviolet spectra enabled Strickland [106] to detect isomeric forms of the dodecamolybdosilicate anion and to investigate the kinetics of their interconversion.

The absorption spectra of aqueous solutions in the region of $d-d$ transitions have been used to investigate the coordination and also to determine the degree of oxidation of both the central atom and of the metal ions entering into the coordination sphere [109,110]. $Na_3CrO_6Mo_6O_{18}.H_6$ (D_{3d}), the luminescence spectra of which are observed even at room temperature, has unusual spectroscopic properties [111]. This phenomenon is unknown for other chromium(III) complexes. On the basis of the calculated and experimental absorption bands in the visible spectra of solutions of dodecamolybdouranic and dodecamolybdoneptunic acids, it was shown that uranium [67] and neptunium [68] in these compounds are in the +4 oxidation state. It is noteworthy that in all instances the absorption bands due to the metal ion in the coordination sphere are appreciably more intense than in the spectra of the usual complexes. Comparison of the absorption spectra of solutions of compounds of the type $MXW_{11}O_{40}H_2^{n-}$ with the reflection spectra of crystalline specimens shows that the environment of the metal ions in the structure of the anion remains unaltered [109]. The study of the absorption spectra of lanthanide heteropolytungstates [59] permitted the determination of the coordination of the Ln ion.

The hyperchromic effect observed in the reduction of one or several metal atoms forming the coordination sphere, i.e. the formation of heteropolyblues, is due to the valence change $MV \rightarrow MVI$, [112] since the usual $d-d$ transitions have much lower extinction coefficients at $\nu \simeq 10-14\,000\ cm^{-1}$. This effect has been used in analytical practice for the quantitative determination of certain elements.

Redox titration and also magnetic measurements have been used for the direct determination of the degree of oxidation and the site of the metal ion in the heteropolycompound.

An anomalous magnetic behaviour of certain heteropolycomplexes was pointed out [28] in 1966. When two cobalt atoms (bivalent and tervalent) were present in the heteropolyanion, an intense intraionic paramagnetic interaction was observed and the magnetic susceptibility of the compound changed by only 13% between −143° and +23°C. This was also noted [89] for the complex $FeNiW_{11}O_{40}H_3^{6-}$. Quite recently these complexes as well as certain others [113] were used to investigate the spin–spin interaction between the paramagnetic ions forming part of the structure of the anion. It was emphasised that the heteropolyanions constitute a very interesting and convenient model in which the second metal atom always occupies a site with the same arrangement of oxygen atoms around it. It has been shown for the 12 : 1 copper heteropolycompound,

which is a convenient model for the investigation of electron transfer processes in copper-containing enzymes, that copper retains its tetrahedral environment in the transition $Cu^{2+} \rightarrow Cu^{+}$.[114]

The polarographic method has been used widely to investigate heteropolycompounds[84,115-124]. The conditions governing the formation of different $XM_{12}O_{40}^{X-8}$ isomers have been determined polarographically[84,117]. The electronic structures of the reduced forms (the so called heteropolyblues) are analogous to the structures of the tungsten bronzes, but there is one difference: the reduced forms are discrete (i.e. they do not give rise to polymeric species) and are soluble in water. The magnetic[121] and spectroscopic properties of reduced heteropolycompounds[108] have been investigated and it has been shown that the first electrons added are located at specific molybdenum or tungsten atoms and that as a result of further reduction the electrons introduced are located in the common delocalised orbital of the coordination sphere. Examination of the bonds in the anion with the Keggin structure (the formation of π-bonds in the coordination sphere so that the structure becomes a π-conducting system)[118] has shown that the reduction of the heteropolyanion may be compared with the reduction of polycyclic aromatic hydrocarbons with formation of the corresponding anions.

An increase of the number of electrons introduced leads to a shift of the region of stability of the heteropolyanion towards higher pH values[117]. It has been shown by X-ray diffraction that the reduced forms retain the Keggin structure[125]. In the general case 12-heteropolyphosphate anions are reduced more readily than the silicon analogues, since the charge of the latter is higher. Heteropolymolybdates have a higher oxidising capacity than heteropolytungstates.

The energies of the first charge-transfer band, observed in the ultraviolet spectra of heteropolyacids, have been correlated[103] with the reduction half-wave potential and it has been shown that the lower the first vacant antibonding orbital the higher the oxidising capacity of the heteropolyanion. The reduction of the heteropolyanions XMo_6O_{24} (D_{3d}) leads to their decomposition[124]. This example and also data for the reduction of the anions[120] $XMo_{12}O_{42}^{8-}$ (T_h) indicate differences between the structures of the anions and the environments of the molybdenum atoms. There is no unanimous view concerning the mechanism of the reduction process. Moreover it is quite probable that the employment of chemical reducing agents frequently used in analytical practice ($SnCl_2$, ascorbic acid, etc.) can lead to irreversible processes and the formation of unknown compounds with the initial heteropolycompounds. These phenomena and also the fact that, with increase of the number of electrons introduced, the maximum of the valence-change bands shifts towards shorter wavelengths, will undoubtedly affect the interpretation of the results. For this reason, studies[126] in which the reduction of heteropolyacids by an $SnCl_2$ solution was investigated quantitatively are not fortuitous.

^{1}H NMR has been widely used to determine the proton groups within the structure of heteropolycompounds[52,127-130]. It has been shown that acid protons in heteropolyacids with the Keggin structure are present in the form of H_3O^+.[127-129] Moreover, it has been established that such acids have a small number of dissociable protons. In contrast to these acids, some of the protons in heteropolymolybdoceric(IV), heteropolymolybdothoric, heteropolymolybdouranic, and heteropolymolybdoneptunic acids are present as H_3O^+ and some are present as OH^- groups, the number of dissociable protons in the acids being eight[68,129]. It has been shown for metatungstic acid, which gives rise to the anion $H_2W_{12}O_{40}^{8-}$ (T_d symmetry), that there are two protons in the tetrahedral cavity. In aqueous solutions the signal due to these protons is displaced towards lower fields by 1.0–1.4 p.p.m., relative to the water signal. This indicates a pronounced insulation of these two protons by the polytungstate shell, which can be clearly seen from Fig. 1*b*.[131]

NMR spectroscopy involving heavy nuclei (^{17}O, ^{31}P, and many others which have non-zero spins) yields valuable information about the molecular and electronic structure of the heteropolyanion[132]. The effect of the metal entering into the coordination sphere on the oxygen atoms has been traced, for example, on the basis of the chemical shifts in ^{17}O NMR of both simple and mixed heteropolyacids. The ^{27}Al NMR spectra of aluminium heteropolytungstate clearly indicate a tetrahedral arrangement of atoms around aluminium.

It is interesting that high-resolution ^{1}H NMR spectra make it possible to follow the *trans*-influence of the central atom X via the inner oxygen atom on the ligand Y in the heteropolyanions $XW_{11}CoO_{39}Y$, where Y is pyrazine[133]. ^{1}H NMR spectra in organic media[134] have shown that $XMo_{12}O_{40}^{X-8}$ exhibits a lower tendency towards the formation of hydrogen bonds than does ClO_4^-. This indicates yet again the low negative charge density (−4 over a sphere with $r = 5.6$ Å) on the surface of the anion.

The present authors' Mössbauer spectroscopic data indicate an effect by the molybdate and tungstate spheres on the iron(III) nucleus in the $SiM_{11}O_{39}Fe(H_2O)^{5-}$ ions, which have the same structures. This is correlated with ESR data for the same complexes[135]. ESR has been used to investigate the reduced $PW_{10}V_2^{IV}O_{40}^{5-}$ anions. It was shown that two vanadium(V) atoms are reduced to vanadium(IV) and that they occupy two non-equivalent positions in the structure of the anion, because the local crystal fields of the anion are directed at different angles with respect to the magnetic field[136].

Vibrational spectroscopy has not been widely used to investigate the molecular structures of heteropolyanions in view of their fairly considerable complexity, although a number of studies dealing with this problem have been published[137-143]. Vibrational spectroscopy can be very useful for the identification of the structures of new hitherto unknown compounds, since each type of structure of heteropolycompounds gives rise to fairly characteristic spectra in consequence of the differences in the structure of the anion. The employment of Raman spectroscopy, particularly with a laser source, permits the identification of the species present in solution, as has been done for vanadium, molybdenum, and tungsten isopolycompounds[142] and also heteropolyacids with T_h (Kazanskii et al.[141]) and T_d (Kazanskii[143]) symmetries. It was established that the structure of the heteropolyacids found in crystalline specimens persists also in aqueous solutions. Raman and infrared spectroscopy of the ether adducts of certain heteropolyacids[140] confirmed the retention of the structure of the anions in ether without any decomposition. The effect of the charge of the central atom X^{X+} is clearly shown in the Raman spectra of the heteropolyanions $XM_{12}O_{40}^{X-8}$ (i.e. there are *trans*- and *cis*-effects on the positions of the vibrational bands A_1 of the terminal M=O and bridging M–O–M groups). With decrease of x, the stability of the terminal M=O bonds falls[143].

Together with ^{1}H NMR, infrared spectroscopy is frequently used to investigate the nature of the water in heteropolycompounds[144,145].

Among other methods, which are purely qualitative, mention may be made of dialysis, which is used to determine the dimensions of the anions, and of chromatography, which has been employed to separate certain heteropolycompounds [146].

Interesting prospects arise in connection with the application of X-ray electronic spectroscopy to the study of the electronic structures of heteropolyanions. X-Ray electronic spectra of the inner $3d_{3/2}$ and $3d_{5/2}$ electrons of heteropolymolybdates and normal molybdates have been obtained [147]. The changes in charge distribution in the valence shell, occurring when the valent state of the atom is altered, influence all the inner levels and the results indicate a decrease of the positive charge on the molybdenum atoms in heteropolycomplexes compared with MoO_4^{2-}. According to X-ray electronic spectra [148], the binding energy of phosphorus $2p$ electrons is higher in $PW_{12}O_{40}^{3-}$ than in $PMo_{12}O_{40}$. This indicates a decrease of the positive charge in $PMo_{12}O_{40}$, which is correlated with results obtained from ^{31}P NMR chemical shifts and the vibrational spectra of these heteropolyanions [143,148].

Presumably much information about the electronic structures and charge distribution within and on the surface of heteropolyanions will be obtained from the photoelectronic spectra of the outer valence energy levels.

IV. PRINCIPAL TRENDS IN THE CHEMISTRY OF HETEROPOLYCOMPOUNDS

Apart from continued interest in the theoretical problems of the molecular electronic structure, the present state of the chemistry of heteropolycompounds is also characterised by the development of the synthesis of mixed and diheteropolycomplexes. Since the coordination sphere is made up of metal and oxygen atoms, heteropolycomplexes can serve as model compounds for the investigation of the chemistry of metal oxides. A wide range of physical methods can be used to investigate heteropolycompounds in a crystalline form, in aqueous and non-aqueous solutions, and in the recently discovered [133] gaseous state.

Many mixed compounds (sometimes one or several molybdenum atoms in molybdate coordination sphere are substituted by tungsten or vanadium) and diheteropolycomplexes (as defined by Baker), in which one atom of the coordination sphere is replaced by some other metal atom (usually a transition metal atom), have been obtained. They must be distinguished from true diheteropolycomplexes in which two atoms of the complex-forming agent are surrounded by the same atoms, which form the coordination sphere (cf. Figs. 2*a* and 5*a*).

We assigned to mixed compounds the complexes in the coordination spheres of which molybdenum, vanadium, or tungsten may be present jointly in the highest oxidation states in proportions of 11 : 1. The formation of these compounds is due to the general tendency of the ions of these elements to link up into polymeric structures. The resulting compounds are mainly complexes having the Keggin structure. Other known types are the mixed molybdotungstates $(NH_4)_4NiMo_{6-n}W_nH_6$, where $n = 0-6$ (Kokorin and Dimant [149]); the acids have been obtained from these salts in a free state.

We may quote several examples where one or several tungsten (or molybdenum) atoms in the coordination sphere are replaced by a vanadium atom. Much work has been done in this field by Kokorin and coworkers [150-168], who investigated the conditions governing the formation of heteropolycomplexes with different degrees of substitution of M by vanadium atoms. The corresponding acids were isolated, for example $H_4PMo_{11}VO_{40}$, $H_5PMo_{10}V_2O_{40}$, and $H_6PMo_9V_3O_{40}$, which decompose at different rates with increase of pH. The synthesis of vanadomolybdenum acids with substitution of up to ten molybdenum atoms, for example of the anion $PV_{10}Mo_2O_{40}^{13-}$, was reported recently [161].

Studies on the electron diffraction patterns of decamolybdotrivanadogermanic acid and of the powder diffraction patterns of hexamolybdohexatungstophosphoric acid [163] confirmed the retention of the Keggin structure in the substituted complexes.

Apart from studies on theoretical problems of mixed heteropolyacids (bond strengths, electronic and molecular structures, oxidation–reduction properties etc.) much effort has been devoted to the determination of the number of dissociable protons in these acids in both aqueous and non-aqueous media. A parallel is frequently drawn with the initial acids ($H_{x-8}XO_4$), although these analogies have no theoretical basis. It is clear from structural considerations that, following the substitution of one molybdenum atom by a vanadium(V) atom, the charge of the anion should increase by -1, since the structure of the anion persists, i.e. the number of oxygen atoms in the anion remains 40. The fact that the number of dissociable protons in the acids is sometimes inconsistent with this suggests instability of the anion, the occurrence of additional equilibria, and changes in the degree of dissociation of protons as the dielectric constant of the solvent is varied.

On the other hand, when a highly charged ion (for example, Zr^{4+}, Ti^{4+}, Th^{4+}, or Nb^{5+}) is introduced into a solution of heteropolyacids, the so called "ternary" complexes are formed. It has been claimed on the basis of spectrophotometric data only [169,170] that phosphorus, niobium, and oxygen form a "central molecule" (a niobium phosphate the composition of which varies with the medium and the pH) surrounded by a molybdate coordination sphere. Later the formation of a zirconium molybdophosphate complex of the same type was postulated [171]. However, subsequently it was shown [172] on the basis of the infrared spectra of solid complexes containing zirconium, titanium, and thorium that the ions of these elements substitute molybdenum in the coordination sphere with formation of mixed heteropolycomplexes. Heteropolycomplexes in which molybdenum is substituted by niobium, for example $PMo_{10}Nb_2O_{40}^{5-}$, have also been obtained and characterised [29]. Dodecamolybdovanadoselenic acid $H_6SeMo_{10}V_2O_{40}.xH_2O$ was obtained by extraction with ether and partly characterised [173].

We shall not consider the numerous studies (see the references in Spitsyn and Torchenkova's paper [174]) in which the preparation of two heteropolycompounds in solution is reported without proof of their individuality. Of the latest studies, we shall mention the isolation of salts of heteropolycompounds, in which rhenium(VI), for example, substitutes a molybdenum atom in 12 : 1 and 18 : 2 molybdophosphate anions. The free acids have been obtained from these salts by ion exchange [175]. We may note that the unsaturated heteropolyacid $H_6[CrW_{11}O_{39}H_3]$ was recently obtained in solution, although unsaturated heteropolyacids with the Keggin structure [176] are not usually formed in a free state. However, one may postulate the formation of a diheteropolycomplex the central cavity of which contains two protons.

Heteropolytungstate complexes with phosphorus(III) and arsenic(III) have been obtained [177]. The X-ray diffraction

study being carried out should reveal certain structural features of these compounds.

It was shown[28] in 1966 that the coordination sphere of the anion with the Keggin structure (Fig. 1) or the Dawson structure (Fig. 2*a*) can incorporate one transition metal atom (usually belonging to the 3*d* group) with simultaneous displacement of one molybdenum or tungsten atom and the formation of a new complex having the general formula

$$[H_hM^{m+}O_5X^{x+}O_4(Mo\ \text{or}\ W)_{11}O_{30}]^{m+x+h-14}.$$

On the other hand, if the sixth coordination site of the transition element is occupied by another ligand, then

$$[Y^{y-}M^{m+}O_5X^{x+}O_4(Mo\ \text{or}\ W)_{11}O_{30}]^{m+x-y-13}$$

or

$$\{Y^{y-}M^{m+}O_5[(P^{5+}\ \text{or}\ As^{5+})O_4]_2(Mo\ \text{or}\ W)_{17}O_{58}\}^{m-y-10}$$

where Y is a monodentate ligand which occupies the site of a non-delocalised oxygen atom; this can be ammonia, pyridine, pyrazine, a halide ion, etc. For a bidentate ligand, there is a possibility of the binding of two anions via this ligand and of the formation of a compound heteropolycomplex in the form of a dumbell whose molecular weight exceeds 6000. The existence of such complexes, which may incorporate a wide range of ligands and different metal atoms, greatly extends the range of complexes under consideration. The inclusion of the metal ion M^{m+} in the coordination sphere via five oxygen atoms leads to a possible overlapping of different atomic orbitals, which is reflected in unusual values of the Racah parameters and unusual magnetic properties and electrical conductivities of the anionic framework. From the standpoint of the investigation of the spectroscopic properties of the injected heteroatom (Baker's definition), these heteropolycomplexes constitute a very convenient model, since the metal ion always has the same environment and only a change in the type of ligand and also the influence of the coordination sphere can affect the spectra. The existence of this new group of compounds has been demonstrated by the following methods: (1) by the analysis of the recrystallised pure products in which the ratios Y : M : X : Mo(W) were 1 : 1 : 1 : 11 (this must be confirmed by determining the molecular weight from the results of crystal-chemical studies); (2) by ion-exchange experiments, which showed that the resin in the K^+-form does not contain M^{m+}; (3) by determining the degree of oxidation of M^{m+} by oxidation-reduction titration; (4) by magnetic measurements; (5) by cryoscopy in $Na_2SO_4.10H_2O$; (6) by studying the absorption spectra of both solutions and solid heteropolycomplexes in the region of $d-d$ transitions; (7) by polarography; (8) on the basis of the isomorphism of the crystals.

The central atom X^{x+} can be P^{5+}, Sr^{4+}, Ge^{4+}, H_2^{2+}, Co^{2+}, B^{3+}, Fe^{3+}, and Zn^{2+} and the metal M entering into the coordination sphere[178-187] can be Co^{2+}, Co^{3+}, Ga^{3+}, Fe^{3+}, Ni^{2+}, Zn^{2+}, Mn^{2+}, Mn^{3+}, Cr^{3+}, and Al^{3+}; the molybdenum analogues are less stable. Complexes with doubly charged metal ions are stable at pH ~ 4, but the corresponding acids have not been obtained, since, on being passed through a cation exchanger in the H^+-form, they split off M^{2+} and only the initial 12 : 1 heteropolyacids were produced. For triply and more highly charged ions, the new heteropolycompounds are fairly stable in acid media, M^{3+} ions are not split off in the presence of the cation exchanger, and for this reason the acids have been obtained in a free state. Derivatives of the $X_2MW_{17}O_{61}^{n-}$ anion, in which X = P^{5+} or As^{5+} and one tungsten atom is substituted by a metal ion (Mn^{2+}, Co^{3+}, Ni^{2+}, or Zn^{2+}), have also been investigated; the properties of these compounds are analogous to those of the complexes $MXW_{11}O_{40}^{n-}$.

Apart from the above data for the formation of the new class of heteropolycompounds which have the Keggin structure and the reactions in which they are synthesised (these can be classified as complex formation reactions), we shall consider cases where the second heteroatom cannot enter the inner sphere and remains on the surface of the anion. When conditions for the formation of anions of the type $XW_{11}O_{39}^{n-}$ or $XW_{17}O_{61}^{n-}$ are created (pH ~ 4–6) and the solution contains a cation with a large radius, for example a lanthanide ion (Ln radius = 1.0 Å), a complex with the ratio An : Ln = 2 : 1 is formed. The $XW_{11}O_{39}^{n-}$ anion provides four electron-donating sites, which are produced following the elimination of one metal atom from the coordination sphere; the lanthanide ion can retain two anions. The coordination number of the lanthanide is 8. On the basis of structural considerations, it is difficult to expect other possibilities in the formation of the complex apart from the manganese(IV) complex (Fig. 9), in which the Nb_6O_{19} ligands provide bridging oxygen atoms as electron-donating atoms. It is quite likely that the formation of compounds of this type is not typical for heteropolyanions having the Keggin structure and a low charge. All other oxygen atoms in the structure of the 12 : 1 anion (T_d) are sterically unsuitable for the formation of compound heteropolycomplexes.

The formation of complexes by the dodecamolybdocerate ion with the cations of lanthanide elements, thorium, niobium, tantalum, and other metals has also been established[67,188-191]. For example, the interaction of erbium chloride with molybouranic acid[67] led to the formation of a complex with the ratio Er : An = 2 : 1. However, compounds with the ratio Er : An = 4 : 3 were isolated in a solid state. It was shown that MO_6 is not split off in this case. The structural features of the $UMo_{12}O_{42}^{8-}$ anion are such that on the surface there are three terminal oxygen atoms of the three combined octahedra, which can make up the coordination polyhedron around the Er^{3+} ion. The erbium ion tends to "saturate" its coordinating capacity by forming complicated structures. This is also observed for $XW_{11}O_{39}^{n-}$ (An). The An : Ln = 1 : 1 complex has not been isolated, although its stability constant is much higher than that of the complex $LnAn_2$. In this case, as in many others, the problem must be solved by X-ray diffraction. With the introduction of modern diffractometer and high-speed computers, one may hope that these problems will be successfully solved.

In a brief review we naturally could not cover many literature sources, since our aim was to write a critical review and not a simple compilation of research results. Here we have presented general relations based on the latest X-ray diffraction studies, on which the understanding of many problems in the chemistry of heteropolycompounds depends.

In addition we endeavoured to show that, although heteropolycompounds were discovered more than a hundred years ago, their chemistry constitutes a fruitful and interesting field for both physicochemical research and for the investigation of new synthetic possibilities.

Silicon Tetrafluoride Adducts

A.A.Ennan and B.M.Kats

The review deals with the compositions, properties, structures, and thermodynamics of silicon tetrafluoride adducts with organic molecules containing electron-donating nitrogen, oxygen, phosphorus, or sulphur atoms. Particular attention has been paid to reactions involving the conversion of the adducts of nitrogen-containing bases into fluorine-containing compounds with a covalent silicon-nitrogen bond. The comparative estimates of the electron-accepting properties of silicon tetrafluoride and other silicon tetrahalides obtained by different workers are discussed.
The bibliography includes 126 references.

I. INTRODUCTION

In the manufacture of simple superphosphate a considerable amount of fluorine-containing compounds, mainly silicon tetrafluoride, which is the principal potential source of industrial fluorine[1], are released into the gas phase. Evidently this is why there has been no weakening of interest in various aspects of the chemistry of silicon tetrafluoride, which was discovered almost 200 years ago.

Among the numerous aspects of silicon tetrafluoride chemistry, particular attention has been devoted to the study of its complex-forming capacity: silicon tetrafluoride, which is very inert with respect to exchange reactions, enters readily into addition reactions with organic electron-donating molecules (R), forming adducts with the composition $SiF_4 nR$ (n = 1 or 2). Very many original studies have been made on silicon tetrafluoride adducts but in monographs on the chemistry of silicon and fluorine these compounds are either not considered at all or ar discussed very briefly. Even in reviews[2,3] on the chemistry of silicon complexes the problem is given very scanty attention.

This review constitutes a first attempt at a systematic and general account of the available literature data on the composition, properties, and structures of silicon tetrafluoride adducts. Account is taken of almost all the original studies on the chemistry of silicon tetrafluoride adducts published up to 1st June, 1973. In accordance with the definition of an adduct proposed by Cotton and Wilkinson[4], we shall consider solid compounds of definite composition formed by silicon tetrafluoride with organic molecules containing an electron-donating nitrogen, oxygen, phosphorus, or sulphur atom, which have been isolated in a pure state.

II. STOICHIOMETRY

Under normal conditions, silicon tetrafluoride is a colourless gas; its melting point is −90°C.[5] It has been established by electron diffraction[6] that gaseous silicon tetrafluoride has the symmetry of a regular tetrahedron with an Si–F distance of 1.54 ± 0.2 Å. In the ground state tetrahedral silicon tetrafluoride has the electronic configuration $(1a)^2(1t_2)^6(2a)^2(2t_2)^6(1e)^4(3t_2)^6(t_1)^6$.

Calculations have shown[7] that the 3*d* atomic orbitals of the central silicon atom in the silicon tetrafluoride molecule are populated to a large extent, which is evidence for a significant involvement of the orbitals in the formation of chemical bonds. Despite the presence of an electron octet, the silicon atom in the molecule is capable of increasing its coordination number from four to six by utilising two of the five vacant 3*d* orbitals and it has been noted[8] that σ-bonding with participation of the silicon 3*d* orbitals is due mainly to the presence of highly electronegative groups located at this atom. From this standpoint, silicon tetrafluoride should behave as an "ideal" silicon halide for the formation of complexes with electron-donating molecules via σ-bonding with expansion of the silicon octet.

The simplest compound of this type is the adduct $SiF_4.2NH_3$, which is a white powder; it was synthesised at the beginning of the past century[9]. It was established later[10] that, on mixing dry SiF_4 with an excess of dry NH_3, only one compound with the composition $SiF_4.2NH_3$ is formed in the solid phase; it sublimes *in vacuo* at 60–65°C and does not undergo ammonolysis even on heating in an excess of ammonia up to 300°C. In contrast to the tetrafluoride, the remaining silicon tetrahalides form with ammonia compounds having the composition $SiX_4.6NH_3$ (X = Cl, Br, or I).[11]

Aliphatic amines react with silicon tetrafluoride like ammonia. Adducts of silicon tetrafluoride with trimethylamine (Me_3N) have been investigated in greatest detail. It has been reported[12] that silicon tetrafluoride reacts with trimethylamine to form a white solid compound $SiF_4.Me_3N$, whose vapour pressure is 45 mmHg at room temperature and 0.1 mmHg at 78°C. The existence of this compound was subsequently confirmed by Berg[5]. However, Wilkins and Grant[13] discovered two compounds in the SiF_4–Me_3N system: $SiF_4.Me_3N$ and $SiF_4.2Me_3N$†, whose existence has been confirmed from the vapour pressure–composition isotherm and by cryoscopic measurements. Both adducts are white crystalline substances, which sublime congruently at atmospheric pressure and melt congruently at higher pressures. Subsequently Schnell[14] reported that the adduct

†Henceforth we shall refer to these adducts as a 1 : 1 and 1 : 2 type respectively.

$SiF_4.2Me_3N$ is deposited as a dense white precipitate when silicon tetrafluoride is passed into a solution of trimethylamine in petroleum ether. When a benzene solution of trimethylamine is used, the product is the compound $SiF_4.Me_3N$, which is readily soluble in benzene, carbon tetrachloride, petroleum ether, and carbon disulphide, while the 1 : 2 adduct is much less soluble in these solvents.

Subsequent investigations[15] confirmed Schnell's conclusions, but the SiF_4–Me_3N system proved to be the only one so far for which the existence of adducts of two types may be regarded as finally proved. Information has also been published on the synthesis of dimethylamine adducts of the 1 : 2 and 2 : 3 types[16], but subsequently these results were not confirmed. Hagen and Callaway[11] showed that dimethylamine forms with silicon tetrafluoride only an adduct of the 1 : 2 type. Methylamine, whose adduct $SiF_4.2MeNH_2$ has been investigated in fair detail, reacts with silicon tetrafluoride similarly[11,17,18]. The synthesis of the compounds $SiF_4.Am$ and $SiF_4.2Am$ (Am = mono-, di-, and tri-ethylamines and mono-, di-, and tri-ethanolamines) has been reported[19].

Alicyclic amines (piperidine, pyrrolidine[20], and aziridine[21]) also form 1 : 2 adducts with silicon tetrafluoride. The earlier data concerning the synthesis of 1 : 2 adducts with ammonia, methylamine, dimethylamine, trimethylamine, pyrrolidine, and piperidine were confirmed recently[22] and the hitherto unknown compounds $SiF_4.2NH_xR_{3-x}$ ($x = 1$, R = Et, n-Pr, or n-Bu; $x = 2$, R = Et, n-Pr, n-Bu, i-Bu, or t-Bu) and $SiF_4.2NMe_xEt_{3-x}$ (x = 0–2), obtained by the direct interaction of the reactants in the gas or liquid phase, were described. On the basis of these data, the authors[22] concluded that the formation of 1 : 2 adducts is characteristic of the silicon tetrafluoride–aliphatic monoamine systems and data[2] concerning the formation of a 2 : 3 methylamine adduct are explained by the hydrolysis of the 1 : 2 adduct by atmospheric moisture. One must agree with this conclusion, since the range of amines employed by Aylett et al.[22] and other investigators[11,17–21] was sufficiently large to extend the observed behaviour to the entire series of aliphatic amines.

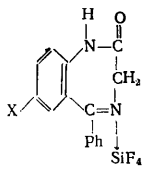
Aliphatic diamines react with silicon tetrafluoride as bidentate ligands, forming 1 : 1 adducts. Ethylenediamine reacts with silicon tetrafluoride in this way, forming a solid white adduct, which sublimes at 225°C and 0.2 mmHg[24]. Adducts of the 1 : 1 type have also been described for piperazine[21] and a number of tetramethylalkylenediamines of the type $Me_2N(CH_2)nNMe_2$, where n = 1, 2, 3, 4, or 6.[25] It is striking that hydrazine reacts with silicon tetrafluoride like the monoamines, forming a white non-hygroscopic compound $SiF_4.2N_2H_4$, which sublimes congruently at 100°C and decomposes on heating above 200°C.[23] Owing to its low molecular dimensions, hydrazine is probably unable to occupy two coordination sites at once about the silicon atom and for this reason behaves as a monodentate ligand. The behaviour of phenylhydrazine, which behaves as a bidentate ligand forming a 1 : 1 adduct with silicon tetrafluoride[21], is therefore incomprehensible. Since there are reliable data concerning the composition of the $SiF_4.2N_2H_4$ adduct[23], which were confirmed by other results[17], we believe that the observed[21] composition of the phenylhydrazine adduct requires an additional test.

Proceeding now to the consideration of the stoichiometry of the adducts of nitrogen-containing heterocycles, we may note that this problem has given rise to the greatest degree of disagreement. An example is provided by the controversy concerning the composition of the silicon tetrafluoride adduct with pyridine (Py). As early as 1888, Comey and Smith[26] described a white compound $SiF_2.2Py$ in powder form, obtained by passing silicon tetrafluoride through a benzene solution of pyridine and noted that it decomposes rapidly. Pyridine is evolved at the same time and a compound close in composition to $2SiF_4.3Py$ is produced. These observations were subsequently confirmed by Wannagat and Schwarz[27], but a final conclusion about the individuality of the compound $2SiF_4.3Py$ was not reached. Thus, taking into account the data[28,29] concerning the existence of the compound $SiF_4.Py$ in the silicon tetrafluoride–pyridine system, three types of adducts have been described altogether. On the other hand, the majority of investigators have reported the existence of only one adduct of the 1 : 2 type[30–33]. In order to resolve the above contradictions, Guertin and Onyszchuk[20] investigated the direct interaction of the two reactants in the gas phase, used for the synthesis a solution of pyridine and ether, and also applied the tensimetric titration method. In all of the above instances they obtained a solid white product of composition $SiF_4.2PY$, which sublimes congruently *in vacuo* at 60–80°C. They emphasised[20] that the method of synthesis of the 2 : 3 [26] and 1 : 1 [28,29] adducts was most carefully repeated, but in all cases only one compound $SiF_4.2Py$ was obtained. On the basis of their results, Guertin and Onyszchuk concluded that other workers who reported the formation of the 1 : 1 and 2 : 3 adducts failed to take into account the loss of pyridine as a result of the hydrolysis of $SiF_4.2Py$. Aylett et al.[22] subsequently agteed with this conclusion. They studied the silicon tetrafluoride–pyridine system in the range of temperatures from 196°C to room temperature and in all cases obtained the compound $SiF_4.2Py$, which melts at 189°C (170–180°C according to Guertin and Onyszchuk[20]) in a sealed capillary. However, Aylett et al.[22] also succeeded in obtaining compounds of other compositions by means of special procedures, but all these proved to be unstable and slowly lost silicon tetrafluoride, forming the adduct $SiF_4.2Py$. Thus we believe that the problem of the stoichiometry of the adducts in the silicon tetrafluoride–pyridine system may be regarded as finally solved in favour of the formation of only one stable compound of the 1 : 2 type.

There was a similar controversy in yet another instance. Thus Comey and Jackson[16] drew attention to the fact that, although pure quinoline does not react with silicon tetrafluoride, when the latter is passed through a benzene solution of quinoline the product is an acicular deposit of $2SiF_4.3C_9H_7N$, which sublimes without decomposition. These results were disproved by Wannagat and Schwarz[27], who pointed out that quinoline does not react with silicon tetrafluoride and the adduct described by Comey and Jackson[16] is quinolinium hydrofluoride formed as a result of the hydrolysis of silicon tetrafluoride when moist quinoline is employed. However, this report was also rejected by Gutmann et al.[21] who reported that, when a benzene solution of quinoline is employed, a 1 : 2 adduct is formed. Subsequently Wannagat et al.[34] reinvestigated the silicon tetrafluoride–quinoline system and confirmed the conclusions of Gutmann et al.[21], stating that their earlier results were erroneous. It is appropriate to mention here also the extremely interesting study by Schnell[35], according to whose results the interaction of isoquinoline with silicon tetrafluoride yields a 1 : 2 adduct. The same investigator reported[14] the existence of the adduct $SiF_4.2\beta\text{-}MeC_5H_4N$, but he presented no data concerning the conditions of the synthesis and properties of this compound.

In general one may assume that the formation of 1 : 2 adducts is characteristic of nitrogen-containing hetero-

cycles as well as of aliphatic and alicyclic amines. Only 2,4-dimethylpyridine and 8-hydroxyquinoline, for which Muetterties[29] described 1 : 1 adducts, constitute an exception to this general rule. The addition of a second amine molecule probably does not occur in this case owing to steric hindrance. The finding that complex polyatomic species, such as 1,4-benzo-2-diazepinium ions, also form 1 : 1 adducts with silicon tetrafluoride[36] supports this hypothesis:



(X = Me, Cl, NO_2) .

Judging from infrared spectroscopic data[36], the tertiary nitrogen atom and not the amide group is responsible for a coordination in these compounds.

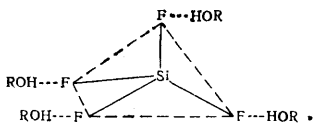
As expected, all the heterocyclic diamines investigated hitherto (2,2′-bipyridyl[21,37,38], 4,4′-bipyridyl[39], and 1,10-phenanthroline[30]) form 1 : 1 adducts with silicon tetrafluoride. Aromatic diamines behave similarly. Among these, the adduct of *o*-phenylenediamine has been most completely investigated. The compound SiF_4.*o*-PDA‡ was obtained for the first time by Gutmann et al.[21], whose finding was subsequently confirmed by Harris and Rudner[40] and also by the authors of the present review[41]. The latter showed that 1 : 1 adducts are also formed by *m*- and *p*-phenylenediamines. All the compounds were obtained by passing gaseous silicon tetrafluoride through benzene solutions of the corresponding diamines. It is therefore surprising that a precipitate is not formed on treating a benzene solution of 3,3′, 4,4′-tetra-aminobiphenyl with silicon tetrafluoride[40], although under the same conditions benzidine, which has a similar structure, gives rise readily to a 1 : 1 adduct[42].

In general the problem of the stoichiometry of the adducts of silicon tetrafluoride with aromatic diamines involves no disagreements, which cannot be said of the adducts of aromatic monoamines, although historically these adducts were in fact the first to attract attention. As early as 1888, Comey and Jackson[16] obtained white or slightly coloured compounds of composition $2SiF_4.3Am$ (Am = aniline, *p*-bromoaniline, *p*-chloroaniline, *p*-toluidine, *o*-toluidine, diphenylamine, and *NN*-dimethylaniline) and described in detail their properties. Later Gutmann et al.[21] showed that, on passing gaseous silicon tetrafluoride through benzene solutions of *p*-chloroaniline, *p*-aminophenol, β-naphthylamine, and *p*-aminobenzoic acid at room temperature, cryptocrystalline 1 : 2 adducts are formed in all cases, but *o*-nitroaniline gives rise to the compound $SiF_4.H_2NC_6H_4NO_2$.

It has also been reported that 1 : 2 adducts are formed by *NN*-dimethylaniline[29], *o*-aminophenol, and 2-amino-4-chlorotoluene[40]. On the other hand, when silicon tetrafluoride was passed through boiling benzene solutions of the initial amines, 1 : 1 adducts of *p*-anisidine[43] and α-naphthylamine[44] were obtained and at room temperature products of the 2 : 3 type were synthesised.

Unfortunately, information about the influence of the conditions of synthesis and of the structure of the initial amine on the composition of the adduct formed in silicon tetrafluoride–aromatic amine systems is extremely limited, so that the general conclusions of Aylett et al.[22] appear to be insufficiently well-founded.

It is noteworthy that the investigations[16,21,29,40,43,44] have been carried out using solutions of the amines in aprotic solvents, mainly benzene, in which silicon tetrafluoride is almost insoluble[45]. The situation is different when aliphatic alcohols, in which silicon tetrafluoride dissolves readily, are employed. Under these conditions, the products[46,47] are the complexes $SiF_4.4ROH$ formed as a result of strong hydrogen bonding[49]§:



We established that in alcoholic solutions aromatic amines (Am) react with silicon tetrafluoride as follows[50-52]:

$$SiF_4 \cdot 4ROH \rightleftarrows SiF_4 + 4ROH , \quad (1)$$

$$\underline{SiF_4 + 2Am \rightleftarrows SiF_4 \cdot 2Am , \quad (2)}$$

$$SiF_4 \cdot 4ROH + 2Am \rightleftarrows SiF_4 \cdot 2Am + 4ROH , \quad (3)$$

with formation of a precipitate consisting of the adduct $SiF_4.2Am$ (Am = aniline, *p*-aminophenyl difluoromethyl sulphone, *m*- and *p*-nitroanilines, *o*- and *p*-aminobenzoic acids, *m*-trifluoromethylaniline, *p*-aminoazobenzene, *o*-, *m*-, and *p*-anisidines, *o*-, *m*-, and *p*-aminophenols, *p*-bromoaniline, *p*-chloroaniline, *o*-, *m*-, and *p*-toluidines, *p*-phenetidine, diphenylamine, and *N*-ethylaniline). In this case the proportions of the initial reactants influence appreciably the rate of complex formation, which makes it possible to employ the proposed technique in the investigation of the kinetic parameters of the reaction.

As a result of higher steric hindrance in the case of the tertiary amines *NN*-dimethyl-, *NN*-dipropyl-, and *NN*-dibutyl-anilines and *NN*-dimethyl-*p*-toluidine, these amines do not form solid products with silicon tetrafluoride either in alcoholic or benzene solutions[52]. *o*-Aminobenzenethiol behaves analogously, although, as mentioned above, under analogous conditions *o*-aminophenol forms a compound with the composition $SiF_4.2H_2NH_6H_4OH$.[40]

Apparently the only known adduct of silicon tetrafluoride with amides is the compound $SiF_4.2Me_2NCHO$, obtained by passing silicon tetrafluoride through a benzene solution of *NN*-dimethylformamide[53,54]. It has also been reported that acetamide absorbs about one quarter of a mole of silicon tetrafluoride with formation of a white solid product[55], while formamide[54] and urea[16] decompose under the influence of silicon tetrafluoride even at room temperature. In contrast to aliphatic amides, aromatic amides, for example chloroacetamidobenzophenones in which the nitrogen atom is conjugated with the π-electron system of the benzene ring, do not form any solid product with silicon tetrafluoride[36]. In this case steric hindrance cannot be of decisive importance, because chloroacetamidobenzophenones are models of 1,4-benzodiazepin-2-ones, which, as mentioned above, form 1 : 1 adducts with silicon tetrafluoride.

On the basis of the results of early studies[45,55], it was believed for a long time that silicon tetrafluoride is incapable of coordination with molecules containing an electron-donating oxygen atom. Muetterties[29] described

‡PDA = phenylenediamine.

§Borodin et al.[48] investigated the silicon tetrafluoride–ethanol system by ^{19}F NMR, but were unable to reach definite conclusions concerning the structure of the alcohol complex of silicon tetrafluoride.

"weak complexes" of silicon tetrafluoride with acetylacetone and tropolone and noted that these complexes are unstable even at room temperature. It has also been reported that under certain conditions silicon tetrafluoride promotes the dissociation of the C–O bond in epoxide molecules [56], but in this case adducts were not isolated. It has been established only in recent years that silicon tetrafluoride reacts with certain oxygen-containing donors (methylene and trimethylene oxides, tetrahydrofuran, tetrahydropyran, and methyl ether), forming white solid 1 : 2 adducts [57,58], which are stable only at room temperature.

According to Guertin and Onyszchuk [58], the adducts of pyridine, dimethylamine, triphenylphosphine, and tricyclohexylphosphine oxides [59] and dimethyl sulphoxide [60] as well as the dimethylformamide adduct described above should also be classified as compounds in which the oxygen atom is responsible for the formation of the coordinate bond. All these compounds react vigorously with silicon tetrafluoride, forming 1 : 2 adducts, which, like the dimethylformamide adduct, are white cryptocrystalline substances insoluble in ether, toluene, benzene, etc. The compounds are much more stable than the adducts of alicyclic ethers. Thus the adduct of dimethyl sulphoxide sublimes congruently at 107–111 °C, while $SiF_4.2Ph_3PO$ and $SiF_4.2(C_6H_{11})_3PO$ decompose with liberation of the initial reactants at 158–161° and 167 °C respectively. The above differences between the stabilities can probably be explained by the increase of the electron-donating capacity of the oxygen atom as a result of the shift of the electron density of the phosphorus, sulphur, or nitrogen atom linked to oxygen. This explanation is supported by the finding that solid products are not formed in the case of diphenyl sulphoxide [61], in which such conjugation should be much weaker than in dimethyl sulphoxide.

The first attempt to synthesise an adduct with an Si ← P coordinate bond was unsuccessful: trimethylphosphine (Me_3P) does not react with silicon tetrafluoride at 25 °C. [62] Subsequently Beattie and Ozin [15,63] obtained at low temperatures the compounds $SiF_4.Me_3P$ and $SiF_4.2Me_3P$. However, the attempt to obtain triphenylphosphine adducts were unsuccessful even on cooling the reaction mixture to −96 °C. [64]

Together with the adducts of "simple" molecular donors, compounds of silicon tetrafluoride with complex ligands—dicyanobis-(1,10-phenanthroline)iron(II) (A) and dicyanobis-(4,7-diphenyl-1,10-phenanthroline)iron(II) (B)—of compositions $SiF_4.A$, $2SiF_4.A$, and $SiF_4.B$ have been described; they are cryptocrystalline powders, very sensitive to atmospheric moisture [65]. Another example of an adduct of silicon tetrafluoride with a complex ligand is the compound $SiF_4.Pt(PPh_3)_2$, colourless crystals of which have been obtained by treating a benzene solution of tris-(triphenylphosphine)platinum(0) with silicon tetrafluoride at room temperature [64]:

$$(Ph_3P)_3Pt + SiF_4 \rightarrow (Ph_3P)_2Pt \cdot SiF_4 + Ph_3P \ . \qquad (4)$$

III. PROPERTIES

Like the initial silicon tetrafluoride, its adducts are readily hydrolysed by water with the formation of the hexafluorosilicate ion, which is characteristic of silicon tetrafluoride [10,23,34,35]:

$$3(SiF_4 \cdot 2Am) + 2H_2O \rightarrow 2(AmH)_2SiF_6 + SiO_2 + 2Am \ . \qquad (5)$$

The quantitative experiments of Aylett et al. [22] showed that the hydrolysis of $SiF_4.2NH_3$ and $SiF_4.2MeNH_2$ is described by the equation for first-order kinetics and that the rate constants at 25 °C are 1.0×10^{-3} and 1.9×10^{-3} s^{-1} respectively. For other adducts, there are only qualitative data, on the basis of which Aylett et al. [22] arranged the 1 : 2 adducts in the following sequence in terms of their resistance to hydrolysis¶: $NH_3 > MeNH_2 \sim EtNH_2 > > i\text{-}BuNH_2 > Me_2NH \sim Et_2NH > Me_3N \sim EtMe_2N \sim Et_2MeN \sim \sim Et_3N$ and $Me_3N > C_5H_5N$. When the adduct reacts with hydrofluoric acid, only the fluorosilicates of the corresponding base cations are formed, for example those of hydrazinium [23] or pyridinium [20]:

$$SiF_4 \cdot 2Am + 2H_3O^+ + 2F^- \rightarrow \underset{\downarrow -2H_2O}{2AmH^+ + SiF_6^{2-}} + 2H_2O \qquad (6)$$
$$(AmH^+)_2SiF_6^{2-} \ .$$

More powerful electron pair acceptors (anhydrous hydrogen chloride and boron trifluoride) are probably capable of displacing silicon tetrafluoride quantitatively from its adducts, but such reactions have been described only for $SiF_4.2C_5H_5N$ (Wannagat et al. [66]) and $SiF_4.2M_2H_4$ (Aggarwal and Onyszchuk [23]). At room temperature gaseous boron trichloride displaces silicon tetrafluoride from its adducts with bis(triphenylphosphine)platinum [67]:

$$(Ph_3P)_2Pt \cdot SiF_4 + BCl_3 \rightarrow (Ph_3P)_2Pt \cdot BCl_3 + SiF_4 \ . \qquad (7)$$

The reactions involving the substitution of one amine by another in the adducts have been studied in much greater detail. The first such reaction was reported by Gutmann et al. [21], who found that, on treatment with dry ammonia, the adduct $SiF_4.2(CH_2)_2NH$ decomposes with liberation of free aziridine:

$$SiF_4 \cdot 2(CH_2)_2NH + 2NH_3 \rightarrow 2(CH_2)_2NH + SiF_4 \cdot 2NH_3 \ . \qquad (8)$$

A similar reaction takes place when the hydrazine and pyridine adducts are treated with free ethylenediamine [20]:

$$SiF_4 \cdot 2C_5H_5N + H_2N(CH_2)_2NH_2 \rightarrow SiF_4 \cdot H_2N(CH_2)_2NH_2 + 2C_5H_5N \ . \qquad (9)$$

Aylett et al. [22] found that for the adducts of aliphatic amines the initial bases can be arranged in the following sequence in terms of their relative strengths in the substitution reaction: $NH_3 \gg MeNH_2 > PhNH_2 > Me_2NH > > Me_3N$; $MeNH_2 > Et_3N$. A similar sequence had been established also for aromatic amine adducts. The substitution of one amine by another takes place almost quantitatively via the mechanism

$$SiF_4 \cdot 2Am + 2Am' \rightarrow SiF_4 \cdot 2Am' + 2Am \ , \qquad (10)$$

in the following sequence on treatment of the adduct of a weaker base by a stronger base: benzylamine > *p*-anisidine, *p*-toluidine > aniline > *p*-chloroaniline, *p*-bromoaniline > *p*-aminoazobenzene > *p*-aminobenzoic acid > > *p*-nitroaniline, i.e. the possibility of the substitution reaction is determined in this case by the basicity of the initial amine [68].

Among other known reactions of silicon tetrafluoride adducts, dehydrofluorination is of particular interest as a method of converting the adducts into simple fluorine-containing compounds with a covalent silicon–nitrogen bond: F_3SiNR_2 (fluorosilylamines) and $(F_3Si)_2NR$ (fluorosilazones). Compounds of this kind are formed as a result of the loss of one or two molecules of hydrogen fluoride on heating the adducts of primary or secondary amines to 200 °C in the presence of powerful reducing agents, for

¶Only the base is indicated.

example $LiAlH_4$, B_2H_6, $NaBH_4$, LiH, $NaNH_2$, Al, or Mg [69-71]:

$$SiF_4 \cdot 2HNR_2 \xrightarrow{-HF} F_3SiNR_2 + HNR_2 , \quad (11)$$

$$SiF_4 \cdot 2HNR_2 \xrightarrow{-2HF} F_2Si(NR_2)_2 , \quad (12)$$

$$2(SiF_4 \cdot 2H_2NR) \xrightarrow{-2HF} (F_3Si)_2NR + 3H_2NR . \quad (13)$$

On further heating of the adducts of primary amines to 300–400°C in the presence of the above reducing agents, more far-reaching reactions take place and polymeric compounds of the type $(-F_2SiNR-)_n$ are formed. Their chains are made up of alternating difluorosilyl and substituted imino-groups [70,71]:

$$SiF_4 \cdot 2MeNH_2 + 2NaNH_2 \rightarrow (-F_2SiNMe-) + 2NaF + 2NH_3 + MeNH_2 . \quad (14)$$

Harris and Rudner [40,72,73] found that the adducts of primary amines readily split off hydrogen fluoride on treatment with tertiary amines, for example trimethylamine, triethylamine, or ethyldi-isopropylamine, with formation of cyclosilazanes and the corresponding pentafluorosilicates:

$$RNH_2 + 2R_3N + 3SiF_4 \rightleftarrows \frac{1}{n}(RNSiF_2)_n + 2R_3NH^+SiF_5^- \quad (15)$$

or of the ammonium salts of other fluorosilicic acids, for example with the anion $Si_2F_{11}^-$:

$$RNH_2 + 2R_3N + (m+1)SiF_4 \rightleftarrows \frac{1}{n}(RNSiF_2)_n + \frac{2}{m+1}(R_3NH^+)_{m+1}Si_mF_{(5m+1)}^{-(m+1)} \quad (16)$$

depending on the structure and properties of the tertiary amine used in the reaction. The reaction proceeds in benzene solution in an atmosphere of silicon tetrafluoride at room temperature, under milder conditions than the analogous reactions of the adducts of phosphorus pentafluoride [74] or boron trifluoride [75].

The above equations (15) and (16) provide a fairly general scheme for the reactions occurring in the dehydrofluorination process, whose mechanism has been hardly investigated. One can only presume that in these processes the dehydrofluorinating agent is not the tertiary amine itself but its adduct, since in all the published instances [40,72,73] the fluorosilicates of the corresponding bases and not the hydrofluorides are formed together with cyclosilazanes. This hypothesis is also supported by the employment of the adduct $SiF_4.Me_3N$ as a dehydrofluorinating agent in the synthesis of polyfluoroalkylketens and polyfluoroalkylsulphenes [76]. It has been noted that the fluoride ion liberated as a result of dehydrofluorination is bound firmly to the adduct, as a result of which the process becomes irreversible.

Fluorine-containing silicon–nitrogen compounds can also be obtained by the direct interaction of silicon tetrafluoride with alkali metal amides, for example with sodium bis(trimethylsilyl)amide [78] or lithium alkylamides [79]. It has been believed for a long time that the aminolysis of an Si–F bond in silicon tetrafluoride proceeds only in the presence of dehydrofluorinating agents. At the same time, the aminolysis of an Si–F bond occurs when primary amines act on alkylfluorosilanes [80] and phenylfluorosilanes [81-83], so that a similar reaction is presumably feasible also for silicon tetrafluoride. In this connection particular interest attaches to the report by Aylett et al. [84]†, who found that fluorosilylamines can be obtained by heating the adducts of certain alkylamines without using any dehydrofluorinating agents. It is recommended that the adducts be heated in a sealed tube in the presence of an excess of silicon tetrafluoride at 100–200°C. Trifluorosilylamines are formed from the adducts of secondary amines:

$$SiF_4 \cdot 2R_2NH \rightarrow F_3SiNR_2 + R_2NH_2F \quad (17)$$

and the excess SiF_4 is combined with formation of the corresponding hexafluorosilicate:

$$2R_2NH_2F + SiF_4 \rightarrow (R_2NH_2)_2SiF_6 . \quad (18)$$

Pentafluorosilicates are hardly formed in this reaction. When primary amine adducts are heated, the situation is complicated because of the formation of products with a tendency towards further dehydrofluorination and disproportionation. It has been noted [84] that the yield of the corresponding hexafluorodisilazane $(SiF_3)_2NR$ depends mainly on the structure of the initial amine. Indeed the yields of the hexafluorodisilazanes obtained from the adducts of n-alkylamines (Table 1, Nos. 9–12) are much lower than for the adduct of a secondary amine—isobutylamine (Table 1, Nos. 13 and 14). In conformity with the above finding, when the adduct of t-butylamine is heated, a fairly high yield of trifluorosilylamine is produced via the reaction

$$SiF_4.2t\text{-}BuNH_2 \rightarrow t\text{-}BuNHSiF_3 + t\text{-}BuNH_3F, \quad (19)$$

since the increase of the steric effect of the substituent on passing to the t-butyl group not only increases the yield of the final product but also alters the reaction mechanism.

Table 1. Conditions governing the synthesis and yields of trifluorosilylamines and hexafluorodisilazanes [84].

*Yield calculated by Eqn. (17);
**yield obtained from the conversion of the amine;
***yield calculated by Eqn. (19).

According to a patent [85], the thermal transformations of the adduct $SiF_4.2NH_3$ are particularly far-reaching, so that silicon–nitrogen films are deposited as a result of the pyrolytic decomposition of this compound. On the other hand, tensimetric measurements have shown [22] that the

†These results have been described in detail in a paper [126] published after the present review had been prepared for the press.

adducts of ammonia, methylamine, dimethylamine, trimethylamine, and pyridine dissociate almost completely into the initial reactants on heating:

$$SiF_4.2Am(solid) \rightleftharpoons SiF_4(gas) + 2Am(gas). \quad (20)$$

The diethylamine adduct melts initially and then decomposes via the mechanism

$$SiF_4.2Et_2NH(liq.) \rightleftharpoons SiF_4(gas) + 2Et_2NH(gas). \quad (21)$$

The adducts of high-boiling amines, for example of triethylamine and diethylmethylamine, decompose on heating via a somewhat different mechanism:

$$SiF_4.2Am(solid) \rightleftharpoons SiF_4(gas) + 2Am(liq.), \quad (22)$$

The last mechanism was proposed previously by the present author to describe the thermal reactions of the isomeric phenylenediamine complexes of silicon tetrafluoride [41] and was subsequently proved [68] for a number of adducts of aromatic amines with the composition $SiF_4.2Am$ (Am = *p*-nitroaniline, diphenylamine, *p*-aminobenzoic acid, *m*-aminophenol, and *N*-ethylaniline). It was reported in the same communication that the adducts of aniline, *p*-phenetidine, *p*-toluidine, *p*-chloroaniline, and *p*-anisidine dissociate on heating in accordance with reaction (20). When the adduct is heated, the amine passes to the gas phase together with silicon tetrafluoride and then interacts with the latter, reforming the adduct at lower temperatures; the adduct is deposited on the less heated components of the sublimation tube, so that the overall process resembles sublimation. In general, although the thermal reactions of silicon tetrafluoride adducts have been clearly inadequately investigated, the sum total of the results quoted permits the conclusion that the pathways and extent of these reactions are determined primarily by the structure of the initial amine.

The basicity and the structure of the initial amine are the controlling factors also in the reactions of silicon tetrafluoride adducts with alcohols and phenols. According to patent data [86], when the ammonia adduct is heated in alcohols, complete alcoholysis of silicon tetrafluoride takes place with formation of a fully substituted orthosilicic acid ester and ammonium hexafluorosilicate:

$$3SiF_4 + 4NH_3 + 4ROH \rightarrow Si(OR)_4 + 2(NH_4)_2SiF_6. \quad (23)$$

The esters of n-propyl, isopropyl, n-butyl, isobutyl, and pentyl alcohols were later obtained in the same way [87], but the possibility of employing aniline and pyridine in reaction (23) suggested in the patent quoted above was not subsequently confirmed. As mentioned previously, aniline and its substituted derivatives form 1 : 2 adducts in alcoholic solutions [52]. Silicon tetrafluoride does not undergo alcoholysis in the presence of pyridine either, although the adducts of tertiary aliphatic amines do react with alcohols and phenols in accordance with Eqns. (24) and (25):[40]

$$5SiF_4 + 4R_3N + 4ROH \rightleftarrows Si(OR)_4 + 4R_3NH^+SiF_5^-, \quad (24)$$

$$\frac{5m+1}{m+1}SiF_4 + 4R_3N + 4ROH \rightleftarrows Si(OR)_4 + \frac{4}{m+1}(R_3NH^+)_{m+1}Si_mF_{5m+1}^{-(m+1)}. \quad (25)$$

When triethylamine and ethyldi-isopropylamine are employed, the reaction proceeds with formation of pentafluorosilicic acid salts [Eqn. (24)] and in the case of triethylamine the products are salts containing the anion $Si_2F_{11}^{3-}$ [Eqn. (25)], which had not been described previously.

Dehydrofluorination is not the only method for the conversion of silicon tetrafluoride adducts into fluorine-containing compounds with a covalent silicon–nitrogen bond.

In contrast to silicon tetrafluoride, its adducts react with disilazanes and cyclosilazanes, forming the corresponding fluorosilazanes. This property of the silicon tetrafluoride adduct was established for the first time by Wannagat and Bürger [88], who obtained difluorobis(trimethylsilylamino)silazane on heating to 100°C a suspension of the adduct $SiF_4.2NH_3$ in hexamethyldisilazane:

$$SiF_4 \cdot 2NH_3 + 2(Me_3Si)_2NH \rightarrow (Me_3SiNH)_2SiF_2 + 2Me_3SiF + 2NH_3. \quad (26)$$

The adducts $SiF_4.2MeNH_2$, $SiF_4.2N_2H_4$, and $SiF_4.2C_5H_5N$ react similarly with hexamethyldisilazane, forming a mixture of fluorosilylamines of the type $(Me_3SiNH)_nSiF_{4-n}$, where $n = 1-3$.[18] Special mention should be made of the fact that, although pyridine does not in fact contain reactive hydrogen atoms, its adduct reacts with hexamethyldisilazane via the mechanism

$$SiF_4 \cdot 2C_5H_5N + n(Me_3Si)_2NH \rightarrow (Me_3SiNH)_nSiF_{4-n} + n\,Me_3SiF + 2C_5H_5N. \quad (27)$$

In this case the main product is difluorobis(trimethylsilylamino)silane ($n = 2$) and also small amounts of trifluorotrimethylsilylaminosilane and fluorotris(trimethylsilylamino)silane ($n = 3$). On heating to 120°C, the ammonia adduct reacts also with cyclosilazanes to form fluorosilazanes of the type $FMeSi(NHSiMe_2)_nF$ ($n = 1$, 2, or 3) among which an *SiSi*-difluoropolysilazane $(-F_2SiNH-)_x$ was isolated.

IV. STEREOCHEMISTRY

It has been noted above that monodentate ligands usually form 1 : 2 adducts with silicon tetrafluoride. Presumably the silicon atom passes to the sp^3d^2 hybridised state as a result of the acceptance of two electrons from the electron-donating atoms (for 1 : 1 adducts, the corresponding transition to the sp^3d hybridised state is postulated), i.e. silicon behaves similarly to transition elements. This explanation was put forward for the first time by Piper and Rochow [54], who found that the infrared spectra of the adducts $SiF_4.2NH_3$ and $SiF_4.2Me_2NCHO$ show very intense broad absorption bands with a maximum in the region of 750 cm^{-1}, which were identified as the ν(Si–F) bands of the hexacoordinate silicon atom. The authors [54] reached this conclusion on the basis of the comparison of the absorption bands corresponding to the stretching vibrations of the Si–F bonds in the ifrared spectra of gaseous SiF_4 and the octahedral SiF_6^{2-} anion. In the first case [89] these bands are observed at 1031 and 800 cm^{-1} whereas ν(Si–F) for the hexafluorosilicate ion is usually [90] in the region of 740 cm^{-1}. Subsequent studies showed that the intense absorption in the region of 740 cm^{-1} is characteristic also of other silicon tetrafluoride adducts. On this basis, it has been concluded [2,14,17,21,23,35,60,91] that the compounds investigated have an octahedral structure.

The octahedral structure has now been adopted for hexacoordinate silicon tetrafluoride compounds, but the problem of the relative positions of the ligands in the adduct molecules still remain controversial. From the examination of the octahedral model alone, different stereoisomeric distributions of the ligands are clearly possible (Fig. 1).

Beattie et al. [92] employed the infrared spectroscopic method to solve the problem of the ligand positions. They found by a [normal] coordinate analysis of the vibrations of the *cis*- and *trans*-models of the molecules of adducts of the type $SiF_4.2R$ that the infrared spectrum of the *cis*-form must be more complex: neglecting the possible band splittings, one may expect the presence in the infrared spectrum of three active high-frequency vibrations, while

only one vibration should be active in this region for the highly symmetrical *trans*-form.

Continuing these investigations, Beattie and Webster[30] identified by comparative analysis the absorption bands in the infrared spectra of the adducts $SiF_4.2Py$ and $SiF_4.2Ph_3PO$ and, on the basis of the number of these bands, concluded that both compounds obtained have the *trans*-octahedral structure. Subsequently the configurations of a number of other adducts, which are listed in Table 2, were determined similarly.

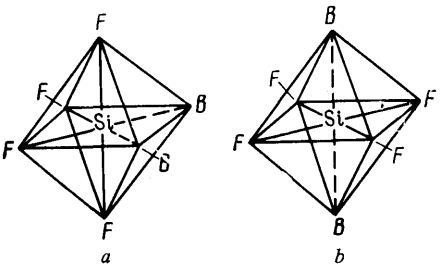

Figure 1. Configuration of hexacoordinate silicon tetrafluoride compounds: *a*) *cis*-octahedron (C_S); *b*) *trans*-octahedron (C_{2v}).

Comparative analysis of the data in Table 2 shows that the probabilities of the formation of the *cis*- and *trans*-configurations of the hexacoordinate silicon tetrafluoride compounds are almost the same. However, one must stipulate that these stereochemical differences have not so far been explained and given a theoretical interpretation.

Table 2. The results of infrared spectroscopic studies of the configurations of octahedral adducts of the type $SiF_4.2R$.

Compound	Configuration	References	Compound	Configuration	References
$SiF_4.2NH_3$	*cis*	17*, 23	$SiF_4.2N_2H_4$	*cis*	17, 23
$SiF_4.2ND_3$	*cis*	17	$SiF_4.2C_5H_5N$	*trans*	30, 93
$SiF_4.2MeNH_2$	*cis*	11, 17	$SiF_4.2Me_2NCHO$	*cis*	53
$SiF_4.2Me_2NH$	*cis*	11	$SiF_4.2Ph_3PO$	*trans*	30
$SiF_4.2Me_3N$	*trans*	15	$SiF_4.2Me_2SO$	*trans*	94
$SiF_4.2Me_3P$	*trans*	15			

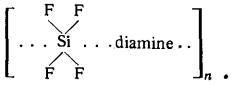
*The authors[17] also investigated the wide-band ^{19}F NMR spectrum of this adduct.

The attempt to estimate theoretically the relative stabilities of the *cis*- and *trans*-isomers of the adducts $SiF_4.2Py$ and $SiCl_4.2Py$ by an approximate parametric calculation of the energies of the $p\pi-d\pi$ bonds with additional ligands was understandably greeted with much interest. Rami and Hensen[95] examined two models in which the pyridine ligand is involved via two or one atomic p orbitals of the π type (apart from the atomic σ orbitals forming σ-bonds with the silicon atom), but they were nevertheless unable to predict the stereochemistry of the adducts investigated and noted that the choice of configuration may be determined by other causes. Moreover, as has been pointed out correctly[20,23,93], one cannot solve unambiguously the problem of the configuration of the adduct on the basis of infrared spectroscopic data alone. Even the identification of the absorption bands corresponding to $\nu(Si-F)$ is usually difficult owing to the strong absorption by the ligands and the frequency shift due to the degeneracy of the vibrations[20,30]. Moreover, gaseous silicon tetrafluoride reacts with NaCl glasses, as a result of which the intensity of the band in the region of the $\nu(Si-F)$ absorption is appreciably enhanced[96]. Analogous difficulties arise also in the analysis of the infrared spectra of other coordination compounds of this type[97].

An X-ray diffraction study has been made so far only of one adduct ($SiF_4.2Py$), the structure of which was determined with the aid of the refined three-dimensional Patterson method and three-dimensional Fourier syntheses[98]. It was shown that the configuration of this adduct is centrosymmetric and *trans*-octahedral, of the type proposed previously[30,93] on the basis of infrared spectroscopic data. Analogous *trans*-octahedral configurations have also been demonstrated for the adducts $SiCl_4.2Py$,[99] $GeCl_4.2Py$,[100] $SnCl_4.2Py$, $SnBr_4.2Py$, $SeCl_4.2Py$, and $TeCl_4.2Py$.[101]

In the case of the diamine adducts reliable data are available only for the silicon tetrafluoride compound with 2,2′-bipyridyl. The ^{19}F NMR spectrum of the adduct $SiF_4.C_{10}H_8N_2$ dissolved in chloroacetonitrile shows at room temperature two equal-intensity triplets, which enabled the authors[37] to conclude that the compound has the *cis*-configuration. A little later the validity of this conclusion was confirmed by X-ray diffraction analysis, which showed that the molecules of the $SiF_4.C_{10}H_8N_2$ adduct are monomeric with a *cis*-disposition of the bipyridyl nitrogen atoms. The Si–N distances are 1.982 and 1.972 Å and the Si–F distances are longer by 0.025 Å for the axial fluorine atoms than for the equatorial atoms. The adducts of 2,2′-bipyridyl with germanium and tin tetrafluorides have an analogous structure[38].

Judging from the infrared spectroscopic data, the adducts of silicon tetrafluoride with 1,10-phenanthroline[30] and ethylenediamine[23] also have the *cis*-configuration. Aggarwal and Onyszchuk[23] noted that additional evidence in support of the *cis*-configuration is provided by the fact that the ethylenediamine molecule is too small to span two coordination sites in the *trans*-configuration. Earlier Gutmann et al.[21] attributed a "polymeric" structure of the following type to the 1 : 1 adducts of diamines:



These workers also assumed the octahedral configuration of the silicon atom but they quote no additional considerations in its support. This structure was later proposed for the isomeric silicon tetrafluoride adducts with phenylenediamine on the basis of a comparison of their thermal stabilities[41]. Evidently the problem of the type of coordination of the primary diamine adducts could be solved successfully with the aid of infrared spectroscopy, but unfortunately such studies have not yet been made.

There is much less information in the literature about the structures of the 1 : 1 adducts formed by silicon tetrafluoride with monodentate ligands. As mentioned above, sp^2d hybridisation has been attributed to the silicon atom in such compounds as a result of the involvement of one of its vacant $3d$ orbitals. Linnett and Mellish[102] showed that

the most probable locations of electrons with identical spins in the $sp^3d_{z^2}$ configuration are the corners of a trigonal bipyramid. The most probable locations for the $sp^3d_{x^2-y^2}$ configuration are provided by a tetragonal bipyramid in which the four electrons located in the base are not coplanar with the central nucleus, forming an angle of approximately 105° with the nucleus and with the electron located at the vertex. The trigonal bipyramidal (D_{3h}) and tetragonal pyramidal (C_{4v}) models for a molecule of the type SiX_5 are presented in Fig. 2.

where ΔH_1 is the enthalpy of formation of the solid adduct, ΔH_2 the enthalpy of desolvation of the ligand, ΔH_4 the crystal lattice energy determined by the dipole–dipole interaction and intramolecular hydrogen bonds, and ΔH_3 the enthalpy of formation of the adduct in the gaseous phase determined by the energy of the Si ← N donor–acceptor bond and intermolecular hydrogen bonds, if the latter exist.

Bearing in mind that the adducts investigated dissociate fully in the gas phase, Aylett et al.[22] concluded that $\Delta H_3 \ll \Delta H_4$ and that ΔH_4 is determined by the energy of the hydrogen bonds, the existence of which in the adducts of ammonia, hydrazine[17], methylamine[22], and primary aromatic amines[91] has been established by infrared spectroscopy. This conclusion agrees well with the finding that the values of ΔH^0 for the solid adducts of ammonia and primary and secondary amines differ little from one another but are appreciably higher than for tertiary amines (Table 5), although the electron-donating properties of pyridine resemble those of primary amines. The anomalous behaviour of pyridine can be readily explained on Mulliken's hypothesis[114] that the pyridine molecule can function not only as an n-donor but also as a π-donor, although the donor–acceptor bond in the adduct is formed via the nitrogen atom.

Unfortunately there are no methods so far for a direct measurement of ΔH_4. Therefore it is usually assumed that it varies little in a series of adducts with the same structures and similar molecular weights[115]. On the basis of these postulates and taking into account the results of earlier studies[32,109,111], Vandrish and Onyszchuk[110] estimated the relative electron-accepting capacities in the series of silicon and germanium tetrahalides investigated, with respect to pyridine and isoquinoline. They found that, as in the reaction with trimethylamine[108], $GeF_4 > SiF_4$, but were unable to reach any conclusions about the variation of the electron-accepting capacity in the series of silicon tetrahalides.

In view of the fundamental importance of this problem, the question of the reliability of the data merits consideration. Gur'yanov et al.[116] recently made a critical assessment of the methods described in the literature for the determination of the enthalpies of formation ΔH^0_{gas} of donor–acceptor compounds in the gas phase from the experimental heat change with the aid of a thermodynamic cycle. They noted that the hypothesis of the similarity of the crystal lattice energies is not always valid, because of difference between the enthalpies of sublimation in a series of similar compounds may be significant and comparable to ΔH^0_{gas} for these compounds[117]. Therefore, in using the heats of formation of the solid adducts as a measure of their relative stabilities, which has been done in a number of studies[109-111,113,118], very great caution must be exercised.

We believe that the attempt by Hensen and Sarholz[119] to estimate the relative electron-accepting capacities of silicon tetrahalides with respect to pyridine on the basis of the shift of the π–π^* transition band in the ultraviolet spectra of free and coordinated pyridine is even more controversial. These workers measured the ultraviolet absorption spectra of suspensions of many adducts in Nujol and found the halides can be arranged in the following sequence in terms of their electron-accepting capacity: $SiF_4 \simeq BF_3 < SiHCl_3 < GeCl_4 < SiCl_4 < SiBr_4$. On the basis of analogous measurements, the authors[39] later reported that the electron-accepting capacity with respect to 4,4′-bipyridyl decreases in the sequence $BF_3 < SiF_4 < SiBr_4$. It is noteworthy that Hensen and Sarholz's data[119] agree well with the conclusions of Wannagat et al.[111], but are in conflict with the results of later thermochemical measurements by Vandrish and Onyszchuk[110]. The latter workers also noted that a relation between the shifts in the ultraviolet spectra, the π-bonding effect, and the enthalpies of dissociation of adducts of the type $SiX_4.2Py$, formed mainly via σ bonds, has not so far been established, so that the earlier conclusions[39,119] require additional confirmation.

As mentioned above, the silicon tetrafluoride adducts with nitrogen-containing donors are much more stable than those with oxygen-containing donors (cf. Tables 5 and 6).

Table 6. Heats of dissociation of the adducts via the reaction $SiF_4.2ether(solid) \rightleftharpoons SiF_4(gas) + 2ether(gas)$ [58].

Adduct	$\Delta H°$, kcal mole^{-1}	Adduct	$\Delta H°$, kcal mole^{-1}
$SiF_4 \cdot 2(CH_2)_2O$	10.7±0.2	$SiF_4 \cdot 2(CH_2)_5O$	10.9±0.3
$SiF_4 \cdot 2(CH_2)_3O$	13.6±0.1	$SiF_4 \cdot 2Me_2O$	9.0±0.1
$SiF_4 \cdot 2(CH_2)_4O$	11.7±0.1		

Unfortunately in this case too the crystal lattice energies are unknown and the differences between the enthalpies of dissociation are too small to reach final conclusions about the relative electron-donating capacities of the ethers investigated. The most stable of the compounds listed, $SiF_4.2(CH_2)_3O$, does not decompose up to 13.6°C, while the remaining adducts exist only below 0°C.

It is noteworthy that BF_3 and GeF_4 form more stable adducts with ethers than does silicon tetrafluoride. Thus the compounds $GeF_4.2R$ (R = methyl ether, tetrahydropyran, or tetrahydrofuran) remain solid at 25°C, although in the case of epoxy-ethane the adduct decomposes at temperatures above −78°C.[57] The boron trifluoride compounds with Me_2O, $(CH_2)_4O$, and $(CH_2)_5O$ are stable liquids at 25°C, the first two distilling without decomposition[120]. The differences between the electron-accepting capacities of the above fluorides are shown particularly clearly with respect to 1,4-dioxane. Although silicon tetrafluoride does not react with the latter even at −94°C, GeF_4 forms with it a 1 : 1 adduct, which sublimes at 125°C and BF_3 forms 1 : 1 and 1 : 2 adducts, the first of which is a white powder at 25°C and the second a colourless liquid[58]. On the basis of a comparison of the behaviour of SiF_4 and GeF_4 with respect to oxygen-containing donors, Aggarwal and Onyszchuk[121] concluded that germanium tetrafluoride is a more powerful electron acceptor than silicon tetrafluoride. This can be explained by the decrease of $p\pi$–$d\pi$ binding on passing from silicon tetrafluoride to germanium tetrafluoride.

Interesting conclusions concerning the variation of electron accepting capacity in the series of silicon tetrahalides were arrived at on the basis of measurements of the vapour pressures of the adducts of SiF_4, $SiCl_4$, and $SiBr_4$ with trimethylamine and trimethylphosphine. Assuming that of two adducts which have similar structures and molecular weights, the thermodynamically more stable adduct has a lower vapour pressure, Beattie and Ozin[63] obtained the following sequences: $SiF_4 \ll SiCl_4$, $SiBr_4$ with respect to trimethylphosphine, $SiF_4 > SiCl_4 > SiBr_4$ with respect to trimethylamine, and $Me_3P \gg Me_3N$ with respect to $SiCl_4$ and $SiBr_4$. Beattie and Ozin[63]

examined the influence of steric factors, the possibility of the formation of bonds not involving the *d* orbitals, and the differences between the rearrangement energies of silicon tetrafluoride and other silicon tetrahalides, but they were still unable to show which of these factors determined the relative electron-accepting capacities with respect to each of the ligands indicated.

Silicon is a typical element of the class of "hard" acids, for which N ≫ P > As > Sb. At the same time the "hardness" of an acid is a function of the oxidation state of the central atom and depends to an equal extent on the nature of the groups linked to this atom [122]. Evidently the anomalous sequence of changes in the stability of the silicon tetrahalide adducts described above is determined by the differences between the electron-accepting capacities of the silicon atom in silicon tetrafluoride and other silicon tetrahalides ($SiCl_4$ and $SiBr_4$), which makes the study of the electron-accepting capacity of silicon tetrafluoride particularly interesting.

---o0o---

The review has shown that the individual aspects of the chemistry of silicon tetrafluori have now been investigated in fair detail. This applies primarily to problems of the stoichiometry and thermal transformations of adducts with nitrogen-containing donors. The interaction of silicon tetrafluoride with oxygen-containing donors has been less thoroughly studied, although there are literature data concerning the high catalytic activity of silicon tetrafluoride in the esterification of carboxylic acids [55,123,124] and in the polymerisation of epoxides [56,125]. There are few data on the reactions of silicon tetrafluoride with other donors, for example phosphorus- and sulphur-containing donors, and also with complex ligands, which hinders a comparative assessment of the electron-accepting capacities of silicon tetrafluoride and other silicon tetrahalides. The lack of thermodynamic quantities characterising directly the strength of the Si ← N, Si ← P, etc. coordinate bonds is particularly serious, which precludes any quantitative assessment of the electron-accepting capacity of silicon tetrafluoride. On the whole, we believe that, together with thermodynamic studies, the investigation of the structures of the 1 : 1 adducts of monoamines and diamines and also fo the reactions of the adducts with formation of fluorine-containing silicon–nitrogen compounds, which frequently exhibit enhanced thermal and hydrolytic stabilities [72,88], is especially interesting at the present stage.

Metallocarboranes

L.I.Zakharkin and V.N.Kalinin

A systematic account is given of the literature data on metallocarboranes. Particular attention is devoted to methods of their synthesis and their structures. The characteristic differences between metallocarboranes with π-linked carboranyl ligands and their π-cyclopentadienyl analogues are considered.
The bibliography includes 134 references.

I. INTRODUCTION

A new field in the chemistry of organic derivatives of the elements arose recently and has been developing vigorously—the chemistry of polyhedral carboranes. One of the most interesting properties of compounds of this class is the ability of carboranes or products of their partial degradation to react with derivatives of transition or non-transition metals to form metallocarboranes containing metal atoms at one or several vertices of the molecule. As a rule, transition metals combine with the carborane fragment in π-type complexes, as happens in their classical cyclopentadienyl derivatives. The bond between non-transition metals and the carbon and boron atoms of the polyhedron is described in terms of many-centre bonds, the main principles of which have been described in Lipscomb's monograph[1] on boron hydrides. The vigorous development of the chemistry of metallocarboranes, particularly in recent years, led us to write the present review, since the reviews in the literature are obsolete[2-4] or deal with selected studies by individual groups of workers[5-8].

In the present review the data have been arranged systematically in terms of types of metallocarboranes. The dicarbollyl complexes of transition metals, the largest class of metallocarboranes, are discussed first. Problems associated with metallocarboranes based on π-mono- and π-hetero-carbollyl ligands isoelectronic with the π-dicarbollyl ligand are considered next. This is followed by an examination of metallocarboranes containing a transition metal (in the vast majority of cases cobalt) and π-linked ligands comprising lower carboranes. The next section deals with metallocarboranes obtained by the polyhedral expansion reaction. Metallocarboranes containing a non-transition metal in the polyhedral molecule are considered in the last section.

Particular attention has been devoted in this review to the methods of synthesis and the structures of metallocarboranes and their most interesting physicochemical characteristics are described. The review embraces all studies in 1965–1972 (and partly in 1973).

II. NOMENCLATURE

The nomenclature in the field of metallocarboranes constitutes a fairly complex problem in view of the wide variety of carborane systems behaving as ligands and the continuous appearance of new derivatives the names of which do not fit within the framework of the IUPAC rules[9]. Therefore, together with the adopted nomenclature, we shall employ the trivial nomenclature widely used in the literature, which greatly simplifies the discussion of the problem and is to a large extent consistent with the literature data. The advantage of this approach to the problem consists also in a considerable abbreviation of the names of the compounds under consideration. For example, instead of the IUPAC name "caesium 3,3′-*commo*-bis(nonahydro-1,2-dicarba-3-chroma-*closo*-dodecaborate) we shall call the compound $[(B_9C_2H_{11})_2Cr]^-Cs^+$, the "caesium salt of bis(dicarbollyl)chromium". We may note that in the IUPAC nomenclature the terms "*commo*" and "*closo*" denote a closed polyhedral system and the term "*nido*" denotes structures containing open planes or B–H–B bridging linkages. The presence of carbon atoms in the polyhedron is designated by the term "*carba*" and their number is given by the prefixes mono-, di-, etc. The number of boron atoms is designated respectively by monobora, dibora, etc. One of the most widely investigated ions employed as a π-ligand, $B_9C_2H_{11}^{2-}$, has been called "dicarbollide" and the isoelectronic ions $B_{10}CH_{11}^{3-}$, $B_9CPH_{10}^{2-}$, and $B_9CAsH_{10}^{2-}$ have been called "carbollide", "phosphacarbollide", and "arsacarbollide" respectively. The numerals before the π-ligand formula denote the position of the carbon atoms or those of carbon and an element (phosphorus, arsenic) in the carborane moiety. For example, the carbon atoms in 1,2-$B_9C_2H_{11}^{2-}$ are in the 1- and 2-positions of the dicarbollyl ligand and in 1,7-$B_9CPH_{10}^{2-}$ the carbon atom is in the 1-position and the phosphorus atom in the 7-position of the phosphacarbollyl ligand. The number in brackets before the name of the ligand denotes the position occupied by the metal in the polyhedron.

III. π-COMPLEXES BASED ON PRODUCTS OF PARTIAL DEGRADATION OF CARBORANES

1. Dicarbollyl Complexes of Transition Metals

Icosahedral carboranes $B_{10}H_{10}C_2H_2$ interact with nucleophilic agents such as alkali metal alkoxides[10-12] and amines[13,14]. This results in the removal of the boron atom from the 3-position in *o*- and *m*-carborane rings and in the formation

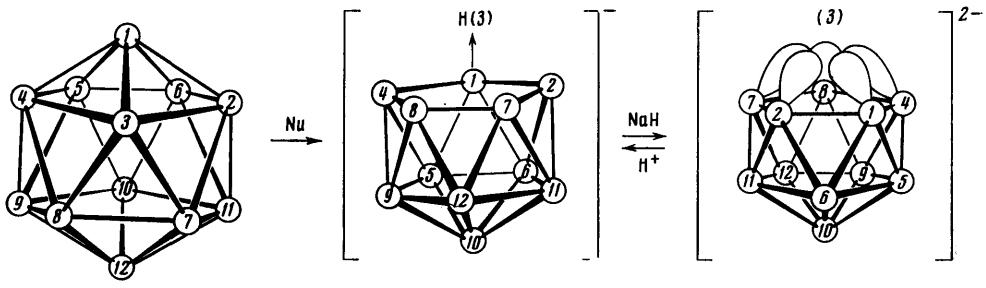

Figure 1.

of dicarbaundecaborate anions $B_9C_2H_{12}^-$. As shown for the first time by Hawthorne and coworkers[15,16], dicarbaundecaborate anions are acids which split off a proton on treatment with sodium hydride and give rise to the dicarbollide ion $B_9C_2H_{11}^{2-}$. The pK_a of the dicarbaundecaborate anion has been determined[17,18] and amounts to 21.3. Butyllithium has been used in some cases to generate the dicarbollide ion[19]. It has been shown that in a strongly alkaline medium there is an equilibrium between the dicarbaundecaborate and dicarbollide ions[16]; this has been used to obtain transition metal complexes in an aqueous medium. The (3)-1,2-$B_9C_2H_{11}^{2-}$ and (3)-1,7-$B_9C_2H_{11}^{2-}$ ions are isoelectronic with the hypothetical ion $B_{11}H_{11}^{4-}$. A structural scheme for the synthesis of dicarbollide ions is presented below (Fig. 1). Fig. 1 shows that the dicarbollide ion is a fragment of an icosahedron and consists of nine BH and two CH units. In the (3)-1,2-$B_9C_2H_{11}^{2-}$ ion the carbon atoms adjoin one another and in the (3)-1,7-$B_9C_2H_{11}^{2-}$ ion they are separated by a boron atom. According to the quantum-mechanical description of the dicarbollide ion[16], five atomic orbitals, largely sp^3-hybridised, are directed from the five atoms in the pentagonal B_3C_2 plane to the vacant position at the apex; six electrons are distributed in these orbitals. The combination of these atomic orbitals leads to one strongly bonding a_1-orbital, two degenerate bonding e_1-orbitals, and two strongly anti-bonding e_2-orbitals. Six electrons occupy the a_1- and both e_1-orbitals. In the reaction of the dicarbollide ion with transition metal salts dicarbollide complexes of the general type $(\pi\text{-}B_9C_2H_{11})_2M$ are formed. On the other hand, when the reaction is carried out in the presence of the cyclopentadienide ion, complexes of the type $[(\pi\text{-}C_5H_5)M\ (\pi\text{-}B_9C_2H_{11})]$ in some cases are formed. We shall examine the dicarbollyl complexes in terms of groups of transition metals.

A. The Iron Group

In the iron group (Fe, Ru, Os) the dicarbonyl complexes have been obtained for iron only. They were the first examples of metallocarboranes in which the transition metal is linked by a π-bond to the carborane moiety[15,20]. Hawthorn and coworkers[15,16] found that the 1,2-dicarbollide ion reacts with iron(II) chloride in tetrahydrofuran (THF) to form the bis(dicarbollyl)iron dianion $[(\pi\text{-}1,2\text{-}B_9C_2H_{11})_2Fe^{II}]^{2-}$ in which the iron atom is in the +2 formal oxidation state (FOS). This ion is readily oxidised by atmospheric oxygen to $[(\pi\text{-}1,2\text{-}B_9C_2H_{11})_2Fe^{III}]^-$ — an analogue of the ferrocinium ion. The structures of the dicarbollyliron complexes are presented in Fig. 2.

A detailed method for their synthesis in an aqueous medium has been published[21]. Iron(II) complexes are mainly obtained by the reduction of the corresponding iron(III) complexes with sodium amalgam:

$$1.2\text{-}B_9C_2H_{11}^{2-} + FeCl_3 \rightarrow [(\pi\text{-}1,\ 2\text{-}B_9C_2H_{11})_2Fe^{II}]^{2-} \underset{Na/Hg}{\overset{O_2}{\rightleftarrows}} [(\pi\text{-}1,\ 2\text{-}B_9C_2H_{11})_2Fe^{III}]^- .$$

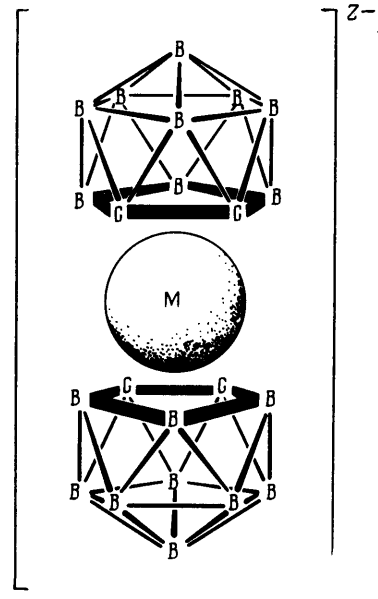

Figure 2.

Complexes based on *CC'*-dimethyl- and *C*-phenyl-1,2-dicarbollide ions have been obtained[16]. A method for the synthesis of dicarbollyliron complexes via the dithallium derivative of 1,2-dicarbollide was proposed recently[22]. The bis(dicarbollyl)iron(III) ion is resistant to the reaction of strong acids and alkalies and is thermally stable up to 300°C, but the corresponding *CC'*-dimethyl- and *C*-phenyl derivatives decompose in an aqueous alkaline solution on boiling via the mechanism

$$[(\pi\text{-}1,\ 2\text{-}B_9C_2H_9Me_2)_2Fe]^- + OH^- + 2H_2O \rightarrow 2\,[1,\ 2\text{-}B_9C_2H_{10}Me_2]^- + Fe(OH)_3.$$

Like ferrocene, the iron(II) complexes have the d^6 configuration and are diamagnetic, while the iron(III) complexes are paramagnetic. When a mixture of $C_5H_5^-$ and $1,2\text{-}B_9C_2H_{11}^{2-}$ ions was treated with iron(II) chloride in THF, low yields of π-cyclopentadienyl-π-dicarbollyliron complexes with the iron atom in the +2 or +3 formal oxidation state were obtained:

$$C_5H_5^- + 1,2\text{-}B_9C_2H_{11}^{2-} + FeCl_2 \rightarrow [(\pi\text{-}C_5H_5)\,Fe\,(1,2\text{-}B_9C_2H_{11})]^- \underset{Na/Hg}{\overset{[O]}{\rightleftarrows}} (\pi\text{-}C_5H_5)\,Fe\,(1,2\text{-}B_9C_2H_{11})\ .$$

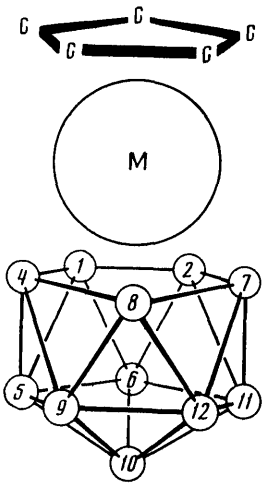

Figure 3.

A convenient method for the synthesis of the neutral complex $(\pi\text{-}C_5H_5)Fe(1,2\text{-}B_9C_2H_{11})$ in methanol with a yield in excess of 50% was proposed recently[23]. The structure of the π-cyclopentadienyl-π-dicarbollyliron(III) was determined[24] and the sandwich type of binding in this complex was confirmed (Fig. 3). It is interesting that the distances from the iron atom to the carbon atoms of the cyclopentadienyl ring and to the carbon and boron atoms in the pentagonal plane of the dicarbollyl ligand are the same, amounting to approximately 2.07 Å. The ESR spectra of all the dicarbollyliron(III) complexes showed the presence of an unpaired electron[25]. The experimental effective magnetic moments of the iron(III) complexes[26] were found to agree well with the values calculated theoretically[27]. Studies on the Mössbauer spectra of the complexes

$$[(\pi\text{-}1,2\text{-}B_9C_2H_{11})_2Fe^{III}]^-,\ (\pi\text{-}C_5H_5)\,Fe^{III}\pi\text{-}1,2\text{-}B_9C_2H_{11}]$$
$$[(\pi\text{-}1,2\text{-}B_9C_2H_{11})_2Fe^{II}]^{2-} \text{ and } [(\pi\text{-}C_5H_5)\,Fe^{II}\,(\pi\text{-}1,2\text{-}B_9C_2H_{11})]^-$$

showed[28,29] that their quadrupole splitting parameters are analogous to the values for the corresponding biscyclopentadienyl derivatives, although they are somewhat higher. The reason for this is the higher s-electron density at the iron atom in the dicarbollyl complexes than in the cyclopentadienyl complexes, which suggests a more effective withdrawal of d electrons through π-bonding from the metal in the former case.

