However, more recent work[85,87,99-111] has revealed a number of interesting aspects of this reaction in the presence of zeolite catalysts. Thus, unlike the MnY zeolite, alkali cationic forms of various zeolites (free from transition metals) are catalytically active in the oxidative dehydrogenation of ethylbenzene and isopropylbenzene[87,95,100], the activity and selectivity of the catalysts and the specific features of the process being strongly influenced by the zeolite structure. Faujasites were found[100,104] to be more active towards deep oxidation, and therefore their selectivity towards oxidation dehydrogenation is low. Narrow-pore type A zeolites, chabazite, erionite, and mordenite are less active towards the deep oxidation and hence they offer a higher selectivity for the formation of styrene. Furthermore the yield of styrene on faujasites increases with time, a stable regime being established 2.5–3 h after the beginning of the reaction, whereas in the presence of narrow-pore zeolites this development period is not observed.

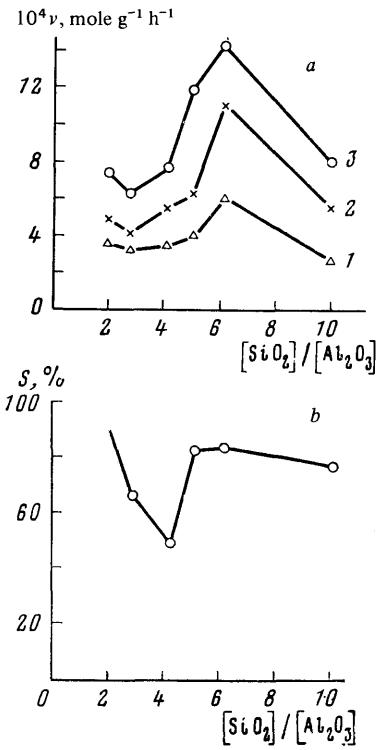

Figure 4. Rate of oxidative dehydrogenation of ethylbenzene (*a*) and selectivity with respect to styrene (*b*) against the $[SiO_2]/[Al_2O_3]$ ratio in zeolite at: *1*) 400, *2*) 425, and *3*) 450 °C (Ref.100).

The effect of the zeolite structure on the activity was investigated on the Na or Na, K forms of various synthetic zeolites[100]. The rates of oxidative dehydrogenation of ethylbenzene and the selectivities with respect to styrene are shown in Fig.4 as a function of the silica to alumina ratio in the zeolite[100]. In oxidation reactions with an O_2:ethylbenzene ratio of 0.4 the narrow-pore zeolites of the erionite type offer a higher activity and selectivity than the faujasites. It is interesting to note that on type A zeolites, chabazite, erionite, and mordenite, whose pores are too small to allow the ethylbenzene molecules to penetrate into the zeolite holes, the oxidative dehydrogenation takes place with a greater selectivity than on the wide-pore faujasites (Fig.4*b*).

Interesting results were obtained also in a study of the oxidative dehydrogenation of alkylaromatic hydrocarbons on synthetic sodalite[87], characterised by the smallest entry windows of any type of zeolite (2.6 Å), a high thermal stability, and a close-packed crystal lattice[17]. In the presence of Na-sodalite the reaction is detectable even at 350°, and at 525° the yield of styrene reaches 45%, making sodalite more active than any other synthetic zeolite towards the oxidative dehydrogenation of ethylbenzene.

The kinetics of the oxidative dehydrogenation of ethylbenzene on the Na, K form of erionite have been studied[102], and the reaction at 400–475° was found to be first-order in ethylbenzene. At temperatures below 425° a zero reaction order with respect to oxygen is observed, and at higher temperatures the dependence is of the Langmuir type. The rate-limiting step of the reaction is thought to be the interaction between weakly adsorbed ethylbenzene and oxygen on the outer surface of the zeolite crystals. The apparent activation energy is 31.5 kcal $mole^{-1}$.

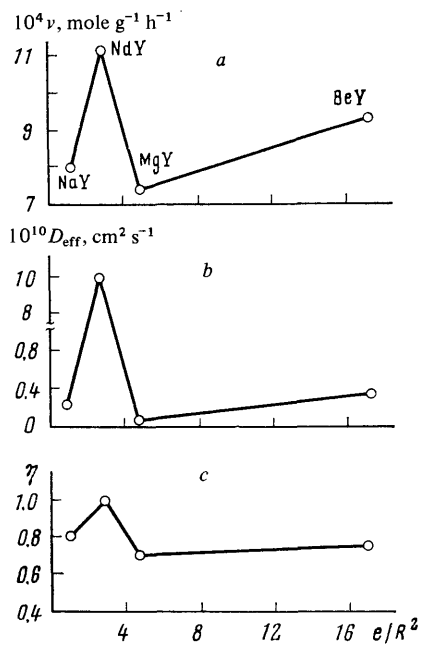

Figure 5. Rate of oxidative dehydrogenation of ethylbenzene (*a*), effective diffusion coefficient (*b*), and effectiveness factor (*c*) against the electrostatic potential of the cation in type Y zeolite at 425 °C (Ref.106).

The interaction of ethylbenzene with various zeolites has been studied by thermo-desorption[106]. Adsorption of ethylbenzene occurs only on type X and Y zeolites; only one desorption peak is observed, whatever the nature and concentration of the cation, and this peak is shifted towards lower temperatures when the sodium is exchanged for multivalent cations. Evidently, the strong adsorption of ethylbenzene on Na-faujasites is responsible for the deep oxidation

observed on these catalysts, and hence for the low selectivity with respect to styrene. From the thermo-desorption results we calculated[106] the activation energies for diffusion, the pre-exponential factors, and the effective diffusion coefficients of ethylbenzene in the zeolites. Plots of the rate of oxidative dehydrogenation of ethylbenzene, of the effective diffusion coefficient, and of the effectiveness factor against the electrostatic potential (e/R^2) of the cation in the zeolite are shown in Fig.5. We note that all three plots go through a maximum for the NdY zeolite, in which the reaction rate is least affected by diffusional limitations.

We have also studied[103,109] the catalytic properties of various types of natural zeolite towards the oxidative dehydrogenation of ethylbenzene and isopropylbenzene. The most active catalysts are heulandite and clinoptilolite, on which the yield of styrene varies between 37.7 and 48.2%. The apparent activation energy of the reaction for these natural zeolites is in the range 5–17 kcal mole^{-1}, i.e. it is lower than the apparent activation energy for synthetic zeolites of the chabazite, erionite, and mordenite types[100]. In the oxidative dehydrogenation of isopropylbenzene the catalysts form the same activity sequence as in the ethylbenzene reaction: the most active is clinoptilolite, and the least active lomontite. However, on all the zeolites the conversion of isopropylbenzene into α-methylstyrene is smaller than the conversion of ethylbenzene into styrene.

The catalytic properties of Pd-containing type Y zeolites towards the oxidative dehydrogenation of alkylaromatic hydrocarbons are discussed in Refs.101 and 107. It is shown that, unlike the starting NaY zeolite (which has a significant and stable activity towards the deep oxidation reaction), samples containing Pd(II) ions yield an amount of CO_2 which decreases as the time of operation of the catalyst increases, so that when steady state is reached the activity and selectivity of PdNaY towards styrene are relatively high. The activity and selectivity of this catalyst towards the oxidative dehydrogenation of ethylbenzene and isopropylbenzene are also higher than those of a Pd catalyst on amorphous alumina–silica.