In C-substituted derivatives the bis-(1,2-dicarbollyl)-iron(II)$^{2-}$ residue exhibits powerful electron-donating properties both via the inductive mechanism ($\sigma_I = -0.27 - -0.43$) and via the conjugative mechanism ($\sigma_R = -0.15 - -0.22$), the properties being more pronounced than those of the ferrocenyl group[30]. The ^1H and ^{11}B NMR spectra and the oxidation-reduction potentials of dicarbollyliron complexes have been published[16]. The latter are presented in Table 1.

The reduction potentials of π-(3)-1,2-dicarbollyliron(III) complexes in 50% aqueous acetone.

Compound	$E_{1/2}$ for $M^{III} + e^- \rightarrow M^{II}$, mV	Compound	$E_{1/2}$ for $M^{III} + e^- \rightarrow M^{II}$, mV
$Me_4N[(1,2\text{-}B_9C_2H_{11})_2Fe]$	−0.424	$Me_4N[(1,2\text{-}B_9C_2H_{10}Ph)_2Fe]$	−0.464
$Me_4N[(1,2\text{-}B_9C_2H_9Me_2)_2Fe]$	−0.538	$(C_5H_5)Fe(1,2\text{-}B_9C_2H_{11})$	−0.080

One should note the higher thermal stability and the higher resistance to the action of acids and bases of the dicarbollyliron complexes compared with their cyclopentadienyl analogues—ferrocene and the ferrocenium ion. In contrast to ferrocene, the dicarbollyliron(II) complexes are rapidly oxidised to iron(III) complexes, which are more stable in this case.

When the 1,2-dicarbollide ion was treated with an excess of iron pentacarbonyl, a dimeric carbonyl product with π-dicarbollyl ligands was obtained[31]:

$$1,2\text{-}B_9C_2H_{11}^{2-} + Fe(CO)_5 \xrightarrow[70^\circ]{THF} \{[\pi\text{-}(3)\text{-}1,2\text{-}B_9C_2H_{11}]_2Fe_2(CO)_4\}^{2-}\ .$$

In the solid state the complex in the form of the tetramethylammonium salt decomposes slowly in air, while in solution in acetone or acetonitrile the decomposition is rapid. The *trans*-structure proposed initially for the dimer[31] was not confirmed and it was shown that, like $[\pi\text{-}C_5H_5Fe(CO)_2]_2$, the μ-carbonylbis-[π(3)-1,2-dicarbollyl-iron] dianion has the *cis*-configuration[32].

The chemistry of dicarbollyliron complexes has been little investigated. It has been established that in a strongly acid medium (concentrated HCl, $HClO_4$–CH_3OH), the complex $[(\pi\text{-}1,2\text{-}B_9C_2H_{11})_2Fe^{II}]^{2-}$, which is an analogue of ferrocene, is protonated[33], but the ^1H NMR spectrum of $[(\pi\text{-}1,2\text{-}B_9C_2H_{11})_2Fe^{II}H]^{2-}$ in a high field does not show the hydrogen signal characteristic of the protonated form of ferrocene $(C_5H_5)_2FeH^+$. The appearance in the infrared spectrum of $[(1,2\text{-}B_9C_2H_{11})_2FeH]^-$ of a band at 1835 cm^{-1} can equally indicate both the presence of an Fe–H bond and of B–H–B bridging linkages. For this reason, the available data do not allow a choice between these two alternative schemes[33]. It has been shown that the protonated form of bis-(1,2-dicarbollyl)iron(II) reacts smoothly with dialkyl sulphides, the reaction being accompanied by the evolution of hydrogen and the formation of *B*-substituted products[33]:

$$R_2S + [HFe^{II}(1,2\text{-}B_9C_2H_{11})_2]^- \rightarrow H_2 + [Fe^{II}(1,2\text{-}B_9C_2H_{11})(1,2\text{-}B_9C_2H_{10}SR_2)]^-\ .$$

The latter are readily oxidised with formation of neutral stable paramagnetic iron(III) complexes. The reverse reduction process is also possible:

$$[Fe^{II}(1,2\text{-}B_9C_2H_{11})(1,2\text{-}B_9C_2H_{10}SR_2)]^- \underset{+e^-}{\overset{-e^-}{\rightleftarrows}} [Fe^{III}(1,2\text{-}B_9C_2H_{11})(1,2\text{-}B_9C_2H_{10}SR_2)]^0\ .$$

When hydrogen chloride was passed into a suspension of $[(1,2\text{-}B_9C_2H_{11})_2Fe^{III}]^-Cs^+$ in diethyl sulphide, a very low yield of the disubstituted complex $Fe^{II}(1,2\text{-}B_9C_2H_{10}SEt_2)_2$ was isolated together with the monosubstituted product. Chemical oxidation of the disubstituted complex led to the first example of cationic bis(dicarbollyl)metal complexes,

namely $[(1,2\text{-}B_9C_2H_{10}SEt_2)_2Fe^{III}]^+$.[33] The substitution mechanism at the boron atom of the dicarbollyl ligand is regarded as acid-catalysed nucleophilic substitution in which the proton removes the most hydridic hydrogen atom of the ligand with subsequent attack by the nucleophile at this position. The structure of the boron-substituted complexes, an example of which is presented in Fig. 4, was established on the basis of ^1H and ^{11}B NMR data.

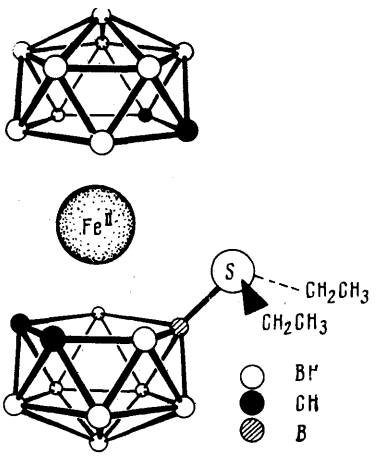

Figure 4.

When hydrogen chloride is passed into suspension of $[(1,2\text{-}B_9C_2H_{11})_2Fe^{III}]^-K^+$ in CS_2 in the presence of $AlCl_3$, a bridge-type dicarbollyl complex with an electron-deficient carbon atom is formed[34]:

$$[(1,2\text{-}B_9C_2H_{11})_2Fe]^- + CS_2 + H^+ \rightarrow \begin{matrix} 1,2\text{-}B_9C_2H_{10}S \\ Fe \\ 1,2\text{-}B_9C_2H_{10}S \end{matrix}\!\!>\!\!^{+}CH \ .$$

B. The Cobalt Group

In the cobalt group (Co, Rh, Ir) dicarbollyl complexes are known for cobalt only. The reaction of the 1,2-dicarbollide ion with cobalt chloride gives a high yield of the bis-(1,2-dicarbollyl)cobalt anion with the cobalt atom in the +3 formal oxidation state[16,35], the anion being an analogue of the cobalticinium ion:

$$2\,(3)\text{-}1,2\text{-}B_9C_2H_{11}^{2-} + 1,5\text{-}CoCl_3 \rightarrow \{[\pi\text{-}(3)\text{-}1,2\text{-}B_9C_2H_{11}]_2Co\}^- + 3Cl^- + 0.5Co^0 \ .$$

A complex with the ion (3)-1,7-$B_9C_2H_{11}^{2-}$ – $\{[\pi\text{-}(3)\text{-}1,7\text{-}B_9C_2H_{11}]_2CO\}^-$ was obtained analogously. When $CoCl_2$ interacts with a mixture of $C_5H_5^-$ and 1,2- or 1,7-$B_9C_2H_{11}^{2-}$ ions, neutral π-cyclopentadienyl-π-(3)-dicarbollylcobalt complexes are formed[16,35].

Improved methods for the synthesis of (π-C_5H_5)Co(π-1,2-$B_9C_2H_{11}$) complexes were proposed recently[23,36]. Dicarbollylcobalt complexes can be obtained via the dithallium dicarbollide[22]. X-Ray diffraction analysis of the caesium salt of bis-[(3)-1,7-dicarbollyl]cobalt(III)[37] confirmed that the structure presented in Fig. 2 is general. A series of π-cyclopentadienyl-π-C-substituted 1,2-dicarbollylcobalt complexes have been obtained[16,38], among which the greatest interest attaches to $(C_5H_5)Co^{III}[B_9C_2H_{10}\cdot(CH_2OH)]$. When CrO_3 was allowed to react with this complex, the *C*-formyl and *C*-carboxy-derivatives were synthesised[38]. The greater ease of the oxidation of the CH_2OH group to CHO compared with the oxidation of the latter to COOH is unusual in this case. The acid chloride was obtained from the acid; it enters into the Friedel–Crafts reaction with benzene in the presence of $AlCl_3$, giving a ketone:

$$(C_5H_5)Co[B_9C_2H_{10}(COCl)] + C_6H_6 \xrightarrow{AlCl_3} (C_5H_5)Co[B_9C_2H_{10}(COC_6H_5)] \ .$$

The pK_a for the acid $(C_5H_5)Co[B_9C_2H_{10}(COOH)]$ in 50% ethanol is 3.54.[38]

It is impossible to isolate dicarbollylcobalt(II) complexes. This suggests that the cobalt(II) complexes formed initially are rapidly oxidised by cobalt chloride with formation of very stable bis(dicarbollyl)cobalt(III) salts with the d^6 configuration. However, the existence of cobalt(II) complexes is supported by the oxidation-reduction potentials obtained by polarographic and cyclic volt-amperometric methods, which indicate the occurrence of one-electron reduction of bis(dicarbollyl)cobalt(III) and its *C*-substituted derivatives, i.e. the transition $d^6 \rightarrow d^7$ or $M^{III} + e^- \rightarrow M^{II}$.

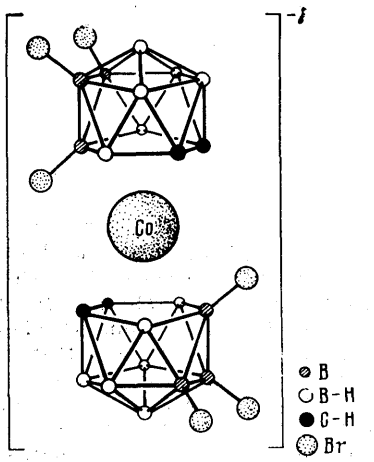

Figure 5.

In the case of an unsubstituted complex, the reversible one-electron M^{III} oxidation wave is observed at +1.57 mV, which led to the hypothesis that a dicarbollyl complex with a cobalt atom in the +4 formal oxidation state exists[16]. A careful electrochemical study of dicarbollylcobalt complexes led to the conclusion that the dicarbollyl ligand stabilises the metal in both the highest and the lowest oxidation states and for the complexes (π-C_5H_5)Co(π-1,2-$B_9C_2H_{11}$) and $[(\pi\text{-}1,2\text{-}B_9C_2H_{11})_2Co]^-$ the $M^{III} + e^- \rightarrow M^I$ transition is observed at –2.11 and –2.24 mV respectively together with $M^{III} + e^- \rightarrow M^{II}$.[39]

Bromination of the rubidium salt of $[(1,2\text{-}B_9C_2H_{11})_2Co]^-$ in acetic acid gave the hexabromo-derivative[16], where there are three halogen atoms in each π-ligand according to X-ray diffraction data[40] (Fig. 5). This compound is

interesting in the sense that its two one-electron reduction waves corresponding to the processes

$$Co^{III} + e^- \xrightarrow{-0.48\ mV} Co^{II} \text{ and } Co^{II} + e^- \xrightarrow{-1.48\ mV} Co^{I},$$

are displaced to the region of highly positive potentials and clearly confirm the possibility of the existence of π-bonded cobalt d^8-complexes[16].

The 1,2-dicarbollide ion reacts with dicobalt octacarbonyl to form π-dicarbollyldicarbonylcobalt, which is readily oxidised[30]:

$$2(1,2\text{-}B_9C_2H_{11}^{2-}) + Co_2(CO)_8 \rightarrow 2\{[\pi\text{-}(3)\text{-}1,2\text{-}B_9C_2H_{11}]Co(CO)_3\}^- + 4CO.$$

In the synthesis of dicarbollyl complexes in a highly alkaline medium there is a possibility of further degradation of the dicarbollyl ligand in the complex with elimination of the BH unit. In this case the product is the bidentate π-bonding ligand $B_8C_2H_{10}^{4-}$, which has been called the (3,6)-1,2-dicarbanastide ion, whose interaction with an excess of the transition metal salt and the π-ligands leads to two- and three-metal derivatives. Thus in a highly alkaline medium $[(1,2\text{-}B_9C_2H_{11})_2Co]^-$ is converted by $CoCl_2$ and $1,2\text{-}B_9C_2H_{11}^{2-}$ ions into

$\{[(3)\text{-}1,2\text{-}B_9C_2H_{11}]Co[(3,6)\text{-}1,2\text{-}B_8C_2H_{10}]Co[(3)\text{-}1,2\text{-}B_9C_2H_{11}]\}^{2-}$ (Fig.6)

and $[\{[(3)\text{-}1,2\text{-}B_9C_2H_{11}]Co[(3,6)\text{-}1,2\text{-}B_8C_2H_{10}]\}_2Co]^{3-}$ (Fig.7) [41-44].

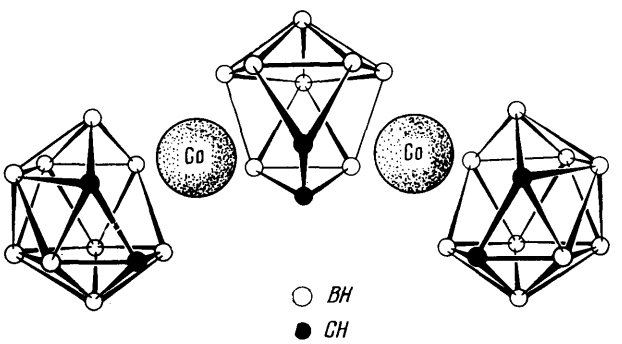

Figure 6.

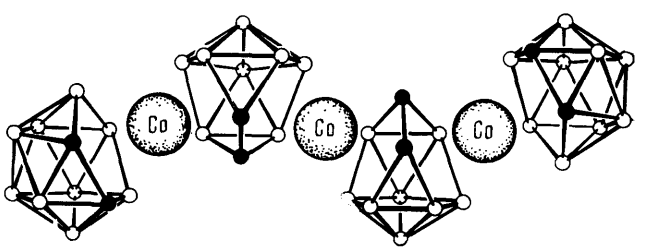

Figure 7.

$(C_5H_5)Co(1,2\text{-}B_9C_2H_{11})$ reacts with $CoCl_2$ and $C_5H_5^-$ in the presence of alcoholic alkali to form $[(C_5H_5)Co]_2[(3,6)\text{-}B_8C_2H_{10}]$ (Fig. 8) and $\{(C_5H_5)Co[(3,6)\text{-}1,2\text{-}B_8C_2H_{10}]\}_2Co$ (Fig. 9).[36] The ^{11}B NMR spectra of the $\eta[\pi\text{-}(3)\text{-}1,2\text{-}B_9C_2H_{11}]_2Co\}^-$ ion and of its *B*-deuteriated and *B*-halogenated derivatives have been recorded[45] at 70.6 MHz and the signals in the spectrum have been assigned to the corresponding boron atoms in the ligand. On the basis of the ^{59}Co NQR spectra of $Cs(\pi\text{-}1,2\text{-}B_9C_2H_{11})_2Co$, Harris[46] concluded that the π-dicarbollyl and π-cyclopentadienyl groups are almost indistinguishable as regards binding to Co^{III} and Fe^{II} and the boron atoms in the dicarbollyl ligand have an electron-donating capacity close to that of carbon atoms. However, subsequently this view was revised[28].

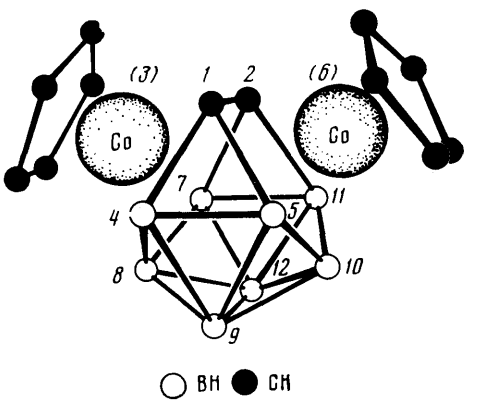

Figure 8.

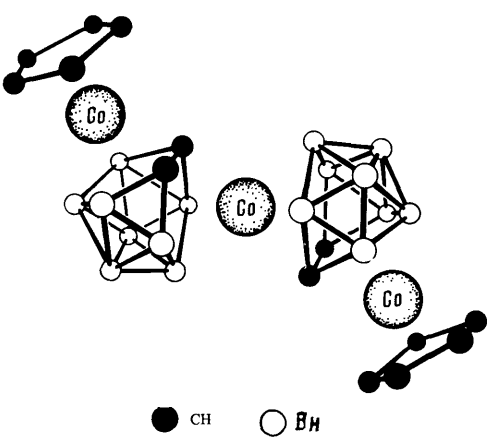

Figure 9.

As a substituent linked via the carbon atoms of the ligand, bis(dicarbollyl)cobalt is a weak electron acceptor via the inductive mechanism ($\sigma_i = -0.01 - 0.06$) and a moderately strong donor via the conjugative mechanism ($\sigma_R = -0.07 - -0.12$)[30]. The replacement of one dicarbollyl group by a cyclopentadienyl group increases the inductive electron-accepting capacity of the complex ($\sigma_i = 0.21$) but hardly alters the resonance electron-donating component ($\sigma_R - -0.10$). The ability of the bis(dicarbollyl) complex to enter into conjugation with π-substituents has been confirmed by the electronic spectra of bis-(*C*-alkenyldicarbollyl)cobalt[47].

In their attempts to alkylate bis(dicarbollyl)cobalt(III) under the conditions of the Friedel–Crafts reaction, Francis and Hawthorne[41,48] observed an interesting reaction involving the formation of a bridge-type derivative of the dicarbollyl complex with an electron-deficient carbon atom. When hydrogen chloride is passed into a suspension of bis(dicarbollyl)cobalt and $AlCl_3$ in CS_2, the –S–CH–S– bridge linked to the boron atoms of the ligands is formed between dicarbollyl ligands:

$$[(1,2\text{-}B_9C_2H_{11})_2Co]^- + CS_2 + H^+ \rightarrow \begin{matrix} 1,2\text{-}B_9C_2H_{10}S \\ Co^- \quad CH \\ 1,2\text{-}B_9C_2H_{10}S \end{matrix} \quad \text{(Fig. 10)}\ ^{49}$$

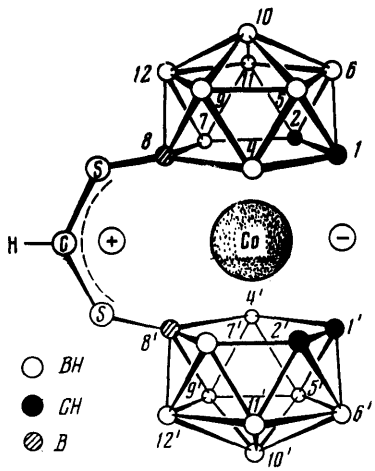

Figure 10.

The complex $(1,7\text{-}B_9C_2H_{10})_2CoS_2CH$ was obtained similarly from $\{[(3)\text{-}1,7\text{-}B_9C_2H_{11}]_2Co\}^-$. A bridge with an electron-deficient carbon atom is formed also in an acetic acid–acetic anhydride mixture in the presence of $HClO_4$ as a catalyst:

$$[(1,2\text{-}B_9C_2H_{11})_2Co]^- + MeCOOH \rightarrow (1,2\text{-}B_9C_2H_{11})Co(1,2\text{-}B_9C_2H_{10}OOCMe) \xrightarrow{H^+} \rightarrow (1,2\text{-}B_9C_2H_{10})_2CoO_2CMe\ .$$

The carbonium ionic centres in $(1,2\text{-}B_9C_2H_{10})_2CoS_2CH$ and $(1,2\text{-}B_9C_2H_{10})_2CoO_2CMe$ are relatively inactive with respect to protic solvents, probably owing to the proximity of the negative charges of the heteroatoms. A solution of $NaBH_4$ in ethanol reduces $(1,2\text{-}B_9C_2H_{10})CoS_2CH$ to $[(1,2\text{-}B_9C_2H_{10})_2CoS_2CH_2]^-$ in quantitative yield. Aqueous ethanol hydrolyses the bridge-type derivatives:

$$(1,2\text{-}B_9C_2H_{10})_2CoS_2CH \xrightarrow{EtOH,\ 70^\circ} \{[1,2\text{-}B_9C_2H_{10}(SH)]_2Co\}^-\ ,$$
$$(1,2\text{-}B_9C_2H_{10})_2CoO_2Me \xrightarrow{EtOH,\ 70^\circ} \{[1,2\text{-}B_9C_2H_{10}(OH)]_2Co\}^-\ .$$

Like bis(dicarbollyl)iron(II), bis(dicarbollyl)cobalt(III) enters into an acid-catalysed nucleophilic substitution reaction in diethyl sulphide, leading to a neutral product[33]:

$$[(1,2\text{-}B_9C_2H_{11})_2Co]^- + HCl + Et_2S \rightarrow Co(1,2\text{-}B_9C_2H_{11})[1,2\text{-}B_9C_2H_{10}SEt_2]\ .$$

When an aqueous solution of $K(1,2\text{-}B_9C_2H_{11})_2Co$ is treated with phenyldiazonium tetrafluoroborate, cation exchange and the formation of the phenyl diazonium salt of bis(dicarbollyl)cobalt$(PhN_2)^+[(1,2\text{-}B_9C_2H_{11})Co]^-$ are observed[50] instead of the expected formation of coupling or arylation products. At room temperature the salt is insoluble in benzene but on heating above 60°C it dissolves completely with liberation of a gas and the formation of biphenyl and a coupling product the structure of which is illustrated in Fig. 11. Decomposition of the phenyldiazonium salt in toluene and of the tolyldiazonium salt in benzene yielded coupling products containing the tolyl and phenyl groups respectively and methylbiphenyl, i.e. the aryl group from the diazonium cation does not enter into the composition of the complex. The reaction scheme in Fig. 12 was put forward on the basis of these products.

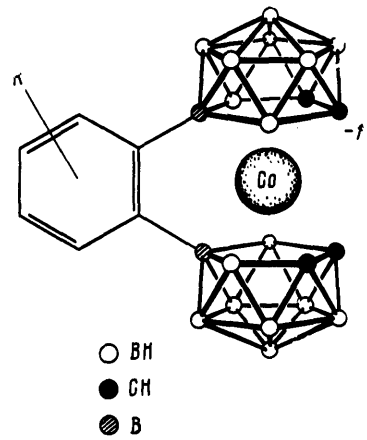

Figure 11.

The complexes $(\pi\text{-}C_5H_5)Co(\pi\text{-}1,2\text{-}B_9C_2H_{11})$ and $[(\pi\text{-}1,2\text{-}B_9C_2H_{11})_2Co]^-$ served as the starting materials for the synthesis of new metallocarboranes containing one and two boron atoms less than in the initial metallocarboranes[51,52]. The reaction has been called the "polyhedral contraction reaction". In general its equation is

$$[LCo(B_nC_2H_{n+3})]^z \xrightarrow[2.\ -2e^-]{1.\ -BH^{+}} [LCo(B_{n-1}C_2H_{n+1})]^g\ ,$$

where $z = 0$ for $L = C_5H_5^-$ and $z = -1$ for $L = (3)\text{-}1,2\text{-}B_9C_2H_{11}^{2-}$.

The base-catalysed degradation of the complexes with subsequent oxidation of the products by hydrogen peroxide gives rise to a new metallocarborane containing the π-(1)-2,4-$B_6C_2H_{10}^{2-}$ ion as one of the ligands (Fig. 13):

$$(\pi\text{-}C_5H_5)Co(\pi\text{-}1,2\text{-}B_9C_2H_{11}) \xrightarrow[2.\ H_2O_2]{1.\ OH^-} (\pi\text{-}C_5H_5)Co[\pi\text{-}(1)\text{-}2,4\text{-}B_6C_2H_{10}]\ ,$$
$$[(\pi\text{-}1,2\text{-}B_9C_2H_{11})_2Co]^- \xrightarrow[2.\ H_2O_2]{1.\ OH^-} \{[\pi\text{-}(3)\text{-}1,2\text{-}B_9C_2H_{11}]Co[\pi\text{-}(1)\text{-}2,4\text{-}B_6C_2H_{10}]\}^-\ .$$

The last complex forms with pyridine an inner salt having the composition $[\pi\text{-}(3)\text{-}1,2\text{-}B_9C_2H_{11}]Co[\pi\text{-}(1)\text{-}2,4\text{-}B_6C_2H_{10}\cdot C_5H_5N]$,[51] in which the 'onium nitrogen atom is linked to the boron atom of the π-(1)-2,4-$B_6C_2H_{10}$ ligand according to X-ray diffraction analysis[53,54]. Oxidation of complexes containing the (1)-2,4-$B_6C_2H_{10}$ ligand by iron(III) chloride in boiling ethanol results in their further degradation. In the case of the cyclopentadienyl-containing complex, a *nido*-metallocarborane is formed as the main product under these conditions. Like the neutral *nido*-carboranes $B_6C_2H_{12}$,[55–57] the *nido*-metallocarborane $(C_5H_5)Co(B_7C_2H_{11})$ slowly splits off hydrogen on heating to

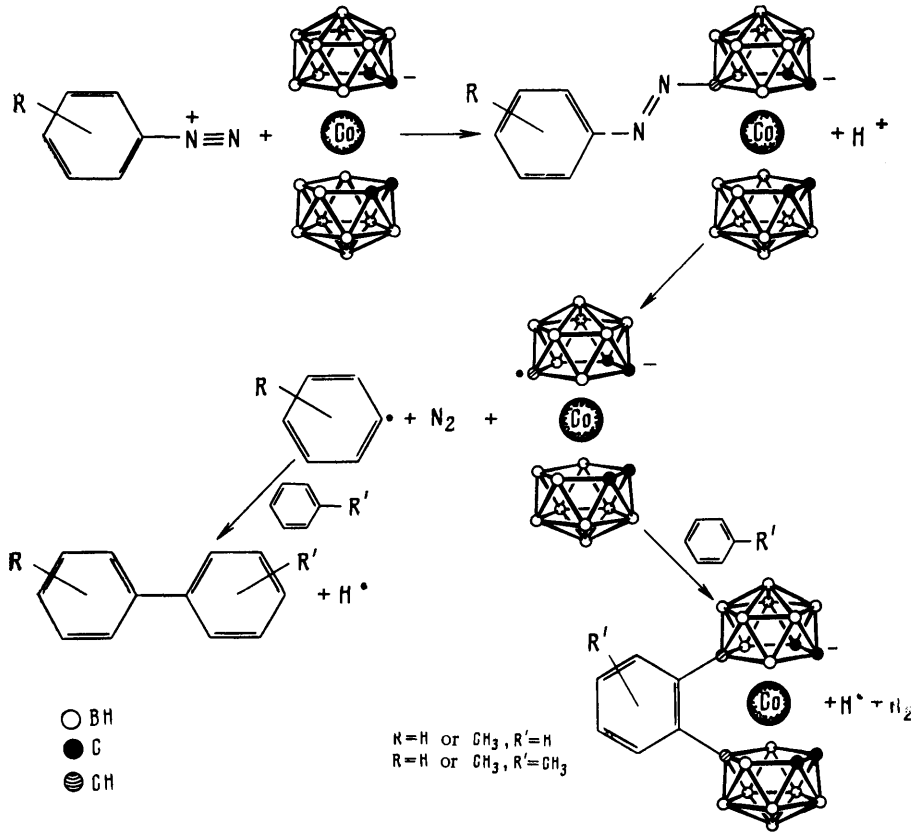

Figure 12.

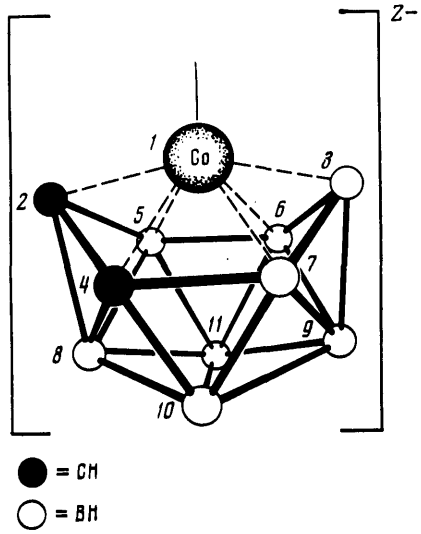

Figure 13.

70°C and is converted into a *closo*-metallocarborane with the π-(2)-6,7-$B_7C_2H_9$ ligand. However, at 70°C the π-(2)-6,7-$B_7C_2H_9$ ligand in the complex rearranges to π-(2)-1,6-$B_7C_2H_9$. Further rearrangement to the 1,10-isomer requires a temperature of 150°C.

The above sequence of reactions is illustrated schematically in Fig. 14. The complex $\{[\pi\text{-}(3)\text{-}1,2\text{-}B_9C_2H_{11}]Co.[\pi\text{-}(2)\text{-}1,6\text{-}B_7C_2H_9]\}^-$ was obtained similarly from $\{[\pi\text{-}(3)\text{-}1,2\text{-}B_9C_2H_{11}]Co[\pi\text{-}(1)\text{-}2,4\text{-}B_6C_2H_{10}]\}^-$ (Fig. 15).

An interesting property of π-cyclopentadienyl-π-(3)-1,2-dicarbollylcobalt and its *CC'*-dimethyl derivative is the ability to undergo a gas-phase rearrangement at 400–700°C with formation of isomeric complexes differing in the distribution of carbon atoms in the dicarbollyl ligand [58] (Fig. 16). In none of the isomers obtained do the carbon atoms in the ligand retain adjacent positions. Therefore the driving force of the rearrangement in the isomerisation of metallocarboranes as well as carboranes [4] is presumably the mutual repulsion of the carbon atoms, which are the most electropositive centres in the molecule.

C. The Nickel Group

In the nickel group (Ni, Pd, Pt) the dicarbollyl derivatives of all the metals are known. The paramagnetic complex $[(1,2\text{-}B_9C_2H_{11})_2Ni^{II}]^{2-}$ with the d^9 configuration, which is extremely readily oxidised to the nickel(III) complex with the d^7 configuration, was obtained by the reaction of the (3)-1,2-dicarbollide ion with nickel(II) salts in THF or in a highly alkaline medium [16,59]. Oxidation of the nickel(III) complex by iron(III) chloride leads to the neutral diamagnetic complex $(1,2\text{-}B_9C_2H_{11})_2Ni^{IV}$ with the d^6 configuration. Nickel complexes with the (3)-1,7-$B_9C_2H_{11}^{3-}$ ligand in which the nickel atom is in the +2, +3, and +4 formal oxidation states were obtained similarly [16].

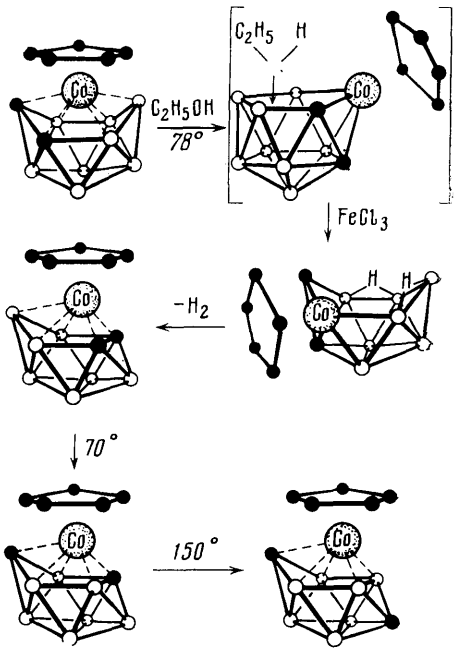

Figure 14.

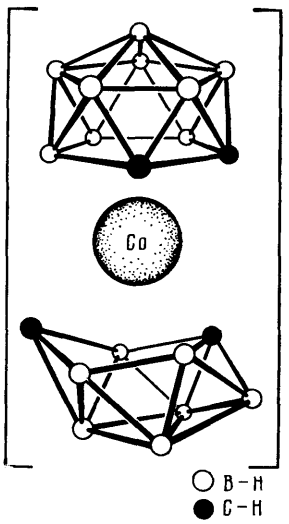

Figure 15.

Dicarbollylnickel complexes have characteristic structural features which depend on the formal oxidation state of the metal. The nickel(II) complexes have a distorted sandwich structure with the ligands displaced relative to one another in opposite directions (Fig. 17).[60] The nickel(III) complexes have the normal sandwich structure (Fig. 2), while a cisoid sandwich configuration, in which both carbon atoms of each ligand are located on the same side of the molecule, is characteristic of nickel(IV) (Fig. 18).[61] This gives rise to an appreciable dipole moment in $(1,2\text{-}B_9C_2H_{11})_2Ni^{IV}$, amounting, for example, to 6.16 D in cyclohexane. Owing to the high positive charge on the metal atom (+4), bis(dicarbollyl)nickel(IV) is a powerful-electron accepting substituent (σ_i = 0.50–0.65).[30] Complexes with *C*-methyl- and *C*-phenyl-1,2-dicarbollyl ligands have been obtained[62]. In this case enantiomers exist, so that three isomers are possible: the *meso*-isomer and the (±)-recemate. This was confirmed by the ^{19}F NMR spectra of *p*- and *m*-fluorophenyl-substituted nickel(IV) complexes, which contain two fluorine signals corresponding to the *meso*-form and the (±)-racemate.[30]

The complex $(1,2\text{-}B_9C_2H_{11})_2Ni^{IV}$ is readily reduced to $[(1,2\text{-}B_9C_2H_{11})_2Ni^{III}]^-$ by "hard" Lewis bases with some degradation of the complex[61]. An interesting property of

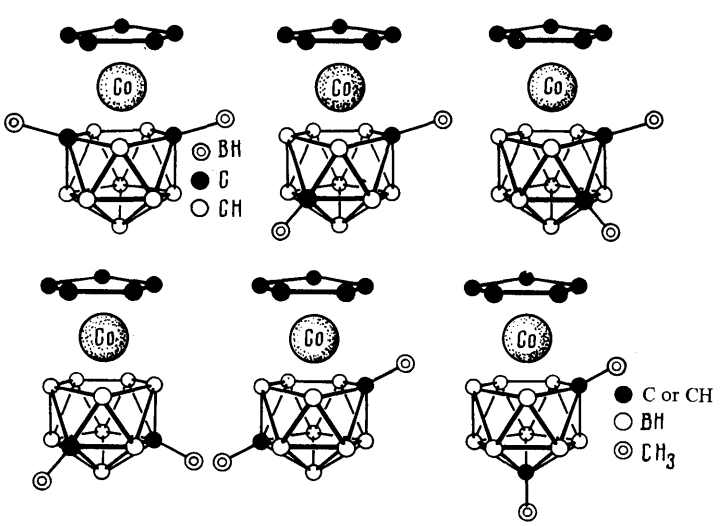

Figure 16.

$(1,2\text{-}B_9C_2H_{11})_2Ni^{IV}$ is the considerable acidity of the C–H bond in the dicarbollyl ligand, which was shown by the ease of deuterium exchange with D_2O in an alkaline medium, while in acid solutions (D_2SO_4 in DOAc) the deuterium exchange is slow and involves only the B–H bonds of the ligand. "Soft" Lewis bases, for example Cl^-, Br^-, and SCN^-, react with $(1,2\text{-}B_9C_2H_{11})_2Ni^{IV}$ to give 1 : 1 adducts, which can be isolated in a crystalline form. Similar adducts have been obtained with condensed aromatic hydrocarbons—pyrene naphthalene, and phenanthrene—and aromatic *n*-bases such as dimethylaniline [61].

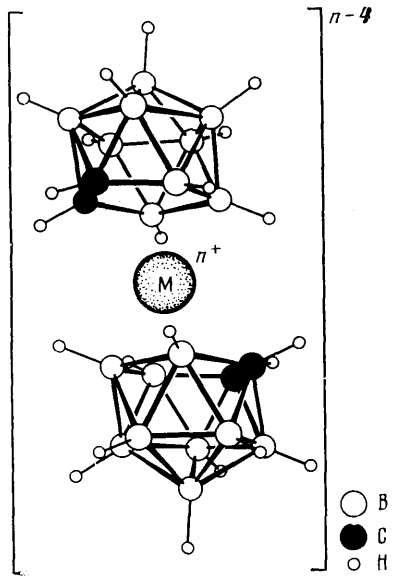

Figure 17.

Molecular rearrangements characteristic of metallocarboranes can be observed in *CC'*-disubstituted dicarbollylnickel complexes. There is a possibility of three isomeric series of compounds [62-64]: series A—compounds with adjacent carbon atoms on the binding surfaces of both ligands; series B—compounds with adjacent carbon atoms in both ligands but in one of the ligands one carbon atom is displaced to the interior of the ligand so that its binding plane contains four boron atoms and one carbon atom; series C—compounds with adjacent carbon atoms in both ligands and with (B_4C) binding surfaces. The conversions of series A compounds into series B and C compounds are irreversible. The reaction sequences and the electrochemical characteristics of the reactions of the bis-(*CC'*-dimethyldicarbollyl)nickel system are presented below:

$$Ni(acac)_2 + 2[(3)\text{-}1,2\text{-}B_9C_2H_9Me_2]^{2-}\dagger \rightarrow$$

Series A

$$\rightarrow [(Me_2Cb)_2Ni^{II}\text{—}A]^{2-} \underset{-0.55\,mV}{\rightleftharpoons} [(Me_2Cb)_2Ni^{III}\text{—}A]^- \xrightarrow[\downarrow 200^\circ]{[O]}$$

Series B

$$[(Me_2Cb)_2Ni^{II}\text{—}B]^{2-} \underset{-1.02\,mV}{\rightleftharpoons} [(Me_2Cb)_2Ni^{III}\text{—}B]^- \underset{+0.15\,mV}{\rightleftharpoons} [(Me_2Cb)_2Ni^{IV}\text{—}B]^0 \downarrow 100^\circ$$

Series C

$$[(Me_2Cb)_2Ni^{II}\text{—}C]^{2-} \underset{-1.19\,mV}{\rightleftharpoons} [(Me_2Cb)_2Ni^{III}\text{—}C]^- \underset{-0.10\,mV}{\rightleftharpoons} [(Me_2Cb)_2Ni^{IV}\text{—}C]^0 .$$

† $Me_2Cb \equiv [(3)\text{-}1,2\text{-}B_9C_2H_9Me_2]$.

Fig. 19 illustrates the structure of bis-*CC'*-dimethyl-1,2-dicarbollylnickel(IV) with one isomerised ligand.

Unsubstituted bis-(1,2-dicarbollyl)nickel(IV) is converted into the series B and C compounds in gas-phase isomerisation at 300–400°C. [62]

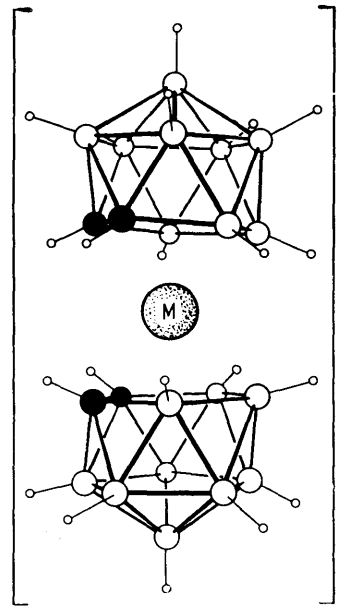

Figure 18.

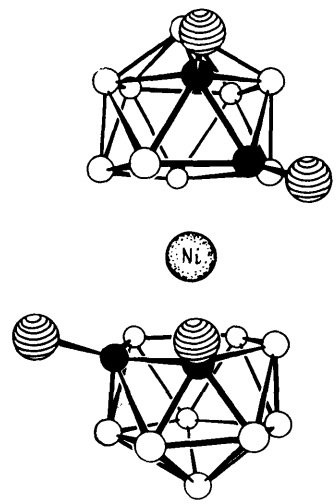

Figure 19.

A neutral mixed nickel(III) complex was obtained in a low yield by the reaction of $NiBr_2$ with $C_5H_5^-$ and $1,2\text{-}B_9C_2H_{11}^{2-}$ ions in THF [65]:

$$C_5H_5^- + 1,2\text{-}B_9C_2H_{11}^{2-} + NiBr_2 \rightarrow [(\pi\text{-}C_5H_5)Ni(\pi\text{-}1,2\text{-}B_9C_2H_{11})]^- \xrightarrow{[O]}$$

$$\rightarrow (\pi\text{-}C_5H_5)Ni(\pi\text{-}1,2\text{-}B_9C_2H_{11}) .$$

The cyclopentadienyl and dicarbollyl complexes of nickel exhibit many characteristic differences. Whereas the dicyclopentadienylnickel complex with the d^6 configuration, i.e. $(C_5H_5)_2Ni^{2+}$, has sometimes not been isolated, bis(dicarbollyl)nickel(IV) is an entirely stable crystalline compound. From this standpoint, the electrochemical reactions (the $E_{1/2}$ values) of the nickel complexes are of interest[65]:

$M^{IV} + e^- \rightarrow M^{III}$ and	$M^{III} + e^- \rightarrow M^{II}$.
$(C_5H_5)_2Ni$ + 0.77 mV	−0.09 mV
$(C_5H_5)Ni(B_9C_2H_{11})$ + 0.46 mV	−0.52 mV
$(B_9C_2H_{11})_2Ni$ + 0.18 mV	−0.56 mV

The wave corresponding to the oxidation of nickel to the quadrivalent state in the dicyclopentadienylnickel complex could be observed only at −40°C; above 0°C, this complex decomposes rapidly. In the d^6 state π-cyclopentadienyl-π-dicarbollylnickel(VI) is more stable and decomposes much more slowly than $(C_5H_5)_2Ni^{2+}$, but it could not be isolated. The higher stability of the dicarbollylnickel complexes has been explained by the higher negative charge of the dicarbollyl ligand (2- compared with 1- for the cyclopentadienyl ligand), which leads to a less effective positive charge of the nickel atom in the d^6 electronic state[65].

When palladium acetylacetonate is added to an excess of 1,2-dicarbollide ions, an unstable diamagnetic d^8-complex $[(1,2\text{-}B_9C_2H_{11})_2Pd^{II}]^{2+}$, extremely sensitive to air, is formed[66]. Its solutions decompose on standing in several hours, but, on rapid oxidation of the palladium(II) complex, an electrically neutral d^6-complex is formed in high yield:

$$[(1,2\text{-}B_9C_2H_{11})_2Pd]^{2-} \xrightarrow[CH_2Cl_2]{I_2} (1,2\text{-}B_9C_2H_{11})Pd \ .$$

When equimolar amounts of the palladium(II) and palladium(IV) complexes are mixed, $[(1,2\text{-}B_9C_2H_{11})_2Pd]^-$ is formed quantitatively[66]. It has been shown that palladium complexes have structures completely identical to those of the corresponding nickel complexes discussed above[62,66]. Chemically they also have much in common. For example, the neutral complex $(1,2\text{-}B_9C_2H_{11})_2Pd^{IV}$ is a strong Lewis acid and forms crystalline adducts with π- and n-bases[62]. Like the nickel complexes, the bis-(*CC'*-dimethyl-1,2-dicarbollyl)palladium system undergoes rearrangements leading to a change in the positions of the carbon atoms in the ligands[62]:

$$Pd(acac)_2 + 2[(3)\text{-}1,2\text{-}B_9C_2H_9Me_2]^{2-} \rightarrow$$

Series A

$$\rightarrow [(Me_2Cb)_2Pd^{II}\text{—}A]^{2-} \underset{-0.44\,mV}{\rightleftharpoons} [(Me_2Cb)_2Pd^{III}\text{—}A]^- \xrightarrow{[O]}$$

Series C

$$[(Me_2Cb)_2Pd^{II}\text{—}C]^{2-} \underset{-0.71\,mV}{\rightleftharpoons} [(MeCb)_2Pd^{III}\text{—}C]^- \underset{-0.47\,mV}{\rightleftharpoons} [(Me_2Cb)_2Pd^{IV}\text{—}C]^0 \ .$$

Mixed neutral complexes have been synthesised (yield 10%) by the reaction of the π-tetraphenylcyclobutadienylpalladium(II) dichloride dimer with the (3)-1,2-dicarbollide ion and its dimethyl derivative[16]:

$$(\pi\text{-}C_4Ph_4PdCl_2)_2 + 2[(3)\text{-}1,2\text{-}B_9C_2H_{11}]^{2-} \rightarrow 2(\pi\text{-}C_4Ph_4)Pd[\pi\text{-}1,2\text{-}B_9C_2H_{11}] \ .$$

A dicarbollide derivative of platinum was obtained by the reaction of cyclo-octa-1,5-dieneplatinum dichloride with the 1,2-dicarbollide ion[62]:

$$(1,5\text{-}C_8H_{12})PtCl_2 + (3)\text{—}1,2\text{-}B_9C_2H_{11}^{2-} \rightarrow (1,5\text{-}C_8H_{12})Pt[\pi\text{-}(3)\text{-}1,2\text{-}B_9C_2H_{11}] \ .$$

A fundamentally new method of synthesising the dicarbollide complexes of nickel, palladium, and platinum was proposed by Stone and coworkers[22], who found that 1,8-$B_9C_2H_{11}$ (Tebbe et al.[67]) undergoes the polyhedral expansion reaction on treatment with $Ni(1,5\text{-}C_8H_{12})_2$, $(1,5\text{-}C_8H_{12})Ni(PEt_3)_2$, $Pd(t\text{-}BuNC)_2$, $Pt(PEt_3)_3$, or $Pt(PMe_2Ph)_3$, yielding respectively $(1,5\text{-}C_8H_{12})Ni(1,7\text{-}B_9C_2H_{11})$, $(Et_3P)_2Ni(1,7\text{-}B_9C_2H_{11})$, $(t\text{-}BuNC)_2Pd(1,7\text{-}B_9C_2H_{11})$, $(Et_3P)_2Pd(1,7\text{-}B_9C_2H_{11})$, and $(PhMe_2P)_2Pr(1,7\text{-}B_9C_2H_{11})$. The (3)-1,7-$B_9C_2H_{11}^{2-}$ ion then behaves as the dicarbollyl ligand. The reaction of 1,8-dicarba-*closo*-undecaborane(II) with bis(cyclo-octa-1,5-diene)nickel is illustrated schematically in Fig. 20.[22]

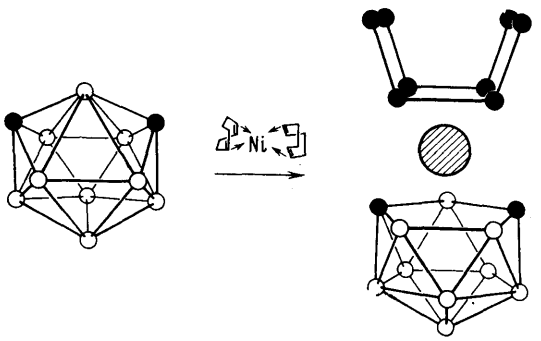

Figure 20.

D. The Copper Group

The dicarbollyl derivatives of all the metals of the copper group (Cu, Ag, Au) are known.

The addition of $CuSO_4$ in a highly alkaline medium to the 1,2-dicarbollide ion yields the paramagnetic d^9-complex $[(1,2\text{-}B_9C_2H_{11})_2Cu^{II}]^{2-}$, which is unstable in air and is readily converted into the diamagnetic d^8-complex $(1,2\text{-}B_9C_2H_{11})_2Cu^{III}$:[16,66]

$$CuSO_4 + 1,2\text{-}B_9C_2H_{11}^{2-} \rightarrow [(1,2\text{-}B_9C_2H_{11})_2Cu^{II}]^{2-} \underset{Na/Hg}{\overset{O_2}{\rightleftharpoons}} [(1,2\text{-}B_9C_2H_{11})_2Cu^{III}]^- \ .$$

The reaction of $AuCl_3$ with a large excess of 1,2-dicarbollide ions in dimethoxyethane with subsequent oxidation by aqueous hydrogen peroxide yields the stable complex $(1,2\text{-}B_9C_2H_9)_2Au^{III}$.[66] The salt is diamagnetic and can be reduced to the paramagnetic complex $[(1,2\text{-}B_9C_2H_9)_2Au^{II}]^{2-}$:

$$AuCl_3 + 1,2\text{-}B_9C_2H_{11}^{2-} \rightarrow [(1,2\text{-}B_9C_2H_{11})_2Au^{II}]^{2-} \underset{Na/Hg}{\overset{O_2}{\rightleftharpoons}} [(1,2\text{-}B_9C_2H_{11})_2Au^{III}]^- \ .$$

The attempts to obtain analogous bis(dicarbollyl) systems for silver were unsuccessful[66], but subsequently[68] the possibility of the existence of such complexes was briefly reported. It has been suggested that the (3)-1,2-dicarbollide ion be used for the qualitative detection of copper in aqueous solutions[69,70].

According to data for the polarographic reduction of the dicarbollyl complexes of copper and gold, the existence of the d^{10}-complexes is possible, since the polarograms show, together with the process $M^{III} + e^- \rightarrow M^{II}$, one-electron reduction waves corresponding to the process $M^{II} + e^- \rightarrow M^I$ (M = Cu or Au).

It is interesting that the most stable states of the copper and gold complexes are those in which the metal atom is in

the +3 formal oxidation state, i.e. the bivalent metal complexes are very powerful reducing agents[66].

An X-ray diffraction study of the bis(dicarbollyl) complexes of copper(II) and copper(III) showed[71,72] that they have a distorted sandwich structure analogous to those of the nickel(II) and palladium(II) complexes. Thus examination of the structures of complexes with electronic configurations ranging from d^5 to d^9 has shown that the d^5-, d^6-, and d^7-complexes have a symmetrical sandwich structure, while the d^8- and d^9-complexes have a distorted sandwich structure. Wing[66,71,72] explains the presence of such structures by π-allyl bonding in which six boron atoms enter into the first coordination sphere of the metal (three atoms from each dicarbollyl ligand).

E. The Chromium Group

The dicarbollyl complexes of all the metals in the chromium group (Cr, Mo, W) have been obtained. The reaction of $CrCl_3$ with the (3)-1,2- or (3)-1,7-$B_9C_2H_{11}^{2-}$ ions in THF leads to paramagnetic bis(dicarbollyl)chromium in which the metal atom is in the +3 formal oxidation state. In contrast to the isoelectronic chromocenium salts, which are readily hydrolysed in aqueous solutions[74], $[(\pi\text{-}B_9C_2H_{11})_2Cr]^-$ salts are stable in air and are not decomposed by hot concentrated H_2SO_4. However, these complexes decompose in a hot alkaline solution, regenerating the dicarbollide ion in a quantitative yield[73]. Neutral π-cyclopentadienyl-π-1,2-dicarbollylchromium has been obtained by the reaction of $CrCl_3$ with the $C_5H_5^-$ and 1,2-$B_9C_2H_{11}^{2-}$ ions. According to Clair et al.,[75] bis-(1,2-dicarbollyl)chromium has a regular sandwich structure.

Chromium, molybdenum and tungsten hexacarbonyls react with the 1,2-dicarbollide ion in THF on ultraviolet irradiation with displacement of three carbon monoxide molecules and the formation of π-dicarbollylmetal tricarbonyl complexes[16,31]:

$$(3)\text{-}1,2\text{-}B_9C_2H_{11}^{2-} + M(CO)_6 \xrightarrow[-3CO]{h\nu} \{[\pi\text{-}(3)\text{-}1,2\text{-}B_9C_2H_{11}]M(CO)_3\}^{2-} \quad (M = Cr, Mo, W)\ .$$

The complexes are isoelectronic with the complexes $(C_5H_5)M(CO)_3^-$ and enter into protonation and alkylation reactions[16]:

$$[(1,2\text{-}B_9C_2H_{11})Mo(CO)_3]^{2-} \xrightarrow{HCl} [(1,2\text{-}B_9C_2H_{11})Mo(CO)_3H]^-\ ,$$

$$[(1,2\text{-}B_9C_2H_{11})W(CO)_3]^{2-} \xrightarrow{MeI} [(1,2\text{-}B_9C_2H_{11})W(CO)_3Me]^-\ .$$

The reactions of the 1,2-dicarbollide ion with two moles of $M(CO)_6$ and the reactions of $M(CO)_6$ with $(1,2\text{-}B_9C_2H_{11})M(CO)_3^{2-}$ (M = W or Mo) lead to the same dinuclear products with the empirical formula $(B_9C_2H_{11})M_2(CO)_x^{2-}$ (x = 7 or 8).[16] Fig. 21 presents the structure of such a dinuclear complex obtained by the reaction

$$\{[\pi\text{-}(3)\text{-}1,2\text{-}B_9C_2H_{11}]Mo(CO)_3\}^{2-} + W(CO)_6 \rightarrow \{[\pi\text{-}(3)\text{-}1,2\text{-}B_9C_2H_{11}]Mo(CO)_3W(CO)_5\}^{2-}\ .$$

F. The Manganese Group

Bromomanganese pentacarbonyl and bromorhenium pentacarbonyl react rapidly with the 1,2-dicarbollide ion at room temperature with liberation of one mole of carbon monoxide. On heating, a further two moles of carbon monoxide are evolved and a π-dicarbollylmetal tricarbonyl anion is formed[16,76]:

$$1,2\text{-}B_9C_2H_{11}^{2-} + BrM(CO)_5 \xrightarrow[-CO]{80^\circ} [(\sigma\text{-}1,2\text{-}B_9C_2H_{11})M(CO)_5]^- \xrightarrow[-2CO]{70^\circ}$$

$$\rightarrow [(\pi\text{-}1,2\text{-}B_9C_2H_{11})M(CO)_3]^- \quad (M = Mn, Re)\ .$$

An X-ray diffraction analysis of the rhenium derivative has been carried out[77]. The closeness of the C–Re and B–Re distances (Fig. 22), which are 2.31 and 2.35 A respectively, is noteworthy.

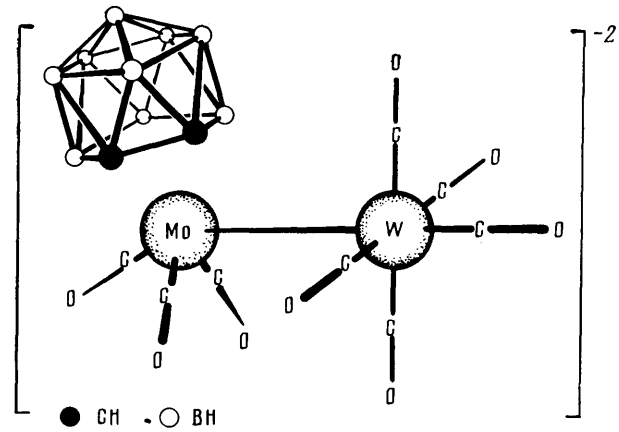

Figure 21.

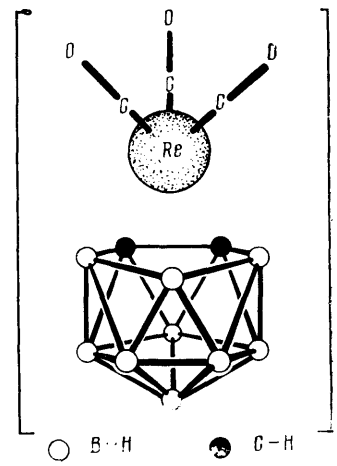

Figure 22.

When $[(\pi\text{-}(3)\text{-}1,2\text{-}B_9C_2H_{11}(Mn)(CO)_3]^-$ is acted upon by triphenylphosphine under ultraviolet irradiation in THF for 12 h at 60°C, one carbonyl group is substituted by the triphenylphosphine group[78]:

$$[(\pi\text{-}(3)\text{-}1,2\text{-}B_9C_2H_{11})Mn(CO)_3]^- + PPh_3 \xrightarrow{h\nu} [(\pi\text{-}(3)\text{-}1,2\text{-}B_9C_2H_{11})Mn(CO)_2PPh_3]^-\ .$$

2. Mono- and Hetero-Carbollyl Complexes of Transition Metals

The monocarbollide ion $B_{10}CH_{11}^{3-}$ is readily formed *in situ* on deamination and deprotonation of the carborane $B_{10}H_{12}CNMe_3$ by metallic sodium in THF[79]. This reaction proceeds more readily and with a higher yield in the

presence of naphthalene[80]. Two general methods have been proposed for the synthesis of π-complexes[81-83].

1. By adding butyl-lithium or sodium hydride to a mixture of $B_{10}H_{12}CNH_2R$ or a salt of $B_{10}H_{12}CH^-$ and the metal halide in THF or by adding the metal halide to the trisodium salt $Na_3B_{10}CH_{11}$ obtained directly.

2. By the interaction in a highly alkaline medium between $B_{10}H_{12}CNH_2R$ or a salt of $B_{10}H_{12}CH^-$ and the metal halide. This method gives high yields for nickel and cobalt.

Both methods have been used to synthesise the bis-(π-carbollyl) complexes of iron, cobalt, nickel, chromium, and manganese. Fig. 23 presents the general type of the structure of the λ-complexes obtained from the $B_{10}CH_{11}^{3-}$ and $B_{10}CH_{10}NH_2R^{2-}$ ions.

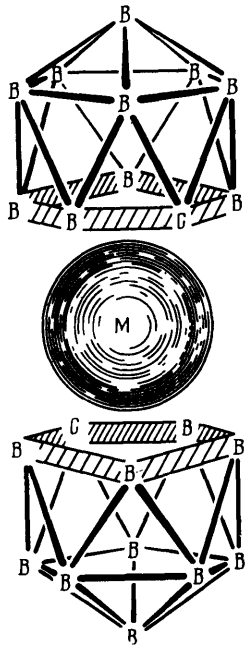

Figure 23.

The π-monocarbollyl ligand stabilises a high oxidation state of the metal to an even greater extent than the π-dicarbollyl ligand. Whereas the synthesis of $(1,2\text{-}B_9C_2H_{11})_2Ni^{IV}$ requires the oxidation of the nickel(III) complex by iodine or iron(III) chloride, $[(B_{10}CH_{11})_2Ni^{IV}]^{2-}$ and $(B_{10}CH_{10}NH_2R)_2Ni^{IV}$ are formed directly during isolation in air. Moreover, the diamagnetic complex $[(B_{10}CH_{11})_2Co]^{3-}$, which contains cobalt in the +3 formal oxidation state, is oxidised by cerium(IV) ions to the paramagnetic complex $[(B_{10}CH_{11})_2Co]^{2-}$ in which the cobalt atom is in the +4 formal oxidation state.

In the monocarbollyl complexes isolated directly from the reaction mixture, manganese is in the +4 formal oxidation state and iron, cobalt, and chromium are in the +3 formal oxidation state. All the complexes obtained, with the exception of that of manganese, are stable in air and do not decompose in acid media.

The complexes obtained from $B_{10}H_{12}CNH_3$ are of interest from the standpoint of reactions involving the amino-group. For example, $(B_{10}H_{10}CNH_3)_3Ni$ reacts with nitric acid and dimethyl sulphate to form $[(B_{10}H_{10}COH)_2Ni]^{2-}$ and $(B_{10}H_{10}CNHMe_2)_2Ni$ respectively[82,83].

Muetterties and coworkers[84] synthesised metallocarboranes with a monocarbollyl ligand starting with the $B_{10}H_{13}^-$ ion and Group VI metal carbonyls (ultraviolet irradiation). The $[(B_{10}H_{10}COH)M(CO)_4]^-$ anions formed initially react with sodium hydride to form the dianions $[(B_{10}H_{10}COH)NCO(CO)_3]^{2-}$, whose structure is illustrated in Fig. 24 for the molybdenum derivative as an example. Both types of compounds are decomposed quantitatively by bases with the removal of a carbon atom from the icosahedral skeleton and the formation of complexes belonging to the class of *nido*-metalloboranes.

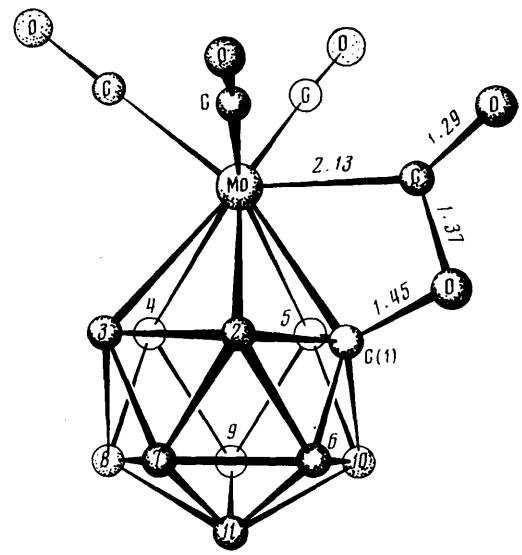

Figure 24.

Like carboranes(10) ($B_{10}H_{10}C_2H_2$), when acted upon by piperidine, 1,2- and 1,7-phosphacarboranes and 1,2- and 1,7-arsacarboranes give rise to the phospha- and arsa-carbaundecaborate anions, whose deprotonation generates heterocarbollide ions[85] isoelectronic with the dicarbollide ion and capable of behaving as π-ligands in transition metal complexes:

$$B_{10}H_{10}CHE \xrightarrow{C_5H_{10}NH} B_9H_{10}CHE^- \xrightarrow{NaH} B_9H_9CHE^{2-} \quad (E = P, As)\ .$$

A characteristic feature of the heterocarbaundecaborate anions is the presence of phosphorus or arsenic atoms which can be alkylated; the compounds then become neutral. Their deprotonation leads to heterocarbollide ions with a single negative charge[85,86]:

$$B_9H_{10}CHE^- + MeI \rightarrow B_9H_{10}CHEMe \xrightarrow{NaH} B_9H_9CHEMe^-\ (E = P, As)\ .$$

When the 1,2- and 1,7-$B_9H_9CHP^{2-}$ ions are acted upon by iron(II) chloride in THF solution, salts of $[(1,2\text{-}B_9H_9CHP)_2Fe^{II}]^{2-}$ and $[(1,7\text{-}B_9H_9CHP)_2Fe^{II}]^{2-}$ are formed

respectively[85,86]. Treatment of $[(1,7\text{-}B_9H_9CHP)_2Fe]^{2-}$ with methyl iodide leads to the neutral compound $(1,7\text{-}B_9H_9CHPMe)_2Fe$, which is identical with the complex obtained from $1,7\text{-}B_9H_9CHPMe^-$ and $FeCl_2$ (Little et al.[86]):

$$[(1,7\text{-}B_9H_9CHP)_2Fe]^{2-} + MeI \rightarrow (1,7\text{-}B_9H_9CHPMe)_2Fe \leftarrow 1,7\text{-}B_9H_9CHPMe^- + FeCl_2 \ .$$

This complex exists as a mixture of isomers (the shaded circles in Fig. 25 indicate the possible positions of the carbon atoms).

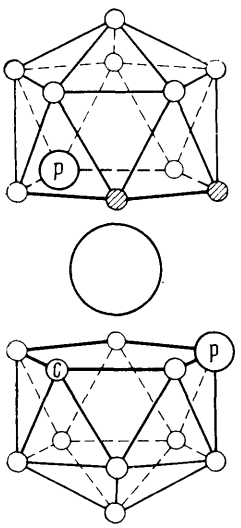

Figure 25.

In contrast to the bis(dicarbollyl) and bis(monocarbollyl) complexes of iron, bis(phosphacarbollyl)iron(II) is not oxidised by air in aqueous solution, although oxidation with cerium(IV) ions gives a small yield of the paramagnetic complex $[(1,7\text{-}B_9H_9CHP)_2Fe^{III}]^-$.[86]

The neutral complex $(\pi\text{-}C_5H_5)Fe(\pi\text{-}1,7\text{-}B_9H_9CHPMe)$ has been obtained by the interaction of the $C_5H_5^-$ and $1,7\text{-}B_9H_9CHPMe^-$ ions and $FeCl_2$. The reactions of 1,2- and $1,7\text{-}B_9H_9CHPMe^-$ ions with $CoCl_2$ give rise to bis(phosphacarbollyl) complexes in which the metal atom is in the +2 formal oxidation state and does not exhibit a tendency towards oxidation. In contrast, the reactions of the 1,2- and $1,7\text{-}B_9H_9CHP^{2-}$ ions with $CoCl_2$ lead to complexes in which the cobalt atom is in the +3 formal oxidation state.

The dianion $1,7\text{-}B_9H_9CHP^{2-}$ reacts with $NiCl_2$ to form bis-(1,7-phosphacarbollyl)nickel in which the nickel is in the +2 formal oxidation state.[85] The mixed complexes $(1,7\text{-}B_9H_9CHPMe)Mn(SO)_3$ and $[(1,7\text{-}B_9H_9CHP)Mn(CO)_3]^-$ have been obtained[86]. The substitution of one carbonyl group by a triphenylphosphine group in $[(1,7\text{-}B_9H_9CHP)Mn.(CO)_3]^-$ takes place readily on ultraviolet irradiation[78].

The reaction of triphenylcyclopropenylnickel carbonyl bromide with $1,7\text{-}B_9H_9CHPMe^-$ in THF gave a mixed nickel complex in 40% yield[87]:

$$[C_3Ph_3NiBr(CO)]_2 + 1,7\text{-}B_9H_9CHPMe^- \rightarrow C_3Ph_3Ni(1,7\text{-}B_9H_9CHPMe) \ .$$

The interaction of allylmagnesium chloride and $1,7\text{-}B_9H_9CHPMe^-$ with $NiCl_2$ results in the formation of a π-allyl complex[87]:

$$CH_2\text{-}CHCH_2MgCl + 1,7\text{-}B_9H_9CHPMe^- + NiCl_2 \rightarrow (C_3H_5)Ni(1,7\text{-}B_9H_9CHPMe) \ .$$

π-Methylallyl-π-phosphacarbollylnickel has been obtained similarly. When nitric oxide was passed through a solution of $1,7\text{-}B_9H_9CHPMe^-$ and $NiCl_2$ in THF, a nitrosyl complex was isolated in a low yield:

$$NO + 1,7\text{-}B_9H_9CHPMe^- + NiCl_2 \rightarrow (NO)Ni(1,7\text{-}B_9H_9CHPMe) \ .$$

The arsacarbollide ion reacts with transition metals like the phosphacarbollide ion. This is illustrated by the synthesis of π-cyclopentadienyl-π-1,2-arsacarbollylcobalt with the metal atom in the +3 formal oxidation state[88]:

$$C_5H_5^- + 1,2\text{-}B_9H_9CHAs^{2-} + CoCl_2 \rightarrow (C_5H_5)Co(1,2\text{-}B_9H_9CHAs) \ .$$

Arsacarbollyl complexes of manganese and iron have been obtained[88]. Under the conditions of the photochemical reaction, bis-(1,7-heterocarbollyl)iron(II) reacts with Group VI metal hexacarbonyls to form complicated complexes[89]:

$$[(1,7\text{-}B_9H_9CHE)_2Fe]^{2-} + M(CO)_6 \xrightarrow{h\nu} \{[1,7\text{-}B_9H_9CHEM(CO)_5]_2Fe\}^{2-} \quad (M = Cr, Mo, W) \ .$$

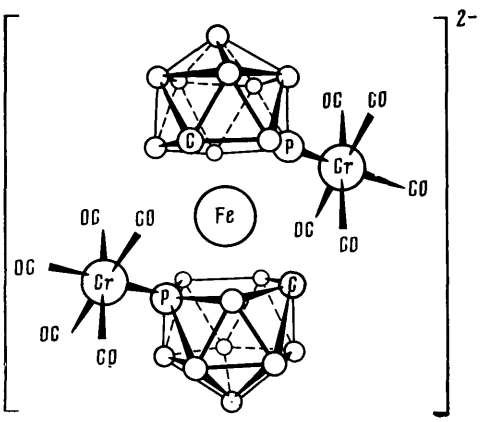

Figure 26.

In these complexes the heterocarbollyl ligand is π-bonded to the iron atom and σ-bonded via the phosphorus or arsenic atom to the Group VI metal atom. The structure of the $\{[1,7\text{-}B_9H_9CHP.Cr(CO)_5]_2Fe\}^{2-}$ ion is illustrated in Fig. 26.

3. Complexes Based on the $\pi\text{-}B_7C_2H_9$ Ligands

The axial hydrogen atoms of the methine groups in 1,3-dicarba-*nido*-nonaborane(13) ($1,3\text{-}B_7C_2H_{13}$) are acidic and when the carborane is treated with sodium hydride one mole of H_2 is evolved with formation of the dianion $B_7C_2H_{11}^{2-}$.[90,91] The reaction of anhydrous $CoCl_2$ with $B_7C_2H_{11}^{2-}$ leads to additional liberation of H_2 and the formation of a complex with the metal atom in the +3 formal oxidation state. It is suggested that five atomic orbitals, in which six electrons are located, originate from the five atoms of the ligand (they are predominantly sp^3-hybridised). The ligand is illustrated schematically in Fig. 27.

The name dicarbazapide given to the $B_7C_2H_9^{2-}$ ligand originates from the Greek work "zapato" (nine)‡. In the synthesis of bis(dicarbazapyl)cobalt products with different positions of the carbon atoms in the ligand are obtained depending on the reaction conditions[91]:

$$2\,(1,3\text{-}B_7C_2H_{11})^{2-} + 1.5\,Co^{2+} \xrightarrow{70^\circ} \{[\pi\text{-}(2)\text{-}1,6\text{-}B_7C_2H_9]_2\,Co\}^- + 0.5\,Co^0 + 2H_2\,,$$

$$2\,(1,3\text{-}B_7C_2H_{11})^{2-} + 1.5Co^{2+} \xrightarrow{25^\circ} \{[\pi\text{-}(2)\text{-}6,7\text{-}B_7C_2H_9]_2Co\}^- + 0.5Co^0 + 2H_2\,.$$

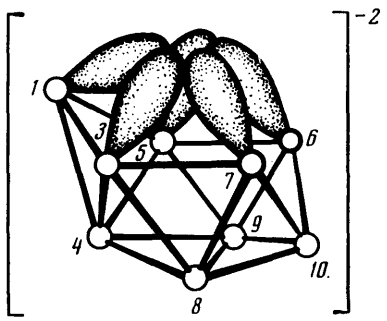

Figure 27.

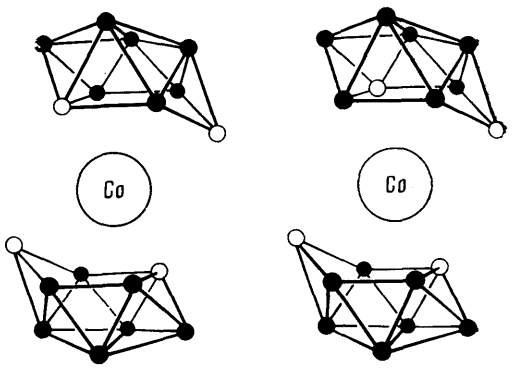

Figure 28.

At 70°C the product is a complex in which the carbon atoms are located in the 1- and 6- or 7-positions according to X-ray diffraction[92]. There is a possibility of the existence of *syn*- and *anti*-isomers (Fig. 28), but there is no information about the formation of more than one isomer. An isomer with the carbon atoms in the 6- and 7-positions is formed at room temperature (Fig. 29). A third isomer in which the carbon atoms are in the 1- and 10-positions has been obtained by heating $Cs(1,6\text{-}B_7C_2H_9)_2Co$ at 315°C for 24 h.[91,93]

‡ "Zapato" is a Spanish noun describing a shoe which resembles the shape of the $B_7C_2H_9^{2-}$ dianion[91] (Ed. of Translation).

The reaction of the $B_7C_2H_{11}^{2-}$ and $C_5H_5^-$ ions with $CoCl_2$ leads to $(\pi\text{-}C_5H_5)Co(\pi\text{-}1,6\text{-}B_7C_2H_9)$. No data have been obtained concerning the formation of the 6,7-isomer. Like the symmetrical complex, π-cyclopentadienyl-π-1,6-dicarbazapylcobalt isomerises on prolonged heating at 315°C with formation of the 1,10-isomer (Fig. 30).

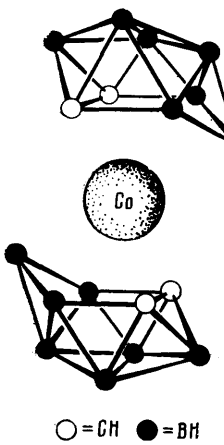

Figure 29.

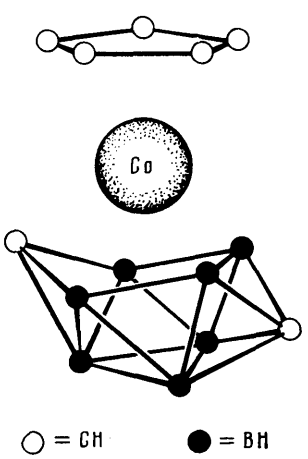

Figure 30.

Acetylation of π-cyclopentadienyl-π-1,6-dicarbazapylcobalt under the conditions of the Friedel–Crafts reaction yielded an acetyl derivative substituted at the boron atom[94]. An attempt to rearrange the compound with the 1,6-carborane structure to the 1,10-structure was unsuccessful. When the acetyl derivative is treated with $LiAlH_4$, the corresponding carbinol is not formed but the carbonyl group disappears. When $(C_5H_5)Co(1,6\text{-}B_7C_2H_9)$ is brominated in CCl_4 at room temperature, the *b*-dibromo-derivative is formed together with an insignificant amount of the *b*-tribromo-product. The bromine atoms are probably bonded to the boron atoms in the 8- and 10-positions in the ligand[94].

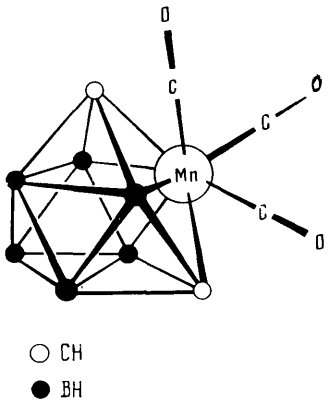

Figure 31.

An attempt was made to synthesise carbonyl derivatives of manganese with the π-$B_7C_2H_9$ ligand by treating $B_7C_2H_{11}^{2-}$ in boiling THF with bromomanganese pentacarbonyl[95,96]. However, the product was a complex with the π-$B_6C_2H_8$ ligand for which the structure presented in Fig. 31 was proposed.

4. π-Complexes Based on the Lowest Carboranes

Certain *nido*-carboranes or their deprotonation products react with transition metal derivatives to form π-complexes in which the π-carborane ligand is regarded as isoelectronic with the π-cyclopentadienyl ligand.

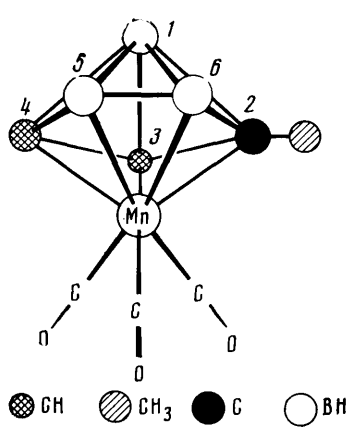

Figure 32.

2-Methyltricarbahexaborane(7) reacts with manganese carbonyl at 175–200°C in a sealed tube and gives rise to a quantitative yield of the isoelectronic analogue (π-2-$MeC_3B_3H_5$)$Mn(CO)_3$ (whose structure is illustrated in Fig. 32) of the known metallocene (π-C_5H_5)$Mn(CO)_3$:[97]

$$MeC_3B_3H_6 + \frac{1}{2}\,Mn_2(CO)_{10} \rightarrow (\pi\text{-}MeC_3B_3H_5)\,Mn(CO)_3 + \frac{1}{2}\,H_2\ .$$

Another method of synthesising this complex uses the reaction of sodium tricarbahexaborate with bromomanganese pentacarbonyl[98]. A σ-derivative is then formed as an intermediate and on heating is converted into a π-complex:

$$NaMeC_3B_3H_5 + BrMn(CO)_5 \xrightarrow[\text{fast}]{25^\circ} (\sigma\text{-}MeC_3B_3H_5)\,Mn(CO)_5 \xrightarrow[\text{slow}]{100^\circ} (\pi\text{-}MeC_3B_3H_5)\,Mn(CO)_3\ .$$

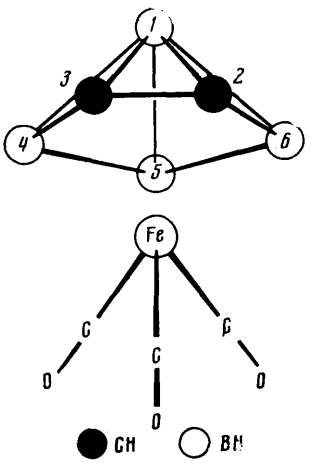

Figure 33.

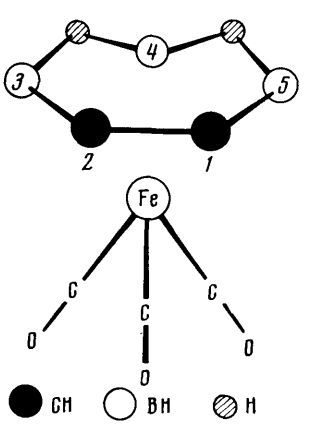

Figure 34.

The interaction of 2,3-dicarbahexaborane(8) ($C_2B_4H_8$) with iron pentacarbonyl at 240°C results in the formation of two π-complexes[99]: (π-$B_4C_2H_6$)$Fe(CO)_3$ (Fig. 33) and (π-$B_3C_2H_7$)$Fe(CO)_3$ (Fig. 34). The second complex is also formed in the reaction between dicarba-*nido*-pentaborane(7) with iron pentacarbonyl under ultraviolet irradiation[100]. The iron complexes obtained are isoelectronic with the (π-C_5H_5)$Fe(CO)_3^+$ cation and the π-$B_4C_2H_6$ and π-$B_3C_2H_7$ ligands have two negative charges.

Another pathway to the synthesis of π-carborane complexes of iron consists of the reaction of sodium dicarbahexaborate with cyclopentadienyliron dicarbonyl iodide and

subsequent photochemical decomposition of the μ-iron complex[101]:

$$NaC_2B_4H_7 + (\pi\text{-}C_5H_5)\,Fe(CO)_2I \xrightarrow{25^\circ} \mu\text{-}[(\pi\text{-}C_5H_5)\,Fe(CO)_2]_2C_2B_4H_7 \xrightarrow{h\nu} (\pi\text{-}C_5H_5)\,Fe^{II}(\pi\text{-}B_4C_2H_7) + (\pi\text{-}C_5H_5)\,Fe^{III}(\pi\text{-}B_4C_2H_6)\,.$$

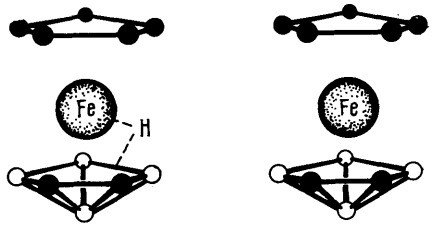

Figure 35.

The structures of both complexes have been deduced on the basis of ^{11}B NMR spectra and are presented in Fig. 35.

IV. METALLOCARBORANES OBTAINED BY THE POLYHEDRAL EXPANSION REACTION

The method of synthesis of metallocarboranes by the reduction of *closo*-carboranes has been called the polyhedral expansion reaction, since the resulting metallocarboranes have the structure of a polyhedron in which the number of vertices is greater by unity than in the initial carborane. The polyhedral expansion reaction has been largely applied to carboranes of the general type $B_nH_nC_2H_2$.

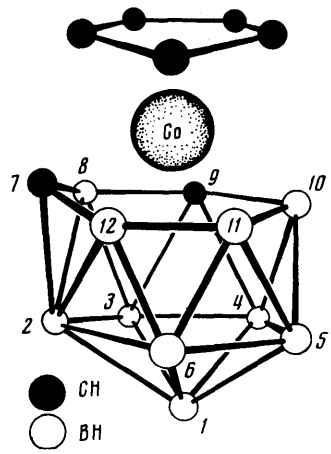

Figure 36.

The carborane 1,2-$B_{10}H_{10}C_2H_2$ is reduced by two moles of naphthalenesodium in THF to the dianion $B_{10}H_{10}C_2H_2^{2-}$,[102-103] which reacts with sodium cyclopentadienide and with $FeCl_2$ or $CoCl_2$ to form π-cyclopentadienyl-π-dodecahydrocarba-*nido*-dodecaboratoiron(III) or the corresponding cobalt(III) complex respectively[104,105]:

$$C_5H_5^- + B_{10}H_{10}C_2H_2^{2-} + MCl_2 \rightarrow [(\pi\text{-}C_5H_5)\,M^{II}(\pi\text{-}B_{10}C_2H_{12})]^- \xrightarrow{-e^-} \rightarrow (\pi\text{-}C_5H_5)\,M^{III}(\pi\text{-}B_{10}C_2H_{12}) \quad (M = Fe, Co)\,.$$

The iron(III) complex is paramagnetic (the effective magnetic moment is 2.12 Bohr magnetons) and is readily reduced by $NaBH_4$ to the iron(II) complex[105].

The red cobalt(III) complex, obtained directly from the reaction mixture, rearranges on boiling in hexane into an orange cobalt(III) complex, which is in turn converted on boiling in benzene into a red-orange cobalt(III) complex. X-Ray diffraction analysis[106] of the red complex (π-C_5H_5)Co^{III} (π-$B_{10}H_{10}C_2H_2$) showed that it exists in the form of a pair of enantiomers with the carbon atoms in the 7- and 9-positions or 7- and 11-positions (Fig. 36).

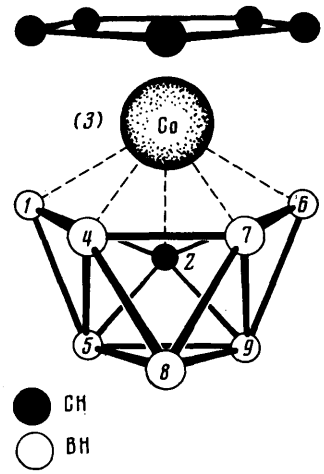

Figure 37.

In the orange isomer the carbon atoms occupy the 6- and 7-positions and in the red-orange isomer the 5- and 7-positions[107]. Alkaline degradation of the orange complex (π-C_5H_5)Co^{III} (π-$B_{10}C_2H_{12}$) leads to a new metallocarborane—π-cyclopentadienyl-π-octahydro-2-carba-*nido*-octaboratocobalt [(π-C_5H_5)Co^{III} (π-2-B_7CH_8)]$^-$,[107,108] for which the structure illustrated in Fig. 37 was proposed.

The reaction of the dianion $B_{10}C_2H_{12}^{2-}$ with cobalt(II), iron(II), and nickel(II) salts proceeds in accordance with the equation

$$2\,B_{10}C_2H_{12}^{2-} + M^{n+} \rightarrow [(\pi\text{-}B_{10}C_2H_{12})_2\,M]^{n-4} \quad (n = 2,3)\,.$$

and leads to bis-(π-dodecahydrodicarba-*nido*-dodecaborate) complexes (Fig. 38)[105,109].

The reaction of the dianion $B_{10}C_2H_{12}^{2-}$ with molybdenum and tungsten hexacarbonyls under ultraviolet irradiation leads to carboranylmetal tricarbonyl units[105]:

$$B_{10}C_2H_{12}^{2-} + M(CO)_6 \xrightarrow[-CO]{h\nu} [(\pi\text{-}B_{10}C_2H_{12})\,M(CO)_3]^{2-} \quad (M = Mo, W)$$

Zakharkin and Kalinin[109,110] found that the iron(III), cobalt(III) and nickel(II) complexes obtained from the dianions of carborane(10) and its *C*-substituted derivatives are readily oxidised by $CuCl_2$ with formation of carboranes. A characteristic feature of these complexes is the

ease of their rearrangements associated with a change in the relative positions of the carbon atoms in the π-carborane ligand. While oxidation of the complexes obtained directly by the reaction leads to the initial carborane 1,2-$B_{10}C_2H_{12}$ and its derivatives, oxidation of the rearranged complexes yields the 1,7- and 1,12-$B_{10}C_2H_{12}$ carboranes and their derivatives. This method has been recommended by the authors for the low-temperature isomerisation of 1,2-$B_{10}C_2H_{12}$ carboranes to 1,7-$B_{10}C_2H_{12}$ carboranes. In the $(B_{10}C_2H_{12})_2M^{n-4}$ complexes reversible transitions from the *closo*- to the *nido*-structure are observed in the ligands:

$$closo\text{-}B_{10}C_2H_{12} \underset{CuCl_2(-4e^-)}{\overset{+2e^-+MX_n}{\rightleftharpoons}} nido\text{-}(B_{10}C_2H_{12})_2\ M^{n-4}\ .$$

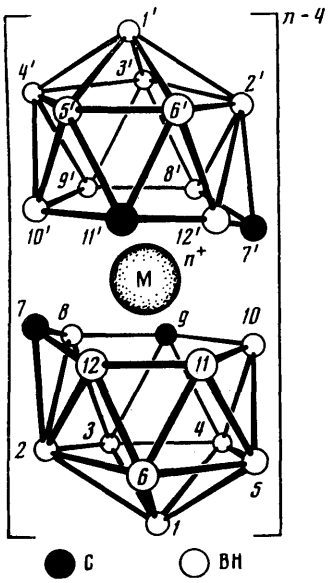

Figure 38.

The oxidation of the complexes $(B_{10}C_2H_{12})_2M^{n-4}$ has also been investigated by Brattsev and Stanko[111], but their results require additional confirmation.

The polyhedral expansion reaction applied to the carborane 1,8-$B_9C_2H_{11}$ leads to a metallocarborane containing the π-(3)-1,7-dicarbollyl ligand (see Section III, 1).

Polyhedral expansion of the carborane 1,6-$B_8C_2H_{10}$ using naphthalenesodium, sodium cyclopentadienide, and $CoCl_2$ leads to two main products[112]: $(\pi\text{-}B_8C_2H_{10})Co^{III}(\pi\text{-}C_5H_5)$ (Fig. 39) and $[(\pi\text{-}B_8C_2H_{10})_2Co^{III}]^-$. Next, on treatment of π-cyclopentadienyl-π-decahydrodicarba-*nido*-decaboratocobalt with naphthalenesodium and subsequent addition of sodium cyclopentadienide and $CoCl_2$, a two-metal carborane complex was obtained[113]:

$$C_5H_5CoB_8C_2H_{10} \xrightarrow[\text{THF, } 50^\circ]{\substack{1.\ 3(Na^+C_{10}H_8^-),\\ 2.\ Na^+C_5H_5^-\\ 3.\ CoCl_2}} C_5H_5CoB_8C_2H_{10}CoC_5H_5\ .$$

A structure with a bidentate π-linked $B_8C_2H_{10}$ ligand (dicarbacanastide), which, in contrast to the ligand considered previously (Fig. 7), contains carbon atoms in the 8- and 10-positions (Fig. 40), was proposed for the complex[113].

Treatment of the carborane 1,7-$B_6C_2H_8$ with two equivalents of naphthalenesodium in THF and subsequent addition of sodium cyclopentadienide and $CoCl_2$ lead to the formation, together with the normal product $(\pi\text{-}C_5H_5)Co^{III}(\pi\text{-}B_6C_2H_8)$ (Fig. 41), of the two-metal complex[114]

$(C_5H_5)_2Co_2B_6C_2H_8$[114].

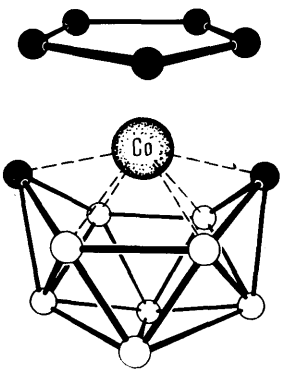

Figure 39.

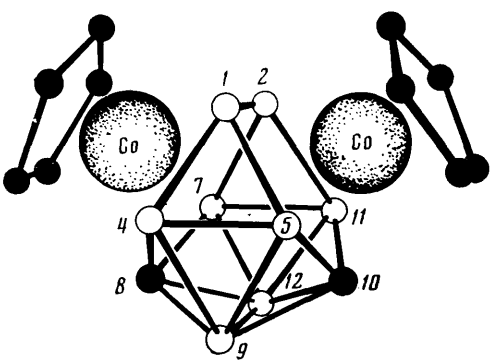

Figure 40.

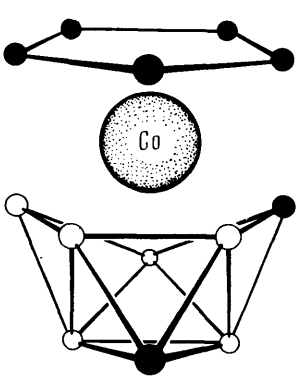

Figure 41.

The complex was shown to have an unusual structure with the two cobalt atoms occupying adjoining vertices of the polyhedron (Fig. 42).[7,8] The structure quoted by Dunks and Hawthorne[114] is incorrect.

Interesting results were obtained by Miller and Grimes when they applied the polyhedral expansion reaction to the carborane 2,4-$B_5C_2H_7$.[115] Its treatment with two moles of naphthalenesodium gave the dianion $B_5C_2H_7^{2-}$ whose interaction with sodium cyclopentadienide and $CoCl_2$ and subsequent oxidation by atmospheric oxygen leads to the formation of more than twenty neutral metallocarboranes, eight of which have been isolated and characterised. The structures proposed for these complexes are illustrated in Fig. 43. All the complexes are formally derivatives of the ligands $B_4C_2H_6^{2-}$, $B_4C_2H_6^{4-}$, $B_5C_2H_7^{2-}$, $B_5C_2H_7^{4-}$, $B_6C_2H_8^{2-}$, and $B_6C_2H_8^{4-}$.

The authors considered the possible mechanism of the formation of the metallocarboranes and proposed the following reaction sequence[115]: (1) the formation of the $B_5C_2H_7^{2-}$ dianion from $B_5C_2H_7$ and naphthalenesodium; (2) the formation of the $(\pi\text{-}B_5C_2H_7)Co^{II}(\pi\text{-}C_5H_5)^-$ anion from $CoCl_2$, NaC_5H_5, and $B_5C_2H_7^{2-}$; (3) the reaction of the $(\pi\text{-}B_5C_2H_7)Co^{II}(C_5H_5)^-$ ion with $B_5C_2H_7^{2-}$ via electron transfer (a) and alkaline degradation (b) mechanisms leading to the formation of the open-chain metallocarborane anions $(\pi\text{-}B_5C_2H_7)Co^{II}(\pi\text{-}C_5H_5)^{3-}$ and $(\pi\text{-}B_4C_2H_6)Co^{II}(\pi\text{-}C_5H_5)^{3-}$ respectively; (4) the insertion of the Co^{2+} ion in

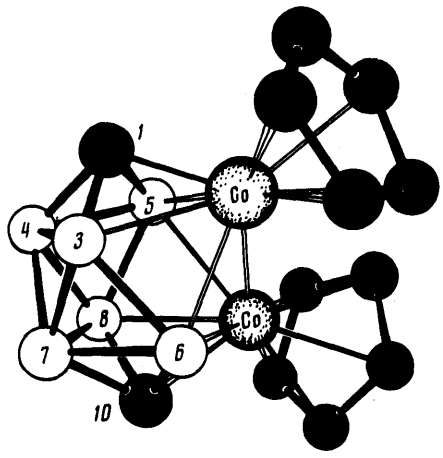

Figure 42.

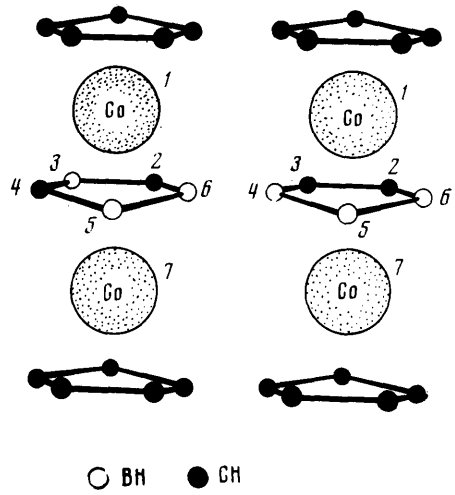

Figure 44.

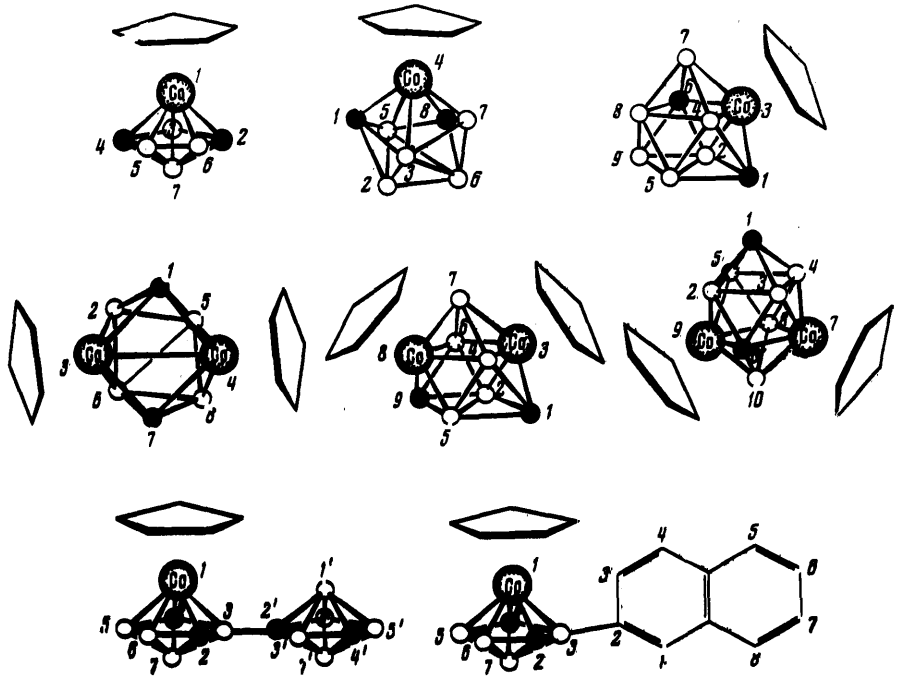

Figure 43.

certain open-chain metallocarborane ions with formation of two-metal units; (5) oxidation by air of the cobalt(II) ions formed in stages (2), (3), and (4) to the neutral cobalt(III) metallocarboranes $(\pi\text{-}B_{n-2}C_2H_n)Co^{III}(\pi\text{-}C_5H_5)$ and $(\pi\text{-}B_{n-2}C_2H_n)Co_2(\pi\text{-}C_2H_5)$; (6) side reactions associated with the deprotonation of the carborane units and the formation of their σ-bonded derivatives.

Nor can one rule out the possibility of the disproportionation of the $B_5C_2H_7^{2-}$ anion to $B_4C_2H_6^{2-}$, $B_6C_2H_8^{2-}$, and other units before the stage in which the metal is inserted into the *nido*-carborane system[115]. All the π-carborane ligands discussed above had a three-dimensional structure. Grimes and coworkers[116] were the first to obtain π-complexes with planar π-ligands. By treating the carborane 1,6-$B_4C_2H_6$ with naphthalenesodium and the subsequent reaction of the dianion $B_4C_2H_6^{2-}$ with $C_5H_5^-Na^+$ and $CoCl_2$, the dinuclear complex $[(\pi\text{-}1,7)\text{-}2,4\text{-}B_3C_2H_5]Co_2(\pi\text{-}C_5H_5)_2$ was obtained; its structure is shown in Fig. 44.

The isomeric complex $[(\pi\text{-}1,7\text{-})\text{-}2,3\text{-}B_3C_2H_5]Co_2(\pi\text{-}C_5H_5)_2$ was synthesised by the reaction of sodium dicarba-*nido*-hexaborate $NaB_4C_2H_7$ with C_5H_5Na and $CoCl_2$ (Fig. 44).[116] Both complexes obtained are formally derivatives of the $B_3C_2H_5^{4-}$ ligand. The π-carborane complexes are structurally similar to the complex $[Ni(C_5H_5)_3]^+$.[117] However, in contrast to the $[Ni_2(C_5H_5)_3]^+$ system, which is readily converted into nickelocene under the influence of moisture, the $(B_3C_2H_5)Co_2(C_5H_5)_2$ systems are resistant to the action of water, atmospheric oxygen, and solvents.

V. CARBORANE DERIVATIVES OF NON-TRANSITION METALS

The possibility of the formal substitution of the BH vertices in the polyhedral carborane structures by isoelectronic units is clearly illustrated, for example, by the isoelectronic series of compounds $B_{12}H_{12}^{2-}$, $B_{11}CH_{12}^-$, and $B_{10}C_2H_{12}$, from which it follows that the BH unit is isoelectronic with the CH^+ unit.[4] By analogy, Be is isoelectronic with the BH unit and therefore one might expect the existence of the neutral compound $BeB_9C_2H_{11}$.

Using the familiar reaction whereby the dicarbollide ion is built up with the aid of phenylboron dichloride to the icosahedral carborane structure[118], Popp and Hawthorne[119,120] attempted to build up the dicarbollide ion with beryllium chloride:

$$(3)\text{-}1,2\text{-}B_9C_2H_{11}^{3-} + BeCl_2 \rightarrow (3)\text{-}BeCl - 1,2\text{-}B_9C_2H_{11}^-.$$

but they were unable to obtain a berylcarborane by this reaction.

The $B_9C_2H_{13}$ carborane, which may be regarded as a diprotonated dicarbollide ion, was used to synthesise a berylcarborane. Its reaction with metal alkyls should result in the formation of an alkane on protolysis of the metal–carbon bond and the metal should be inserted in the open face of the icosahedral fragment. For dialkylberyllium, the presence of electron-donating solvents is necessary to stabilise the product. Accordingly, dimethylberylliumdiether and diethylberyllium-diether were used for the synthesis[119,120]:

$$(3)\text{-}1,2\text{-}B_9C_2H_{13} + BeR_2 \cdot 2(OEt_2) \xrightarrow{\text{benzene/ether}} 2RH + (3)\text{-}Be\text{-}1,2\text{-}B_9C_2H_{11} \cdot OEt_2.$$

The product is very sensitive to moisture and on hydrolysis yields the (3)-1,2-$B_9C_2H_{12}^-$ ion.

When the reaction was carried out with diethylberyllium containing only one-third of the required amount of ether, an insoluble polymeric product consisting of [(3)-Be-1,2-$B_9C_2H_{11}$]n units with icosahedral geometry, linked by Be–H–B bridges, was obtained. When the ether adduct of the berylcarborane is treated with trimethylamine, the complex (3)-[BeNMe$_3$]-1,2-$B_9C_2H_{11}$, whose structure is illustrated in Fig. 45, is formed.

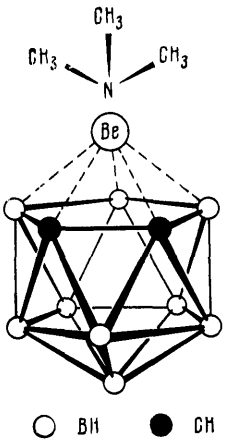

Figure 45.

Mikhailov and Potapova obtained an aluminacarborane in the form of an adduct with two THF molecules by the reaction of the 1,2-dicarbollide ion with ethylaluminium dichloride in THF[121]:

$$1,2\text{-}B_9C_2H_{11}^{3-} + EtAlCl_2 \xrightarrow{THF} (3)\text{-}EtAl - 1,2\text{-}B_9C_2H_{11} \cdot 2THF.$$

This compound was the first example of metallocarboranes containing a non-transition metal in the polyhedron. Subsequently the ability of the carborane $B_9C_2H_{13}$ to undergo protolysis at the metal–carbon bond was used to synthesise alumina- and galla-carboranes[122,123]. When equimolar amounts of trialkylaluminium and $B_9C_2H_{13}$ were mixed and heated at 50°C for 1 h, 7,8-μ-dialkylalumina-1,2-dicarba-*nido*-undecaborane(13) was formed:

$$(3)\text{-}1,2\text{-}B_9C_2H_{13} + R_3Al \rightarrow (3)\text{-}AlR_2\text{-}1,2\text{-}B_9C_2H_{13} + RH.$$

According to X-ray diffraction[124,125], the aluminium atom in $B_9C_2H_{12}AlR_2$ deviates from the open face of the icosahedral fragment and the angle between the $B_{(7)}$–Al–$B_{(8)}$ and $B_{(7)}$–$B_{(8)}$–$B_{(4)}$–$C_{(1)}$–$C_{(2)}$ planes is 130° (Fig. 46). It is suggested that the aluminium atom is linked to the $B_{(7)}$ and $B_{(8)}$ atoms by two bridging hydrogen bonds. A low-temperature study of the ^{11}B NMR spectra established[123] the occurrence of a tautomeric process involving the exchange of the bridge positions between the dialkylaluminium fragment and the proton H_b, as shown in Fig. 46. At low temperatures the ^1H NMR spectra reveal the splitting of the signal corresponding to the Me_2Al group, which indicates the *endo*- and *exo*-locations of the methyl groups relative to the open face[123]. The gallium derivative was obtained similarly:

$$(3)\text{-}1,2\text{-}B_9C_2H_{13} + Et_3Ga \rightarrow (3)\text{-}GaEt_2\text{-}1,2\text{-}B_9C_2H_{13} + C_2H_6.$$

When 7,8-μ-dialkylalumina-1,2-dicarba-*nido*-undecaborane(13) is heated in benzene, 3-alkyl-3-alumina-1,2-dicarba-*closo*-dodecaborane(12) is formed:

$$(3)\text{-}AlR_2\text{—}1,2\text{-}B_9C_2H_{12} \xrightarrow[25\ h]{77^\circ} (3)\text{-}RAl - 1,2\text{-}B_9C_2H_{11} + RH\ .$$

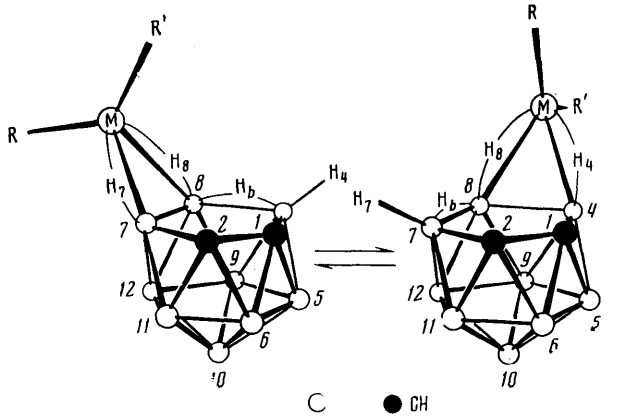

Figure 46.

It has been established that the monoethylaluminium derivative has the closed icosahedral structure with an EtAl unit [122,126]. This compound forms with THF the adduct obtained previously by Mikhailov and Potapova.

Heating the diethylgallium derivative also leads to the formation of a closed structure:

$$(3)\text{-}1,2\text{-}B_9C_2H_{12}GaEt_2 \xrightarrow{77^\circ} (3)\text{-}GaEt - 1,2\text{-}B_9C_2H_{11} + C_2H_6\ .$$

At 410°C 3-ethyl-3-alumina-1,2-carborane undergoes thermal isomerisation in the gas phase forming 3-ethyl-3-alumina-1,7-carborane [123]:

$$(3)\text{-}AlEt - 1,2\text{-}B_9C_2H_{11} \xrightarrow{410^\circ} (3)\text{-}AlEt - 1,7\text{-}B_9C_2H_{11}\ .$$

The selective formation of the 1,7-isomer in the isomerisation process resembles the behaviour of the carborane $1,2\text{-}B_{10}C_2H_{12}$, which rearranges to $1,7\text{-}B_{10}C_2H_{12}$ at 400–500°C, [4] but its behaviour differs from that of other metallocarboranes, particularly $Ni[(3)\text{-}1,2\text{-}B_9C_2H_9Me_2]_2$ and $Pd[(3)\text{-}1,2\text{-}B_9C_2H_9Me_2]_2$, [62,63] for which rearrangements leading to a 1,6- disposition of the carbon atoms are characteristic.

Alumina- and galla-carboranes are sensitive to the action of moisture and are readily hydrolysed with formation of the $(3)\text{-}1,2\text{-}B_9C_2H_{12}$ ion. Their reaction in benzene with anhydrous HCl gives a quantitative yield of $(3)\text{-}1,2\text{-}B_9C_2H_{13}$. An interesting property of the compounds $B_9C_2H_{12}AlEt_2$ and $B_9C_2H_{11}AlEt_2$ is their ability to form with $TiCl_4$ complexes whose solutions polymerise ethylene like the Ziegler–Nata catalysts [123].

The dicarbollide ion interacts with bivalent Group IVB metal salts, forming a product resulting from the insertion of the metal in the open face of the dicarbollide [127,132]:

$$(3)\text{-}1,2\text{-}B_9C_2H_{11}^{2-} + MX_2 \rightarrow (3)\text{-}M\text{-}1,2\text{-}B_9C_2H_{11} \quad (Me{=}Ge, Sn, Pb)\ .$$

The metallocarboranes obtained are stable in air, but are hydrolysed in acid and alkaline media to the anions $B_9C_2H_{12}^-$.

A similar reaction involving the building up of 1,2- and 1,7-phosphacarbollide and 1,2- and 1,7-arsacarbollide ions with the aid of GeI_2 leads to phospha- and arsa-germacarboranes containing three heteroatoms in the icosahedral structure [129]:

$$1,2\text{-}B_9H_9CHE^{2-} + GeI_2 \rightarrow 1,2,3\text{-}GeB_9H_9CHE,$$
$$1,7\text{-}B_9H_9CHE^{2-} + GeI_2 \rightarrow 1,2,7\text{-}GeB_9H_9CHE. \qquad (E = P, As)$$

When the monocarbollide ion was built up with trichloromethylgermane, a germacarborane was obtained [130]:

$$Na_3B_{10}H_{10}CH + MeGeCl_3 \rightarrow B_{10}H_{10}CHGeMe - 1.2\ .$$

The gas-phase reaction of trimethylgallium or trimethylindium with 1,3-dicarba-*nido*-hexaborane(8) yields 1-methyl-1-galla- or 1-methyl-1-inda-2,4-dicarba-*closo*-heptaborane(7): [131,132]

$$B_4C_2H_8 + GaMe_3 \xrightarrow{215^\circ} MeGaB_4C_2H_6;\ B_4C_2H_8 + InMe_3 \xrightarrow{95-110^\circ} MeInB_4C_2H_6\ .$$

The structure of the gallacarborane is illustrated in Fig. 47. The indacarborane probably has a similar structure.

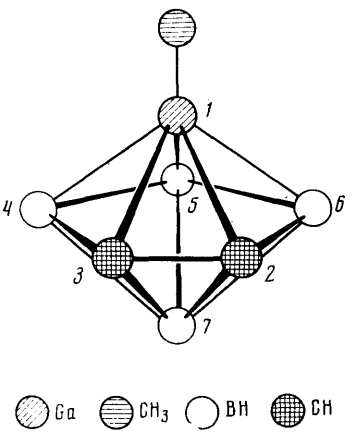

Figure 47.

After the manuscript had been sent to the editors, a number of papers on metallocarboranes were published. Certain early investigations have been summarised in Snaith and Wade's review [133]. The polyhedral expansion reaction has been developed further. Hawthorne and coworkers [134] described in detail the application of this reaction to the $1,7\text{-}C_2B_6H_8$, $4,5\text{-}C_2B_7H_9$, $1,6\text{-}C_2B_8H_{10}$, $1,10\text{-}C_2B_8H_{10}$, and $1,8\text{-}C_2B_9H_{11}$ systems. Using $CoCl_2$ and NaC_5H_5, metallocarboranes of the following types were obtained: $C_5H_5CoC_2B_nH_{n+2}$, $(C_5H_5Co)_2C_2B_nH_{n+2}$, and $C_5H_5CoC_2B_nH_{n+1}(C_2B_nH_{n+1})$. The formation of the mixed ferracarboranes from the $1,7\text{-}C_2B_6H_8^{2-}$ and $1,6\text{-}C_2B_8H_{10}^{2-}$ dianions, NaC_5H_5, and $FeCl_2$ has been described [134].

The application of the polyhedral expansion reaction to metallocarboranes yielded interesting results. The reduction of the complex $(\pi\text{-}C_5H_5)Co^{III}(\pi\text{-}1,6\text{-}C_6B_7H_9)$ by naphthalenesodium in THF and its subsequent reaction with NaC_5H_5 and $FeCl_2$ led to the formation of the bimetallocarborane $(\pi\text{-}C_5H_5)Co(\pi\text{-}C_2B_7H_9)Fe(\pi\text{-}C_5H_5)$ in which there is one paramagnetic and one diamagnetic centre [135].

The cobaltaferracarborane $(\pi\text{-}C_5H_5)Co^{III}(\pi\text{-}C_2B_9H_{11})Fe^{III}(\pi\text{-}C_5H_5)$ was obtained by the alkaline degradation of the complex $(\pi\text{-}C_5H_5)Co^{III}(\pi\text{-}C_2B_{10}H_{12})$ in the presence of $FeCl_2$ and C_5H_6.[135]

The reaction of the reduced form of $(\pi\text{-}C_5H_5)Co^{III}(\pi\text{-}1,6\text{-}C_2B_7H_9)$ with NaC_5H_5 and $CoCl_2$ leads to the formation of $(C_5H_5Co)_2C_2B_7H_9$ and $(C_5H_5CO)_3C_2B_7H_9$.[136] It is suggested that the last complex has an icosahedral structure with the cobalt atoms at three vertices. The reaction of the reduced complex $[Me_4N](\pi\text{-}C_5H_5)Co^{III}(\pi\text{-}CB_7H_8)$ with NaC_5H_5 and $NiBr_2$ yielded the two-metal monocarbon metallocarborane $(\pi\text{-}C_5H_5)Co^{III}(\pi\text{-}CB_7H_8)Ni^{IV}(\pi\text{-}C_5H_5)$.[137]

Salentine and Hawthorne[137] quote tentative structures for metallocarboranes. The study of the chemical properties of certain metallocarboranes has been continued[138]. Hawthorne and coworkers[139] attempted to classify metallocarboranes in terms of the total number of electrons involved in the formation of the polyhedra. The $2n + 14$, $2n + 16$, and $2n + 26$ electron rules are valid for *closo*-polyhedral heteroboranes containing one transition metal at the vertex, for *nido*-polyhedra of this type, and for *closo*-polyhedra with two transition metals at the vertices respectively. A series of X-ray diffraction studies have been made on metallocarboranes, confirming the structures proposed previously: $(B_6C_2H_8)Mn(CO)_3$,[140] $(B_3C_2H_7)Fe(CO)_3$,[141] and $(B_9C_2H_{11})_2Ni$.[142]

Modern Methods for the Chromatographic Analysis of Nucleic Acids and Their Components

L.I.Gus'kova and V.P.Demushkin

The literature data for the chromatographic separation of nucleic acids and their components are considered in the review. Particular attention has been devoted to the commonest types of column chromatography, thin layer chromatography using different adsorbents, and electrophoresis. The applicability of each type of chromatography in the study of the primary nucleic acid structure and the formation of complexes by nucleic acids with natural products of other classes is demonstrated. The bibliography includes 597 references.

I. INTRODUCTION

The development of modern biology, which has led to many important discoveries, would have been impossible without the development of microanalytical methods. Paper chromatography and electrophoresis and ion exchange column chromatography have played an outstanding role in the establishment of this science, permitting the elucidation of the most general characteristics of the structures of nucleic acids and proteins. However, further improvement in the extent of our knowledge and the acquisition of more detailed information in this field required the solution of specific problems in the isolation and determination of the structures of specific individual nucleic acid and protein molecules, only a few of which are sometimes present in the cell. The previous micromethods were relatively unsuitable for the solution of these new problems and, although the old procedures were still used in the determination of the structures of the first individual nucleic acids, the necessity for the development and utilisation of new, much more sensitive analytical methods became quite evident.

Nowadays the employment of thin-layer chromatography in combination with labelled compounds permits the analysis of amounts of compounds not less than 10^{-12} g. So far column chromatography has a lower sensitivity (10^{-7}—10^{-9} g) but it often permits the necessary spectroscopic analysis of the substance. The contribution of ultramicromethods to modern research is continuously increasing.

This review gives a general account of the advances in the field of analytical methods for nucleic acids in the last 10 years. Readers interested in work carried out prior to this can become acquainted with it in reviews published previously[1-5].

In the present review attention has been concentrated on ultramicromethods. Since the principles and chromatographic systems employed in ultramicroanalysis are general, the review includes also less sensitive methods which can be employed in ultramicroanalytical procedures.

The analytical methods for nucleic acids are general and can be used also in other fields of research. The authors hope that the review will be useful not only to chemists, physicists, and biologists working in the field of molecular biology but also to organic chemists employing micromethods in their work.

To facilitate the practical employment of the review, the data are divided into sections combining identical types of compounds to be analysed. The abbreviations and symbols for nucleic acids and their components employed in the review are those recommended by the IUPAC Commission and IUB.[6]

Large numbers of adsorbents of different types are used to analyse nucleic acids and their components. The detailed characteristics of these adsorbents and the names of the firms manufacturing them are given in Lur'e's handbook[7].

II. NUCLEIC ACIDS

The number of different types of nucleic acids in the cell is fairly large and it is therefore extremely difficult to isolate the individual components. Moreover, their limited solubility in aqueous solutions and their capacity for aggregation and non-specific interaction with sorbents greatly reduce the number of methods available for the fractionation of nucleic acids. However, fairly numerous systems are described in the literature for the chromatographic resolution of nucleic acids into individual components. Experience gained in their application shows that, for a successful isolation of a homogeneous substance, it is insufficient to employ a single chromatographic procedure. Stepwise fractionation of nucleic acids is most useful. The nucleic acid mixtures are initially divided into fractions with identical specific features—transfer RNA (tRNA), ribosomal RNA (rRNA), messenger RNA (mRNA), DNA, etc. Selective extraction, a combination of different precipitation methods, centrifugation[8], and chromatographic methods are frequently employed for this purpose. The nucleic acid fractions are then subjected to a more detailed resolution. Among chromatographic methods separation on ion-exchange resins, partition and affinity chromatography, and other procedures are most widely used.

1. ION-EXCHANGE CHROMATOGRAPHY

A. Adsorbents Containing Proteins

One of the types of such chromatography—fractionation on columns with methylated albumin sorbed on Kieselguhr (MAK-chromatography)—has become very common in the separation of all types of nucleic acids. Their mobility on MAK-columns is determined largely by three factors: (1) the length of the polynucleotide chain (the overall molecular charge), (2) the conformation of the nucleic acid in solution, and (3) its nucleotide composition. The first factor determines the strength of ionic binding of the substance chromatographed to the adsorbent. The second and third factors determine the degree of hydrophobic interaction and the interaction via hydrogen bonding. The chromatographic behaviour of nucleic acids on MAK columns shows that the second and third factors play a more significant role in the separation of nucleic acids.

During elution in an NaCl concentration gradient from 0.2 to 1.2 M, nucleic acids are separated into fractions corresponding to their functions in the cell: tRNA, DNA, etc.[9,10]. The separation is carried out at 15—25°C and sometimes at 35°C. An increase of temperature is undesirable, since part of the nucleotide material is then retained by the adsorbent. A decrease of temperature is likewise undesirable in view of the less clear-cut separation. One should recall that the NaCl concentration at which the given type of nucleic acid is eluted can vary for different batches of Kieselguhr and methylated albumin, which can be accounted for by the different degrees of methylation of the albumin. However, the elution sequence [tRNA—DNA—(rRNA, mRNA)] does not as a rule change[9-12].

The elution profile depends on the source of nucleic acid. Thus, in the separation of bacterial nucleic acids on MAK columns, tRNA and both types of rRNA (16S and 23S) are satisfactorily separated from one another and the rapidly labelled RNA are separated into several fractions. In nucleic acids from animal tissues the rRNAs are separated somewhat less satisfactorily and mRNAs are eluted as a mixed fraction[10-11]. If the nucleic acid is denatured, it is eluted from the column at higher salt concentrations than the native form. This is true of both DNA [13-15] and RNA.[16-18] The yield of substance from the column is usually 90—100% for native preparations, but is much lower for denatured nucleic acids (50—70%),[13,14] and when the column is overloaded the deoxynucleotides for example, may not be eluted at all.[19]

The optimal separation conditions on an MAK-column are 0.5—2 mg of the nucleic acid mixture per 10 ml of the MAK suspension with an overall volume of the gradient solution of 800 ml. The methods of preparation of the adsorbents and the chromatographic techniques have been described[9,10,20-25]. In the preparation of the columns one can employ both bovine albumin[10,20,23-25] and human albumin[26,27]. Kieselguhr can be replaced by silica gel[17,28-31] (MASA-chromatography); the adsorbent capacity with respect to the amount of nucleotide material is then significantly increased[30,32].

Chromatography on MAK and MASA columns is also used to separate the nucleic acid fractions into individual components. In the separation of DNA the position of the DNA being eluted depends on the length of the molecule, its conformation, and nucleotide composition. DNA with long molecules and containing more guanine—cytosine pairs (GC pairs) are eluted at higher salt concentrations[24,32]. Certain types of DNA, for example those of *B. subtilis* and calf and mouse thymus are eluted at the same salt concentrations[33]. The *E. coli* and T2 and T4 phage DNA are satisfactorily separated from one another. The T5 phage DNA can be resolved into two components[8,34]. Glycosylation of the DNA bases leads to firmer binding to the sorbent[35].

Chromatography on MAK and MASA columns has been widely used for the separation of the native and denatured forms of DNA.[13,15,36-43]. With the aid of this method, it is possible to isolate DNA-RNA hybrids, the replicated forms of phage DNA and complementary DNA strands[44-47]. MAK chromatography has been proposed by Japanese investigators for the separation of tRNAs [48] and has been successfully used for the fractionation of tRNAs [49-58] from a wide variety of sources[16,22,25,26,49-58] and of its chemically modified derivatives[30,31,59].

Basic proteins and polypeptides adsorbed on Kieselguhr are also used as supports for the chromatography of nucleic acids[60-67]. The chromatographic profile and the characteristics noted previously (the effect of the molecular weight, nucleotide composition, etc.) in fractionation on these adsorbents are the same as in chromatography on MAK and MASA columns[68-71]. An interesting modification of the method is the separation on Celite of a ribonucleoprotein complex (RNP complex)[72]. The RNP proteins are then adsorbed on Celite and are not eluted from the column, while the RNA is fractionated as in the separation on MAK. The chromatography of DNA on protein powders from wool has been described[73]. The behaviour of DNA on such columns resembles its chromatography on MAK.

It is noteworthy that the principle of the chromatography of nucleic acids on proteins sorbed on carriers of the type of Kieselguhr or silica gel is extremely promising, since in this case separation is determined primarily by specific adsorption and hydrogen bonding forces. We believe that the employment for these purposes of other proteins, for example, immunoglobulins, etc. might significantly extend the scope of the fractionation of nucleic acids.

B. Adsorbents Based on Cellulose and Sephadex

In the separation of nucleic acids on ion-exchange polysaccharides the binding of nucleic acids to the resin via ionic interactions is stronger than for adsorbents containing methylated and basic proteins. For this reason, the effect of other factors (conformation and composition of the nucleic acid and non-ionic interactions with sorbent) on the separation is significant only for nucleic acids with a low molecular weight. High-polymer nucleic acids are adsorbed by anion exchangers so strongly that their elution requires high salt concentrations. For this reason, the separation of DNA and high-polymer RNA on ion-exchange celluloses and different types of Sephadex is comparatively rare[8,74,75]. These adsorbents have found extensive applications only in the fractionation of tRNA.[76-78] The chromatography of tRNA on diethylaminoethylcellulose (DEAE-cellulose)[76-85], triethylaminoethylcellulose (TEAE-cellulose)[86], and DEAE-Sephadex[76-78,87-99] has been used in numerous modifications (Table 1).

The behaviour of tRNA from *E. coli* and yeast on ion exchangers has been most thoroughly investigated. tRNA from *E. coli* is eluted from the column at higher salt concentrations, but the elution sequence of the tRNAs in terms

of their specificity with respect to a particular aminoacid is retained. Chromatography on polysaccharide anion exchangers is nowadays used in the first stage of the purification of tRNA. The method permits the separation in a single step of up to 100 g of the total tRNA.[100]

Table 1. Conditions in the separation of tRNA on ion-exchange resins.

Adsorbent	Separation conditions	Concn. of eluent for tRNA		Refs.
		from *E.coli*	from yeast	
DEAE-cellulose	pH 5.0; salt gradient	0.4-0.7 M NaCl	0.4-0.65 M NaCl	76
	pH 7.5; urea, salt gradient	0.33-0.40 M NaCl	0.28-0.35 M NaCl	76
	pH 7.5; 0.36 M NaCl, urea gradient	2-5 M urea	2-6 M urea	76
	pH 4.2; 7 M urea	0.35-0.45 M NaCl	0.30-0.40 M NaCl	76
	pH 4.2; 0.40 M NaCl urea gradient	1-6 M urea	1-6M urea	76
	pH 4.2; 4 M urea, salt gradient	0.42-0.53 M NaCl	0.38-0.50 M NaCl	76

* tRNA from *I. utilis*.
** tRNA from rat liver.

The most effective separation of tRNA takes place in chromatography of benzoylated DEAE-cellulose (BD-cellulose). The use of this hydrophobic adsorbent increases the contribution of adsorption forces to the chromatographic separation process. BD-cellulose was first proposed for the separation of tRNA by Tener's group[101,102]. Effective fractionation of tRNA is observed (Fig. 1) for elution by salt solutions at low temperatures. The method has been widely used to isolate the individual tRNAs.[95,97,103-109]. The chromatographic profiles for tRNAs from different sources mainly give rise to similar patterns. Phe-, Cys-, Tyr-, Ser-, and Leu-specific tRNAs are retained on BD-cellulose more strongly than other tRNAs. Phenylalanine tRNA from yeast and rat liver is eluted at higher salt concentrations than the analogous tRNAs from *E. coli*[102,107] and halophilic bacteria[109]. The lower degree of adsorption can probably be accounted for by the absence from these tRNAs of the hydrophobic base Y, which has been found in the $tRNA^{Phe}$ from yeast and rat liver.

The employment of additional procedures—gradient elution by alcohol[110,111] and ether[112,113] solutions—in many instances improves the separation and increases the elution from the column. BD-cellulose proved to be extremely effective in the chromatography of DNA and other types of RNA.[8,114-117] A sorbent analogous to BD-cellulose was proposed recently by Osterman for the fractionation of tRNA.[118]

C. Hydroxyapatite

Hydroxyapatite (HA) is a weak anion exchanger, which permits its employment for the chromatography of anions. The range of applications of HA chromatography is fairly considerable: the behaviour of low- and high-molecular-weight and RNA and DNA from different sources on HA columns has been thoroughly investigated[119-144]. In the elution of nucleic acids from HA columns one usually employs a phosphate buffer at pH 6.8 (Table 2). However, more acid solutions have also been used for elution.

Table 2. The concentration of phosphate buffer and the recovery of nucleotide material from the column in chromatography on HA.

Substance	Concn. of phosphate buffer at pH 6.8, M	Recovery from column, %
Mononucleotides	0.001	100
Oligonucleotides	0.01—0.02	100
Polynucleotides		
polypyrimidine	0.1—0.12	100
polypurine	0.22—0.25	60—80
Polynucleotides in 1% formaldehyde	0.05—0.17	100
RNA	0.11—0.18	100
Denatured DNA	0.11—0.18	50—100
Native DNA		
from higher organisms	0.11—0.18	50—100
from bacteria	0.20—0.22	90
from phages	0.25—0.27	90

A significant factor in chromatography on HA is that the adsorption of nucleic acids is almost independent of the concentration of anions other than phosphate. For this reason, this method is very convenient in rechromatography after other procedures involving the separation and concentration of nucleic acids in salt solutions. One must make certain that the solutions do not contain substances forming complexes with Ca^{2+}. If a phosphate buffer containing other anions (for example Cl^-) is used in the elution of the test substance from HA columns, the concentration of phosphate at which nucleic acids are eluted from the column increases.[138,144] The separation is usually carried out at +4°C or at about 20°C.

In most cases the separation is independent of temperature. However, for certain polynucleotides, for example polyuridylic and polycytidylic, which have an ordered structure at low temperatures, the eluting concentration is higher at low temperatures than at 20°C.[138] An impression has been created that a polynucleotide with an ordered structure is eluted after the same polynucleotide whose secondary and tertiary structures have been disrupted[128,138,139,144]. The method permits the separation of denatured and native DNA,[128,135,139,144-154] of different isoacceptor tRNA,[123,129,130,131,133,140,143,155,156] and different

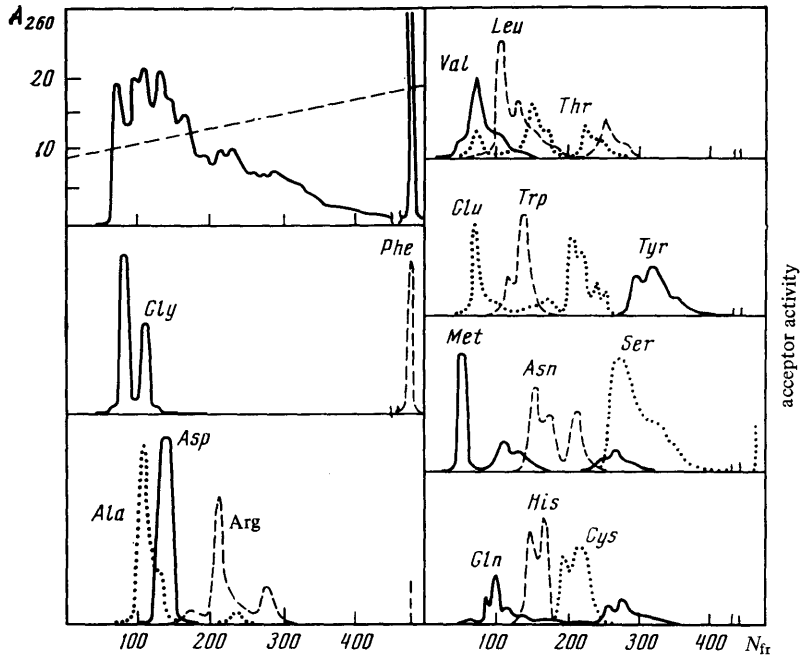

Figure 1. Fractionation of tRNA from *E. coli* on BD-cellulose[102].

forms of cyclic DNA.[157,158] Glycosylated DNA from T-even phages are retained more firmly on HA than the DNA from *E. coli* or from T-odd phages[138,159].

The behaviour of DNA on HA columns depends also on the nucleotide composition. The greater the number of GC pairs in the molecule the more firmly is it bound to HA.[128,139,144]

Both gradient and stepwise elution from HA has been used for the fractionation of nucleotide material. In connection with the stepwise fractionation of nucleic acids on HA, one should bear in mind the presence of "false fractions", i.e. fractions of the substance which on rechromatography are eluted at a lower molarity of the phosphate buffer[128,144]. To avoid this, it is useful to employ gradient elution.

A satisfactory separation requires 10 ml of HA per milligram of the nucleotide material for an overall volume of the gradient eluent of 200–300 ml. The optimal rate of elution is 0.1–0.2 ml min^{-1} cm^{-2}. The preparation of the sorbent and the chromatographic technique have been described[138,144,160-162].

D. Cation Exchangers with Charges Balanced by Polyvalent Metal Cations

Ion exchangers with charges balanced by the cations of polyvalent metals should have properties resembling those of weak anion exchangers of the type of HA. It has been noted that DNA is adsorbed from solutions by Amberlite IRC-50 electrically neutralised by Mg^{2+}. On elution, it was possible to isolate several DNA fractions differing in composition and sedimentation coefficient[163,164]. Chromatography of DNA on Amberlite IR-120 columns electrically neutralised by Al^{3+} leads to the isolation of seven DNA fractions differing sharply in their chromatographic properties[165-167]. The separation profile is independent of the protein impurities[168], RNA,[169] and the pH,[170] but does vary markedly as a function of the method of isolation of DNA,[171] which is probably due to the degradation of DNA during its isolation.

Chromatography on cation exchangers electrically neutralised by Al^{3+} appears to be very promising, since it permits the separation under mild conditions and does not entail the degradation of DNA. The elution of the nucleotide material from the resin is complete.

2. COUNTERCURRENT DISTRIBUTION AND REVERSED-PHASE CHROMATOGRAPHY

The separation of nucleic acids by countercurrent distribution has been proposed at the beginning of the 1960's and immediately proved useful as a qualitative method for the fractionation of DNA and different types of RNA.[172-179] This chromatographic technique has been most widely used for tRNA.[180-182] However, the complexity of the equipment, the small amounts of substances separated, and the fairly low resolving power greatly limited the scope of the method. The principle of countercurrent distribution has been used in chromatography in aqueous organic systems on different adsorbents. The adsorbent is saturated by the organic phase and is then transferred to a column and equilibrated with the aqueous phase. Systems for this type of chromatography were initially taken from studies on the countercurrent distribution of nucleic acids[183-190]. Partition chromatography on columns (reversed-phase chromatography) eliminated the above disadvantages of countercurrent distribution.

The introduction into the organic phase of ammonium salts containing aliphatic hydrocarbon residues significantly improved the resolving power of the method[191-194]. Chromatography on Chromosorb impregnated with tricaprylmethylammonium bromide in tetrafluoropropane (Freon) has been most widely used[192,195-198]. The application of a special type of PTFE impregnated with trioctylpropylammonium bromide[199,200], which was proposed recently, permits a satisfactory separation of tRNA (Fig. 2). The separation curves clearly show that the resolution of tRNA in the "reversed phase" is very promising.

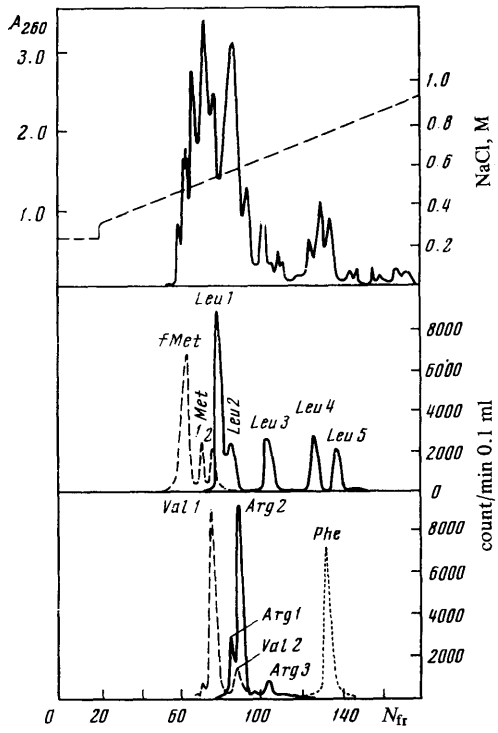

Figure 2. Chromatography of tRNA from *E. coli* on PTFE.[199]

It is noteworthy that reversed-phase chromatography can probably be used also for the fractionation of other types of nucleic acids, since it is well known that aliphatic amine salts of different types of nucleic acids are soluble in aqueous solutions at different NaCl concentrations[201].

3. AFFINITY CHROMATOGRAPHY

The name of this method comes from the English word "affinity", since this type of chromatography employs the interaction between two substances exhibiting affinity with respect to one another. One of these is in solution and the other is on an insoluble matrix (adsorbent). The test mixture is passed through a column containing the adsorbent under optimal conditions for the interaction of the fixed substance and one of the mixture components. In this interaction the adsorbent retains only the component which exhibits affinity with respect to the substance on the adsorbent. The remaining mixture components are not retained. Thus the substance exhibiting affinity with respect to that fixed on the adsorbent is separated from the remaining components of the mixture.

The application of affinity chromatography for the separation of polynucleotides and nucleic acids dates back to 1962 when two types of adsorbents were proposed at the same time. The first of these comprised gels containing nucleic acids (mechanical adsorption)[202] and the second consisted of cellulose with mono- and poly-nucleotides bound by covalent bonds (chemical binding)[203,204]. Mechanical adsorption in agar–agar[202,205-208], acetylated phosphocellulose[202], and polyacrylamide[209] gels permits the preparation of sorbents with a high content of nucleotide material. Nucleic acids and polynucleotides are within the grains.

The gels exhibit a high selectivity with respect to mRNA and adsorb from solutions only their "own" mRNA, while "foreign" mRNA is not retained[202-208]. The retained mRNA can be removed from the gels by a temperature gradient elution or by reducing the ionic strength. The mRNA fractions with a high GC content are then eluted from the column at a higher temperature[207]. Polyuridylic acid in polyacrylamide gel forms complexes with oligo- and poly-adenylic acids[209].

The simplicity of the preparation of the gels containing polynucleotides and the fairly mild conditions in their preparation, which tend to preserve the native form of nucleic acids, constitute undoubted advantages of the mechanical method of preparation of affinity adsorbents. It is noteworthy that in this case adsorption from solutions can be observed only for substances with a lower molecular weight than that of the nucleotide in the gel. This disadvantage can be eliminated by employing gels whose grains are coated on the outside by polynucleotide molecules and are then "cross-linked" to one another under the influence of ultraviolet irradiation[210-212]. It is noteworthy that the gels frequently have a low mechanical strength. These disadvantages must be borne in mind in experiments with these materials.

Nitrocellulose is also used as an adsorbent for the affinity chromatography of nucleic acids. Under certain conditions, nitrocellulose is known to bind irreversibly denatured DNA. The nature of the binding is unknown, but neither native DNA nor RNA are retained by nitrocellulose. Low-molecular-weight fragments of denatured DNA are not sorbed by nitrocellulose[213]. Denatured DNA immobilised by nitrocellulose binds selectivity polynucleotides with affinity for DNA. This method can be used to investigate the formation of complexes with DNA.[214-223]

Proteins immobilised by nitrocellulose, particularly the aminoacids of tRNA ligase, permit the investigation of the complexes of these enzymes with tRNA and the isolation of enriched tRNA preparations[224,225].

Mention should also be made of DNA immobilised by cellulose as a mechanical affinity sorbent[225,226]. However, this sorbent is so far used widely only for the purification of proteins forming specific complexes with nucleic acids[226-229].

The affinity chromatography of nucleic acids and polynucleotides has been widely used on sorbents containing covalently bound polynucleotides. Such sorbents are synthesised by the condensation of cellulose or phosphocellulose with mono-[203,230-232], oligo-, and poly-nucleotides[204,230,232-235], RNA,[204,230,232] and DNA [236-238] in the presence of dicyclohexylcarbodiimide or Sepharose treated

with cyanogen bromide[239]. RNA—DNA complexes[236-238], the purification of tRNA,[235] and the separation of poly- and oligo-nucleotides[231,233-235] can be investigated by chromatography on such adsorbents.

The employment of enzymes covalently bound to Sephadex[240], and of mercury-containing adsorbents which are capable of specific binding of DNP complexes containing SH groups[241,242], for the chromatography of nucleic acids has also been described. To isolate polynucleotides with a free *cis*-glycol group at the 3′-end of the molecule, one can use borate-containing cellulose[243,244].

Thus it is evident that affinity chromatography can be used successfully to fractionate various nucleic acids and polynucleotides. In contrast to the methods described previously, this type of chromatography makes it possible to employ more refined mechanisms for separation—the affinity of the substance to be isolated for a specially prepared adsorbent. In the application of this affinity, one can use a specific reactive group (the affinity of the SH groups of DNA for the terminal ribose residue), the complementary interaction forces (RNA—DNA complexes, polynucleotide interactions), and the formation of complexes with proteins.

4. GEL FILTRATION AND OTHER SEPARATION METHODS

The separation of nucleic acids on Sephadex and polyacrylamide gels is used only for the partial elimination of other types of nucleic acids and low-molecular-weight compounds. Gel chromatography has been most widely used for the purification of tRNA [245-255] and even partial fractionation of tRNA is then observed[256,257]. The method is likewise suitable for the isolation of large tRNA fragments and for the investigation of their interaction with one another[258,259]. Gel filtration is of limited applicability to nucleic acids with large molecular weights, since their aqueous solutions are very viscous, which greatly hinders chromatographic separation by this procedure.

Nucleic acid fractionation methods, such as paper and thin-layer chromatography, have found only limited applications[260-262].

III. OLIGONUCLEOTIDES

Recently the development of methods for the fractionation of oligonucleotides has been determined by trends associated with the elucidation of the structures of nucleic acids and their fragments responsible for important biochemical functions and by studies on the synthesis of oligonucleotides and nucleic acids. The advances in this field (the determination of the structures of more than 50 tRNAs, of several 5S RNAs, and of large fragments of ribosomal and viral RNA, the synthesis of the DNA copy of alanine tRNA, etc.) can be accounted for in many respects by the achievements in the development of micromethods for the fractionation of oligonucleotides, Column, paper, and thin-layer ion-exchange chromatography, partition paper and thin-layer chromatography, and combinations of these methods with electrophoresis have found extensive applications in the separation of nucleotides.

1. ION-EXCHANGE CHROMATOGRAPHY

The method has a high resolving power and can be used on both preparative and analytical scales. The main factor determining separation is the overall charge of the nucleotide. This quantity can be readily calculated[263,264] at different pH using the pK of the ionic groups of the nucleotides. Since the force of binding to the adsorbent is determined primarily by the charge of the oligonucleotide (the higher the charge the stronger the binding), it follows that, having determined this quantity, it is possible to predice the mobility of the oligonucleotides relative to one another under the conditions of the separation. The sequence of the elution of the oligonucleotides from the column based on the calculation of the charges will undoubtedly be approximate, since, apart from the ionic interaction with the adsorbent, hydrophobic and hydrogen bonding interactions are also observed. However, calculation of the charges of the nucleotides is in many cases undoubtedly useful, since it permits the selection of the optimal pH for the separation.

The literature data for oligonucleotide chromatographic fractionation systems lead to the conclusion that single-stage ion-exchange column chromatography yields satisfactory results only for simple mixtures of oligonucleotides and is insufficiently effective for complex mixtures. In such cases repeated fractionation is necessary.

The principles of the selection of the binary systems (two-dimensional column chromatography), put forward in 1963,[263] proved to be justified in the separation of complex oligonucleotide mixtures[265-270].

In the selection of the binary systems it is desirable to employ different types of adsorbents and to carry out the separation at significantly different pH values. Satisfactory results have been obtained in the successive separation at initially neutral pH values in aqueous solutions of salts in 7 M urea (chromatography by Tener's method)[271-273] on DEAE-cellulose or TEAE-Sephadex and then either in an acid or in an alkaline medium for adsorbents of any type. In 7 M urea solution in the pH range 5.4—8.0 mixtures of oligonucleotides are resolved into fractions, each of which contains an identical number of nucleotide residues (mono-, di-, and tri-nucleotides, etc.). This system can be used to separate both ribo- and dioxyribo-oligonucleotides[271-276] and gives a satisfactory resolution of the fractions down to decanucleotides. Other conditions being equal, best results are achieved on DEAE-Sephadex[266,270]. The use of urea is not obligatory for homo-oligonucleotides[277,278].

The separation in an acid medium is usually carried out at pH 2—5. Among the adsorbents which give rise to the best results mention may be made of Dowex-1,[263,268,279] DEAE-cellulose[275,280,281], DEAE-Sephadex[263,264,270], and TEAE-cellulose[282]. DEAE-Sephadex and DEAE-cellulose are as a rule employed in fractionation in an alkaline medium. A satisfactory separation is observed at pH 8.5—9.0.[263,283,284] As an example of the two-dimensional fractionation of oligonucleotides, one may quote the separation of the oligonucleotides in the pyrimidyl-ribonuclease (pyridyl-ribonuclease) hydrolysate of tRNA^{Val} from yeast[285] (Fig. 3).

It is noteworthy that in both acid and alkaline media the individual isomeric oligonucleotides are separated[263,286].

A few words should be said about chromatography on hydroxyapatite. This sorbent was proposed recently for oligonucleotides[144,287,288]. The efficiency of the separation of oligonucleotides on HA in 7 M urea in a phosphate buffer concentration gradient (0.001—0.2 M) at pH 6.8 is higher than in chromatography by Tener's method on DEAE-Sephadex.

In order to achieve a satisfactory resolution in the fractionation of oligonucleotides on ion-exchange resins,

the separation is usually carried out on columns with a diameter : height ratio in the range from 1 : 10 to 1 : 50, an amount of the gradient eluent equivalent to 100—200 column volumes, and a rate of elution of 0.2—0.6 ml min^{-1} cm^{-2}. It is then desirable to employ an adsorbent whose particles have the same dimensions. The accounts of methods of fractionation of ion exchangers with respect to dimensions published by Hamilton[289] and Koprda and Fojtik[290] may be recommended. The homogeneity of the dimensions of the adsorbent particles (a scatter of 5—10 μm) is particularly necessary in experiments on columns and on the ultramicroscale.

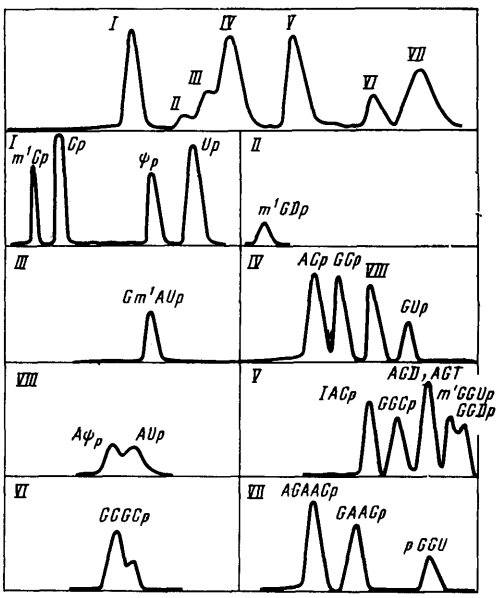

Figure 3. Separation of the oligonucleotides in the pyrimidyl-ribonuclease hydrolysate of $tRNA_1^{Val}$ from yeast on an ultramicroscale[285].

The sensitivity of the chromatographic column methods may be increased in two ways—by increasing the sensitivity of the detector[291] and by reducing the scale of the chromatographic process. The decrease of the chromatographic scale permits the reduction of the amount of the substances to be separated by 2—3 powers of 10 for the same detector sensitivity[285,291]. Thus, in experiments on 0.6 × 100 mm columns and with 300 μl of the gradient eluent, it is possible to separate 10^{-7}—10^{-9} mole of nucleic acids and oligonucleotides[285,292-294]. A significant factor in experiments on the ultramicroscale is that published chromatographic systems, tested on large amounts of substances[285,292-294], can be used.

The fractionation of oligonucleotides on ion-exchange papers[295-298] is less common than column chromatography, since it does not allow the application of gradient elution and has a lower resolving power. Moreoever, the low mechanical strength of ion-exchange paper makes this method relatively unpromising. As a result, chromatography on ion-exchange papers is hardly used nowadays as an independent method.

The disadvantages of fractionation on ion-exchange papers were eliminated by the fractionation of oligonucleotides in thin layers of ion-exchange cellulose. The application of this method to the components of nucleic acids is due to Randerath[299-302]. The ease of preparation of the sorbents and the simplicity of the preparation of the plates make this method extremely attractive. The thin-layer chromatography of oligonucleotides is usually carried out on polyethyleneimine cellulose (PEI-cellulose) in two-dimensions. The sensitivity of the method with the detection of fractions based on ultraviolet absorption is extremely high, amounting to 0.5—1 μg of the substance in the spot and can be significantly improved by using radioactive preparations *in vivo* or by the artificial introduction of a radioactive label, as suggested for oligonucleotides[303,304]. Thin-layer chromatography on PEI-cellulose is distinguished by a high resolving power[305-307] (Fig. 4).and does not require either complicated equipment or long separation times. Moreover, mixtures of PEI-cellulose with other adsorbents, for example with cellulose[308], can be used to prepare the plates, which gives rise to great possibilities for varying the separation conditions.

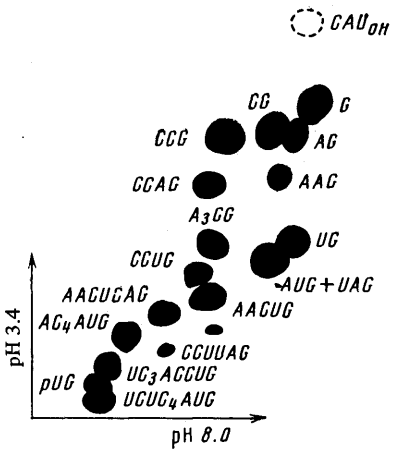

Figure 4. Separation of the pyrimidyl-ribonuclease hydrolysate of 5S RNA from *E. coli* on PEI-cellulose plates[307].

Various salt systems are used to develop the chromatograms[305,306,309,310]. To facilitate the experiment, one frequently employs volatile buffer solutions based on pyridine, or based on lithium salts, since these are effectively extracted by methanol. This makes it easy to desalinate the oligonucleotides directly on the plates. Unfortunately, thin-layer chromatography on PEI-cellulose is still not used on a sufficiently large scale for the fractionation of oligonucleotides. However, advances in the separation of various mixtures of oligonucleotides[305-310], studies on the formation of complexes by polynucleotides with oligonucleotides[311], and also the excellent results obtained in the separation of complex mixtures of long oligonucleotides in combination with electrophoresis (see below) make it possible to state confidently that the fractionation of oligonucleotides in

thin layers of PEI-cellulose is one of the most promising separation procedures. The preparation of adsorbents for thin-layer chromatography and the technique of the separation have been described[305,312-314].

2. PARTITION CHROMATOGRAPHY

The chromatography of oligonucleotides on various adsorbents in aqueous organic media is not a new method. It was discovered at the beginning of the 1950's but it still has not lost its importance in the study of nucleic acids and their components. The classical version of this chromatography—two dimensional paper chromatography—has played a significant role in the study of the structure of tRNA [315-319] and in the analysis of the cleavage products of DNA.[320,321] The commonest solvent system is isobutyric acid—0.5 M NH_3 at pH 3.7 for chromatography in one direction and either a 1:1 butanol—formic acid mixture at pH 3.8 [315,317-319,321] or a mixture of butanol with volatile buffers[316,320,322] for chromatography in the other direction. Apart from the above systems, solvents containing acetonitrile[323] and ethanol[324] can be recommended for the separation of simple mixtures of oligonucleotides. The knowledge or the R_f values in different systems for synthetic oligonucleotides and their derivatives may be of great assistance to chemists engaged in synthesis[325-336].

The solvent systems used in paper chromatography have proved extremely effective also in the separation of oligonucleotides in thin layers of cellulose[337-339] and silica gel[336,340]. Nevertheless partition chromatography is nowadays rarely used, since, in view of the availability of other methods of separation, the difficulties associated with the desalination of the oligonucleotides before and after separation make the experiments on the separation of oligonucleotides by this procedure extremely laborious.

3. ELECTROPHORESIS AND VARIOUS COMBINATIONS OF CHROMATOGRAPHIC METHODS

The presence of a negative charge on oligonucleotides permits their separation by electrophoresis. At a potential gradient E the oligonucleotide molecule migrates to the anode. The rate of migration V is described fairly satisfactorily by the equation $V = EQ/K$, where E is the potential gradient, Q the overall charge of the oligonucleotides, and K a constant which depends on the dimensions and shape of the molecule and on the medium in which the separation takes place (adsorbent, composition of the ions, etc.). K increases with the ionic strength of the buffer solution in which the separation takes place and decreases with increase of temperature[341,342]. If the electrophoresis is carried out on a neutral carrier, for example on paper or in a thin layer of cellulose, the rate of migration is higher the higher the overall charge of the substance. A different picture arises when the electrophoresis is carried out on ion-exchange columns. In this case the rate of migration of the substance is higher the smaller its charge. The decrease of the rate of migration of substances with a large charge is due to the fact that they are more firmly retained by the ionic groups of the carrier. Both types of carriers are used to fractionate oligonucleotides.

Best results are obtained when the electrophoresis is carried out in an acid medium in two perpendicular directions on acetylated cellulose and DEAE-paper. In this version the method was proposed for the first time by Sanger et al.[343] for [^{32}P]-oligonucleotides. The separation on acetylated cellulose is carried out in a pyridine—acetate buffer at pH 3.5 or in the same buffer in 7 M urea[343-348]. The technique of the electrophoresis has been described[342-354].

DEAE-paper[349] at pH 9.7 is also used instead of cellulose acetate. The replacement of the acetylated cellulose by Whatman 3 MM paper leads to somewhat worse separation[350].

The solvents employed for separation in the second direction are a mixture of 2.5% formic acid and 8.7% acetic acid (by volume) at pH 1.9, 7% formic acid[344-347], or a buffer solvent at pH 3.5 and 6.5.[346,349] The electrophoresis is carried out on DEAE-cellulose[343-349], aminoethylcellulose (AE-cellulose) and ECTEOLA-cellulose[349].

Sanger's method gives a satisfactory separation with a resolution of up to 200 fractions of oligonucleotides (Fig. 5) and has been widely used to analyse the structures of nucleic acids.

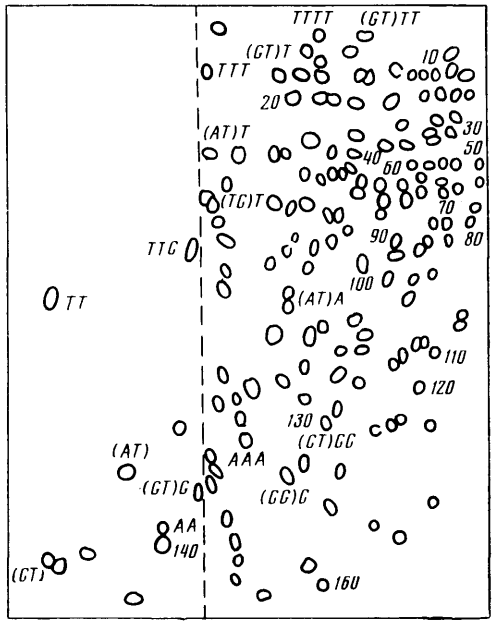

Figure 5. Separation of [^{32}P]-deoxyribo-oligonucleotides by two-dimensional high-voltage electrophoresis[349].

Interesting modifications of this method involve the employment of the electrophoresis in combination with ion-exchange chromatography on thin layers of PEI-cellulose[306,308] and the "homochromatographic" method[351-356]. The essential feature of "homochromatography" is as follows. When a plate with a thin layer of ion-exchange cellulose is placed with one end dipping in a solution of a mixture of oligonucleotides and the solution is allowed to rise a certain distance, the oligonucleotides are separated in the following way along the plate. At the top of the plate are the mononucleotides with the dinucleotides below, etc. i.e. the oligonucleotides are distributed in bands of equal chain length.

Hence the name of the method—"homochromatography". It is noteworthy that this distribution in bands of substances of equal chain length is possible only if the amount of oligonucleotide is greater than the capacity of the ion exchanger bands, since only then would longer oligonucleotides displace shorter oligonucleotides in consequence of their less strong binding to the ion exchanger.

In the chromatography of [^{32}P]-oligonucleotides in "homomixtures" of non-radioactive oligonucleotides an effective separation of long oligonucleotides (down to 40–50 nucleotide residues and less) is achieved. The fractionation is carried out at elevated temperatures (50–60°C), which gives rise to better equilibration and rules out the possibility of the formation of complexes by complementary oligonucleotides. The compositions of the "homomixtures" have been published[294,345,351,352].

The two-dimensional method for the fractionation of oligonucleotides permitted the determination of the structures of a number of tRNA,[354,357-367] low-molecular-weight RNA,[317,351,368-370] large fragments of 16S and 23S ribosomal RNA,[346,371,372,379] and phage RNA.[353,373-378] The possibility of the employment of this method for the analysis of the DNA structure has also been demonstrated[349,355,356]. One disadvantage, associated with the impossibility of identifying the substance by ultraviolet spectroscopy, which is particularly important for minor components, is not of fundamental importance. For nucleic acids which are difficult to obtain in a radioactive form, a radioactive label may be introduced into the terminal nucleotide[303,304,379], which greatly extends the scope of the method. The method is undoubtedly one of the best for the fractionation of oligonucleotides.

IV. NUCLEOTIDES

1. THIN-LAYER CHROMATOGRAPHY

A. Cellulose

This method is apparently most widely used at present for the analysis of mixtures of nucleotides, nucleosides, and nucleic acid bases. The preparation of cellulose layers has been described in fair detail in reviews[305,380-383] and other publications[384-387].

Randerath carried out a comparative separation of nucleotides in a thin layer of cellulose and on paper in four different solvents under identical conditions[384,388]. He established that the solvent systems developed for paper can be used for separation on a thin layer.

A multiplicity of systems have been used for the fractionation of nucleotides in a thin cellulose layer[380,382,385-390]. The corresponding R_f values for certain solvents are listed in Table 3. In most cases, the nucleotides are separated both with respect to the bases and with respect to the carbohydrate residue. To achieve a satisfactory reproducibility of the results, the specimen to be chromatographed must be neutralised and freed from salts and proteins[385]. In the separation of nucleotides with similar R_f values one can re-run the solvent in the same direction.

Nucleotides are satisfactorily separated by two-dimensional chromatography[385,390-395] or by a combination of thin-layer chromatography and thin-layer electrophoresis[337,396-398]. For example, Bergquist[337] separated the enzymatic tRNA hydrolysate by electrophoresis in one direction (phosphate buffer, pH 2.45), then by chromatography in another direction using the 50 : 50 : 2 t-butyl alcohol–0.08 M formic acid–isopentyl alcohol solvent system, and finally by chromatography again in the same direction using the 86 : 14 n-butyl alcohol–water solvent system. All four ribonucleotides and the isomeric 5'- and 3'-phosphates of adenylic and guanylic acids were separated by thin-layer electrophoresis and subsequent chromatography on cellulose using the 80 : 18 : 2 saturated ammonium sulphate–1 M sodium acetate–isopropyl alcohol solvent system[396]. This method was also used for determining the nucleotides composition of RNA. The R_f values for each nucleotide have been published[396].

Table 3. The R_f values in the chromatography of ribonucleotides and deoxyribonucleotides in a thin layer of cellulose[385,395].

Nucleotide	Solvent I	II	III	IV	Nucleotide	Solvent I	II	III	IV
AMP	0.34	0.34	—	0.38	dAMP	0.25	0.27	0.07	0.54
CMP	0.39	0.73	—	0.34	dCMP	0.53	0.63	0.09	0.49
GMP	0.26	0.53	—	—	dGMP	0.15	0.47	0.05	0.33
UMP	0.62	0.71	—	0.37	dTMP	0.89	0.54	0.18	0.58

Solvent composition: I) Isopropyl alcohol–HCl–water (65 : 16.7 : 18.3); II) n-butyl alcohol–water (86 : 14); III) n-butyl alcohol–water–90% formic acid (60 : 30 : 10); IV) n-butyl alcohol–acetone–acetic acid–5% aqueous ammonia–water (3.5 : 2.5 : 1.5 : 1.5 : 1.0 for deoxyribonucleotides and 4.5 : 1.5 : 1 : 1 : 2 for ribonucleotides).

Two-dimensional chromatography in various solvent systems permits a successful separation of the alkaline hydrolysates of RNA [396-400] or enzymatic hydrolysates of DNA.[401]

B. Silica Gel

Among inorganic sorbents, silica gel is frequently used in the chromatographic analysis of nucleic acid components, usually without a binder[402-420], although in some cases binders are also employed[421-428]. The separation on silica gel is as a rule poorer than on cellulose[300,381,384,426,427] and therefore it is rarely employed for analytical purposes and for the separation of unprotected derivatives. However, since the capacity of silica gel layers greatly exceeds that of cellulose, separation on silica gel is frequently used for preparative purposes, particularly in the case of synthetic derivatives of nucleic acids[402,415,418,419,426]. Various silica gels are employed for the separation[426-432]. The R_f values for nucleotides have been published[426]. Nucleoside 2'(3')-monophosphates can be separated from the 5'-phosphates but neither can be separated with respect to the bases. When the solvent is rerun in the same direction, the separation is improved. Silica gel treated with 5% tetraborate has been suggested for the fractionation of a mixture of adenosine, 3'- and 5'-adenylic acid, and cyclic AMP.[411]

The separation of the nucleotides in an alkaline hydrolysate of RNA was achieved by employing a 9 : 1 mixture of cellulose and silica gel[433]. Under these conditions, the presence of salts in the hydrolysate had hardly any influence on the separation of the nucleotides.

C. Ion-Exchange Resins

Methods for the chromatography of nucleotides and their derivatives in a thin layer of ion-exchange cellulose have been rapidly developed and adopted in the last 10 years. Ion-exchange celluloses can be prepared by treating unmodified or modified cellulose with high-molecular-weight basic or acid derivatives[391,434].

A comparative study of the fractionation of nucleotides and oligonucleotides on various kinds of ion-exchange cellulose[434-437] showed that cellulose treated with PEI is superior to other ion-exchange celluloses as regards the clear-cut separation of compounds. Evidently the results of the separation depend on the PEI-content, which determines the capacity of the layer[438]. A satisfactory separation has been achieved on layers containing 0.5—1% PEI,[380,388,435,438]. Cellulose plates prepared as described by Randerath are usually employed[309,311,380,388,391,435,436,438].

In contrast to layers of unmodified cellulose, a large volume of solution may be deposited on a PEI-cellulose plate without partial drying, since nucleotides are fairly firmly bound to the ion exchanger and are therefore concentrated in the centre of the spot. It was noted that, for optimal separation of nucleotides, the pH of the specimen deposited should be approximately equal to that of the first solvent[439]. The solutions analysed must be very dilute. For analytical purposes, it is best to employ concentrations ranging from 0.0005 to 0.005 M and in micropreparative studies (with several milligrams of the test substance) from 0.005 to 0.02 M.[305]

Nucleotides are separated on PEI-cellulose plates with development by aqueous electrolyte solutions[305,438,440-449]. In certain cases organic solvents are added to electrolyte solutions[305]. Both stepwise and continuous gradient elution is usually carried out in the fractionation of nucleotides. The mobility of each substance is largely determined by the negative charge, which depends on the pH. Best and most clear-cut results in the separation of nucleotides are obtained at acid pH (1—3 M formic acid with added LiCl).[305,438,439,443]. Table 4 lists the R_f values for various mononucleotides.

Mixtures of nucleotides can be successfully separated by the stepwise elution with a solvent at an increasing electrolyte concentration[438]. The first solvent is allowed to rise to a certain height after which the plate is transferred, without drying, to a chamber with another solvent, etc. Alkaline RNA hydrolysates and mixtures of nucleoside 5′-monophosphates are separated with the aid of one-dimensional chromatography on PEI-cellulose layers using stepwise elution with acetic acid and LiCl solutions[309,444]. The rate of migration of the components of the alkaline RNA hydrolysate decreases in the following sequence: nucleosides > 2′- + 3′-CMP, 2′-AMP > 3′-AMP > 2′- + 3′-UMP > 2′- + 3′-GMP. The same elution sequence holds for the 5′-isomers and the corresponding derivatives containing deoxyribose[380,444]. Sometimes elution using a salt concentration gradient is employed[440-445].

In the stepwise chromatography of a mixture of nucleoside mono-, di-, and tri-phosphates in 0.6, 0.8, and 1.25 M NaCl without intervening drying of the plates, a clear-cut separation of these derivatives is achieved[310,436,446,447].

The components of alkaline RNA hydrolysates are usually satisfactorily separated by continuous ascending chromatography[380,440]. The technique employing a continuous linear salt gradient has been described in fair detail[448].

Deoxyribonucleotides can be separated from ribonucleotides in solvents containing borate[437,438,450-452]. The borate complexes of ribonucleotides have an additional negative charge and move more slowly than deoxyribonucleotides[438]. The following solvent systems are usually employed in the separation of ribonucleotides and deoxyribonucleotides: 2 : 1 2% H_3BO_3—2 M LiCl for nucleoside monophosphates and 4 : 3 4% H_3BO_3—4 M LiCl for nucleoside triphosphates[438,453]. Since satisfactory fractionation of deoxyribonucleotides is achieved in the reverse system, it is sometimes used to separate enzymatic DNA hydrolysates[442,453,454].

Table 4. The R_f values (×100) for nucleotides and their derivatives in thin-layer chromatography on PEI-cellulose[380,438].

Mixtures of nucleotides or RNA hydrolysates can also be fractionated by two-dimensional chromatography on PEI-cellulose layers[439,449]. Before passing the second solvent, it is important to remove the first from the plate. Randerath[380,438] proposed previously that, after drying, the plate be washed with methanol for this purpose. However, when a volatile solvent is used in the first direction, for example formic acid, it is sufficient to simply dry the plate before the second chromatographic step[439]. A mixture of ribonucleotides containing various nucleoside mono-, di-, and tri-phosphates was fractionated by ascending two-dimensional chromatography and PEI-cellulose[455] (Fig. 6). Stepwise elution by LiCl solutions was used in the first direction and stepwise elution by a sodium formate buffer (pH 3.4) in the second direction. The entire separation of the nucleotide mixture lasts about 3 h. The fractionation of a complex mixture of ribonucleosides and deoxyribonucleoside triphosphates by two-dimensional chromatography has been described[450]. In later studies[452,456-458] analogous chromatography was used to separate biological materials. For best separation,

extracts from the biological material are sometimes subjected to preliminary purification before chromatography, but in most cases chromatography is carried out without such purification. The chromatography of specimens containing large amounts of salts has been described by Foster et al.[441]

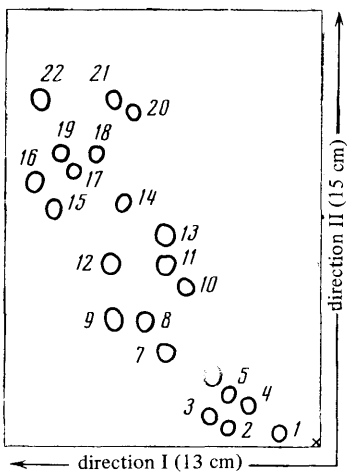

Figure 6. Two-dimensional chromatography of nucleotides on a PEI-cellulose layer. First direction: 0.2 M LiCl for 2 min, 1 M LiCl for 6 min, and 1.6 M LiCl up to 13 cm. Second direction: 0.5 M buffer for 30 s, 2 M buffer for 2 min, and 4 M buffer up to 15 cm (sodium formate buffer, pH 3.4)[455]: 1) GTP; 2) ITP; 3) UTP; 4) ATP; 5) CTP; 6) GDP; 7) IDP; 8) UDP; 9) UDPGA; 10) ADP; 11) CDP; 12) GDPM; 13) GMP; 14) IMP + TPN; 15) UDPG; 16) UDPAG; 17) ADPG; 18) UMP; 19) CDPG; 20) AMP; 21) CMP; 22) DPN.

Since PEI-cellulose has a high capacity, it can be used also in micropreparative separations. Layers 1–1.5 mm thick, which permit the fractionation of milligram amounts, are used for this purepose[305,438]. In thin-layer chromatography the fractions are desalinated by washing the entire plate with methanol and subsequent elution (usually with volatile buffers or with dilute HCl solutions) of the individual spots[380,438,439]. For the standard method of preparation of the plates, the average deviations of the R_f values do not exceed those for the usual thin-layer chromatography, amounting to ±0.005–0.025 on the basis of 10 determinations[459]. However, the reproducibility of the R_f depends on the amount of cellulose. When the plates are stored for about 100 days (in the dark at room temperature), the R_f values hardly change[459].

Quantitative extraction of nucleotides from a PEI-cellulose layer has been described in fair detail[380,382,442,443,458,460]. The optimal amounts of substances for a quantitative determination are 5–50 nanomoles[380,442]. The sensitivity of the method can be greatly improved and substances in amounts down to 1 nanomole and less can be determined by reducing the volume of the eluent and by measuring the absorption in microcuvettes or by employing a radioactive label[443,458].

Together with cellulose, DEAE- and ECTEOLA-cellulose layers have been used for the analysis of ribonucleotides and deoxyribonucleotides phosphorylated to different extents[385,392,440,461-481]. The principal advantage of these celluloses is the rapidity of separation. For example, a mixture of 10^{-2} mole of ADP and ATP is separated in 4–5 min on ECTEOLA-cellulose[461,464,467]. The preparation of DEAE-cellulose[302,385,440,463] and ECTEOLA-cellulose[462,475] plates has been described. Dilute solutions of hydrochloric or formic acids are usually employed as eluents[302,385,392,461,463,464,467]. The use of dilute sodium chloride solutions gives a less clear-cut separation[461]. Randerath[461,464] claims that DEAE- and ECTEOLA-cellulose layers give approximately identical results, the fractionation on an ECTEOLA-cellulose layer being the faster.

The rate of migration of different nucleotides decreases in the sequence C > A > G > U. Adenine and cytidine nucleotides with the same content of phosphate groups are poorly separated in a dilute acid, but can be separated in 0.1 M NaCl.[461,464] The R_f values for mono-, di-, and tri-nucleotides on DEAE-cellulose in dilute formic or hydrochloric acid solutions are listed in Table 5.

Table 5. The R_f values for nucleoside mono-, di-, and tri-phosphates in thin-layer chromatography on DEAE-cellulose[461,463,467].

Satisfactory results are obtained in the analysis of a mixture of ribonucleotide and deoxyribonucleotide mono-, di-, and tri-phosphates with identical heterocyclic bases by two-dimensional chromatography on DEAE-cellulose. A clear-cut separation with respect to the number of phosphate groups takes place in the first direction and with respect to the sugar residue in the second[385,465].

The employment of two-dimensional gradient elution (1.0 M NH_4HCO_3–0.15 M NH_4HCO_3 for the first direction and 2.0 M NH_4HCO_3 at pH 4.2–0.2 M NH_4HCO_3 at pH 2.8 for the second) permits the separation of a mixture of the mono-, di-, and tri-phosphates of the four principal nucleotides with the exception of CTP and UTP.[440] This method can be used to analyse biological materials[462,463,466,476]. The authors suggest gel filtration in a thin layer on G-25 Sephadex before chromatography in order to separate them from polysaccharides and

fluorescent materials which are always present[440]. The nucleotide material is eluted from Sephadex by water and lyophilised.

A DEAE-cellulose layer can be used also to separate ribonucleoside and deoxyribonucleoside 2′- amd 3′-phosphates in alkaline or enzymatic RNA and DNA hydrolysates[385,477,478]. Nucleotide 2′- and 3′-phosphates are chromatographed in 0.05 *N* HCl for both ribonucleoside and deoxyribonucleoside derivatives in the first direction and in 0.035 *N* HCl for ribonucleoside derivatives and 0.02 *N* HCl for deoxyribonucleotide derivatives in the second[385,464,477]. 2′ and 3′-Adenylic acids are fractionated under these conditions[385,464]. The separation of the 2′- and 3′-isomers of all nucleotides is achieved on DEAE-cellulose containing 10% of $CaSO_4$.[478]

2. PAPER ELECTROPHORESIS AND ELECTROPHORESIS IN A THIN LAYER OF CELLULOSE

Nucleotides and their derivatives contain different ionisable groups so that electrophoresis on paper and in a thin layer of cellulose is a valuable method for their analytical and preparative separation. The relative mobilities of nucleotides can be calculated at any pH from their charges using the pK_a of the ionisable groups, which are known[265].

The four principal ribonucleotides and deoxyribonucleotides are separated at pH 3.5. At this pH the 2′- and 3′-isomers of guanylic acid have different mobilities[265,343,482,483].

Certain minor nucleotides can also be separated from other nucleotides by paper electrophoresis, but for a complete analysis, for example of a tRNA hydrolysate, additional separation and by thin-layer or column chromatography (see the relevant Sections) is necessary[343,482,483]. The mobilities of ribonucleotides are listed in Table 6.

Table 6. The relative mobilities of ribonucleotides* in paper electrophoresis[265].

Nucleotide	pH 3.5**	pH 2.1***
4,5-Dihydrouridylic acid	1	–
Ribothymidylic acid	0.98	–
Pseudouridylic acid	0.98	–
Inosinic acid	0.90	–
Guanylic acid	0.73	0.38
7-Methylguanylic acid	0.98	–
1-Methylguanylic acid	–	0.30
N^2-Methylguanylic acid	–	0.30
N^2N^2-Dimethylguanylic acid	0.76	0.25
Adenylic acid	0.50	0
N^6-Methyladenylic acid	0.46	–
N^6N^6-Dimethyladenylic acid	0.42	–
2-Methyladenylic acid	0.25	–
Cytidylic acid	0.41	0

* The mobility of uridylic acid was adopted as unity.
** 0.05 M ammonium formate at pH 3.5.[343,348]
*** 0.05 M phosphate buffer at pH 2.1.[482]

Mono-, di-, and tri-phosphates are separated best in a citrate buffer at pH 5.0 or 7.0 depending on the number of dissociable phosphate groups. In the presence of bivalent cations the mobility of nucleoside triphosphates decreases[265].

2′- and 3′-Ribonucleotides can be separated from 5′-ribonucleotides in a borate buffer at pH 9.2.

Electrophoretic separation of nucleotides after hydrolysis can be used to determine the incorporation of various nucleotide analogues in nucleic acids. For example, the p*K* of 5-fluoro-, 5-bromo-, 5-chloro-, and 5-iodouridylic acids, 2-thiouridylic acid, and 8-azaguanylic acid are lower than those of uridylic, guanylic, and thymidylic acids and therefore at pH 9.0 these nucleotides migrate faster than all others[265].

The components of the RNA or DNA hydrolysates can also be separated by electrophoresis on cellulose layers[397,461,483-486]. Best separation is then achieved on carefully degassed cellulose washed with a solution of the sodium salt of EDTA[485].

Fractionation of 2′, 3′-ribonucleotides and deoxyribonucleotides is achieved at pH 3.4–3.5.[397,484,486] Adenine and inosine nucleotides are separated at pH 5.1.[486] Deoxyribonucleoside mono-, di-, and tri-phosphates can be easily separated from one another with respect to each base at pH 5.5.[484]

The employment of thin-layer electrophoresis permits the improvement of the separation of certain nucleotide mixtures which are difficult to fractionate by partition or ion-exchange chromatography. For this purpose, the electrophoresis is usually carried out in one direction in two-dimensional chromatography[337,396-398]. A microversion of electrophoresis was employed by Edström to analyse the nucleotides obtained fron the nucleic acids in a single cell [487,488].

3. ION-EXCHANGE COLUMN CHROMATOGRAPHY

Ion-exchange column chromatography on polystyrene resins, introduced by Cohn[1], has been used successfully for the fractionation of various natural nucleic acids on analytical and preparative scales. The general principles of separation by ion exchange column chromatography were examined by Cohn as early as 1955. Ion-exchange column chromatographic methods have been described in fair detail in three articles in the "Methods in Enzymology" series[489].

A mixture of ribo- or deoxyribo-nucleotides[490,491] can be very conveniently separated on a strong anion exchanger of the type of Dowex-1 in acid[492] or alkaline[493-496] systems. In acid systems the elution sequence of the nucleotides is as follows: cytidylic, adenylic, uridylic, and guanylic acids. In columns with a large height : diameter ratio guanylic acid sometimes overtakes uridylic acid[497]. Isomeric nucleotides can be separated into the 5′-, 2′-, and 3′-phosphates and are eluted from the column in this sequence[497].

In alkaline systems the elution sequence of nucleotides changes as follows: cytidylic, uridylic, adenylic, and guanylic acids[495].

In the simplest cases the relative dimensions of the column are unimportant, but in the separation of complex multicomponent mixtures tall columns (height : diameter = 50 : 1) give a satisfactory separation[497].

In the majority of systems used to separate a known mixture of nucleic acid derivatives on columns, the concentration or the pH of the eluent are increased in steps. However, in selecting the separation conditions or in the separation of a complex mixture, gradient elution is employed in which the eluent composition varies smoothly in accordance with the specified gradient. A linear gradient is usually employed.

Chromatographic separation of nucleotides on ion-exchange columns has been described in greater detail in other reviews[1,5,491,497].

The ability of purine and pyrimidine derivatives to absorb radiation intensely in the region 260—290 nm has been used to develop micromethods for the chromatography of nucleotides permitting the determination of small amounts of the latter and greatly reducing the duration of the fractionation[498-501]. Thus Anderson and coworkers[498,499] and somewhat later Hori et al.[500] described a method for the automatic analysis of nucleic acids whereby it is possible to separate and analyse the nitrogenous bases, nucleosides, and nucleotides in 24 h on a single column with Dowex-1 × 8 (200—400 mesh) resin using a linear acetate buffer concentration gradient at pH 4.4. For qualitative analysis, 0.02 μmole of substance is sufficient. Specimens containing large amounts of salts (for example, RNA and DNA hydrolysates) are subjected to preliminary desalination by gel filtration and then dissolved in a buffer solution. Pyrimidine and purine bases and nucleosides are eluted first and then nucleotides. Under these conditions, 2′-UMP is not completely separated from 3′-UMP; with the exception of 5′-CMP, 5′-nucleotides are not separated from 2′- and 3′-nucleotides and 5′-IMP and 5′-AMP are not separated at all. However, this hardly reduces the practical value of the method. It can be used to separate the 5′-nucleotides obtained from RNA by nuclease hydrolysis and 2′- and 3′-nucleotides formed in the alkaline hydrolysis of RNA. Deoxyribonucleotides are separated under analogous conditions[498].

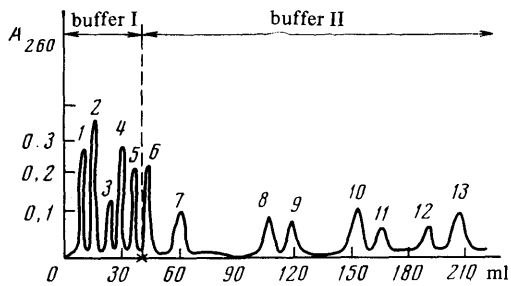

Figure 7. Chromatography of nucleotides, nucleosides and bases on Aminex A-4 cation-exchange resin (0.9 × 50 cm column); citrate (I) and acetate (II) buffers used for separation; rate of elution 60 ml h^{-1};[503] 1) UMP-5′ + IMP-5′ + UMP-2′ and UMP-3′ + ATP; 2) GMP-5′ + ADP + GMP-2′ + GMP-3′; 3) CMP-5′; 4) uridine + AMP-2′; 5) AMP-5′ + CMP-2′ + CMP-3′ + AMP-3′; 6) uracil; 7) inosine + thymine; 8) hypoxanthine; 9) guanosine; 10) adenosine; 11) cytosine; 12) guanine; 13) adenine.

The employment of AG-50W × 4 cation-exchange resin for the fractionation of ribo- and deoxy-ribonucleotides was described in 1967 by Blattner and Erikson[502], who achieved a clear-cut separation of the four principal 5′-deoxyribonucleotides after the enzymatic hydrolysis of DNA and of 2′- and 3′-ribonucleotides after the alkaline hydrolysis of RNA. They employed 0.1 M ammonium formate at pH 3.2 as the eluting solution in the first case and 0.25 M ammonium formate at pH 4.1 in the second. The sequence in which the nucleotides are eluted from the column is the same for deoxyribonucleotides and ribonucleotides: T(U) > G > C > A. The presence of Ca^{2+} and Mg^{2+} ions, snake venom phosphodiesterase, and pancreatic deoxyribonuclease in the specimen does not interfere with the separation. A change in pH or in the molarity of the buffer impairs the separation. The employment of a volatile buffer for elution makes it possible to obtain the nucleotides in a pure form after the evaporation of the solutions.

A clear-cut separation of four 5′-mononucleotides was achieved also on another cation-exchange resin Aminex A-4 (Fig. 7)[503].

Nucleotides phosphorylated to different extents can be readily separated quantitatively with the aid of DEAE-Sephadex A-25 in an ammonium bicarbonate or triethylammonium acetate gradient at pH 7.0.[504,505] Nucleotides are eluted from the column in order of increasing acidities[504].

The efficiency of column chromatography and the speed of analysis were subsequently significantly improved by employing very fine anion- and cation-exchange resins and high pressures[506-509]. New types of resin such as Zipax[507-510], AA-15,[506] and a surface-layer cation-exchange resin[511] were developed for this purpose. The application of highly sensitive detector systems permits nowadays the quantitative analysis of nucleic acid hydrolysates at the level of 10^{-12} mole without the use of a radioactive label[511].