The effect of the structure and composition of the zeolite on the activity of Pd-containing catalysts is discussed in Ref.110. Alkaline-earth and decationated forms of type Y zeolite have an initially high activity towards the cracking of ethylbenzene, but the yield of cracking products decreases with time, and after a development period small amounts of styrene can be detected. On an amorphous alumina–silica catalyst the yield of styrene decreases during the reaction. The introduction of palladium into CaY and HY zeolites and into amorphous alumina–silica lowers their cracking activity and increases the yield of deep oxidation and oxidative dehydrogenation products. However, all three samples are inferior to PdNaY zeolite in the yield of styrene and in the selectivity of the process. A possible explanation is electron deficiency of the palladium in CaY, HY, and amorphous alumina–silica as a result of the repulsion of the Pd 4*d* electrons by the acidic centres of the matrix. At the same time, because of the low acidity and of the weak electrostatic fields of the sodium cations, the influence of NaY on the valency state of the metal is much slighter[112]. We have shown[110] that the addition of Pd(II) cations to zeolites of the chabazite, erionite, and mordenite types increases their activity only in respect of deep oxidation, and as a result the Pd-containing zeolites of these types have a lower selectivity towards styrene formation than the initial zeolites.

The kinetics of the oxidative dehydrogenation of ethylbenzene on 0.5 wt.% PdNaY zeolite prepared by ion exchange have been investigated[111]. The reaction is kinetically of the first order with respect to ethylbenzene and of order 0.5 with respect to oxygen. The activation energy is 15 kcal mole^{-1}, i.e. about one-half of the activation energy of the same reaction on Na, K-erionite.[101]

By postulating the reaction scheme

$$O_2 + 2[\ ] \overset{k_1}{\rightleftarrows} 2[O]$$
$$C_2H_5C_6H_5 + [\ ] \overset{k_2}{\rightleftarrows} [C_2H_5C_6H_5]$$
$$[C_2H_5C_6H_5] + [O] \overset{k_3}{\rightleftarrows} [C_2H_3C_6H_5] + [H_2O]$$
$$[C_2H_3C_6H_5] \overset{k_4}{\rightleftarrows} C_2H_3C_6H_5 + [\ ]$$
$$[H_2O] \overset{k_5}{\rightleftarrows} H_2O + [\ ]$$

(where [ ] denotes an active centre on the catalyst surface, and [O], $[C_2H_5C_6H_5]$, $[C_2H_3C_6H_5]$, and $[H_2O]$ are adsorbed forms of oxygen, ethylbenzene, styrene, and water), and by taking as the slow step the desorption of styrene from the internal zeolite holes, we obtain the kinetic equation

$$v = v_{stat}(1 - e^{-k_4\tau})$$

where τ is time. This equation describes the changes in reaction rate in both the non-stationary and the stationary ($e^{-k_4\tau} \ll 1$) regime.

The oxidative dehydrogenation of ethylbenzene on the zeolite-containing catalysts AShNTs-3 and TsEOKAR-2 has been studied[113]. The yield of styrene at 525° on AShNTs-3 containing 20 wt.% of decationated zeolite Y was 31%; the selectivity of the process was 77%. The authors suggest[113] that the ethylbenzene molecule is adsorbed through the π-electrons of the benzene ring on a coordinationally unsaturated Al atom. On the "stronger" acidic centres the adsorption of ethylbenzene is stronger, and the molecule can undergo deep oxidation.

In the absence of oxygen isopropylbenzene can be dehydrogenated on zeolites[114,115] at high temperatures, but the selectivity is low and the reaction is accompanied by cracking of the initial hydrocarbon. Hence we may assume that the role of oxygen in oxidative dehydrogenation on zeolites is not to oxidise the hydrogen produced by the dehydrogenation of the hydrocarbon but to form carbon-containing intermediates which decompose to give styrene. This hypothesis is consistent with the low activity of zeolites containing no transition metals towards the dehydrogenation of hydrocarbons[114–117] and the oxidation of hydrogen[27,28].

V. OXIDATION OF INORGANIC COMPOUNDS

The reaction between hydrogen and oxygen is the simplest model reaction used to study the oxidation properties of catalysts. Ref.27 and 28 describe a study of the relative activities of type Y zeolites containing upwards of 50 equiv.% of transition-metal cations (Cu, Cr, Fe, Co, Mn, Ni, Ag). The highest activity was observed in AgY, followed by CuY, FeY, CrY, NiY, and CoY. The same activity sequence applies, on the whole, to the oxidation of CO, but in this reaction CoY is as active as AgY.

The activity of different cationic forms of type X zeolite towards the oxidation of hydrogen was found[118] to decrease in the series PdHX > CuHX > FeHX > NiHX > CrHX > ZnHX > MnHX > CoHX > HX. The activity of the CuHX sample increases with the concentration of copper ions in the zeolite. Copper cation pairs connected by bridging oxygen are suggested[118] as the active centres.

The main features of the oxidation of CO on zeolites containing transition metals are discussed in detail in Refs.119–127. The addition of up to 36% of copper is shown[119] to increase the activity in direct proportion, changing to an exponential dependence for copper contents

up to 90%. The reaction is first-order with respect to carbon monoxide and zero-order with respect to oxygen. The active centres are thought to contain more than one copper cation. The effect of the ion exchange conditions on the activity of the Cu(II), Cr(III), Ni(II), Co(III), and Fe(III) forms of type Y zeolite towards the oxidation of CO is discussed in Refs.120–122. Samples prepared at pH values corresponding to hydrolysis of the salts have a catalytic activity per atom 4–5 orders of magnitude greater than samples prepared under conditions in which the transition metals are stabilised as isolated ions. In the former case the metal cations are partly coordinated by an oxygen atom not belonging to the zeolite skeleton and having a high reactivity as a result of the greater covalence of its bond with the metal cation.

Isolated Cu(II) cations in zeolites have been shown[123] not to interact with CO at temperatures between −196 and 500°. Weak magnetic groups of associated Cu(II) cations form adsorption complexes with CO at temperatures between −196 and 100°, and at 300–500° they oxidise CO to CO_2 [the Cu(II) being reduced to Cu(I)]. Strong magnetic associations of Cu(II) cations, including bridging (non-skeleton) oxygen, can oxidise CO to CO_2 even at low temperatures.

A study of the oxidation of CO on X and Y zeolites containing cations with low charges has led to the conclusion[124] that CO molecules from the gas phase can react with dissociatively adsorbed oxygen in bridging positions. Very little oxygen is adsorbed on the Tl(I), Co(II), and Mn(II) forms, and none on the Cu(II) and Ni(II) forms, because of the difficulty of raising the oxidation state of these cations. The catalytic activity of all these samples is low. Zeolites containing Fe(II) and Cu(I) are more active, and they can chemisorb up to 0.5 oxygen atom per metal atom. The following reaction mechanism was proposed[124] from the kinetic results:

$$2\mathrm{Fe(II)} + {}^1/_2\mathrm{O_2} \rightarrow \mathrm{Fe(III)}{-}\mathrm{O^{2-}}{-}\mathrm{Fe(III)}$$
$$\mathrm{Fe(III)}{-}\mathrm{O^{2-}}{-}\mathrm{Fe(III)} + \mathrm{CO} \rightarrow 2\mathrm{Fe(II)} + \mathrm{CO_2}\,.$$

The series of decreasing activity for the oxidation of CO is given[125] as CoY > CuY > FeY > NaY > MnY. The activity of the initial NaY zeolite is quite high at 400° but falls off rapidly at lower temperatures. The authors conclude that the catalytic activity of these zeolites is determined by the presence of isolated metal cations on the surface. I.r. spectral studies have shown[126] that the interaction of CO and O_2 on the surface of zeolites containing transition-metal cations leads (at high temperatures) to the formation of physisorbed CO_2 and of surface carbonates, produced by the interaction of CO and O_2 with the cations.