V. NUCLEIC ACID BASES AND NUCLEOSIDES

1. THIN-LAYER CHROMATOGRAPHY

Partition chromatography in a thin layer of cellulose is widely used for the analytical determination and identification of the nucleic acid bases and nucleosides[380,382,385-401]. As in paper chromatography, the usual solvent systems for the separation of the bases and nucleosides are mixtures of water or aqueous solutions of salts, acids, or bases with organic solvents (alcohols, acids, etc.). Table 7 lists the R_f values for various nucleic acid bases, their derivatives, and nucleosides in a series of solvents[385]. These systems are fairly simple and give reliably reproducible results. Comparison of the R_f values in the above systems provides an idea about the influence of the pH of the solution and the salt concentration in the systems on the chromatographic mobilities of the substances being separated. The amphoteric properties of nucleic acid bases, as a result of which the pH of the system can alter the polarity of the bases and nucleosides and hence the partition coefficient, plays an important role in this process. The introduction of substituents alters significantly the polarity and the dissociation constants, so that, knowing the position and nature of the substituent, it is possible to predict, at least by analogy, the R_f value.

A satisfactory separation of the bases by thin-layer chromatography has been achieved with the aid of different versions of Kirby's system[380,401], widely used in the paper chromatography of the bases. Thus the separation of all four bases after the acid hydrolysis of DNA was achieved by one-dimensional chromatography in a 65 : 17 : 18 MeOH—HCl—H_2O mixture[380,401]. The standard system for paper chromatography isopropyl alcohol—HCl—water has also been used successfully[385,512].

The bases and the corresponding nucleosides can be readily separated on cellulose with elution by water[386]. A number of other less common systems have been described for the separation of bases and nucleosides[386,390,392,393,513-523].

Table 7. The R_f values for bases and nucleosides in thin-layer chromatography on cellulose[38].

*Solvent composition: I) isopropyl alcohol—HCl—H_2O (65 : 16.7 : 18.3); II) n-Butyl—alcohol—water (86 : 14); III) isobutyric acid—water—25% NH_4OH (400 : 208 : 0.4); IV) isopropyl alcohol—water—conc. (28%) NH_4OH (85 : 15 : 1.3); V) n-butyl alcohol—water—formic acid (77 : 13 : 10); VI) sat. $(NH_4)_2SO_4$—1 M sodium acetate—isopropyl alcohol (80 : 18 : 2).

The R_f values for methylated purines and purine nucleosides have been quoted by Broom and coworkers[517,520]. Data for the separation of deoxyribonucleosides and their R_f values have also been published[395,402,524]. Ribonucleosides can be readily separated from deoxyribonucleosides or ribonucleosides with substituted *cis*-glycol hydroxy-groups in alkaline systems containing borate[382]. The formation of borate complexes with the *cis*-glycol group of the ribose residue has a marked influence on chromatographic mobility.

In this case, when the mixture of bases is too complex for a satisfactory separation by one-dimensional chromatography, two-dimensional chromatography can be employed. An example of a successful application of this method is probided by the separation of a mixture of bases using the 70 : 20 : 10 MeOH—HCl—H_2O system in the first direction and the 60 : 20 : 20 : 2 BuOH—MeOH—H_2O—conc.NH_4OH in the second system[380,525]. A mixture of 6-methyladenine, adenine, cytosine, and 5-methylcytosine can be readily separated into individual compounds by two-dimensional chromatography using the solvent system I in the first direction and the solvent system II in the second (for solvent systems I and II, see Table 7), while the employment of only one system does not lead to a clear-cut separation of the mixture[385].

In the two-dimensional fractionation of the enzymatic hydrolysate of tRNA from *E. coli* and yeast there is a clear-cut separation of 8 nucleosides including minor nucleosides: dehydrouridine, inosine, pseudouridine, and ribothymidine[521]. Electrophoresis is sometimes employed in one direction in two-dimensional thin-layer chromatography[401,484]. For example, a mixture of the five principal and eight methylated bases found in DNA and RNA was separated by this method and it was shown that it yields better results than one-dimensional chromatography[385]. The application of high-voltage electrophoresis and two-dimensional chromatography helps the separation of the majority of bases and deoxyribonucelosides present in DNA hydrolysates[401].

Thus the fractionation of nucleic acid derivatives in a thin layer of cellulose is used nowadays in all cases where paper chromatography was employed previously, but separation in a thin cellulose layer is of shorter duration than paper chromatography, more clear-cut, and the sensitivity is higher by a factor of approximately 10.

The employment of labelled nucleic acid preparation and also of chemical methods for the introduction of radioactive isotopes into nucleic acid components increases the sensitivity of the method to 10^{-12} mole[343,526-528]. In particular, Randerath oxidised the *cis*-glycol group of the ribose residue by periodate with subsequent reduction by sodium borotritide in order to introduce the isotope label into ribonucleosides in the analysis of RNA hydrolysates. The resulting mixture of tritium-labelled compounds was resolved into components by two-dimensional chromatography in thin layers of cellulose or silica gel[304,529-533]. The positions of the individual compounds on the chromatograms were determined by radioautography. The quantitative analysis was carried out by measuring the radioactivity of the eluted substances. The method has a high resolving power and sensitivity[304,529-531]. It was developed and applied to determine the nucleotide composition of RNA in those cases where a minimal amount of RNA is available and cannot be labelled *in vivo*. The authors estimate the sensitivity of the method as several picomoles[304], while the lower limit of spectrophotometric analysis is one nanomole. By studying the factors influencing the sensitivity of the method, Randerath achieved a level of sensitivity which proved to be sufficient for the detection of minor components of tRNA.[530,532,533] However, 2-*O*-methylnucleosides cannot be identified by this method, because they are not oxidised by periodate, and 4-thiouridine is converted into [^{3}H]uridine by reduction with borotritide[530,531,534]. In view of the instability of the borotritide, the reduction is carried out in an alkaline medium, where certain minor bases of tRNA are known to decompose[531,534]. The imidazole ring of 7-methylguanine is partly decomposed (about 35%) and 1-methyladenine is converted into N^6-methyladenine. 3-Methylcytosine also decomposes to the extent of 10—15%.[531,534,535]

Randerath employed his highly sensitive ultramicromethod for systematic studies on the composition of the bases of the tRNA isolated from various normal and neoplastic mammalian brain tissues[536]. The nucleoside derivatives are separated largely on cellulose layers.

Among other adsorbents giving satisfactory results in the fractionation of nucleic acid bases and nucleosides in a thin layer, mention may be made of polyamide[382,392,537]. Table 8 lists the R_f values for ten bases and nucleosides. The use of distilled water as a solvent greatly improves the mobilities of all the compounds, while the addition of a salt reduces the mobility[537]. Best results were achieved in aqueous sodium chloride solutions, although sodium

acetate or borate can also be used[537]. The polyamide layers can be employed repeatedly[537].

Chromatography in a thin layer of silica gel is sometimes used to separate the synthetic analogues and certain derivatives of nucleosides and bases[402,404,414,418,419,426,427,538,539]. Although silica gel layers are, in fact, used for the fractionation of the free bases and nucleosides[300,410,426], they give less satisfactory results than cellulose[300,426,427].

Table 8. The R_f values for bases and nucleosides in chromatography on polyamide layers[537].

Substance	Solvent*				Substance	Solvent*			
	I	II	III	IV		I	II	III	IV
Adenine	0.75	0.85	0.54	0.51	Inosine	0.32	0.30	0.23	0.85

*Solvent composition: I) heptane–butyl alcohol–acetic acid (4 : 4 : 1); II) carbon tetrachloride–acetic acid–acetone (4 : 1 : 4); III) toluene–pyridine–ethylene chlorohydrin–0.8 M NH_4OH (5 : 1 : 5 : 3); IV) 0.5 M aqueous NaCl.

2. PAPER ELECTROPHORESIS AND ELECTROPHORESIS IN A THIN CELLULOSE LAYER

The fractionation of nucleic acid bases and nucleosides by electrophoresis on paper or in a thin layer of cellulose has no special advantages over thin-layer or paper partition chromatography of these compounds. However, by combining this method with chromatography in thin cellulose layers, it is sometimes possible to improve the separation of certain mixtures containing, apart from the four main components, also minor components—methylated in the base moiety or in the 2′-hydroxy-group of ribose[382,484]. The most striking example of such application of electrophoresis and chromatography is provided by the separation of a mixture of five main and eight methylated bases with the aid of two-dimensional chromatography[484] (Fig. 8).

Deoxyribonucleosides and 2′-*O*-methylribonucleosides can be separated from ribonucleosides in a borate buffer at pH 9.2.[265,484] Borate complexes of ribonucleosides migrate as anions and the relative mobilities of adenosine, cytidine, guanosine, and uridine are respectively 0.64, 0.74, 0.88, and 1.0.[265] The four main ribonucleosides and deoxyribonucleosides are separated by paper electrophoresis at pH 3.2. The mobilities of uridine (thymidine), guanosine, and adenosine are respectively 0, 0.05, and 0.29 (the mobility of cytidine was adopted as 1.0)[265]. Adenine, guanine, cytosine, and uracil can also be separated by electrophoresis at pH 3.2.[265]

3. ION-EXCHANGE CHROMATOGRAPHY

The principles and methods of the separation of nucleic acid bases and nucleosides on ion-exchange resins have been described in fair detail in Cohn's papers and reviews[11,489,491,497]. Since all the data published hitherto on the fractionation of these components on ion-exchange resins proved to be comparable with one another and with Cohn's data (the same or similar ion-exchangers were employed in all cases), our discussions will be restricted only to those few ion-exchange resins which are used nowadays in micropreparative studies. The problem of the separation of nucleosides and bases by adsorption chromatography on gel filtration materials of the type of Sephadex and biogels, which have been recently used successfully for this purpose, will be discussed in somewhat greater detail in this Section.

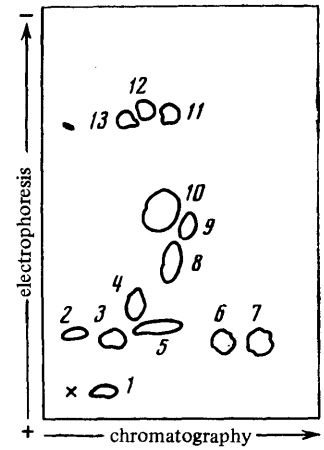

Figure 8. Separation of methylated bases on a thin layer of microcrystalline Pevikon cellulose. First direction: electrophoresis in 0.1 M sodium acetate at pH 3.5, 1000 V, and 20 mA for 3 h. Second direction: chromatography in the 65 : 16.7 : 18.3 isopropyl alcohol–HCl–water system[484]: 1) guanine; 2) 1-methylguanine; 3) 2-dimethylguanine; 4) adenine; 5) 2-methylguanine; 6) uracil; 7) thymine; 8) 6-methyladenine; 9) 6-dimethyladenine; 10) 2-methyladenine; 11) 5-methylcytosine; 12) cytosine; 13) 1-methyladenine.

In 1968 Cohn and coworkers modified Anderson's nucleotide analyser[498,499] and used it to separate nucleosides on cation-exchange resins such as Amberlite GG-120 (type III), Bio-Rad A-6, and Dowex 50 × 4.[540] The four main nucleosides obtained by the hydrolysis of RNA are readily separated on elution with 0.4 M ammonium formate at pH 4.65. The sequence in which nucleosides are eluted from the column is as follows: U > G > A > C. Minor nucleosides such as N^6-dimethyladenosine 7-methylguanosine, and N^2-dimethylguanosine are readily separated from one another and so do not interfere with the separation of the main nucleosides. Pseudouridine ribothymidine, uridine, inosine, and 4-thiouridine are incompletely separated. Although the authors investigated only the separation of nucleosides, a similar nucleoside analyser can probably also be used to analyse nucleic acid bases[502,541–543]. For example, a method was proposed in 1970 for the fractionation of a mixture of nucleotides, nucleosides, and bases on the cation-exchange resin Aminex A-4 [503] (Fig. 7). The separation was carried out using stepwise elution, initially with sodium citrate at pH 3.0 and then with 0.25, 0.50, and 1.00 M

sodium acetate at pH 6.4. All four 5′-mononucleotides are separated when the first buffer is passed through the resin. The second buffer gives rise to individual peaks of the nucleosides and nucleic acid bases. The employment of this cation-exchanger was also described previously for the separation of purine bases from pyrimidine bases and for the separation of hypoxanthine, guanine, and adenine[544].

A convenient method for the isolation and separation of purine bases from biological extracts using AG50W × 4 (H^+) resin has been proposed[545]. The elution is carried out with 0.05 *N* HCl, which results in the separation not only of purine bases but also of the entire nucleotide material present in the extract.

4. GEL FILTRATION AND ADSORPTION CHROMATOGRAPHY ON GELS

Gel filtration or fractionation of compounds on molecular sieves (dextran gels) of the type of Sephadex was described as early as 1959 [546] and has been widely used to separate various nucleic acid derivatives in accordance with their molecular weights. Thus nucleotides are readily separated from RNA or oligonucleotides[547,549] and are always eluted before nucleosides and bases, which constitutes a rapid and technically very simple method for the separation of these derivatives into groups of approximately equal molecular weights[549,550]. Sephadex, a relatively inert, insoluble, and hydrophilic material, is manufactured with different porosities (G-10, G-15, G-25, G-50, G-75, G-100, and G-200) and in the form of ion-exchange celluloses (CM- and DEAE-Sephadex), which combine the properties of molecular sieves and ion exchangers[551,552]. The elution of substances from columns is almost quantitative. About 3% is lost as a result of irreversible adsorption[553].

Soon after the introduction of gel filtration, Gelotte showed that nucleic acid derivatives are retained by the gel to different extents and are eluted from the latter by different volumes of the eluent, depending on the structure[553-557]. It was shown that, apart from the molecular weight, the separation of compounds on different types of Sephadex is greatly influenced both by the ionic strength and the pH of the eluting buffer and by the reversible adsorption of the substances[549,550,554-561]. The mechanism of the adsorption on Sephadex has not been established yet, but it is suggested that the adsorption involves the formation of hydrogen bonds between the heterocyclic bases and the ether bridges in the matrix[553,556,557]. Purine derivatives as a rule exhibit a greater affinity for different types of Sephadex than pyrimidine derivatives[549,550,553,556,557]. The separation on G-10, G-15, and G-25 is virtually the same for pyrimidine derivatives, while the use of more cross-linked gels, for example G-10, for purines results in an increased affinity for the matrix[549,550,553,556].

The relative volume of the eluent or the elution constant R_m for different derivatives is independent of the amount of gel and, when the conditions are standardised, can serve as the first criterion for the identification of the compound[556]. The elution constants for 50 purine and pyrimidine derivatives on a G-10 column in 0.01 ammonium carbonate at pH 9 are listed in the same report. In a single step it is possible to separate up to 16 compounds[556]. The elution constants of nucleosides and bases at other pH values have been published[559,561]. All four principal deoxyribonucleosides and ribonucleosides can be successfully separated on Sephadex G-25 or G-10.[141,547,550,562] The amount of each nucleoside in the mixture was $(1 - 10) \times 10^{-9}$ mole. The ratio of the column diameter to its height should be in the range 1:50–1:150 to ensure a clear-cut separation[547,562]. The sequence of the elution of the nucleosides from the column under these conditions is U(T) > C > G > A. The bases are separated in the same sequence, but in the presence of nucleosides the separation of adenosine and guanine is incomplete[553,556].

A mixture of nucleosides and bases can be analysed also in the presence of nucleotides, since the latter are eluted under these conditions as a separate peak ahead of nucleosides[547,553]. The amount of nucleotides should not exceed 50% of the total amount of substance injected. However, if longer columns are employed, then at lower rates of elution it is possible to separate a 12:1 mixture of nucleotides and nucleosides[547].

The fractionation of nucleosides and G-10 can be achieved also at neutral pH. However, an additional separation of uridine and cytidine, which overlap either partially (elution with phosphate buffer at pH 7.0) or completely (elution with water), is then necessary. Adenosine and guanosine are completely separated[549,558].

A similar behaviour has been observed at the same pH values also for nucleic acid bases[557]. Elution with 0.05 M phosphate buffer at pH 7.0 leads to a clear-cut fractionation of purine bases, including the minor bases, and to an incomplete separation of the pyrimidine bases. It is noteworthy that under these conditions not only hypoxanthine, xanthine, adenine, and guanine are separated, but also various methylated purine derivatives. The separation of methylated purines shows that the introduction of the methyl group decreases the degree of reversible adsorption of the compound[557].

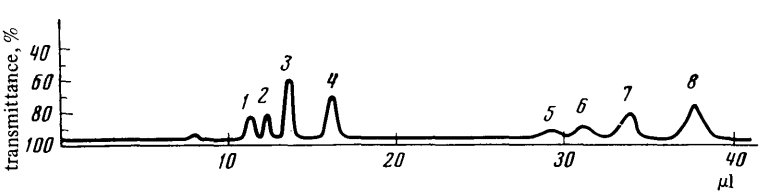

Figure 9. Chromatography of a mixture of deoxyribonucleosides and ribonucleosides on a fractionated Biogel P-2 (0.8 × 0.68 column); rate of elution 2.8 ml h^{-1}; volume of eluate 50 μl; 1) uridine; 2) guanosine; 3) deoxyguanosine; 4) thymidine; 5) cytidine; 6) adenosine; 7) deoxycytidine; 8) deoxyadenosine[566].

Guanylic and adenylic 2′:3′-cyclic phosphates can also be successfully separated on a G-10 Sephadex column[549]. Nucleotides are not separated from one another[141,557,562-565].

Another material most frequently employed recently for the separation of alkaline and acid DNA hydrolysates is polyacrylamide gel (Biogel P-2 and P-6).[136,158,566-574]. The advantage of polyacrylamide gel over different types of Sephadex is that a smaller volume of the gel is needed for separation, which shortens the elution time; the compounds are eluted in much smaller volumes and quantitatively[566]. It is recommended that nucleosides be separated on a fractionated Biogel P-2 at high pH.[158,566,572,573] The fractionation of the Biogel and the preparation of the columns have been described[566,572]. A mixture of ribonucleosides and deoxyribonucleosides was separated in a 0.1 M ammonium bicarbonate buffer with 1×10^{-3} M $Na_2B_4O_7$ at pH 10.1 (Fig. 9)[566,573]. The presence of nucleotides or high salt concentrations in the initial mixtures does not interfere with the separation of nucleosides, since both nucleotides and salts are readily separated from them[566,572,575,576].

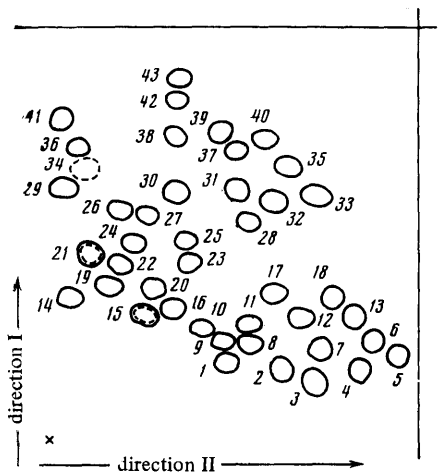

Figure 10. Two-dimensional chromatography of a complex mixture of nucleotides, nucleosides, and nucleic acid bases on a thin layer of cellulose. First direction: 6:3:1 n-propyl alcohol—25% ammonia—water system. Second direction: 2:79:19 isopropyl alcohol—sat.ammonium sulphate—water system[519]: 1) ATP; 2) GDP; 3) GTP; 4) ITP; 5) CTP + UTP; 6) CDP + UDP; 7) IDP + TTP; 8) GMP-5′; 9) TPN; 10) GMP-3′ + ATP; 11) GMP-2; 12) IMP-5′ + TDP; 13) CMP-5′ + CMP-2′ + CDPG + UMP-5′; 14) uric acid; 15) TPNH; 16) AMP-5′ + DPN + ADPG; 17) TMP-5′; 18) CMP-3′ + UMP-2′ + UMP-3′; 19) AMP-3′; 20) AMP-2′; 21) DPNH; 22) guanine; 23) orotic acid; 24) xanthine + GMP-2′:3′; 25) guanosine; 26) 7-methylxanthine; 27) deoxyguanosine + xanthosine; 28) 5-aminothymine; 29) adenine; 30) hypoxanthine; 31) inosine; 32) isocytosine; 33) uridine; 34) 2-aminopurine; 35) uracil + cytidine + cytosine + deoxyuridine; 36) adenosine; 37) 4-methyluracil; 38) 2-thiouracil; 39) thymidine + thymine; 40) 3-methylcytosine + deoxycytidine; 41) deoxyadenosine; 42) nicotinic acid; 43) nicotinamide.

VI. MIXTURES OF NUCLEOTIDES, NUCLEOSIDES, AND NUCLEIC ACID BASES

Partition[518,519] or ion-exchange thin-layer chromatography[438,577], electrophoresis[484,487], and ion-exchange[498-504,543] or adsorption[549,553,556,568,570] column chromatography can be used to fractionate complex mixtures of different nucleic acid components as well as for the separation of compounds of the same type.

Thin-layer chromatography on cellulose and cellulose ion-exchangers has been mainly used recently for the rapid analysis of microamounts of a mixture of nucleotides, nucleosides, and bases. Clear-cut fractionation of a large number of compounds on cellulose can be achieved with the aid of two-dimensional chromatography[518,519].

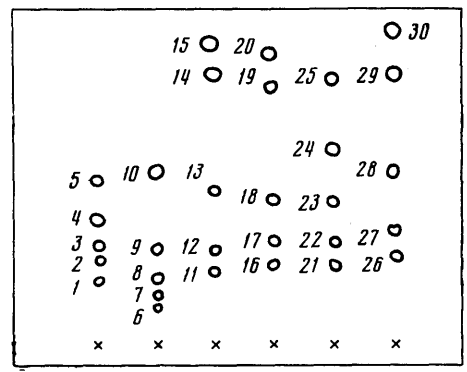

Figure 11. Chromatography of a mixture of nucleotides, and nucleosides, and bases on a layer of PEI-cellulose[577]; gradient: 0.6 ml of 0.1 M LiCl, 0.6 ml of 0.2 M LiCl, 0.6 ml of 0.5 M LiCl, 0.6 ml of 1 M LiCl, and 1.2 ml of 2 M LiCl: 1) ATP; 2) ADP; 3) AMP; 4) adenine; 5) adenosine; 6) GTP; 7) GDP; 8) GMP; 9) guanine; 10) guanosine; 11) UTP; 12) UDP; 13) UMP; 14) uracil; 15) uridine; 16) ITP; 17) IDP; 18) CMP; 19) cytosine; 20) cytidine; 21) ITP; 2) IDP; 23) IMP; 24) hypoxanthine; 25) inosine; 26) TTP; 27) TDP; 28) TMP; 29) thymine; 30) thymidine.

The separation of 22 compounds on MN-300 cellulose using the 57:4:39 isobutyric acid—concentrated ammonia—water solvent system in the first direction and the 7:3 methanol—1 M ammonium acetate system for two runs in the second direction may be quoted as an example[518]. Not only nucleoside mono-, di-, and triphosphates but also the 3′- and 5′-nucleotides are separated from one another fairly distinctly.

Fig. 10 illustrates the chromatographic separation of more than 60 nucleotides derivatives[519]. Special mention should be made of the satisfactory fractionation of the bases and the corresponding ribonucleosides, deoxyribonucleosides, the mono-, di-, and tri-phosphates of various nucleosides, and the 2′-, 3′-, and 5′-phosphates of ribonucleosides. Compounds with the same chromatographic mobility can be refractionated in another solvent.

Separation of the bases, nucleosides, and nucleotides with a high resolution has been achieved on PEI-cellulose using a salt gradient[578] (Fig. 11). Since the R_f values for nucleotides depend on the salt concentration[438], the bases and nucleosides can be readily separated from nucleotides by employing as the initial solvent distilled water or a 1:1 methanol—water mixture[438,442,578].

The separation of a complex mixture of bases, nucleosides, and nucleotides on columns has been described[498-500,503,504,543,549,553,556,557,568,570].

Gas—liquid chromatography (GLC), proposed initially only for the separation of acetyl, methyl, and isopropylidene derivatives of nucleosides[579] and methylated bases[580,581], has also been used recently to separate nucleic acid derivatives. In consequence of the low volatility and instability in the chromatographic process of the substances to be separated, these derivatives can be used only for qualitative analysis. The above difficulties were partly eliminated in the chromatography of trimethylsilyl derivatives of nucleosides[581-585]. Many modifications of the method are employed[581,583-591]. Chromatography of bis(trimethylsilyl)trifluoroacetamide derivatives has been most widely used[589,590,592-596]. However, in this case too certain nucleosides (cytidine, adenosine) give rise to several products after silylation[595,596]. For cytidine, this difficulty was obviated by modifying the cytidine derivatives with hydroxylamine derivatives before silylation[596]. GLC can be used to analyse the nucleotide composition of DNA and RNA,[589,593] but the sensitivity of the method is still insufficient (1—5 μg of nucleic acid per analysis). The GLC method can be usefully employed to analyse the compositions of synthetic oligonucleotides. The separation of rare nucleic acid components has been described[586,590,594,596,597].

Chemical Treatment of Seeds and Its Application to Plant Growing

K.E.Ovcharov and M.I.Shtil'man

Considerable attention is paid to the action on seeds of various plant-growth regulators and vitamins. A special place is occupied by the possibility of using chemicals to change the genetic peculiarities of plants, and also by the use of special polymer films as seed coatings. Great value attaches to the local introduction with the seeds of substances that protect both seeds and shoots from various pests and diseases. A list of 575 references is included.

V. Application of chemicals to seeds 609

I. INTRODUCTION

As early as 1800 the founder of plant physiology, Jean Sénébier, remarked in his many-volume treatise that the attention of chemists must be drawn to processes of plant growth[1]. Only a hundred years later, in an address given at Moscow University in 1901 on "A Century of Progress in Plant Physiology", Timiryazev was able to state that "chemistry and physics, having come to the assistance of plant physiology, have given to man, over the course of a century, the possibility of extending his right to life and curtailing the power of death: no knowledge could have a more valuable application"[2].

The application of chemicals to the growing of plants has now acquired immense significance. This has been especially clearly shown in the treatment of problems connected with the root nutrition of plants and the production and application of fertilisers. During the past decade the attention of research workers has been attracted to the preparation and investigation of chemicals capable of controlling the growth and development of plants. The organisation of a laboratory for the preparation of physiologically active substances in 1946, by S.S.Nametkin at the Institute of Plant Physiology of the USSR Academy of Sciences, played an important part in the development of these investigations in the Soviet Union. High yields are at the present time unthinkable without the widespread application of various methods of plant protection.

One of the most convenient modes of application of the chemicals (pesticides) used in agriculture—in several cases the only method—is to treat the seeds. This plays an important part in the struggle against micro-organisms and pests, diminishing seed losses both during storage and during germination. The field germinating power of seeds is enhanced by enriching them before sowing with the vitally necessary compounds and substances controlling their germination and growth. The use of polymers to coat seeds is of considerable practical interest, and provides a solution to several important problems.

Although the production, properties, and application of pesticides are covered in a large number of reviews and monographs[3-8], insufficiently detailed consideration has been given during recent years to the whole complex of problems associated with the chemical treatment of seeds[9,10]†.

In the present Review, without claiming complete coverage of the literature and while disregarding problems connected with the biology of the germinating seed, we would like to examine the main classes of chemical substances employed for the treatment of seeds, together with certain aspects of their action. We have used information published mainly during the past 15–20 years both in original papers and in abstracts and books.

II. STIMULANTS AND INHIBITORS OF GERMINATION

Methods of treating seeds with growth regulators have been developed during the past forty years, and several groups of regulators, now being widely studied, were discovered only during the last two decades. The quantity of publications concerned with the action of regulators on germination is continually increasing. This information is being systematised to some extent in several monographs, reviews, and symposia[9,10,13-22].

Plant-growth regulators usually include stimulants and inhibitors, herbicides (substances causing destruction), desiccants (which dry up plants), and defoliants (causing leaves to fall). The last two groups are not used for treating seeds, and will not be discussed below.

Growth regulators are widely represented in plants, being products of normal metabolism. Such substances are often termed *plant hormones*. Synthetic products, by means of which it is also possible to control the vital activity of plants, are widely studied together with natural growth regulators. In this case stimulation is a consequence of the disturbance (usually only slight) of the normal functioning of the living system caused by the

† The first summaries of work on the treatment of seeds with various substances appeared in 1763 and 1876[11,12].

chemicals: the accompanying intensification of metabolism is a kind of protective reaction of the organism aimed at restoring its normal functioning as rapidly as possible[5].

The action of a regulator may vary with its concentration. Thus at low concentrations it has a stimulating effect, it retards metabolism with increase in concentration, and at doses exceeding the inhibiting dose it leads to destruction of the plant.

Various organic substances are mostly used as artificial regulators. The main groups of these compounds used for treating seeds before sowing are discussed below.

1. Auxins

An auxin was first isolated in 1931 by Kögl and Haagen-Smit[23]. They gave to the product the name *auxin*—a substance causing the growth and elongation of cells—and thereby introduced a new general term into scientific use. Some time later they isolated a second auxin, and then a third, termed a "heteroauxin", which on investigation proved to be indol-3'-ylacetic acid. This compound has since been detected in many plants. The ease with which indolylacetic acid can be synthesised explains its wide study as a stimulating regulator of plant growth.

It has since been found that auxin activity is possessed by other acids, e.g. those containing an aromatic carbocyclic or heterocyclic ring in the aliphatic radical[24]. The group of auxins most widely used for treating seeds are carboxylic acids derived from indole—indol-3'-yl-acetic, -propionic, and -butyric acids, as well as their esters, salts and amides.

Kholodnyi was the first Soviet worker to investigate[25] the effect of heteroauxin on the germination of seeds and the productivity of plants. Response to such treatment has since been confirmed by many investigators. Thus dipping rice seeds in auxin solutions before sowing was shown[26] to improve their germination in an unflooded soil, but this effect disappears on flooding. Indolylacetic acid increases the energy of germination of carrot and onion seeds by 9.0% and 9.4% respectively, and the germinating capacity by 5.6% and 13.7%.[27] It stimulates the germination of beans[28] and several other plants[29-31]. Keeping apple pips in a 0.01–0.001% solution for 30 min increases their germinating capacity by 10.6–18.1%.[32]

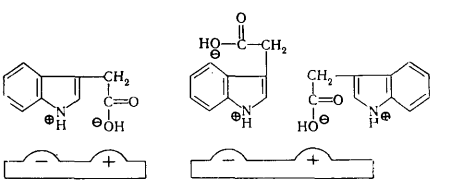
The intense physiological activity of auxins indicates that they are involved in the fundamental processes of metabolism. Thus indolylacetic acid plays a part in the phosphorus metabolism of plants[33], enhances the activity of 3'-nucleotidase[34], enhances oxidative phosphorylation, and activates the absorption of water[35]. It improves the binding of calcium by ribonucleic acid[36]. Activation of shoots of the cotton plant grown from seeds treated with the optimum concentration of auxin is accompanied by increased synthesis of nucleic acid and especially of ribonucleic acid[37].

The interconnection between the action of auxins and that of other growth stimulants is very interesting. Thus McLeod and Palmer have shown[38] that indolylacetic acid improves the conditions for the formation of α-amidase, which is dependent on the presence of gibberellins. The dependence of the action of gibberellic acid on the presence of auxins in plants has been confirmed[39]. The action of auxins on plants has been reviewed[40].

Many investigators were attracted by the discovery of auxins and by their great effectiveness in growth processes. The range of research on auxins has since been considerably extended: study of the responses of plants to treatment with auxins has been accompanied by attempts to synthesise new chemical compounds possessing auxin activity. In particular, the effect of introducing substituents into the heteroauxin molecule has been established. For example, auxin activity is suppressed by most substituents in the pyrrole ring[41]. Introduction of a 2-halogen, however, enhances it[42]. 2'-Substituted indolylacetic acids are considerably less active than their 3'-analogues[43]. Acids derived from naphthalene—naphth-1'-yl-acetic, -propionic, and -butyric acids—also exhibit auxin properties. On the other hand, 2-substituted naphthalenes are considerably less active[44]. Esters of the acids are used when a solution of the stimulant in a non-polar solvent is to be obtained. Naphth-1'-ylacetic acid is often used to treat seeds of various plants to stimulate germination and the development of shoots. It has been employed in particular to treat the seeds of wheat[45], tomato[44], red-currant[46], carrot[47], sunflower[29], and maize[48].

Acids containing a phenyl group, e.g. phenylacetic and phenoxyacetic, also exert a stimulating action. The nuclear-substituted acids often possess herbicidal properties, but at low concentrations even they have a stimulating effect. Thus 4'-chloro-2'-methyl-, 4'-chloro-2'-hydroxymethyl-, and 4'-chloro-2'-formyl-phenoxyacetic acids stimulate germination of seeds and development of the shoots of barley[49], tomato, and kidney-bean[50,51]. In low concentrations 2,4-dichlorophenoxyacetic acid (2,4-D) and its esters act as stimulants, e.g. on the seeds of pine, spruce, acacia, ash, and oak[52], annual weeds[53], and wheat[45]. Similar activity is developed also by substituted phenylbutyric acids[54] and indol-2'-ylglyoxylic esters[55].

Seeds and shoots are extremely sensitive to excess of auxins. This is apparent both in a diminution of germinating power and in the retardation of growth processes. A schematic model has been suggested to explain this phenomenon on the assumption of a two-point interaction between the auxin molecule and the enxymic centres with formation of a growth-stimulating auxin–receptor complex[56]:



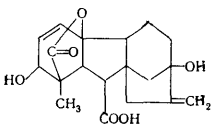
At high concentrations of indolylacetic acid two auxin molecules are adsorbed on the active site of the enzyme, and the required chemical conversion does not take place.

Study of the response of seeds to enrichment of their auxins has enabled the physiological role of auxins in the vital activity of seeds to be elucidated, and has also promoted the search for new plant-growth stimulants.

2. Gibberellins

The first gibberellin (subsequently termed gibberellin A_1) was obtained in 1937.[57] Several gibberellins were isolated, including gibberellin A_3—gibberellic acid—the most frequently used in practice and the most active of the 37 gibberellins known at the present time. Lona and Fioretti[58] have compared the activities of several gibberellins towards the germination of lettuce seeds.

Several new gibberellins have been described quite recently [16,59]. Gibberellic acid



like other gibberellins, is a fluorene derivative [320].

In industry, gibberellins are most often isolated from the fungus *Fusarium moniliforame* Sheld. A Soviet crystalline preparation of gibberellin A_3 contains gibberellic acid contaminated with certain other gibberellins, which widens the spectrum of its action and enhances its effectiveness. An inexpensive preparation—"gibberelate", containing ~10% of the active principle—has been manufactured in the Soviet Union since 1968. Its effectiveness has been demonstrated by trials [60]. Attempts are now being made to synthesise gibberellins [61].

Several surveys have appeared on the action of gibberellins [62-64]. The chemical structure of the compounds has been discussed in a review [65].

Although gibberellins are present in plants and seeds, the latter are extremely responsive to treatment with this plant hormone. Thus positive results have been obtained on treatment of the seeds of cotton [66,67], wheat [68,69], pea [69-71], barley [68,72], cucumber [73], maize [70,74], kidney-bean, parsley [70], lettuce [75,76], cabbage [77], radish [78], bean [71], belladonna [79-81], ginseng [82,83], and several other plants [84-90]. A large number of papers have dealt with the action of gibberellins on the germination of seeds of certain kinds of wood having seeds which germinate with difficulty (lime, ash, hornbeam) [91-99]. Such treatment with gibberellins increases the capacity for and vigour of germination of the seeds [68,71,78,91], and intensifies respiration [100]. Wheat and barley have shown rapid and harmonious growth with good development of the root system [68] (which is not usually characteristic of gibberellins). Beans and peaks have given good results with an increased moisture content in the soil [71].

The action of gibberellins can be promoted by preliminary chilling [84] and illumination [101] of the seeds. These and other facts suggest that a positive effect of gibberellins depends on the state of the seeds, the species of plant, and also the ambient conditions. Thus under identical conditions of treatment of the seeds, gibberellic acid stimulates the germination of cabbage but may depress that of carrots and tomatoes [77]. However, certain plants remained insensitive to such treatment [92]. Among 304 varieties of rice studied, seeds of southern origin were distinguished by a longer period of dormancy. These seeds proved especially sensitive to treatment with a gibberellin [102]. Early treatment of wheat grains undergoing prolonged storage was inadvisable, since it lowered the sowing qualities of the seeds [103]. The total quantity of gibberellins is determined photometrically [104] in practice, and the physiological activity of the preparations by means of a biological trial, e.g. on a dwarf pea [60].

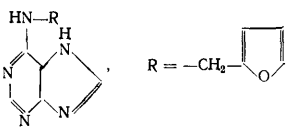
The mechanism of the action of gibberellins is illustrated by data published by Paleg [105] and Iomo [106] on the role of gibberellic acid in the formation of the hydrolytic enzymes of the endosperm of germinating barley. Work in this field has been continued very vigorously, and the main details of the mechanism have now been elucidated by researches on barley grains [38,107-113]. Zabolotskii has made a detailed survey of the regulatory mechanisms of the germination of seeds [114]. Formation of gibberellic acid during germination is assumed to be preceded by the synthesis of ribonucleic acid and of a protein in the embryo, which in turn are due to the activity of certain genes [21]. The synthesised gibberellin enters the endosperm, where it activates several enzymes—α-amidase, protease, ribonuclease, etc.—which reach the storage tissue, where they split up starch, proteins, and other materials. The cleavage products ensure normal growth of the shoot. Gibberellic acid also intensifies glycolysis and the activity of the ring in polycarboxylic acids [79]. Gibberellins promote plant growth by cell elongation, but do not stimulate cell division [86,115,116]. Such elongation assists better germination of the seeds.

Establishment of the presence in seeds of antagonists to gibberellins suggests that their favourable effect is due to the neutralisation of inhibitors [570]. A synthetic antagonist to gibberellins is chlorocholine chloride [117], which is used to oppose the flattening of wheat and other cultivated crops.

The treatment of seeds with gibberellins has provided a deeper insight into the favourable effects of light and low temperatures. The enrichment of seeds with this hormone replaces the stimulant action of light and temperature on germination [86,118]. These factors in the environment have been shown to stimulate the biosynthesis of gibberellins in seeds.

3. Kinins

During recent years the attention of research workers has been attracted by kinins, which are involved in the biosynthesis of proteins, chlorophyll, and other vitally necessary compounds [22,119]. Kinins are widely distributed in seeds, and have been detected in those of maize, sunflower, plum, peach, and other plants [120,121]. They are aminopurine derivatives, of which the best known is 6-fur-2′-ylmethylaminopurine or "kinetin"



Only eighteen years have elapsed since kinetin was obtained and its great physiological activity established [122], but many of its analogues have already been studied. Thus 6-benzylaminopurine surpasses kinetin in activity [123]. Another natural kinin—zeatin [R = $CH_2.CH:C(CH_3).CH_2OH$], isolated in 1967 from maize seeds [124]—also possesses very high activity. Many other purine derivatives have a stimulant effect, in particular those containing NRR′ and SR″ groups at position 6 (where R, R′, and R″ represent hydrogen or organic radicals). For example, 6-aminopurine and nitrogen-substituted aminopurines have proved active in experiments on the germination of horseradish and potato seeds [125]. 6-Benzylaminopurine raises the germinating capacity of lettuce seeds [126], as well as the long-keeping seeds of lupin, pea, maize, and barley [127,128]. Several other aminopurines have also been used to treat seeds [129]. Kinetin itself disrupts the dormancy of the seeds of beech, hazel, and mountain ash [130]; it stimulates germination of lettuce seeds [133] that have been treated with an inhibitor [131,132].

The initial effect of kinetin resembles that of gibberellins in enhancing the synthesis of nucleic acids. However, the second stage involves stimulating cell division, not elongation [134-138]. Kinetin and its analogues influence

mainly processes associated with the replication of deoxyribonucleic acid in cells. It intensifies the synthesis of ribonucleic acid and protein in cells, and stimulates the formation of ribosomes [139].

Kinins may delay the aging of plants. Thus treatment with kinetin has restored the colour of isolated yellowed leaves [140]. Finally, kinins restore the vital activity of irradiated plants. For example, viable ears could be obtained after the action of 6-benzylaminopurine on irradiated wheat grains [141].

Further study of the chemistry and biological action of kinins will be of great interest.

4. Vitamins

Seeds of all plants contain definite quantities of vitamins, which play an important part in germination and the development of shoots. The content of vitamins in seeds depends on many factors, in particular the ambient conditions. Therefore the quantity of vitamins necessary for germination sometimes accumulates in a seed; but sometimes the quantity present is insufficient. Although the vitamin content increases during germination, under unfavourable Spring conditions the accumulation of certain vitamins is insufficient for the normal course of the physiological processes. The presence in seeds of antivitamins and of enzymes which break down vitamins increases still further the deficiency of vitamins in germinating seeds. This makes it clear why supplying certain vitamins to such seeds will normalise metabolism and stimulate their germination.

Nicotinamide (vitamin PP) has been shown to act in this way towards the seeds of cotton [142,143], citrus [144], and vine [145]; pea, sorghum, cucumber, wheat, and beet seeds are also sensitive. Treatment raises the germinating power of the seeds, enhances development of the plant, and increases their yield [146-148]. This vitamin also improves the genetic properties of wheat, which is evident in a great development of vegetative parts, a higher grain content in the ear, increased weight of the seeds, and a higher protein content [149,150]. Treatment of the seeds of lemon, orange, and grapefruit considerably increases the number of seeds capable of giving several shoots [144].

Skrabka found [152] that wheat seeds of diminished germinating power and seeds germinating under anaerobic conditions contain lower contents of ascorbic acid and glutathione. The germinating capacity is raised appreciably by enriching the seeds with these two substances. Ascorbic acid has a favourable effect also on the germination of other seeds [88,153,155].

Seeds respond also to treatment with biotin, the sensitivity increasing during ripening. Seeds differing in quality react differently: seeds from the middle of the maize cob are usually more sensitive to enrichment with biotin, which is less active towards those from the upper part of the cob [156].

Treatment of the seeds of flax, pea, radish, buckwheat, and carrot with thiamine before sowing improves their germination and increases the yield [146]. This vitamin has a favourable effect on cotton seeds [143,158,159], whose growth processes are intensified by vitamin B_6. [142]

The observed biological action of vitamins involves not only normalisation of the metabolism in which a particular vitamin takes part but also an ensuing change in composition of the soil microflora [9]. For example, enrichment with thiamine, riboflavin, and nicotinamide of beans before sowing stimulates more intense formation of root nodules and nitrogen-fixing bacteria, which improves the supply of nitrogen to the plants and enhances growth processes and development of cultivated crops [146,161].

The above results indicate that seeds of several plants are deficient in certain vitamins. Timely treatment of such seeds with vitamins will therefore intensify metabolism, increase germinating capacity, and strengthen the growth and development of the plants.

5. Other Organic Compounds

Organic acids are widely represented in seeds, and are actively formed during germination [162]. The resulting organic acids are utilised in respiration, as well as for the synthesis of amino-acids and other vitally necessary compounds. In several cases, however, the quantities of such compounds remain insufficient for normal metabolism, and treating seeds with them has a favourable effect on growth processes.

Thus treatment of the seeds with succinic acid improves the germination of maize [163], cotton [164], pea [165], wheat [153,165,166], barley, and rye [166,167]. Improvement of germination and intensification of further growth are observed also with other plants [167-173]. The best results are obtained by treating seeds which are germinating in the presence of deficiencies of noisture and oxygen [166]. Not only succinic but also citric, malic, and fumaric acids increase the yield of wheat [153]. Succinic acid has a greater effect on radish and cucumber seeds than has fumaric acid [174]. Certain analogues of succinic acid, e.g. dodecylsuccinic acid, also have a stimulant effect [175]. The action of polycarboxylic acids on seeds has also been discussed in several papers [121,176-178].

Intensified germination of seeds is observed also on treatment with several other acids, e.g. amino-acids [179, 180,568], keto-acids [181], phenylboric acid [182], naphthenic acids [183-187], quinonecarboxylic acids [188,189], cinnamic acid [171,190], 1,2-benzocyclo-hept(and oct)ene-3-carboxylic acids [191], cedrenecarboxylic acid [192], and several others [193-195]. The seeds of wheat, barley, and several other plants are sensitive to formic and acetic acids (Ref. 10, p. 200). In some cases inorganic acids also accelerate germination [196,197].

Many substances belonging to other groups of organic compounds also affect the germination of seeds. Phenols (guaiacol, phloroglucinol, catechol) stimulate growth of the seeds of rye, beet, celery, carrot, and alder [198]; and quinol has a similar effect on wheat and pea [199]. In other cases phenols (tannin, guaicol, gallic acid, etc.) delay or completely suppress growth [200]. Vanillin and ferulic acid in small concentrations stimulate germination, increase the germinating capacity of seeds, and promote the development of shoots [171].

A method has been worked out for obtaining active furan derivatives, whose use for the treatment of wheat seeds produces better development of the root system together with an increased yield [201-204]. Derivatives of several other heterocycles also have a stimulant effect. Thus growth is stimulated, the yield of plants is raised, and resistance to wilting is improved by addition to seed disinfectants or use as a component part of steeping solutions. The greatest activity is exhibited by 1-cyano-2-methyl-5(6)-nitrobenzimidazole, 1-cyanoethyl-5(6)-nitrobenz-

imidazole, 5(6)-nitrobenzimidazole [205,206], 2-methyl-5(6)-nitrobenzimidazole, 5(6)-amino-2-methylbenzimidazole, 2-diethylaminobenzimidazole [171], and several other imidazoles [208]. Good results have been obtained by treating seeds with amino-, hydroxy-, and mercapto-derivatives of pyrimidine [209,210].

Development of the root system of maize, with simultaneous diminution of the height of the plants, is produced by the use of alkyl carbamates [211].

Halogenated alcohols—2-chloroethanol [67,212], 1,2-dibromo-3-chloropropanol [213], *N*-substituted chloroacetamides [214], dibromoethane [213], and *gem*-diarylcyclohexanol derivatives [215]—accelerate germination. In several cases preliminary treatment of the seeds with alcohols facilitates the penetration of moisture [216].

6-Aminopurine and several of its derivatives have a favourable effect on tomato and mustard seeds [217]. Salicylohydroxamic acid has proved useful for the germination of pea and tomato [218]. Wheat and pea germinate better after treatment of the seeds with derivatives of cyclohexane and cyclohexene containing hydroxy- and keto-groups [219], and seeds of grain crops with solutions of melamine and aminoethanol [220]. Seed germination has been enhanced by streptomycin [221], acetone [222], sucrose and hexoses [223], and chlorides of certain cyanine dyes [224].

Thiourea has a positive effect on the seeds of the Russian dandelion and of lettuce [225-228]. *N*-Alkyl-*N'*-arylthioureas, which have been tested on wheat grains, are more active [229]. The combined action of thiourea and indol-3'ylacetic acid on oats exhibits synergism [230]. The dry weight of the roots is increased by soaking peas, barley, and flax in glycothiourea solution [231], and cultivated lettuce seeds in methylurea solution [132].

Germination is stimulated also by certain nitrosulphonamides [232], mixtures of manganese salts of lower carboxylic acids [233], amines [101,234], and other synthetic compounds [235].

The supply of oxygen to seeds is of considerable importance. This is obviously responsible for the favourable effect of hydrogen peroxide on rice [236], sugar-beet [237], tobacco [238], and wheat [9]. Germination is accelerated and the percentage germination of seeds increased by the action of benzoyl peroxide, its halogenated derivatives, methyl hydroperoxide, and t-butyl perbenzoate [239].

Various products which protect plants from diseases and pests may also influence germination. Thus treatment of the seeds of certain crops with disinfectants has in several cases increased their germinating capacity [240-248]. Certain systemic pesticides have proved toxic to seeds [249]. Biologically active compounds containing sulpho-groups may also depress seeds [250].

It is interesting that ethylene is used to bring seeds out of their dormant state [126,251].

There are indications that certain inorganic substances—calcium cyanamide [9,252] and dilute alkalis [197]—may stimulate germination. Keeping seeds in solutions of salts of metals (potassium, calcium) and hydrohalic acids increases the accumulation of amino-acids [161,253].

The list of chemical compounds which have been tested for controlling the rate of germination of seeds could be considerably extended. However, most of the publications involve no knowledge of the mechanism of the action, but pursue the aim of determining whether a given compound stimulates germination and plant growth. Such work, of course, despite its usefulness, conveys little information on the germination of seeds and the mechanism of the action of particular compounds. Yet a solution of this problem would be invaluable for practical agriculture.

6. Inhibitors and Herbicides

A seed is a complicated biological system whose life is controlled by stimulants and inhibitors. The presence of the latter has long been known [254,255], and they have since been detected in many seeds [256-258]. Their quantity and nature depend both on genetic features of the plants and on the physiological state of the seeds. Thus extracts from 60-day green peas retarded the development of bean shoots more strongly than did extracts from ripe seeds [259]. Germination of seeds inside over-ripe fruits of the tomato, pumpkin, and water-melon is associated with a diminution in the content of inhibitors.

The retarding action of plant inhibitors is suggested by other facts. Germination of lime is delayed by extracts of the pericarp [260]. Flavonoid pigments, which inhibit the germination of cereals, have been found in the seed coat of barley [261]. Aqueous extracts of rice bran retard the germination and growth of rice and cultivated lettuce [262]. An extract of sugar-beet nodules greatly diminishes the germinating capacity of wheat [263].

Water-soluble substances from the leaves of steppe plants, which form a rosette at the roots, inhibited the germinating capacity of radish and poppy [211]; an onion paste delayed the germination of maize [224]. Extracts of several other plants exert an inhibiting effect on seeds [264-267].

Not only have several inhibitors occurring in plants now been identified, but in some cases the mechanism of their action has been established. Examples are coumarins in the seeds of sweet clover [268], cyanides in beans [269], parasorbic acid in the fruit of mountain ash [270], ferulic, vanillic, *p*-hydroxybenzoic, and *p*-hydroxycinnamic acids in sugar-beet seeds [271], and abscisic and paracoumaric acids in cotton seeds [173]. Abscisic acid has been detected in many seeds and plants [272-277]. It acts by inhibiting gibberellins and retarding the synthesis of nucleic acids. Several other inhibitors have been isolated from seeds [10,278].

A retarding and herbicidal effect on seeds and seedlings is exerted not only by natural inhibitors but also by many synthetic compounds. The considerable interest in this question led to study of the theoretical principles of the action of inhibitors and herbicides, which are antimetabolites of growth stimulants. Antimetabolites take the place of the most important metabolites in biological transformations during enzymic reactions and inhibit them. The antimetabolite, which is assumed to combine with the active centre of such a protein, forms a system which does not undergo the usual reactions, and the required products are not formed [279].

The structure of an inhibitor is often closely similar to that of the corresponding metabolite. The most active antimetabolites are those which show only slight structural differences from the corresponding metabolites. The main interrelationships in chemical structure between metabolites and antimetabolites have been established [279]. In particular, an inhibiting effect is produced by the replacement of e.g. carboxyl by sulpho, hydroxyl by alkoxyl, etc.

Antimetabolites can be divided into several groups according to the mechanism of their action [279]. Thus some inhibitors and herbicides—e.g. derivatives of phenoxy-, *p*-chlorophenoxy-, 2,4-dichlorophenoxy-, and *p*-methylphenoxy-propionic acids—suppress the activity of auxins and other growth stimulants [422]. A group of synthetic compounds which cause shortening of the stem, thickening of the cell walls, and intensification of leaf colour ("retardants") are antagonists of gibberellins [280,281].

The most widely known of such compounds is chlorocholine chloride ("CCC") $[ClCH_2.CH_2.N(CH_3)_3]^+Cl^-$, whose physiological action was first observed by Tolbert in 1960.[282] It was shown later that CCC is an antagonist of gibberellins[117,283,284]. A Soviet product TUR based on chlorocholine chloride is now available[285]. Plants are usually sprayed with chlorocholine chloride. Recently, however, seeds have also been treated with solutions or powders of retardants[286,287]. Thus the action of retardants on seeds of spring wheat, barley, oat[288-290], pea[291], and cotton[292] has been investigated. Treatment of seeds with CCC may determine the sex of plants[293].

Maleic hydrazide (brand MG-T) and its derivatives act as antagonists to plant-growth stimulants. The hydrazide inhibits cell division[294]. Gibberellins and maleic hydrazide have opposite effects when applied together[295]. These compounds are often used to treat seeds to prevent germination during storage. Maleic hydrazide inhibits the germination of cotton[296], beet[297], soya[298], peas, beans, cucumber, wheat, barley, maize, turnip, radish, tomato, and rye[300]. Analogous effects on metabolism are produced by hydrazides of several other acids—chloromaleic, methylmaleic, phthalic, and succinic[299]—*NN*-dimethylsuccinamic acid[296], 6-azauracil[300], and certain other uracil derivatives[301].

Halogenated aliphatic acids, which retard the biosynthesis of individual groups of enzymes, inhibit germination[279]. Thus investigations have been made on the action of sodium trichloroacetate on wheat and millet grains[302], of trichloroacetamidine on mono- and di-cotyledonous crops[303], of propionic acid, which protects grain forage of high moisture content from germination[304], and of chloral hydrate, which has a herbicidal action on the seeds of barley, millet, oats, mustard, and wheat[302].

Several other substances have an inhibiting action on seeds. Thus 3-acylated aminotriazines delay the germination of radish[305], sulphanilamide[306] and aminopteridine[307] that of maize and peas, diepoxides the germination of wheat, millet, and radish[308], and 1,3-diphenylprop-2-ylamine that of wheat and kidney-beans[309]. Vital activity is completely suppressed by isocyanates[310] and several other substances[311-316].

Study of the effect of physiologically active substances on the germination of various plants has shown that, whereas some seeds are destroyed by a particular compound, others are resistant. This has been used to develop ways of destroying the seeds of weeds in the soil. Thus many weeds are killed by introducing industrial herbicides into the soil before sowing.

Further study of the dependence of the inhibiting effect of synthetic antimetabolites on their chemical structure and examination of the mechanism of their action will permit the development of new types of selective weed-killers.

III. CHEMICAL MUTAGENS

Chemical compounds are able not only to stimulate or inhibit germination and plant growth but also to influence heredity[317]. The ability of chemical compounds to change genetic features was first observed as early as 1916.[318] A few new mutagens were discovered in the 1930s, when aziridine, diethyl sulphate, and several other substances were found to be highly active[318]. A broad investigation of this phenomenon was begun after valuable results had been obtained on barley and peas[3]. Whereas radiation methods became widely used in the 1930s to change heredity, nowadays chemical mutagens occupy the primary place[319].

The seeds are usually soaked in a solution of the mutagen of definite concentration[321]. *N*-Nitrosoethylurea, 1,8-bisdiazo-octane-2,7-dione, aziridinopiperidine[322-327], diazoacetic ester, bis-2,2-dichloroethyl hydrogen phosphate, *N*-nitrosomethylurea[328], ethyl methanesulphonate[329-334], *NN'N"*-triethyl-thiophosphoramide[335], diethyl dimethyl pyrophosphate, and tetraethyl dithiopyrophosphate[336] have found use for these purposes. Colchicine[337,338] and other substances[24] are employed as mutagens.

The largest number of publications have been concerned with obtaining valuable mutations in wheat and rice, as well as in maize[329], barley[330,333,339], sugar-beet[337], cotton[332], and peas[340].

Since traces of mutagens (or their decomposition products, e.g. ethyl hydrogen sulphate[341]) may have a deleterious effect, they are removed by washing with water, sometimes with the addition of chemicals, e.g. sodium thiosulphate[319]. Treatment and washing with water are followed by sowing.

The possibility of obtaining agriculturally valuable mutations of cultivated crops by treating the seeds with active compounds opens up new prospects for changing the genetic character of plants and will provide a deeper insight into the chemical nature of heredity[154].

IV. TREATMENT OF SEEDS WITH PLANT-PROTECTION AGENTS

Plants synthesise not only compounds that are directly involved in metabolic processes but also those which have a toxic effect on bacteria and fungi. The latter compounds were termed "phytoncides" by Tokin[342]. Investigation of the composition of gaseous and liquid examples showed that such products comprise various aldehydes, phenols, essential oils, and other compounds[343]. Available results indicate that treating seeds protects them from diseases caused by micro-organisms.

Thus during 1953–1954 it was found that treatment of clover and lucerne with the "phytoncides" of garlic had a protective effect on the seeds for a year[344]. Treatment of seeds of perennial grasses with onion "phytoncides" proved to be more effective. The morbidity of perennial grasses[345], barley, kidney-beans, peas, wheat, cucumbers, flax, and other plants[346] was lowered by applying analogues of pseudoallicin to their seeds. "Phytoncides" of onion, garlic, and horseradish lowered the incidence of vascular bacteriosis in cabbage, and of bacterial cancer in tomatos (seeds were treated before plants)[347,348]. Antimicrobial substances of mustard, horseradish, and eucalyptus protected cotton seeds from gummosis[346].

Treatment of tomato seeds with "phytoncides" from the fruit of nightshade completely eliminated morbidity due to bacterial disease[349], and of clover, lucerne, and tomato seeds with arenarin (a "phytoncide" of everlasting sandwort) tended to lower the susceptibility of the plants to bacteria, in some cases to fungi as well, and to a greater extent than treatment with Gramosan [an ethylmercuric chloride seed fungicide equivalent to Ceresan][346]. Fusariosis in melons is prevented by treating the seeds with anabasine (an alkaloid isolated from a leafless blackberry)[350]. Extracts of the seeds of certain kinds of wood (ash, acacia, wild rose) have a bactericidal effect on wheat grains[351].

Antibiotics have a special place in the fight against plant diseases. Streptomycin is the most widely used for disinfecting seeds. Thus tests on beet seeds in England gave such promising results that in 1960 almost all beet growers in that country had changed to treating seeds with a solution of streptomycin. It gave good results with oats, wheat, and barley [352]. However, products of the vital activity of organisms and plants have not found wide application for protecting seeds from fungal and bacterial diseases. This is due not only to the complexity of their isolation in considerable quantities but also to the inhibiting effect of some of them on germination.

Nevertheless, agriculture demanded readily available and effective agents to reduce the immense losses of production due to micro-organisms and pests. According to the most recent data, for example, the world losses merely of wheat are 85.6 Mt or 23.9% of the total production of this most important crop [353]. Comparable losses occur in stored grains and rice: in 1947 the United Nations estimated them to be 33 Mt, a quantity which would have fed a human population of 150 millions for a year [354].

A considerable proportion of plant disease is transmitted through the seed stock from generation to generation. Furthermore, the eggs of many insects are distributed with the seeds on sowing, so that the great attention paid to the chemical disinfection (decontamination) of seeds becomes understandable. This plays an important part also in the struggle against pests and micro-organisms inhabiting the soil, as well as against granary pests [3,355-359,160].

The local treatment of seeds with protective agents has considerable advantages over the continuous application of chemicals. Contamination of the soil with poisons is avoided. The introduction of protective agents is combined with sowing, which eliminates additional types of field operations, and considerably diminishes the quantities of pesticides required [360-363].

Although the disinfection of seeds with various chemical reagents has been employed for a long time, widespread use has occurred only during the past 30–40 years. At the present time hardly any seeds of agricultural crops are sown in developed countries without chemical treatment [364-366]. When especially injurious substances are applied, the seeds are dyed bright colours or are treated with compounds having a characteristic odour [367].

Substances used for plant protection can be divided according to their type of action into insecticides, fungicides, bactericides, zoocides (against rodents), nematocides (against roundworms—nematodes), repellents, and several others. The same substance can offer different types of protective action, but such pesticides are usually classified according to their most characteristic range of activity.

Below we shall survey the main classes of synthetic chemical compounds used for the protective treatment of seeds, primarily on the basis of their chemical structure, and secondarily their type of action.

1. Phosphorus Compounds

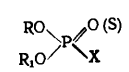
Phosphorus compounds form one of the chief classes of pesticides used for plant protection [368]. Several thousands of active phosphorus compounds are already known, among which about 80 are employed in agriculture. In the present Review, of course, it is impossible to consider all these products. We shall mention only the main phosphorus compounds used for the disinfection of seeds.

Although these are usually organophosphorus compounds, there are several active inorganic compounds, primarily zinc phosphide Zn_3P_2, which is used as a zoocide [4]. In several cases it also possesses insecticidal properties. Zinc phosphide has a strong disinfectant effect, but the substantial disadvantage of high toxicity towards farm animals: thus wheat, barley, and sunflower seeds remained toxic towards cows, calves, and pigs for 35, 43, and 96 days respectively after disinfection with zinc phosphide [369].

Organophosphorus compounds occupy a most important position among pesticides. Their total production now approaches that of chlorinated pesticides. Their useful properties include high activity, wide spectrum and rapidity of action, low consumption of products, and decomposition to give non-toxic or only slightly toxic products. An important aspect is that several of the organic compounds of phosphorus have a systematic effect [4].

The basis of the action of organophosphorus compounds is supposed to be inhibition of the enzyme choline esterase [4]. An impetus to a broad study of active organophosphorus compounds was given by the publication of Schrader's papers [370]. Soviet scientists have made a great contribution to developing the chemistry of organophosphorus compounds. Several reviews and monographs have appeared on the chemistry and application of organophosphorus pesticides [4,370,372,374].

Mel'nikov [4] made a detailed examination of the dependence of the pesticidal activity of organophosphorus compounds on their chemical structure. Compounds of general formula



are most often used, in which R and R_1 are organic radicals, usually lower alkyls (methyl, ethyl, isopropyl), while X is a group which can be replaced by a nucleophilic agent [371]. Increase in chain length leads to loss of activity. New active derivatives are therefore obtained by varying X. Replacement of oxygen by sulphur lowers the toxicity towards mammals without significant loss of pesticidal activity. The toxicity is still further reduced in derivatives of phosphorodithioic acids, which are more resistant to hydrolysis, so that the duration of their action is lengthened [4].

Among the large number of organophosphorus compounds for treating seeds use is made in particular of the products—2,2-dichlorovinyl dimethyl phosphate, 1,2-dibromo-2,2-dichloroethyl phosphate (Dibrom), dimethyl *N*-isopropoxycarbamoylphosphonate (Avenin, K-69-79), dimethyl 2,4,5-trichlorophenyl phosphorothioante (Ronnel, Trolene, trichlormetaphos, Etrolene, Dow ET-14, Korlan, Nankov), diethyl 2-isopropyl-4-methylpyrimidin-6-yl phosphorothionate (Dianisone), and 2-ethylthioethyl *OO*-dimethyl phosphorothioate (a mixture of isomers) (Meta-Systox, methyl demeton) for the treatment of grain [4,375]; *S*-1,2-diethoxycarbonylethyl *OO*-dimethyl phosphorothiolothionate (Carbophos, Malathion) for treating the seeds of kidney-bean, maize [4,376], barley, oats, rye, rice, sorghum, and wheat [4,377]; and *OO*-dimethyl *S*-*N*-methylcarbamoylmethyl phosphorothiolothionate (Phosphamide, Rogor, Dimethoate, BI-58) and pyrophosphoric octamethyltetra-amide (Octamethyl, OMPA, Tradane, Systam, Pestox-111) for the seeds of wheat, sugar-beet, and savoy [4,378]. Several other organophosphorus compounds are also used for disinfecting seeds [4,377-384].

Organophosphorus insecticides can be arranged in the sequence—Diazinon, Guthion, Ronnel, DDVP, Dibrom—according to the maintenance of the protective effect on the grain. Protection becomes weaker with increase in the moisture content and rise in the temperature of the grain.

Certain organophosphorus insecticides exert a stimulant effect on the germination of sugar-beet [378].

2. Mercury Compounds

Organic compounds of mercury occupy a leading position among means of protecting plants from fungal and viral diseases and from bacterioses. They possess the advantage of high toxicity towards micro-organisms and lack of toxicity towards seeds. In several cases, moreover, a stimulating effect on the growth processes of plants is observed [4]. Organic mercury compounds have already been widely used for several years in the disinfection of seeds. The history of and the prospects for their application have been discussed in several reviews [385,386]. Mercury preparations are considered to act by inhibiting the functioning of respiratory enzymes [387,388].

The compounds used as fungicides and bacteriacides usually have the formula R–Hg–X, where R is an unsubstituted or substituted aliphatic, aromatic, or heterocyclic radical, and X is an organic or inorganic acid radical [4,387]. The relation between the activity of these compounds and their chemical structure has been revealed by Mel'nikov [4]. Mercury compounds are often applied as components of combined disinfectants, but they also find independent usage. Many mercury compounds are used as seed disinfectants, of which only a few will be discussed here.

Ethylmercuric phosphate (NIUIF-1) is mostly used for the moist disinfection of seeds of various crops. However, other modes of disinfection are also applied. Thus a semi-dry treatment with ethylmercuric phosphate of the seeds of rye, winter wheat, and maize increases the yield, the energy of germination, and the germinating capacity [389]. Good results are obtained by immersing the seeds in a solution of the fungicide [390].

Methylmercury cyanodiamide (as the preparations Panogen, Aldrogen, Radogen [392]) is used in the form of solutions, often with mechanised treatment of the seeds [4]. This product gives favourable results for seed disinfection on flax [391], cereals, maize, tobacco, and vegetables [392].

Methoxymethylmercuric chloride (Ceresan Universal, Arethan) is a disinfectant for the seeds of grain, sugar-beet, and other crops [4].

Phenylmercuric acetate (Ceresan, PMATs, FMA, Tag, Quixane [4], Ruberone [393]) is sometimes supplied mixed with ethylmercuric chloride. Phenylmercuric acetate is used against kernel smut on seeds [393]. It can be mixed with a synergistic additive—dehydroabietylamine [394].

Phenylmercuric propionate is a bactericidal and fungicidal product [395].

Ethylmercuric chloride is the active principle of the disinfectant Granosan (NIUIF-2 [396]). It ensures decontamination of the seeds of almost all agricultural crops—cereals [397,398], fodder [400], industrial [399], horticultural, and ornamental [401]—from bacteria and fungi. Granosan increases the germinating capacity of the seeds of various crops [240].

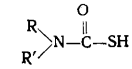
Among other mercury compounds used to disinfect seeds mention must be made of methylmercuric oxide [394], methylmercuric pentachlorophenoxide [402], and compounds of formula R'HgSR (where R' is a lower alkyl and R the residue of a polyhydric alcohol) [403]. The advantages of this group include the possibility of the advance treatment of wheat seeds with mercury-containing products [404], their comparatively high efficiency [405], and the possibility of application as oil emulsions [406].

Liquid disinfectants based on organomercury preparations have found wide application [357]: they are active not only on direct contact but also by the action of the gas phase. The best known are the above products Panogen and Aldrogen, as well as liquid preparations based on phenylmercuric acetate, mercury toluene-*p*-sulphonamide [407], and other products [408].

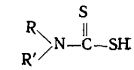
Czech workers have proposed an interesting method for obtaining small-volume arylmercury disinfectants by a series of ion-exchange reactions [409-412].

3. Thiocarbamates and Dithiocarbamates

A large group of seed disinfectants are derivatives of thiocarbamic acid



and dithiocarbamic acid

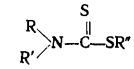


These compounds exhibit herbicidal activity, but they can also be used as fungicides or nematocides. Dithiocarbamates are the most widely used to disinfect seeds, although isolated publications have appeared on the use of derivatives of thiocarbamic acid to disinfect seeds of e.g. wheat and cotton [413].

Many papers have been published on the mechanism of the action of dithiocarbamates. It is assumed that their conversion products, isothiocyanates, possess toxic properties [387]. It is noteworthy that various isothiocyanates are used independently to treat seeds [414,415]. Discussions of the relation between the chemical structure of these compounds and their activity [4,387] reveal that the most active are those in which R and R' are methyl groups: lengthening the radical diminishes the activity.

The fungicidal properties of dithiocarbamic acids were discovered in 1934. [416] Many derivatives, primarily salts, are now used to treat seeds. Thus fungicidal activity is exhibited by the chelated dimethyldithiocarbamates of zinc [4,387,417] (marketed as Zineb), iron (Ferbam) [4,387], and manganese (Maneb) [4].

Another large group of derivatives of dithiocarbamic acid used for disinfecting seeds are compounds of general formula



where R'' may be various organic radicals, while R and R' both represent methyl. For example, compounds in which R'' = $SArX_nY_k$ (where X = NO_2; Y = H, Cl, cyclo-C_6H_{11}; and $n + k = 3$) are harmless to heat-resistant seeds and do not affect the properties of the grain [418]; compounds with R'' = $-\overline{N.CO.[CH_2]n.CO}$ are used to decontaminate rye seeds and possess slight phytotoxicity [419]; a preparation containing $(CH_3)_2N.NH.CO.S.S.CO.NH.N(CH_3)_2$ is used as a fungicidal disinfectant for the seeds of wheat and

oats[420]; and preparations containing a furan ring in the group R″ are applied to wheat and cotton seeds. Fungal diseases of wheat and cotton are resisted by treating the seeds with several heterocyclic derivatives of dimethyldithiocarbamic acid[413].

Derivatives of polymethylenethiocarbamic acids (usually ethylenethiocarbamic) form a separate group. The best known are manganese and zinc ethylenedithiocarbamates and bisdimethylthiocarbamoyl ethylenebisdithiocarbamate (Tekoram)[4]. Compounds of these salts with ethylenebis(thiuram disulphide) possess stronger fungicidal properties[4,421]. Tetramethylthiuram disulphide finds very wide application as a seed disinfectant, both alone and in various mixtures (Thiuram D, Thiuram, TMTD)[4]. It not only decontaminates the seeds of cereals, beans, and several other crops[397,423–425] but also raises the field germinating capacity of wheat, maize, and cotton[240,241]. The fungicidal and bactericidal properties of TMTD are strengthened by the addition of dehydroabietylamine[394].

4. Chlorinated Hydrocarbons

Chlorinated hydrocarbons (and more rarely other halogenated derivatives) form the main group of plant-protection agents, widely used both in the Soviet Union and abroad. They are employed mainly as effective insecticides and nematocides, although several also possess fungicidal properties. This class of compound is usually divided into three groups according to their chemical nature and mode of synthesis. The first group comprises halogen derivatives of aliphatic hydrocarbons, among which those which produce a sufficient concentration in the gas phase (fumigants) are usually applied to seeds.

The simplest member of the second group—halogenated aromatic hydrocarbons—is hexachlorobenzene, employed as a seed disinfectant in various mixtures against smut fungi of cereals, often together with the toxic ethylmercuric chloride[4]. Halogenated derivatives of diphenylmethane—primarily bis-*p*-chlorophenyl-2,2,2-trichloroethane (DDT)—have found considerably greater use. Several monographs have been published on the production, properties, and application of DDT.[426–428] In the treatment of seeds DDT is used mainly as a component of composite disinfectants, but references have been made to its independent application, e.g. for dusting the seeds of maize, kidney-bean, and ground-nut to protect them from pests. The germinating capacity of the treated seed was undiminished by storage in sealed vessels for up to 18 months[429]. In spite of the thorough study and adequate manufacturing capacity, the question of reducing the scale of production of DDT [4] arises from its considerable toxicity towards human beings and animals.

The third of these groups of seed disinfectants comprises halogenated alicyclic hydrocarbons. One of the most widely used insecticides of this group is hexachlorocyclohexane. Among its eight stereoisomers only the γ-isomer exhibits toxicity. A preparation containing 99–100% of the γ-isomer appears on the market as Lindane[4,430]. Hexachlorocyclohexane may also be a component of composite disinfectants. It can find independent application, e.g. to protect a seed stock from harmful insects[429]. The δ-isomer is used in disinfectant mixtures as a synergistic additive to certain fungicides[4].

Chlorinated derivatives of polycyclic compounds are widely used. Several effective products, which have found application in composite and in individual disinfectants, are obtained by diene synthesis, in particular with hexachlorocyclopentadiene as one of the reactants. Several of these products are listed below.

Allodan is 1,2,3,4,7,7-hexachloro-5,6-bischloromethylbicyclo[2,2,1]hept-2-ene

Endrin is 1,2,3,4,10,10-hexachloro-1,4 : 5,8-di-*endo*-methylene-6,7-epoxy-1,4,4a,5,6,7,8,8a-octahydronaphthalene

Aldrin is 1,2,3,4,10,10-hexachloro-1,4-*endo* : 5,8-*exo*-dimethylene-1,4,4a,5,8,8a-hexahydronaphthalene

Heptachlor is 1,4,5,6,7,8-heptachloro-4,7-*endo*-methylene-3a,4,7,7a-tetrahydroindene

Dieldrin is 1,2,3,4,10,10-hexachloro-1,4 : 5,8-di-*endo*-methylene-6,7-epoxy-1,4,4a,5,6,7,8,8a-octahydronaphthalene.

These products proved effective against harmful insects on treatment of the seeds of maize, sorghum, kidney-bean[431], carrot, onion[432], and cotton[433]. Dieldrin gives better results than other insecticides in protecting seeds from the Swedish fly[434]. These products are used also for several other plants.

Among other halogenated derivatives we must note the chlorothiophens, which are no less active than mercury preparations[435,571].

5. Other Groups of Seed Disinfectants

The earliest seed disinfectants were copper compounds, mainly organic derivatives. Copper 2,4,5-trichlorophenoxide is used[4], also constituting 20% of the disinfectant of the same name. The major portion of the product, marketed as a dust, is talc[355]. Copper trichlorophenoxide is employed e.g. for treating cotton[436] and soya[437] seeds. Another copper compound is the quinolin-8-yl oxide, the active principle of the disinfectant Quinolate-15 [438] (Quinolene-15 [439]).

Derivatives of trichloromethanethiol possess good fungicidal properties[440]. Attention was first directed by Kitleson[441] to the fungicidal activity of compounds containing a trichloromethylthio-group. Compounds of this series at present in use for treating seeds are tetrahydro-*N*-trichloromethylthiophthalimide (Captan)[4] and bistrichloromethyl trisulphide (possesses also stimulant properties)[242].

Among other groups of disinfectants used for treating seeds we must mention inorganic and organic arsenic compounds (e.g. calcium arsenite in Protas Preparation PD [355] and methylarsine sulphide[442]), tin compounds[443,444], and nitro-compounds, e.g. dinitrobenzene[397] and dihalogenonitrobenzenes[445,446].

The search for seed disinfectants less toxic than organometallic compounds led to the discovery of a large group of biologically active *N*-substituted carbamic esters, which were mainly highly active insecticides and herbicides. Derivatives of carbamic acid possessing also fungicidal activity are known[4,396,447]. These compounds have not yet found wide application for the treatment of seeds, but show promise in this respect[447].

Substances used to overcome pests and diseases by seed disinfection include pentachlorophenylmethanethiol and its zinc salt[449], *p*-hydroxyphenylazoformamide[450], lower 2,4-dihalogenophenyl halogenoalkanesulphonates[451], ethylenedisulphonic acids[452], 2-methoxyethylamine[453], methanol[454–456], various heterocyclic derivatives—of isothiazole[457], benzimidazole[458], benzoxazolinone[459], and thiophen[460]—oxathi-in derivatives (in particular

3-carboxyanilido-5,6-dihydro-2-methyl-1,4-oxathi-in—Vitavax)[461,572-575], substituted maleimides[462], sorbic acid[463], and several other substances[454,464]. In particular sorbic acid diminishes considerably the disease of fusariosis in cotton seeds.

Great attention has recently been paid in seed treatment to disinfectants containing more than one active principle, e.g. one or two fungicides, an insecticide, sometimes with the addition of trace elements and other active substances[157]. Such preparations are highly efficient[207,373,379,448,508]. In individual cases mixtures of different insecticides are used[151].

A mixture of the disinfectants—tetramethylthiuram disulphide and γ-hexachlorocyclohexane—is most often employed, against pathogenic fungi and bacteria, by treating seeds of grain crops[241,439,465], peas[466], and maize[246,467]. The mixture is marketed as the composite disinfectants Thiuram-gamma (50% TMTD + 20% γ-isomer + filler)[465-467], Germal (50% TMTD + 40% γ-isomer + filler)[439], and Thiramin[468]. Other mixtures are also used[241]. Manganese sulphate may be introduced into such a composition[246].

Tetramethylthiuram disulphide (40%) and γ-hexachlorocyclohexane (20%) are widely used in combination with copper trichlorophenoxide (10%) as the disinfectant Phenthiuram (containing also 5% of sulphite–alcoholic residue + 3% of carboxymethylcellulose + 20% of kaolin), employed for treating seeds of cotton and cereal–legume crops[439,469-472]. Phenthiuram possesses a broader fungicidal and bactericidal action than tetramethylthiuram disulphide[4]. Phenthiuram mixed with 8% of ammonium molybdate is marketed as Phenthiuram Molybdate[4], which gives good results against pea ascorosis[473].

Mercurhexane (containing 1% of ethylmercuric chloride + 15–20% of hexachlorobenzene + 15–20% of γ-hexachlorocyclohexane + talc + kaolin) has found widespread application as a composite disinfectant. It possesses high fungicidal activity, together with insecticidal properties[471,474-476]. Other composite disinfectants containing mercury include a mixture of Granosan and Hexachloran used for treating sugar-beet seeds[477], the preparation VV (a mixture of Lindane and organomercury compounds) for the seed treatment of wheat[478], a fungicidal mixture of ethylmercuric chloride and tetramethylthiuram disulphide stabilised with thioglycerol for preventing the infestation of seeds with fungi[479], and a mixture of tetramethylthiuram disulphide and methylmercuric dicyanodiamide[480] for grain.

Other composite disinfectants—e.g. mixtures of copper trichlorophenoxide and γ-hexachlorocyclohexane[481], tetramethylthiuram disulphide and pentachloronitrobenzene[482], zinc chromate and Heptachlor[467], tributyltin and chlorinated aliphatic compounds[483], and of tetramethylthiuram disulphide, chlorinated hydrocarbons, glycols, and quinones[484]—are also used for treating seeds to protect them from various pathogens.

Seeds are treated also with active vapours to protect them from pests and diseases. Halogenated lower hydrocarbons are most widely used in this way (as fumigants). They are applied to the seeds of sunflower[485,486] wheat[487,488], pea[489,490], barley[491-493], maize[491,494], oats[491,492], flaz[494], sorghum[491], carrot, cabbage, radish, and turnip[495].

Methyl bromide, which destroys nematodes as well as certain injurious insects, is most often used[185,485,488,490-497]. However, several disadvantages are entailed: being an alkylating agent, methyl bromide may act as a mutagen, disturbing the growth processes of plants[4] and in several cases retarding the germination of seeds[242]. Furthermore, this compound may also impair the quality of the oil obtainable from treated seeds of oil-yielding crops[486]. In this connection, the brief application of high concentrations is more effective than prolonged exposure at lower concentrations[491].

Among other halogenated hydrocarbons used for fumigation we must mention chloroform[487,498], carbon tetrachloride[485,487,499], dichloromethane[498], dichloroethane[485,499], dibromoethane[485,497], and dichloropropene (the active principle of the fumigants DD and Telon[497]), as well as dichloroethylene, trichloroethylene, dibromoethylene[499], and 1,2-dibromo-3-chloropropene[497]. The application of mixtures of these halogenated hydrocarbons has been reported. In some cases better results are given by halogenated nitro-hydrocarbons, such as chloropicrin and dichloro-1-nitroethane[490,500].

Other groups of compounds are also used as disinfestants in fumigation. Thus aluminium phosphide pellets, which evolve phosphine on hydrolysis, lead to complete destruction of granary weevils[498,501]. Sulphur derivatives—carbon disulphide[499], sulphuryl fluoride[502], sulphur dioxide, and volatile sulphur-containing decomposition products of coal[503]—are used for fumigation. This has been effected also by means of hydrogen cyanide[504] and oxiran[490]. Application of morpholino-α-methylacetonitrile and 2,2-dichloro-1-hydroxyvinyl dimethyl phosphonate showed high activity[505].

To prevent infestation with insects it is recommended that grain should be stored in an atmosphere of an inert gas, e.g. carbon dioxide or nitrogen[506], or else heptane[498].

Special attention is paid to the preservation of seeds of high moisture content[485,500,507] as well as seeds of oil-yielding crops[486,509-514], which are sensitive to several fumigants.

Repellents—in particular a mixture of 2-methylquinoline and naphthenic acids[515], cycloheximide[516]—are used against insects and rodents in the storage of grain reserves, as well as bird repellents[569].

Thus the combined efforts of plant growers and chemists have led to the manufacture of effective products that have greatly reduced crop losses. An intense search has recently been made for compounds possessing a wide spectrum of action and high activity but yet harmless to man, animals, and useful insects, as well as decomposing within required periods of time. For these reasons, in particular, interest has diminished in chlorinated, copper, and mercury products, and the use of derivatives of carbamic acid and certain other substances has increased[364,365,517].

V. APPLICATION OF CHEMICALS TO SEEDS

The seeds of certain plants are small (carrot, onion, tomato, parsley, etc.), and contain little of the reserve materials required for germination. Owing to the small size it is difficult to mechanise sowing: considerable quantities of these expensive seeds must be sown, and the shoots thinned after germination, which makes large demands on labour. As a consequence, the size of such seeds has been increased by covering their coats with bulky materials[518-524]. Such treatment (seed pelleting) was undertaken in the Soviet Union by Peterburgskii[525], who coated seeds with superphosphate mixed with starch paste. Peat, humus, feldspar, bentonite, and several other inert bulking materials are most often used for

pelleting[526,527]. The supply of mineral nutrients to the germinating seeds is improved by introducing major and minor fertilisers[528,529], as well as pesticides, into the pellet.

The experience which has accumulated shows that pelleting is a promising method, reducing the consumption of seeds, improving their germination and the development of shoots, and increasing the yield[519-521,526,530]. An important advantage over steeping seeds is that they can be prepared long before sowing, whereas soaked seeds must be sown immediately.

Protective substances are usually applied in three ways—dry, semi-dry, and moist disinfection—and usually in special equipment—disinfectors[4,356].

In dry disinfection the surface of the seeds is covered with a thin layer of the dry product. A dust is often used for this purpose, consisting of the active principle and an inert filler (kaolin, bentonite, gypsum, talc, etc.); the active part is applied from solution with subsequent evaporation of the solvent or with joint grinding[4]. In spite of the cheapness and convenience of application, dry treatment has several substantial disadvantages, primarily poor adhesion of chemicals, increased consumption thereof, and the dispersion of substances into the air, which impairs the hygienic conditions of the work[356]. Better results are obtained by applying substances in an electrostatic field, but this procedure has not been widely used[531].

"Semi-dry" disinfection improves adhesion to the seed surface and diminishes dispersion of the materials in the air[356]. This implies treatment of the seeds with moistened products and a liquid consumption usually not exceeding 30 litres per tonne of seeds. With a larger quantity of liquid such treatment is termed "moist disinfection". This is not usually applied to large batches of seeds, and requires preliminary slight drying before sowing or storage[356].

A great problem is retention of the chemical on the surface of the seeds. So called stickers are used to improve adhesion, among them a concentrate of sulphite–alcoholic residues[532], sulphite lye[533], silicate cement, flour paste, skimmed milk, molasses, liquid manure[534,535], oils[536], and alabaster[537].

The quality of the applied coating of pesticides is considerably improved by introducing a polymeric film-forming agent into the composition. This is most often a water-soluble polymer—polyacrylamide[538], methylcellulose[539], carboxymethylcellulose[540], a vinylpyrrolidone polymer or copolymer[540,541], partly hydrolysed poly(vinyl acetate)[542], polyvinyl alcohol[526], or a urea—formaldehyde resin[543]—usually amounting to a few percent. However, there are references to the use of compositions containing up to 15% of the polymer, e.g. polyvinylpyrrolidone, polyvinylimidazole, polyvinyloxazolidone, or their mixtures[544,545], epoxide resins, poly(vinyl chloride), polyethers, polyesters, polyurethanes, poly(vinyl acetate), and synthetic rubber[546]. These compositions can be applied from solution or from a dispersion in kerosene[544].

Polymeric materials are also applied that possess intrinsic fungicidal, bactericidal, and herbicidal properties without the addition of active agents of low molecular weight. Thus the polymeric complex of polyvinylpyrrolidone and iodine[547] and ligninacetic acid[548] have a bactericidal action, the product of the condensation of aminoethanol with formaldehyde is fungicidal[547], and poly(vinyl aryloxyacetates), obtained by polymerisation of the monomeric vinyl esters or by aryloxyacetylation of polyvinyl alcohol, are herbicidal[549].

Wetting powders—products giving stable suspensions when mixed with water—have recently occupied an important place among preparations applied to seeds. They are produced by introducing surface-active agents into the compositions[4,550-553].

It has long been established that seeds of many crops, after having been subjected to the action of low temperatures, will give more productive plants: they ripen sooner and give a higher yield. However, practical application of these results encountered considerable difficulties, since seeds sown early in Spring, on germinating, were destroyed by Spring frosts. In this case germination could be delayed by coating the seeds with water-repellent films. By restricting the entry of water into the seeds, such films thereby delay the metabolic processes governing germination. The application of hydrophobic films is especially important for Spring wheat, whose cultivation encounters certain difficulties in several regions. The use of water-repellent seed coatings enables Summer crops to be sown not in Spring but in Autumn, even before the soil is frozen.

Attempts were made to use paraffin wax and a liquid silicone to effect such water-repellency[554-557], but polymeric seed coatings were found to be more promising. Even previously pelleted seeds can be coated with such polymer films. In particular, the presowing treatment of pelleted vegetable seeds with copolymers of vinyl chloride and vinylidene chloride has been reported[558].

Polymer coatings comprising several layers are used for seed treatment[559,560]. The outer, poly(vinyl chloride) film, by disintegrating under the influence of variable temperatures, frees the inner, hydrophilic layers, thereby promoting penetration of moisture into the seeds. Cellulose derivatives have been used as the second layer. The application of such coatings enables the yield to be raised by 15–16% and more convenient sowing times to be used for Spring crops. Plants were found to bush more intensely, have a shorter and stronger culm, ripen two weeks sooner, and give a grain of enhanced protein content.

Union Carbide has proposed an interesting method for controlling germination, by the factory sealing of the seeds into a continuous polymer ribbon which, when placed in the soil, will dissolve within a short period (from 1 min to 1 h). Use of such a ribbon facilitates the sowing of vegetable crops, assists the production of harmonious seedlings and uniform plant growth, increases the yield, and improves the quality of production[561].

It is seen that polymers are finding increasing application for improving the sowing qualities of seeds. In the future the coating of seeds with special films may occur on a larger scale.

A solution in water or in an organic solvent is usually employed for the coating of seeds with polymers. Organic solvents are used also for the application of compounds of low molecular weight. The solvents employed have been acetone, methanol and ethanol[562], halogenated hydrocarbons[4], dimethyl sulphoxide, dimethylformamide, and dimethylacetamide[450]. The germinating power of the seeds may be affected by the organic solvent[563,564].

References have been made to the possibility of the direct polymerisation of monomers on the seed surface. Thus Kozlov and Tarusov polymerised vinylpyrrolidone on the surface of irradiated seeds in aqueous solution at 30–70°C for 2–24 h.[566,567]

---o0o---

The facts reported here indicate the wide possibilities of the application of chemicals to the treatment of seeds. These include disruption of their dormancy, stimulation of germination, increase in field germinating capacity, and heightened resistance to pathogenic micro-organisms and unfavourable weather conditions. Further cooperation of chemists with physiologists and growers may not only promote a more fundamental study of the processes occurring during storage and germination but also yield new possibilities of controlling the vital activity of seeds.

Unstable Silicon Analogues of Olefins and Ketones

L.E.Gusel'nikov, N.S.Nametkin, and V.M.Vdovin

In contrast to carbon, silicon does not tend to form multiple bonds. Until recently it was believed that compounds with multiple bonds at the silicon atom do not exist, but in recent years results were obtained which permitted a new approach to this interesting and important problem in the chemistry of organosilicon compounds.
The present review considers unsaturated compounds the compositions and properties of which may be described in terms of the hypothesis that the silicon atom forms $(p-p)_\pi$ double bonds.
The bibliography includes 81 references.