A very steep, non-linear increase in the adsorption of CO on zeolite Y as a function of the degree of exchange of sodium by multivalent cations has been noted[127], and ascribed to the fact that the cations are located in S_1 sites where CO adsorption cannot take place.

Amorphisation of FeY and CoY by a shock wave[128] has little effect on the oxidation of CO. The activation energy changes by 1–2 kcal mole^{-1}, and the catalytic activity per atom remains almost the same. Obviously, the catalytic properties are determined mainly by the nature of the transition-metal ions in the zeolite and by the way in which these ions are bound to the surface.

A method of preparing a zeolite catalyst containing 10% of rare-earth elements and 0.3% of Pt for the re-oxidation of CO to CO_2 in the regeneration of cracking catalysts has been proposed[129]. The conversion of CO can be as high as 95.8%, and the catalyst is stable towards carbon, hydrogen, and olefins.

The oxidation of ammonia on Mn(II), Fe(III), Co(II), Ni(II), Cu(II), Cr(III), and Ag(I) forms of type Y zeolite has been studied by a pulse method[27,28]. The reaction product on all the catalysts is molecular nitrogen, but on the Cr(III) and Ag(I) forms nitrous oxide is also found, the selectivity for this compound being ~25% on Ag(I)Y at 400°. A series–parallel reaction is postulated, in which the N_2O reacts with NH_3 to give N_2. The catalysts can be arranged in the following series of decreasing activity: CuY > CrY > AgY > CoY > FeY > NiY, MnY. We note that this activity sequence differs quite markedly from that of the corresponding oxide catalysts[130,131]: this may be due to differences in the type of chemical interaction during catalysis on zeolites and on oxides.

The oxidation of ammonia on Cu(II)Y zeolite at 160–185° was found to be kinetically of the first order in ammonia and of zero order in oxygen[132]. The activation energy is 36.7 ± 2.6 kcal mole^{-1} for samples with different extents of ion exchange. The presence of $[Cu(II)(NH_3)_4]^{2+}$ complexes in the large zeolite holes has been detected by ESR and i.r. spectroscopy. The authors suggest[132] rate limitation by the reduction of Cu(II) to Cu(I).

VI. OXIDATION OF OXYGEN- AND SULPHUR-CONTAINING COMPOUNDS

The conversion of methanol on zeolites in the presence of oxygen has been investigated[133–140]. On zeolites not containing transition metals the methanol was found to react only by an acid–base mechanism to give dehydration and etherification products[133,134]. In the presence of zeolites containing groups of associated cations the methanol is oxidised to CO, CO_2, and formaldehyde[134], and when the reaction is carried out on zeolites containing isolated transition metal cations the main product is ether.

On NaX zeolite containing 21.2% of Ag the conversion of methanol at 320–350° is 91%, with a selectivity of 87% towards formaldehyde[135]. In the presence of a large excess of oxygen the methanol is oxidised to CO_2 and H_2O almost quantitatively.

The effect of the preparative conditions on the activity of the Cu and Ag forms of types A and Y zeolites towards the oxidation of methanol is discussed in Ref.136. Conversion of the copper ions in the zeolite into an oxide ($\xrightarrow{H_2}$ Cu° $\xrightarrow{O_2}$ CuO) does not affect the yield of formaldehyde, but the overall extent of reaction increases because of an increase in the yield of CO and CO_2, which the authors ascribe[136] to the greater covalency of the Cu–O bond in CuO as compared to the Cu–O–Cu associated groups in zeolite. Reduction of the silver to the metallic state in zeolites increases the yield of formaldehyde very substantially, possibly by facilitating the electronic transitions attending the oxidative dehydrogenation of methanol.

Natural zeolites of the mordenite and clinoptilolite type have been used as methanol oxidation catalysts[137,138]. Decationation of mordenite lowers the yield of formaldehyde, while the yield of ether increases by a factor of 2. On the Cu form of mordenite the reaction sets in at a temperature 100 K lower than on the sodium or the decationated form[137]. Among the many cationic forms of clinoptilolite the highest activity and selectivity are found in the magnesium-containing decationated form[138].

On the Na, Ni, and Co forms of type X zeolite at temperatures below 300° the main product of the oxidation of methanol is dimethyl ether, but when the temperature is raised to 450° a large proportion of the ether is converted

into formaldehyde[139]. The specific catalytic activity of the samples goes through a maximum as the degree of exchange is increased, and decreases in the sequence NiX > CoX > NaX. The authors[139] point out that the activity of CoX samples with a low degree of exchange is not very different from that of the NaX zeolite. They suggest that the reaction involves either oxygen in the coordination sphere of the cation (non-skeleton oxygen) or oxygen resulting from the dissociative adsorption of O_2 from the gas phase on the zeolite.

CH_3OH, CH_4, and NO are oxidised on NaX zeolite after u.v. irradiation[140], with formation of surface carbonate, formate, and nitrate complexes. As in the case of some metal oxides, these photo-stimulated reactions on NaX zeolite seem to be associated with the presence of impurities or structural defects. According to Shchuklov and coworkers[141] the impurity centres consisting of a transition metal ion in zeolites can capture an electron and thus stabilise the chemically active positive holes formed by the u.v. irradiation. Stabilisation of the free radicals formed by the decomposition of organic peroxides can occur by an electron-donor or an electron-acceptor mechanism on the surface of NaX and NaY zeolites[142].

In an oxidising medium, isopropanol reacts on the polycationic Fe–Zn form of type A zeolite to give acetone[143]. The activity of the Fe–Zn form is much greater than that of the separate Fe and Zn forms of type A zeolite. The yield of acetone increases with the degree of exchange, but the order in which the Fe and Zn ions are introduced into the zeolite has little effect on the activity. It has been shown[144] that, unlike the Li and Na forms of type X zeolite (which catalyse only the dehydration of isopropanol), the K, Rb, and Cs forms are active towards the dehydrogenation of isopropanol to give acetone.

The oxidation of benzyl alcohol on various zeolites has been studied[145,146]. In the presence of decationated type Y zeolite benzaldehyde, benzoic acid, benzyl ether, and CO_2 are formed[145]. Hydrogen treatment of the catalyst at 500° lowers its activity towards the oxidation by 60%. The addition of pyridine to the reaction mixture lowers the overall conversion of the benzyl alcohol, whereas the addition of water increases the yield of benzyl ether and lowers the yields of the oxidation products. On the Cu(II)Y zeolite the main products are benzaldehyde, CO, and CO_2.[146] The kinetic order of the reaction is unity for both oxygen and alcohol. The active centres are thought to be Cu(II) cations located in large zeolite holes. A recent patent[148] describes the oxidation of benzyl alcohol to benzaldehyde on type X and Y zeolites containing transition metal cations. The addition of initiators (peroxides, halides, etc.) to the reaction mixture is shown to increase the yield of benzaldehyde.

The oxidation of hydrogen sulphide on zeolites was first reported[24] in 1961, but detailed studies of this reaction were published much more recently[149–152]. It has been shown by ESR that when H_2S is adsorbed on NaX zeolite at room temperature the addition of oxygen leads to the formation of chain radicals [$^{\cdot}S-(S)_x-S^{\cdot}$ and $HS-(S)_x-S^{\cdot}$] and ion radicals (O_2^-, SO_2^-, and SO_3^-), which take part in the oxidation reaction[149]. According to the authors the high catalytic activity of NaX zeolite is due to the very strong deformation of the H_2S molecule after adsorption, and to the ease with which an electron can be transferred with H–S bond breaking. Lin and Lunsford[150] studied the interaction of H_2S with oxygen on MgO, amorphous alumina–silica, NaY, and MnNaY. On the MgO surface S^-, S^{2-}, and sulphite ions are formed during the oxidation. On NaY zeolite hydrogen sulphide dissociates with formation of elemental sulphur; the addition of Mn(II) ions to the zeolite increases the formation of sulphur. On an amorphous alumina–silica surface the rate of oxidation of H_2S is negligibly small.