V. The stability of silicon analogues of unsaturated compounds 627

I. INTRODUCTION

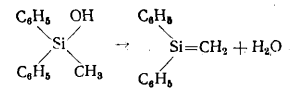
Silicon, the closest analogue of carbon has a similar structure of the outer electron shell: $2s^2 2p^2$ for carbon and $3s^2 3p^2$ for silicon. In most of its compounds silicon is quadrivalent owing to the transition of one $3s$ electron to the $3p_z$ orbital. Like carbon, silicon readily forms compounds with single bonds as a result of the overlapping of the hybridised $3sp^3$ orbitals. On the other hand, it is striking that compounds with multiple bonds of the type $(p-p)_\pi$ are very common in carbon compounds but are completely absent from silicon compounds stable under the usual conditions[1,2]. However, silicon has unfilled $3d$ orbitals which might form bonds of the $(p-d)_\pi$ type with substituents containing lone electron pairs, which would increase the multiplicity of the single bond[2].

The present review deals only with silicon compounds the structure of which can be described in terms of the hypothesis that a multiple bond is formed at the silicon atom. These are the silicon analogues of olefins (R_2Si = = SiR_2; R_2Si = CR_2) and ketones (R_2Si = O). The analogous compounds of bivalent silicon (for example SiO) are not considered, since their properties are largely determined by the presence of the lone electron pair[3].

Until recently it was believed that such unsaturated silicon compounds do not exist. However, the results obtained in recent years give grounds for a modification of this view.

The characteristics of the methods of synthesis of the organosilicon compound belonging to this new class and evidence for their existence are given in the present review and their structures and possible use in syntheses are considered. The employment of the symbol for the double bond, for example, R_2Si = CH_2, in this and in the majority of the studies quoted should be regarded as representing one of the possible structures which explains many of the reactions of these compounds, although the alternative structures $R_2\dot{S}i-\dot{C}H_2$ and $R_2\overset{+}{S}i-\overset{-}{C}H_2$ are also quite possible.

A structure with multiple bonds at the silicon atom was put forward for the first time by Gattermann[4] in 1889 for compounds obtained by treating silicon tetrachloride, trichlorosilane, etc. with ammonia (HN = Si = NH; N = Si = = NH_2). In 1912 Schlenk and Renning[5] reported the synthesis of a stable compound with a silicon-carbon double bond via the mechanism



However, later these results were disproved by Kipping[6], who, having repeated the experiment, showed that Schlenk and Renning[5] did not obtain an individual compound but a mixture of dimethyldiphenylsilane, methyldiphenylsilanol, and biphenyl. In general, towards the end of the 1920s it became clear that the earlier studies[7] where structures with multiple bonds at the silicon atom were attributed to stable compounds must have been erroneous. Moreover, it was shown that the reactions usually employed to form multiple bonds between carbon atoms are unsuitable for the synthesis of the corresponding silicon compounds. Thus the loss of a single water molecule by a tertiary silanol does not occur at all. Disiloxanes are formed instead. Nor are silicon analogues of olefins formed as a result of the dehydrochlorination of silyl chlorides. The latter are extremely stable and can be distilled without decomposition (even in the presence of quinoline). The formation of unsaturated silicon compounds by treating tertiary silyl chlorides with Grignard reagents is also unknown, although many tertiary halogenomethanes do form olefins. Other attempts to prepare stable compounds with a multiple bond at the silicon atom were also unsuccessful[8].

Towards the end of the 1940s and the beginning of the 1950s, the problem of the instability of compounds with multiple bonds at the atoms of elements in the Third and succeeding Periods began to be considered in terms of graphical representations of orbitals and quantum-mechanical calculations (see Section V).

In 1952 Andrianov and Sokolov[9] reported the detection of the dimethylsilanone ion in the mass spectrum of octamethylcyclotetrasiloxane and also the mass spectrometric identification of several dialkylsilanones formed when organopolysiloxanes are heated to 150–200°C and in the gas-phase hydrolysis of dichlorodimethylsilane.

Nevertheless the earlier ideas concerning the possibility of the existence of stable compounds with multiple bonds at the silicon atom were so attractive that even in the 1960s they resulted in the publication of two erroneous communications: concerning the preparation of $Me_3SiCH = SiMe_2$ [10] and of the silicon analogue of benzene[11]. It was soon shown that, instead of the former compound, the authors obtained 1, 1, 3, 3-tetramethyl-1, 3-disilacyclobutane, which was mistaken for an unsaturated compound by virtue of its ability to combine with bromine[12]. The structure of the second compound was not confirmed either[13].

In later studies compounds with double bonds at the silicon atom were regarded only as short-lived species responsible for the formation of particular reaction products. Thus dimethylsilanone was postulated as an intermediate in the cleavage of polysiloxanes by the Iotsich reagent[14]; $MeHSi = CH_2$ was regarded as a product of the carbene–olefin isomerisation of dimethylsilylene[15] and the biradical $Me_2\dot{S}i-\dot{C}H_2$ was introduced into the mechanism of the thermal decomposition of tetramethylsilane to account for the formation of 1, 1, 3, 3-tetramethyl-1, 3-disilacyclobutane[16]; here mention may also be made of the study of Müller and Müller, who considered the dechlorination of chloromethanes in the presence of a silicon–copper alloy[17]. However, all these cases involved complex non-selective processes in which other interpretations of the mechanism are equally probable.

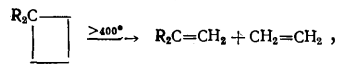
In 1965 the present authors discovered the selective thermal decomposition of monosilacyclobutanes[18,19] via the formation of silicon analogues of olefins. The study of this reaction yielded for the first time kinetic and chemical evidence for the existence of an intermediate compound with a silicon-carbon double bond[20–22] and led to methods for their stabilisation. As a result, these species and other compounds with double bonds at the silicon atom again attracted the attention of chemists, as can be judged from the publication of numerous studies on this subject in recent years. The results of this new stage in the development of the chemistry of silicon analogues of unsaturated compounds are discussed below.

II. MONOSILICON ANALOGUES OF OLEFINS

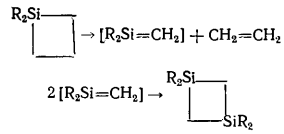
In a study of the pyrolysis of a number of monosilacyclobutanes we observed the elimination of ethylene and the formation of 1, 3-disilacyclobutanes[18,19].

For example, in the pyrolysis of 1, 1-dimethyl-1-silacyclobutane the only reaction products were ethylene and 1, 1, 3, 3-tetramethyl-1, 3-disilacyclobutane. The yield of 1, 3-disilacyclobutane was lower when chlorine atoms were attached to the silicon atom. However, it amounted to 34.8% even for 1, 1-dichloro-1-silacyclobutane, which was of preparative interest for the synthesis of 1, 1, 3, 3-tetrachloro-1, 3-disilacyclobutane which is otherwise difficult to obtain.

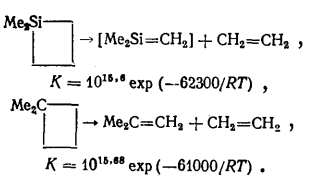
For the analogous thermal decomposition of compounds of the cyclobutane series[23],



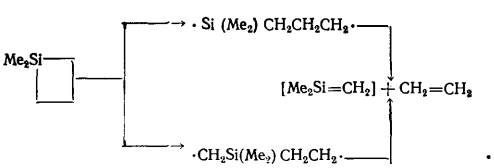
we assumed that the reaction proceeds via an intermediate unstable compound — a silicon analogue of an olefin, which is in fact responsible for the formation of 1, 3-disilacyclobutane[20]:



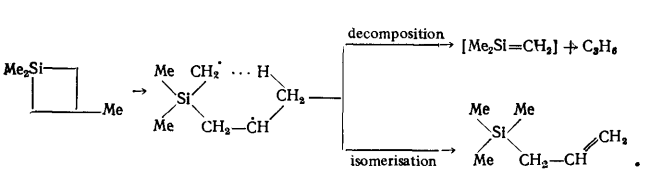
Indeed, kinetic data for the thermal decomposition of 1, 1-dimethyl-1-silacyclobutane proved to agree well with this hypothesis[21,22]. The reaction was of first order with respect to monosilacyclobutane and was homogeneous and the variation of the decomposition rate constant with temperature was very close to the corresponding variation for the thermal decomposition of 1, 1-dimethylcyclobutane[24]:



The closeness of the Arrhenius parameters of these reactions suggests that they have the same mechanism, namely the reaction begins with the dissociation of one bond in the ring (Si–C or C–C) and a consequent formation of a biradical, which decomposes spontaneously to a short-lived compound and ethylene (the biradical mechanism provides a satisfactory explanation of the characteristics of the thermal decomposition of cyclobutanes[25]):



The dissociation of the ring C–C bond is consistent with the isomerisation of 1, 1, 3-trimethyl-1-silacyclobutane[26,27] to allyltrimethylsilane during its thermal decomposition †. Such isomerisation is probably due to the 1, 5-migration of a hydrogen atom in the biradical:



† We may note incidentally that the above reaction is the first instance of the isomerisation of monosilacyclobutanes to silaolefins.

A subsequent investigation established[28] that in the pyrolysis of 1,1-dimethyl-1-silacyclobutane in a flow reactor at low pressures the processes involving the formation and disappearance of the silicon analogue of an olefin can be separated. Thus we found that, when the pyrolysis is carried out at pressures below 1 torr, the region where $Me_2Si = CH_2$ undergoes cyclodimerisation moves to an increasing distance beyond the reactor, as shown by the increase of the ratio $[C_2H_4]/[Me_2SiCH_2)_2]$ by two powers of ten on reducing the pressure to 10^{-3} torr (Fig. 1) owing to the formation by the silicon analogue of isobutene of a polymeric product $(-Me_2SiCH_2-)_x$ on the cold surface.

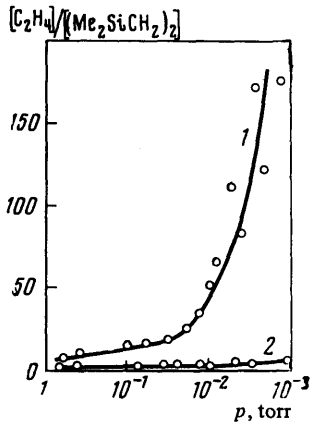


Figure 1. Variation of $[C_2H_4]/[(Me_2SiCH_2)_2]$ with pressure in the pyrolysis of 1,1-dimethyl-1-silacyclobutane in a flow reactor; distance between the pyrolysis and condensation zones: *1*) 30; *2*) 250.

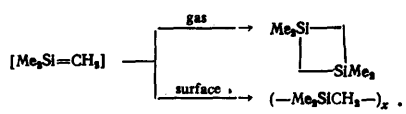
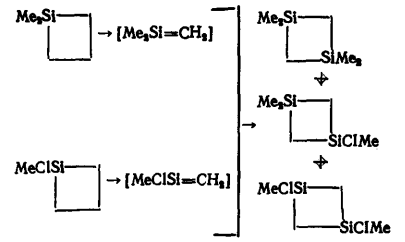
Walsh[29], who employed our kinetic data for the pyrolysis of 1,1-dimethyl-1-silacyclobutane and Davidson and Lambert's data[30] for the pyrolysis of trimethylsilane, found that the π-bond energy in the silicon analogues of olefins is in the range 30–42 kcal mole^{-1} and Barton and McIntosh[31], who investigated the pyrolysis of 1,1-dimethyl-1-silacyclobutane at -196°C by infrared spectroscopy, observed a band at 1407 cm^{-1} which they believe to be due to the presence of $Me_2Si = CH_2$. The methylenediamethylsilane ion is also formed in the dissociative ionisation of 1,1-dimethyl-1-silacyclobutane[32,33] (the peak of this ion is the most intense in the mass spectrum).

Certain reactions of the silicon analogues of olefins, which may be regarded as chemical evidence for the existence of these compounds, are discussed below in relation to $Me_2Si = CH_2$.

It has already been mentioned that, in the absence of trapping agents, cyclodimerisation takes place in the gas phase and polymerisation on the cold surface:

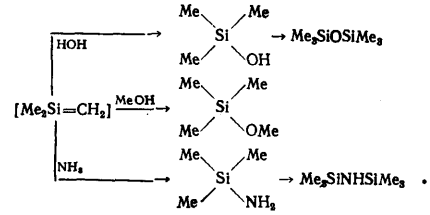


Products of direct and cross cyclodimerisation are formed in the pyrolysis of two different monosilacyclobutanes[20,34]:

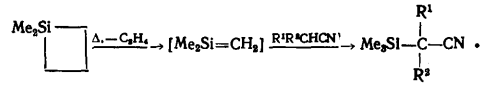


One should note that we never observed among the reaction products dimers of the "head to head" type or cyclic trimers.

Trapping agents form adducts with silicon analogues of olefins. Chemical trapping of $Me_2Si = CH_2$ was first achieved with the aid of water and ammonia in the pyrolysis of 1,1-dimethyl-1-silacyclobutane in their presence[21,22]. The reaction with alcohols occurred similarly:



Quite recently Sommer and coworkers[35] carried out this reaction with acetonitrile and its derivatives:



Another reaction of silicon analogues of olefins is cycloaddition to olefins. However, since the rate constant for this reaction is low compared with the cyclodimerisation rate constant, its contribution can be observed only at olefin concentrations greatly exceeding that of the intermediate. For example, this reaction results in a decrease of the rate constant for the thermal decomposition of 1,1-dimethyl-1-silacyclobutane at conversions in excess of 60%[22]. Kinetic evidence for the cycloaddition of $Me_2Si = CH_2$ to ethylene was obtained in a study of the pyrolysis of 1,1-dimethyl-1-silacyclobutane in the presence of added ethylene[22]. Indeed the apparent first-order reaction rate constant was found to depend on ethylene concentration, in agreement with the kinetic mechanism involving a reversible first stage of the thermal decomposition:

$$A \underset{k_3}{\overset{k_1}{\rightleftharpoons}} B + C$$

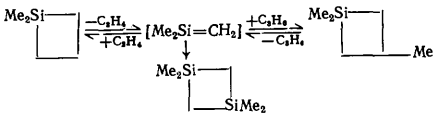
$$2B \xrightarrow{k_2} D$$

$$-\frac{d\ln A}{dt} = k_1\left\{1 - \frac{k_3 C}{(2k_1k_2)^{1/2}A^{1/2}}\left(1 - \frac{k_3 C}{2(2k_1k_2)^{1/2}A^{1/2}}\right)\right\} .$$

where A = 1,1-dimethyl-1-silacyclobutane, B = Me_2Si = $= CH_2$, C = ethylene, and D = 1,1,3,3-tetramethyl-1,3-disilacyclobutane [or the corresponding concentrations (Ed. of Translation)] variation of the apparent first-order reaction rate constant with $(C/A^{1/2})[1-k_2/2(2k_1k_3)^{1/2}-C/A^{1/2}]$ should be linear, which was in fact observed experimentally at different temperatures (Fig. 2). It was also possible to estimate the ratio $k_2/k_3^{1/2}$ and $E_2 - \frac{1}{2}E_3 = 14.5 \pm 4$ kcal mole^{-1}.

The formation of 1,1,3-trimethyl-1-silacyclobutane in the pyrolysis of 1,1-dimethyl-1-silacyclobutane in the

presence of a 15–20-fold excess of propane and the formation of 1,1-dimethyl-1-silacyclobutane in the pyrolysis of 1,1,3-trimethyl-1-silacyclobutane in ethylene constituted chemical evidence for the reversibility of the first stage of the thermal decomposition[36,37]:



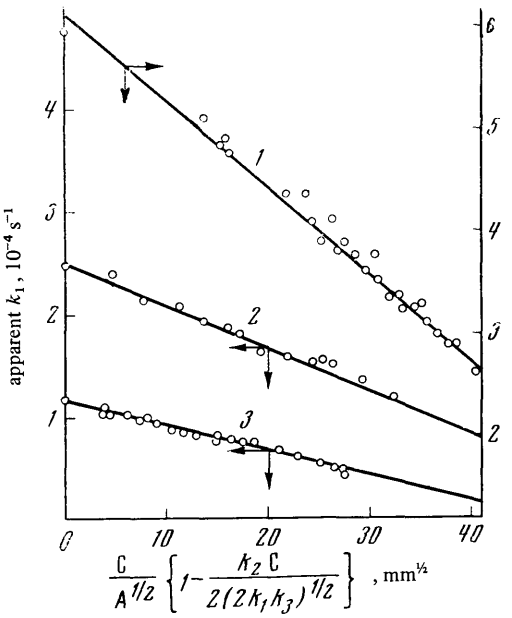


Figure 2. Variation of the apparent rate constant for the thermal decomposition of 1,1-dimethyl-1-silacyclobutane with the concentration of added ethylene (in terms of the coordinates corresponding to the kinetic equation quoted); temperature (°C): *1*) 450.7; *2*) 437.1; *3*) 423.

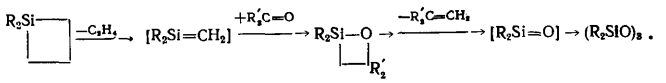
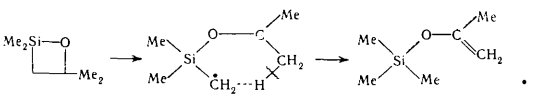
Silicon analogues of olefins readily undergo cycloaddition to the double bond of the carbonyl group. Cyclosiloxanes (mainly the cyclic trimer), ethylene, and new olefin are formed in the pyrolysis of 1,1-dimethyl-1-silacyclobutane in the presence of isobutyl methyl betone[38] and in the pyrolysis of 1,1-diphenyl-1-silacyclobutane in the presence of 2-pentanone, 2-heptanone, and benzophenone[39]:

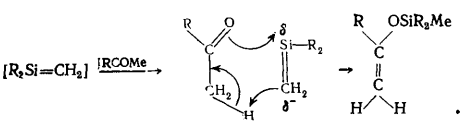


The cycloaddition product (silaoxetan) was not isolated, although Barton and Kline[38] reported its mass-spectrometric identification. We isolated a compound with the corresponding composition in the pyrolysis of 1,1-dimethyl-1-silacyclobutane in the presence of acetone (*m/e* 130), but its spectrum showed bands due to a double bond and the band due to the Si–O bond was in the usual region (1050 cm^{-1}) (in strained rings, this band should undergo a pronounced bathochromic shift — 100 cm^{-1} and more). This made it possible to assign the isomeric structure $Me_3SiOC(Me)=CH_2$ to the product.

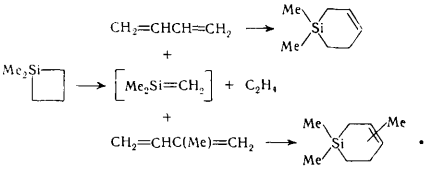
The formation of isopropenyloxytrimethylsilane can be readily represented as a result of the isomerisation of the silaoxetan, which is unstable under the reaction conditions, via the 1,5-migration of the hydrogen atom in the biradical formed on dissociation of the C–C bond of the four-membered ring:



The mechanism of the formation of analogous products based on the addition of the enolised form of the ketone of the silicon–carbon double bond[39] appears more likely. The argument based on the fact that the reaction does not occur in the presence of benzophenone is not convincing, since the 1,5-migration of hydrogen in the biradical is also impossible in this case. In his latest investigations[35,40] Sommer proposes an essentially new mechanism, which includes a six-centre transition state, but, in contrast to our mechanism, no account is taken of the formation of the intermediate silaoxetan:



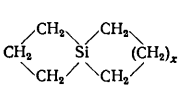
Silicon analogues of olefins are effective dienophiles; they readily enter into the diene synthesis reaction. Thus the corresponding Diels–Alder adducts are formed in the pyrolysis of 1,1-dimethyl-1-silacyclobutane in the presence of butadiene[37], isoprene[37], or 2,3-dimethylbutadiene[41]:



The formation of a single adduct with butadiene and of two adducts with isoprene suggests that the reaction proceeds via a single-state 1,4-cycloaddition mechanism.

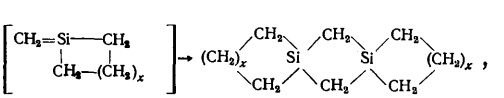
Thus there are many reactions demonstrating the existence of short-lived silicon analogues of olefins. The pyrolysis of 1-methyl-1-vinyl-1-silacyclobutane[26] and 1,1-diphenyl-1-cyclobutane[39] proceeds similarly.

We observed an interesting feature in a study of the thermal decomposition and dissociative ionisation of silaspiroalkanes[43] containing the monosilacyclobutane ring:

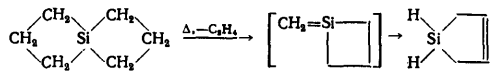


(where x = 1, 2, or 3).

Whereas 4-silaspiro[3,4]octane (x = 2) and 4-silaspiro[3,5]nonane (x = 3) form the corresponding 1,3-disilacyclobutanes,



4-silaspiro[3,3]heptane ($x = 1$) behaves anomalously in the pyrolysis[23,43]. Oily products with the composition corresponding to that of the initial compound after the elimination of an ethylene molecule are mainly formed in a flow system in an atmosphere of helium. On the other hand, *in vacuo* this compound decomposes into hydrogen, ethylene, propene, butadiene, and 1-silacyclopent-3-ene, the relative contents of which depend on temperature (Fig. 3). It is significant that compounds with 1,3-disilacyclobutane rings were not formed and the precipitation of elemental silicon on the reactor walls was noted. We believe that these characteristics of the thermal decomposition are in many ways determined by the specific features of the behaviour of the methylenecyclobutane analogue formed from this silaspiroheptane, which is capable of isomerising, in contrast to other compounds of this type:



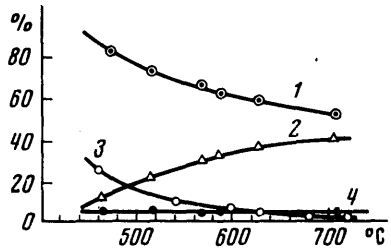


Figure 3. Temperature variation of the relative contents (%) of the decomposition products in the pyrolysis of 4-silaspiro[3,3]heptane: *1*) ethylene; *2*) butadiene; *3*) 1-silacyclopent-3-ene; *4*) propene.

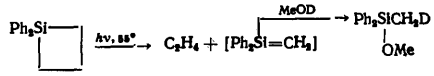
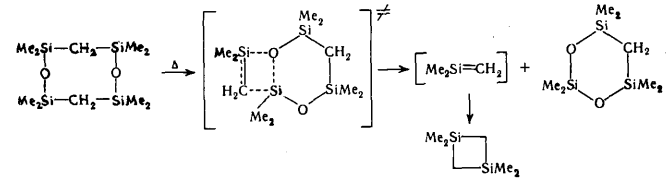
In conclusion of the discussion of the thermal decomposition reactions of monosilacyclobutanes as a method for the generation of silicon analogues of olefins, we may mention that in the series of compounds (where E = C, Si, or Ge) the selectivity of the olefin decomposition process is maintained only for the first two members of the series. The reaction of the germanium compound is significantly complicated by a carbenoid decomposition[44], which precludes its employment for the selective generation of germanium analogues of olefins.

Monosilacyclobutanes are also effective sources of silicon analogues of olefins in the liquid-phase photochemical decomposition reaction[45], as can be seen from the formation of an adduct with deuteriomethanol (yield 80%):

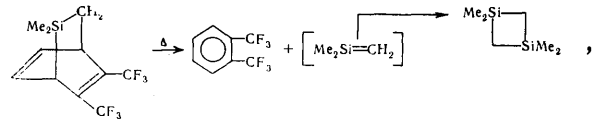


We noted the formation of a silicon analogue of isobutene in the pyrolysis of eight-membered cyclocarbasiloxanes containing siloxane and silmethylene groups[46,47], for example:



However, an alternative decomposition with formation of dimethylsilanone also takes place in this case (see Section IV).

Bicyclo[2,2,2]octa-2,5-dienes proved to be extremely promising for the generation of silicon analogues of olefins. Barton and Kline[48] found that the pyrolysis of 7,7-dimethyl-2,3-bis(trifluoromethyl)-7-silabicyclo[2,2,2]octa-2,5-diene takes place at 400°C in the gas phase with formation of *o*-bis(trifluoromethyl)benzene and 1,1,3,3-tetramethyl-1,3-disilacyclobutane via the mechanism



and the photolysis of this compound at 77° and 28°K resulted in the formation of a large amount of the first product and only of traces of the second. The latter is probably due to the polymerisation of $Me_2Si = CH_2$ in the condensed phase. $Et_2Ge = CH_2$, formed as a result of the pyrolysis, gives rise to 1,3-digermacyclobutane and in the presence of 2,3-dimethylbuta-1,3-diene the product is 1,1,3,4-tetramethyl-1-germacyclohexene.

* * *

The formation of silicon analogues of olefins was also postulated in a number of gas-phase thermal decomposition reactions of cyclic organosilicon compounds. However, in contrast to the majority of the cases which have been discussed, these reactions are not selective and the yield of products due to the formation of unstable species with a multiple bond at the silicon atom is usually low. The thermal decomposition of tetramethylsilane[18], where the formation of 1,1,3,3-tetramethyl-1,3-disilacyclobutane and 1,1,3,3,5,5-hexamethyl-1,3,5-trisilacyclohexane was attributed to the cyclodimerisation and cyclotrimerisation of the silicon analogue of isobutene, was mentioned above:

$$Me_4Si \rightarrow Me_3Si\cdot + Me\cdot ,$$
$$Me\cdot + Me_4Si \rightarrow Me_3SiCH_2^{\cdot} + MeH ,$$
$$Me_3SiCH_2^{\cdot} \rightarrow [Me_2Si{=}CH_2] + Me^{\cdot} .$$

The authors[16] suggest that the intermediate is formed as a biradical species in the decomposition of the trimethylsilylmethyl radical. However, Davidson and Lambert[30,50], who investigated the thermal decomposition of trimethylsilane, showed that the disproportionation of the radicals is more important under these conditions:

$$HMe_2Si^{\cdot} + \dot{C}H_2SiMe_2H \rightarrow Me_2SiH + [CH_2{=}SiMeH] ,$$
$$Me_3Si^{\cdot} + \dot{C}H_2SiMe_2H \rightarrow Me_3SiH + [CH_2 = SiMe_2] ,$$
$$2\,\dot{C}H_2SiMe_2H \rightarrow Me_2SiH + [CH_2{=}SiMe_2] .$$

The competing radical recombination reaction proceeds less vigorously at elevated temperatures owing to the low

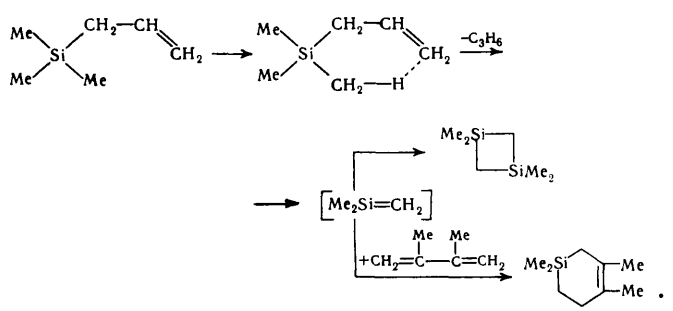
stability of disilanes. The cyclodimerisation of the above olefin analogues leads to the formation of the corresponding three 1,3-disilacyclobutanes. It is important to note that the formation of a cyclic trimer was not observed in this case either.

Moreover, a recent study of the kinetics of the thermal decomposition of tetramethylsilane[51] showed that the disproportionation of silyl radicals

$$2\,Me_3Si^{\cdot} \rightarrow Me_3SiH + [Me_2Si=CH_2]\ ,$$

plays an important role among the reactions involving the formation of $Me_2Si=CH_2$. In particular, whereas at 900°K the ratio of the disproportionation and recombination rate constants for trimethylsilyl radicals is 1.2,[51] at 300°K it is less than 10^{-3}.[52] This corresponds to a disproportionation activation energy of 6–7 kcal mole^{-1}.

According to Bailey and Kaufmann[41], $Me_2Si=CH_2$ is an intermediate in the pyrolysis of allyltrimethylsilane. Together with other products, 1,1,3,3-tetramethyl-1,3-disilacyclobutane is formed in the process and pyrolysis in the presence of 2,3-dimethylbuta-1,3-diene gives 1,1,3,4-tetramethyl-1-silacyclohexene:



However, Sakurai et al.[53] found that the thermal decomposition of allyltrimethylsilane occurs at a low as 500°C. Under these conditions, the main reaction is α-elimination of methylene:

$$Me_3SiCH_2CH=CH_2 \xrightarrow{\Delta} Me_3Si\cdots CH=CH_2 \rightarrow Me_3SiCH=CH_2 + CH_2:\ .$$

Comparison of the results of these studies suggests that the formation of $Me_2Si=CH_2$ in the first case is more likely to be associated with the decomposition to the trimethylsilyl radical and its disproportionation:

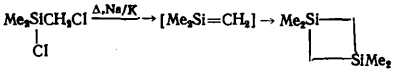
$$Me_3SiCH_2CH=CH_2 \xrightarrow{\Delta} Me_3Si^{\cdot} + CH_2{\cdot}{\cdot}{\cdot}CH{\cdot}{\cdot}{\cdot}CH_2\ ,$$
$$2\,Me_3Si^{\cdot} \longrightarrow Me_3SiH + [Me_2Si=CH_2]\ .$$

This is consistent with the non-selectivity of the reaction noted by Bailey and Kaufmann[41].

According to the latest results[54,55], the pyrolysis of hexamethyldisilane in a flow system at a low pressure proceeds with formation of trimethylsilane, $Me_3SiCH_2Si(H)Me_2$, and 1,1,3,3-tetramethyl-1,3-disilacyclobutane via $Me_2Si=CH_2$:

$$R^{\cdot} + Me_3SiSiMe_3 \rightarrow RH + Me_2SiSiMe_2CH_2^{\cdot}\ ,$$
$$Me_2SiSiMe_2CH_2^{\cdot} \rightarrow Me_2SiCH_2\dot{S}iMe_2\ ,$$
$$Me_2SiCH_2\dot{S}iMe_2 \rightarrow Me_2Si^{\cdot} + [Me_2Si=CH_2]\ .$$

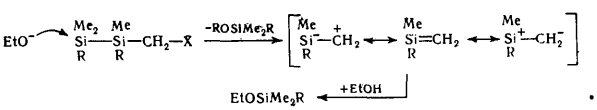
Among other ways of generating intermediates with a double bond at the silicon atom, mention may be made of the gas-phase dechlorination of chloromethyldimethylchlorosilane by sodium and potassium vapours[56]:



and of the photolysis of methylsilane[57,58] by vacuum ultraviolet radiation.

* * *

The hypothesis of the formation of silicon analogues of olefins was also used in the treatment of the mechanisms of certain liquid-phase reactions. Thus Kumada et al.[59] suggested that, when sodium ethoxide is allowed to react with 1-chloromethylpentamethyldisilane and other halogenomethyldisilanes in ethanol solution, there is a synchronous β-elimination of $Me_2Si=CH_2$, which is trapped by ethanol:

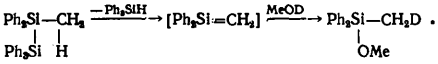


and Jarvie and Rowley[60] introduced this intermediate into the mechanism of the anomalous reaction between dimethylsilylmethylmagnesium bromide and benzophenone:

$$Ph_2C=O + Me_2Si(H)CH_2MgBr \rightarrow Ph_2CHOMgBr + [Me_2Si=CH_2]\ ,$$
$$[Me_2Si=CH_2] + Ph_2CHOMgBr \rightarrow Me_2SiCH_2MgBr \xrightarrow{+H_2O} Me_2SiOCHPh_2\ ,$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad OCHPh_2$$
$$[Me_2Si=CH_2] + Me_2Si(H)CH_2MgBr \xrightarrow{+H_2O} HMe_2SiCH_2SiMe_3\ .$$

However, one should note that in both cases there are alternative reaction mechanisms[60,61] which do not involve the formation of species with a double bond at the silicon atom.

From our point of view, the most convincing studies demonstrating the generation of silicon analogues of olefins in liquid-phase reactions are the investigation of the photolysis of 1,1-diphenyl-1-silacyclobutane already discussed[47] and a study of the photochemical dehydrosilylation of methylpentaphenyldisilane[62], where it was shown that the photolysis of this compound in methanol-d_1 leads to the formation of triphenylsilane and $Ph_2(CH_2D)SiOMe$ in 60% yield. The formation of these products is indeed consistent with the dehydrosilylation mechanism in which the intermediate compound is trapped by deuteriomethanol:

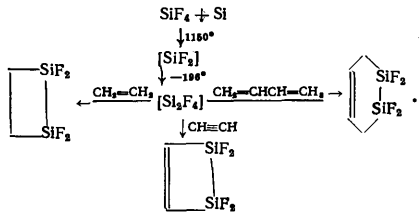


Likewise photolysis of $Ph_2(CD_3)SiSiPh_3$ in methanol yields $Ph_2(CD_2H)SiOMe$ and triphenyldeuteriosilane.

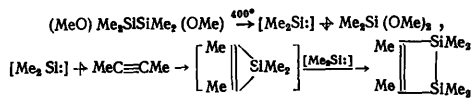
III. DISILICON ANALOGUES OF OLEFINS

After considering data on the joint condensation of difluorosilylene with unsaturated compounds and also the

low-temperature infrared and ESR spectra of difluorosilylene, Margrave and Wilson[63] suggested the formation of the biradical Si_2F_4 at -196°C:



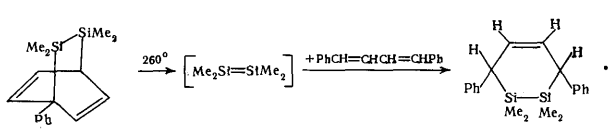
A similar conclusion was reached in a study of the reactions of difluorosilylene with BF_3, benzene, methylacetylene, and dimethylacetylene. However, the reactions of difluorosilylene with methanol, water, hydrogen sulphide, iodine, and germane could not be accounted for by the involvement of the dimeric biradical. It is therefore interesting to note a recent investigation[64] in which a reaction analogous to that described above was also explained without postulating the involvement of Si_2F_4:



Moreover, the observation of the ESR spectrum of singlet difluorosilylene condensed on a cold surface probably cannot be regarded as evidence for the triplet structure of Si_2F_4. This spectrum may be due to the polymeric species $\cdot SiF_2(SiF_2)_xSiF_2\cdot$, where $x = 1, 2, 3\ldots$, and not to Si_2F_4.

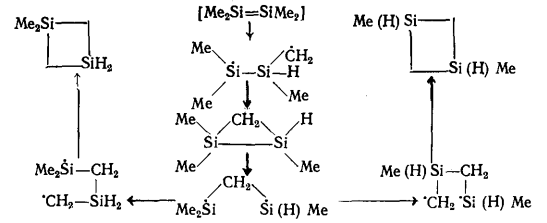
Thus, although there is no doubt about the possibility of the formation of olefin analogues by the dimerisation of silylenes and the structures of the products of the cocondensation of difluorosilylene with alkenes, alkynes, and butadienes can be described in terms of the Woodward–Hoffmann rule as a result of the cycloaddition of tetrafluorodiselene[65], the involvement of the latter as well as its biradical in the above reactions requires additional evidence.

More convincing data concerning the existence of disilicon analogues of olefins were obtained in a study of the thermal decomposition of 7,8-disilabicyclo(2,2,2]octa-2,5-dienes. Peddle, Roark, and coworkers[66,67] found that the pyrolysis of 7,8-disilabicyclo[2,2,2]octa-2,5-dienes leads to the formation of the intermediate $Me_2Si = SiMe_2$, which may be captured by anthracene, naphthalene, and *trans*, *trans*-1,4-diphenylbuta-1,3-diene to form adducts, for example:



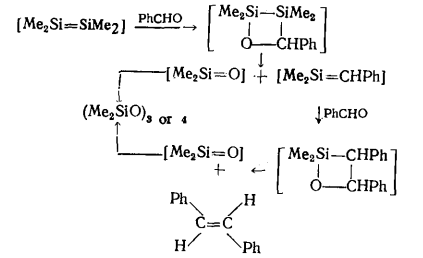
The $Me_4Si_2^+$ ion is the main species also in the mass spectra of these compounds.

In the absence of trapping agents, 1,1-dimethyl-1,3-disilacyclobutane (30%), 1,3-dimethyl-1,3-disilacyclobutane (10%), and a polymer were formed[67]. The mechanism of the formation of 1,3-disilacyclobutanes proposed by the authors is given below:



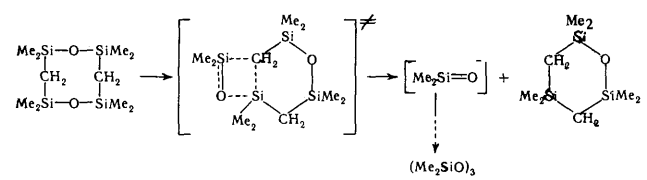
Since the short-lived compound is formed in a thermally activated concerted retrodiene synthesis reaction, it should be in the singlet form, provided that the repulsion of the vicinal methyl groups does not exceed the π-bond energy.

Barton and Kilgour[68] found that the joint pyrolysis of 7,7,8,8-tetramethyl-1-phenyl-7,8-disilabicyclo[2,2,2]octa-2,5-diene or 7,7,8,8-tetramethyl-5,6-benzo-7,8-disilabicyclo[2,2,2]octa-2,5-diene with an excess of benzaldehyde leads to the formation of *trans*-stilbene and cyclosiloxanes together with biphenyl or naphthalene. The following mechanism involving the formation and reactions of $Me_2Si = SiMe_2$ was proposed:



IV. SILICON ANALOGUES OF KETONES

In a systematic study of the pyrolysis of organosilicon compounds, we found that eight-membered cyclocarbosiloxane decompose with formation of products resulting from the elimination of monomeric units[46,47,69]. In particular, it was shown that one of the decomposition pathways involves the scission of dimethylsilanone:



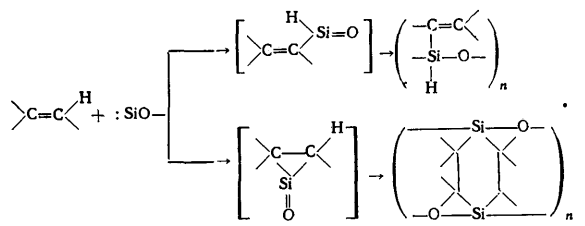
We obtained similar results also in a study of the mechanism of the thermal decomposition of cyclosiloxanes $D_n (n = 3-7)$[70,71]. It was found that in the initial stages of the reaction the main monomolecular decomposition products are compounds of the type D_{n-1} and that virtually the only example of products of the type D_{n+m} is D_{n+1}. This is consistent with the scission of dimethylsilanone, which either forms a cyclic trimer or is inserted in the Si–O bond of the initial compound, yielding D_{n+1}:

$$D_n \rightarrow [Me_2Si=O] + D_{n-1},$$
$$[Me_2Si=O] + D_n \rightarrow D_{n+1},$$
$$3[Me_2Si=O] \rightarrow (Me_2SiO)_3.$$

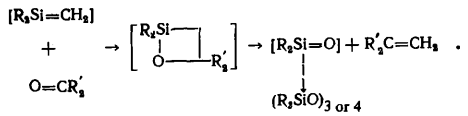
While the scission of dimethylsilanone is characteristic of the cyclic tetramer and pentamer, for higher cyclosiloxanes direct decomposition into D_3 or D_4 is energetically more favourable.

Similar results were obtained by Davidson and Tomson[72], who later investigated the pyrolysis of octamethylcyclosiloxane. The main reaction products D_3 and D_5 were detected in proportions of 1.3 : 1, which is consistent with the above mechanism. As was to be expected, their activation energy for the decomposition reaction (71.9 kcal $mole^{-1}$) was higher than for the cyclic pentamer (61 kcal $mole^{-1}$)[70,71]; they estimated the lower limit of the π-bond energy in dimethylsilanone as 38 kcal $mole^{-1}$).

Silanones are probably also formed in the joint condensation of silicon monoxide with organic compounds at 196°C.[3] However, in contrast to the compound discussed above, they undergo uncontrollable polymerisation:



As already mentioned above, the thermal decomposition of silaoxetans (see Section II), formed in the reaction of $R_2Si = CH_2$ with ketones and aldehydes, is a very effective reaction for the generation of silicon analogues of ketones:



The reaction with aromatic carbonyl compounds follows a more specific pathway[40]. In the case of aliphatic ketones and aldehydes the decomposition of the silaoxetan is accompanied by its isomerisation to the corresponding alkenyloxysilane. A similar reaction was observed in the decomposition of the adduct of $Me_2Si = SiMe_2$ with benzaldehyde[68] (see Section III).

V. THE STABILITY OF SILICON ANALOGUES OF UNSATURATED COMPOUNDS

As can be seen from the studies discussed above, there are numerous data in agreement with the hypothesis of the existence of silicon analogues of olefins and ketones as short-lived species. Their number increases still further if mass-spectrometric data are included. Only some of these were mentioned in the present review, while others can be found in Orlov's review[73].

In contrast to unsaturated carbon compounds, their silicon analogues exhibit an enhanced reactivity in bimolecular reactions, which hinders their isolation in a monomeric form. The latter can be stabilised only at low temperatures.

On the other hand, compounds of this type are extremely resistant to monomolecular decomposition. Among the examples discussed above, the only exception was methylenesilacyclobutane, formed in the pyrolysis of 4-silaspiro[3, 3]heptane; it undergoes a more profound decomposition or isomerises as a result of its specific structure.

A number of attempts have been made to explain the low stability of the π-bond in double-bonded compounds of elements in the Third and subsequent Periods. On the basis of a graphical representation of orbitals, Pitzer[74] postulated that the low stability of the multiple bonds in such molecules is due to the appreciable repulsion between the bonding orbitals and the filled inner shells of these atoms (*inner shell repulsion*). However, Mulliken[75,76] demonstrated by calculations of overlap integrals that this repulsion is no greater for elements of the Third Period than for elements of the Second Period and therefore it cannot be the cause of the absence of π-bonds in compounds of heavy elements. According to Mulliken, a possible explanation of this phenomenon is that the formation of two σ bonds is more favourable than the formation of a double bond, i.e. there should be a greater tendency towards the formation of a polymeric form than towards the formation of a monomeric form.

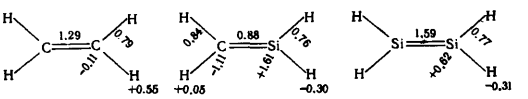
On the basis of the structure of the energy bands in diamond and crystalline silicon, Levin et al.[77] estimated the extent of $(p-p)_\pi$ interaction between carbon and silicon atoms and showed that the corresponding resonance integral for silicon is smaller by a factor of approximately two than for carbon. The authors regard this finding as a possible cause of the absence of silicon compounds with multiple bonds.

Quite recently Curtis[78] carried out calculations on the $H_2Si = CH_2$ and $H_2Si = SiH_2$ molecules using the extended Hückel molecular orbital method and found that 3*d* orbitals contribute significantly to the π-overlap population. Moreover the contribution of the $(p-d)_\pi$ bond actually exceeds that of the $(p-p)_\pi$ bond:

π-Overlap populations

	$(p-p)_\pi$	$(p-d)_\pi$	$(d-d)_\pi$	Σ
$CH_2=SiH_2$	0.130	0.197	—	0.327
$H_2Si=SiH_2$	0.277	0.348	0.038	0.663

The π-overlap populations and atomic charges in ethylene and its silicon analogues are quoted below (after Curtis)[78]:



Evidently the silicon–carbon double bond is extremely polar. The high polarity of this bond also follows from a CNDO calculation on $H_2C = SiH_2$ [79]; the dipole moment of this molecule has been estimated as 2.99 D. The barrier to rotation about the π-bond (and hence the π-bond energy) increases in the following sequence: C = Si < Si = Si < C = = C, and the low stability of the C = Si bond is explained by the energy discrepancy between the carbon and silicon *p* orbitals. Damrauer and Williams[80] carried out CNDO calculations on the $H_2Si = CH_2$, $F_2Si = CH_2$, $H_2Si = CF_2$, and $F_2Si = CF_2$ molecules in order to determine the influence of the positions of the fluorine atoms on the strength of the π-bond. Their high π-bond orders and the small lengths of the silicon-carbon bonds (1.75 Å in $H_2C = SiH_2$ and $H_2C = = SiF_2$; 1.80 Å in $F_2C = SiF_2$ and $F_2C = SiH_2$) indicate the olefinic character of these compounds. The FSiF and FCF angles are 110° and ∠ HSiH and ∠ HCH are 120°. Calculation showed that, in contrast to $H_2Si = CH_2$ and $F_2Si = = CH_2$, the $H_2Si = CF_2$ and $F_2Si = CF_2$ molecules have less polar π-bonds. It is interesting to note that analysis of the reactivities of the above compounds by electrostatic methods led to the conclusion that the formation of 1, 2-disilacyclobutane from $H_2Si = CF_2$ should be more favourable than the formation of 1, 3-disilacyclobutane.

In conclusion of this section, we should note that the stability of the silicon analogues of olefins is in general correlated with the lack of tendency of the silicon atom towards sp^2 hybridisation noted in recent publications[81] on the structure of silyl radicals. It was found that, in contrast to the methyl radical, the silyl radical is non-planar and has a pyramidal configuration. The substitution of a hydrogen atom by methyl group has only a slight influence on the geometry of the radical.

Nevertheless the nature of the bonds in silicon analogous of unsaturated compounds still remains one of the unsolved problems of chemistry. The advances achieved in the stabilisation of compounds of this class, which made possible spectroscopic and other physical studies on these compounds, are promising in this connection.

* * *

The results discussed above have shown that monosilacyclobutanes still remain some of the most effective and most readily available sources of silicon analogues of olefins. Mono- and di-silabicyclo[2, 2, 2]octa-2, 5-dienes are particularly convenient for this purpose. There is no doubt that the discovery of new selective and simple methods for the synthesis of silicon analogues of unsaturated compounds will permit a wider employment of the interesting synthetic possibilities of this new class of organosilicon compounds.

Ultraviolet Spectroscopic Determination of the Stabilities of Weak Organic Complexes

E.G.Polle

The methods described in the literature for the determination of the stability constants K and extinction coefficients ϵ of weak organic electron-donating and electron-accepting complexes are discussed. It is shown that the majority of the methods based on a combination of the Bouguer-Beer-Lambert law and the law of mass action and involving the use of an excess of one component suffer from the same disadvantages as the parent spectrophotometric method—the Benesi-Hildebrand method (the inconsistency between K and ϵ, the appearance of negative values of K, the dependence of K on the wavelength used, the dependence of K and ϵ on the relative amounts of the donor and acceptor, etc.). The reliability criteria of Pearson and Deranleau are discussed and their limitations are demonstrated. It is suggested that the absolute values of K and ϵ obtained spectrophotometrically are of interest only from a comparison of complex formation in series of organic compounds with similar structures and that all measurements should as far as possible be made under identical conditions. The review covers studies published up to the middle of 1973.
The bibliography includes 177 references.

IV. The reliability of the literature values of K and ϵ 638

I. INTRODUCTION

Numerous reviews[1-6], dealing mainly with the stable inorganic and organic-inorganic complexes, have been devoted to studies on the stabilities of complexes in solution. There have also been a fair number of publications on weak organic electron donor–acceptor complexes[7-17], but attention has been concentrated on the properties of the complexes and not on the calculation of the stability constants. The group of complexes under consideration ($K \leqslant 20$ litre mole^{-1}) exhibit a specific absorption in the electronic spectrum. Even very weak complexes frequently give rise to an appreciable deviation from additivity of optical densities in the spectrum of a mixture of the reacting molecules. The reasons for this phenomenon are being widely discussed—it may be due to a charge-transfer band, or to a singlet–triplet absorption by the donor, or to the resolution of latent bands of the acceptors, etc.—and in the present review they will not be considered. However, the appearance of a new absorption following interaction has led to a very frequent application of spectrophotometric methods. On the other hand, there is not in the literature even one critical study of the entire series

of methods used to investigate weak molecular complexes. Such an examination is particularly necessary, since the determination of the stability constants was not the main aim of the majority of investigators; one may say that, for organic chemists dealing with syntheses, the constant K provides a comparison of the complex-forming capacities of new substances with those investigated previously, etc. A method widely described in the literature, usually the Benesi–Hildebrand method [18] (or its modifications) which is very easy and clear-cut, is employed.

The aim of the present review is to demonstrate the limitations of the spectrophotometric methods for the determination of K and ϵ and the necessity for much caution in the assessment of the results.

II. SPECTROPHOTOMETRIC METHODS FOR THE DETERMINATION OF THE STABILITY CONSTANTS OF WEAK ORGANIC COMPLEXES

Spectrophotometric methods for the investigation of the stability of organic complexes have been known for a long time (see, for example, Halban and Zimpelmann [19] and Michaelis and Granick [20]), but the methods became widely used only from the beginning of the 1950s. This was stimulated by Mulliken's theoretical studies [21–24], partly based on the experimental data of Benesi and Hildebrand [18,25]. The basic postulates used in the analysis of complex-forming systems by the Benesi–Hildebrand (B–H) method [18] can be formulated as follows: (a) the system is in a state of equilibrium; (b) the optical density of the solution is due to a molecular compound; (c) only one complex is formed in solution; (d) the absorption by the complex obeys the Bouguer–Beer–Lambert law.

For the reaction

$$A + nB \rightleftarrows AB_n \quad , \tag{1}$$

we have

$$K = C_{AB_n}/C_A \cdot C_B^n \quad , \tag{2}$$

where A and B are the components, K is the stability constant, C_{AB_n} the concentration of the complex at equilibrium, $C_A = a - C_{AB_n}$, and $C_B^n = (b - C_{AB_n})^n$, a and b being the initial acceptor and donor concentrations and C_A and C_B the equilibrium concentrations.

According to the Bouguer–Beer–Lambert law, one can write for the complex

$$D = C_{AB_n}\epsilon_{AB_n}l \quad , \tag{3}$$

where D is the optical density of the solution, ϵ_{AB_n} the molar extinction coefficient of the complex, and l the optical pathlength.

On combining Eqns. (2) and (3), Benesi and Hildebrand arrived at the expression

$$al/D = (1/K \cdot \epsilon_{AB_n})(1/b^n) + 1/\epsilon_{AB_n} \quad . \tag{4}$$

The plot of al/D against $1/b^n$ is linear, $1/\epsilon_{AB_n}$ being the slope and $1/\epsilon_{AB_n}K$ the intercept. Three possibilities arise for this linear plot: (a) the intercept is positive, i.e. ϵ_{AB_n} and K are positive and non-zero; (b) the intercept is zero, i.e. $\epsilon_{AB_n} = \infty$ and $K = 0$; (c) the intercept is negative, i.e. $\epsilon_{AB_n} < 0$ and $K < 0$.

As an illustration we shall consider the *m*-dinitrobenzene (DNB)–*o*-bromoaniline and *m*-dinitrobenzene–2-methylnaphthalene systems [26] (Figs. 1 and 2). In both systems different straight lines are obtained at different donor concentrations. In the presence of a 60–124 and 124–200-fold excess of *o*-bromoaniline the first system gives rise to straight lines *a* and *b* respectively in Fig. 1. In the presence of a 40–120- and 120–320-fold excess of 2-methylnaphthalene the second system gives rise to straight lines *a* and *b* respectively in Fig. 2.

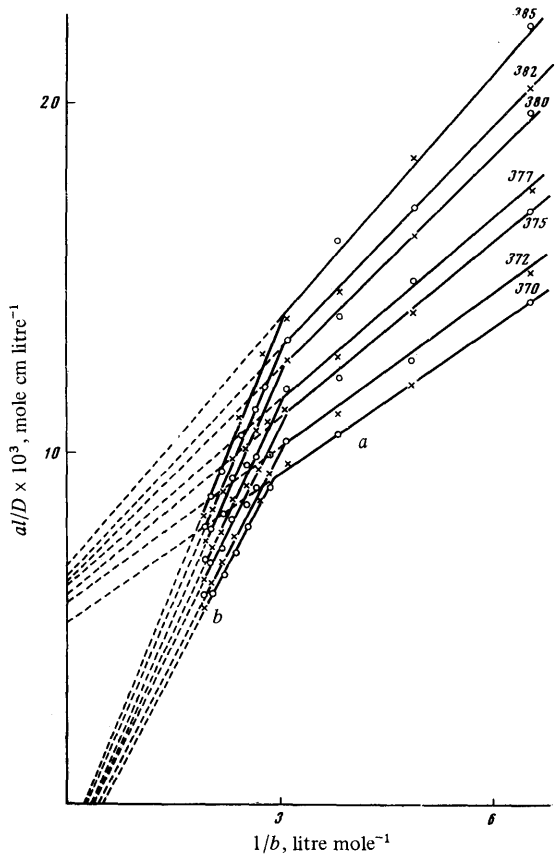

Figure 1. Application of the Benesi–Hildebrand method to the *m*-dinitrobenzene–*o*-bromoaniline system [26] in methanol; the numerals against the plots represent wavelengths (nm).

The Benesi–Hildebrand method is most commonly used at present [25,27] and the investigators do not always treat the results critically. The equation of Ketelaar et al. [58], which differs from the Benesi–Hildebrand expression by taking into account the absorption by the acceptor, is more accurate for the calculation of K and ϵ_{AB}:

$$1/(\epsilon_a - \epsilon_A) = 1/K \cdot b \quad (\epsilon_{AB} - \epsilon_A) + 1/(\epsilon_{AB} - \epsilon_A) \quad , \tag{5}$$

where $\epsilon_a = D/la$. The plot of $1/(\epsilon_a - \epsilon_A)$ against $1/b$ is linear and permits the determinations of K and ϵ_{AB}. [59–62] Landauer and McConnell [63] derived an expression for the estimation of K_1 and K_2 for 1 : 1 and 1 : 2 complexes present

simultaneously in solution[51,60,64-73]. An effective extinction coefficient is introduced: $\bar{\epsilon} = D/al$, where D is the total optical density of the solution. If $l = 1$, then

$$D = a\bar{\epsilon} = \varepsilon_A \; C_A + \varepsilon_{AB} \; C_{AB} + \varepsilon_{AB_2} \; C_{AB_2} \; , \qquad (6)$$

since

$$a = C_A + C_{AB} + C_{AB_2}$$

or

$$a = C_A(1 + K_1 b + K_2 b^2) \; . \qquad (7)$$

Putting

$$Q = b/(\bar{\epsilon} - \epsilon_A) \qquad (8)$$

and using Eqns. (6) and (7), we obtain

$$Q = \frac{1 + K_1 b + K_2 b^2}{(\varepsilon_{AB} - \varepsilon_A) K_1 + (\varepsilon_{AB_2} - \varepsilon_A) K_2 b} \; . \qquad (9)$$

It is assumed that $C_{AB} \gg C_{AB_2}$ and therefore to a first approximation one can neglect the term containing K_2, i.e.

$$Q = (1 + K_1 b)/(\varepsilon_{AB} - \varepsilon_A) K_1 \; . \qquad (10)$$

Q varies linearly with b and K_1 and ϵ_{AB} can be obtained from the plot. Knowing them, it is possible to estimate K_2 and ϵ_{AB_2}:

$$(1 + K_1 b)/Q = (\varepsilon_{AB} - \varepsilon_A) K_1 + (\varepsilon_{AB_2} - \varepsilon_A) K_2 b \; .$$

After substitution of Q from Eqn. (8) and a slight rearrangement, Eqn. (10) becomes

$$al/(D - \varepsilon_A l) = 1/(\varepsilon_{AB} - \varepsilon_A) K_1 b + 1/(\varepsilon_{AB} - \varepsilon_A) \; . \qquad (11)$$

When $\epsilon_A = 0$, Eqn. (11) transforms into Eqn. (4), i.e. when the acceptor does not absorb the method reduces to the Benesi–Hildebrand method and differs from the latter by the arrangement of the parameters.

Using Eqns. (1)–(3), Foster and coworkers[74-76] arrived at the expression

$$D/b^n = Kal\varepsilon_{AB_n} - KD \; . \qquad (12)$$

When the relation between L/b^n and L is linear, it is possible to find K and ϵ_{AB_n}. Three cases arise in the application of the method[55,60-69,72,77-85]: (*a*) the slope is negative, i.e. K and ϵ_{AB_n} are positive and non-zero; (*b*) the slope is zero, i.e. $K = 0$ and $\epsilon_{AB_n} = \infty$; (*c*) the slope is positive, i.e. $K < 0$ and $\epsilon_{AB_n} < 0$.

Scott[86] modified the Benesi–Hildebrand method and suggested that $x_B al/D$ be plotted against x_B, where x_B is the mole fraction of the donor. This permits the investigation of the initial slope at very low concentrations since the plot is extrapolated through the region of decreasing concentrations to the intercept[55,87].

Rose and Drago[88,89] demonstrated the applicability of the following relation to systems comprising a Lewis base and molecular iodine:

$$K^{-1} = (D - D_A)/(\varepsilon_{AB} - \varepsilon_A) - a - b + ab(\varepsilon_{AB} - \varepsilon_A)/(D - D_A). \qquad (13)$$

Eqn. (13) is valid for an optical path length of 1 cm. The presence of two unknowns necessitates the calculation of K and ϵ_{AB} for two solutions with different ratios of a and b. If the experimental conditions are such that $(D - D_A)/(\epsilon_{AB} - \epsilon_A) - a$ is negligibly small compared with $ab(\epsilon_{AB} - \epsilon_A)/(L - L_A) - b$, then Eqn. (13) assumes the form of Eqn. (5). When the bands do not overlap at the chosen wavelength, D_A and ϵ_A are zero and Eqn. (13) reduces to

$$K^{-1} = D/\varepsilon_{AB} - a - b + ab \; \varepsilon_{AB}/D \; . \qquad (14)$$

If $L/\epsilon_{AB} - a$ is negligibly small, Eqn. (14) readily transforms into Eqn. (4), i.e. the Benesi–Hildebrand and Ketelaar equations are special cases of Eqn. (13), which is widely used in practice[54,90-94]. Kortüm and Weber[95] introduced the modulus of extinction $m = \epsilon_A C_A + \epsilon_B C_B + \epsilon_{AB} C_{AB}$ for the calculation of the stability. For reaction (1), we have

$$(m - \varepsilon_A a - \varepsilon_B \; b)/a - b = (\varepsilon_{AB} - \varepsilon_A - \varepsilon_B)[K_1 - K_1^2(a + b)] \; , \qquad (15)$$

it is suggested that Eqn. (15) be used for 1 : 1 complexes. The authors propose the following relation for the determination of the parameters of 1 : 1 and 1 : 2 complexes when they are present simultaneously:

$$m/ab = \varepsilon_{AB} \; K_1[1 - K_1(a + b) + K_1^2 ab - 2K_1 K_2 ab - K_1 K_2 b^2] + \\ + \varepsilon_{AB_2} \; K_1 K_2[b - 2K_1 ab - K_2 b] \; .$$

The present author investigated twenty systems by this method[96]. The results differ little from those calculated using the literature data[18,63,74].

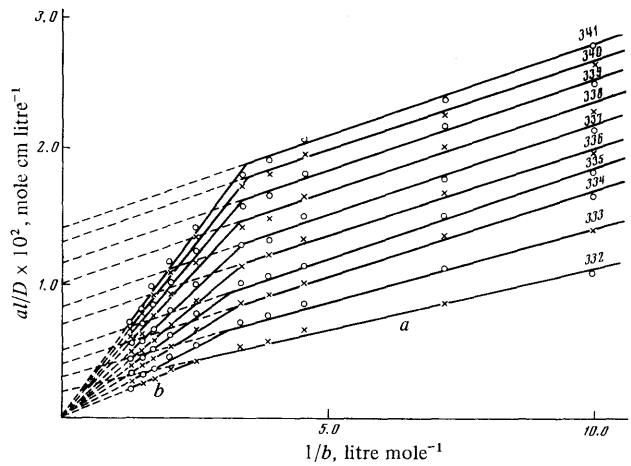

Figure 2. Application of the Benesi–Hildebrand method in the *m*-dinitrobenzene–2-methylnaphthalene system[26] in cyclohexane; the numbers against the plots represent wavelengths (nm).

Liptay[97] was the first to propose a method requiring a computer treatment and applicable for any concentration ratio of the components[98].

Lang[99] and Chandra[100-102] proposed modifications of the Benesi–Hildebrand method. Cilento and Sanioto[103] used a method on dilution. The working equation is

$$V^n = K\varepsilon_{AB} \; l \; m_A m_B^n / VD - K m_B^n \; ,$$

where V is the volume of the solution, D its optical density, and m_A and m_B are the numbers of moles of A and B. The plot of V^n against $1/VD$ should be linear. The intercept is $-Km_B^n$ and the slope is $K\epsilon_{AB} l m_A m_B^n$. Data for different wavelengths should yield the same intercept but different slopes.

Lavrushkin et al.[104] proposed two equations permitting a graphical determination of K and ϵ_{AB} when $b \gg a$:

$$a/(D-D_A) = 1/(\varepsilon_{AB}-\varepsilon_A) + 1/Kab(\varepsilon_{AB}-\varepsilon_A) ,$$
$$(D-D_A)/a = \varepsilon_{AB}-\varepsilon_A-(D-D_A)/Kab \quad .$$

Dewar and Thompson[105] put forward a system of four equations to be used for computer calculations whereby it is possible to find K, ϵ_{AB}, and C_{AB} (l = 1 cm):

$$C_{AB} = \{Ka+Kb+1-\sqrt{[K(a-b)+2Ka+2Kb+1]}\}/2K , \quad (16)$$
$$D_{AB} = \varepsilon_{AB}\ C_{AB} = D-\varepsilon_A(a-C_{AB})-\varepsilon_B(b-C_{AB})\ldots , \quad (17)$$
$$ab/D_{AB} = 1/K\cdot\varepsilon_{AB}+(a+b-C_{AB})/\varepsilon_{AB}\ldots , \quad (18)$$
$$ab/D_{AB}(a+b-C_{AB}) = 1/K\cdot\varepsilon_{AB}(a+b-C_{AB})+1/\varepsilon_{AB}\ldots \quad (19)$$

The method of solution is as follows: using an arbitrary value of K, Eqn.(16) is solved for C_{AB}, D_{AB} is subtracted from Eqn.(17), and $1/\epsilon_{AB}$ and $1/K\epsilon_{AB}$ are found from Eqns.(18) and (19) respectively. The latter two values are used to find a new value of K.

Complex formation is not always accompanied by an increase of the optical density; the reverse process, i.e. an absorption by the reaction mixture less than the additive value, is commonly observed in the spectrum of the mixture of interacting components. Gol'tsev et al.[106] modified the method of Foster et al.[74] K can be obtained by plotting $(D_A-D)/b^n$ against D_A-D. The slope of this relation is numerically equal to K.

Hammond[107,108] simplified the method of Cilento and Sanioto[103] by introducing the dilution coefficient n into the equation and obtained the relation

$$1/nD = n/Ka^2\varepsilon_{AB}+1/\varepsilon_{AB}\cdot a+1/\varepsilon_{AB}\cdot b \quad . \quad (20)$$

Hence we have the working equation

$$d\lg D/d\lg n = -\{1+1/[1+(Ka+Kb)/n]\} \quad . \quad (21)$$

Eqns.(20) and (21) are valid when $a \gg b$ or $b \gg a$, which permits the neglect of $(1/\epsilon_{AB})b$ or $(1/\epsilon_{AB})a$ respectively, or when $a = b$.

Mamedov and Aleskerova[109] proposed a method which hardly differs from Nagakura's procedure[110,111]. Here

$$K = [a(D_0-D_1)+a'(D-D_0)]/a\cdot a'(D_1-D) , \quad (22)$$

where D_0, D, and D_1 are the optical densities of solutions in which the concentrations of the molecules of A are zero, a, and a' respectively. Eqn.(22) can be used when $C_{AB} \ll a$ and when D_A is negligibly small at the wavelengths used to determine the stability constant.

Gol'dshtein and Gur'yanova[112] developed a procedure called the "method for eliminating one of the unknowns" and suitable for the evaluation of K from spectroscopic (ultraviolet, infrared, Raman, and NMR), dielectric, calorimetric, etc. data for complexes of any stoichiometry. The method has been analysed in detail[113] and therefore is not quoted here. We shall only describe the general procedure. One unknown is eliminated from the general equation with two unknowns ϵ and K. This is achieved by taking logarithms in the general equation for K and by subsequent differentiation of the resulting expression. This yields a quadratic equation with one unknown. The method is suitable for a computer treatment and gives good results when not less than ten experimental points are used.

Meallier et al.[114] demonstrated the application of the following relations to the dioxane (A)–aniline (B) complex in hexane:

$$a/(\bar{\varepsilon}-\varepsilon_0) = [1/(\varepsilon_1-\varepsilon_0)]\,1/K+a/(\varepsilon_1-\varepsilon_0)+b(\varepsilon_1-\varepsilon_0)+b(\bar{\varepsilon}-\varepsilon_0)/(\varepsilon_1-\varepsilon_0)^2 , \quad (23)$$

where ϵ_0 and ϵ_1 are the molar extinction coefficients of aniline in hexane and dioxane respectively and $\bar{\epsilon} = D/bl$ is the formal extinction coefficient of aniline in the dioxane–hexane mixture. When $a \gg b$, Eqn.(23) becomes

$$a/(\bar{\varepsilon}-\varepsilon_0) = [1/(\varepsilon_1-\varepsilon_0)]\,1/K+a/(\varepsilon_1-\varepsilon_0) ,$$

whence

$$K = (\bar{\varepsilon}-\varepsilon_0)/a(\varepsilon_1-\bar{\varepsilon}) \quad .$$

An equation describing a hyperbolic curve and suitable for 1 : 1 complexes has been put forward[26,115]:

$$y^2+Kxy-y[Ka(\varepsilon_{AB}-\varepsilon_A-\varepsilon_B^*)+\varepsilon_B^*]-x\varepsilon_B^*K = 0 , \quad (24)$$

where $x = D$, $y = D/b$, and ϵ_B^* is the extinction coefficient of the donor in solution in the acceptor. The plot of D/b against D should yield a hyperbola or one of its branches [cf. Eqn.(12)]:

$$K = -\tan 2\alpha,$$

where α is the angle of rotation of the coordinate axes relative to the axis of the hyperbola. Fig. 3 illustrates the application of the method for a system which cannot be treated by the Benesi–Hildebrand method[18] and the method of Foster et al.[74] (Fig. 1): $K_1 = 0.69$ litre mole^{-1}.

Eqn.(24) can only be used effectively in a computer treatment using the method of least squares, since a manual graphical plot gives errors of the order of 20–30%.

Using the method of differential spectroscopy, Kampar and Neiland[116] put forward the relation

$$cl/\Delta D = 1/\varepsilon_{AB}+[(1-KC_{AB})/2K\ \varepsilon_{AB}]\cdot 1/c , \quad (25)$$

where $c = a = b$ and $\Delta D = \epsilon_{AB}C_{AB}\times 2l$ is the difference between the optical densities of the test and reference systems. Since in the majority of cases $KC_{AB} \ll 1$, it is assumed that $KC_{AB} = 0$ and Eqn.(25) represents the linear correlation between the function $cl/\Delta D$ and the argument $1/c$. When the linearity fails, the authors suggest an expression permitting a more accurate determination of K and ϵ_{AB}:

$$cl/\Delta D = 1/2\varepsilon_{AB}+[(1+\sqrt{4Kc+1})/4K\cdot\varepsilon_{AB}]1/c \quad .$$

The method can be used to determine K and ϵ_{AB} in those cases where both components and the complex absorb in the same region. The authors proposed their method for complexes of the ion–ion type, but it can also be used to investigate complexes of other types. However, it undoubtedly suffers from some of the disadvantages of the Benesi–Hildebrand method.

Apart from the equations discussed above, many expressions have been proposed for the determination of K and ϵ, differing from those quoted mainly by their form or by a different arrangement of the initial parameters[65,98,117–133].

Thus all the expressions employed to calculate K and ϵ were derived by combining the mass action and Bouguer–Beer–Lambert Laws and the majority presupposed the employment of an overwhelming excess of one of the components. For this reason, the fundamental defects of the Benesi–Hildebrand method are characteristic of all spectroscopic methods for determining K and ϵ for weak molecular complexes[134,135].

III. THE DIFFICULTIES ARISING IN THE DETERMINATION OF K AND ϵ

The main difficulties are the inconsistency of K and ϵ for weak molecular complexes, i.e. low values of K and very high values of ϵ are determined experimentally.

Orgel and Mulliken[136] were the first to attempt to elucidate this behaviour. They put forward the concept of contact charge transfer, according to which complexes with zero stability and appreciable absorbance can exist, i.e. the absorption by the complex arises in the course of random collisions. To illustrate their concept, the authors employed complexes of molecular iodine with saturated and aromatic hydrocarbons treated by the Benesi–Hildebrand method. The slight curvature obtained in the plot of $\ln K$ against $1/T$ was used by Orgel and Mulliken as evident proof that several geometrical isomers are present. It was shown that the iodine–n-heptane system forms only contact pairs and this is why the Benesi–Hildebrand line intersects the ordinate at the origin. Taking into account the "contact", Eqn.(4) becomes

$$al/D = 1/Kbe_{\text{eff}} + 1/e_{\text{eff}} ,$$

where $\epsilon_{\text{eff}} = \epsilon_{AB} + \alpha C_{AB}/K$, α being a coefficient characterising the number of molecules of B near the molecules of A.

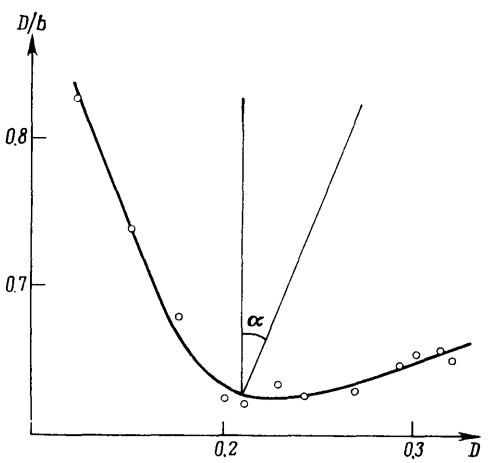

Figure 3. The *m*-dinitrobenzene–*o*-bromoaniline system[26] in methanol; $\lambda = 380$ nm; $l = 1$ cm.

Prue[137] derived an equation for the stability constants of 1 : 1 contact charge-transfer complexes of electron-donating and electron-accepting molecules: $K = 4\pi r^2 \Delta r N$, where r and $r + \Delta r$ are the distances between the centres of the molecules for which the presence of complexes is revealed in the charge-transfer spectra. When $r = 5$ Å and $\Delta r = 0.94$ Å, we have $K \simeq 0.2$ litre mole^{-1}. It was shown that values of K smaller than this and estimated from charge-transfer spectra do not constitute evidence for any kind of attractive forces between the donor and acceptor molecules in the ground state apart from the usual dispersion forces.

It should be noted that the estimation of r and $r + \Delta r$ in real systems is very complicated.

Murrell[138], who considered the inconsistency between K and ϵ, suggested that in a series of related complexes the relative behaviour of the intensity of the charge-transfer band and of the stability of the complex depends on the energy difference between the most stable configuration and the configuration contributing most to the intensity.

Many investigators attribute the inconsistency between K and ϵ to the effect of the solvent[86,124,139–148].

In an analysis of the concept of contact charge transfer, Carter et al.[142] concluded that it is unsatisfactory for two reasons: (a) the small thermodynamic justification of the hypothesis of two types of complexes one of which obeys the law of mass action and the other does not; (b) failure to take into account the role of the solvent in the theory despite the fact that in the case of weak complexes the donor competes with the solvent for a site around the acceptor.

Bearing in mind the competition between complex formation and solvation, there is no need to introduce two types of complexes and the behaviour of weak complexes can be accounted for by the same theory as that of strong complexes[142–144]:

$$AS_n + BS_m \rightleftarrows ABS_p + qS ,$$

where $q = n + m - p$, i.e. the donor, acceptor, and the complex are surrounded by a solvation shell:

$$K = C_{AB} x_S q / C_{AS_n} C_{BS_m} ,$$

where x_S is the mole fraction of the free solvent determined from the total number of moles of A, B, and S (bound and free). K is determined in the same way as in the Benesi–Hildebrand method:

$$al/D = (x_S q/K \cdot \varepsilon_{AB})(1/b) + 1/\varepsilon_{AB} .$$

The authors conclude that the Benesi–Hildebrand analysis underestimates K by an amount $q(m + 1)/G_0$ (G_0 is the total concentration of the solvent and $b = 0$) and overestimates ϵ_{AB} by an amount K/K_{B-H}. For stable complexes, $K \gg q(m + 1)/G_0$ and the Benesi–Hildebrand method gives good results.

The method proposed cannot be widely employed, since it is by no means easy to determine the numbers of solvent molecules with which the donor and acceptor are combined.

Semiempirical methods for the assessment of the influence of solvents have been proposed[124,145]. Hunter et al.[146], who examined four-component systems, demonstrated a method permitting the separation of the role of the solvent for moderately strong complexes of the type of chloranil–hexamethylbenzene (HMB)–n-heptane–carbon tetrachloride. The fundamental equation is

$$1/\varepsilon_A = 1/Y \cdot \varepsilon_{AB} + 1/K_{AB} \cdot Y \varepsilon_{AB} X b . \qquad (26)$$

Eqn.(26) differs from Eqn.(4) only by the presence of the terms X and Y, ϵ_A being the formal extinction coefficient of the acceptor calculated by dividing the total optical density of the solution by a and l.

$$X = 1 - (C_2 + C_3 + \ldots)b, \; Y = 1 - (C_2' + C_3' + \ldots)/a ,$$

where C_2, C_3, etc. are the concentrations of complexes of the solvent with the donor and C_2', C_3', etc. are the concentrations of complexes of the solvent with the acceptor. The method is based on the same postulates as the Benesi–Hildebrand method, i.e. $C_{AB} \ll b$. X and Y are expressed in terms of the concentrations of the four components present in the system:

$$X = (1 + T)^{-1}, \; Y = [1 + S/(1 + K_{AB} \; b \; X)]^{-1} ,$$

where

$$T = \sum_{n=2}^{n} K_n(x) x_l^{n-1}, \; S = \sum_{m=2}^{m} K_m(x) x_h^{m-1} ,$$

in which K_m is the stability constant of the chloranil–(n-heptane)$_{m-1}$ complex, K_n is the stability constant of the hexamethylbenzene–$(CCl_4)_{n-1}$ complex, and x_h and x_l

are the mole fractions of n-heptane and carbon tetrachloride respectively.

In the experimental test of the method, the concentration ratio of n-heptane and carbon tetrachloride was varied but K and ϵ remained constant in all cases. The fact that the K are much higher than for the complexes in pure carbon tetrachloride[149] (although the hexamethylbenzene–carbon tetrachloride complex is very weak) indicates the influence of carbon tetrachloride on the complex formation process.

It has been shown[146] that, even for very strong complexes, the interaction of the components with the solvent is comparable to the complex formation proper. The authors suggest that the formation of competing complexes with the solvent is the most likely explanation of the inconsistency between K and ϵ.

The simultaneous employment of different concentration scales (litre mole^{-1} in the determination of K_{AB} and the reciprocal of the mole fraction in the determination of K_{As} and K_{Bs}) hinders the application of the method[142].

Scott[147] considered the determination of the stability constants of weak complexes from the standpoint of a quasichemical calculation for a cell with donor, acceptor, and inert solvent molecules. Using Guggenheim's theory[150], the author showed that the stability constants calculated by methods of the Benesi–Hildebrand type are imaginary. A disadvantage of the proposed method is that it is based on the concept of contact charge transfer. Moreover, the author considers the possibility of the existence of contact complexes with $\epsilon = 0$ and $K > 0$.

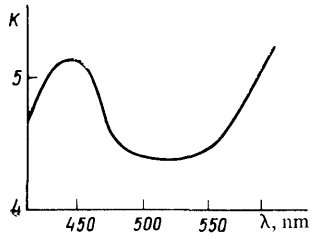

Figure 4. Variation of K with wavelength[32] in the tetracyanoethylene–naphthalene system in carbon tetrachloride at 25°C.

To predict the effect of solvents on the equilibrium, Christian et al.[148] employed a non-polar analogue model (NAM) in which a non-polar analogue of the polar solute is used in the calculation of the properties of the solutions. The chosen NAM molecule must have the same molecular volume and the same energy of interaction with the surrounding solvent as the polar solute. It was shown that NAM can be used under a wide range of conditions.

Kuntz et al.[36] attribute the inconsistency between K and ϵ to an incorrect choice of the concentration scale. They considered reaction (1) in the presence of an inert solvent S, i.e. they assumed that there is no competition between the donor and the solvent. This resulted in relations between different concentration scales:

$$(K_x)_{B-H} = K_c/v_S + (v_B - v_S)/v_S;\ (\epsilon_x)_{B-H} = K_c\epsilon_{AB}/(v_B - v_S + K_c);$$
$$(K_m)_{B-H} = \rho_S(K_c + v_B);\ (\epsilon_m)_{B-H} = \epsilon_{AB}\ K_c/(K_c + v_B)\ ,$$

where x is the concentration expressed in terms of mole fractions, m the molality, c the molarity, ρ the density, and v the molar volume. It is concluded that reasonable values of K_C, v_B, and v_S can give rise to zero or negative values of K_X when the Benesi–Hildebrand method is used. However, the form of the Benesi–Hildebrand linear plot cannot be used to conclude that one or other concentration scale is preferable; an experimental study with the aid of two inert solvents is necessary. For complexes of the aromatic amine–aromatic nitro-compound type, the concentration is best expressed on the molar scale.

General equations for the interaction with solvents relating different concentration scales have been published[143].

The problem of the inconsistency between K and ϵ can also be approached in a different way. On the basis of solvation theory, one should observe constant products $K\epsilon$, obtained by the Benesi–Hildebrand or similar methods, over a wide range of donor and acceptor concentrations. This was in fact done in a study of the *NN*-dimethylaniline–1,3,5-trinitrobenzene (TNB) in chloroform. K varied from 0.62 to 1.18 litre mole^{-1} and ϵ from 1800 to 954. Ross and Labes[151] explained this result by postulating the existence of 1 : 2 and 2 : 1 complexes in the system. Foster and coworkers[152,153] suggested that the observed extinction coefficient is a function of the concentration of the component present in excess, usually the donor: $\epsilon = \epsilon_0(1 + \alpha b)$, where ϵ_0 is the extinction coefficient at infinite dilution. Application of this expression showed that appreciable variation in K_{B-H} and ϵ_{B-H} may occur for very small values of α; ϵ is overestimated and K underestimated. On the other hand, the product $K\epsilon$ remains unchanged. It is nowadays frequently recommended that $K\epsilon$ and not K be used to determine the thermodynamic parameters[12,154].

A remarkable phenomenon has been noted by a number of workers[29,32,34,53,66–69,105,121,144,155–163]—the dependence of K on wavelength. This has been interpreted in different ways. Thus Johnson and Bowen[32] (Fig. 4) believe that this relation cannot be explained by the presence of isomeric 1 : 1 charge-transfer complexes and (or) contact absorption. They postulate the existence of stable charge-transfer complexes with at least two different stoichiometric compositions.

The study of complexes of aromatic nitro-compounds with alkylbenzenes in carbon tetrachlorides[156] demonstrated a dependence of K on the wavelength for all the systems studied. For example, K for the *p*-dinitrobenzene–1,3,5-trinitrobenzene complex decreases from 2.24 to 0.62 litre mole^{-1} when λ is raised from 325 to 390 nm. Jurinski and de Maine[156] suggest that the results cannot be accounted for by the existence of any isomeric 1 : 1 complexes or higher-order complexes.

Carter[144] extended the Benesi–Hildebrand method to the case of the simultaneous presence of 1:1 and 1 : 2 complexes:

$$al/D = (1/K_1 \cdot \epsilon_1)(1/b) + (K_1 - \epsilon_2K_2/\epsilon_1)/K_1\epsilon_1\ .$$

When the condition $b \gg a$ is maintained, the observed $K = K_1 - (\epsilon_2/\epsilon_1)K_2$ and the slope yields $K_1\epsilon_1$, which was in fact observed on the assumption that 1 : 2 complexes exist. Hence follows the conclusion that the presence of 1 : 2 complexes should lead to a dependence of K on λ. Christie and Selinger[160] analysed the experimental data and conclusions of Johnson and Bowen[32] and showed that the dependence of K on λ need not be explained by the presence of isomeric complexes, but could simply be a result of the algebraic addition of the optical densities of the donor, acceptor, and the complex.

A clear example of the dependence of the observed K on λ and on the ratio of the donor and acceptor concentrations is illustrated in Table 1. The method[105] described above was used.

Table 1.

λ, nm	[TCNE] = 1.8×10^{-3} M [HMB] = (1.2–4.1) × 10^{-3} M	[TCNE] = 1.4×10^{-4} M [HMB] = 0.222–0.333 M	λ, nm	[TCNE] = 1.8×10^{-3} M [HMB] = (1.2–4.1) × 10^{-3} M	[TCNE] = 1.4×10^{-4} M [HMB] = 0.222–0.333 M
450	47.4	19.1	560	26.6	19.1
460	46.9	19.4	570	28.8	19.2
470	39.3	20.1	580	27.6	19.1
480	39.0	20.2	590	26.1	19.2
490	36.7	20.4	600	27.2	19.6
500	33.3	20.1	610	28.4	20.1
510	32.0	20.3	620	24.7	21.1
520	27.7	20.2	630	27.5	22.2
530	31.6	19.7	640	25.5	26.5
540	30.7	19.6	650	23.2	28.6
550	29.7	19.3			

Note. TCNE = tetracyanoethylene, HMB = hexamethylbenzene.

It is remarkable that the values of K obtained for more concentrated solutions vary little with the wavelength and the direction of their variation is the opposite to that observed at low concentrations. If the relation between K and λ is due to the appearance of complexes with a higher stoichiometry[32,144], the opposite behaviour should have been observed, i.e. the changes should have been greater at higher concentrations, since there is a greater probability of the formation of higher-order complexes.

The dependence of K and ϵ on the ratio of the donor and acceptor concentrations has been observed and discussed frequently[13,53,56,105,164]. Using the Benesi–Hildebrand method, Inoue and Kato[53] put forward two series of K values for the *NN*-dimethylaniline–nitrobenzene system in cyclohexane. When a donor concentration less than 0.3 M was used, $K_{ev} = 0.22$ litre mole^{-1}; at donor concentration greater than 0.3 M, $K_{ev} = 0.083$ litre mole^{-1}. The nitrobenzene concentration was 0.0162 M. Generally speaking, the Benesi–Hildebrand lines have the form analogous to that illustrated in Figs. 1 and 2 with the sole difference that the intercept is positive for both donor concentration ranges.

All three types of intercept (positive, zero, and negative) in the application of the Benesi–Hildebrand method were demonstrated for real systems by Davis and Farmer[34]. A negative intercept of the Benesi–Hildebrand method [Eqn. (4)] corresponds to a positive slope of Foster's method [Eqn. (12)]. We shall refer to the slope as anomalous, since it yields values of K and ϵ lacking physical significance.

The first attempt to account for the anomaly was undertaken by Fofonova[165] in connection with the interpretation of the results of Syrneva and Fofonova[77]. When the singlet–singlet band of the acceptor, displaced to one side under the influence of intermolecular interaction, is superimposed on the singlet–triplet band of the donor, the following observations may be made. If in the spectral region studied the intensities of both bands are of the same order of magnitude (the singlet–triplet band is located on the wing of the singlet band), then the intensities of both bands increase simultaneously with increase of the concentration of one of the components. Under these conditions, the experimental straight lines of the Benesi–Hildebrand method and the method of Foster et al. will have anomalous slopes and the characteristics of the complex cannot be determined.

It is possible to examine the cause of the anomaly from a different standpoint. Consider the commonest cases arising in the study of the absorption spectra of complex-forming systems (we are considering systems with a positive deviation of the optical density from additivity).

1. The complex AB absorbs in the region where A and B are absolutely transparent. The solvent is put in the reference cuvette, $b \gg a$, and K is calculated from Eqns. (4) or (12). For any numerical values of ϵ_{AB}, the straight lines should have the normal slope.

2. A also absorbs in the region of absorption by the complex, the reference cuvette contains a solution of A at a concentration a, and $b \gg a$. The spectrophotometric data are analysed in terms of Eqns. (5) and (27):

$$D/b^n = -KD + Kal(\varepsilon_{AB} - \varepsilon_A) \quad . \tag{27}$$

Since $\epsilon_{AB} > \epsilon_A$ (positive deviation from additivity), the straight lines described by Eqns. (5) and (27) will always have the normal slope regardless of the value of ϵ_A. Thus the intrinsic absorption by the component A does not alter the form of the straight line, but does affect the value of K. Calculation without allowing for ϵ_A yields values of ϵ_{AB} which are too low by an amount equal to ϵ_A.

3. The deviation from additivity in the mixture of components is observed only in the regions where A and B absorb.

On the basis of the Bouguer–Beer–Lambert law, the optical density of the solution (1 : 1 complex) can be written as follows:

$$D = l[(a - C_{AB})\varepsilon_A + (b - C_{AB})\varepsilon_B^* + C_{AB} \cdot \varepsilon_{AB} - a\varepsilon_A] \quad , \tag{28}$$

where ϵ_B^* is the extinction coefficient of the donor in solution in the acceptor (one must not confuse this with ϵ_B — the extinction coefficient of the donor in the pure solvent).

An expression for the concentration of the complex can be obtained from Eqn. (28).

$$C_{AB} = (D - bl\varepsilon_B^*)/l(\varepsilon_{AB} - \varepsilon_A - \varepsilon_B^*) \quad . \tag{29}$$

Next we have

$$(D - bl\varepsilon_B^*)/l(\varepsilon_{AB} - \varepsilon_A - \varepsilon_B^*) = Kab/(1 + Kb) \quad , \tag{30}$$

where the right-hand side of the equation is an expression obtained from the law of mass action subject to the condition $b \gg a$. The replacement of $(b - c)$ by b does not give rise to a large error.

When $l = 1$, Eqn. (30) can be written as:

$$D - \varepsilon_B^* b + KbD - Kb^2\varepsilon_B^* = Ka'(\varepsilon_{AB} - \varepsilon_A - \varepsilon_B^*) \quad . \tag{31}$$

After elementary transformations, we obtain from Eqn. (31)

$$D/b + KD = Ka(\varepsilon_{AB} - \varepsilon_A - \varepsilon_B^*) + \varepsilon_B^* + Kb\varepsilon_B^* \quad . \tag{32}$$

When the notation $D/b = y$, $D = x$, and $b = x/y$ is introduced, Eqn. (32) can be rewritten in the form of the fundamental equation (24). If $\epsilon_{AB} = \epsilon_A + \epsilon_B^*$, the hyperbola defined by Eqn. (24) splits into two straight lines:

$$\begin{cases} y_1 = \varepsilon_B^* \\ y_2 = -Kx \end{cases} \quad . \tag{33}$$

The coordinates of the focus of the hyperbola are

$$\begin{cases} y = \varepsilon_B^* \\ x = -\varepsilon_B^*/K \end{cases} \quad . \tag{34}$$

When $\epsilon^*_B = 0$, Eqn.(24) becomes

$$y^2 + Kxy - yKa(\varepsilon_{AB} - \varepsilon_A) = 0 \ . \qquad (35)$$

Eqn.(35) describes a degenerate hyperbola, which splits into two intersecting straight lines:

$$\begin{cases} y_1 = 0 \\ y_2 = -Kx + Ka(\varepsilon_{AB} - \varepsilon_A) \ . \end{cases} \qquad (36)$$

Fig. 5 illustrates two limiting cases of Eqn.(24): $\epsilon^*_B = 0$ and $\epsilon_{AB} = \epsilon_A + \epsilon^*_B$. The A'B'C' lines corresponds to two intersecting asymptotic lines defined by Eqns.(33): the section $y_0 = \epsilon^*_B$ and the section $x_0 = -\epsilon^*_B/K$. The ABC line describes two intersecting straight lines defined by Eqn.(36), the line AB representing the linear plot of Foster's method [Eqn.(12)]. When $\epsilon^*_B = 0$, the line BC coincides with the abscissa axis and, when $\epsilon^*_B > 0$, it lies above the axis and is responsible for the appearance of anomalous slopes in the graph.

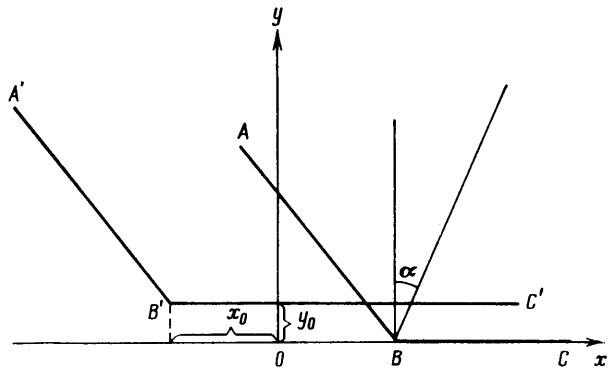

Figure 5. The limiting cases of the equation of the hyperbola [26].

Thus the slopes of the straight lines are influenced by the ratio ϵ^*_B/K. The higher its value (i.e. the higher the value of ϵ^*_B and the lower the value of K) the greater the probability of obtaining lines with an anomalous slope and neither a change in the donor concentration nor in the other experimental conditions yields straight lines with a normal slope. Hence the appearance of anomalous straight lines for weak complexes and the absence of "anomalies" for strong complexes with $K \gg \epsilon^*_B$ becomes understandable. For high values of ϵ^*_B/K, methods taking into account the absorption by the donor [88,112] will not help either, since there is no possibility of an experimental determination of ϵ^*_B. For low values of ϵ^*_B/K and high values of $\epsilon_{AB} - \epsilon_A - \epsilon^*_B$ in a study covering a fairly wide range of donor concentrations, we obtain hyperbolic plots of D/b against D and the stability constant is determined in terms of the tangent of the angle of rotation of the coordinate axes, in accordance with Eqn.(24).

IV. THE RELIABILITY OF THE LITERATURE VALUES OF K AND ϵ

The need to determine K and ϵ, the fundamental characteristics of complex-forming systems, has given rise to publications where the conditions under which the usual methods are applicable are discussed.

Thus Hammond [167,168] examined the influence of experimental errors on K and ϵ obtained when four terms of the Benesi–Hildebrand equation [Eqn.(4)] are used.

$$ab/D = 1/K\varepsilon_{AB} + b/\varepsilon_{AB} \ ; \ (a) \quad b/D = 1/K \cdot \varepsilon_{AB}\ a + b/\varepsilon_{AB}\ a \ ; \ (b)$$
$$a/D = (1/K \cdot \varepsilon_{AB})(1/b) + 1/\varepsilon_{AB} \ ; \ (c) \quad 1/D = (1/K \cdot \varepsilon_{AB}\ a)(1/b) + 1/\varepsilon_{AB}\ a \ (d)$$

The scatter of the points around the straight lines has different effects on K. Thus Eqns.(a) and (b) give rise to a significant scatter for low values of K and Eqn.(c) and (d) give rise to a large scatter for high values of K. This means that, for the same value of a, b, and D, Eqns.(a) and (b) are most suitable when $K < 1$ litre mole^{-1}. Eqn.(d) is suggested for the case where the scatter of the points is caused only by errors in the determination of b and D (a = const.). It has been shown that, when the error in the measurement of D is 1%, the relative error in the determination of K increases from 11% (K = 1 litre mole^{-1}) to 83% (K = 0.10 litre mole^{-1}). The errors in the determination of ϵ are approximately the same; 9 and 81% respectively. The optimal conditions in the determination of K by the Benesi–Hildebrand method are obtained when $5 < K < \epsilon/12$.

In an analysis of the methods described [18,58,86,88], Pearson [163] concluded that reliable stability constants are obtained only when the equilibrium concentration of the complex is of the same order of magnitude as the equilibrium concentration of the dilute component. If the donor and acceptor form 1 : 1 compounds only, then $D_{AB} = \epsilon_{AB} l C_{AB} = \epsilon_{AB} l K C_A C_B$. When $b \gg a$, we have $C_B \simeq b$ and $C_A \simeq a - C_{AB}$.

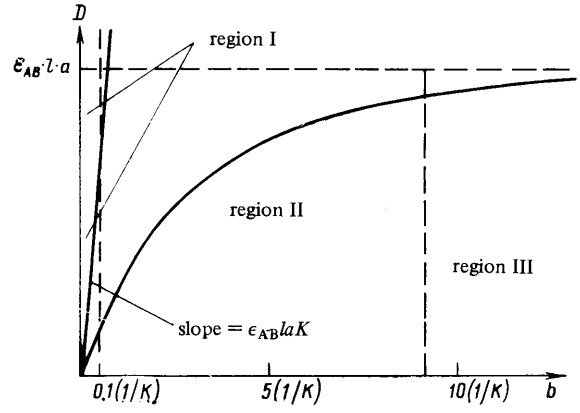

Figure 6. Variation of the absorption of the complex as a function of increasing donor concentration [169].

If a slight excess of the donor is used, the concentration of the complex in solution will be very small, so that $C_A \simeq a$. In this case $D_{AB} = \epsilon_{AB} lKab$ and the absorption by the complex increases linearly with increase of the initial concentration of the donor. On the other hand, in

the presence of a large excess of the donor the entire acceptor is in the complex and the addition of more donor does not alter the optical density.

Fig. 6 shows that the plot of the absorption by the complexes against donor concentration can be divided into three regions. In region I, where the donor concentration is low, the absorption increases linearly. For large values of b, the absorption remains unaltered. Between these two extremes, there is region II where the absorption does not increase linearly with increase of b. It is suggested that measurements should be made in the intermediate concentration range. This range has been determined approximately:

$$0.1a < C_{AB} < 0.9a \text{ or } 0.1(1/K) < b < 9.0(1/K) . \quad (37)$$

From this it follows that a zero slope in the methods of Foster et al.[74] and Scott[86] or a zero Benesi–Hildebrand intercept[18] can be obtained for any complexes, including strong complexes—this depends on the ratio of the donor and acceptor.

Deranleau[168,170] uses the term "saturation fraction" s:

$$s \equiv C_{AB}/a = Kb/(1 + Kb) . \quad (38)$$

The saturation fraction varies in the range $0 \leqslant s \leqslant 1$. For region II (Fig. 6) with $b = 0.1(1/K)$ and $9(1/K)$ the saturation fraction is respectively 0.09 and 0.9; the half-saturation point ($s = 0.5$) occurs when $b = 1/K$. For $b \gg a$, C_{AB} is neglected in Eqn. (38) and an error is introduced into the calculation:

$$(K^1 - K)/K = -sa/b , \quad (39)$$

where K^1 is an approximate value of the constant and K the value calculated from the exact equation.

This error cannot exceed a/b and is always negative[116] whatever the value of s, i.e. K calculated with this approximation is always greater than the correct value. If the errors in a and b are insignificant compared to the error in s, the relative error in K is in practice determined explicitly:

$$\Delta K/K \geqslant \Delta s\,[1/s^2 - 1/(1-s)^2] .$$

The error in ϵ_{AB} is given by the equation

$$\Delta e_{AB}/e_{AB} \geqslant \Delta s \sqrt{2/s} . \quad (40)$$

Eqns. (39)–(40) give the minimum values, but their derivation in a practical experiment is difficult. The relative errors defined by Eqns. (39) and (40) have been plotted as a function of s in Fig. 7. The most accurate values of ϵ_{AB} are obtained when the concentration of the complex is a maximum ($s = 1$), but an adequate accuracy can be achieved above a saturation fraction of 0.2. The correct values of K are obtained when s varies from 0.2 to 0.8. Beyond the limits of this range, the values investigated become indefinite and the error reaches 100% and more.

Deranleau believes that only by measuring 75% of the saturation curve can one asses with certainty the validity of the composition and the parameters of the complex being analysed. Generally speaking, the author reaches this conclusion for weak complexes, but notes that the proposed criterion is suitable for any instance of complex formation.

Table 2 illustrates[134] the employment of the reliability criteria of Pearson[168] and Deranleau[166]. Analysis of the data presented shows that systems with $K > 1$ satisfy Pearson's requirement (37). We shall consider the values of s for the tabulated systems. Complexes of 2-methylnaphthalene with nitro-compounds satisfy Deranleau's criterion, i.e. the measurements are in the region where the errors in K and ϵ_{AB} are minimal. For nitrobenzene–benzene ($K = 0.094$ litre mole^{-1}) and 1,3,5-trinitrobenzene–benzene ($K = 0.184$ litre mole^{-1}) complexes, the optical density measurements do not fall within the region of reliability as defined by Pearson and Deranleau. In measurements on the nitrobenzene–benzene system the donor (benzene) concentration was varied in the range 0.68–1 M, which correspond to the variation of the saturation fraction from 0.06 to 0.09, whereas according to Deranleau's reliability criterion, the benzene concentration should vary in the range from 1.5 to 40 M and according to Pearson's criterion from 1 to 90 M. For complexes with $K < 1$ litre mole^{-1}, it is difficult to reach in practice even the lower limit of reliability, let alone achieve the measurement of 75% of the saturation curve.

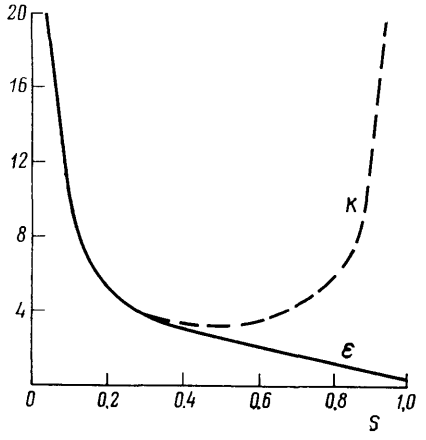

Figure 7. The relative percentage errors 100 $\Delta K/K$ and 100 $\Delta\epsilon/\epsilon$ as a function of s.[166]

The reliability criteria proved to be the most favourable for complexes with stability constants in the range 2–10 litre mole^{-1}. Thus for $K = 2$, 3, 5, and 10 litre mole^{-1}, the concentration ranges are respectively 0.12–2.0, 0.06–1.33, 0.05–0.8, and 0.025–0.40 M. These values are quite realistic for donors and the saturation fraction can be used as a criterion of the reliability of the results for complexes with stability constants in the above range. For complexes with stability constants of the order of 20 litre mole^{-1} and above, other difficulties arise in the choice of concentrations. According to both Pearson and Deranleau, the required donor concentration is so low that it is difficult to select an acceptor concentration satisfying the condition $b \gg a$.

The assessment of the reliability of the results by the Deranleau and Pearson methods is complicated by the fact that, not knowing the stability constant, it is impossible to predict the choice of the concentrations of the component present in excess for a correct determination of the parameters of the complex but, having determined the constant (possibly incorrectly), we will know whether the right concentration range has been used. This uncertainty in the values of K makes it difficult to employ the above reliability criteria.

The criteria have been used[40,54,164], but they have also been criticised. Heric[171] concluded that under certain conditions Pearson's criterion leads to incorrect findings.

Using the principles of mathematical statistics, the author suggests the investigation of groups of points on the Benesi–Hildebrand straight line and not all the points at once. One group includes points differing by not more than two standard deviations from the average Benesi–Hildebrand line fitted by least squares and the other includes the remaining points. Next these groups are divided into subgroups containing points differing along the ordinate by not more than two standard deviations. Similar subgroups are set up also with respect to the abscissae. Next the application of a special statistical table makes it possible, according to the author, to obtain more reliable results than those achieved with the aid of Pearson's criteria.

Table 2. The limits of reliability according to Pearson and Deranleau.

System	$-\Delta K/K$		s		b (after Pearson)	
	min.	max.	min.	max.	min.	max.
m-DNB-2-methylnaphthalene	$0.4\cdot10^{-5}$	$0.22\cdot10^{-3}$	0.08	0.44	$0.37/K$	$0.87/K$
o-DNB-2-methylnaphthalene	$0.5\cdot10^{-4}$	$0.5\cdot10^{-3}$	0.40	0.80	$1.04/K$	$5.2/K$
p-DNB-2-methylnaphthalene	$0.14\cdot10^{-4}$	$0.4\cdot10^{-3}$	0.04	0.32	$0.16/K$	$0.68/K$
1,3,5-TNB-2-methylnaphthalene	$0.25\cdot10^{-4}$	$0.24\cdot10^{-3}$	0.40	0.77	$0.66/K$	$3.32/K$
NB–2-methylnaphthalene	$0.8\cdot10^{-4}$	$0.13\cdot10^{-2}$	0.16	0.52	$0.20/K$	$1.14/K$
NB–benzene	$0.13\cdot10^{-3}$	$0.24\cdot10^{-3}$	0.06	0.09	$0.066/K$	$0.094/K$
1,3,5-TNB–benzene	$0.25\cdot10^{-4}$	$0.21\cdot10^{-3}$	0.05	0.17	$0.062/K$	$0.184/K$

The errors in the determination of K and ϵ have been analysed in studies [172,173] other than those discussed above.

---o0o---

To summarise, one can point out the causes of the anomalies discussed above (the inconsistency between K and ϵ, zero and negative values of K when the complexes absorb strongly, the dependence of K on wavelength, etc.).

1. The calculated stability constants are concentration constants, since the activity coefficients are in most cases totally unknown. This is probably the reason for the dependence of K on the ratio of the donor and acceptor concentrations. There is no doubt that an incorrectly chosen concentration scale also has an effect.

2. The possible failure of the Bouguer–Beer–Lambert Law for the complexes under investigation. If the law holds, then in the presence of a large excess of the donor a linear relation should be observed between the optical density of the complex and the initial acceptor concentration [174].

3. Effect of the solvent, i.e. competition of the solvent with the components in the formation of association complexes. Absolutely inert solvents are known not to exist; moreover, the choice of the inert solvent is affected by the solubilities of the reactants. If the equilibrium constants for the reactions between A and S and between B and S are negligibly small compared with K for the reaction between A and B, the solvent is assumed to be neutral and can be used in the investigation.

4. The absorption by the donor in the acceptor solution, which is usually assumed in practice to be equal to its absorption in the pure solvent. It was shown above that the higher the value of ϵ^*_B/K the greater the probability of a curvature in the Foster, Benesi–Hildebrand, and other plots.

5. The existence of complexes with a higher stoichiometry. As a rule conclusions concerning the existence of 1 : 2, 1 : 3, etc. complexes are speculative or based on Foster, Benesi–Hildebrand, and other plots. To obtain a linear relation between D/b^n and D (Foster's method) when there is a curvature for $n = 1$, one substitutes $n = 2$, 3, etc. until a straight line is obtained. It was shown in Section III that the deviation of Foster's plot from linearity is due to ϵ^*_B; when this is taken into account, the parameters of the 1 : 1 complex can be calculated. An independent determination of the compositions of weak complexes is extremely difficult, but in many cases the application of Job's and Bent and French's methods [171,175] gives good results.

6. The error of the calculations of K and ϵ_{AB}. The few reports where graphs from which K and ϵ were calculated are published [34,40,41,43,62] show that on average not more than five points are used for 2–3 wavelengths. We may recall the non-equivalence of the points corresponding to high and low donor concentrations when methods of the Benesi–Hildebrand type are used. For example, for six consecutive additions the value for the most dilute solution (the least accurate value) will have a statistical weight approximately equal to the statistical weight for the four values corresponding to more concentrated solutions [166]. Experience shows that in such cases the line is drawn on the basis of the two least accurate values (the most dilute solutions). This reduces the probability of detecting the curvature in the graph. The application of the method of least squares without a preliminary analysis of the relation conceals the error in the determination of K and ϵ. When a small number of experimental points are used, no reliability criteria can be of assistance. In the determination of K it is necessary to employ not less than 10–15 points over the longest possible concentration range and the investigation should be carried out over the entire wavelength range where the complex absorbs. The variation of K with the wavelength can be used for an unambiguous determination of the electron-donating component of the donor–acceptor complex [56]. Thus, in publishing K and ϵ values, it is essential to indicate the concentration ranges, the number of experimental points, and the wavelength range in which the study was made.

The employment of published literature values of K and ϵ requires a certain amount of caution. The values of K obtained for a series of donors with a single acceptor and under identical conditions and conversely are valuable. We then obtain an unambiguous answer to the question of the relative stabilities of the complexes and can infer the structure of the association complexes formed. It is interesting to use the relative stabilities K/K_S, [176,177] where K_S is the stability constant of a reference acceptor for a series of donor or of a reference donor for a series of acceptors.

The objective nature of spectrophotometric results can be confirmed by a comparison with the results of fundamentally different techniques (dielectric constant measurements, calorimetry, NMR spectroscopy, etc.).

The Application of Certain Physical Methods in the Study of the Properties of Carborane-12† and Its Derivatives

V.I.Stanko, V.V.Khrapov, and T.A.Babushkina

The review presents the results of the application of various physical methods (X-ray diffraction analysis, electron diffraction, ^{1}H, ^{11}B, and ^{13}C nuclear magnetic resonance, nuclear quadrupoler resonance, nuclear gamma-resonance, and the dipole moment method) in the study of the geometric and electronic structures of the isomers of carborane-12 and a number of its derivatives. The results obtained with the aid of these methods are compared.
The bibliography includes 165 references.

I. INTRODUCTION

In view of the nature of the bonds in which boron and particularly carbon atoms are involved, which is unusual for classical organic chemistry, and the capacity of carboranes to take part in various chemical reactions such as metallation, electrophilic substitution, and others, their chemistry now constitutes one of the most interesting and vigorously developing fields in the chemistry of organic derivatives of the elements.

However, many problems associated with the reactivity and structure, with the transmission of the influence of substituents via the icosahedral skeleton, with the dynamics of structural rearrangements, etc. are still not entirely clear. The difficulty of solving these problems by the methods of classical chemistry are evident. On the other hand, with the aid of a series of physical methods, it is possible to make a significant approach to an understanding of the phenomena associated with the characteristics of the structure and the nature of the bonds in carborane systems.

Bearing in mind the continuous growth of interest in the chemistry of carboranes (the number of publications has now exceeded 500), the fact that the relevant information is scattered in a wide variety of journals, and also the virtual absence of reviews on the application of physical methods in the study of carboranes, it appeared interesting to compile the available information in a single review. The aim of the present review was to give the fullest possible description of the state of research using a series of familiar physical methods. Since the review deals mainly with the thoroughly investigated *closo*-carborane-12, subsequently the prefix "*closo*" will be omitted.

The numbering of the atoms in the icosahedron differs from that which has been proposed and follows the rule that the 2nd atom is linked to the 7th and 8th atoms, the second carbon atom in the isomers corresponding to the 2nd atom for *ortho*-carborane, the 7th atom for *meta*-carborane, and the 12th atom for *para*-carborane‡.

† Dicarba-*closo*-dodecaborane(12) [Ed. of Translation].

‡ *o*-, *m*-, and *p*-Carboranes are 1,2-, 1,7-, and 1,12-dicarba-*closo*-dodecaboranes(12) [Ed. of Translation].

The following abbreviations have been adopted: NMR = nuclear magnetic resonance; NGR = nuclear gamma-resonance [Mössbauer spectroscopy]; CS = chemical shift in NMR spectra; IS = isomer shift in Mössbauer spectra; QS = quadrupole splitting in Mössbauer and NQR spectra; SSIC = spin–spin interaction constant in NMR spectra; LCAO – MO = method of molecular orbitals with linear combination of atomic orbitals; SCF = self-consistent field method; NEMO = non-empirical molecular orbital method; CNDO/2 = method of complete neglect of differential overlap.

Table 1. The bond lengths (Å) in *o*-, *m*-, and *p*-carboranes (according to X-ray and electron diffraction studies).

shows that the results obtained by semi-empirical computational methods are of greatest interest for the experimental chemist.

Certain information concerning the charge distribution on the boron atoms was obtained recently[42] by determining the pK_a or of all possible *B*-carboranols (Table 2). Although the introduction of a hydroxy-group at a boron atom in the carboranes-12 can lead to certain deviations from the charge distribution in the unsubstituted molecules, nevertheless the overall sequence and the calculated charges should be correlated with the changes in the pK_a. Table 2 shows that the charges on the boron atoms calculated theoretically are only of qualitative significance.

IV. DIPOLE MOMENTS

X-Ray diffraction studies on carboranes-12 and their *C*- and *B*-derivatives showed that a nearly icosahedral structure is retained in all the compounds.

The dipole moment method in conjunction with microwave spectroscopic methods (NMR and NQR) yields extremely valuable information about the structures of derivatives of carborane-12 isomers and particularly their *B*-halogeno-derivatives. This method, developed by a number of investigators[43-49], proved to be very convenient for the determination of the positions of the halogen atoms in *o*-, *m*-, and *p*-carboranes. It is based on a comparison of experimental and calculated dipole moments of various isomers of carborane-12, the calculated values being obtained as a rule with allowance for the differences between the B–B and the B–C bond lengths and some distortion of the valence angles. This is caused both by the infringement of the ideal symmetry of the icosahedral skeleton and by some steric hindrance between the hydrogen atoms attached to neighbouring boron atoms (the B–B–Hal angle is 122° instead of the ideal value of 120°). The calculations were based on the following dipole moments of the B–Hal bond: 1.67 D for *o*-carborane and 1.61 D for *m*-carborane. When the molecules of the halogeno-derivatives of *o*- and *m*-carboranes are regarded as ideal icosahedra, the B–Hal dipole moments are 1.59 D for *o*-carborane and 1.58 D for *m*-carborane. Since the dipole moment of *p*-carborane is zero, that of 2-chloro-*p*-carborane should in fact be equal to the B–Cl bond moment. It has been found[47] that the dipole moment of 2-chloro-*p*-carborane is 1.47 D.

Table 3 lists the experimental dipole moments of various carboranes and heterocarboranes-12 and Table 4 gives a compilation of the experimental and calculated dipole moments of a series of *B*-halogenocarboranes. It is interesting to note that, in the presence of boron–halogen and carbon–halogen bonds respectively, the dipole moment is higher and lower than that of unsubstituted carboranes[43]. This is evidence that the carbon and boron atoms form the positive and negative poles of the dipole respectively. All these considerations apply equally to *o*-, *m*-, and *p*-carbaphosphaboranes and carba-arsaboranes[58,59].

In a series of chemical and structural studies[50-53] it has been shown that, in the electrophilic halogenation of *o*-carborane, four halogen atoms enter the boron skeleton. The first and second halogen atoms enter preferentially the 10- and 12-positions, involving to some extent, depending on the halogenation conditions, also the boron atoms in the 9- and 11-positions of the *o*-carborane nucleus[54]. The third and fourth halogen atoms enter the 9- and 11-positions. In electrophilic halogenation two halogen atoms enter the *m*-carborane nucleus in the presence of $Fe(FeX_3)$ and four and more atoms in the presence of $AlCl_3$.[52,54,55] The first and second atoms enter mainly the 9- and 10-positions. The sites of the third and particularly the fourth halogen atoms could not be determined in this case from the number of the isomers formed (the principle first applied to carboranes by Wiesboeck and Hawthorne[56]). This was done with the aid of the dipole moment method and it was shown that one of the isomers has the 3(5, 8, 11), 9, 10-structure and the other the 4(12), 9, 10-structure[44,57].

Table 3. The dipole moments of the isomeric carboranes-12 and their derivatives.

m-Arsacarborane	2.76	59		
p-Arsacarborane	0.5	59		

Thus owing to the geometry of carborane-12, the dipole moment method is an effective procedure for the determination of the site of the substituent in the icosahedral skeleton of the molecule.

V. NMR SPECTROSCOPY

There are two main aspects to the application of nuclear magnetic resonance in the study of carboranes-12: in the study of the electronic properties of the carborane system and in the determination of the structures of newly synthesised compounds.

The elucidation of the electronic properties of carborane systems behaving as substituents and the transmission effects in carboranes are important for the determination of the nature of the bond in polyhedral molecules. Hawthorne et al.[61] investigated the electronic properties of 1,2- and 1,7-dicarbadodecaboranes and determined the σ constants by Taft's method[62] from the ^{19}F chemical shifts of the *m*- and *p*-fluorophenyl derivatives of *o*- and *m*-carboranes. They showed that the negative inductive effect ($-I$) of the *C*-substituted *o*-carbonyl group is close to that for halogens and that its resonance effect in the ground state is close to zero. A smaller inductive effect and a very small resonance (electron-donating) effect are characteristic of the *C*-substituted *m*-carbonyl group. It was found that in cyclohexane $\sigma_I = +0.375 \pm 0.010$ and $+0.194 \pm 0.010$ and $\sigma_R = +0.003 \pm 0.005$ and -0.039 ± 0.05 for the 1,2- and 1,7-carboranyl groups respectively.

Table 4. Comparison of the calculated and experimental dipole moments[44,46,47] of halogeno-derivatives of *o*-, *m*-, and *p*-carboranes.

Compound	μ_{exp}, D	Possible positions of halogen atoms in ring	μ_{calc}, D

B-Decachloro-*m*-carborane	4.39	2,3,4,5,6,7,8, 9,10,11,12	4.41

The difference between the electronic properties of the carborane system depending on the atom involved in the formation of a bond with the fluorophenyl substituent was demonstrated for 1-substituted and 3-substituted *o*-carborane derivatives[63]. It was shown that the chemical shifts of the fluorine atoms relative to fluorobenzene in chloroform are $\delta_p^F = -2.51$ and -2.22 p.p.m. and $\delta_m^F = -2.22$ and -0.35 p.p.m. Hence $\sigma_I = +0.40$ and $+0.13$ and $\sigma_R = +0.01$ and $+0.06$ were calculated for 1-substituted and 3-substituted *o*-carboranes respectively.

The dependence of electronic properties on the type of solvent was also investigated by Taft's method on the basis of the ^{19}F chemical shifts of the 1-*o*-, 3-*o*-, and 1-substituted *m*-carborane derivatives with *m*- and *p*-fluorophenyl substituents[64].

The study of the influence of substituents at the carbon atoms in *o*- and *m*-carborane systems on their electronic properties[65] demonstrated that Taft's method cannot be used to estimate the properties of *C*-substituted *o*-carboranyl groups. This is in all probability due to the specific "cisoid" disposition of the substituent X and the fluorophenyl ring, which leads to a marked dependence of the ^{19}F chemical shifts on the magnetic anisotropy of the substituent. The influence of the unusual "*ortho*-effect" was also noted in the ^{35}Cl NQR spectra of 1-CH_2Cl-2-X-*o*-carboranes[66].

The most complete investigation of the electronic properties of carborane systems, their anions, and metallocarboranes was made by Adler and Hawthorne[67]. They give a kind of compilation of the available data on the electronic properties of carborane molecules. They note that the $-I$ effect for *C*-substituted *o*-carboranes is greater than for *m*-carboranes. The decrease of σ_I for 3-substituted *o*-carboranes (almost to zero) confirms that the transmission of the electrostatic Coulombic effect of carbon atoms diminishes fairly rapidly with distance. Carboranes with substituents at the boron atoms furthest away from the carbon atoms should have an appreciable $+I$ effect.

A second important problem involved in the understanding of the nature of the bond in carboranes is that of the transmission of the electronic influence of substituents via the carborane nucleus. An attempt was made to solve it[68] by investigating methylmercuri-derivatives of *o*- and *m*-carboranes, namely 1,7-R-$CB_{10}H_{10}$.CHgMe and 1,2-R-$CB_{10}H_{10}$CHgMe. The HgMe group served in this case as an indicator of the influence of the substituent characterised by the spin–spin interaction constant $J_{^{199}Hg-C-^1H}$. It was shown that, depending on R, $J_{^{199}Hg-C-^1H}$ in *o*-carborane varies very significantly (137.2–149.0 Hz in CCl_4). In *m*-carboranes the influence of R is greatly reduced: in weakly solvating solvents $J_{^{199}Hg-C-^1H}$ remains constant within the limits of the error of the measurements (135.9–136.3 Hz in CCl_4). For *o*-carboranes in highly solvating solvents (dioxane, pyridine, dimethyl sulphoxide) and CH_2Cl_2, a satisfactory correlation

$$J^R_{Hg-Me} = J^0_{Hg-Me} + m\sigma^*$$

was found for all R, except R = $PhCH_2$, $MeOCH_2$, or H. For these substituents R, the authors[68] suggest an intramolecular coordination. The above relations indicate a change in the shape of the electron cloud in the Hg–Me bond as a function of the inductive properties of the substituent R. Unfortunately the transmission of effects by the *o*-carborane nucleus ($C_2B_{10}H_{10}$) is difficult to assess from these results, since they reflect the transmission through the *o*-R–C–$B_{10}H_{10}$–C–Hg–Me system only.

Table 5. The ^1H chemical shifts in the spectra of *C*-monosubstituted *o*-, *m*-, and *p*-carboranes in carbon tetrachloride relative to HMDS*.[69,70]

* Possibly hexamethyldisiloxane [Ed. of Translation].

Evidently direct information about the transmission of effects through carborane nuclei can be obtained in studies on the chemical shifts of the protons in the C–H bond with different R at the second carbon atom[69] (Table 5). The introduction of a halogen atom at one of the carbon atoms in *o*-carborane causes a shift of the signal due to the proton in the C–H bond involving the second atom to a lower field,

the chemical shifts varying in parallel with the σ* constants of the halogens (Table 5), which reflect the variation of their electron-accepting properties. In *C*-halogeno-substituted *p*-carboranes, whose carbon atoms are located at the opposite corners of the icosahedron, the C–H proton chemical shifts and the σ* constants of the halogen atoms were found to vary in opposition.

The transmission of effects through icosahedral molecules containing three-centre bonds is difficult to describe in terms which are at present generally accepted; nevertheless the variation of the chemical shifts of the C–H protons in *C*-monohalogeno-substituted *o*- and *p*-carboranes indicates two opposed effects of the halogen atoms on the electron density at the second carbon atom. For *C*-halogeno-substituted *m*-carboranes, these effects cancel out to such an extent that the chemical shift of the C–H proton hardly changes regardless of the nature of the halogen.

The introduction of substituents into the carborane ring at the boron atoms alters the chemical shifts of the C–H protons and the form of the ^{1}H NMR spectra[70]. Thus a doublet structure associated with the non-equivalence of the C–H bonds is observed in the spectra of *10*-monosubstituted *o*-carboranes and also of the spectra of *B*-substituted *m*- and *p*-carboranes permits conclusions concerning the symmetry of the molecules of these compounds. The appreciable change in the C–H proton chemical shifts is evidence for a ready transmission of the effect of the substituent in carborane nuclei (Table 6).

Table 6. The chemical shifts of the protons in the C–H bonds of *B*-substituted *o*-, *m*-, and *p*-carboranes[69,70].

* Tetramethylsilane [Ed. of Translation].

Hitherto all that has been said referred to the ^{1}H NMR of the protons linked to the carbon atoms in the carborane system. Fairly numerous studies have been made on ^{11}B NMR and ^{1}H NMR of the protons linked to the boron atoms[14,36,69,71-79]. In most of these investigations the second aspect of the problem was solved—the determination of the structure of newly synthesised compounds.

The ^{1}H NMR spectra of the protons linked to boron atoms are always greatly complicated both by quadrupole broadening (owing to the nuclear quadrupole moment of ^{11}B) and by the ^{1}H–^{11}B spin–spin interaction. The ^{1}H NMR spectra are greatly simplified when ^{1}H–{^{11}B} heteronuclear resonance is employed with the application of the frequency at the resonance value for ^{11}B. The chemical shifts of the protons at the boron atoms and also the spin–spin interaction constants $J_{^{11}B-^1H}$ for *o*-, *m*-, and *p*-carboranes and their organotin derivatives have been determined[69] (Table 7).

The difficulties associated with the employment of ^{11}B NMR spectroscopy are due mainly to two causes: (1) the broadening of the NMR line owing to the quadrupole moment of the ^{11}B nucleus and (2) due to the fact that in the usually employed NMR spectrometers (frequencies of 19, 124, and 32.08 MHz) the spin–spin interaction constants $J_{^{11}B-^1H}$ are of the same order of magnitude as the ^{11}B chemical shift. This hinders the assignment of the ^{11}B frequencies to the structurally non-equivalent boron atoms in the complex molecules of carboranes and their derivatives. The method of ^{11}B–{^{1}H} heteroresonance has been used recently in the study of the ^{11}B NMR spectra in conjunction with a noise generator to suppress the ^{11}B–^{1}H spin–spin interaction.

Table 7. The chemical shifts of the protons at the boron and carbon atoms in certain carboranes[69].

* Tetramethylsilane (Ed. of Translation).

Some of the results of the authors of the review (see Refs. 71 and 79) for ^{11}B NMR of carborane-12 isomers and a number of its derivatives are presented in Table 8. On the basis of the structure of the carborane-12 isomers, it is possible to postulate the number of equal-intensity lines which should comprise the ^{11}B–{^{1}H} NMR spectrum of the given compound. Thus in the spectra of unsubstituted *o*- and *m*-carboranes there are four types of structurally non-equivalent boron atoms and in the ^{11}B–{^{1}H} NMR spectra of each of these compounds there should be four lines with the intensity ratios 2 : 4 : 2 : 2, which is in fact observed experimentally. Since all the boron atoms in *p*-carborane are equivalent, the ^{11}B–{^{1}H} spectrum of this compound consists of one line. The ^{11}B–{^{1}H} spectra of 2-halogeno-*p*-carboranes and 10-halogeno-*o*-carboranes should consist of six lines with the intensity ratios 2 : 2 : 2 : 2 : 1 : 1 and the spectra of 9-halogeno-*m*-carboranes should consist of seven lines with the intensity ratios 2 : 2 : 2 : 1 : 1 : 1 : 1. Although Table 8 shows that the

* Assignment not determined. For explanation, see text.

experimental spectra differ from the theoretical spectra both as regards the number of lines and their intensities (owing to the overlapping of lines with close chemical shifts), nevertheless the results[79] permit the assignment of the lines in the ^{11}B NMR spectrum of each compound. This assignment is unambiguous for *B*-monohalogeno-derivatives of *o*- and *p*-carboranes, although there are certain difficulties for the analogous *m*-carborane derivatives. Thus the assignment of the lines in the spectra of 9-halogeno-*m*-carboranes for the B(5, 11) and B(3, 8) atoms and also for B(2) and B(6) is fairly difficult without additional data and the ^{11}B chemical shifts quoted in Table 8 for these groups may have to be interchanged.

The application of ^{13}C NMR in the study of carboranes is so far extremely limited. There have been only two communications[80,81] on the ^{13}C NMR chemical shifts of carborane isomers and some of their analogues (Table 9). Presumably the ^{11}B and ^{13}C chemical shifts in similar chemical environments are influenced by the same factors. It was noted that on substitution the change in the chemical shifts of these nuclei in carboranes is in the same direction.

The observation of ^{31}P NMR spectra of carbaphospha-dodecaborane derivatives[82] has been only mentioned.

Hitherto we have spoken of high-resolution NMR spectra for the nuclei of various atoms forming the carborane skeleton. The application of broad-line NMR and the spin–echo method, which permit the investigation of the geometry of relative positions, molecular mobility, exchange processes, and the dynamics of the motions in solids, are extremely promising. Only one study has been published[83] in which broad-line NMR was used in conjunction with calorimetric and X-ray diffraction data in the study of molecular mobility in crystalline *o*- and *m*-carboranes. All the results support the view that the reorientational disorder in crystalline carboranes has a kinetic basis. A phase transition was observed in the *o*-isomer at 4.0° ± 3.0°C. The measurement of the second moments of the proton lines in the NMR spectra of carborane isomers as a function of temperature showed that molecular reorientational motions occur down to −130°C. It is difficult to overestimate the value of these first experimental data, which lead to new fields in the study of the characteristics of the crystal structures of carboranes and to the understanding of the dynamics of the molecular motions in solids.

VI. NQR SPECTROSCOPY

NQR data constitute a completely new type of information about molecular structures and permit the determination of the type of electron distribution in space near the nucleus of the given atom.

Although the nuclei of the boron atoms forming the carborane skeleton do have quadrupole moments, purely NQR studies have been made not on boron nuclei (owing to experimental difficulties) but on halogen nuclei (^{35}Cl, ^{79}Br, and ^{127}I) in various derivatives of *o*-, *m*-, and *p*-carboranes[53,84-92] (Table 10). ^{35}Cl and ^{79}Br NQR spectroscopy was applied to halogenocarboranes for the first time[84] in 1965 to elucidate the nature of the carborane nucleus as a substituent in the systems *o*-

$HCB_{10}H_{10}C-C_6H_4-Y$ and *o*-$HCB_{10}H_{10}C-(CH_2)_nCl$ (I), where

$n = 1, 2, 3, 4 \ldots$ (series I) and to investigate the transmission of effects via the carborane nucleus in the system *o*-$Y-CH_2C_2B_{10}H_{10}CH_2-Y$ (II) (series II, Y = Cl or Br).

Table 9. ^{13}C chemical shifts of certain carboranes in acetone[80,81].

Compound	^{13}C chemical shifts relative to CS_2, p.p.m.	Compound	^{13}C chemical shifts relative to CS_2, p.p.m.
1,2-$B_{10}C_2H_{12}$	137.3	1,7-$Me_3SiCB_{10}H_{10}CSiMe_3$	125.4
1,7-$B_{10}C_2H_{12}$	137.4	1,7-$MeSCB_{10}H_{10}CSMe$	120.1
1,7-$B_{10}C_2Br_2H_{10}$—9,10-dibromo	139.7	1,12-$B_{10}C_2H_{12}$	129.3

It was found that the *o*-carborane system exhibits powerful electron-accepting properties, occupying an intermediate place between the NO_2 and COOH groups. The Hammett σ constant for the *o*-carboranyl substituent was estimated from the NQR frequencies as 0.4 ± 0.2, which agrees well with the estimates of the σ_I and σ_R constants from NMR spectra. The decay coefficient for the transmission of the effect of a substituent X in a chain consisting of methylene groups in series I (see above) has also been determined[84] and found to be 0.44 ± 0.01. The study of the transmission of effects through the carborane nucleus itself by comparing the ^{35}Cl NQR frequencies in series II for Y = Cl and in series I for $n = 1$ with the frequencies for $ClCH_2-C\equiv C-CH_2Cl$ and $HC\equiv C-CH_2Cl$ showed that the carbon atoms in the carborane ring do transmit effects. The powerful electron-accepting properties of the $CH_2-C_2B_{10}H_{11}$ and $Ph-C_2B_{10}H_{10}$ substituents follow also from the investigation of the 79Br and ^{81}Br NQR of the corresponding halogen-containing organomercury compounds[88]. Comparison of the ^{35}Cl and ^{127}I frequencies of 2-halogeno-*p*-carboranes, 9-halogeno-*m*-carboranes, and 10-halogeno-*o*-carboranes[86,87] showed that the polarity of the boron–halogen bond decreases in the series *o*-carborane > *m*-carborane > *p*-carborane, which is consistent with the variation of the reactivity of these isomers.

A number of studies have been made[66,90-93] on the ^{35}Cl NQR spectra of the *o*-$XC-B_{10}H_{10}-C-CH_2Cl$ system, where X = H, $ClCH_2$, Et, Me, SMe, HS, $SiMe_3$, MeOOC, NH_2CO, MeHg, Cl, Br, I, Ph, ClCO, or COOEt.

To elucidate the transmission of the effects of substituents in this system, the entire set of ^{35}Cl NQR data were examined[66]. Problems of this kind are usually solved by establishing a correlation between the changes in the characteristics investigated in the given method (NQR frequency, chemical shift, or the spin–spin interaction constant for NMR, etc.) and the Taft–Hammett constants of the substituents in the given series of molecules. It has been shown[66] that in the *o*-$X-C-B_{10}H_{10}C-CH_2Cl$ system the two-parameter correlation of the ^{35}Cl NQR frequencies with the σ constants of the substituents is absent as well as the one-parameter correlation. This is probably evidence for the important role of the steric factors due to the specific disposition of the substituent and the CH_2Cl group, which are in the cisoid positions relative to one another in the *o*-carborane system (a kind of *"ortho"* effect). It appears evident that in the study of the transmission of the electronic influence of substituents in the *o*-carborane series there is no point in subdividing the substituents in accordance with the type of the electronic effect (this was attempted, for example, by Voronkov et al.[91]), since steric interactions are of decisive importance in the behaviour of both NQR frequencies and the NMR chemical shifts in these systems.

NQR spectroscopy is one of the physical methods for the determination of the structural characteristics, identification, and determination of the purity[53,85,86] of the *B*-halogenocarboranes-12 which have been synthesised. Thus it has been shown by ^{35}Cl NMR spectroscopy that the monochloro-derivatives of *o*-, *m*-, and *p*-carboranes are individual compounds and not mixtures of structural isomers, i.e. they are respectively 10-chloro-*o*-carborane, 9-chloro-*m*-carborane, and 2-chloro-*p*-carborane. Similar conclusions concerning the structures of the isomers have been reached[85] for di-, tetra-, octa-, and decachloro-derivatives of *o*- and *m*-carboranes. It is interesting to note that the ^{35}Cl NQR spectrum of 9, 10, 11, 12-tetrachloro-*o*-carborane consists of two doublets, the difference between the average frequencies of which gives a clear idea about the differences between the electron densities in the 10, 12- and 9, 11-positions. The higher frequency is due to the chlorine atoms in the 9- and 11-positions. This finding agrees with the postulated sequence of the electrophilic halogenation of *o*-carborane. The complex structure of the ^{35}Cl NQR spectra of the decachloro-derivatives of *o*- and *m*-carboranes suggests that the molecules of these substances do not have the ideal icosahedral structure[85,89,90]. Broad ^{35}Cl NQR lines are characteristic of decachloro-*o*-carborane, while in the ^{35}Cl NQR spectrum of decachloro-*m*-carborane there are narrow lines, which suggest a high degree of order in its crystals. The presence of an asymmetric broad line[85] in the ^{35}Cl NQR spectrum of 4(12), 9, 10-trichloro-*m*-carborane is evidence for a slight difference between the ^{35}Cl NQR frequencies of the chlorine atoms in the 9- and 10-positions on the one hand and in the 4(12)-position on the other and may be caused by a statistical disorder in the distribution of molecules in the crystals of this substance.

VII. MÖSSBAUER SPECTROSCOPY

Like NQR spectroscopy, the nuclear gamma-resonance method, based on the Mössbauer effect[94,95] and widely used in studies on properties of various compounds[96,97], has been applied to the study of the nature of the bonds between carbon and elements having Mössbauer nuclei. Studies on the ^{119}Sn Mössbauer spectra of organotin derivatives of carboranes[93,98] (Table 11) showed that the *o*-, *m*-, and *p*-carboranyl groups have a greater electron-accepting effect in relation to the tin atom than all the organic substituents investigated hitherto by this procedure. Comparison of the ^{119}Sn Mössbauer parameters of the Et_3Sn derivatives of *o*-, *m*-, and *p*-carboranes as well as other organotin

* The difference between the spectra quoted by Bryukhova et al.[85] and Smith and Tong[89] is that the signal obtained by the former investigators[85] at 25 050 MHz was resolved by Smith and Tong[89] into two lines at 25 043 and 25 050 MHz.

derivatives shows[93] that in the tin compounds the electron-accepting properties of *o*- and *m*-carboranes exceed those of the C_6F_5, C_6Cl_5, CF_3, C≡CH, and C≡CMe groups and are close to those of the C≡C–Cl, C≡C–Br, and C≡C–Ph groups, while the electronegativity of *p*-carborane is close to that of the C≡C–Me group. In turn, the electron-accepting properties of the carborane isomers vary in the sequence *ortho* > *meta* > *para*, which is consistent with the reactivities of these carborane isomers and with the NQR data (see above).

It is interesting to note a significant difference between the spectra of phenyl-*o*-carboranyltriphenyltin and *o*-carboranyltriphenyltin[98] (Table 11). The difference between the Mössbauer parameters of these compounds cannot be explained from the standpoint of the usual concept of the inductive effect. It is difficult to suppose that the higher electron-accepting capacity of the phenyl-*o*-carboranyl residue compared with the *o*-carboranyl residue is due to the electron-accepting effect of the phenyl group, which

cannot be so large. Possibly the reason for the difference is a specific interaction of the electron systems of the *o*-carborane and benzene rings.

Mössbauer spectroscopy has been used to identify and investigate the electronic structures of new carboranyl derivatives of the elements. Thus it has been shown[98] that ^{119}Sn Mössbauer spectroscopic data provide direct evidence that bis(phenyl-*o*-carboranyl)tin (Ph–$C_2B_{10}H_{10}$)$_2$Sn contains bivalent tin and is the first example of true organic derivatives of bivalent tin. By measuring the Mössbauer spectra of this substance as a function of time and the presence of oxygen, it is possible, in principle, to investigate the kinetics and mechanism of the polymerisation and oxidation of compounds of this kind. A study of the *B*-iodocarborane derivatives labelled with the ^{125}I radioactive isotope by ^{125}I Mössbauer emission spectroscopy showed[99] that the radioactive breakdown of ^{125}I results in the formation of carboranyl derivatives of tellurium which are isoelectronic with the corresponding iodine compounds. The linear relation[100] between e^2Qq derived from ^{127}I NQR and ^{125}Te Mössbauer spectra: $e^2Qq_{^{125}Te} = 0.60e^2Qq_{^{127}I} - 492.3$ M Hz (with a correlation coefficient of 0.983) confirms the hypothesis that the radioactive breakdown of ^{125}I in the matrices of *B*-iodo-derivatives of *o*-, *m*-, and *p*-carboranes does indeed result in the formation of tellurium derivatives[99,100].

VIII. COMPARISON OF THE RESULTS OF VARIOUS PHYSICAL METHODS

It is quite evident that, for a detailed investigation of the electronic properties of carborane systems, it is necessary to adduce and compare the results obtained with the aid of different methods. Consideration of the entire set of different physical methods (NMR, NQR, and Mössbauer spectroscopy) already permits an assessment of the electron-accepting properties of carborane isomers, which vary in the sequence

ortho > *meta* > *para*.

It is interesting to note that the spin–spin interaction constant $J_{^{119}Sn\text{-}Me}$ (from the NMR spectra) and the isomeric shifts and quadrupole splittings in the ^{119}Sn Mössbauer spectra of organotin derivatives of carboranes also vary consistently in the same sequence.

If it is supposed that the Grant–Litchman model[101] proposed for the spin–spin interaction constant $J_{^{13}C\text{-}H}$ is valid also for $J_{^{119}Sn\text{-}Me}$, then the expression for $J_{^{119}Sn\text{-}Me}$ may be written in the form

$$J_{(k)} = \frac{\Delta_{ref}}{\Delta_k}\left(\frac{N_k}{N_{ref}}\right)^2\left(\frac{\alpha_k}{\alpha_{ref}}\right)^2\left(\frac{Z_k}{Z_{ref}}\right)^3 J_{ref.}\ , \qquad (1)$$

where $J_{(k)}$ is the constant $J_{^{119}Sn\text{-}Me}$ for the kth Sn–Me bond, $J_{(ref)}$ is the constant $J_{^{119}Sn\text{-}Me}$ for the compound chosen as the standard, Δ is the average excitation energy, N are normalised coupling constants, α is a quantity proportional to the amount of s character of the bond, and Z is the effective nuclear charge, which can be written in the following form for the 5s orbital of the tin atom:

$$(Z_k/a_0)^{3/2} = (A + Bzr + Cz^2r^2 + Dz^3r^3 + Ez^4r^4)e^{z\cdot r/5}\ , \qquad (2)$$

where α_0 is the first Bohr radius and r the radius of the 5s orbital of the tin atom. The ratios Δ_{ref}/Δ_k and $(\alpha_k/\alpha_{ref})^2$ may be assumed to be unity[102]. On the other hand, the isomer shift for the tin compound is defined by the relation

$$IS = A\cdot\frac{\Delta R}{R}\{|\psi_{5s}(0)|^2_{abs} - |\psi_{5s}(0)|^2_{source}\}\ , \qquad (3)$$

where A and $\Delta R/R$ are constants and the $|\psi_{5S}(0)|^2$ are the 5s-electron densities for the absorber and source of the resonance γ-quanta.

The isomer shift as well as Z^3 (see chapter I of the monograph of Goldanskii and Herber[102]) are proportional to $|\psi_{5S}(0)|^2$, i.e. the isomer shift can be substituted for Z^3 in Eqn. (1) and we obtain

$$J_{(k)} = \frac{\Delta_{ref}}{\Delta_k}\left(\frac{N_k}{N_{ref}}\right)^2\left(\frac{\alpha_k}{\alpha_{ref}}\right)^2\left(\frac{IS_k}{IS_{ref}}\right) J_{(ref)}. \qquad (4)$$

Thus, when there is a linear relation between $J_{^{119}Sn\text{-}Me}$ and the isomer shift for a series of organotin compounds, one can assume that the effective nuclear charge model is valid in this case. Such a relation has been observed[69].

The increase of $J_{^{119}Sn\text{-}Me}$ for a given class of compounds on passing from triethylstannyl derivatives of *p*-carborane to those of *o*- and *m*-carboranes is probably associated with the increase of the 5s-electron density at the tin atom in this series. A similar behaviour obtains also in the trimethylstannyl derivatives of the carborane-12 isomers.

The quadrupole splittings by ^{119}Sn in the spectra of organotin derivatives of carboranes vary in the sequence of the *ortho*-, *meta*-, and *para*-compounds in parallel with the reactivity and the values of $J_{^{119}Sn\text{-}Me}$ and pKa.[63,93] This finding can be explained by a change in the electron populations of the 5p orbitals of tin owing to interaction with the many-centre orbitals of the bonds in the C_2B_{10} icosahedron. In this case the decrease of the screening of the 5s electrons by 5p electrons[103], leading to an increase of the 5s-electron density at the ^{119}Sn nucleus, reflects the electron-accepting properties of the carborane nuclei. Linear relations are observed also between the parameters of organotin derivatives of carboranes, namely between $J_{^{119}Sn\text{-}Me}$ and the isomer shift, between the quadrupole splitting and the isomer shift, and between the

quadrupole splitting and pK_a; there is also a linear relation between ^{127}I eQq_{zz} and the ^{35}Cl NQR frequency for *B*-halogeno-derivatives of *o*-, *m*-, and *p*-carboranes [87]. The latter can be written in the form

$$eQq_{zz}(^{127}\mathrm{I}) = \{-638.7 + 83.3\nu(^{35}\mathrm{Cl})\}\ \mathrm{MHz}. \quad (5)$$

This suggests that the asymmetry parameters of *o*-, *m*-, and *p*-*B*-monochlorocarboranes are small as for *B*-monoiodocarboranes. On the other hand, comparison of the electric field gradients along the axis of the B–Hal bond in monohalogenocarboranes showed [87] that the gradients along the bond involving the iodine atom are somewhat higher than for the chlorine atom. This is probably due to certain differences between the polarisations of the boron–iodine and boron–chlorine bonds in carboranes.

It follows from the ^{11}B NMR spectra of monohalogeno-substituted isomers of carborane-12 [79] that the chemical shifts of the boron atoms to which the halogen (chlorine, bromine, and iodine) is attached vary in the sequence *para* > *meta* > *ortho* (Table 8). Whereas the ^{11}B NMR data for the isomeric monochloro- and monobromo-carboranes suggest the descreening of the boron atom to which the halogen is attached, in the spectra of the isomeric iodo-derivatives of carborane-12 the signal of the same boron atom undergoes a shift to a higher field (relative to the chemical shifts of the unsubstituted carborane-12 isomers).

On the basis of the general theory of chemical shifts, the screening of nuclei (for which NMR is observed) depends on the ratios of three contributions:

$$\sigma = \sigma_{dia} + \sigma_{para} + \sigma', \quad (6)$$

where σ_{dia} is the diamagnetic screening of the given nucleus, σ_{para} is the paramagnetic contribution to the screening, and σ' is a term which includes the screening due to the other atoms in the given molecule.

The contribution of σ' depends on the anisotropy of the magnetic susceptibilities of the groups of atoms in the molecule remote from the nucleus under consideration. It has been shown [104] that for heavy nuclei, including ^{11}B, σ' amounts in most cases to only several per cent of the observed shift. Therefore in the consideration of the ^{11}B chemical shifts the σ' contribution may be neglected. Moreover a number of investigators have shown [104-106] for ^{13}C and other heavy atoms that the diamagnetic contribution σ_{dia} is usually small and also can be neglected in the interpretation of the chemical shift. For this reason, the paramagnetic term gives the main contribution to the chemical shifts of heavy atoms. In this connection mention should be made of the study by Lipscomb and coworkers [75], who estimated the extent of the diamagnetic and paramagnetic screening for *o*-, *m*-, and *p*-carboranes. The estimates were carried out under the following conditions. The constancy of the average energy for the entire series was assumed. The electrons in the 2*p* orbitals of both the nucleus under consideration and in the bonds involving all other atoms were taken into account. The diamagnetic screening, averaged over all orientations, was calculated from the formula [105]

$$\sigma_{dia} = \alpha/3 \sum_{n=1}^{m} \sum_{b=1}^{m} P_{ab} \langle r^{-1} \rangle_{ab}, \quad (7)$$

where P_{ab} are the elements of the usual charge matrix with respect to all the orbitals *a* and *b* of the centre *A*. The corresponding expression for the paramagnetic screening is

$$\sigma_{para} = -\frac{\alpha^2}{2\Delta E} \langle r^{-3} \rangle_{2p} \left(Q_{AA} + \sum_{A \neq B} Q_{AB} \right) = -\frac{19{,}5}{\Delta E} \left(Q_{AA} + \sum_{A \neq B} Q_{AB} \right). \quad (8)$$

where

$$Q_{AA} = 4/3 [(P_{X_A X_A} + P_{Y_A Y_A} + P_{Z_A Z_A}) - 1/2 (P_{X_A X_A} P_{Y_A Y_A} + P_{Z_A Z_A} P_{Y_A Y_A} + P_{Z_A Z_A} P_{X_A X_A}) + 1/2 (P^2_{X_A Y_A} + P^2_{Y_A Z_A} + P^2_{Z_A X_A})], \quad (9)$$

$$Q_{AB} = 2/3 [-(P_{X_A X_B} P_{Y_A Y_B} + P_{Y_A Y_B} P_{Z_A Z_B} + P_{Z_A Z_B} P_{X_A X_B}) + (P_{X_A Y_B} P_{Y_A X_B} + P_{Y_A Z_B} P_{Z_A Y_B} + P_{Z_A X_B} P_{X_A Z_B})], \quad (10)$$

α is the fine structure constant and $\langle r^{-3} \rangle_{2p} = K^3/3$ is the one-centre integral, K being the Slater 2*p* exponent of the boron atom.

Using the diborane and ethane data [107] obtained by the SCF method for the calculation of the borohydride wave functions, Lipscomb and coworkers [75] calculated Q_{AA}, ΣQ_{AB}, and σ_{dia} for the non-equivalent atoms in all three carborane isomers. It was found that the observed chemical shifts, corrected for the diamagnetic shift ($\delta = \delta_{obs} - \delta_{dia}$), are satisfactorily correlated with the sum $Q_{AA} + \Sigma Q_{AB}$. The changes in σ_{dia} on passing from one atom to another are small (Table 12).

Table 12.

Carborane		Q_{AA}	Q_{AB}	σ_{dia}	δ, p.p.m.	
					obs.	calc.
ortho-	B3 3*	1.211	0.123	187.8	15.2	16.7

	B9 8	1.300	0.131	190.0	9.9	7.4
	B10 9	1.300	0.136	190.0	2.7	6.8
meta-	B2 2	1.197	0.123	187.6	17 3	18.2
	B3 4	1.251	0.127	188.8	13.6	12.5
	B4 5	1.252	0.131	188.8	11.0	11.9
	B9 9	1.301	0.132	190.0	7.0	7.2
para-	B2	1.251	0.128	188.8	15.2	12.5

* The numbering is based on the data of Lipscomb and coworkers [75] and the ^{11}B shifts are quoted relative to $Et_2O.BF_3$.

The calculation reflects satisfactorily the effects of the nearest adjacent carbon atom but the influence of the carbon atom is inadequately reflected in calculations on remote boron atoms [cf. B(9) and B(10) in *o*-carborane]. Thus the chemical shifts of the boron atoms in icosahedral carboranes vary mainly owing to the variation of the paramagnetic screening of the boron atoms in different chemical environments. LCAO-MO calculations have shown [108] that the paramagnetic screening can also be formulated by the expression

$$\sigma_{para} = -2/3 (e^2h^2/m^2c^2)(1/\Delta E) \langle 1/r^3 \rangle_{2p} \cdot P_u, \quad (11)$$

where ΔE is the average electronic excitation energy for the molecule or ion, r the radius of the 2*p*-electron orbital (in ^{11}B), and P_u a quantity which reflects the electron populations of the 2*p* orbitals, and is proportional to the number of unbalanced *p* electrons.

Thus the degree of descreening of ^{11}B nuclei must depend on the number of unbalanced *p* electrons. It is also known that the NQR frequencies ν and the electric field gradients eQq_{zz} at the halogen nuclei are directly proportional to the number U_p of unbalanced *p* electrons. According to the Townes–Dailey theory [108], under these

conditions the number of unbalanced p electrons responsible for the electric field gradient at the halogen nuclei is defined by the expression

$$U_P = \frac{N_x + N_y}{2} - N_z, \qquad (12)$$

where N_x, N_y, and N_z are the electron populations of the P_x, P_y, and P_z orbitals of the halogens.

Hence it is reasonable to compare the ^{11}B chemical shift data for the atoms involved in the boron–halogen bond[79] with ^{35}Cl and ^{127}I NQR spectroscopic data for a series of B-halogeno-derivatives of o-, m-, and p-carboranes[86,87]. Since atoms involved in the same bond are considered, the change in U_p for halogen atoms will reflect the change in the number of the unbalanced $2p$ electrons of the corresponding boron atoms.

Comparison of ^{11}B NMR and ^{35}Cl and ^{127}I NQR data shows[79] that, with increase of the number of unbalanced p electrons in the halogen atoms, i.e. with decrease of the number of unbalanced $2p$ electrons in boron, the chemical shifts in the ^{11}B spectra increase. The results confirm that the main contribution to changes in the chemical shifts of the ^{11}B nuclei comes from the paramagnetic term. On the basis of a comparison of ^{11}B NMR and ^{35}Cl and ^{127}I NQR data, Babushkina et al.[79] also postulated that the ^{11}B chemical shifts for the boron atom in carborane-12 linked to halogens should be greatly influenced by the effect of the lone electron pair of the halogen, which causes a high-field shift of the NMR signal due to the boron atom linked to iodine, relative to those of the atom linked to bromine and chlorine.

We shall restrict to these examples the comparison of the results of various physical methods used in the study of the isomers of carborane and its derivatives, assuming that an increase in the number of correlations of this kind will not only make it possible to estimate certain quantities from the results of different investigations but will also allow a new approach to the study of the electronic properties of carborane-12 isomers.

Organoarsenic Compounds of the Acetylene Series

I.N.Azerbaev, Z.A.Abramova, and Yu.G.Bosyakov

The review gives a systematic account of the literature on the methods of preparation and certain physical and chemical properties of acetylene derivatives of arsenic.
The bibliography includes 46 references.

CONTENTS

I. Introduction 657
II. Methods of synthesis 657
III. Chemical properties 661

I. INTRODUCTION

Although the syntheses of acetylene derivatives of arsenic were first mentioned in 1921 [1] and 1923, [2] the main studies in this field were made in the last 10–15 years. Fairly complete reviews have now been published [3,4], but these are concerned only with α-ethynyl derivatives of arsenic and cover the literature up to 1967.

The methods of synthesis of acetylene derivatives of Group III–V elements are discussed by Davidson and Henry [3], who also examine the chemical properties of organoarsenic acetylene derivatives and compare them with other organic derivatives of the elements.

Apart from a brief discussion of the chemical properties, Cadiot and Chodkiewicz [4] quote infrared, NMR, and ultraviolet frequencies for certain organoarsenic acetylene derivatives.

In the present review, the first published in the USSR on this subject, an attempt is made to give a systematic account of the methods of synthesis of ethynyl organoarsenic compounds and of the types of their chemical reactions. Data published up to November 1973 and embracing organoarsenic acetylene derivatives in which the ethynyl groups are in the α- and other positions [5-10] relative to the arsenic atom were used.

Continuing the traditional review format [3,4], the authors have presented data on the methods of synthesis and certain physical properties of these compounds (including infrared, ultraviolet and NMR spectroscopic data), in the form of compilations in Tables.

II. METHODS OF SYNTHESIS

Direct and Indirect Ethynylation of Organosilicon Compounds

The commonest method of synthesising organoarsenic acetylene derivatives (OAAD) involves the interaction of organoarsenic halides with ethynyl derivatives of Group I, II, and IV metals.

In contrast to the syntheses in the series of carbochain and organophosphorus acetylenes, sodium and lithium acetylides have not found an extensive application in the OAAD synthesis. It was discovered that the reactions carried out in liquid ammonia (method 1a, Table 1) are much less effective than in oxygen-containing solvate-forming solvents (method 1b)—tetrahydrofuran (THF), [10,11] ether [12], and a 2:1 THF–benzene mixture [13] for sodium acetylides, ether [14,15] and THF [16] for lithium acetylides, and a 2:1 benzene–THF mixture for the reaction of silver acetylides with $AsCl_3$. [17] As a rule, the synthesis of OAAD by method 1b proceeds smoothly in the cold, although in certain cases heating is required to complete the reaction [12].

Carty et al. [15] obtained from ethynyldiphenylphosphine a disubstituted acetylene containing phosphorus and arsenic atoms:

$$Ph_2PC{\equiv}CH \xrightarrow[N_2;\ -78°]{n\text{-BuLi; } Ph_2AsCl} Ph_2PC{\equiv}CAsPh_2\ (50\%)\ .$$

The main bulk of OAAD have been synthesised using the Iotsich reagent (method 2). This procedure proved to be the most convenient on a preparative scale.

Compounds with the general formula $R_2AsC{\equiv}CR'$ [10,11,18,19] have been obtained in THF solution by adding a disubstituted halogenoarsine to an Iotsich reagent at room temperature. For R ranging from C_2H_5 to n-C_6H_{13} and R' = H, subsequent heating is required [18]. For R = C_6H_5 or α-$C_{10}H_7$ and R' = H, [10,11] the reaction reaches completion in several minutes. Dialkynyl compounds [10] $PhAs(C{\equiv}CR)_2$, where R = Me or Ph, and trisethynylarsines $As(C{\equiv}CR)_3$, where R = H, [20] Me, [10] or Ph, [13] are formed in high yields under similar conditions.

Polyacetylene derivatives of the type $R_2As(C{\equiv}C)_mR'$ have been synthesised [10]:

$$R_2AsX + R'(C{\equiv}C)_mMgX \xrightarrow[48-83\%]{THF} R_2As(C{\equiv}C)_mR'\ .$$

For compounds with $m = 2$, the reactions were carried out at −5°C but for $m = 3$ the reaction temperature had to be reduced to −20°C.

Diacetylene diarsenic compounds $R_2AsC{\equiv}C-C{\equiv}C-AsR_2$ (R = Et, Pr, i-Pr, n-Bu, or i-Bu) have been obtained by the reaction of dialkyliodoarsines with a diacetylene Iotsich reagent in ether [21]. OAAD with the general formula $R_2AsC{\equiv}CAsR_2$, where R = Pr, n-Bu, i-Bu, n-C_5H_{11}, or n-C_6H_{13}, were synthesised similarly [8] using $BrMgC{\equiv}CMgBr$ as the acetylenic component [17,22]. It has been shown for R=Et, C_6H_{11}, and α-$C_{10}H_7$ that the replacement of ether by chloroform promotes a greater degree of completion of the reaction [23].

Fluorine-containing OAAD $CF_3C{\equiv}CAsMe_2$ and $(CF_3C{\equiv}C)_2AsMe$ have been obtained [24] in low yields via the mechanism (n = 1, 2)

$$n\,CF_3C{\equiv}CMgI + Me_{3-n}AsI_n \xrightarrow{ether} (CF_3C{\equiv}C)_nAsMe_{3-n}\ .$$

Ethynylarsenic acids $C_6H_{11}C{\equiv}CAs(O)(OH)_2$ and $(C_6H_{13}C{\equiv}C)_2As(O)(OH)$ have been synthesised by a general method [25] using the corresponding aminohalogenoarsines:

$$n\,RC{\equiv}CMgBr \xrightarrow[3.ether,\ 30\%\ H_2O_2]{\substack{1.Cl_nAs(NEt_2)_{3-n},\ ether\\ 2.hydrolysis\ with\ dil.HCl}} (RC{\equiv}C)_nAs(O)(OH)_{3-n}\ .$$

Compounds in which the arsenic atom is in the α-position relative to the triple bond have been examined so far. Benaim [8] synthesised a large series of propargyl derivatives of arsenic with the general formula $R_2AsCH(R')C{\equiv}CR''$ via the mechanism

$$R_2AsX + R'CH(MgBr)C{\equiv}CR'' \xrightarrow[12-70\%]{20°;\ \text{ether}} R_2AsCH(R')C{\equiv}CR'' + MgBrX \quad .$$

It was established the the yield of the required product increases when the disubstituted halogenoarsine is taken in excess. The synthesis of propargyl arsines by the reaction of sodium derivatives of disubstituted arsines with propargyl bromides is not useful, since the yield is low [8]. Thus, for R = Ph, R′ = Me, and R″ = H, one obtains a 65% yield of the product via the first scheme and only 18% via the second.

$$Ph_2AsNa + Me\text{—}\underset{Br}{CH}\text{—}C{\equiv}CH \xrightarrow[18\%]{\text{liq. } NH_3;\ -40°} Ph_2AsCH(Me)\text{—}C{\equiv}CH \quad .$$

The exchange reaction between diarylchloroarsines and acetylene and diacetylene dizinc and ditin derivatives, leading to the formation of diarsenic acetylene derivatives (method 3), is of theoretical interest:

$$Ar_2AsCl + Y(C{\equiv}C)_nY \xrightarrow{t°} Ar_2As(C{\equiv}C)_nAsAr_2 \quad .$$

For Ar = Ph, Y = $SnMe_3$, and $n = 1$, Borisov et al. [26] used an alcoholic medium. For Ar = Ph or naphthyl, $n = 2$, and Y = ZnMe [27] or $ZnMe_3$, [28] the reaction was carried out in absolute toluene and benzene.

In 1968 Kuz'min and Panfilovich [19] proposed a novel method for the synthesis of OAAD having the general formula $\begin{matrix}R_1\\R_1\end{matrix}\!\!>\!AsC{\equiv}CPh$, based on the use of the nucleophilic properties of phenylacetylene:

$$\begin{matrix}R_1\\R_2\end{matrix}\!\!>\!As\text{—}OH + HC{\equiv}CPh \rightarrow \begin{matrix}R_1\\R_2\end{matrix}\!\!>\!As\text{—}C{\equiv}CPh \xrightarrow{\text{thermal isomerisation}}$$

$$\rightarrow \begin{matrix}R_1\\R_2\end{matrix}\!\!>\!AsOC{\equiv}CPh \xrightarrow{PhC{\equiv}CH} \begin{matrix}R_1\\R_2\end{matrix}\!\!>\!AsC{\equiv}CPh \quad .$$

By heating dialkylarsinic acids and phenylacetylene in molar proportions of 1 : 2 in benzene or toluene with azeotropic distillation of water, OAAD with different R were obtained: $R_1 = R_2 = C_2H_5$; $R_1 = R_2 = C_3H_7$; $R_1 = C_3H_7$, $R_2 = C_4H_9$; $R_1 = R_2 = C_4H_9$; $R_1 = C_4H_9$, $R_2 = C_5H_{11}$; $R_1 = C_4H_9$, $R_2 = C_6H_{13}$.

Subsequently this method was extended to arsenic(III) derivatives (method 4b) [29]:

$$PhC{\equiv}CH + \begin{cases} R_2AsI \\ R_2AsOC\,(O)\,Me \\ R_2AsOR\ (\text{где } R = Alk) \end{cases} \rightarrow R_2AsC{\equiv}CPh \quad .$$

Quaternary arsonium salts with the general formula $[Ph_2As(R)CH_2C{\equiv}CH]^+X^-$, where R = Ph or Et and X = Br, I, or OTs, are formed in high yields [10] when tertiary arsines are refluxed in acetonitrile with the corresponding propargyl derivatives (method 5). Diacetylene compounds $[Et_3AsC{\equiv}C-C{\equiv}CR]^+Br^-$, where R = Me or Ph, were obtained similarly in ether.

The method of indirect ethynylation of organoarsenic compounds is not of particular importance in the synthesis of OAAD (method 6). Here, mention should be made of the synthesis in high yield of the acid (p-$PhC{\equiv}C)C_6H_4As(O).(OH)_2$ from its styryl analogue (bromination of the olefin and dehydrobromination by KOH in butanol) [9] and also of chlorodiphenylarsinoacetylene via the mechanism [30]

$$Ph_2AsBr + ClCH = CHCl + 2Na \xrightarrow[82\%]{\text{liq. } NH_3,\ -60^\circ} Ph_2AsC{\equiv}CCl \quad .$$

2. Synthesis Based on Organoarsenic Acetylene Derivatives

Many OAAD have been obtained using ethynylarsenic(III) derivatives, described in the preceding section, with a terminal $-C{\equiv}CH$ group (method A).

Thus, secondary and tertiary ethynyl alcohols with the general formula $R_2AsC{\equiv}C-C(OH)R'R''$ have been synthesised by the carbonylation of OAAD via the Favorskii reaction [10] and by the reaction of organomagnesium derivatives of the type $R_2AsC{\equiv}CMgBr$ with compounds containing carbonyl groups [18,31]. The condensation of diphenylethynylarsine with benzophenone and cyclohexanone proceeds smoothly in the presence of KOH in THF solution [10].

Iotsich reagents obtained from dialkylarsinoacetylenes react with aldehydes and acetone with evolution of heat, while the reactions involving other aliphatic ketones (ethyl methyl, diethyl, butyl methyl, and dipropyl ketones) require heating.

The ketones $R_2AsC{\equiv}C-\underset{\underset{O}{\|}}{C}-R'$ were obtained by the reaction [32]

$$2\,R_2AsC{\equiv}CMgBr + 2\,(R'CO)_2O \rightarrow 2R_2AsC{\equiv}\underset{\underset{O}{\|}}{C}C-R' + MgBr_2 + (R'COO)_2Mg \quad .$$

When an excess of the anhydride is taken and the synthesis is carried out at a temperature not exceeding $-60^\circ C$, adding the organomagnesium derivative of the dialkylethynylarsine to an ethereal solution of the anhydride, the reaction stops at the ketone formation stage.

Dialkyl arsino-α-ethynyl ketones are slightly coloured liquids, which distil without decomposition but are unstable in air.

Diphenylarsinoacetylenecarboxylic acid $Ph_2AsC{\equiv}CCOOH$ is formed when ethynyldiphenyl arsine reacts with carbon dioxide in THF solution (using magnesium as the condensing agent) [10]. The corresponding dialkyl derivatives have been synthesised via the magnesium derivatives of the dialkylethynylarsine by adding solid carbon dioxide to its ethereal solution [33]:

$$R_2AsC{\equiv}CMgBr + CO_2 \rightarrow R_2AsC{\equiv}CCOOH \quad .$$

Ethyl esters of dialkylarsinoacetylenecarboxylic acids $R_2AsC{\equiv}CCOOEt$ were obtained [33] in low yields by the reaction of the organomagnesium derivative of dialkylethynylarsine and ethyl chlorocarbonate:

$$R_2AsC{\equiv}CMgBr + ClCOOEt \xrightarrow[-15^\circ]{\text{ether}} R_2AsC{\equiv}CCOOEt \quad .$$

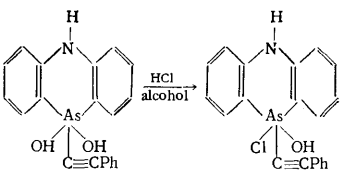
In contrast to dialkylethynylphosphines [33,34] dialkylethynylarsines enter into the Mannich reaction. The compound $Bu_2AsC{\equiv}C-CH_2-NEt_2$ is formed in low yield on heating for 24 h a reaction mixture consisting of paraformaldehyde, diethylamine, and dibutylethynylarsine in the presence of copper acetate as the catalyst [18,34,35].

The reaction of terminal OAAD with copper(I) salts in aqueous ammonia does not lead to the formation of acetylides. Copper diphenylarsinoacetylide was obtained [36] only by the decomposition with a dilute ammonia solution of the ternary complex of CuCl, the ethynyl compound, and dimethyl sulphoxide (DMSO), which had been prepared beforehand.

Oxidative addition and arsenic(III) quaternisation reactions have been used to synthesise a series of ethynyl derivatives of tetracoordinate and quinquevalent arsenic.

Owing to the reduced (compared with tervalent phosphorus) nucleophilicity of arsenic(III), the quaternisation of ethynylarsines proceeds with greater difficulty than that of the corresponding phosphines. It was established that dialkylethynylarsines are more reactive in this process than their aromatic analogues [16,19]. The quaternisation of polyacetylenic arsines with the general formula $R_{3-n}As.[(C{\equiv}C)_mR']_n$ is hardly observed in ether, but is markedly facilitated in acetonitrile [10]. Diarsenic compounds $R_2AsC{\equiv}CAsR_2$ react with methyl iodide in ether in the cold only for R = Et and C_6H_{11}. For R = Ph or α-$C_{10}H_7$, the formation of salts was not observed even after prolonged heating [23].

Ethynylarsine oxides and hydroxides have been obtained by the oxidation of OAAD with hydrogen peroxide in acetone or acetic acid. The OAAD employed were ethynyldiphenylarsines $Ph_2AsC{\equiv}C-R$, [10] tris-(t-butylethynyl)arsine [16], bis(di-α-naphthylarsino)acetylene [23], and 10-phenylethynyl-9,10-dihydrophenarsazine [12]. In the last case it was shown that one hydroxy-group in the oxidised product is readily substituted by chlorine via the reaction



Tris-(t-butylethynyl)arsine forms the sulphide [24] $(Me_3C-C{\equiv}C)_3As{=}S$ on refluxing with sulphur in CS_2.

III. CHEMICAL PROPERTIES

OAAD contain in their structure several reactive centres (As^{III}, $\equiv C-H$, $C{\equiv}C$, $As-C{\equiv}C-$), which is the reason for the wide variety of the chemical properties of compounds of this class. These properties have already been partly considered in the second part of the previous

section. Below we shall consider problems of the thermal and hydrolytic stability and light resistance of OAAD, the effect of the tetracoordination of arsenic on the properties of OAAD, and certain spectroscopic data.

1. Thermal Stability and Light Resistance of OAAD

In Davidson and Henry's review [3] OAAD are classified as potentially explosive substances. However, judging from the latest data, in the vast majority of cases no special precautions are necessary in handling OAAD.

Trisalkylethynyl derivatives of Group VB elements are known [3,4] to be unstable under the usual conditions and compounds of the type $(HC{\equiv}C)_3E$ (E = element) explode in air. As for polyethynyl derivatives of the elements in other Groups, the arsenic(III) compound with t-butylethynyl substituents $(Me_3C-C{\equiv}C)_3As$ proved to be thermally stable and insensitive to light [16].

The monoethynylarsine $Me_2AsC{\equiv}CCF_3$ is hardly coloured by ultraviolet light, but darkens on heating to 160–180°C. However, according to infrared and NMR spectroscopic data, these visual changes are not accompanied by the decomposition of the initial OAAD. [24] The diethynylarsine $MeAs(C{\equiv}CCF_3)_2$ is less stable: thus marked charring was observed after heating the specimen at 140°C; the specimen, which was colourless at the end of ultraviolet irradiation, soon became black [24].

It has been reported [16] that the compound $Ph_2AsC{\equiv}CCF_3$ may be stored for a long time at room temperature without decomposition. Dialkylethynylarsines remain unchanged after oxidative condensation [40] in the absence of a catalyst. The triethynylarsine $(MeC{\equiv}C)_3As$ is resistant to the action of oxygen and atmospheric moisture at −20°C in the course of many months [20]. Bis(dialkylarsino)acetylenes $R_2AsC{\equiv}CAsR_2$ (R = Pr, n-Bu, i-Bu, or C_5H_{11}) are stable in air indefinitely [22].

In contrast to the corresponding arsines, the acids $(C_6H_{13}C{\equiv}C)_nAs(O)(OH)_{3-n}$ (n = 1, 2) proved to be fairly unstable [9].

2. The Cleavage of OAAD at the ≡C–As Bond

As a rule ethynylarsines are fairly inert with respect to water. Thus the compound $Me_2AsC{\equiv}CCF_3$ withstands contact with water without decomposition over a period of four months at 20°C and for five days at 110°C. [24] The resistance to hydrolysis persists in diethynylarsines [for example $MeAs(C{\equiv}CCF_3)_2$] [24] and triethynylarsines [$(HC{\equiv}C)_3As$], [20] while the diarsenic alkyl derivatives $R_2AsC{\equiv}CAsR_2$ are slowly cleaved by water even in the cold [23].

Among all the OAAD whose behaviour in relation to alkalis was investigated, only 10-phenylethynyl-9,10-dihydrophenarsazine is not decomposed by aqueous solutions of alkali, but hydrochloric acid cleaves its ≡C–As bond [12].

Strong alkalis decompose the ethynylarsines $Ph_2AsC{\equiv}CPh$, $(\alpha\text{-}C_{10}H_7)_2AsC{\equiv}CPh$, and $(\alpha\text{-}C_{10}H_7)_2AsC{\equiv}CH$ with evolution of $PhC{\equiv}CH$ and acetylene respectively [11]. The cleavage of the bisarsines $R_2AsC{\equiv}CAsR_2$ by alkalis takes place readily and more so for R = C_6H_{11} than for R = Ph. [23]

The arsenic(III) derivatives of trifluoromethylacetylene $Me_nAs(C{\equiv}CCF_3)_{3-n}$ (n = 1, 2) evolve the initial acetylene in low yield (36% for n = 1 and 29% for n = 2) on treatment with 10% aqueous sodium hydroxide [24]. Triethynylarsine $As(C{\equiv}CH)_3$ is decomposed by alkalis with evolution of acetylene [20].

Bis(di-α-naphthylarsino)acetylene oxide remains unchanged when treated with alkalis, decomposing partly on refluxing with aqueous silver nitrate [23].

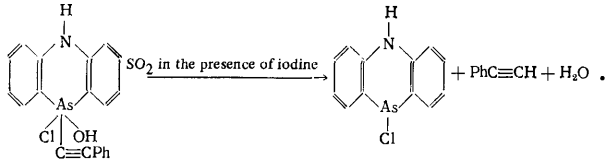
Acetylene and diacetylene derivatives of arsenic [40] are unstable on treatment with dry hydrogen chloride. Apart from hydrochlorination, the As–C≡ bond is broken.

Shpanskii [12] showed that, on treatment with iodine in the cold, 10-phenylethynyl-9,10-dihydrophenarsazine is cleaved with formation of 9-iodo-9,10-dihydrophenarsazine and iodophenylacetylene.

3. Tetracoordination of Arsenic

Although the resistance to oxidation of the acetylene derivatives of Group VB elements decreases from phosphorus to bismuth [4], OAAD do not obey this rule. In the general case the formation of ethynylarsine oxides and hydroxides under the influence of atmospheric oxygen or other oxidants (for example H_2O_2) proceeds with greater difficulty than for the corresponding ethynylphosphines [10,23]. For compounds of the type $R_2AsC{\equiv}CAsR_2$, the oxide was obtained only with R = $\alpha\text{-}C_{10}H_7$; for R = Ph or C_6H_{13}, only the cleavage of the As–C≡ bond was observed under the same conditions [23].

On passing from tervalent to quinquevalent arsenic, the properties of OAAD change significantly, in particular the resistance of the As–C≡ bond to the action of electrophilic agents increases. Thus 10-phenylethynyl-9,10-dihydrophenarsazine hydroxide no longer reacts with iodine, hydrochloric acid does not split off phenylacetylene, and on treatment with alcoholic hydrogen chloride the product of the substitution of one hydroxy-group by chlorine is formed. Its reduction proceeds via the mechanism



It has been noted [23] that bis-(di-α-naphthylarsino)-acetylene oxide is not hydrolysed by alkali, in contrast to the initial compound.

The arsenic(III) OAAD are converted into sulphides, like phosphines, on refluxing with sulphur in carbon disulphide [41–44], but they lose sulphur on isolation.

The quaternisation of ethynylarsines is difficult [10,23].

4. Addition to the Triple Bond

All attempts at the catalytic hydrogenation of ethynylphosphines were unsuccessful [44,45], while similar experiments involving arsines were not performed.

To investigate the properties of the triple bond in OAAD, Kuz'min et al. [40] hydrochlorinated certain acetylene and diacetylene derivatives of arsenic by passing hydrogen chloride through a chloroform solution of the compound:

The polarisation of the triple bond is responsible for the addition of a proton to the α-carbon atom. The chloride ion is directed to the *trans*-position, which is characteristic of disubstituted acetylene derivatives. Hydrogen chloride adds to one of the triple bonds of the diyne group of bis(diethylarsino)diacetylene.

The hydrochlorination of OAAD is accompanied by the dissociation of the As–C≡ bond with formation of the corresponding chloroarsines and monosubstituted acetylenes and diacetylenes. The increase of the polarity of the As–C≡ bond probably facilitates the nucleophilic attack on the arsenic atom and the electrophilic attack on the carbon atom. It has been shown [40] that the rate of formation of products of nucleophilic substitution at the arsenic atom is much higher than the rate of addition of hydrogen chloride to the triple bond.

The behaviour of OAAD in relation to halogens has been hardly investigated. It has been suggested that chlorine and bromine add to the triple bond in 10-phenylethynyl-9,10-dihydrophenarsazine and not to the arsenic atom [12].

Benain [4] reported the addition of diazomethane to acetylenic arsenic-containing compounds.

Cullen and Leeder [24] obtained a cyclopropane derivative, stable at 20°C and even on heating, by the reaction of an organotin trifluoromethyl derivative with a fluorine-containing ethynylarsine:

$$Me_2AsC{\equiv}CCF_3 + Me_3SnCF_3 \rightarrow Me_2As{-}C(CF_2){=}C{-}CF_3 + Me_3SnF$$

5. Reactions of the Acetylenic Hydrogen

Ethynyl derivatives of Group VB elements can be metallated by Grignard reagents [10,18] or by lithium alkyls [33].

The condensations of Iotsich reagents obtained from OAAD with a terminal ≡C–H group [18,31–33,35],

$$R_2AsC{\equiv}CMgBr + \begin{cases} R'R''C{=}O \rightarrow R_2AsC{\equiv}CC(OH)R'R'' \\ (R'(CO_2)O \rightarrow R_2AsC{\equiv}CC(=O){-}R' \\ CO_2 \rightarrow R_2AsC{\equiv}CCOOH \\ ClCOOEt \rightarrow R_2AsC{\equiv}CCOOEt \end{cases}$$

and also the involvement of such acetylene derivatives in the Favorskii [10] and Mannich [33] reactions were examined previously (see Section II, 2). In these reactions the introduction of an arsenic atom in the α-position relative to the triple bond does not alter the type of reactivity of the ethynyl hydrogen atom. However, when an attempt was made to carry out oxidative condensation [40] to obtain organoarsenic derivatives of diacetylene,

$$2R_2AsC{\equiv}CH \xrightarrow[CuCl]{O_2} R_2AsC{\equiv}C{-}C{\equiv}CAsR_2 + 2H$$

bis(dialkylarsino)acetylenes were obtained in all the experiments instead of the expected diacetylene derivatives. Under oxidative condensation conditions, a more complex reaction probably takes place and its overall course can be represented by the equation

$$2\,R_2AsC{\equiv}CH \underset{70\%}{\rightarrow} R_2AsC{\equiv}CAsR_2 + HC{\equiv}CH$$

6. Certain Spectroscopic Data

By comparing the infrared spectra of dialkylarsinoacetylenes, dialkylarsinoacetylenic alcohols, and also dialkylarsinoacetylenic acids and their esters, Kuz'min and Pavlova [35] showed that the vibration frequency of the acetylenic bond changes only slightly as a function of the nature of the group substituting the ethynyl hydrogen atom while the intensity of the band due to the acetylenic linkage depends significantly on the substituent.

Continuing the study of the spectra of dialkylethynylarsines, dialkylarsinoalkynes, bisdialkylarsinoacetylenes, and bisdialkylarsinodiacetylenes, Shagidullin et al. [34] established that the introduction of an arsenic atom in the α-position relative to the acetylene and diacetylene groups greatly reduces the C≡C vibration frequency, which may be due both to a specific interaction of the p_π–d_π type and to the effect of the mass of the arsenic atom.

Table 3.

Compound	*m/e* for parent ion	*m/e* for fragment			
		$-CH_3$	$-(CH_3)_2$	$-(CH_3)_3$	$-(CH_3)_3C$
$^{75}As(C{\equiv}CCMe_3)_3$	318	303	288	273	261

Monosubstituted dialkylethynylarsines are capable of self-association with formation of hydrogen-bonded complexes.

The absorption and photoconduction spectra of copper acetylides having the general formula $R_2AsC{\equiv}CCu$, where R = Ph or Bu, have been investigated in detail [39]. The stretching vibration frequencies of the C≡C and ≡C–H groups are presented in Table 1. Certain NMR and ultraviolet spectroscopic data are in Table 2.

Reiff and Pant[16] reported mass-spectrometric data for tris-(t-butylethynyl)arsine (Table 3).

Organosilicon compounds containing one or several ethynyl groups in the molecule are nowadays attracting increasing attention. Such compounds are of definite theoretical and practical interest as models for the study of the transmission of conjugation via the arsenic atom and also, for example, as potential physiologically active substances.

A more vigorous investigation of the properties of organosilicon compounds of the acetylene series has been made in recent years. Thus it has been established that copper acetylides exhibit photosemiconducting properties[36].

Hay and coworkers[14] reported the synthesis of an interesting group of highly stable arsenic-containing phenylethynyl polymers.

A search is being made for new ligands among organoarsenic compounds[15]. Ethynylarsinic acid synthesised recently may find application in the extraction of heavy lanthanide ions[25].

An important practical factor is the availability of an industrial source of arsenic raw materials (the waste from non-ferrous metallurgy), which leads to the expectation of a further expansion of studies on this interesting class of compounds.

Ring-Chain Isomeric Transformations of Hydroxy-, Amino-, and Mercapto-Derivatives of Carbonyl Compounds and Their Heteroanalogues

R.Valters

The ring-chain isomeric (including tautomeric) transformations of hydroxy-, amino- and mercapto-derivatives of aldehydes, ketones, other carbonyl compounds, imines, hydrazones, and nitriles are examined. The effect of molecular structure and the structure of substituents at the interaction functional groups and also of external factors on the relative stabilities of the isomers and on the nature of the equilibrium has been analysed.
The bibliography includes 246 references.

I. INTRODUCTION

Since the appearance of the first review[1] dealing with ring–chain tautomerism, numerous experimental studies in this field based on modern spectroscopic techniques have been published. The ring–chain isomerism of carboxylic acids with formyl and oxo-groups and their derivatives formed by the modification of the carboxy-group were discussed in a recently published review[2].

This review considers the advances during the last decade in the field of ring–chain isomeric (including tautomeric) transformations[3-6] of hydroxy-, amino-, and mercapto-derivatives of aldehydes, ketones, other carbonyl compounds†, imines, hydrazones, and nitriles. In the above series of compounds the formation of a cyclic isomer takes place via the intramolecular addition of a nucleophilic centre (OH, NH, SH) to the electrophilic carbon atom of the polar bond C=O, C=N, or C≡N (see Scheme 1).

It is possible to distinguish three fundamental types of ring–chain isomeric transformations[2,4].

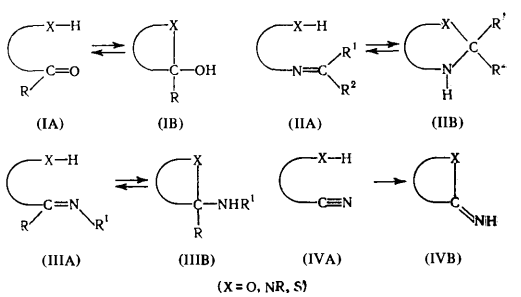
1. Tautomerism

Only one or, more rarely, both isomers are isolated in a pure form. With the aid of spectroscopic methods, it is possible to demonstrate a dynamic equilibrium between the open-chain (A) and cyclic (B) forms in solution at room temperature.

The case where only one isomer (for example A) is isolated in a pure form and its stability in solution has been demonstrated requires special consideration. One cannot then rule out the possibility of an equilibrium $A \rightleftharpoons B$ displaced so much towards A that the concentration of the isomer B is below the limit of sensitivity of the identification procedure employed. Such a possibility can be rigorously excluded only by the isolation of both isomers in a pure form, provided that their stability in solution has been proved.

†With the exception of monosaccharides.

Scheme 1



2. Reversible Isomerism

Both isomers are obtained in a pure form. They are stable in solution at room temperature and equilibrium mixtures are not formed. The isomerisation processes A → B and B → A take place under the influence of specific reagents, acid or alkaline catalysts, or on heating.