Chabazite tuffs of various compositions are very active towards the oxidation of hydrogen sulphide[151]. The high selectivity of the reaction for sulphur (>98%) in the presence of a large excess of oxygen (15-fold excess over stoichiometry) is specially noteworthy. The formation of SO_2 among the reaction products begins after a definite induction period, suggesting that this compound is formed by consecutive reactions. It has been shown[152] that the Mn(II)Y zeolite catalyses the oxidation of SO_2 at room temperature to the sulphate ion (strongly bound in the zeolite micro-pores). As the dehydration temperature of the catalyst is raised the Mn^{2+} cations migrate into less accessible sites, with a loss of activity.

In the oxidation of methyl mercaptan NaX zeolite is more active than NaY, and Na-mordenite is practically inactive[153]. The activity of the zeolite has been shown to be related to the density of the cations in the elementary cell. The optimum reaction temperature is 450°; at higher temperatures the degree of conversion increases, but the selectivity of the reaction becomes unacceptably low.

VII. CONCLUSIONS

It is clear from the results considered here that zeolite catalysts have a high activity towards the oxidation of various organic or inorganic compounds. The selectivity of the process, the course of the oxidative transformation, and the specific features of the reaction are determined by the structure of the zeolite, by the state of oxidation of the transition metals, and by the nature and concentration of the ion-exchange cations. Clarification of the activation mechanism of molecular oxygen and of the hydrocarbon on the zeolite surface as a function of the zeolite composition and structure should make a valuable contribution to our understanding of the mechanism of catalytic oxidation.

Oxidation on oxide catalysts may involve both the oxygen contained in the catalyst and oxygen adsorbed from the gas phase[154–157]. In the case of zeolite catalysts the oxygen in the skeleton is very strongly bound[158,159], and isotope exchange between the skeleton oxygen and oxygen from the gas phase in NaX and NaY zeolites cannot take place below 600°. The existence of strongly bound oxygen, adsorbed from the air during heat treatment of decationated type Y zeolite and retained after vacuum heat treatment at 550°, has also been reported[160–162]. The correlation between the number of molecules of chemisorbed oxygen and the amount of cation radicals formed suggests the involvement of oxygen in this process as a reactant[162]; the observation that oxidation properties are confined to dehydroxylated surfaces of decationated zeolites has led to the conclusion[163] that oxygen chemisorption occurs on anion and cation lattice vacancies.

Strong oxidation–reduction centres have been detected on zeolite surfaces in an ESR study of the adsorption of various organic compounds[164–166]. The adsorption interaction of naphthalene molecules with a Na-faujasite surface to give a donor–acceptor charge transfer complex suggests[167] that NaX and NaY zeolites can retain (after vacuum heat treatment) strongly bound oxygen which is responsible for the oxidation properties of these zeolite surfaces. The important contribution of chemisorbed oxygen to the oxidation properties of mordenite is stressed also in Refs.168–172.

The formation of oxygen anion radicals by adsorption on different cationic forms of faujasites has been reported[173-183]. In most cases the ESR signals from the oxygen anion radicals are observed after irradiating the sample with γ-rays, X-rays, or u.v. light. However, on the Li, Na, Ti, and Pd forms of type Y zeolite the oxygen anion radicals are formed by adsorption of oxygen on vacuum heat-treated samples[179-184]. A thermo-desorption study has shown[185] that oxygen is adsorbed in different amounts and in different states on the Mn, Co, Ni, and Cr forms of type Y zeolite. On CuY zeolite (an active oxidation catalyst, which adsorbs large amounts of oxygen) five different states of adsorbed oxygen, with different reactivities, have been detected[186]. Inactive O^{2-} oxygen, which does not take part in oxidation reaction, is also present on CuX zeolite[187].

The catalytically active oxidation centres in zeolites have been identified as associated groups of transition metal atoms coordinated by non-lattice oxygen[119-124]. The adsorption and catalytic properties of isolated ions in the zeolite are quite different from those of an ion pair bound by a bridging oxygen atom. Measurements by γ-resonance spectroscopy have shown the existence of this type (M–O–M) of cation pair[45,83]. The oxidation of simple molecules (CO, H_2) on these centres is assumed[156,188] to involve a collision mechanism,

$$M^{(n+1)+}—O—M^{(n+1)+} + H_2(CO) \rightarrow 2M^{n+} + H_2O(CO_2),$$

followed by oxidation of the transition metal ions (M^{n+}) by oxygen.

The oxidation of low-molecular-weight hydrocarbons on zeolites yields mainly deep oxidation products; zeolites containing transition metals are the most active towards this reaction. Therefore the reactivity of oxygen is often discussed in terms of this reaction. With naphthene and alkylaromatic hydrocarbons oxidative dehydrogenation takes place in parallel with the deep oxidation. However, whereas the zeolites containing transition metals are the most active towards the oxidation of low-molecular-weight hydrocarbons, Na faujasites show a high activity in the deep oxidation of cyclohexane, and in this case the introduction of transition-metal cations favours oxidative dehydrogenation with formation of benzene[62,73].

Unlike the faujasites, the Na forms of various narrow-pore zeolites catalyse the oxidative dehydrogenation of cyclohexane with formation of cyclohexene[84,88]; the Na forms of various zeolites are active also in the oxidative dehydrogenation of iso-pentylenes[60] and ethylbenzene[100]. However, whereas the faujasites have a lower selectivity than the narrow-pore zeolites for the formation of styrene, in the oxidative dehydrogenation of iso-pentylenes the selectivity of the Na faujasites is greater than that of narrow-pore zeolites in the Na form.

Thus, though the Na forms of faujasites have no weakly bound lattice oxygen[158] and adsorb very much less oxygen than zeolites containing transition metals[185,186], they can nevertheless catalyse the oxidative dehydrogenation of iso-pentylenes, cyclohexane, and ethylbenzene. This can be explained by postulating a difference in behaviour towards oxygen between a zeolite surface covered with an adsorbed hydrocarbon and a pure zeolite surface. Alternatively, the reaction can be assumed to involve the formation of carbon–oxygen intermediate complexes with oxygen from the gas phase: in this case the course of the reaction should be determined mainly by the interaction between the zeolite and the hydrocarbons.

Thermo-desorption studies have demonstrated the strong dependence of the adsorbate–absorbent interactions on the structure and composition of the zeolite, and on the nature of the hydrocarbon[61,89,106]. Thus, in the case of cyclohexane and ethylbenzene the low selectivity of the faujasites towards the oxidative dehydrogenation reaction stems from the strong adsorption of these hydrocarbons, which favours deep oxidation. The more selective, narrow-pore zeolites adsorb neither ethylbenzene[106] nor cyclohexane[89]. On the other hand, 2-methylbut-2-ene is adsorbed both on faujasites and on narrow-pore zeolites[61]. However, in this case the diffusion of the hydrocarbon in the narrow-pore zeolite is slower than in the faujasite, as shown by the relative values of the effective diffusion coefficient. This may also explain the greater activity of the narrow-pore zeolites towards the deep oxidation of 2-methylbut-2-ene, whereas the faujasites show more selectivity towards the formation of isoprene. Furthermore, as the ionic radius of the alkali metal cation increases, the rate of the deep oxidation of 2-methylbut-2-ene also increases, and the selectivity towards isoprene decreases, possibly as a result of the obstacles to the diffusion of the hydrocarbons in the zeolite Y pores resulting from the presence of large cations.

Thus, our survey of published data on the oxidation of various compounds on zeolites from the standpoint of the influence of the structure and state of the crystalline aluminosilicates on the course of the reaction has revealed some interesting features. The similarity in size between the zeolite pores and the oxidisable molecules gives rise to large changes in the selectivity of the reaction for a particular product from quite small changes in the ratio of these two sizes. The possibility of controlling the course of the transformation of a given hydrocarbon towards the formation of different products by varying the structure and the composition of the zeolite is very attractive. This combination of flexibility and selectivity suggests many potential applications of zeolite reactions in the oxidative transformation of hydrocarbons.

Some Problems in the Theory of Solid Electrolytes

Yu.Ya.Gurevich, A.K.Ivanov-Shits, and Yu.I.Kharkats

Modern theoretical views on solid electrolytes (i.e. solids whose ionic conductivity is anomalously high) are reviewed, and various mechanisms for the creation of disorder in one of the ionic sublattices are analysed, together with schemes for the phase transitions to the superionic state and with the dependence of the characteristics of these transitions on the parameters of the crystal and on the charge transfer phenomena in the solid electrolyte. Problems in the microscopic description of ionic transport in solid electrolytes are examined, and the theoretical foundations of the experimental methods used to study the properties of solid electrolytes are discussed.

I. INTRODUCTION

In recent years solid electrolytes have increasingly claimed the attention of researchers (physicists, chemists, materials scientists) as well as of technologists, engineers, and system designers[1-11]. One of the most important features of solid electrolytes (their anomalously high ionic conduction) can be exploited at temperatures well below the melting point of the material. For example, whereas the ionic conductivity of "normal" solids at room temperature is not greater than 10^{-7}–10^{-8} Ohm^{-1} m^{-1}, that of "good" solid electrolytes is approximately 10 Ohm^{-1} m^{-1} at the same temperature, i.e. it is similar to the conductivity of melts and of concentrated (liquid) solutions of electrolytes. Thus materials of this type can be said to have "hybrid" properties, combining the conductivity of a melt or of a liquid solution with the mechanical strength and elasticity of a solid.

Solid electrolytes (also called "superionic conductors") can be arbitrarily classified into various types, depending on the magnitude of their ionic conductivity and on their structural features.

The first type includes crystals in which one of the sublattices (cation or anion) is structurally disordered. Many (several tens) of these compounds have already been discovered and studied, and their number is increasing[4,7,11]. The most typical example of this type of solid electrolyte is the compound $RbAg_4I_5$, with a room-temperature conductivity (due to the disordered Ag^+ cations) of ~25 Ohm^{-1} m^{-1}. This is 16 orders of magnitude higher than the ionic conductivity of common salt at the same temperature.

Another type of solid electrolyte includes substances which owe their high ionic conductivity to a high concentration of impurity ions able to activate the structural disorder. For example, if CaO is added to the ZrO_2 lattice the Ca^{2+} ions distribute themselves over the Zr^{4+} sublattice, and the O^{2-} ions complete the oxygen sublattice. However, because of the difference in charge between Ca^{2+} and Zr^{4+}, oxygen vacancies must appear in the mixed crystal, leading to disorder in the oxygen sublattice. These compounds are impurity solid electrolytes, or solid electrolytes with impurity-induced disorder. Examples are provided by the MO_2–M'O series of compounds (where M = Zr, Hf, Ce, and M' = Ca, Sr, Ba), whose ionic conductivity (due to oxygen ions) is ~1–10 Ohm^{-1} m^{-1} at 1000–1500°.

Lastly, amorphous glassy solids with a measurable ionic conductivity due to the presence of electrically active impurities[12,13], and ion-exchange resins, are also occasionally classified among solid electrolytes.

Most of the solid electrolytes with structural disorder show, at some characteristic critical temperature, a discontinuous change in ionic conductivity by a large factor (even by several orders of magnitude). Above this critical temperature the crystal is in a state of high ionic conductivity, and behaves as a solid electrolyte. In other words, we have a rational method of identifying superionic crystals among all the known crystalline compounds. Below their critical temperature (i.e. in their dielectric phase) these materials behave as "normal" crystals, and above their critical temperature they are converted into a qualitatively different state: the superionic (electrolyte) phase.

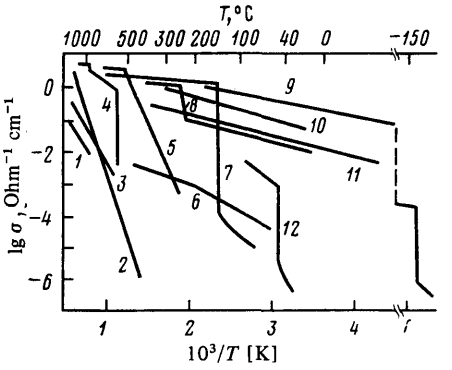

Figure 1. Temperature dependence of the conductivity of some solid electrolytes[5]: *1*) ThO_2–Y_2O_3, *2*) CaF_2, *3*) ZrO_2–CaO, *4*) Li_2SO_4, *5*) PbF_2, *6*) CeF_3, *7*) AgI, *8*) Ag_3SI, *9*) $RbAg_4I_5$, *10*) $Ag_6I_4WO_4$, *11*) Na–β-Al_2O_3, *12*) Ag_2HgI_4.

Unlike the superionic crystals, solid electrolytes with disorder due to impurities do not usually show a discontinuity in the temperature dependence of ionic conduction, though anomalies in this dependence may arise from phase transformations resulting in impurity redistribution.

The structure and the ionic conductivity of solid electrolytes of both these types are fully discussed in Refs.1–11. Therefore we shall not dwell on this set of problems, except to mention that the temperatures at which

solid electrolytes of the first class become good ionic conductors are usually much lower than those for the second class, and often even lie below room temperature. High ionic conductivity (≥ 1 Ohm^{-1} m^{-1}) is observed in a temperature range of over 1500 K, which includes all the known solid electrolytes: some examples are shown in Fig.1.

The electronic conductivity of solid electrolytes is usually much lower (by several orders) than their ionic conductivity, though it plays an important role in some materials. The theory of electronic conduction is dealt with in Refs.14–16, and will not be discussed here.

The problems in the behaviour of solid electrolytes lie at the "junction" of solid-state physics, crystallography, solid-state chemistry, and electrochemistry. By exploiting the wide range of experimental approaches offered by all these disciplines a very comprehensive fund of information (both specific, and generalised) has been generated. The aim of this review is to present some new theoretical concepts in the science of solid electrolytes and to discuss the theoretical foundations of the physicochemical methods used in their investigation.

II. THERMODYNAMICS OF SOLID ELECTROLYTES

The distinguishing feature of all solid electrolytes, which is ultimately responsible for their anomalously high ionic conductivity, is the presence of disorder (full, or partial) in one of the crystal sublattices. In the superionic crystals, for example, this disorder consists in the random distribution of the ions of one kind over the interstitial positions, whose number in these compounds is usually greater than the number of disordered ions. Because the relevant activation energy is very small, the interstitial ions have a very high mobility. In other words, the dynamic effect (anomalously high ionic conductivity) is unambiguously related to a thermodynamic effect (lattice disorder). The system can be described in terms of the somewhat arbitrary concept of an "ionic liquid" pervading a rigid crystalline skeleton consisting of ordered ions, analogous to the concept of an electronic liquid in metals+.

The most important problem in the thermodynamics of solid electrolytes is to explain and to describe quantitatively the sudden disordered ("melting") of one of the crystal sublattices. The formation of disorder is accompanied not only by a discontinuous increase in ionic conductivity but also by other anomalous effects in the temperature dependence of various thermodynamic and kinetic parameters[17,22].