3. Irreversible Isomerism

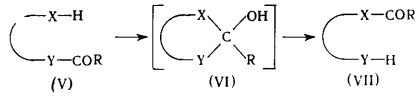
The isomerisation can take place in only one direction (A → B).

We shall also consider cases where either open-chain (A) or cyclic (B) isomers are formed, depending on the structure of the substituents at the interacting functional groups, but for a given set of substituents the isomeric interconversions cannot be achieved.

This review deals only with the results of studies where the structure of the isomers and the presence of a tautomeric equilibrium has been reliably established by spectroscopic methods (infrared, ^{1}H NMR, and ultraviolet spectroscopy). The formation of derivatives of both forms (A and B) in chemical reactions does not as a rule constitute a rigorous proof of a tautomeric equilibrium[1,7].

The electronic and steric effects of the substituents at the interacting functional groups and the effect of the structure of their connecting link on the relative stabilities of isomers and on the equilibrium are of greatest interest. It has been demonstrated in many instances that all the structural changes resulting in an enhancement of the nucleophilic properties of the oxygen, nitrogen, or sulphur atoms (OH, NH, SH) or the electrophilic properties of the carbon atoms in the C=O, C=N and C≡N bonds stabilise the ring form and displace the equilibrium towards it. The steric approach of the interacting groups is even more important. The open-chain form is stabilised by electronic effects acting in the opposite direction (the diminution of the nucleophilic properties of the XH groups or of the electrophilic properties of the carbon atom) and by the steric screening of the interacting groups by bulky substituents.

We are unable to discuss studies in which the isomers were not isolated or the ring–chain equilibrium was not demonstrated by spectroscopic methods and its occurrence in an intermediate stage is merely postulated to account for the mechanism of the formation of the final reaction products. However, such an equilibrium frequently constitutes the only possible explanation of the occurrence of the reaction in question. For example, the intramolecular rearrangement (V) → (VII), involving the migration of the acyl residue between two nucleophilic groups (OH, NH, SH), proceeds via the intermediate cyclic isomer (VI):

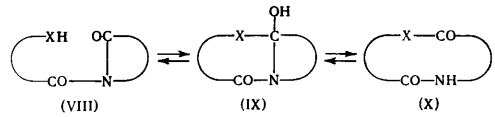


(V) (VI) (VII)

(X, Y = O, NR', S)

In view of its low stability, it is rarely possible to isolate this compound in a pure form or to demonstrate rigorously its presence in solution[4,8].

An interesting example of intramolecular transacylation is also provided by the reaction involving the inclusion of the residues of hydroxy- or amino-acids in lactam, peptide, or depsipeptide rings. This reaction proceeds via the intermediate formation of the so called cyclols [IX, X = O (oxacyclols) or X = NR (azacyclols)] and leads to cyclic peptides (X, X = NR) or depsipeptides (X, X = O):[9-16]



(VIII) (IX) (X)

(X = O, NR, S)

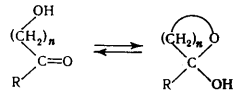
Studies on *N*-hydroxyacyl-lactams (VIII, X = O) showed that[9,14,17-21], depending on ring size and the structure of the hydroxyacyl group, either spontaneous isomerisation (VIII) → (X) takes place or it is possible to isolate the oxacyclols (IX, X = O), which are incapable of isomerisation to macrocyclic derivatives (X). In certain cases (*N*-glycolylvalerolactam[14], *N*-glycolylcaprolactam[20], *N*-hydroxyacyldioxopiperazines[22] and others[9,23]) the presence of the tautomeric equilibrium (VIII) ⇌ (IX) in solution was confirmed spectroscopically. *N*-Hydroxyacylbutyrolactams do not form cyclols.

The isomeric transformations (VIII) → (IX) → (X) have been observed also in the series of azacyclols. However, the azacyclols themselves (IX, X = NR) are relatively unstable and cannot be isolated[9,24-32]. The azacyclol formed from *N*-(2-methylaminobenzoyl)butyrolactam has been isolated in a pure form[33]. The tautomeric equilibrium (VIII) ⇌ (IX) ⇌ (X) occurs in solutions of thiacyclols (IX, X = S) formed from *N*-(thiosalicyloyl)-lactams[34,35]. With increase in the lactam ring size and also with increase of the dielectric constant of the solvent, the equilibrium shifts towards the macroring (X).

II. CARBONYL COMPOUNDS

Hydroxy-derivatives (IA ⇌ IB, X = O)

The simplest examples of hydroxycarbonyl compounds which can give rise to a cyclic form are hydroxyketones and hydroxyaldehydes[1,4,6,36]. The equilibrium (XIA) ⇌ (XIB) is rapidly established[36-38] in solutions of 5-hydroxy-2-pentanone (XIa) and 6-hydroxy-2-hexanone (XIb), with the open-chain form predominating slightly:



(XIA) (XIB)

a) R = Me, *n* = 3; b) R = Me, *n* = 4;
c) R = H, *n* = 3; d) R = H, *n* = 4

The contents of the tautomeric forms were determined[38] from the intensities of the proton signals of the methyl groups of both tautomers (the tautomeric transformations are slow on the ^{1}H NMR time scale) and also by measuring the intensities of the 265–280 nm bands observed in the ultraviolet spectra of the open-chain isomers (XIA).

Table 1. The tautomeric equilibrium constants in solutions of 5-hydroxy-2-pentanone (XIa) and 6-hydroxy-2-hexanone (XIb) determined[38] by ^{1}H NMR and ultraviolet spectroscopic methods.

Solvent	K_T = [B]/[A]			
	^{1}H NMR at 37°C		u.v.spectra at 25.1°C	
	(XIa)	(XIb)	(XIa)	(XIb)
Pure liquid	0.83	0.85	—	—
Cyclohexane*	0.81	0.95	0.78	0.87
Dioxane	—	—	0.83	0.74
Carbon tetrachloride	0.73	0.95	0.75	0.96

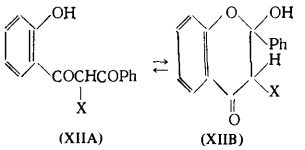
Acetonitrile*	0.82	0.79	0.79	0.61
Dimethyl sulphoxide*	0.64	0.81	0.56	0.77
Water*	0	0	0	0

*The ^{1}H NMR spectra were recorded in deuteriated solvents.

An increase of temperature[38,39] and of solvent polarity[38] displaces the equilibrium towards the open-chain form, although the equilibrium constants in various solvents, with the exception of water, differ insignificantly (Table 1). The cyclic form predominates in aqueous solution. The addition of water to solutions of hydroxyketones in dioxane, ethanol, or dimethyl sulphoxide rapidly displaces the equilibrium towards the open-chain form. The thermodynamic properties (ΔH° and ΔS°) of the (XIA) ⇌ (XIB) transformation in various solvents have been determined[38].

Compared with hydroxyketones, in solutions of hydroxyaldehydes (XIc and XId) the equilibrium is displaced appreciably towards the cyclic form [in 75% aqueous dioxane at 25°C K_T = 7.8 for (XIc) and K_T = 15.4 for (XId)].[40]

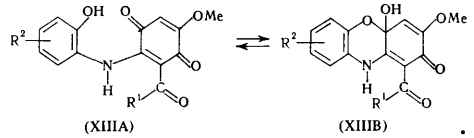
The formation of the cyclic form via the intramolecular addition of the phenolic hydroxyl to the formyl or keto-group has been observed in *o*-hydroxyphenylglyoxal[41], 2-(*o*-hydroxybenzyl)cyclohexanone[42], and in a series of substituted benzoyl(*o*-hydroxybenzoyl)methanes (XII, a–c).[43,44] In the crystalline state, the compounds (XII, a–c) have a cyclic structure, while in chloroform solution the equilibrium (XIIA) ⇌ (XIIB) is established rapidly [K_T = 3.7 for (XIIa) and K_T = 0.5 for (XIIb)]. The substitution of the hydroxy-group by bromine enhances the electrophilic properties of the carbon atom of the keto-group and shifts the equilibrium towards the cyclic form:



(XIIA) (XIIB)

a) X=Br; b) X=OH; c) X=OOCPh)

As a result of the intramolecular addition of the phenolic hydroxyl to the C=O group of the quinone, (XIIIA) ⇌ XIIIB) equilibrium mixtures are formed in solutions of substituted 2-(*o*-hydroxyphenylamino)-1,4-benzoquinones[45–47]. A similar tautomeric equilibrium was observed previously[48] in solutions of 2-(*o*-hydroxyphenylamino)-1,4-naphthoquinones. The amounts of the tautomers were determined by ultraviolet spectroscopy[48]:

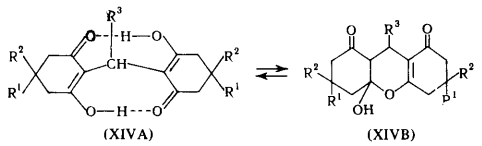


(XIIIA) (XIIIB)

a) R^1 = Me, and R^2 = 3' – Ac.

The long-wavelength band is at 470 and 394 nm respectively in the spectra of model compounds with fixed open-chain and cyclic structures[45,46]. In ethanol solution of 3-acetyl-2-(3'-acetylphenylamino-2'-hydroxy-)-5-methoxy-1,4-benzoquinone (XIIIa) the cyclic form predominates, while in non-polar solvents the equilibrium is displaced towards the open-chain form (XIIIA). The authors assume that[46] the open-chain form is stabilised by the intramolecular hydrogen bond O–H...O=C (3'-acetyl). Both isomers were isolated in a pure form: (XIIIa – A) as a black powder on crystallisation from benzene and (XIIIa – B) as yellow crystals on crystallisation from methanol. The ultraviolet spectra of solutions of both isomers are identical, i.e. after dissolution identical equilibrium mixtures are formed regardless of which isomer is used to prepare the solution.

Lielbriedis and Gudriniece[49–52] observed an interesting type of tautomerism in which the cyclic form is produced as a result of the intramolecular addition of the enolic hydroxyl to the keto-group:

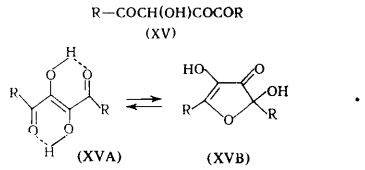


(XIVA) (XIVB)

a) $R^1 = R^2$ = Me; b) $R^1 = R^2$ = H;
c) R^1 = Ph, R^2 = H; d) R^1 = Me, R^2 = H

Bisdimedonylmethanes (XIVa), obtained by the condensation of dimedone with aliphatic aldehydes and also with *m*- and *p*-substituted benzaldehydes, have the open-chain structure (XIVa – A) in the crystalline state. This structure is stabilised by two intramolecular hydrogen bonds. The products of the condensation of dimedone with *o*-substituted benzaldehyde have the cyclic structure (XIVa – B). Both isomers of *p*-[*NN*-bis(β-chloroethyl)amino]phenyl bisdimedonylmethane [XIVa, R^3 = *p*-$(ClCH_2CH_2)_2NC_6H_4$] were isolated in a pure state. Isomerisations in both directions were achieved: (XIVA) → (XIVB) on refluxing in alcohol or on recrystallisation from acetic acid and (XIVB) → (XIVA) on slow crystallisation from dioxane. The products of the condensation of cyclohexane-1,3-dione and its 5-phenyl- and 5-methyl-substituted derivatives with aldehydes (XIV, b – d) were isolated either in the open-chain (XIVA) or cyclic (XIVB) forms, but no clear relation between the structure of the substituents and the preferential formation of one of these isomers could be traced in this instance.

As a result of the intramolecular addition of the enediol hydroxyl to the keto-group, the cyclic form of acetylformoins is produced[53–60]. The enolisation of acetylformoins (XV) can proceed to two direction. The symmetrical enediol has the open-chain structure (XVA) with two intramolecular hydrogen bonds, while the asymmetric enediol has the cyclic structure (XVB). Both forms can be readily identified from their infrared spectra [ν(C=O) = 1620 – 1630 cm^{-1} for (XVA) and ν(C=O) = 1695 – 1705 cm^{-1} for (XVB)] and ultraviolet spectra [λ = 355–360 nm for (XVA) with R = alkyl, λ = 390–410 nm for (XVA) with R = aryl, λ = 305–310 nm for (XVB) with R = alkyl, and λ = 355–360 nm for (XVB) with R = aryl][58]:



R–COCH(OH)COCR

(XVA) (XVB)

Here R = Me(A)‡, i-Pr(B), t-Bu(B), *p*-XC_6H_4 [X = H(B), Me(B), MeO(A), t-Bu(B), Me_2N(A), Cl(A and B), Br(A and B), or NO_2(B)], 2,4,6-$Me_3C_6H_2$(A), α-naphthyl (A), or β-naphthyl (A and B).

The introduction of electron-donating substituents (MeO, Me_2N) into the aromatic ring of aroylbenzoins diminishes the electrophilic properties of the carbon atom of the keto-group and stabilises the open-chain form, while electron-accepting substituents act in the opposite direction[59]. Both isomers of *p*-bromo- and *p*-chlorobenzoylformoins[58] and β-naphthoylformoins[60] were isolated in a pure form: (XVB) crystallises as yellow crystals from ethanol and (XVA) as red crystals from benzene after prolonged heating of the solution. When the cyclic isomers are fused, the isomerisation (XVB) → (XVA) takes place[54,58].

In proton-accepting solvents (ethanol, tetrahydrofuran) acylformoins exist exclusively in the cyclic form (XVB). This form is stabilised by the hydrogen bonds (OH...O<) between the hydroxyl of the cyclic form and the solvent molecule[56]. Mesitoylformoin, which does not give rise to a cyclic form, evidently due to the steric screening of the carbonyl group by the bulky substituent, constitutes

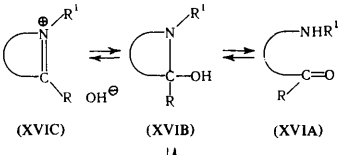
‡ The structure of the crystalline substance is indicated in brackets.

an exception (cf. Refs. 2, 61–63). In solvents which are not proton-acceptors the open-chain form (XVA) predominates[58,59].

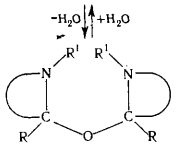
In polar proton-accepting solvents the equilibrium involving the above examples of the ring-chain tautomerism of compounds (XIIIa), (XIV), and (XV), where the open-chain is stabilised by one or two intramolecular hydrogen bonds, is displaced towards the cyclic form. The formation of the latter as a result of the intramolecular addition to the C=O group of the hydroxy-group at a nitrogen atom (NHOH, =NOH) has also been observed[64,65].

Amino-derivatives (IA ⇌ IB, X = NR)

The aminoaldehyde or aminoketone ⇌ hydroxyalkylamine ring–chain tautomeric systems (XVIA) ⇌ (XVIB) can be formed on covalent hydration[66-69] of heterocycles containing an immonium nitrogen atom. The equilibrium (XVIC) ⇌ (XVIB) has been most frequently investigated. In a study of the hydroxyalkylamines obtained from isoquinoline or 3,4-dihydroisoquinoline bases, Beke[70,71] established that the less basic the nitrogen atom in the (XVIB) molecule the greater the probability of the formation of the open chain form (XVIA):



(XVIC) (XVIB) (XVIA)



(XVII)

Four cases are considered[70].

1. Strong bases. In the crystalline state and in non-polar solvents they exist as the hydroxyalkylamines (XVIB), while in polar solvents they exist in the ionic form (XVIC). The presence of the open-chain form (XVIA) cannot be demonstrated by either chemical or physical methods.

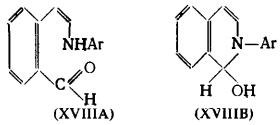
2. Moderately strong bases. In the crystalline state they have the structure (XVIB). The equilibrium (XVIC) ⇌ (XVIB) ⇌ (XVII) is observed in aqueous solution. The open-chain form (XVIA) is absent.

3. Hydroxyalkylamines incapable of giving rise to the ionic form (XVIC) isomerise to the open-chain form (XVIA). The existence of both forms can be demonstrated in solution or they can be actually isolated in a pure state[71].

4. Compounds showing no pseudobasic properties exist only in the open-chain form (XVIA). The hydroxyalkylamine (XVIB), formed when the solution of a quaternary salt of the nitrogen-containing heterocycle is made alkaline, is unstable and isomerises spontaneously to (XVIA).

It is clear from the foregoing that the equilibria (XVIC) ⇌ (XVIB) and (XVIB) ⇌ (XVIA) are not observed simultaneously. Hydroxyalkylamines capable of giving rise to the ionic form (XVIC) are not converted into the open-chain form (XVIA) and conversely.

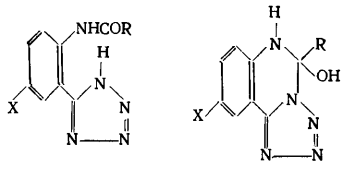
The products of the covalent hydration of *N*-arylpyridinium compounds[72] have an open-chain structure. On hydration of *N*-(2,4-dintrophenyl)isoquinolinium[71], both isomers, (XVIIIA) and (XVIIIB), were obtained and their interconversions were achieved. By investigating the esterification kinetics, it was established that under the reaction conditions the equilibrium (XVIIIA) ⇌ (XVIIIB) obtains. The absence of the open-chain form in the crystalline state and in solutions of covalent quinazoline hydrates has been demonstrated by infrared spectroscopy[66,73,74].



(XVIIIA) (XVIIIB)

[Ar-2,4-$(NO_2)_2C_6H_3$]

Postovskii[75-79] showed that the covalent hydrates of 5-R-9-X-tetrazolo[1,5-c]quinazolines have the structures (XIXA) or (XIXB) depending on the structure of the substituents R and X:

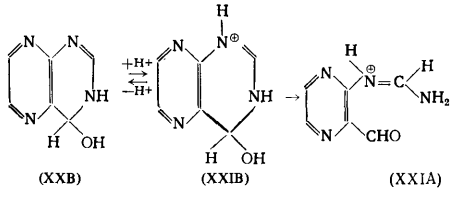


(XIXA) (XIXB)

Here X = R = H (A and B),[76] X = H and R = Me (B),[75] X = COOH and R = Ph (B),[78] X = Br and R = Me (A), and X = Br and R = Ph (A).[77,79]

Both isomers of the unsubstituted compound (XIX, X = R = H) were isolated in a pure state[76]. It has been shown for the methyl derivative (XIX, X = H, R = Me) that an acid medium stabilises the cyclic form and on dissolution in pyridine the isomerisation (XIXB) → (XIXA) takes place[75].

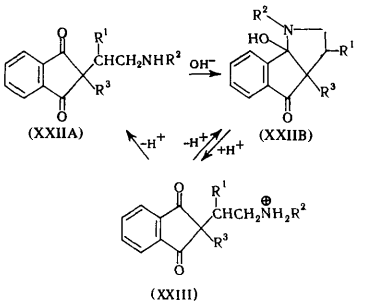
The covalent hydrates of pteridines[66,67,80,81] (XXB) and of 1,3,6-triazanaphthalenes[82] are rapidly converted in an acid medium into the open-chain isomers (XXIA). The opposite process takes place on neutralisation. Evidently the isomerisation (XXIB) ⇌ (XXIA) can be accounted for by the fact that the basicity of the nitrogen atom is sharply reduced by protonation:



(XXB) (XXIB) (XXIA)

Depending on the molecular structure, the protonation of aminocarbonyl compounds can stabilise either the cyclic or the open-chain form. Vanags and Dregeris obtained[83] both isomers of 2-β-(*N*-cyclohexyl)aminoethyl-2-phenylindan-1,3-dione—(XXIIa – A) and (XXIIa – B). The isomerisation (XXIIa – A) → (XXIIa – B) takes place in the

presence of bases. Such base-catalysed isomerisation has also been observed for a series of γ-ketoacid amides[2,84-86] and other aminocarbonyl compounds[87,88].



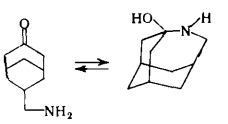
(XXIIA) (XXIIB)

(XXIII)

a) R^1 = H, R^2 = cyclo-C_6H_{11}, and R^3 = Ph.

The protonation of the cyclic isomer entails ring opening, (XXIIB) → (XXIII), while deprotonation is accompanied by the reverse process[83,89].

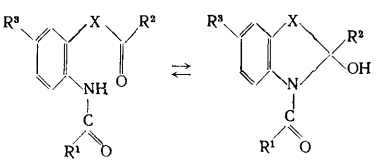
In solution 7-aminobicyclo]3, 3, 1]nonan-3-one gives rise to the equilibrium mixture (XXIVA) ⇌ (XXIVB).[90]



(XXIVA) (XXIVB).

The total absence of the C=O absorption from the spectrum of the hydrochloride suggests that the protonated form has a cyclic structure.

In the crystalline state, *o*-acetamidobenzil (XXV, R^1 = Me, R^2 = Ph, R^3 = H, X = CO) has the cyclic structure (XXVB), while in solution an equilibrium is established slowly[91]. A similar equilibrium has been observed[92-95] for a series of *N*-acyl-2-(2′-oxoalkyl)anilines (XXV, X = CH_2 or CHMe), the cyclic form predominating for the formyl derivatives (R^2 = H) and the open-chain form for the keto-derivatives (R^2 = Me). Analysis of the mass spectra established[96] that in the gas phase the equilibrium is completely displaced towards the open-chain form (XXVA):

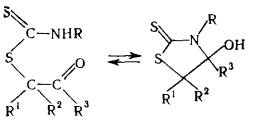


(XXVA) (XXVB)

(X = >CO, >CH_2, >CHMe)

There are many examples of ring–chain tautomerism in the series of aminocarbonyl compounds of more complex structure, where the cyclic isomer is a heterocycle with two or more heteroatoms.

The contents of the tautomers in solutions of S-(2-oxoalkyl)dithiocarbamates (XXVI) have been determined by infrared spectroscopy[97]. The open-chain isomer (XXVIa – A) and the cyclic isomer (XXVIa – B) were isolated on crystallisation from methylenechloride and from a methanol–water mixture respectively:



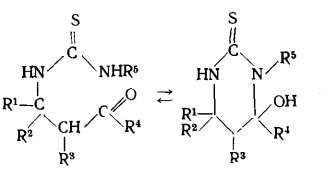
(XXVIA) (XXVIB)

a) R = Ph, R^1 = R^2 = H, and R^3 = *t*-Bu.

The introduction of the alkyl substituents R^1 and R^2 displaces the equilibrium towards the cyclic form (the *gem*-dimethyl effect[3,98]). The enhancement of the electron-donating properties of the substituent R^3 and the increase of the steric bulk of the substituents R and R^3 stabilise the open-chain form[97,99].

S-(3-Oxoalkyl)dithiocarbamates[100,101] exhibit a smaller tendency towards the formation of the cyclic form. However, compounds of this series, containing the *gem*-dimethyl fragment, have the cyclic structure in the crystalline state and in solution the equilibrium is displaced towards the open-chain form[101].

Unkovskii and coworkers[102-104] showed that *N*-(3-oxoalkyl)-*N*′-substituted thioureas have the cyclic structure in the crystalline state, with one exception[103], and in solution they give rise to the equilibrium mixtures (XXVIIA) ⇌ (XXVIIB), the equilibrium being established slowly (over a period of 6–15 days):



(XXVIIA) (XXVIIB)

The equilibrium concentrations of the tautomers were determined[104] from the intensities of the C=O band in the infrared spectra of the solutions. The introduction of methyl groups as the substituents R^1, R^2 and R^3 (R^4 = Me throughout) stabilises the cyclic form in the following sequence (the arrow indicates the direction of the increase of stability of the cyclic form):

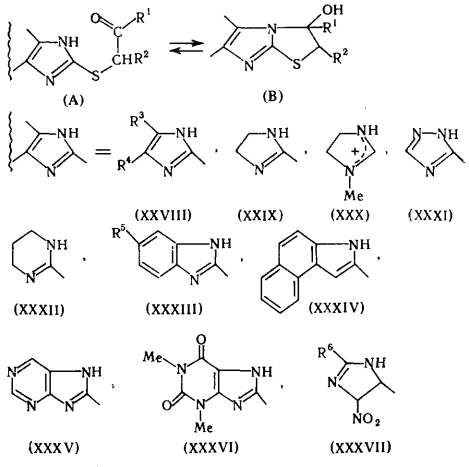
R^1	H	H	Me	Me	Me
R^2	H	H	H	H	Me
R^3	Me	H	Me	H	H

An increase of the effective bulk of the substituent R^5 is accompanied by an increase of the rate of ring opening and a shift of the equilibrium towards the open-chain form (XXVIIA). One cannot agree with the assertion[104] that the enhancement of the electron-donating properties of the substituent R^5 acts in the same direction. In contrast to keto-derivatives, the aldehydes (XXVII, R^4 = H) exist in solution entirely in the cyclic form.

A similar situation, where the crystalline compounds have the cyclic structure and equilibrium mixtures are produced in solution, has been described for a series of *S*-methyl-*N*-(3-oxoalkyl)isothioureas[105,106].

2-Ureido-,[107,108] 2-thioureido-,[109,110] and 2-guanidinoindan-1,3-diones[108] and 2-ureido- and 2-thioureidobenzophenones[111-113] have cyclic structures and there is no evidence for the occurrence of the ring–chain equilibrium in solution.

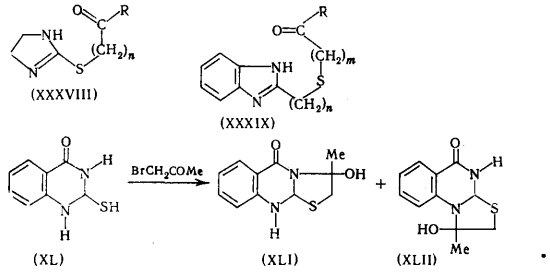
The ring–chain tautomerism of *S*-acylalkyl-substituted 2-mercaptoimidazole (XXVIII),[114-119] 2-mercaptoimidazoline (XXIX),[114,117,119-121] 2-mercapto-1-methylimidazolinium (XXX),[122] 3-mercapto-1,2,4-triazole (XXXI),[119] 2-mercapto-3,4,5,6-tetrahydropyrimidine (XXXII),[119] 2-mercaptobenzimidazole (XXXIII),[114,120,121,123-129] 2-mercaptonaphtho[1,2-*d*]imidazole (XXXIV),[114,130,131] 8-mercaptopurine (XXXV),[114,132] 8-mercaptotheophylline (XXXVI),[114,132] and 5-mercapto-4-nitroimidazole (XXXVII,[133,134] which were isolated in most cases as intermediates in the synthesis of imidazo[2,1-*b*]thiazoles and their condensed derivatives, was investigated by infrared and ^{1}H NMR spectroscopy. In a study of the effect of the structure and the state of aggregation on the stability of the tautomers and on the equilibrium, it was established[114,127] that 2-formylmethylmercaptoimidazoles and their condensed derivatives have cyclic structures both in the crystalline state and in solution. On passing from aldehydes to ketones of the aliphatic (R^1 = Me) and aromatic (R^1 = Ph) series, the stability of the open-chain form increases.



It has been shown[127] that in the series of 2-acylmethylmercaptobenzimidazoles (XXXIII, $R^2 = R^5 = H$) with a wide range of substituents R^1, the open-chain form is stabilised by bulky substituents R^1 and also by the conjugation of the carbonyl group with the aromatic ring and the ethoxycarbonyl or cyclopropyl group. The compounds (XXXIII, R^1 = *p*-XC_6H_4, COOEt, cyclo-C_3H_5, $R^2 = R^5 = H$) exist exclusively in the open-chain form (A) in the crystalline state and in solution. It is remarkable that the stability of the open-chain form is unaffected[125] by the introduction of electron-accepting substituents in the *para*-position of the aromatic ring (R^1 = *p*-$NO_2C_6H_4$), although it has been shown for the trifluoromethyl derivative (XXXIII, $R^1 = CF_3$, $R^2 = R^5 = H$) [126,127] that the presence of a powerful *I*-effect in the substituent R^1 completely displaces the equilibrium towards the cyclic form. The introduction of the nitro-group into the benzimidazole ring to give (XXXIII, R^1 = Me, $R^2 = H$, $R^5 = NO_2$) diminishes the nucleophilic properties of the nitrogen atom and displaces the equilibrium towards the open-chain form relative to the unsubstituted compound (XXXIII, $R^5 = H$).

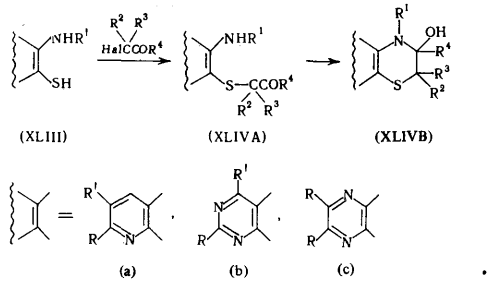
The crystalline state stabilises the cyclic form[114]. While the compound has the open-chain structure (A) in the crystalline state, in solution the equilibrium is completely displaced towards (A). Crystalline cyclic isomers (B) have either the cyclic structure also in solution or (A) ⇌ (B) equilibrium mixtures are produced[127].

A study of the effect of the size of the ring formed on the stability of the cyclic isomer in a series of hydroxyderivatives of imidazoline (XXXVIII, n = 1 or 2) and benzimidazole (XXXIX, n = 0 or 1 and m = 1 or 2) established[120,121] that the cyclic form is produced only on closure of a five-membered ring (XXXVIII, n = 1; XXXIX, n = 0, m = 1).



The reaction of 2-mercapto-4-oxotetrahydroquinazoline (XL) with bromoacetone results in the formation[135] of a mixture of products (XLI) and (XLII) in proportions of **9**:1. On this basis, the authors conclude that the formation of the cyclic form involves preferentially the sterically less hindered nitrogen atoms even if the competing nitrogen atom is more basic.

In reactions of *o*-aminomercapto-derivatives of pyridine (XLIIIa),[136-140] pyrimidine (XLIIIb),[88,141-144] and pyrazine (XLIIIc)[145,146] with α-halogenocarbonyl compounds, Safonova and coworkers obtained in most cases only the most stable isomer [either (XLIVA) or (XLIVB)] and their dehydration products.



Electron-accepting substituents R^4 and electron-donating substituents in the heterocycle (R and R^1) stabilise the cyclic form[137,142,144-146]. Phenylacyl derivatives show a smaller tendency towards the formation of the cyclic form (XLIVB) than the products of the condensation with aliphatic halogenoketones. Both isomers were isolated in reactions of 5-amino-4-chloro-6-mercaptopyrimidine (XLIIIb, R = R^1 = H, R^1 = Cl) with phenylacyl bromides ($R^4 = C_6H_4X$, X = H, 4-Br, 3-NO_2, or 4-NO_2)[88,141] and of 3-amino-6-chloro-2-mercaptopyridine (XLIIIa, $R^1 = R'$ = H, R = Cl) with *o*-substituted (F, Br, Me) phenylacyl halides[140]. In a medium close to neutrality 5-amino-4-chloro-6-phenylacylmercaptopyrimidines (XLIVb – A) are formed. The isomerisation (XLIVb – A) → (XLIVb – B) is base-catalysed. However, after the introduction of a methyl group into the amino group (R^1 = Me), such isomerisation could not be achieved[88].

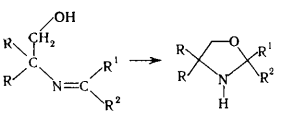
Tautomeric equilibria in solutions of 6-alkyl-4-chloro-6-hydroxy-5,6-dihydropyrimido[4,5-*b*][1,4]thiazines (XLIVb – B, R = R^1 = R^2 = R^3 = H, R′ = Cl, R^4 = Me, CH_2Cl, or CH_2COOEt) were not observed by infrared and ^1H NMR spectroscopic methods[144]. The derivatives of these compounds having a methyl group at the nitrogen atom (R^1 = Me) form equilibrium mixtures in solution. In deuteriochloroform solution of the 6-methyl derivatives (XLIVb, R^1 = R^4 = Me, R′ = Cl) the equilibrium is displaced towards the open-chain form and in solutions of the compounds (XLIVb, R^1 = Me, R′ = Cl, R^4 = CH_2Cl or CH_2COOEt) it is displaced towards the cyclic form. The addition of a proton-accepting agent (C_5H_5N-d_5) to the solutions displaces the equilibrium towards the cyclic form. The destabilising effect of the methyl group (R^1 = Me) at the nitrogen atom on the cyclic form cannot be accounted for in terms of electronic hypotheses, because the methyl group enhances the nucleophilic properties of the nitrogen atom and consequently should have the opposite effect. The experimentally observed influence of the methyl group can be explained[144] by the steric interaction of *peri*-substituents in the cyclic form (XLIVb – B, R′ = Cl, R^1 = Me), which destabilises the 1,4-thiazine ring.

Apart from the examples discussed above, there is evidence for ring–chain tautomerism (IA ⇌ IB, X = NR) in the series of monohydrazones of 1,3-dicarbonyl compounds[147,148], *N*-(2-oxoalkyl)triazenes[149,150], *N*-acylmalonodianilides[151], *O*-(3-oxoalkyl)hydroxylamines[152], urethanes derived from benzoin[153], 2-benzoylbenzenesulphonamide and 2-phenylacylbenzenesulphonamides[154], *NN*′-dimethylhydrazides of 2-acylbenzoic acids[155], and 6-hydroxycrinamines[156].

III. IMINES AND HYDRAZONES

Hydroxy-derivatives (IIA ⇌ IIB, IIIA ⇌ IIIB, X = O)

The tautomeric equilibrium (XLVA) ⇌ (XLVB) is observed in solutions of oxazolidines[1,157-161]. An increase in the steric bulk of the substituents R^1 and R^2 stabilises the open-chain form. It has been established that an enhancement of the electron-accepting properties of the substituents X in the aromatic ring in the series of 2-(3′- or 4′-X-phenyl)-4,4-dimethyloxazolidines (XLV, R = Me, R^1 = H, R^2 = 3′ or 4′-XC_6H_4) displaces the equilibrium towards the cyclic form[160]:

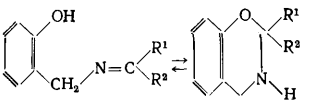


(XLVA) (XLVB).

A linear correlation has been observed between the tautomeric equilibrium constants K_T = [B]/[A] and the σ or better σ* constants of the substituents X in the aromatic ring [$\lg(K_T/K_0) = 0.86\sigma$, $r = 0.973$; $\lg(K_T/K_0) = 0.54\sigma^*$, $r = 0.999$]. The equilibrium constants were determined from the intensities of the signals of the geminal proton relative to the aryl group (R^1 = H) in both tautomeric forms[159,160].

The products of the condensation of 3-aminopropanol with carbonyl compounds were obtained either in an open-chain form or as tetrahydro-1,3-oxazines[162,163]. They show a greater tendency towards cyclisation than *N*-(2-hydroxyethyl)imines. 4-Aminobutanol gives rise to hexahydro-1,3-oxazepine in the reaction with formaldehyde and the products of its condensation with benzaldehyde and acetophenone have an open-chain structure[164].

In the crystalline state *N*-(2-hydroxybenzyl)imines of aromatic aldehydes (XLVI, R^1 = H, R^2 = 4′-XC_6H_4) have the open-chain structure (XLVIA), while in solutions the equilibrium (XLVIA) ⇌ (XLVIB) is established rapidly[165,166]:



(XLVIA) (XLVIB).

The tautomeric equilibrium constants are satisfactorily correlated with the σ or σ* constants of the substituents X [$\lg(K_T/K_0) = 0.74\sigma$, $r = 0.993$; $\lg(K_T/K_0) = 0.68\sigma^*$, $r = 0.999$].[160,166]. The *N*-(2-hydroxybenzyl)imines derived from aliphatic aldehydes and ketones have the cyclic structure (XLVIB) and in solutions the equilibrium is almost entirely displaced towards the cyclic form. It has been established by ^1H NMR [167] that protonation of the compounds (XLVI, R^1 = H, R^2 = alkyl or aryl; R^1 = R^2 = alkyl) in solution in trifluoroacetic acid results in the formation of open-chain immonium ions. Protonated cyclic forms were obtained only for the imines derived from formaldehyde and trichloroacetaldehyde.

The 1,3-oxazine–Schiff base tautomerism was observed also in solutions of the products of the condensation of 2-hydroxybenzylamine with α-dicarbonyl compounds[168]. 2,4-Diaryl-2,3-dihydro-1*H*-nathpho[1,2-*e*]-1,3-oxazines obtained[169] by the condensation of 1-(α-aminobenzyl)-2-naphthol with aromatic aldehydes have a cyclic structure in the crystalline state and in solution give rise to equilibrium mixtures; an equilibrium has also been observed between the cyclic and open-chain protonated forms in solution in trifluoroacetic acid.

Table 2. Effect of the proton-accepting properties of solvents on the constants of the tautomeric equilibrium (XLVA) ⇌ (XLVB) (R = Me, R^1 = H, R^2 = Ph).[159]

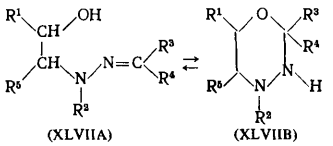
Solvent	$\Delta\nu^*_{OH}$, cm^{-1}	K = [B]/[A]**	Solvent	$\Delta\nu^*_{OH}$, cm^{-1}	K = [B]/[A]**
Carbon tetrachloride	0	1.89	Acetone	110	0.42
Chloroform	8	1.72	Tetrahydrofuran	156	0.51
Dimethyl carbonate	69	0.80	Dimethylacetamide	193	0.12
Acetonitrile	87	0.62	Dimethyl sulphoxide	224	0.10

* The shift of the hydroxyl band frequency in the infrared spectra of solutions of di-t-butylmethanol as a measure of the proton-accepting properties of the solvent.
** Determined by ^1H NMR at 38°C.

Under the influence of solvents, the constants of the tautomeric equilibria (XLVA) ⇌ (XLVB) and (XLVIA) ⇌ (XLVIB) vary over a wide range, but they are not correlated either with the dipole moments, or with the dielectric constants, or with Kosower's *Z* constants of the solvents[166]. A satisfactory correlation has been found[159], between the frequency shifts of the hydroxyl band $\Delta\nu$(OH) in the infrared spectra of solutions of di-t-butylmethanol on formation of intermolecular hydrogen bonds with the

solvent and the activation enthalpies ΔH° for the tautomeric transformations (XLVA) ⇌ (XLVB) (R = Me, R^1 = H, R^2 = Ph) in the same solvents. Consequently the ability of the solvents to form intermolecular hydrogen bonds with the hydroxy-group of the Schiff base plays the main role in determining the state of equilibrium. The enhancement of the proton-accepting properties of the solvent displaces the equilibrium towards the open-chain form (Table 2).[159]

Potekhin and coworkers[170-175] made a systematic study of the tautomerism (XLVIIA) ⇌ (XLVIIB) of *N*-(2-hydroxyalkyl)hydrazones. The tautomeric composition was determined by measuring the molecular refraction and by ^{1}H NMR. Freshly prepared products of the condensation of *N*-alkyl-*N*-(2-hydroxyalkyl)hydrazines with aldehydes and ketones in most cases have the cyclic structure of alkyl-substituted perhydro-1,3,4-oxadiazines (XLVIIB). On storage and in solution, they form the equilibrium mixtures (XLVIIA) ⇌ (XLVIIB). The equilibrium concentration of the open-chain form (XLVIIA) increases with increase of the number and steric bulk of the alkyl substituents at the carbon atom of the C=N bond (R^3, R^4).



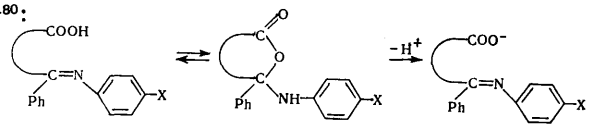
(XLVIIA) (XLVIIB)

The introduction of the methyl group in the hydroxyethyl group (R^1 = Me), the introduction of an alkyl substituent at the nitrogen atom (R^2 = alkyl), and an increase of the steric bulk of the latter substituent shift the equilibrium towards the cyclic form (XLVIIB). *N*-Unsubstituted 2-hydroxyethyl- and 2-hydroxypropyl-hydrazones (XLVIIA, R^1 = H or Me, R^2 = H) [172,173] and also products of the condensation of lactic acid hydrazide with carbonyl compounds[176] do not give rise to the cyclic form. In the series of *N*-aryl-*N*-hydroxyethylhydrazones (XLVII, R^1 = H, R^2 = *p*-XC_6H_4) a shift of the equilibrium towards the cyclic form was observed[175] with enhancement of the electron-accepting properties of the substituent X in the aromatic ring.

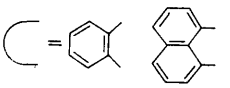
The greater tendency of aldehyde hydrazones to form the cyclic form (XLVIIB) compared with ketone hydrazones can be explained[172] by the fact that perhydro-1,3,4-oxadiazines with two alkyl substituents at $C_{(2)}$ have an increased conformational energy. An important factor facilitating intramolecular cyclisation is also the higher electrophilicity of the carbon atom in the C=N bond in aldehyde derivatives compared with ketone derivatives[38,177].

The tautomeric equilibrium constants of the products of the condensation of *N*-amino-(-)-ephedrine with aliphatic aldehydes (XLVII, R^1 = Ph, R^2 = R^5 = Me, R^3 = H, R^4 = alkyl) at different temperatures in solution in tetrachloroethylene were measured by ^{1}H NMR [178] in the presence of an acid catalyst (0.1% CF_3COOH), which increases the rate of tautomerisation. An increase of the polarity of the solvent, an increase of solution temperature (cf. Potekhin and Zaitsev[173]), and also an increase of the steric bulk of the alkyl substituent R^4 displace the equilibrium towards the open-chain form.

In the crystalline state the anils of 2-benzoylbenzoic acid[179,180] have the cyclic structure of 3-arylamino-3-phenylphthalides (XLVIIIa – B), while in solution the equilibrium (XLVIIIa – A) ⇌ (XLVIIIa – B) is appreciably displaced to the right. Electron-accepting substituents in the aromatic ring stabilise the cyclic form. The enhancement of the polarity and proton accepting properties of the solvents shift the equilibrium to the open-chain form[180]:



(XLVIIIA) (XLVIIIB) (XLIX)

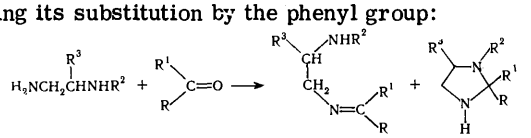


(a) (b)

Compared with the molecule of the anil of 2-benzoylbenzoic acid (XLVIIIa – A), in the (XLVIIIb – A) molecule the interacting COOH and C=N groups are sterically in greater proximity and therefore the equilibrium in solutions of 2-benzoylnaphthoic acid anils is fully displaced towards the cyclic form (XLVIIIb – B).[181] When (XLVIIIa) and (XLVIIIb) are treated with bases, the open-chain anions (XLIX) are formed.

Amino-derivatives (IIA ⇌ IIB, IIIA ⇌ IIIB, X = NR)

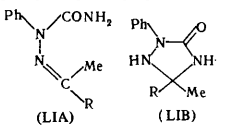
Mixtures of open-chain and cyclic isomers, (LA) and (LB), are formed in reactions of ethylenediamines with aldehydes and cyclic ketones. However, Chapuis et al.[182] were unable to confirm the existence of the tautomeric equilibrium (LA) ⇌ (LB) in solution. It has been shown by ^{1}H NMR that the fraction of the cyclic isomer in the mixture of reaction products decreases with increase of the steric bulk of the alkyl substituent R^1 (for R = H) or following its substitution by the phenyl group:



(LA) (LB)

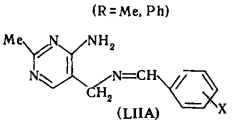
Acetone and acetophenone 2-phenylsemicarbazones have been obtained[183] in both the open-chain (LIA) and cyclic (LIB) forms. The isomerisation (LIA) → (LIB) takes place in the presence of acid.

The reactions of 4-amino-5-aminomethyl-2-methyl-(or phenyl)pyrimidine with aromatic aldehydes give rise to open-chain (LIIA) or cyclic (LIIB) condensation products or their mixtures[184]. However, it is impossible to find a relation between the electronic properties of the substituent in the aromatic ring of the aldehyde and the structure of the isomer formed.



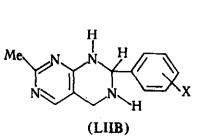
(LIA) (LIB)

(R = Me, Ph)



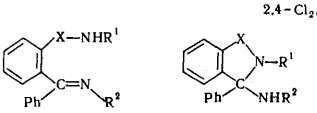
(LIIA)

(X = 4-Cl, 4-Br, 4-F)



(LIIB)

(X = 4-F, 4-MeO, 4-NO_2, 2,4-Cl_2, 3,4-Cl_2)



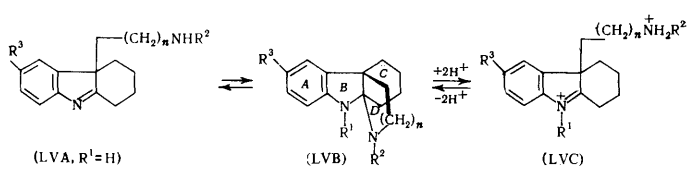
(LIIIA, LIVA) (LIIIB, LIVB)

(LIII, X = CO; LIV, X = SO_2)

Both isomers have been obtained in the series of imines[154] and anils[185] derived from 2-benzoylbenzamides—(LIIIA) and (LIIIB). The imine derived from 2-benzoyl-*N*-methylbenzamide has been obtained only in the cyclic form (LIIIB, R^1 = Me, R^2 = H). The anilide has been isolated in the open-chain form (LIIIA, R^1 = Ph, R^2 = H). When its solution in deuteriochloroform is stored at room temperature or its solution in ethanol is heated, the isomerisation (LIIIA) → (LIIIB) takes place readily. A similar isomerisation occurs in a series of anils of *N*-alkyl-2-benzoylbenzamides (LIII, R^1 = n-Pr, $PhCh_2$, i-Pr, or t-Bu, R^2 = Ph[5]), obtained by treating 3-chloro-2,3-diphenylisoindolinone with alkylamines[185]. An increase of the steric bulk of the substituent R^1 hinders the isomerisation (LIIIA) → (LIIIB): the *N*-benzylamide isomerises more slowly at room temperature in ethanol solution than the *N*-propylamide, while the *N*-isopropyl- and *N*-t-butyl-amides are stable under these conditions. They isomerise on refluxing the ethanol solutions with added triethylamine. In solutions in dioxane at room temperature both isomers (LIIA and LIIIB, R^1 = alkyl, R^2 = Ph) are stable and equilibrium mixtures are not formed when the solutions are stored for 24 h.

The imine derived from *N*-methyl-2-benzoylbenzenesulphonamide has been obtained[154] in the cyclic form (LIVB, R^1 = Me, R^2 = H) and the *N*-phenyl derivative has been obtained as a mixture of both isomers with the open-chain form predominating.

Ring—chain tautomerism has been observed[186] for echiboline (LVB, $R^1 = R^2 = R^3$ = H, n = 1) and its derivatives. In all cases protonation results in the open-chain dication (LVC) and deprotonation is accompanied by cyclisation:

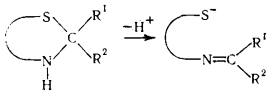


(R^1=H, Me; R^2= H, Me; R^3=H, OMe; n=1,2,3)

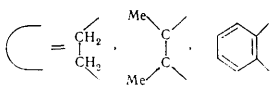
Certain echiboline derivatives (LV, R^1 = H, R^2 = H or Me, R^3 = MeO) exist in the cyclic form in solvents of low polarity, while in methanol solutions they form equilibrium mixtures with the open-chain form. Ring opening is facilitated by the presence of unsubstituted nitrogen atoms ($R^1 = R^2$ = H), by the introduction of the methoxy-group into the aromatic ring (R^3 = MeO) which decreases the electrophilicity of the carbon atom of the C=N bond in the molecule of (LVA), and by increase of ring size. Echiboline itself (LVB, $R^1 = R^2 = R^3$ = H, n = 1) exists in the cyclic form in solution, an equilibrium is observed with n = 2, and on further increase of ring size (n = 3) the cyclic form is not formed at all.

Mercapto-derivatives (IIA ⇌ IIB, X = S)

The products of the condensation of 2-mercaptoethylamine[187-189], 2-mercapto-3-butylamine[187], and 2-mercaptoaniline[190-192] with carbonyl compounds have exclusively the cyclic structure (LVIB). The formation of open-chain derivatives when the alkylation reactions are carried out in highly alkaline media is indirect evidence for the open-chain structure of the anionic form (LVIC):



(LVIB) (LVIC)



In reactions with formaldehyde and cyclohexanone, 3-mercaptopropylamine forms the corresponding tetrahydro-1,3-thiazines and the reaction with benzaldehyde gives a mixture of both isomers with the Schiff base predominating[193]. The reaction of 4-mercaptobutylamine with cyclohexanone gives rise to hexahydro-1,3-thiazepine[164].

The concept of the ring—chain equilibrium of mercaptoalkylimines has been used[194] to explain the mechanism of ring contraction in the 5,6-dihydro-1,4-thiazines under the influence of hydrogen sulphide as well as the reverse reaction—the expansion of the rings of thiazolidines under the influence of elemental sulphur.

Mayer and Lauerer[195] quote interesting examples of the ring—chain tautomerism in the series of 1,3,4-thiadiazolidine and 1,3,4-thiadiazoline derivatives (Schemes 2—4). The state of equilibrium depends on the pH of the medium. The anionic forms (Schemes 2 and 3) have the open-chain structure.

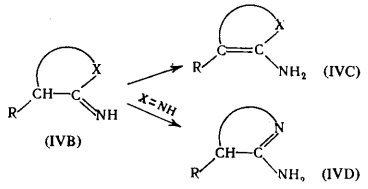
IV. NITRILES

(IVA → IVB, X = O, NR, or S)

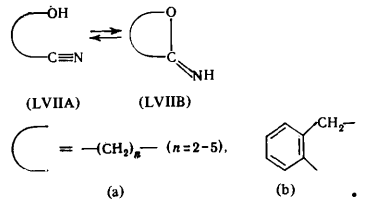
Numerous ways of synthesising heterocyclic imines or amines whose final stage is intramolecular nucleophilic addition of OH, NH, and SH groups to the C≡N bond have been developed[196,197]. The intermediates formed in these syntheses, namely hydroxy-, amino-, or mercapto-nitriles (IVA, X = O, NR, or S), were frequently not isolated.

Examination of studies where the compounds (IVA) were isolated in a pure form shows that the isomerisation (IVA) → (IVB) takes place readily and irreversibly on heating in polar solvents[198-200], in the presence of acids[201-206] and bases[197,207-218], or simply on heat treatment[198,200,203,218-220]. Double melting points, i.e. the crystallisation of the substance after fusion and its second fusion ar the melting point of the cyclic isomer, are important phenomena in the thermal isomerisation of

2-cyanobenzamide[219] and 2-thioureidobenzonitrile[198]. The heterocyclic imines (IVB) formed frequently isomerise to heterocyclic amines (IVC or IVD) as a result of the migration of the double bond to the ring:

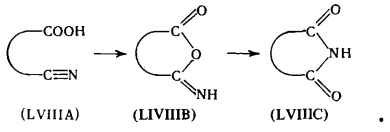


Matsui and also Renson observed $\nu(C\equiv N)$ and $\nu(C=N)$ bands in the infrared spectra of the ω-cyanoalcohols (LVIIa)[221] and 2-hydroxymethylbenzonitrile (LVIIb) [222] and concluded that the ring–chain tautomeric equilibrium (LVIIA) $\rightleftharpoons$ (LVIIB) occurs:



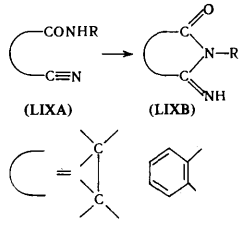
This conclusion requires additional confirmation, which can be secured by spectroscopic study of solutions of (LVIIa) and (LVIIb) in various solvents. Numerous data on the cyclisation reactions of hydroxynitriles[196,197,201] suggest that the isomerisation (IVA) → (IVB) (X = O) is irreversible. One cannot rule out the possibility that some investigators[221,222] did not work with the equilibrium system (LVIIA) $\rightleftharpoons$ (LVIIB) but with a mixture of isomers (LVIIA) and (LVIIB) (cf. des Abbayes[214]).

The mononitriles of phthalic[219], homophthalic[223], and other γ- and δ-dicarboxylic acids[197] readily isomerise to the imides (LVIIIC). This isomerisation can proceed through the stage involving the formation of the relatively unstable iminolactone (LVIIIB).[216,223] A study[218] of the infrared spectra of 2-cyanobenzoic acid in various solvents showed that the acid is stable in solution at room temperature and the equilibrium (LVIIIA) $\rightleftharpoons$ (LVIIIB) is not observed.

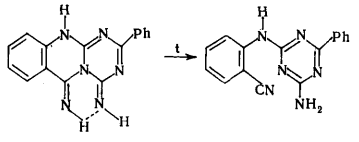


Both γ-and δ-aminonitriles[202,203,209,217,224-226], β-hydrazinonitriles[213,217,227], the hydrazones of cyanoketones[200], and β-cyanoacid hydrazides[190] isomerise to the corresponding heterocyclic imines or amines. The amides of β-cyanopropionic[208,210,215] and 2-cyanobenzoic acids (LIXA) [218-220] isomerise in the presence of bases (sodium alkoxides or triethylamine) or by a thermal process to the iminolactams (LIXB).

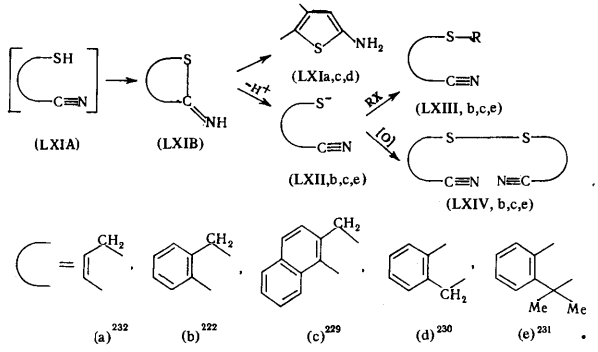
It has been shown that an increase in the bulk of the substituent R at the nitrogen atom in the series of 2-cyanobenzamides hinders the isomerisation (LIXA) → (LIXB) and for this reason *N*-(t-butyl)- and *N*-(1-adamantyl)-2-cyanobenzamides do not cyclise. In solutions in dioxane 2-cyanobenzamides and their cyclic isomers (LIXB) are stable and the equilibrium (LIXA) $\rightleftharpoons$ (LIXB) has not been observed by infrared spectroscopy[218]. 2-Ureido and 2-thioureido-benzonitriles[198,212,228] as well as urethanes derived from α-cyanohydrins[211] isomerise similarly.



Among amino-derivatives of nitriles, there is one unusual example[226] where the cyclic form undergoes thermal isomerisation to the open-chain form [(LXB) → (LXA)]. Evidently the gain of the aromatisation energy on formation of the *s*-triazine ring in the open-chain isomer (LXA) is of decisive importance here:



At the instant of their formation γ-mercaptonitriles (LXIA) cyclise[196,222,229-232] to iminothiophen derivatives (LXIB). If there is a hydrogen atom attached to the carbon atom which is α to the C=N bond, the latter undergo spontaneous further isomerisation to the aminothiophens (LXIa – c) and (LXId – C).[230,232] Stacy[229,231] and Renson[222] speak of the ring–chain tautomerism (LXIA) $\rightleftharpoons$ (LXIB), since the compounds (LXIb – B), (LXIc – B), and (LXIe – B) form both cyclic and open-chain derivatives. For example, alkylation in an alkaline medium gave the open-chain *S*-alkyl derivatives (LXIII, b, c and e) and on oxidation the products were the open-chain disulphides (LXIV, b, c, and e). Evidently the open-chain anion (LXII) is formed in an alkaline medium. However, the presence of the open-chain form either in the crystalline state or in solution could not be demonstrated by spectroscopic methods (Raman spectroscopy and ^{1}H NMR), i.e. the tautomeric equilibrium (LXIA) $\rightleftharpoons$ (LXIB) does not occur within the limits of the sensitivity of these methods.



---o0o---

Thus the application of infrared, ^{1}H NMR, and ultraviolet spectroscopic methods permits a quantitative characterisation of the phenomenon of ring–chain tautomerism. However, few such studies have been made in this field. A quantitative assessment of these processes,

based on at least two spectroscopic methods, is of greatest interest and evidently such investigations will be the first to develop.

A common defect of the majority of the experimental studies carried out to date in this field is the narrow range of test systems. Whereas the influence of the substituents on ring–chain equilibrium has been very thoroughly characterised[160,166,233-237] by correlation constants, attempts to assess quantitatively the influence of the structure of the link joining the two interacting groups are not described in the literature. Nevertheless, the study of the relation between the quantitative characteristics of intramolecular reversible addition reactions and the steric disposition of the reacting functional groups in the presence of a fairly rigid connecting link is of great theoretical interest.

ADDED IN PROOF

During the preparation of the review for the press, a number of studies on the ring–chain tautomerism of hydroxyketones[238-241], hydroxyiminoketones[242,243], 2-oxoalkyltriazenes[244,245], and *N*-(β-hydroxyalkyl)hydrazones[246] were published.

The Ullmann Ether Condensation

A.A.Moroz and M.S.Shvartsberg

The review deals with the Ullmann condensation as the most important method for the synthesis of aromatic ethers. The available information about the dependence of the reactivity of the reactants on structure and the reaction mechanism is examined and the experimental condensation conditions are discussed.
The bibliography includes 241 references.

8. The reaction mechanism 684

1. INTRODUCTION

In 1904 Ullmann[1] observed that the presence of metallic copper greatly facilitates the substituion of a halogen atom in an aromatic ring by a phenolic residue:

$$ArX + KOAr' \xrightarrow[Cu]{t^\circ} ArOAr' + KX \ .$$

This catalytic method for the synthesis of aromatic ethers, usually referred to as the Ullmann condensation[2], has become widely used in catalysis and industrial chemistry.

The Ullmann condensation is a method for the synthesis of phenyl ether (used to prepare heat exchangers and in the perfume industry[3-8]), substituted phenyl ethers (monomers for thermostable polymers[9-11]), and polyphenyl ethers, which have found important applications in various branches of modern engineering, for example, as oils for the creation of an ultrahigh vacuum, as high-temperature greases, hydraulic liquids, etc.[12-20]

A wide variety of aryl ethers, including intermediates in the synthesis of complex natural products such as alkaloids[21-36] and also diphenylene dioxides, have been synthesised on a preparative scale by the Ullmann condensation[37-41].

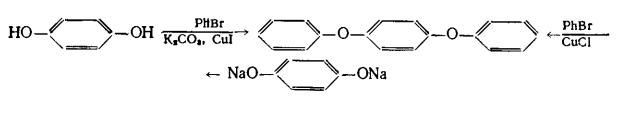
During the last ten years, a number of studies undertaken to determine the principal characteristics of this reaction and to elucidate its mechanism, have been published. Despite the extensive applications of the Ullmann condensation, there is no special review in the literature dealing with the synthetic aspects of this reaction.
The Ullmann ether condensation has been only briefly examined among other reactions in reviews on the synthesis and properties of phenyl[6] and polyphenyl[13,14] ethers, nucleophilic substitution[42], and copper-catalysed processes[43].

2. EXPERIMENTAL CONDENSATION CONDITIONS

The condensation is carried out by heating the initial reactants at 100-300°C in the presence of a copper catalyst in a solvent or without one (in the absence of a solvent, the optimal temperature is usually 180-220°C). To avoid the oxidation of the phenol, the reaction is sometimes performed in an inert atmosphere[44-51].

The phenolic components are frequently introduced in the form of salts, which are obtained by treating phenols with alkalis, alkali metals, and their alkoxides as well as sodamide[52] and sodium hydride[53]. Potassium salts are apparently more reactive. They are employed more frequently than sodium phenoxides[44,45,50,54]. However, a rigorous quantitative estimate of the comparative reactivities of different salts has not been made.

Free phenols can also be introduced into the reaction with aromatic halogeno-derivatives. Potassium carbonate is then added to the mixture and the method of synthesis is greatly simplified without reducing the yield of ethers[50,55]. This version of the condensation has undoubted advantages in the synthesis of aromatic polyethers. The difficulties in the preparation of such ethers are associated with the instability of the alkali metal salts of dihydric phenols which char to a considerable degree[56]. This can be partly avoided by preparing dry phenoxides beforehand under special conditions[53], which, however, complicates the synthesis. The use of K_2CO_3 and of free phenols eliminates altogether the stage involving the preparation of phenoxides and as a rule leads to higher yields of polyethers[57,58]. Thus bromobenzene condenses with hydroquinone in the presence of K_2CO_3, forming *p*-diphenoxybenzene in 63% yield[57], while the disodium salts of hydroquinone gives rise to the same product in a yield of only 0.3%:[53]



It is interesting that other salts, for example $Na_2B_4O_7$, MeCOOLi, MeCOONa, MeCOOK, $(NH_4)_2CO_3$, Na_2CO_3, and $CaCO_3$, are ineffective[57].

The oxides Cu_2O and CuO, which evidently combine the functions of a catalyst and a base, have an unusual effect[45,55,59,60]:

$$2ArX + 2Ar'OH + Cu_2O \rightarrow 2ArOAr' + 2CuX + H_2O \ .$$

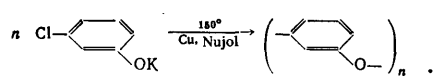
The rate of condensation is in this case lower than in the presence of K_2CO_3 and copper salts [57].

3. THE CATALYST

Metallic copper [1,10,11,15-17,20,21,23-29,35,36,41,47-52,55,56,61-166], the copper salts $CuCl_2$, [15,16,166-170] $Cu(OCOMe)_2$, [46,57,58,61,171-174] $CuSO_4$, [175-179] CuCl, [53,57,180,181] CuBr, [57,182,183] CuI, [57] $CuCO_3$, [7,184,185] and the copper oxides CuO [34,55,186,187] and Cu_2O [45,55,56,62,63,188-190] have been used as catalysts. In addition the copper salts of alkylnaphthalenesulphonic acids [191], alkylbiphenyldisulphonic acids [191], and phenols [192-194] as well as the copper(II) complexes $(C_5H_5N)_2 \cdot CuCl_2$ and $Cu(OCH_3)_2$ [51] have been proposed as catalysts of the Ullmann condensation. Powdered copper is obtained by reducing $CuSO_4$ with zinc [64] or by electrolytic deposition [65,195]. Copper comminuted mechanically, the so called copper bronze [22,66,67,196-211], is also used. Sometimes copper is employed in combination with its salts, for example with $Cu(OCOMe)_2$, [22,39,40,68-70,212-251] CuCl, [222] CuI, [197] and $CuNO_3$. [37,38]

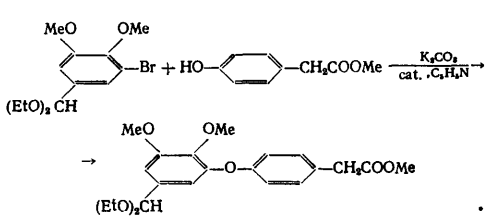
Attempts have been made to replace copper catalysts by other metals, salts, and oxides: titanium [223], iron [224], $Co(OCOMe)_2$, [225] $Ni(NO_3)_2$, [225] and Al_2O_3, [224] but these catalysts have not been widely used, probably owing to their low activity.

Despite the initial view [166], the relative catalytic activities of various forms of copper depend significantly on the method of preparation of the catalyst, the reaction conditions, and many other factors [44,53,55,71,195]. Thus, in a study of the polycondensation of potassium *m*-chlorophenoxide in Nujol in the presence of metallic copper, Brown and Goldman [195] observed that the method of preparation of the catalyst ("chemically" reduced or electrolytically precipitated copper with an admixture of 1% of zinc) and its preliminary treatment have a significant influence on the course of the reaction and the properties of the resulting polymer:



Under these conditions, copper oxides have an insignificant catalytic activity.

On the other hand, in the condensation of phenols and methyl *p*-hydroxyphenylacetate with certain aryl bromides, copper oxides proved to be more active [55]. An appreciable difference between CuO and Cu_2O was not observed and the relative efficiency of the catalyst depended on the nature of the initial compounds and the solvent. For example, in the condensation of the diethyl acetal of 5-bromoveratraldehyde with methyl *p*-hydroxyphenylacetate in boiling pyridine in the presence of copper, Cu_2O, and CuO the yields were 10, 30, and 35% for reaction times of 15, 10, and 9 h respectively:



In a study of the condensation of α-bromonaphthalene with phenols in collidine, Bacon and Stewart [45] also concluded that copper oxides are more active than copper and its salts (Table 1):

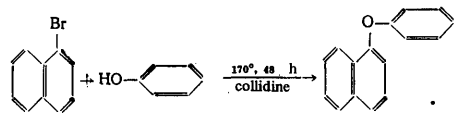


Table 1.

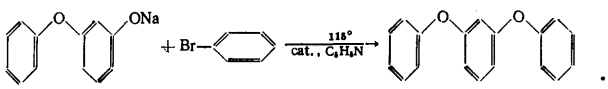
Catalyst	Cu_2O	CuO	Cu	CuCl	CuBr	$CuCl_2$
Yield of α-phenoxynaphthalene, %	50	31	23	traces	traces	0

However, in this case the condensation was carried out in the absence of potassium carbonate and the enhanced activity of copper oxides may have been due to the fact that they are capable of behaving as both catalysts and bases. The presence of oxidised species in finely divided metallic copper also cannot be ruled out.

According to Weingarten [44], $CuBr_2$, $CuCl_2$, $Cu(OCOMe)_2 \cdot H_2O$, CuI, CuBr, and CuCl are equally effective as catalysts of the condensation of bromobenzene with potassium phenoxide in diglyme. Metallic copper, Cu_2O, CuO, and $CuSO_4$ are inactive in this reaction.

Copper(I) and copper(II) salts exhibit approximately equal catalytic activities also in the condensation of sodium *m*-phenoxyphenoxide with bromobenzene in pyridine, while copper is ineffective [53]:



The first attempt to discover the catalytically active form of copper [226] did not elucidate the problem appreciably. More convincing results were obtained later [44] in a study of the condensation of bromobenzene with potassium phenoxide in diglyme in the presence of CuBr and $CuBr_2$. These salts showed equal catalytic activities and the ESR spectra and antimagnetic susceptibilities of the catalytic solutions were similar in the two cases. However, a CuBr solution prepared in an atmosphere of nitrogen gave a weaker ESR signal than a $CuBr_2$ solution and its magnetic susceptibility was negligible. On the other hand, when the condensation was carried out in an inert atmosphere, the reaction rate increased. Hence it followed that the active form of the copper catalyst is univalent copper. The catalytic activity of bivalent copper may have been due to its reduction by the phenoxide anion, which was then oxidised to a relatively stable free radical. The latter in fact made the reaction mixture paramagnetic. Indeed, the white precipitate deposited when the solution of $CuBr_2$ and potassium phenoxide in diglyme was poured into water proved to be a copper(I) salt and the addition to the catalytic solution of 2,6-di-t-butyl-4-methylphenol, 2,5-di-t-butylhydroquinone, or phenothiazine—compounds which trap free radicals—resulted in appreciable changes in the ESR spectrum but did not affect the rate of the Ullmann ether condensation.

It has been found[53] that metallic copper does not catalyse the condensation of bromobenzene with sodium *m*-phenoxyphenoxide in boiling pyridine and that, when CuBr is used as a catalyst, the introduction of copper powder into the reaction mixture does not affect the rate of this reaction. Since powdered copper completely reduced bivalent copper to the univalent state under these conditions, the authors[53] concluded that the only possible active form of the catalyst is univalent copper. These workers also believe that bivalent copper may be reduced by phenoxide anions. The low yields of products and the formation of large amounts of resins in the condensation of readily oxidised polyhydric phenols (catechol, hydroquinone, 2,6- and 1,5-dihydroxynaphthalenes and phloroglucinol) were explained by polymerisation processes involving radical-ions of the semiquinone type:

Thus the available literature data show that the active principle of the catalyst is probably univalent copper. On the other hand, bivalent copper compounds and metallic copper are active by virtue of the oxidation-reduction processes occurring in the reaction medium.

However, in the practical selection of the catalyst, one probably should not ignore also the role of factors such as the solubility of copper compounds, the effects of the chemical nature of the solvent and the reactants, etc.

4. THE SOLVENT

An excess of the phenol[7,49,67,72-79,184,185,198,200,220], heavy unsaturated and aromatic hydrocarbons[48,80,172,177-179], alcohols and glycols[22,63,81,82,197,224], diglyme[15,42,44,222], dioxan[22,171,173,174,176], ketones[65,83,169,180], dimethylformamide[11,55,187,189], dimethyl sulphoxide[11,227], nitrobenzene[84,197,204], pyridine and its derivatives[23,26,28,29,34,46,55,57,58,85,86,172,188], quinoline[63], and certain other organic compounds[11,55,63,169] have been used as solvents.

One of the best solvents is pyridine[53,55,57,58]. Thus, in the condensation of bromobenzene with the sodium salt of *m*-resorcinol in pyridine, the yield of *m*-diphenoxybenzene was 74% and the overall yield of this ether and *m*-phenoxyphenol reached 89%. In other solvents the yields were significantly lower[53] (Table 2):

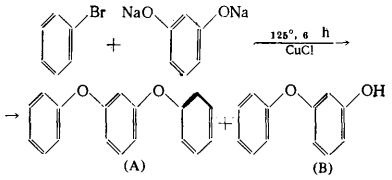


Table 2.

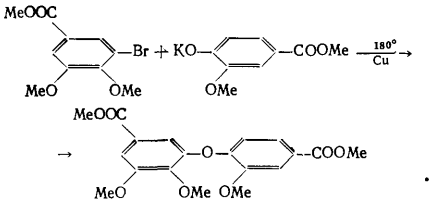
Solvent	Yield, %		Solvent	Yield, %	
	ether (A)	ether (B)		ether (A)	ether (B)
Pyridine (117°C)	74	15	Dimethylformamide	4	34
Pyridine + 2% of water (112°C)	4	22	Hexamethylphosphoramide	5	47
2,4,6-Collidine	17	25	Methyl sulphoxide	14	42
Pyridine *N*-oxide	18	40	n-Propyl sulphone	42	33
Di-n-butylamine	32	19	2-Methoxyethyl ether	21	25
1-Methyl-2-pyrrolidinone	11	46			

Attempts to find rigorous correlations between the effectiveness of the solvent and its characteristics, for example its basicity, have been unsuccessful[45].

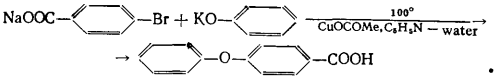
On the other hand, it is significant that the majority of the solvents employed contain in their molecules a heteroatom having a lone electron pair. The dissolution of the copper catalyst is apparently accompanied by complex formation in which the solvent participates via its heteroatom[53]. If it is presumed that the action of the catalyst is also in some way related to the formation of complexes with the reactants, then it is necessary that the copper–solvent complex should be dissociated to a fairly high extent. Indeed, in the above example of the condensation of bromobenzene with the sodium salt of *m*-resorcinol the replacement of 9% pyridine by $\alpha\alpha'$-bipyridyl, which is a more powerful ligand, reduces the yield of *m*-diphenoxybenzene from 74 to 31%. Thus the solvent plays to some extent the role of a cocatalyst[53].

In the light of these findings the promoting effect of the addition of compounds with a tertiary nitrogen atom[87,169,180,211] and the enhanced activity of the complex catalyst $(C_5H_5N)_2CuCl_2Cu(OMe)_2$ [51] become understandable. Admixtures which may be present in the solvent probably also have the same type of effect on the rate of reaction. Thus it has been shown that the reaction of bromobenzene with potassium phenoxide is faster in unpurified diglyme. After the solvent has been purified by distillation from $LiAlH_4$, the rate of reaction falls[44]. The active ingredient was isolated chromatographically; it is suggested[44] that it has the structure of the diester $CH_3OCH_2COOCH_2CH_2.OCHO$. It was observed that the addition of certain other esters, namely ethylene carbonate, the diacetate of propylene glycol, 1,2-diacetoxycyclohexane, etc. to the solvent has a similar activating effect.

The possibility of carrying out the reaction in aqueous media is not altogether clear. An example was quoted above (Table 2) where the addition of 2% of water to pyridine reduced the yield of condensation products almost threefold. Small amounts of water also inhibit the reaction between methyl 5-bromoveratrate and 4-hydroxy-3-methoxybenzoate; however, the process does not require the complete absence of water[71]:



On the other hand, a favourable effect of water on the reaction has also been noted[88,228]. For example, according to Vainshtein et al.[228], sodium *p*-bromobenzoate condensed in aqueous pyridine with potassium phenoxide to give a 90% yield of 4-carboxyphenyl phenyl ether, while in anhydrous pyridine the reaction did not occur at all:



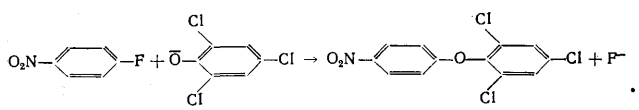
There are data concerning both unsuccessful[173,175] and successful[177] attempts at condensation in aqueous solutions. Instances are also known of its successful achievement in mixtures of organic solvents with water[172,179].

5. THE REACTIVITY OF ARYL HALIDES

As in the majority of copper-catalysed reactions of aryl halides[43,229,230], the case of substitution of halogen atoms in the Ullmann condensation decreases in the sequence I > Br > Cl ≫ F.[45,50,60,65,167,227] Thus, under standard conditions (170°C, 72 h, Cu_2O, collidine), the yields of phenyl ether in the condensation of iodo-, bromo-, and chloro-benzene with phenol were 70, 42, and 10% respectively[60].

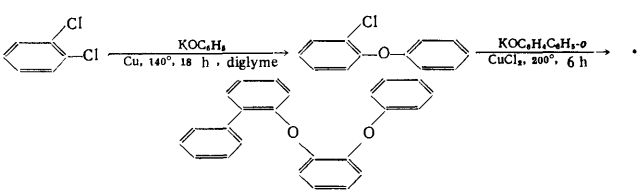
The relative rates of condensation of halogenobenzenes with potassium phenoxide in diglyme at 160°C in the presence of $CuCl_2$ have been determined[167]. For iodo-, bromo-, chloro-, and fluoro-benzenes, they are respectively 40, 40, 1, and 0.001% and more refined kinetic measurements showed that the rate for iodobenzene is approximately threefold higher than for bromobenzene.

On the other hand, there are literature data demonstrating a high reactivity of certain aryl fluorides[89,231]. For example, according to Dahlgard and Brewster[231], *p*-chloronitrobenzene and 2,4,6-trichlorophenol do not condense in an alkaline medium in the presence of a copper catalyst, but the condensation does proceed when *p*-fluoronitrobenzene is used as the halogen-containing component:

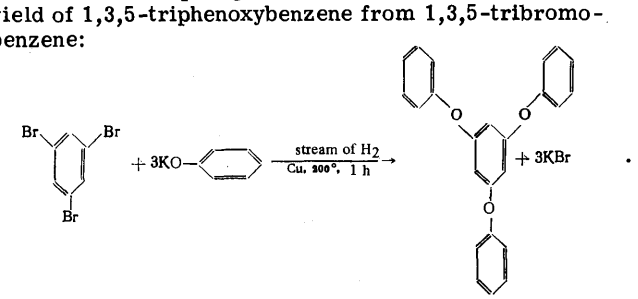


However, one cannot rule out the possibility that in this case the main role is assumed by the non-catalytic halogen-substitution reaction, which fluoro-derivatives in fact tend to undergo to the greatest extent[42,232].

The Ullmann ether condensation usually permits the introduction of several aryloxy-groups into the benzene ring[16,37,50,61,90-92,171]. In this case a stepwise substitution of halogens is possible. Thus 1,2-dichlorobenzene was condensed in succession with phenol and *o*-hydroxybiphenyl; the yield of the intermediate 2-chlorophenyl phenyl ether reached 70% and the yield of the final ether with four benzene rings, formed from the latter, was 62%:[15]

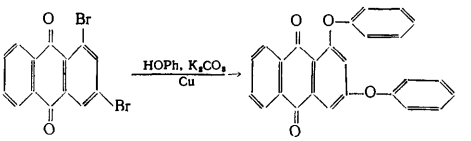


Ullmann and Sponagell[50] succeeded in obtaining a 90% yield of 1,3,5-triphenoxybenzene from 1,3,5-tribromobenzene:



However, the attempt to substitute the four bromine atoms in 1,2,3,5-tetrabromobenzene was unsuccessful. Owing to a dehalogenation side reaction, the initial tetrabromo-compound was reduced to 1,3,5-tribromobenzene and the only condensation product was 1,3,5-triphenoxybenzene (50% yield).

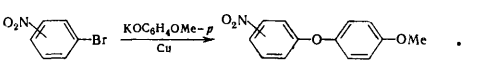
The condensations of various dihalogenoanthraquinones have been described: the yields of the diethers were 64 to 97%.[61,84] For example, 1,3-diphenoxyanthraquinone was synthesised from the corresponding dibromo-derivative by refluxing for 2 h with an excess of phenol in the presence of copper and potassium carbonate, the yield being 97%:[61]



Aryl halides containing a wide variety of substituents in the aromatic ring have been successfully employed in the Ullmann condensation. Even chemically reactive groups such as CHO,[36,85,93-95,211] OH,[15,24,37,49,67,68,78,90] and NH_2[61] do not then require special protection.

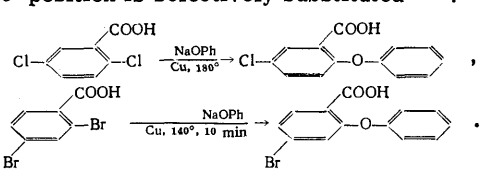
The nature and positions of the substituents have a significant influence on the reactivity of aryl halides. Highly electronegative groups in the *ortho*-position relative to the halogen have a marked activating effect on the latter. Unfortunately, the available literature data are insufficient for a comparison of the activating effects of these groups.

The nitro-group apparently has one of the most powerful activating effects. Its influence is clearly shown when it is present not only in the *ortho*- but also the *para*-position. The *meta*-nitro-group is in this respect less effective. Whereas *p*-bromonitrobenzene condensed with the potassium salt of the monomethyl ether of hydroquinone to give 4-methoxyphenyl 4-nitrophenyl ether in 80% yield, the yield of the corresponding phenyl ether from *m*-bromonitrobenzene under comparable conditions was only 31%:[96]

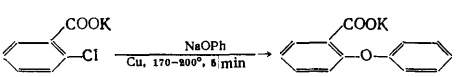


Owing to the enhanced reactivity of *o*- and *p*-halogenonitrobenzenes, the yields of their condensation products as a rule reach 80–90%.[45,64,89,93,96,197]

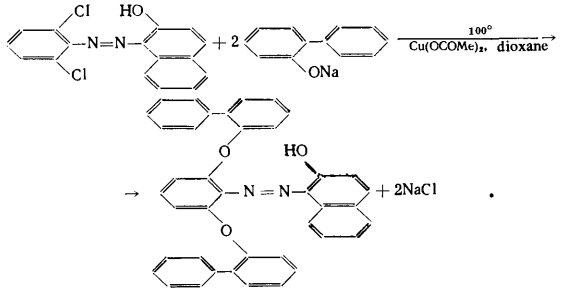
The activating effect of the carboxy-group is shown mainly when it is in the *ortho*-position with respect to the halogen. In dihalogenobenzoic acids the halogen atom in the *ortho*-position is selectively substituted[97,98]:



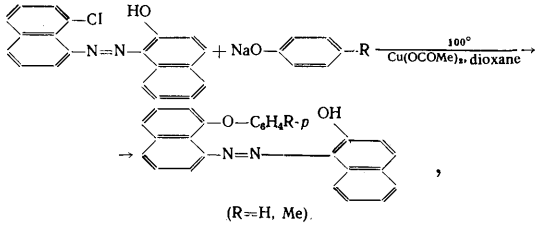
It is also instructive that in preparative syntheses the yields of *o*-aryloxybenzoic acids frequently exceed 80 to 90%.[99,100,166,197] For example, *o*-chlorobenzoic acid (in the form of a salt) condenses with sodium phenoxide on brief heating to 170–200°C in the presence of copper powder to give 90% of *o*-phenoxybenzoic acid[166]:



The *ortho*-halogen in azo-compounds exhibits a high reactivity [171-174,176-179]. The condensation of such compounds proceeds at comparatively low temperatures (93° to 110°C) and reaches completion in 4–16 h; the yields of the ethers are invariably high (70–100%). For example the reaction of 2,6-dichlorobenzene(1-azo-1′)-2′-naphthol with the sodium salt of 2-hydroxybiphenyl in boiling dioxan resulted in the quantitative substitution of both chlorine atoms in 4 h: [171]



The azo-group in the *peri*-position of α-chloronaphthalene has a similar effect [173]:



(R=H, Me).

(R=o-Me, p-Me, H, p-OMe)

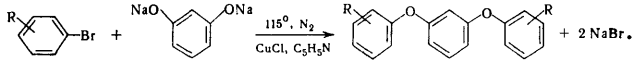
The presence of electron-donating substituents in the aryl halide molecule does not affect significantly the mobility of the halogen [45,53,101,167,233]. Thus the reaction of *p*-cresol with bromobenzene, *o*- and *p*-bromotoluenes, and *p*-bromoanisole in the presence of Cu_2O in collidine at 170°C in the course of 16 h gave similar yields of ethers: 43, 42, 41, and 54% respectively [45].

Table 3.

R(X=Cl)	H	*o*-Cl	*m*-Cl	*p*-Cl	*p*-Me	*p*-OMe
Relative rate	1.0	1.4	2.5	1.9	0.78	1.2
R(X=Br)	H	*o*-Me	*m*-Me	*p*-Me		*m*-Br
Relative rate	40	15	31	31		130

Nevertheless in the measurements of the relative rates of condensation of potassium phenoxide in diglyme at 160°C (Table 3) it was possible to observe a weak deactivating effect of the methyl group in various positions of the substituted halogenobenzene, which is typical for nucleophilic aromatic substitution. A slight activating effect of the second halogen atom, which increases in the series of isomers $o < p < m$, was also noted [167]:

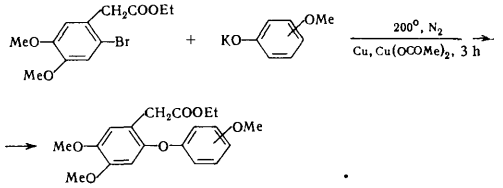
In agreement with this, Williams et al. [53] found that in the condensation of substituted bromobenzenes with the sodium salt of resorcinol the effect of substituents is in general typical for nucleophilic substitution and is described satisfactorily by the Hammett equation with the reaction constant $\rho = +1.4$:



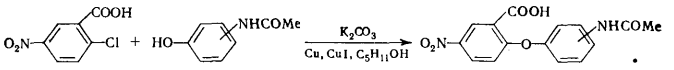
In this reaction the *p*-methoxy-group has a deactivating effect on the halogen and therefore, contrary to other data [45,167], also does not deviate from the general rule. However, one must emphasise that all these quantitative or semiquantitative determinations were made for extremely limited series of substituents.

6. THE PHENOLIC COMPONENT

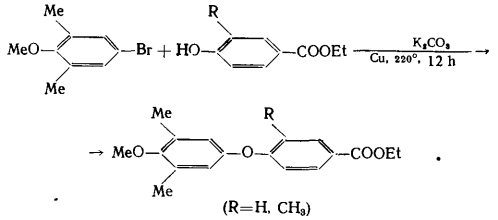
There are almost no literature data on the effect of the structure of the phenolic component on the rate of condensation. Electron-donating groups in the *ortho*-position probably reduce its reactivity. Thus potassium *o*-, *m*-, and *p*-methoxyphenoxides react under identical conditions with ethyl 2-bromo-4,5-dimethoxyphenylacetate, forming the corresponding phenyl ethers in yields of 6, 42, and 46% respectively [212]:



The reaction of *p*-*N*-acetamidophenol with 2-chloro-5-nitrobenzoic acid (boiling pentyl alcohol, potassium carbonate, copper powder, and CuI) resulted in the formation of 2-(*p*-*N*-acetamidophenoxy)-5-nitrobenzoic acid in 79% yield, while only 19% of the ether was obtained from *o*-*N*-acetamidophenol [197]:

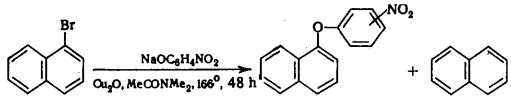


Whereas the introduction of one methyl group in the position adjoining the hydroxyl in ethyl *p*-hydroxybenzoate had only a slight effect on the yield of the product of its condensation with 4-bromo-2,6-dimethylanisole, two *ortho*-methyl-groups completely inhibited this reaction [102]:

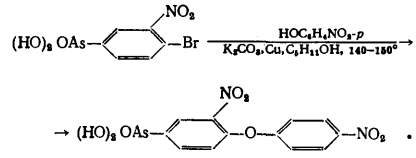


(R=H, CH_3)

Nitrophenols as a rule enter with difficulty into the Ullmann condensation. Thus potassium *p*- and *m*-nitrophenoxides condensed with α-bromonaphthalene in boiling dimethylacetamide in the presence of Cu_2O to give 9 and 38% yields of α-nitrophenoxynaphthalenes after 48 h. The *o*-nitrophenoxide did not condense but the initial bromo-derivative was reduced to naphthalene in all three cases to the extent of 9, 20, and 50% respectively[45]:



A relatively low yield of the ether was obtained also in the condensation of *p*-nitrophenol with 4-arsono-1-bromo-2-nitrobenzene: 10% against 54% for the unsubstituted phenol under the same conditions[82]:



The deactivating effect of the *p*-nitro-group was also noted by McRue et al.[22]

It is very difficult to obtain information concerning the influence of other substituents in phenol on its reactivity by comparing the available data. The differences between the reactivities of phenols based on the results of condensations with α-bromonaphthalene and 4-arsono-1-bromo-2-nitrobenzene under the conditions indicated above for the reactions with nitrophenoxides (in the condensation with α-bromonaphthalene, collidine was employed as the solvent instead of dimethylacetamide) are instructive in this respect, the yields (expressed as percentages) are indicated in brackets:

$$p\text{-MeO}(72) > p\text{-Me}(62) > p\text{-Cl}(49) > o\text{-COOH}(32) > p\text{-COOH}(11) \simeq$$
$$\simeq m\text{-NO}_2(12) \simeq p\text{-NO}_2(12)^{45};$$
$$o\text{-COOH}(82) > p\text{-Cl}(78) > p\text{-COOH}(60) > \text{H}(54) > p\text{-Me}(46) >$$
$$> o\text{-Me}(25) > p\text{-NO}_2(10)^{82}.$$

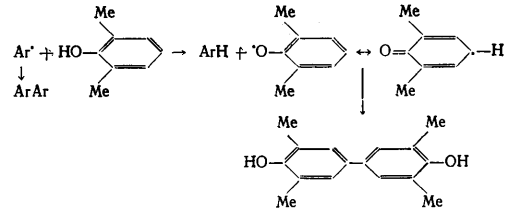
7. SIDE REACTIONS

Typical side reactions accompanying the Ullmann ether condensation are reductive dehalogenation[45,57,65,66,79,103,104,196,234,235], the Ullmann coupling process[45,86,235], and the exchange of halogens between the aryl halide and the copper salt[45].

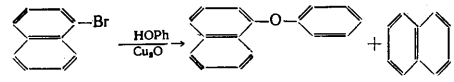
In the reduction process the phenolic component can behave as a hydrogen donor[45,235]. The importance of the side reaction probably increases when the reactivity of the phenol in the condensation is low. For example, the reaction of equimolar amounts of *o*-bromonitrobenzene with *p*-cresol in boiling collidine in the presence of Cu_2O gives a 48% yield of the ether together with 22% of nitrobenzene and 3% of *oo'*-dinitrobiphenyl as by-products. In the reaction with 2,4- and 2,6-dimethylphenols the yield of the ether falls to 0–2%, while that of nitrobenzene increases to 70–80%. At the same time bisphenols were identified in the reaction products, the yield of 4,4'-dihydroxy-3,5,3',5'-tetramethylbiphenyl reaching 20% in the latter case.