The discontinuity in the number of highly mobile ions in interstitial positions is a phase transformation of the first kind. This transition may be produced in a number of ways, depending on the properties of the sublattice which remains rigid. In particular, the rigid sublattice may be quite unaffected by the disorder transition, or it may undergo secondary structural changes. In this case collective interactions in the system of crystal defects can be expected to play a major role. The theory of the disordering of one sublattice through collective interactions while the other sublattice remains unchanged has been developed by many workers[23–32]. However, there are crystals in which the disordering of one sublattice is accompanied by a rearrangement (polymorphic change) in the other sublattice which may have an important effect. The case of negligible interaction in the defect system, such that the disorder is induced exclusively by the lattice rearrangement, is analysed in Ref.33 (see also Ref.34); several special features of phase transitions involving disorder with comparable thermodynamic contributions from both factors are discussed in Ref.35.

One special feature of the thermodynamic behaviour of solid electrolytes is the possibility of forming domain structures. Some of the problems associated with domain formation are discussed in Refs.36–39.

1. Structural Disorder Induced by Lattice Rearrangement

Structural disorder in the absence of collective interactions in the defect system, and due entirely to a polymorphic transition, is the simplest to describe mathematically[33].

The traditional treatment of polymorphic changes in crystals relates these transitions to changes in the vibrational (phonon) spectrum of the solid[40,41]. Thus, it is assumed that the contribution of the phonon subsystem to the free energy increases with the temperature of the crystal, so that at some temperature $T_{tr}^{(p)}$ the transition of the crystal into a higher-energy modification (with "dumping" of the lattice vibration energy) becomes thermodynamically favourable.

However, if the polymorphic transition is accompanied by a substantial amount of disordering of one of the sublattices it is reasonable to assume that the thermodynamics of the process will be determined predominantly by the disordering process, with a much smaller contribution from the changes in phonon spectrum. In other words, polymorphic transitions in one sublattice may be induced by disorder in the other sublattice.

We shall use as our starting point some standard thermodynamic expressions from the theory of ionic crystals[2,3,42]. The free energy F of the crystal can be written as the sum

$$F = F^{(0)} + F^{(d)}, \qquad (1)$$

where $F^{(0)}$ is the free energy of the ideal (defect-free) crystal, and $F^{(d)}$ is the free energy resulting from the presence of disorder. The quantity $F^{(d)}$ can be expressed as

$$F^{(d)} = wn - T \ln \left\{ \frac{N_2!}{(N_2 - n)!\, n!} \frac{N_1!}{(N_1 - n)!\, n!} \right\} - nT \ln \chi, \qquad (2)$$

where N_1 and N_2 are the numbers of interstitial sites and of lattice sites per unit volume respectively, n is the number of ions per unit volume transferred from lattice sites to interstitials (and thus giving rise to Frenkel' defects in the crystal), w is the energy of formation of one defect#, T is the absolute temperature (expressed in energy units), and χ is a quantity related to the entropy of formation of one defect. In the simplest model $\chi = (\omega_2/\omega_1)^3$, where ω_1 and ω_2 are the vibration frequencies of the disordered ions in the interstitial sites and in the lattice sites respectively. The concentration n corresponding to thermodynamic equilibrium is defined by the condition of minimum disorder free energy: $\partial F/\partial n = 0$ [since $F^{(0)}$ is not a function of n]. Differentiating Eqn.(2), and using the expression

$$\frac{d}{dz} \ln z! = \ln z, (z \gg 1),$$

+For example, in $RbAg_4I_5$ the ionic liquid is formed by the disordered Ag^+ ions, and the rigid sublattice by the Rb^+ and I^- ions; in solid electrolytes with impurity disordering the "liquid" can consist, in principle, of vacancies.

#We can allow for effects associated with changes in volume of the crystal by replacing w by h (the enthalpy of formation of one defect).

we obtain the following expression for n:

$$n^2/(N_2-n)(N_1-n) = \chi \exp(-w/T) . \quad (3)$$

Assuming N_1 to be substantially higher than N_2 (as in the great majority of solid electrolytes) we can simplify Eqn.(3) to

$$x^2/(1-x) = \nu \exp(-w/T) , \quad (4)$$

where $\nu = \chi N_1/N_2$, and $x = n/N_2$ is a dimensionless concentration ($0 < x < 1$) used as a quantitative description of the degree of disorder. Using Eqn.(4) we can rewrite Eqn.(2) for $F^{(d)}$ as

$$F^{(d)} = N_2 T[\ln(1-x) - x] . \quad (5)$$

It follows from (3) and (4) that the function $x(T)$ increases monotonically with T from $x = 0$ at $T = 0$ to the value $x = x_\infty$ formally corresponding to the limit at $T = \infty$ and given [according to Eqn.(4)] by the expression

$$x_\infty = -\nu/2 + (\nu^2/4 + \nu)^{1/2} .$$

Hence, and using Eqn.(5), we find that $F^{(d)}$ decreases monotonically as T increases, with $F^{(d)} = 0$ at $T = 0$ and $F^{(d)}$ varying linearly with T for $T \gg w$.

Let us now consider two crystalline modifications (α and β), having free energies $F_\alpha(T)$ and $F_\beta(T)$. The modification having the lower free energy is present when the system is in thermodynamic equilibrium. As the temperature changes, the functions $F_\alpha(T)$ and $F_\beta(T)$ change at different rates, and the cross-over temperature (when $F_\alpha = F_\beta$) corresponds to the phase transition between the α and β modifications. This transition causes a rearrangement of the crystal lattice (polymorphic change) accompanied by a sudden change in the degree of disorder.

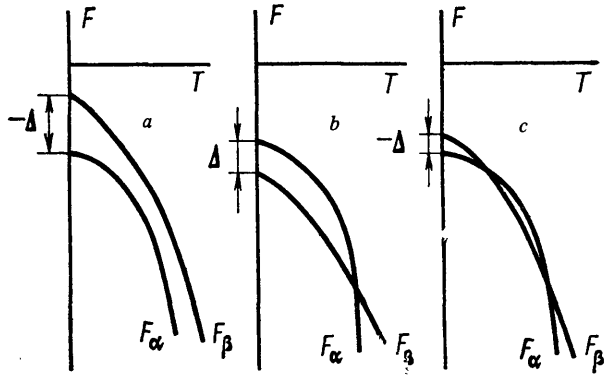

Figure 2. Idealised temperature dependences of the free energy F for α and β modifications: (*a*) no transitions, (*b*) single transition, (*c*) double transition.

The condition $F_\alpha = F_\beta$ can be written, using Eqn.(1),

$$F_\beta^{(d)} - F_\alpha^{(d)} = N_2\Delta , \quad (6)$$

where, by definition, $N_2\Delta = F_\alpha^{(0)} - F_\beta^{(0)}$, and the quantity Δ in our case is approximately independent of T and is determined by the difference in internal energy between the α and β crystalline modifications. The different mutual dispositions of the $F_\alpha(T)$ and $F_\beta(T)$ curves which are possible according to Eqns.(5) and (6) are shown in Fig.2. Case *a* corresponds to the absence of phase transitions, the crystal remaining in the α modification at all temperatures. In case *b* the low-temperature α modification is converted into the high-temperature β modification at the intersection point. Case *c* corresponds to two polymorphic transitions in succession ($\alpha \to \beta \to \alpha$, or bitransition).