Bacon and Stewart[235] proposed the following mechanism for the formation of by-products:

$ArBr + Cu^+ \rightleftharpoons$ complex on the surface of $Cu_2O \rightleftharpoons Ar^\cdot + Cy^{2+} + Br^-$,



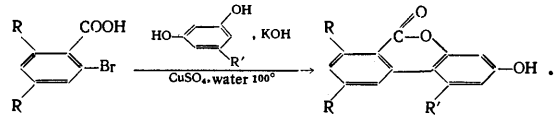
The solvent has an appreciable influence on the relative contributions of the main and side reactions. Thus, the reaction of α-bromonaphthalene with phenol in the presence of Cu_2O gives 61% of α-phenoxynaphthalene in 2,4,6-collidine, 46% in quinoline with 12% of naphthalene as a second product, while in pyridine *N*-oxide the yields are 38% of the ether and 36% of naphthalene[45]:



It is important to note that the characteristics of the structure of the aryl halide, which are responsible for its high reactivity in the Ullmann ether condensation, are probably favourable also for the side reactions.

The reactions enumerated above, occurring under the conditions of the Ullmann ether condensation as side processes, acquire independent synthetic value under special conditions[45,229,230,235,236].

Among other side reactions, mention should be made of condensations involving the mobile hydrogen atoms in the aromatic ring of one of the reactants. An interesting illustration of the possibility of reactions of this kind is provided by the formation of the lactones of substituted 2',4'-dihydroxybiphenyl-2-carboxylic acids in an aqueous alkaline medium in the presence of $CuSO_4$:[175,237,238]



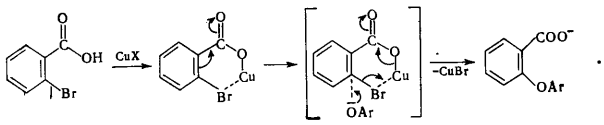
(R=OMe, R'=Me, R=R'=H)

8. THE REACTION MECHANISM

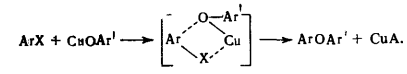
In 1941 Bunnet and Zahler[42] put forward a hypothesis concerning the mechanism of the Ullmann ether condensation according to which the action of the copper catalyst reduces to the formation of a halogenonium compound and a consequent increase in the mobility of the halogen under nucleophilic attack:

Bunnet and Zahler's mechanism had the importance of a general principle only and, owing to the lack of experimental data, could not specify the valence state of the catalytically active form of copper.

Later this hypothesis was used to account for the high activating effect of the *ortho*-carboxy-group and its almost total absence for the *para*- and *meta*-carboxy-groups [73]:

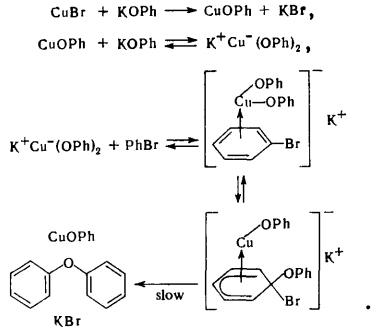


An essentially similar idea constituted the basis of the hypothesis [192] that the condensation proceeds via the usual four-centre mechanism, proposed for the exchange reactions of aryl halides with copper salts [43]:



According to this hypothesis, copper(I) phenoxide is formed in the reaction. The possibility of the direct formation of ethers from aryl halides and copper phenoxides has been demonstrated experimentally [192,194].

The condensation mechanism proposed by Weingarten [44] is based on a somewhat different principle. The author begins with the following experimental findings: (1) the catalytically active form of the copper catalyst is univalent copper; (2) the effect of the nature and positions of the substituents in the aryl halide on the mobility of the halogen atom is typical for nucleophilic substitution; (3) the mobility of the halogen decreases in the series I > Br > Cl > F, which is correlated with the ease of dissociation of the carbon–halogen bond. According to Weingarten, the catalytic effect of copper is determined by its interaction (as the phenoxide) with the π electrons of the aromatic system of the aryl halide and not with the halogen atom undergoing substitution. Copper thus plays the role of, as it were, an additional electron-accepting (i.e. activating) substituent:



The main idea of this mechanism is seen to be confirmed by data demonstrating the existence of a copper(I)–benzene complex [239] and the greater ease of substitution of the halogen by the nucleophilic agent in the π-complexes of aryl halides with transition metals, such as the complex of chlorobenzene with chromium tricarbonyl [240]. The proposed mechanism is consistent with kinetic data obtained in a study of the condensation of bromobenzene with potassium phenoxide in diglyme in the presence of CuBr: the reaction is of first order with respect to the aryl halide and the copper salt and of a fractional order with respect to the phenoxide, which increases from a value close to zero at high concentrations to approximately unity at low concentrations. The reaction equation, describing satisfactorily the experimental findings and reflecting the variable order with respect to the phenoxide, may be based either on the hypothesis that at high concentrations the phenoxide is associated but only the monomeric species are reactive or on the hypothesis of a salt effect due to the phenoxide itself. The author was unable to make a choice between these two alternatives.

Kopylov [241] suggested a free-radical mechanism of the Ullmann ether condensation:

This mechanism essentially reflects the tendency to combine within the framework of a fundamentally the same mechanism oxidative polycondensation of phenols [13], oxidative substitution at the halogen in halogenophenols [13], and the Ullmann ether condensation. The validity of this attempt is doubtful and conflicts with experimental data showing that free radicals are not involved in the Ullmann reaction and that the true catalyst of this reaction is univalent and not bivalent copper. Moreover, the first two reactions can occur also under the influence of non-copper oxidants, whereas copper is a specific condensation catalyst. It is more likely that the free radicals, whose formation is indeed possible under the conditions of the Ullmann reaction, are not responsible for the main process but only for the accompanying side reactions.

Immobilised Enzymes

A.I.Këstner

Adsorption, covalent bonding, and occlusion into the structure of a gel can be used to attach enzymes to insoluble carriers in order to obtain heterogeneous enzymic catalysts. The kinetic characteristics of the enzymes are affected by immobilisation, but these changes—quite often more apparent than real—are due to changes not in the properties of the enzyme molecules themselves but in their microenvironment. Immobilised enzymes possess enhanced stability, and can be employed in technical processes, biochemical analyses, and medicine. A list of 506 references is included.

I. INTRODUCTION

Artificial insoluble derivatives of enzymes are attracting increasing interest from chemists, biochemists, technologists, and medical men. These products—which, according to the recommendations of an international symposium[1], should be termed *immobilised enzymes*—have been recommended for use in technical processes, analytical chemistry, and medicine. Immobilised enzymes, especially in the form of membranes, may serve as models for subcellular structures. The prospects for the application of immobilised enzymes and certain convenient aspects for theoretical investigations have already been reflected in hundreds of papers and patents, which have been covered in dozens of reviews. Disregarding popular reviews and publicity, as well as relatively inaccessible publications, we can refer to several extremely serious and thorough surveys[2-20].

The immobilisation of enzymes forms part of the broader problem of the purposeful modification of biologically active substances. The present Review deals mainly with immobilised enzymes and insoluble complexes of enzymes with polymers. However, the immobilisation of enzyme inhibitors, antibodies, antigens, nucleic acids, hormones, and other biologically active substances is omitted, as well as the chemical modification of enzymes with simple substances. It must be emphasised here that the immobilisation of various biologically active substances capable of specific complex formation with biopolymers has become the foundation of an extremely effective technique for separating and purifying proteins and other biologically important substances by affinity chromatography (chromatography based on specific sorption). This method has developed especially rapidly during recent years, and has formed the subject of several detailed reviews[21-28].

The ability of enzymes to function when present in cell membranes has been known since the establishment of enzymology as a science. It may be supposed that most enzymes act in an insoluble form in cells, and that their total quantity contained in membrane structures exceeds the quantity present in dissolved form in the protoplasm. McLaren illustrates[11] the antiquity of heterogeneous enzymic catalysis by the use even in the nineteenth century of columns filled with earths to investigate nitrification. On the other hand, good yields of enzymic activity in adsorption chromatography have proved that the binding of enzymes with insoluble materials may not involve irreversible inactivation.

However, we can speak of the immobilisation of enzymes only after the specific catalytic action of intentionally prepared insolubilised enzymes with a substrate had been proved. The first results of this kind were published during the first half of the present century by Nelson[29,30] and by Langmuir[31,32]. The instability of enzymic adsorption complexes limited their application, and a broad investigation of immobilised enzymes began only in the 1950s, when the covalent bonding of enzymes and the occlusion of biological macromolecules in the three-dimensional structure of various gels came to be employed as well as adsorption. Methods for the retention of dissolved enzymes in microcapsules made of semipermeable membranes, in hollow fibres, and also in large-scale reaction vessels fitted with ultrafiltration membranes have now been developed together with molecular immobilisation (the immobilisation of each molecule).

Many immobilisation procedures are now known, hundreds of insoluble derivatives of enzymes have been obtained, and the possibility of their repeated and prolonged use has been shown. Technical processes, analytical techniques, and several therapeutic procedures have been based on the use of immobilised enzymes. The value of these products in industrial biochemistry is stressed in a special resolution of the Presidium of the USSR Academy of Sciences[33].

At the present time there are more than a thousand publications and two hundred patents on immobilised enzymes. It is clearly impossible to mention all these references in this Review, and the literature is therefore cited selectively. Since complete patent specifications are comparatively inaccessible and patented results are quite often published subsequently in the open press, a restriction was first imposed on the number of references to the patent literature. Nevertheless, the absence of an exhaustive bibliography does not prevent the reader from obtained a sufficiently general idea of the present position of the problem.

II. METHODS FOR THE IMMOBILISATION OF ENZYMES

1. Principles of Immobilisation

Methods of immobilising biologically active substances can be divided into two main groups: in molecular immobilisation each molecule is attached to the carrier individually; immobilisation occurs in solution when larger or smaller volumes of the enzyme solution are separated from the external medium by a semipermeable membrane. Molecular immobilisation can in turn be effected in three ways, according as the molecules are retained on the carrier by adsorption or covalent bonds or are held mechanically in the three-dimensional network of chains in the macromolecules of a polymeric carrier. Methods are also possible in which several of the above principles are combined.

2. Immobilisation of Enzymes by Adsorption

Ion exchangers and "neutral" adsorbents, which are not well defined exchangers, are used for the immobilisation of enzymes by adsorption.

Silicon dioxide as silica gel or glass is most often used as neutral carrier. Such materials have been applied to the immobilisation of glucose oxidase[34,35], cytochrome-c[36-38], malic dehydrogenase[39], succinic dehydrogenase[40-42], glucose 6-phosphate dehydrogenase[43], catalase[40-42], hexokinase[40-42,44,45], amyloglucosidase[34], trypsin[46,47], chymotrypsin[46], papain[35,48], alkaline protease[49], acid phosphatase[40-42,50], ribonuclease[46,51,52], aminoacylase[53], and phosphoglucomutase[40-42]. Interesting work has been done by Poltorak and his coworkers[54,55], who adsorbed enzymes on silica gel by means of an intermediate lipid layer. They thus achieved tenfold increases in activity of several enzymes, which is a very rare concomitant of immobilisation[40-42]. These results have been summarised and discussed in reviews by the same workers.

Various clays are suitable for obtaining active adsorbents. They have yielded immobilised glucose oxidase[56,57], catalase[56], glucoamylase[58,59], lysozyme[60], invertase[56], neuraminidase[56], trypsin[61], chymotrypsin[61-63], alkaline protease[49], bacterial protease[64], phosphatase[65,66], urease[67-69], and penicillinamidase[70]. Enzymes which have been immobilised on the mineral supports are nicotinamide—adenine dinucleotide pyrophosphorylase[71], invertase[30], proline iminopeptidase[72], alkaline protease[49], leucine aminopeptidase[73], aminoacylase[53,74], and penicillinamidase[75].

Activated carbon has been used as carrier for glucose oxidase[34], succinic dehydrogenase[40], invertase[29,30], glucoamylase[34,58,59,76], catalase[41 42 77], alkaline phosphatase[78], acid phosphatase[42,77], hexokinase[42,77], and phosphoglucomutase[42,77]. Peroxidase[79], cellulase[80], and deoxyribonuclease[81] have been adsorbed on cellulose; and glucose 6-phosphate dehydrogenase[82] and adenosine triphosphatase[83] have been immobilised on cellulose nitrate. Liver cells adsorbed on cellulose nitrate have been used to obtain material having ribonucleic-acid synthetase activity[84]. The efficiency of adsorption of amylase on Millipore filters can be enhanced by preliminary acylation of the enzyme with aliphatic acids[85,86]. Glycerol dehydrogenase has been adsorbed on a dextran gel—Sephadex[87].

Ion-exchange resins are used far more often than neutral carriers for immobilising enzymes. Insoluble derivatives of catalase[88], invertase[89], glucoamylase[90,91], aminoacylase[53,74,92-95], β-galactosidase[96], pepsin[96], kidney proteinase[96], asparaginase[97], adenosine triphosphate deaminase[98], glucose isomerase[99], and D-oxynitrilase[100] have been obtained on di- and tri-ethylaminoethylated celluloses. The enzyme column for the first industrial installation having an insoluble enzyme was obtained by adsorbing aminoacylase on diethylaminoethylated Sephadex[53,74,101,102]. Dextransucrase has been immobilised by the same method[103]. Catalase[104], glucose oxidase[34], glucoamylase[34,105], ribonuclease[51,52], aminoacylase[53], and penicillinamidase[106] have been attached to synthetic polymeric anion-exchange resins.

Among cation exchangers, carboxylated carriers are most often employed for immobilising enzymes. Carboxymethylcellulose has served for the immobilisation of catalase[88], peroxidase[107], asparaginase[108], and phosphomonoesterase[109]; and carboxymethylated Sephadex for glucose oxidase and glucoamylase[34], as well as aminoacylase[74]. Glucose oxidase[34], glucoamylase[34], ribonuclease[51,52,110], and trypsin[111] have been immobilised on carboxylated polymeric cation-exchange resins. Among special carboxylated carriers mention may be made of a copolymer of alanine and glutamic acid, as well as polygalacturonic acid for the immobilisation of acetylcholine esterase[112] and succinylated glass for binding lactate dehydrogenase[113]. Aminoacylase[74] and ribonuclease[114] have been immobilised on sulphonated cation-exchange resins.

Soluble polyelectrolytes are used, as well as insoluble exchangers, for the modification of enzymes. The resulting soluble polymer—enzyme complexes also possess enhanced stability[115-118].

3. Occlusion of Enzymes into Gel Structures

When enzyme and substrate differ considerably in size, a gel can be chosen whose pores are sufficiently large for diffusion of the substrate but completely exclude that of the large enzyme molecules. Such a situation ensures irreversible bonding of the enzyme with retention of its activity. A limited number of gel-forming substances have hitherto been used in this method of immobilisation. Trypsin[119] and acetylcholine esterase[120] have been occluded into gelatinous silicic acid. A process for obtaining choline esterase, alkaline phosphatase, trypsin, lipoxidase, urease, catalase, and prostaglandin synthetase occluded in silica gel has also been patented[121,122]. Aminoacylase has been trapped in hydroxymethylcellulose[53], acylase[123] and choline esterase[124] in agar-agar, choline esterase[124-126] and urease[127] in starch, trypsin[128], chymotrypsin[128], acetylcholine esterase[129], and a complex of glucose oxidase with peroxidase[129] in silastic silicone, and penicillinamidase[53] in polyurethane. An unusual method for obtaining complexes of this type is the electrodeposition of collagen fibres in a solution of the enzyme, which has been used to immobilise urease[127,130], α-amylase[131], amyloglucosidase[132], and invertase[132].

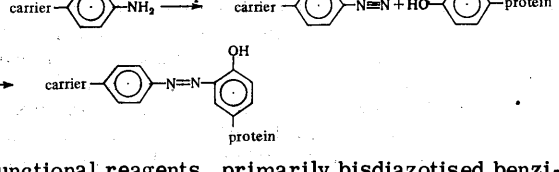
The most widely used carrier for obtaining enzymes enclosed in a gel is cross-linked polyacrylamide. Acrylamide and methylene-*NN*-bisacrylamide in various proportions are readily polymerised by a free-radical mechanism. The free radicals required are most often provided by a photochemical or a redox reaction, but ionising radiation is sometimes used[133,134]. Capture in a polyacrylamide gel has served for the immobilisation of glucose oxidase[135-139], L-amino-acid oxidase[140-142], D-amino-acid oxidase[143-147], xanthin oxidase[143], alcohol

dehydrogenase[143,144], lactic dehydrogenase[137,143,144], catalase[137,144], glucose 6-phosphate dehydrogenase[145,146], glyceraldehyde 3-phosphate dehydrogenase[143], peroxidase[148], hexokinase[146,149], phosphofructokinase[149], α-amylase[150], β-amylase[150], glucoamylase[151,152], invertase[153-155], β-glucosidase[156,157], β-galactosidase[158], trypsin[133,134,150,158,159], chymotrypsin[150], papain[150], urease[126,142,160,161], asparaginase[147], choline esterase[126,162], aminoacylase[53,163], phosphatases[164,165], adenosine trisphosphate diphosphohydrolase[166], ribonuclease[150], aldolase[149,150,167,168], enolase[167-169], decarboxylase[143,159], aspartase[170], phosphoglycerate mutase[167,168,171], glucoisomerase[172], phospho-gluco-isomerase[149], citrate synthetase[173], thiocyanase[174], and injectase[174]. Other polyacrylic gels have been used, e.g. hydroxyethyl methacrylate for the fixation of glucose oxidase[175], but considerably more rarely than polyacrylamide. The extremely long list of products obtained indicates the universality of this method. Polyacrylamide gel has been used to immobilise not only individual enzymes but also enzymic complexes[145,146,149,176-178] and entire cells of micro-organisms[159,179,180].

4. Covalent Bonding of Enzymes

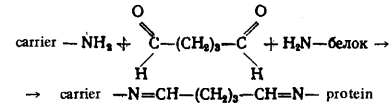
Covalent immobilisation is often considered separately for cases in which the new covalent bonds are formed between activated groups of the carrier and reactive groups in side-chains of the protein and for those in which the protein is cross-linked by a bifunctional reagent into an insoluble "superpolymer" in the pores or on the surface of an unreactive carrier or else in the complete absence of such a carrier. The distinction between these processes disappears when the carrier contains the same reactive groups as the protein, while immobilisation is effected by means of a bifunctional reagent. In such cases covalent bonding of the protein molecule with the carrier and immobilisation by formation of a superpolymer may take place simultaneously. In the present Review all these cases are regarded as the single method of covalent immobilisation. "Superpolymerisation" of an enzyme involves immobilisation in the absence of a carrier, although the resulting insoluble, intermolecularly cross-linked enzyme can then be regarded as a carrier.

One of the first processes suggested was the covalent bonding of proteins by azo-coupling, primarily with tyrosine residues of the protein molecule:



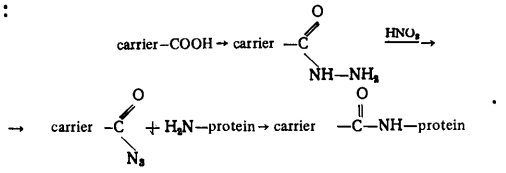
Bifunctional reagents, primarily bisdiazotised benzidine-2,2′-disulphonic acid, have also been used in this process. Immobilisation has thus been applied to papain in the absence of a carrier[181], glucose oxidase[182,183], trypsin[182], chymotrypsin[182], papain[184,185], apyrase[83], adenosine triphosphatase[83], and carbonic anhydrase[182,183] on cellulosic carriers, and papain on collagen[181]. Enzymes are more often bonded to an already diazotised carrier. Thus glass treated with 3-triethoxysilylpropylamine and *p*-nitrobenzoyl chloride, and then subjected to reduction and diazotisation, has been used for the fixation of glucose oxidase[186], peroxidase[186], L-amino-acid oxidase[187], invertase[188], trypsin[186,189], papain[189], ficin[186], pronase[190], alkaline phosphatase[186,191,192], urease[186,193], acetylcholine esterase[194], aminoacylase[52], aryl sulphatase[195], steroid esterase[196], and glucoisomerase[197]. Immobilisation of the coenzyme, nicotinamide–adenine dinucleotide, has been accomplished in the same way[198,199]. Carriers which already contain benzene rings are merely nitrated and reduced. Polystyrene has been used in this way for the immobilisation of glucose oxidase[200], catalase[201,202], lipase[201], α-amylase[203,204], pepsin[204], ribonuclease[204], carboxypeptidase[204], and aminoacylase[205]; and copolymers of *p*-amino-DL-phenylalanine with aliphatic amino-acids for that of trypsin[206,207], chymotrypsin[207], papain[181,207], thrombin[208], prothrombin[206,208], pronase[107,209], urease[207,210], and plasminogen[211]. Polytyrosyl derivatives of the enzymes—trypsin[212-214] and papain[215]—have been fixed by the same procedure. Polytyrosyl derivatives containing a larger number of phenolic groups attackable by diazo-compounds are obtained by treating the enzyme with *N*-carboxy-L-tyrosine anhydride. Diazotised *p*-aminobenzylcellulose has been attached to invertase[188], various amylases[216,217], pullulanase[218], dextranase[218], β-glucosidase[216], chymotrypsin[219], trypsin[216], thrombin[220], ficin[219], papain[218], carboxypeptidase[218], aminoacylase[53,205], and ribonuclease[219]. Aromatic amino-groups are present in the polyacrylic resin Enzacryl AA, which is marketed especially for the immobilisation of enzymes[221]. The diazotised resin has been used to bind amylase[222,223], cathepsin[224], aminoacylase[53], and adenosine deaminase[225,226]. Mention must be made also of the immobilisation of enzymes on diazotised polysaccharide anthranilates[227,228].

Most procedures for the covalent immobilisation of enzymes are based on the reactions of nucleophilic groups in the proteins—in particular their primary amino-groups—with electrophilic groups of an activated carrier on a bifunctional reagent. We shall firstly consider the reaction of amino-groups with aldehydes



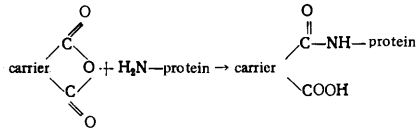
Dialdehydes, mainly glutaraldehyde, are mostly used in this reaction. This bifunctional reagent has been employed to immobilise, in the absence of a carrier, catalase[229-232], glucose oxidase[232], peroxidase[232], trypsin[232-234], chymotrypsin[233,235,236], papain[237-241], carboxypeptidase[242-244], lysozyme[127,232,236], subtilysine[245], urease[230], asparaginase[230], ribonuclease[232], aminoacylase[53], and certain zymogens[128,234,236]. The use of glutaraldehyde to cross-link a protein adsorbed on a neutral carrier has served to immobilise glucose oxidase, urate oxidase, trypsin, chymotrypsin, urease, carboanhydrase[246], and adenylate cyclase[247] on cellulose, as well as trypsin on silica gel[248]. Enzymes are more often cross-linked by glutaraldehyde with a carrier containing amino-groups: trypsin[234,249,250], pepsin[251], rennin[252], and aldolase[253] have been attached to aminoethylcellulose; alcohol dehydrogenase[217], lactate dehydrogenase[217], glucose oxidase[254], uric oxidase[255], urease[254,255], and L-asparaginase[256,257] to a partly hydrolysed polyamide; peroxidase[258], glucose oxidase[259], cytochrome[258,259], trypsin[258,259], chymotrypsin[259], acid phosphatase[259], and ribonuclease[260] to polyacylamide; and adenylate cyclase to aminopolystyrene[247]. Aldehyde-containing carriers are used considerably more rarely: e.g. poly(acrylamidoacetaldehyde dimethylacetal) has been employed for binding trypsin[260], papain[260], α-amylase[260,261], and dextranase[260,261], and an acrylaldehyde–styrene copolymer to bind invertase[262].

The reaction of acid azides with the amino-groups of a protein finds widespread use for the immobilisation of enzymes:



Diazides are seldom employed as bifunctional reagents because of their sparing solubility in water. It is preferred to convert carboxy-groups of a hydrophilic carrier, generally carboxymethylcellulose, into azides. Insoluble derivatives have been obtained by this method from catalase[263], chymotrypsin[219,264-269], trypsin[269], ficin[219,270], bromelain[56], pronase[271], ribonuclease[219,272], adenosine triphosphatase[83], alkaline phosphatase[273], apyrase[83,274], aminoacylase[53], penicillinamidase[275], asparaginase[276], streptokinase[277], adenylate cyclase[247], and various amylases[203,278,279]. Another widely used carrier of this type is polyacrylohydrazide, known also under the proprietary name Enzacryl AH,[221] on which have been fixed glucose oxidase[280], luciferase[281], α- and β-amylases[272,282], trypsin[283-286], chymotrypsin[286], aminoacylase[285,286], and ribonuclease[287]. Other carriers are comparatively rarely used in the azide method of immobilisation: carboxymethyldextran has given insoluble acetylcholine esterase[112], asparaginase[288], and streptokinase[277]; pectin has been used for trypsin and chymotrypsin[289]; and nylon for trypsin[290].

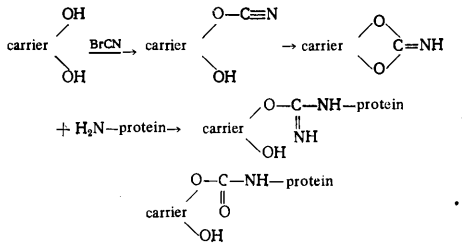
Reaction with anhydrides of dibasic acids is also extremely popular:



Since this involves the formation not only of a covalent bond but also of an ionisable carboxy-group, electrostatic interaction may be observed between protein and carrier molecules. Carriers of this type are usually obtained by the copolymerisation of maleic anhydride and ethylene, and are simply termed EMA polymers. This method of immobilisation has been applied predominantly to proteolytic enzymes, mainly trypsin[2,144,181,212,213,292-298], and a special review has been devoted to derivatives of this type[291]. Other proteinases are represented by chymotrypsin[2,144,297,298], pepsin[299], plasmin[2], kallikrein[144], papain[297,299,300], bromelain[300], ficin[300], pronase and neutral proteinase[299], and Novo and Carlsberg subtilisines[297].

Proteinases inhibited by mercury compounds have in certain cases been immobilised in order to protect the active centres of the enzymes from acylation: attachment of the enzymes to the carrier was followed by reactivation[300]. Immobilisation has been applied not only to proteolytic enzymes but also to catalase[298], D-amino-acid oxidase[298], xanthine oxidase[298], amylase[299,301], dextranase[301], cellulase[298,301], β-glucosidase[298], naringinase[302], ribonuclease[303], acetylcholinesterase[304], lipase[299,301], penicillinamidase[106,302], asparaginase[298,301], urease[301], alkaline phosphatase[273], pyrophosphatase[298], hexokinase[298], adenylate cyclase[247], and oxynitrilase[301]. Soluble EMA polymers have served for the preparation of soluble polymer—enzyme complexes[301]. Among other polymeric anhydrides only that of polymethacrylic acid has been used, to immobilise trypsin, chymotrypsin, and papain[362,386].

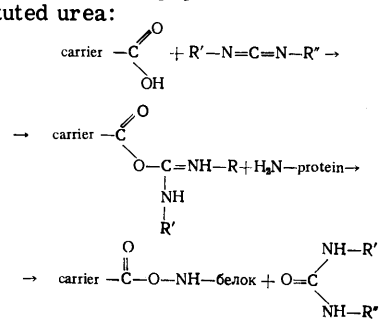
The activation of hydroxylated carriers with cyanogen bromide, proposed by Porath et al.[305], has gained very great popularity during recent years. This reagent acts on the carrier surface to form iminocarbonate groups capable of bonding with the amino-groups of proteins:



This method is mostly used to activate agarose (Sepharose), which, because of its ability to swell strongly in water (dry content 2%, 4%, or 6%), has an extremely large-pored structure. This ensures that large enzyme molecules are trapped in the pores of the carrier, and that diffusion coefficients shall be high even for substrates of high molecular weight. Enzymes which have been immobilised in this way are glucose oxidase[306], lactoperoxidase[307], lipoxygenase[308], isocitrate dehydrogenase[309,310], pyridine nucleotide transhydrogenase[311], protocatechuate 3,4-dioxygenase[312], glucose 6-phosphate dehydrogenase[146], glucoamylase[306], trypsin[313-317], chymotrypsin[252,305,316,318,319], pepsin[320,321], rennin[252,322], cathepsin[224], elastase[323], leucine aminopeptidase[324,325], amino- and carboxy-peptidases[326], papain[316], bacterial proteinase[327], various nucleases[328-334], choline esterases[335], aminoacylase[53], penicillinamidase[336], aldolase[337], glucogen phosphorylase[338], and transfer ribonucleic acid histidine[339] and isoleucine[340] synthetases.

Although Sepharose activated with cyanogen bromide enables extremely high activities to be attained with many immobilised enzymes, the poor mechanical and thermal stability of this material must not be overlooked. In order to obtain insoluble enzymes more suitable for technical application, other polysaccharide materials have been activated with cyanogen bromide. Thus cellulose has served for the attachment of glucoamylase[341], pronase[271], acetylcholinesterase[112], penicillinamidase[336], asparaginase[276], polynucleotide phosphorylase[342], and streptokinase[277]. The dextran gel Sephadex has been used to immobilise glucose oxidase[343], catalase[343], lipoxygenase[344], glucose 6-phosphate dehydrogenase[345], isocitrate dehydrogenase[309], glucoamylase[343], β-galactosidase[345], trypsin[314,346-348], chymotrypsin[319], leucine aminopeptidase[336], ribonuclease[331], hexokinase[345,349], and streptokinase[277].

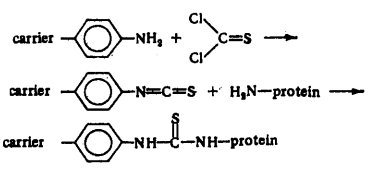
The carbodi-imides employed in peptide synthesis are good condensing agents. The reaction takes place in two stages, addition of the agent to a carboxy-group being followed by formation of a peptide link with elimination of a disubstituted urea:



This reaction can be used to form intra- and inter-molecular amide bonds[360], and enables an immobilised enzyme to be obtained in the absence of a carrier (e.g. the immobilisation of aminoacylase[53]). In most cases carbodi-imides are used to condense carboxy-groups of the carrier with amino-groups of the enzyme. In this way glutamate dehydrogenase[351], peroxidase[352,353], chymotrypsin[351], pronase[354], asparaginase[276], and acetylcholinesterase[112] have been immobilised on carboxymethylcellulose; glutamate dehydrogenase[351], chymotrypsin[351], and pronase[355] on dextran; glucose 6-phosphate dehydrogenase[146], glutamate dehydrogenase[351], β-galactosidase[155], pullulanase[356], trypsin[155], chymotrypsin[351], and citrate synthetase[159] on acrylic polymers; and trypsin[290] on nylon.

Several compounds having mobile halogen atoms—in particular bromo- and iodo-acetyl derivatives, acid chlorides, fluoronitrophenyl compounds, and cyanuryl halides (triazinyl trichlorides, Procion dyes)—have been used for immobilisation. They are able to react with amines and mercapto, hydroxy, and imidazole groups. Fluorophenyl-containing polymers have served for the immobilisation of alcohol dehydrogenase[357,358], invertase[358,359], amylases[357,358,360-362], pepsin[357,358], papain[360-362], alkaline phosphatase[273], and aminoacylase[205]. Triazinyl halides have been used for the immobilisation of enzymes mainly on aminoethylated celluloses, as well as on other polysaccharides. Insoluble preparations have been obtained in this way from glucose oxidase[363], lactate dehydrogenase[364], glucoamylase[363,365,366], dextranase[363], α-galactosidase[363], β-galactosidase[367,368], invertase[369], hyaluronidase[370], trypsin[363,371], chymotrypsin[189,372,373], papain[263], penicillinamidase[363,374,375], acetylcholinesterase[112,376], alkaline phosphatase[363], ribonuclease[363], pyruvate kinase[363,368,377], and creatine phosphokinase[363]. Derivatives of iodo- and bromo-acetic acids and also iodoalkyl esters have effected the immobilisation of chymotrypsin[378,379], trypsin[380], thrombin[381], pronase[355], glucoamylase[341,382], aminoacylase[53,383], penicillinamidase[275], urease[380], aldolase[384], and streptokinase[277]. The action of ethyl chloroformate has immobilised pepsin[385], trypsin[289], chymotrypsin[289], and ficin[289]. Penicillinamidase[106,275] and alkaline proteinase[386] have been attached to acid chlorides of carboxylated cation-exchange resins. Among inorganic compounds sulphuryl and thionyl chlorides have been used[387,388] to immobilise lactate dehydrogenase, invertase, pepsin, alkaline phosphatase, and threonine deaminase. New bonding agents of this type are transition-metal chlorides (in particular titanium tetrachloride[389,390]), by means of which glucose oxidase, uricase, glucoamylase, α-amylase, invertase, trypsin, urease, and glucose isomerase have been attached to various carriers, including yeast cells.

Various cyanates are quite often used to establish covalent bonds between protein and carrier. Among them we must first mention isothiocyanates, obtained by the action of thiocarbonyl chloride on amines:



Similarly, treatment with carbonyl chloride leads to the formation of isocyanate groups. Insoluble derivatives of glucose oxidase[391], catalase[201], various amylases[222, 282,361,392,393], proteinases[358,361,393,394], and lipase[201] have been obtained by these procedures. Isocyanides[319,395] and cyanates[396] are employed considerably more rarely for immobilisation.

Among the less widely used methods for the covalent fixation of enzymes is the application of 2-ethyl-5-phenylisoxazole-3-sulphonate[276,397-401] to the immobilisation of trypsin and chymotrypsin, as well as asparaginase[276], apyrase[399], deoxyribonuclease[399], and choline esterase[399]. β-D-Glucosidase, α-amylase, glucoamylase, and trypsin have been immobilised on cellulose carbonate[402]. Reaction with compounds containing epoxy-groups has been used to immobilise certain proteinases[403]. Several enzymes have been immobilised on Enzacryls containing thiolactam and thiol groups[221,284]. Commercial preparations of insoluble enzymes have been produced by the above methods[404-410].

5. Isolation of Enzymes by means of Membranes

Repeated application of enzymes is achieved also by isolating the enzyme solution by means of membranes whose pores are impermeable to protein macromolecules but permeable to the substrate and the reaction products. This is accomplished by microencapsulation, in which polymeric envelopes are formed around the enzyme solution, by producing artifical fibres containing minute droplets of the enzyme solution, and by enclosing the enzyme solution between membranes on an electrode surface. The application of enzymes in a reaction vessel with ultrafiltration of the reaction mixture through a membrane which retains protein macromolecules might have been included in this type of isolation. In the last case a solution of the substrate is introduced into the reaction vessel, omitting the membrane, and the enzyme can act on macromolecular substrates provided that the products are of low molecular weight.

Since in these systems the enzymes retain a certain mobility in solution, isolation of this type is difficult to relate completely to our problem of immobilisation. In view of the similarity between the methods of practical application of microencapsulated enzymes—in particular those enclosed in fibres—and of molecularly immobilised enzymes, we shall mention some of the relevant work and give a list of products obtained in this way (Table 1).

Table 1. List of immobilised enzymes.

No.	Enzyme	Ref.
1	Alcohol dehydrogenase	143, 204, 214, 357, 406
2	Acetaldehyde dehydrogenase	421
3	Glycerophosphate dehydrogenase	406
4	Lactate dehydrogenase	113, 137, 143, 144, 217, 388, 406, 411
5	Glycerate dehydrogenase	39, 40—42
6	Malate dehydrogenase	38, 217, 406
7	Isocitrate dehydrogenase	309, 310
8	Glucose 6-phosphate dehydrogenase	43, 82, 145, 146, 345, 406
9	Steroid dehydrogenase	179
10	Glucose oxidase	34, 35, 56, 57, 129, 135, 136, 137, 139, 175, 182, 183, 186, 200, 232, 246, 254, 259, 280, 306, 343, 363, 390, 391, 406, 408, 409, 420
11	Glyceraldehyde phosphate dehydrogenase	406
12	Xanthin oxidase	377
13	Glutamate dehydrogenase	351
14	L-Amino-acid oxidase	140—142, 187
15	D-Amino-acid oxidase	143, 147, 298
16	NAD transhydrogenase	311
17	Nitrite reductase	421
18	Urate oxidase	246, 255, 390
19	Catalase	32, 41, 42, 56, 77, 88, 104, 121, 122, 144, 187, 188, 202, 229, 231, 263, 298, 343, 411, 416, 420

Table 1 (continued).

No.	Enzyme	Ref.
20	Peroxidase	120, 129, 148, 186, 232, 258, 259, 352, 353, 405, 406, 409
21	Cytochrome-c	36, 37, 258, 405, 409, 121, 122, 308, 344
23	Protocatechuate 3,4-dioxygenase	312
24	Polyphenol oxidase	422
25	Luciferase	281
26	Lactoperoxidase	307
27	β-Tyrosinase	419
28	α-Glucan phosphorylase	338
29	Dextransucrase	103
30	Galactosyl transferase	423
31	Nucleoside-ribosyl transferase	350
32	Aminotransferase	420
33	Hexokinase	40, 41, 42, 44, 77, 146, 149, 298, 338, 345, 349, 377, 406, 419
34	Creatine kinase	363
35	Phosphoglycerate mutase	406
36	NAD pyrophosphorylase	71
37	Polynucleotide phosphorylase	342
38	Thiocyanase	423
39	Lipase	51, 201, 299, 301, 411
40	Acetylcholesterase	89, 112, 120, 129, 335, 376
41	Cholinesterase	121, 122, 124—126, 162, 335
42	Glycerol dehydratase	87
43	Acid phosphatase	40—42, 51, 77, 164, 259, 408
44	Alkaline phosphatase	40—42, 78, 122, 164, 165, 186, 191, 192, 273, 363, 388, 404, 408
45	Phosphatase	65, 66
46	Phosphomonoesterase	109
47	Phosphodiesterase	404
48	Deoxyribonuclease	81, 404
49	Nuclease	330, 332, 334
50	α-Amylase	85, 86, 131, 150, 203, 216, 217, 222, 223, 260, 261, 282, 389, 390, 393, 405, 406
51	β-Amylase	150, 217, 222, 358
52	Glucoamylase	34, 58, 59, 76, 90, 91, 105, 132, 151, 152, 200, 216, 261, 279, 306, 341, 363, 365, 366, 389, 390, 404
53	Maltase	416
54	Diastase	204, 301, 357, 361, 362
55	Cellulase	80, 298, 301
56	Dextralase	363
57	Lysozyme	60, 128, 232, 236
58	Neuraminidase	56, 406
59	β-Glucosidase	156, 157, 216, 298, 397
60	α-Galactosidase	363
61	β-Galactosidase	96, 158, 345, 367, 419, 420
62	Invertase	29, 30, 56, 89, 153—155, 262, 416, 419, 420
63	Naringinase	302
64	Pullulanase	218, 261, 301
65	Ribonuclease	46, 51, 52, 110, 114, 156, 204, 219, 232, 259, 272, 287, 328, 329, 331, 333, 334, 363, 404—409, 419, 420
66	Leucine aminopeptidase	73, 324, 325, 405
67	Aminopeptidase	326, 393
68	Carboxypeptidase	204, 218, 242, 243, 244, 326, 406, 408, 420
69	Iminopeptidase	72
70	Alkaline protease	49, 186, 228, 299, 386
71	Bacterial protease	198, 228
72	Neutral protease	299
73	Pepsin	31, 95, 204, 251, 299, 320, 321, 357, 358, 385, 387, 393
74	Kallikrein	144
75	Trypsin	46, 47, 61, 111, 119, 121, 128, 133, 144, 150, 158, 159, 182, 186, 289, 206, 207, 212, 213, 216, 228, 232, 234, 246, 248, 250, 258, 260, 269, 283, 286, 289, 290, 292, 293—298, 304, 313, 314, 316, 346—348, 358, 363, 371, 380, 389, 390, 393, 401, 404—410
76	Papain	48, 140, 148, 150, 155, 181, 184—186, 189, 207, 215, 227, 236, 238—241, 260, 278, 300, 304, 316, 346, 361, 363, 394, 397, 405—410, 420
77	Chymotrypsin	5, 41, 61—63, 112, 128, 144, 150, 182, 207, 219, 233, 236—238, 246, 252, 259, 264—267, 286, 297, 305, 315, 316, 319, 351, 358, 373, 378, 393, 395, 397, 398, 401, 405—410
78	Elastase	323
79	Cathepsin	224
80	Ficin	106, 186, 219, 270, 289, 300, 406, 407, 409
81	Thrombin	206, 208, 220 381,
82	Plasmin	47, 211
83	Rennin	252, 322
84	Bromelain	300, 407, 409
85	Pronase	107, 190, 209, 271, 355, 406
86	Subtilisin	64, 297, 405—407
87	Asparaginase	27, 108, 147, 230, 256—277, 288, 298, 301, 406
88	Aminoacylase	51—53, 74, 92—95, 101, 102, 163, 205, 285, 383
89	Urease	31, 32, 67, 68, 69, 122, 126, 129, 160, 161, 186, 193, 210, 230, 246, 254, 255, 286, 301, 380, 390, 405, 406, 411, 413, 414, 416, 420
90	Penicillinamidase	53, 70, 75, 106, 274, 336, 363, 374, 375, 419
91	Arginase	420
92	Adenosine deaminase	225, 226
93	Pyrophosphatase	298
94	Adenosine triphosphatase	83
95	Adenosine triphosphate deaminase	98
96	Adenosine triphosphate dihydrolase	166
97	Apyrase	83, 271
98	Orsellin decarboxylase	159
99	Arginine decarboxylase	143, 196
100	Cysteinesulphinate decarboxylase	143, 195
101	Oxynitrile lyase	145
102	Aldolase	149, 150, 167, 168, 253, 337, 384, 406, 419
103	Carbonic anhydrase	182, 183, 246, 317, 412, 417
104	Enolase	167—169
105	Hyaluronate lyase	370
106	Threonine deaminase	388
107	Aspartase	170
108	Glucose isomerase	99, 172, 416, 419

Table 1 (continued).

No.	Enzyme	Ref.
109	Glucose phosphate isomerase	149, 406
110	Triose 3-phosphate mutase	406
111	Phosphoglycerate phosphomutase	41, 42, 40, 77, 145, 167, 168, 171
112	Tryptophan synthetase	419
113	Isoleucine-tRNA synthetase	340
114	RNA synthetase	84
115	Histidine-tRNA synthetase	339
116	Citrate synthetase	159, 173
117	Prostaglandin synthetase	121, 122
118	Injectase	174

Inclusion in microcapsules has been applied mainly to urease[230,411-415], and also to lipase[411], maltase[416], glucose isomerase[416], carbonic anhydrase[317,412,417], catalase[411,418], and asparaginase[230]. By dispersing an aqueous solution of one or more enzymes in a solution of a linear polymer in an organic solvent, various enzymically active fibres and cloths have been obtained, which are able to retain such activity for a long time[419,420].

In order to facilitate the finding of references on the immobilisation of any individual enzyme, Table 1 gives a list of the immobilised enzymes known at the present time, their sequence corresponding to the generally accepted classification of enzymes.

III. EFFECT OF IMMOBILISATION ON THE PROPERTIES OF ENZYMES

1. General Description of Changes

It can be concluded from all the accumulated experimental results that immobilisation produces no fundamental changes in the catalytic properties of enzymes. Furthermore, even the quantitative parameters of their action—the catalytic constants, activation energies, optimum pH and temperature—quite often undergo no significant change. Henceforward, therefore, we shall consider only those cases in which the properties of the immobilised enzyme differ from its original properties.

In examining the experimental differences in properties between soluble and insoluble enzymes, we must bear in mind that the molecules of an immobilised enzyme function in a microenvironment which may differ considerably from the macroenvironment, i.e. that the medium may differ in composition inside and outside a particle of a heterogeneous enzymic catalyst. For this reason the International Commission has recommended that the experimental kinetic characteristics of immobilised enzymes should be qualified as "apparent".

We propose to discuss the kinetics of immobilised enzymes, and hence the production of the observed kinetic changes, at several levels (Table 2). Changes in enzymic kinetics at the molecular level (No. 5) are of greatest interest to theoretical enzymology, of course, but study of the kinetics of enzymes at this level requires that perturbations at levels 1—4 be taken into account.

In principle it is easiest to eliminate the effect of the apparatus, for which purpose we must operate at sufficiently low degrees of conversion of the substrate. The necessity must then be emphasised of verifying experimentally that the reaction velocity is independent of the degree of conversion. Our own experimental results have shown that, when the enzyme is inhibited by

reaction products, non-linearity arises even when only a few percent of the substrate has been converted. Development of the kinetics of apparatus with immobilised enzymes is of immense value for the introduction of heterogeneous enzymic catalysis into technical processes, and several theoretical and experimental papers have been devoted to this problem. Lack of space prevents discussion of all this work here, and the Reviewer prefers to refer only to a few of the most recent and interesting publications[424-429].

Table 2. Changes in kinetic properties of immobilised enzymes at various levels.

No.	Kinetic level	Causes of changes	Nature of effect	Conditions for maximum changes
1	Apparatus	conc. gradients along apparatus; variation in concn. during operation	dynamic: depends on activity of enzyme prep.	thorough conversion of substrate, especially when a product is an activator
2	Material	concn. gradients at interface of soln. with enzymically active material	as above	high moduli $\kappa = E/\rho\beta c^*$
3	Particle	concn. gradients through enzymically active material	as above	high moduli $\lambda = R^2E/D^*$
4	Matrix	effect of matrix on activity coeff. of solutes; partition of substrate and activator between soln. and matrix	static: independent of activity of gel	charged matrix; hydrophobic matrix when substrate hydrophobic
5	Molecule	direct action of matrix on conformation of protein macromolecule and on active centre	as above	not generalised

*E = activity of enzyme preparation; ρ = specific surface of material; β = mass-transfer coefficient; R = radius (half-thickness) of material; D = diffusion coefficient of substrate (product) in the grain.

By solving numerically the appropriate equations following from the mass-transfer balance at the surface and within the particle we have shown[430] that the mass-transfer resistance at the interface does not affect the form of the Michaelis–Menten equation, but increases the apparent value of K_m. The main parameter determining the concentration drop in the mass-transfer layer, and responsible also for the increase in the apparent K_m, is the modulus

$$\varkappa = \frac{E}{\rho \cdot \beta \cdot c} \quad , \tag{4.1}$$

where E is the enzymic activity of the product, ρ the specific surface of the material, β the mass-transfer coefficient, and c the concentration of the substrate in the solution. When $\kappa \leqslant 0.1$, the mass-transfer resistance can be neglected. Values of $\kappa \geqslant 10$, on the other hand, correspond to processes which are completely controlled by external diffusion, i.e. to infinite K_m.

Rony[431] has described the kinetics in a multilayer material in the presence of mass-transfer resistance. The kinetics of mass transfer in an enzymically active membrane has been described also for the presence of an electrostatic potential[432], for inhibition of the reaction by a product[433], and for a membrane with two consecutive reactions[434].

Disregarding external diffusion, we can describe the kinetics of reactions in a particle (membrane) in a steady state by the general equation

$$\operatorname{div}(D \cdot \operatorname{grad} c) = g(c) \, , \tag{4.2}$$

where D is the diffusion coefficient of the product within the material, and $g(c)$ a function describing the dependence of reaction velocity on substrate concentration. The concrete form of this equation and hence the possibility of its analytical solution depend on the geometry, the material, and the function $g(c)$. It is of practical importance to solve Eqn. (4.2) for an infinite sheet (membrane), for a sphere, and in certain cases also for an infinite cylinder (fibre). In the case of a membrane, solution presents no difficulty for various forms of kinetic equation. Among the many papers giving solutions of this equation, mention must be made of that by Moo-Young and Kobayashi[435], who give a general solution for certain of the most often encountered forms of the function $g(c)$.

For a sphere Eqn. (4.2) becomes

$$\frac{d^2c}{dr^2} + \frac{2}{r} \cdot \frac{dc}{dr} = \frac{1}{D} g(c) \tag{4.3}$$

and can be solved analytically only for reactions of zero or the first kinetic order: only an approximate solution is available for real enzyme kinetics. In the case of Michaelis–Menten kinetics better approximate solutions of the same equation were obtained by Blum and Jenden[436], and subsequently developed by O'Sullivan[437]. Murray[438] solved the same equation by a single-perturbation method. The paper mentioned above[435] gives approximate solutions of Eqn. (4.3) for several forms of the function $g(c)$, and exact numerical solutions for Michaelis–Menten kinetics have been obtained by Keller[439] and by Kěstner[440,441].

From all the approximate and numerical solutions it may be concluded that the form of the fundamental kinetic equation is unaffected by either internal or external diffusion, but the apparent value of K_m increases. In this case the diffusion resistance may be measured by the dimensionless modulus

$$\lambda = R \sqrt{\frac{E}{K_m \cdot D}} \quad , \tag{4.3'}$$

where R is the radius of the grain, and K_m the Michaelis constant for the immobilised enzyme. To a first approximation the apparent K_m varies linearly with λ:

$$K_{m(\text{app.})} = K_m (1 + 0.018 \cdot \lambda) \, , \tag{4.4}$$

in which 0.018 is a coefficient determined from the numerical solutions. Thus diffusion resistance at the surface and inside the material itself leads to an increase in the apparent K_m. The smallest difference between observed and actual values of K_m is ensured by the lowest activity and minimum linear dimensions of the material. Increasing the diffusion coefficient by controlling the pore size and raising the mass-transfer coefficient by stirring assists the achievement of this aim.

Interaction of solutes with the matrix of an immobilised enzyme may lead to considerable changes in the concentration of the solutes within the carrier. A typical example is the variation in the effective hydrogen-ion concentration in an electrically charged matrix. The change in the effective pH is given by

$$\Delta \text{pH} = 0.43 \cdot e\psi/kT, \tag{4.5}$$

where ϵ is the charge on the proton, ψ the electrostatic potential in the matrix, k Boltzmann's constant, and T the

absolute temperature. A similar equation describes the variation of the concentration of an electrically charged substrate in the matrix. The applicability of the above equation has been shown by Goldman, e.g. in his review[7]. Agreement between calculated and experimental shifts in pH has been found[119] for trypsin trapped in silica gel.

The crowding of a hydrophobic substrate into a comparatively hydrophobic matrix has also been confirmed experimentally[129,442], but a quantitative description of this phenomenon is lacking. Laurent[443] examined the effect of a polymer medium on the activity coefficients of enzyme, substrate, and enzyme–substrate complex, which may produce a change in the apparent value of K_m.

Thus the microenvironment of the molecules of an immobilised enzyme is formed under the influence of various factors, which are quite often difficult to assess quantitatively.

2. Change in Activity and Stability of Enzymes

The main purpose of obtaining immobilised enzymes is to increase the integral activity of the enzyme defined by the total quantity of product obtained. The effectiveness of immobilisation η_{imm} is given by the ratio of the integral activities of the insoluble derivatives and of the initial enzyme:

$$\eta_{imm} = \frac{P_{imm}}{P_{sol}} \quad , \tag{4.6}$$

where P_{imm} is the quantity of product formed by the insoluble enzyme under practical conditions, and P_{sol} the corresponding quantity for the soluble enzyme.

We shall suppose that P_{sol} is determined mainly by the quantity of enzyme employed A_{sol} and the duration of the reaction t_{sol}. The latter is governed by the practical requirements of completing the reaction within acceptable periods. On the assumption that the activity of the soluble enzyme does not diminish significantly under the operating conditions during the period t_{sol}, we obtain for the effectiveness the formula

$$\eta_{imm} = \frac{A_{imm}}{A_{sol}} \cdot \frac{1}{t_{sol}} \int_0^{t_{imm}} [1 - f(t)]\, dt \quad , \tag{4.7}$$

where A_{imm} is the initial activity of the immobilised enzyme, t_{imm} its time of operation determined by its stability, and $f(t)$ the rate of inactivation of the immobilised enzyme under the working conditions.

The ratio A_{imm}/A_{sol} determines the retention of activity on immobilisation (or the "activity yield" of immobilisation), and will henceforward be denoted by γ. The remaining part of Eqn. (4.7)—the integral coefficient of prolongation of the action of the enzyme—is denoted by I_{pr}:

$$I_{pr} = \frac{1}{t_{sol}} \int_0^{t_{imm}} [1 - f(t)]\, dt \quad . \tag{4.8}$$

Equation (4.7) thus simplifies to

$$\eta = \gamma \cdot I_{pr} \quad .$$

The quantity I_{pr} is evaluated from two fairly arbitrary values of t_{sol} and t_{imm}, and can hardly be determined accurately. Immobilisation is regarded as advisable in practice for values of I_{pr} exceeding unity.

The coefficients γ can be regarded as the product of the coefficients α and β of immobilisation of the enzyme and development of activity:

$$\gamma = \alpha \cdot \beta = \frac{B_{imm}}{B_{sol}} \cdot \frac{E_{imm}}{E_{sol}} \quad , \tag{4.9}$$

where B_{sol} is the initial quantity of enzymic protein, B_{imm} the quantity of protein in the preparation obtained, E_{sol} the specific activity of the soluble enzyme, and E_{imm} the observed specific activity of the immobilised enzyme. The enzymic protein remaining in the reaction mixture or in the wash-waters can hardly be utilised, so that there is no need to practice to separate the coefficient γ into two components. However, such an approach is quite often used in elucidating the nature of immobilisation processes.

Complete bonding of a protein, when $\alpha = 1$, is well known in ion-exchange sorption, but α is considerably less than unity in most of the methods described for obtaining immobilised enzymes. The actual values of α depend significantly on the conditions of immobilisation, and it is extremely difficult to make any generalisations. In some cases, especially with adsorption, an enzyme washes out for weeks, which prevents accurate determination of α.

The coefficient β is also almost always smaller than unity, but an increase in enzymic activity has been demonstrated quite reliably in several researches[39,42,69,72,78,95,391,444]. An increase is often observed when enzymes are adsorbed, the activity sometimes increasing dozens of times[42,444]. This is fully consistent with the considerable conformational changes in a native protein detected by various methods on adsorption, which in other cases leads to almost zero values of β. Nor is the nature of such a phenomenon as the enhanced activity of trypsin on freezing or coagulation of its solutions entirely clear. These processes for enhancing enzymic activity have been patented[445,446].

An interesting example of an increase in the total activity of a jointly immobilised three-enzyme system has been reported by Mattiasson and Mosbach[345]. The increase is attributed to facilitation of the transfer of the product of the first reaction to molecules of the enzymes which effect subsequent stages.

The diminution in specific activity of enzymes on fixation may be due to chemical modification of certain groups in the active centre, shielding of the enzyme molecule or of its active centre from access by the substrate, and change in conformation of the protein macromolecule. Undesirable modification of the active centre on covalent immobilisation can be diminished by preliminary formation of a complex of the enzyme with an inhibitor, which is subsequently rinsed out of the preparation. The presence of shielding is proved by a difference in the activity of the preparation towards substrates of low and of high molecular weight. A linear decrease in observed activity with increase in the logarithm of the molecular weight of the substrate has been shown for certain immobilised enzymes[107,109]. The existence of this "sieve effect" has been demonstrated also by the restoration of the original activity on solubilisation of the matrix[313]. To eliminate undesirable effects of the matrix on the enzyme molecule it is advisable to effect attachment through an "extension bridge" or "arm" of 6–10 methylene groups[113,178,258,447-449]. Carriers with ligands immobilised "on the arm" are most suitable for use as affinity sorbents.

The reasons for the well known increase in stability of enzymes on immobilisation have been summarised by Zaborsky[450]. They are indirect, such as shielding of the enzymes from the action of lytic micro-organisms and elimination of autolysis (or proteolysis by proteinase impurities), owing to separation of the enzyme molecules on the carrier. These factors may partly explain the prolonged retention of enzymic activity, but the enhancement of resistance to the short-lived action of denaturing factors indicates the operation of molecular mechanisms of stabilisation. It is most often reported that immobilised enzymes resist the action of high temperatures[87,120,152,166,173,198,217,219,226,256,270,281,285,350,376,383].

It is interesting that Surovtsev et al.[265] have shown the presence of two fractions differing in thermal stability in an immobilised enzyme. However, other workers have reported a worsening of the temperature stability of enzymes[185,225,281,433,451-453]. Nevertheless, on the whole an increase in lability of enzymes is rarely encountered on immobilisation.

Extremely long periods of operation or retention of activity during storage have been reported for immobilised enzymes. A column of a gel containing invertase, for example, functioned for between 18 months and 3 years[419,454,455]. Specimens of certain covalently bound dehydrogenases have been used for more than a thousand analytical determinations[217].

It has been quite often reported that immobilised enzymes are less liable to be inhibited[120,249,452,456]. It is astonishing that they retain their activity in 4–8 M solutions of urea and other reagents which rupture hydrogen bonds[101,203,314,347]. The protective action may depend on the nature of the matrix: the immobilisation of trypsin on cyanogen bromide-Sephadex, for example, protects the enzyme from the action of urea, but bonding to agarose by the same method has no protective effect[347]. According to several workers[101,314] urea may increase the vulnerability of a substrate to attack by an enzyme, and may thus even increase the effectiveness of the latter. If a denaturing agent leads to a loss of enzymic activity, the bonds between the protein molecule and the matrix may help to restore the native three-dimensional structure[113,249,309,326,457].

Deoxyribonuclease immobilised on glass is able to develop its activity in the absence of the bivalent cations required by the soluble enzymes[465,458].

Immobilisation protects enzymes also from oxidation and denaturation on exposure to γ-rays[202].

3. Effect of Immobilisation on Fundamental Characteristics of Enzymes

Differences in the substrate specificity of immobilised and soluble enzymes can be explained by differences in the accessibility of the enzyme molecule to substrates of different molecular weights. This is true, for example, for proteolytic enzymes[107,209,219,268,294]. Such differences enable other peptide fragments to be obtained by means of immobilised proteinases than by the action of the soluble enzymes, and hence yield additional information in establishing the primary structure of proteins[294]. Immobilised amylases do not act on amylopectin[152], but form more products of low molecular weight from starch[459]. Immobilised luciferase is more sensitive to variation in the molecular weight of synthetic substrates[281]. Immobilisation of dextransucrase eliminates the factor controlling the type of glucosidic bonds formed, and therefore leads to more strongly branched products[103].

The increase in the Michaelis constant predicted by theory is observed in many cases. Increases by factors of 2–10 are found with creatine phosphotransferase[460], apyrase[274], cholinesterase[376], lactase[461], phosphomonoesterase[109], and glucoamylase[279] covalently fixed on cellulose. The same effect is observed with lipoxygenase attached to Sephadex[308], with adsorbed invertase[452] and glucoamylase[59], and also with many enzymes enclosed in microcellular fibres[419]. Phosphatase in a collodion membrane shows increases in K_m by factors up to 350.[433] For unknown reasons lyophilisation increases the apparent K_m of immobilised lactase[461]. When immobilised enzymes are used in a column, increasing the rate of flow of the substrate diminishes K_m,[5,256,452,462] in good agreement with the hypothesis that the apparent K_m depends on the conditions of mass transfer. Decreases of 90% or more are observed with glucose oxidase[391], succinate dehydrogenase[39], trypsin[292], bromelain[463], cholinesterase[129], and penicillinamidase[374]. This phenomenon can in principle also be explained by concentration of the substrate into the matrix. In particular, a 90% decrease in K_m is observed with bromelain covalently bound to carboxymethylcellulose only at low ionic strengths, whereas at high ionic strengths, when interaction between the substrate and the carboxy-groups of the carrier is suppressed, insoluble and soluble enzymes have the same Michaelis constant.

It is interesting that an improvement in thermal stability on immobilisation is sometimes accompanied by a fall in the temperature optimum of the enzyme[90,188,383,452]. However, the optimum temperature usually rises[169]. The apparent activation energy of an enzymic reaction most often remains unchanged, but increases[391] or decreases[169,383] have been shown in some cases. A change in form of the Arrhenius plot may occur[169].

The change in the pH dependence of enzyme activity depends on the carrier used. The optimum pH has become more acid with protocatechate dioxygenase[312], trypsin[292], chymotrypsin[63], invertase[89], urease[193], and penicillinamidase[374]; and more alkaline with lipoxygenase[306,344], trypsin[119,292], chymotrypsin[267,313], elastase[323], and invertase[188,369]. The shifts in the optimum pH are usually 0.5–1.0, and seldom reach 2. They are explained by the difference between the local pH of the microenvironment of the active centre of the enzyme and the pH measured in the bulk of the solution. This produces a change in the measured apparent values of pK_a for ionisation of the functional groups in the enzyme. The local microenvironmental pH is influenced by the charge on the matrix, the change in the charge on the substrate on coversion into the products, diffusion of substrate and product, change in the total charge of the protein on immobilisation, etc. The variation in the optimum pH of a two-enzyme system can be explained by the cooperative action of the enzymes[306].

Furthermore, immobilisation quite often produces a change in the form of the pH dependence. Broadening of the bell-shaped curve is observed with adsorbed succinate dehydrogenase[39], covalently bound acetylcholinesterase[194], pronase[190], enolase[169], adenosine deaminase[226], and also with many enzymes enclosed in cellular fibres[419]. Narrowing of the bell is observed with adsorbed glucoamylase[90] and with covalently bound papain[300], invertase[464], asparaginase[256], and penicillinamidase[374]. A detailed analysis of the reasons for the variation in the pH dependence will be found in the review by Goldman and his coauthors[7].

IV. APPLICATION OF IMMOBILISED ENZYMES

1. Use in Technical Processes

Most papers on immobilised enzymes are concerned with the preparation of heterogeneous enzymic catalysts for use in industrial technology. General aspects of the introduction of enzymic catalysis, prospects for its development, and possible difficulties are discussed in several reviews and symposia[17,19,465-469]. In the present Review we shall disregard specific aspects of the technical application of immobilised enzymes, and give only the principles underlying their use.

Processes in which immobilised enzymes are employed can be classified according to their purpose—(*a*) preparation of a required product as a pure substance or as a component of a mixture, (*b*) removal of an undesirable impurity from production or from industrial wastes, (*c*) chemical conversion of one optical isomer to facilitate resolution of a racemic mixture, or (*d*) concentration or isolation of a required substance by specific sorption. Table 3 gives examples of specific proposals for the application of immobilised enzymes. It includes only those suggestions which have been subjected to at least preliminary testing on a laboratory scale: it omits those for which such testing is lacking.

According to the Reviewer's information, processes for the separation of racemic amino-acids and for the production of 6-aminopenicillanic acid have been introduced on an industrial scale. In view of the comparatively high cost of immobilised enzymes we may expect in the near future the introduction firstly of processes in which expensive products—medicinals and biochemical reagents—are manufactured. The following stage may be large-scale processes in the food and chemical industries.

2. Application in Laboratory Investigations and in Medicine

Immobilised enzymes are being increasingly widely used in fundamental biochemical research as models of subcellular structures and for the study of steric effects on enzyme kinetics. Working models of active transfer have been produced by means of enzyme membranes[486,487]. Brown et al.[487] have effected the active transfer of glucose in a membrane containing hexokinase and phosphatase, and termed the phenomenon "vector catalysis". Certain other researches[281,327] can be regarded as an approach to the production of model biological systems.

The application of immobilised enzymes in practical analysis is also being extended. Several reviews have appeared on this topic[3,21,488-490]. Analytical applications of enzymes can be divided into three groups—(*a*) affinity chromatography, (*b*) determination of substrates in flow-type systems with optical transducers or by means of enzyme electrodes, and (*c*) determination of enzyme inhibitors.

Very many individual papers have been devoted to affinity chromatography, several reviews have been written[21,26,491,492], and Cherkasov has recently published a review in this journal[28]. Here only a few references are given to work in which an immobilised enzyme has been used as affinity adsorbent[291,346,485,493,494].

The use of enzyme electrodes offers a convenient method for determining substrates. They are made from a specific electrochemical transducer, whose sensitive surface is covered with a membrane containing the enzyme[235]. Enzyme electrodes are divided into two groups according to the principle on which they act, i.e. to the nature of the substance determined: (*a*) the product is determined; (*b*) the decrease in the diffusion of the substrate through the enzyme membrane is determined. Data on enzyme electrodes are given in Table 4. In most cases, however, the stability of such electrodes is inadequate, and they are not manufactured by industry, probably for this reason.

Table 3. Proposals for the introduction of enzyme catalysis into industrial technology.

Enzyme	Initial substance or mixture	Product and effect	Reference
	preparation of required product		
Amylase	starch	glucose, glucose syrup	34, 85, 282, 365, 470-473
Invertase	sucrose	invert syrup	89, 369, 441, 454, 455, 474
Proteinase	milk	curdled milk for cheese product	252, 322, 475, 476
Penicillinamidase	benzylpenicillin	6-aminopenicillanic acid	8, 31, 70, 336, 363, 374, 477, 478
Glucose oxidase	glucose	gluconic acid	7
Glucose isomerase	glucose	invert syrup	172, 479
Steroid dehydrogenase	cortisol	prednisolone	179
Oxynitrilase	benzaldehyde	mandelonitrile	100
Polynucleotide phosphorylase	mononucleotides	oligonucleotides, polynucleotides	342, 428
Laevansucrase	sucrose	laevans	103
Adenylate kinase	acetyl phosphate; adenosine diphosphate	adenosine triphosphate	480
NAD pyrophosphorylase		nicotinamide-adenine dinucleotide	71
	removal of undesirable impurities		
β-Galactosidase	milk, whey	hydrolysis of difficultly soluble and assimilable lactose	481, 482, 483
Protease	beer	hydrolysis of proteins which cause cloudiness	225, 423
Protease	antibiotics	hydrolysis of immunogenic protein impurities	355
Naringinase	citrus joices	removal of bitter taste of naringin	302
	resolution of racemic mixtures		
Aminoacylase	acetylated DL-amino-acids	free L-amino-acids and acetyl-D-amino acids	94, 102, 383, 484
	concentration by specific sorption		
Proteases	treated stock	natural protease inhibitors	144, 291, 346, 485

Substrates can be determined also in a system comprising measuring devices, a column of an immobilised enzyme, and a flow-type colorimeter (or fluorometer). The column can be replaced by a tube with the enzyme attached to its inner surface[217,200]. Such systems have been assembled for determining glucose (by means of glucose oxidase[136,137,254]), urea (by means of urease[210,254,255]), uric acid (by means of urate oxidase[254]), and ethanol and lactic and malic acids (by means of the appropriate dehydrogenases[217]).

Fundamentally similar types of equipment are used for determining enzyme inhibitors. Especially high sensitivity is achieved when fluorogenic substrates are used. This method has been employed to determine organophosphorus compounds which inhibit immobilised cholinesterase[126,142,268,500]. Besides high sensitivity, it has the further substantial advantage that, in contrast to chemical

methods of analysis, in which substances are determined by means of their functional groups, enzymic analysis enables toxic substances to be determined from their biological action, which consists precisely in the inhibition of certain key enzymes.

Another application of immobilised enzymes is to controlled proteolysis in determining the primary structure of proteins[159,224,501]. The electrophoretograms of certain enzymes can be developed by applying to the test strip a polyacrylamide sheet in which have been immobilised the enzymes and substrates required for the development[145]. Thus a film containing glucose 6-phosphate dehydrogenase is used to develop phosphoglucomutase, and a film containing these two enzymes to develop pyrophosphorylase.

Table 4. Principles of the action of enzyme electrodes.

Compound determined	Enzyme in membrane	Species determined by transducers	References
Glucose	glucose oxidase	O_2	135, 280, 495, 496
Urea	urease	NH_4^+	142, 161, 497, 498
Glutamine	glutaminase	NH_4^+	466
Asparagine	asparaginase	NH_4^+	147
L-Amino-acids	L-amino-oxidase	NH_4^+	140–142, 499
D-Amino-acids	D-amino-oxidase	NH_4^+	147
Ethanol	alcohol oxidase	H_2O_2	491
Amygdalin	β-glucosidase	CN^-	156, 157

The therapeutic effect of the parenteral introduction of soluble enzymes has been known for a long time. Among the many applications of enzyme therapy the greatest attention has recently been attracted by the treatment of certain malignant growths with asparaginase. But the success of enzyme therapy is very often brought to naught by the rapid decomposition of the enzyme in the living organism and because of the serious immunological reactions caused by the added enzyme as a foreign protein. A way to overcome these obstacles is to replace native enzymes by insoluble or soluble derivatives[502]. Immobilised enzymes can be introduced into the bloodstream, of course, only when their particle size does not exceed a few micrometres. In particular, the use of microencapsulated enzymes is recommended for these purposes. The effectiveness of encapsulated asparaginase[242,276,503,504], catalase[418,505], and streptokinase[277] has already been demonstrated by animal experiments. The injected enzymes possessed negligible immunogenicity and greater stability. But it is not yet clear how the organism will react to the prolonged introduction of considerable quantities of a polymeric carrier of the enzyme. It may therefore be advisable to use biodegradable polysaccharide carriers.

A fundamentally different way of using immobilised enzymes for the controlled variation of blood composition consists in passing the blood through an enzyme column outside the organism. It has been recommended, for example, that the cumbersome and expensive dialysis equipment of the "artificial kidney" should be replaced by a small column and immobilised urease[129,414,458]. The column should contain also a sorbent to bind the ammonia formed.

Many polymeric materials on contact with blood cause haemolysis, which is harmful to the human organism, and extremely dangerous thrombosis. In order to obtain improved implantation materials it has been recommended that polymers should be produced with proteolytic enzymes or proteins attached to them[151]. Materials of this type have been used for the treatment of burns and wounds[446].

The above examples show the possibilities of the use of immobilised enzymes in medical practice. However, the realisation of these possibilities is evidently still more complicated than the modification of technical processes or the establishment of new analytical methods.

NOTE ADDED IN PROOF

While the Review was being prepared for press the number of papers and patents on immobilised enzymes almost doubled, but it was impossible to include this material in the Review. Several symposia have also been held on this topic, among which it is necessary to mention the First All-Union Symposium on the Preparation and Application of Immobilised Enzymes[506] (held in Tallinn in May 1974).

Principal Practical Applications of Ferrocene and Its Derivatives

A.N.Nesmeyanov and N.S.Kochetkova

A little more than 20 years have elapsed since the discovery of ferrocene (dicyclopentadienyliron) and during this period its chemistry has developed quite extensively. The present authors have seen the beginning of practical studies on the applications of ferrocene and its compounds.
The review does not deal with the applications of ferrocene-containing polymers.
The bibliography includes 81 references.

CONTENTS

I. Introduction 710
II. Radiation absorbers: agents enhancing thermal stability and light resistance 710
III. Ferrocene dyes 711
IV. Combustion regulators (antiknock-, antifouling-, and antismoke-agents, and combustion catalysts) 712
V. Medicinal substances 712
VI. Electron-exchange resins and other redox systems 713

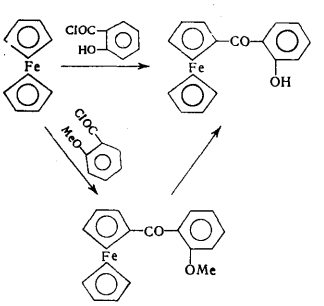
I. INTRODUCTION

The practical applications of ferrocene and its derivatives[1-4] can be grouped in the following main classes: absorbers of different types of radiation, including cosmic rays, regulators of combustion processes, highly effective non-toxic medicinal substances, components of various redox systems, and certain others.

At the present time many different ferrocene derivatives can be obtained in amounts necessary for practical applications. The wide assortment of commercial ferrocene derivatives which are available, for example, in the USA, is indicated by the advertisements of the American firm Research Organic Inorganic Chemical Corporation[5]. Ferrocene homologues, mono- and di-acylferrocenes, ferrocenecarboxylic acids, and many other compounds are quoted as available to a prospective buyer. The possibility of carrying out classical organic reactions with ferrocene[1-4] and the possibility of employing normal chemical apparatus give rise to the hope that the industrial chemistry of ferrocene derivatives will develop in the immediate future on the widest possible scale. A brief survey of the principal practical applications of ferrocene and its derivatives is given below.

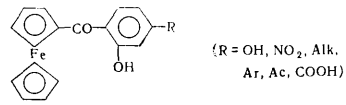
II. RADIATION ABSORBERS: AGENTS ENHANCING THERMAL STABILITY AND LIGHT RESISTANCE

Many aroylferrocene derivatives containing OH groups and other substituents in the *ortho*- or *para*-position of the aromatic ring proved to be effective inhibitors of the light-induced ageing of polymers. The best of these—*o*-hydroxybenzoylferrocene—was obtained by the present authors[6] from salicyl chloride and by Schaaf[7] from methoxysalicyl chloride with subsequent replacement of the methoxy-group by the hydroxy-group:



An interesting report has been published[8] according to which polymers containing *o*-hydroxybenzoylferrocene can be used to coat space ships to protect them from various types of radiation. The Table shows that the best effect is achieved when the inhibitor is introduced into a melamine-alkyd resin. The authors suggest that the action of this inhibitor is associated with its capacity to absorb radiation strongly in the range 200—500 nm; possibly the stabilising role is ensured not only by the ferrocene moiety of the molecule but also by the *o*-ketophenol residue, since agents enhancing light resistance, consisting of derivatives of benzoylbenzene and salicylic acid, are generally known. The replacement of one of the benzene rings of benzoylbenzene by the ferrocene residue enhances the inhibiting capacity of these substances.

Substituted *o*-hydroxybenzoylferrocenes with the substituent in the *para*-position are used to stabilise polyolefins[9].



(R = OH, NO_2, Alk, Ar, Ac, COOH)

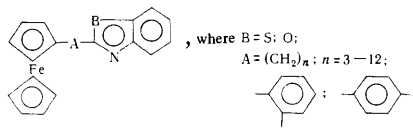
Products obtained by the condensation of ferrocene with ethyl methyl ketone[10] and many others[11] have also been proposed.

Agents enhancing the light resistance of polymers.

Polymeric resin	Inhibitor	Expt. PE*
Melamine-alkyd	1% 2-hydroxybenzoylferrocene	5000
Melamine-formaldehyde	5% 2-methoxybenzoylferrocene	375
Polyvinylbutyral	5% 2-hydroxybenzoylferrocene	320
Melamine-modified polyvinylbutyral	5% 2-hydroxybenzoylferrocene	275
Melamine-alkyd	1% dibenzoylferrocene	260
Silicone-alkyd	1% 2-hydroxybenzoylferrocene	200
Silicone-alkyd	5% 2-hydroxybenzoylferrocene	200
Silicone-alkyd	5% dibenzoylferrocene	200
Melamine-formaldehyde	5% 2-hydroxy-4-methoxybenzoylferrocene	154
Melamine-formaldehyde	5% dibenzoylferrocene	160

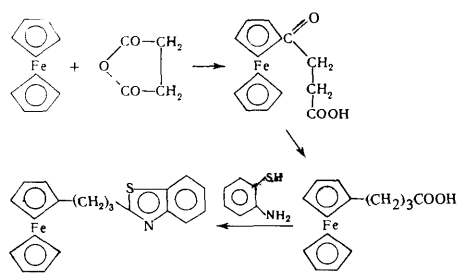
* PE are relative units of the efficiency of the ultraviolet light absorber, expressing its capacity to inhibit the decomposition of polymeric materials.

Heterocyclic ferrocene derivatives can be used as bleaching agents in the textile industry and as scintillators. For example, a number of patents[12] deal with compounds having the general formula



, where B = S; O;
$A = (CH_2)_n$; $n = 3-12$;

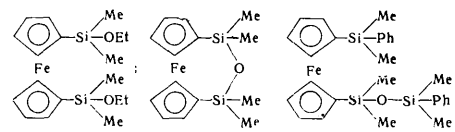
An example of the synthesis of one of them—1-ferrocenyl-3-benzothiazolylpropane—is given below:



The compounds indicated in Rei's Patent[12] include substituted naphthothiazoles, naphthoxazoles, anthrothiazoles, and anthroxazoles.

Stabilisers of another type are ferrocene derivatives of a number of elements. For example, tetraferrocenyl derivatives of Group IV elements are used as stabilisers (antioxidants)[13].

Organosilicon derivatives of ferrocene are used to enhance the thermal stability of organosilicon polymers[14].



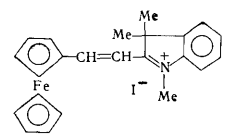
In their presence organosilicon materials withstand longer heating without appreciable signs of decomposition. A number of reports on this field were published recently[15-18].

III. FERROCENE DYES

1. Cyanine and Indolenine Dyes

Substances capable of absorbing light in the far visible region are of greatest interest among cyanine dyes: compounds of this kind are effective sensitisers, increasing the sensitivity of photographic materials with respect to light at longer wavelengths. These dyes contain as a rule fairly long polymethine chains and their stability in air is low; the period during which photographic materials based on them are serviceable does not amount to years, as is usually the case, but to days and even hours. These factors present considerable difficulties both in the synthesis and in the application of photographic materials of this kind. The introduction of a ferrocene chromophore into the molecule of a cyanine dye results in an appreciable bathochromic shift of the absorption bands in their spectra, which leads to new prospects for the development of the chemistry of ferrocene-containing organic sensitisers.

Titov et al. synthesised a green indolenine dye[19]:

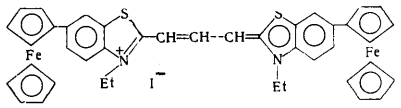


Possibly the α-ferrocenylcarbon atom of the conjugated chain plays the role of the second positively charged atom in the conjugated system, as was shown in studies by Nesmeyanov, Sazonova, and Postnov[20-22].

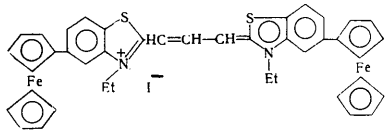
The interest in dyes of this type (sensitisers for light-sensitive layers) is illustrated by French and American patents[23,24].

Cyanine dyes (thiacarbocyanines) containing a ferrocenyl substituent in the benzene ring of benzothiazole and also dyes containing such a substituent in the main chain are known. These are blue-green substances, the spectra of

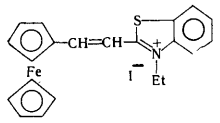
whose solutions contain absorption bands in the visible region (600–610 nm).[25]



λ = 608 nm;



λ = 592 nm;

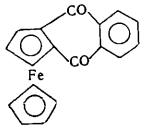


λ = 601 nm.

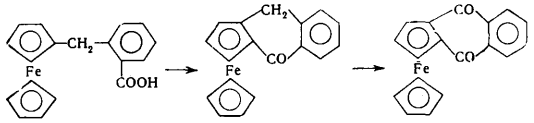
A negative reproduction material based on unsubstituted or substituted ferrocene has also been mentioned[26].

2. Ferrocene anthraquinone

Another type of ferrocene-containing dyes are compounds of the ferrocene anthraquinone series: here the anthraquinone molecule is modified by replacing one benzene ring by one cyclopentadiene ring of the ferrocene system:



Such compounds have been synthesised by Vil'chevskaya and the present authors[27–29] by the cyclisation of *o*-carboxybenzylferrocene with polyphosphoric acid,

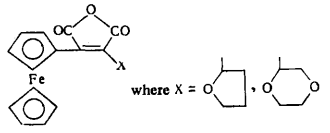


followed by oxidation using activated manganese dioxide. These compounds dye wool, silk, and artificial fabrics, giving various pink and brown shades without the use of a mordant, which is of great interest in the last instance.

3. Other Dyes

A United States patent[30] describes yellow pigments consisting of products of the condensation of ferrocene with phthalic anhydride which are insoluble and infusible up to 360°C.

Unusual compounds, described in a patent[31], were obtained by the condensation of ferrocene with maleic anhydride in tetrahydrofuran, dioxane, and other solvents in the presence of peroxides:



Possibly a polyrecombination reaction, similar to that achieved by Korshak and Sosin[32], takes place in this case.

It is interesting that the above substances have been patented not only as inks soluble in organic solvents but also as anticorrosion agents, pesticides, fungicides, and even as antidetonators.

IV. COMBUSTION REGULATORS (ANTIKNOCK-, ANTIFOULING-, AND ANTISMOKE-AGENTS, AND COMBUSTION CATALYSTS)

There is a fairly extensive, mainly patent literature on these applications of ferrocene and its derivatives. It is noteworthy that antismoke[33], antifouling and antiknock[34], and catalytic properties[34–37] are characteristic of the same compounds.

Various classes of organic derivatives of ferrocene have been mentioned in patents: ferrocene[34,35], ferrocene homologues[39–41], vinylferrocene[42], cyclopentenylferrocene[42], carbinols[35], formylferrocene[35], alkenylferrocenes[36,38], ferrocenecarboxylic acid[35], and certain other compounds[35]. Apart from data on individual compounds, mixtures with two and more components have been described[36]. For example, mixtures of ferrocene or its homologues with cyclopentadienylnitrosylnickel containing 85–50% $C_{10}H_8R_2Fe$ (where R = H, Me, or Et) and 15–50% C_5H_5NiNO and a mixture of ferrocene with cyclopentadienylthallium[38] are used as antidetonators. However, so far ferrocene and its derivatives have not yet been generally recognised as antiknock agents. The reason for this is that they all suffer from a common disadvantage—the *deposition* of iron(III) oxide as the combustion product on the components of the engine and primarily on the sparking plugs of a carburator engine greatly impairs the working parameters and accelerates the wear of such components[41].

Fuel compositions based on nitrocellulose with added ferrocene (1–2%), which exhibit a high plasticity[43], and also compositions containing 30–70% of ferrocene, benzoylferrocene, or dibenzoylferrocene in the presence of nitric acid[44] have been proposed in British patents.

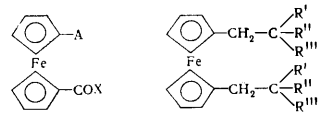
Pyrotechnic compositions based on triferrocenylphosphine and mercury nitrate have been obtained[45].

V. MEDICINAL SUBSTANCES

Iron enters into the composition of haemoglobin—the basis of the vital activity of the organism. For this reason various inorganic iron preparations were used previously to treat diseases associated with iron deficiency in the organism. However, most of these are relatively inefficient and have many side effects (irritation of the gastrointestinal tract and others).

Ferrocene derivatives proved to be much more effective and relatively non-toxic medicinal substances.

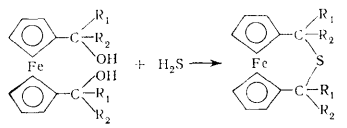
Ferrocene homologues described in patents possess anti-anaemic properties[46–48]. Homologues containing secondary and tertiary alkyl and cyclohexyl groups joined to ferrocene via a methylene unit have been obtained from the corresponding ketones:



(A = H or COX)
(X = s- or t-alkyl or C_6H_{12})

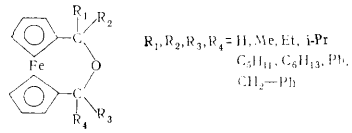
Homologues with the same alkyl substituents linked directly via a secondary or tertiary carbon atom to the cyclopentadiene ring have been obtained by the direct alkylation of ferrocene[49]. These are thick reddish liquids, which are introduced into the organism in the form of capsules, oil emulsions, and other medicinal forms; the application of ferrocene derivatives together with anticoagulants (nitro-compounds, tetrahydrofuran, and others) has also been mentioned in a patent[48].

Ethers and thioethers derived from ferrocene have been proposed in the USA for the same purposes. For example thioepoxyferrocene[50] obtained by the reaction of carbinols with hydrogen sulphide,



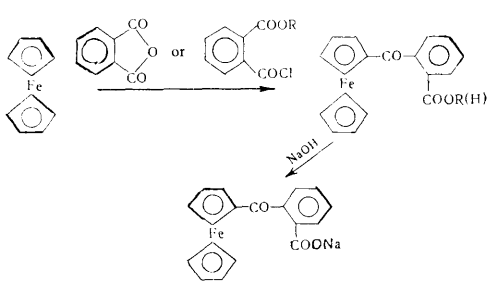
and a number of other compounds[51,52] have been suggested.

Epoxyferrocene[53,54], which combines simultaneously anti-anaemic and anticoagulant activities in the organism, has been recommended:



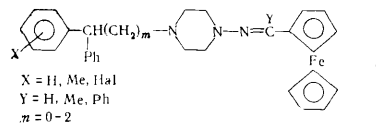
A characteristic feature of the ferrocene derivatives listed above is their insolubility in water. Possibly this is why they require the simultaneous employment of anticoagulants, very toxic compounds such as nitro-derivatives, tetrahydrofuran, and others being recommended.

Until recently medicinal preparations derived from ferrocene were unknown in the world market. The first such preparation is *"ferrocerone"*, which was synthesised in the USSR. It is the sodium salt of *o*-carboxybenzoylferrocene and was developed by Vil'chevskaya and Palitsyn together with ourselves at the Leningrad Institute of Haematology and Blood Transfusion[55-61]. It was synthesised from ferrocene and the half-ester half-chloride of phthalic acid and also from ferrocene and phthalic anhydride[58,59] according to the following scheme:

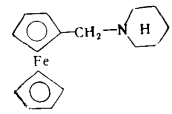


Ferrocerone is soluble in water, is non-toxic, and is readily assimilated by the organism; it exhibits a wide therapeutic spectrum. It can be used to treat various forms of iron deficiency anaemia[55,57], a severe infection of the nasopharynx[56], and others. Ferrocerone is manufactured in the form of tablets and is administered orally, which is very convenient for the patient, particularly when the gastrointestinal tract is affected.

Ferrocene derivatives have not been recommended solely for the treatment of various iron deficiency diseases. It has been suggested that many other diseases be treated with ferrocene derivatives. For example, an antiulcer preparation has been recommended[62]:



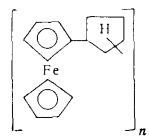
The physiological activity of aminoferrocene derivatives[63] having the composition



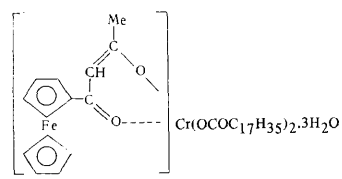
has also been briefly mentioned.

VI. ELECTRON-EXCHANGE RESINS AND OTHER REDOX SYSTEMS

The capacity of ferrocene to undergo reversible oxidation-reduction made possible the practical application of this system in various redox processes. The first example of organoiron electron-exchange resins was polyferrocenylcyclopentene, which we obtained by the decomposition of ferrocene in the presence of aluminium chloride[64,65]:



This oligomer is insoluble in water. In oxidation by potassium dichromate in the presence of sulphuric acid the capacity of this redox resin under static conditions proved to be 2.00—2.38 milliequivalents per gm. of air-dry resin. It was reduced with ascorbic acid. The cycle was repeated three times without appreciable effect on the capacity. At the present time the chemistry of ferrocene-containing polymeric redox resins has developed fairly extensively[66-71]. A ferrocene electrode[72-76] as well as ferrocene-containing antistatic agents are known. A mixed chromium chelate salt derived from ferrocenoylacetone,



has been proposed as an antistatic agent[77,78]. The possible applications of organometallic compounds in electronics are described in a monograph[79].

Thus the known practical applications of ferrocene and its derivatives can be grouped in a number of classes. In one of them the applications are based on the ability of ferrocene and its derivatives to absorb various types of radiation. A ferrocene chromophore imparts a bright

colour ranging from yellow-orange to blue-green and as a rule these products are firmly fixed on various materials, including synthetic fabrics. All this makes it possible to employ ferrocene derivatives as dyes of a new type and also as photographic materials and light sensitisers.

Another important application is based on the ability of ferrocene and its derivatives to regulate various combustion processes. This leads to the possibility of using them as antismoke, antifouling, and antidetonation agents and also as combustion catalysts.

Iron is a component of the organism important for its vital activity. A deficiency of this element leads to severe illnesses. The low toxicity of ferrocene and its derivatives and their ability to treat diseases associated with iron deficiency in the organism as well as many other ailments gives rise to the third important practical application—medicinal preparations based on ferrocene derivatives.

Ferrocene is capable of undergoing reversible oxidation–reduction under mild conditions. As a result of this property, ferrocene derivatives sparingly soluble in water have been proposed as electron-exchange resins (redox resins) and also as other redox systems.

In conclusion of this brief review, we may mention that cyclopentadienyl and other derivatives of almost all transition and non-transition metals are now known. Many of these compounds are quite stable in air and there are easy methods for their synthesis.

Thus there are very many possible practical applications of these compounds in a wide variety of fields[80,81].

Ferrocenophanes

G.B.Shul'pin and M.I.Rybinskaya

The review deals with unusual cyclophanes of the ferrocene series, which are known as ferrocenophanes. The methods of synthesis of ferrocenophane systems are described and the dependence of their properties and structures on the type and length of the bridge is discussed. Special attention has been devoted to the employment of ferrocenophane models for the solution of a number of theoretical problems in ferrocene chemistry. The stereochemistry and practical applications of ferrocenophanes are discussed. Other organometallic analogues of cyclophanes, only a limited number of examples of which are so far known, are also described. The literature up to 1973 inclusive has been covered.
The bibliography includes 231 references.