From Eqns.(4)–(7) we can obtain a system of three equations defining the polymorphic phase transition temperatures $T_{tr}^{(p)}$ and the concentrations x_α and x_β of the interstitial ions before and after the transition:

$$T_{tr}^{(p)}\{\ln[(1-x_\beta)/(1-x_\alpha)] - (x_\beta - x_\alpha)\} = \Delta \quad (7)$$

$$x_\alpha^s/(1-x_\alpha) = \nu_\alpha \exp(-w_\alpha/T_{tr}^{(p)})$$

$$x_\beta^s/(1-x_\beta) = \nu_\beta \exp(-w_\beta/T_{tr}^{(p)}) , \quad (8)$$

Using Eqns.(5) and (6), the heat of the phase transition for a single particle is given by the expression

$$Q_p = \Delta + w_\alpha x_\alpha(T_{tr}^{(p)}) - w_\beta x_\beta(T_{tr}^{(p)}) , \quad (9)$$

and the specific heat of the disordering process ΔC for the α and the β modifications is

$$(\Delta C)_{\alpha,\beta} = w_{\alpha,\beta}x_{\alpha,\beta}(1-x_{\alpha,\beta})/T^2(2-x_{\alpha,\beta}) . \quad (10)$$

A detailed analysis of the conditions leading to single and to double transitions (bitransitions) is given in Ref.33, together with expressions for the corresponding transition temperatures.

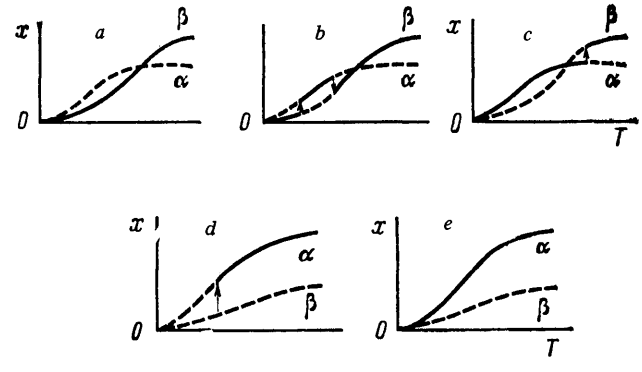

Figure 3. Possible temperature dependences of the degree of disorder $x_{\alpha,\beta}$, and schematic representation of the phase transitions for different relative values of the parameters Δ, $w_\alpha < w_\beta$, ν_α, and ν_β;[33] the full lines show the realisable situations, the arrows show transitions between these situations.

These expressions for the degree of disorder x as a function of temperature with allowance for polymorphic ($\alpha \rightleftharpoons \beta$) transitions are not trivial: different types of relationship are shown in Fig.3. We should stress that the relative amounts of disorder, and therefore also other characteristics of the solid electrolytes, can change by large amounts.

2. Structural Disorder Induced by Defect Interactions

We shall now consider how collective interaction between defects can be incorporated into a general thermodynamic scheme for describing the behaviour of the crystal.

Interstitial ions and the empty sites which they leave behind (vacancies) can interact both among themselves and with members of the other group (cross-over interaction), the total number of interacting pairs being proportional to n^2 in the case of $n \gg 1$. As a result, if in the absence of interactions the internal energy E of the system of n defects is $E = wn$, allowing for the collective interactions gives

$$E = wn - \frac{\lambda}{2}\frac{n^2}{N_a} ,$$

where λ is a phenomenological constant whose sign and value are determined by the nature of the inter-particle (including indirect) interactions in the ensemble of interstitial ions and vacancies. The case of $\lambda > 0$ corresponds to effective attraction, $\lambda < 0$ to repulsion.

An analysis of the specific interactions which contribute to λ is beyond the scope of this review. We shall only stress that contribution to effective attraction is possible not only from self-consistent Coulombic interactions[43] but also from the elastic deformations accompanying the formation of defects in the crystal[44], and from the changes in vibrational spectrum of the crystal predicted by second-order perturbation theory[45].

Replacing wn in Eqn.(2) by the corrected expression for E, and using the condition $\partial F^{(d)}/\partial n = 0$, we obtain instead of Eqn.(4) the equation of state[27-29]

$$x^2/(1-x) = \nu \exp[-(w-\lambda x)/T] \quad . \qquad (11)$$

The average field approximation used in the derivation of (11) is equivalent to the standard Bragg–Williams approximation in the theory of alloys[46] or to the Curie–Weiss approximation in the theory of magnetism[47]. Effectively the same approximation is used to describe regular solutions, adsorption with inter-particle interactions[48,49], the properties of liquid crystals[50], etc.

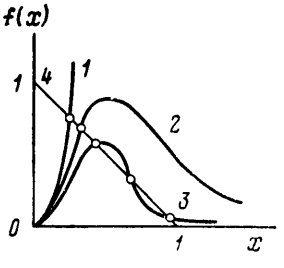

Figure 4. Graphical solution of Eqn.(11) ($f(x) = x^2\nu^{-1} \exp[(w - \lambda x)/T]$): *1*) for $\lambda = 0$, *2*) $0 < \lambda < w$, *3*) $\lambda > w$, *4*) is the $(1 - x)$ straight line.

Let us now consider, as in Refs.27 and 28, the thermodynamic behaviour of the system. If $\lambda = 0$ Eqn.(11) reduces to (4), and under these conditions (as well as for $\lambda < 0$) Eqn.(11) has only one solution (Fig.4). However, as Fig.4 shows, for large positive values of λ Eqn.(11) has three solutions $\{x_1 \leq x_2 \leq x_3\}$ in the range $0 \leq x \leq 1$. If the equation of state has only one solution, the free energy at a fixed value of T will have one minimum at the value of x corresponding to this root (Fig.5). In the case of three roots the function $F(x)$ has two minima (at the points x_1 and x_3) and one maximum (at the point x_2). The crystal is found in the state (x_1 or x_3) corresponding to the lower of the two minima in $F(x)$; the state x_2 corresponds to a local maximum in $F(x)$ and therefore is unstable.

Changes in T alter the shape of the $F(x)$ curve, and at a particular temperature $F[x_1(T)]$ becomes equal to $F[x_3(T)]$. This indicates a phase transition of the first kind which makes the parameter x (the degree of disorder) change discontinuously from x_1 to x_3 (or from x_3 to x_1). These phase transitions can arbitrarily be classified into weak or strong[27]. Weak transitions are those in which the jump in the value of x is small ($x_3 - x_1 \ll 1$); the strong transitions correspond to $x_1 \ll 1$ and $x_3 = 1 - \varepsilon$, with $\varepsilon \ll 1$. From the condition $F[x_1(T)] = F[x_3(T)]$, and using the equation of state (11), we obtain the following expression for the transition temperature in the two cases:

$$T_{tr}^{(w)} = (w - \lambda x_*)/\ln(\nu/\nu_*); \; T_{tr}^{(s)} = (w - \lambda/2)/(1 + \ln\nu) \qquad (12)$$

where $x_* = 2 - \sqrt{2}$, $\nu_* \equiv x_*^2/(1 - x_*)$, and therefore numerically $\nu_* = 2(\sqrt{2} - 1)$.

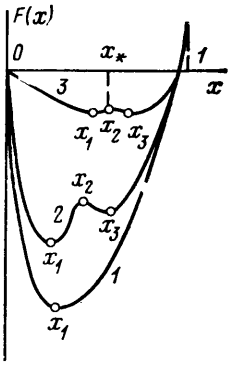

Figure 5. Idealised plots of F against x for different x and T: *1*) the equation of state has one solution, *2*) and *3*) the equation of state has three solutions $\{x_1, x_2, x_3\}$.

A full analysis of the variation of x with temperature for different values of the parameters of the system is given in Refs.28 and 29. Let us examine the main conclusions (Fig.6).

Firstly, gradual and continuous disordering of the initial sublattice with increase of T is possible, as in ordinary ionic crystals (Fig.6*a*), or a relatively slight discontinuity may occur, accompanied by a small jump in x (weak transition, Fig.6*b*).

Secondly, we can have a large jump from a state with a small x to a state with $x \cong 1$ (Fig.6*c*). As the temperature is increased still further the crystal remains in this state, or x may even decrease (compare Figs.6*a* and 6*c*). Physically, a decrease of x with increase of T implies that the state $x_3 > x_\infty$ is created and maintained if sufficiently strong interactions are present ($\lambda > 0$). As the temperature increases, the interaction is effectively "diluted", and at $\lambda/T \to 0$ the "defect gas" becomes ideal. Accordingly, in the state shown in Fig.6*c* the concentration of defects decreases as T increases, approaching (from above) the value $x = x_\infty$.

Thirdly, the system can show two successive transitions (Figs.6*d* and 6*e*). In the former case the second transition does not bring the crystal out of the superionic state,

whereas in the latter case we observe two genetically related phase transitions (bitransitions).

Lastly, the parameters of the system can be such ($\lambda > 2w$) that even at $T = 0$ the crystal is in the state with $x \cong 1$ (Figs. 6*f*, 6*g*, and 6*h*). In this case x decreases as T increases. We note that in the special case of $N_1 = N_2$ (see Ref. 23) double transitions cannot occur, and the temperature of the single transition in such a symmetrical system is given, irrespective of the magnitude of the jump in x, by the expression

$$T_{tr}^{sym} = (w - \lambda/2)/\ln \nu \ .$$

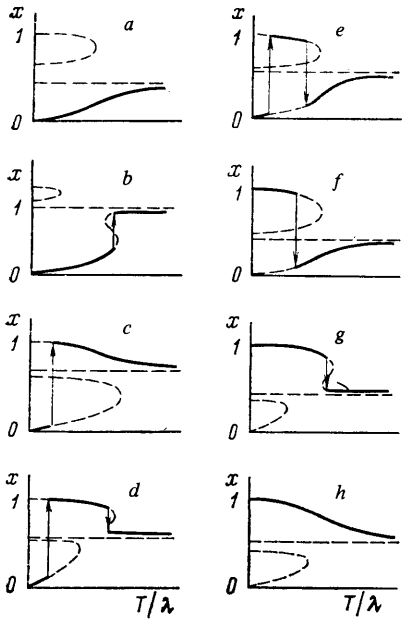

Figure 6. Idealised plots of the possible solutions of the equation of state and of the transitions between solutions: the full lines are realisable situations, the arrows are transitions between these situations.

The case of a collective interaction energy varying arbitrarily but monotonically with the defect concentration is discussed in Refs. 51 and 52, and more complex energy structures of the lattice points and of the interstitial sites are discussed in Refs. 31 and 53. In particular, in the presence of a small concentration of impurities ($c_{imp} = N_{imp}/N_2 \ll 1$) giving rise to interstitials with a different energy structure, the temperature of the strong transition is given[53] by the expression

$$T_{tr}^{(s,imp)} = T_{tr}^{(s)}[1 + c_{imp}/(\ln \nu + 1)] \ , \qquad (13)$$

where $T_{tr}^{(s)}$ is defined by Eqn. (12).

The dependence of the transition temperature T_{tr} on the pressure P is described by the Clausius–Clapeyron equation: $dT_{tr}/dP = (V - V')/(S - S')$, where V, V', S, and S' are the specific volumes and entropies of the states between which the transition is taking place. If the transition is strong the change in specific volume is $\nu_0 N_2$, where ν_0 is the "free volume" of formation of one defect. Assuming that the contribution of the polymorphic change to the thermodynamics of the transition is relatively minor, and using the expressions given above for $E(n)$ and $T_{tr}^{(s)}$, we obtain[54]

$$\frac{dT_{tr}^{(s)}}{dP} = \frac{N_2|v_0|T_{tr}^{(s)}}{w - \lambda/2} = \frac{N_2|v_0|}{1 + \ln \nu} \ . \qquad (14)$$

If the vibration frequencies ω_1 and ω_2 of the ions in interstitial positions and in lattice sites [which determine the parameter ν, see Eqns. (2) and (4)] have similar pressure dependences, the denominator of Eqn. (14) is independent of P, and the function $T_{tr}^{(s)}(P)$ can be treated as the sum of a linear and a quadratic term in P, since ν_0 varies linearly with P.

A model similar to the above has been used in Refs. 55 and 32 in a detailed analysis of weak transitions for particular values of the parameter N_1/N_2.

Attempts to apply scale invariance (scaling) concepts[56,57] to phase transitions in solid electrolytes are described in Refs. 58 and 59.

Spatially inhomogeneous regions (domains) in single crystals of solid electrolytes with structural disorder have been observed experimentally[36–39], and the theoretical possibility of thermodynamically stable inhomogeneities in solid electrolytes has been examined in detail[39,60].

3. Comparison of the Thermodynamic Theory of Disorder with Experiment

Theoretical models can be used to calculate the transition temperatures and the specific heats ΔC of the disorder, and these can be compared with experimental values. However, in order to find the excess specific heat associated with intrinsic disorder we must subtract from the measured value the specific heat of the defect-free crystal: this is usually done by choosing a particular model to describe the vibrational spectrum[61].

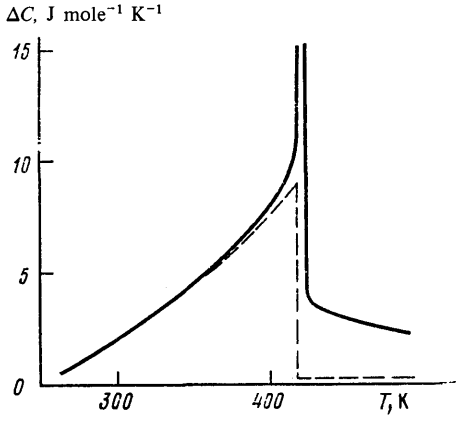

Figure 7. Experimental (full line) and theoretical (broken line) specific heat curves for the disorder in Ag_2S.[30]

The first attempt at interpreting experimental data[61] on the specific heat of superionic $RbAg_4I_5$ near the phase transition at $T_{tr}^{(s)} = 122$ K by the theoretical formulae which allow for defect interactions (see previous Section) is

described in Ref. 27. The same approach was later applied[30] to superionic crystals of AgI, $RbAg_4I_5$, Ag_2S, and others. As an example, the theoretical and the experimental ΔC curve for Ag_2S are compared in Fig. 7. The agreement is satisfactory for the low-temperature regions of the $\Delta C(T)$ curves, but above the transition temperature we note a substantial discrepancy, due no doubt to the polymorphic transition which takes place at the same time as the disorder transformation and for which no allowance is made in the calculation[62]. By comparing data on the excess specific heat of $RbAg_4I_5$ with calculations by a combined disorder and polymorphic transformation model a satisfactory description of the $\Delta C(T)$ curve has been obtained for $T > T_{tr}$ as well as for $T < T_{tr}$.

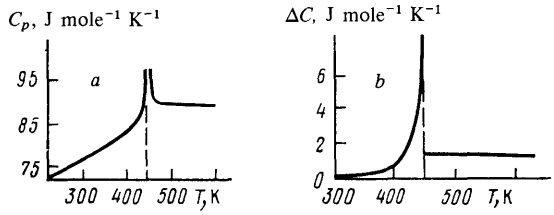

Figure 8. (*a*) Experimental plot of the full specific heat C_p, and (*b*) calculated plot of the specific heat of disordering ΔC in AgI.[34]

In Fig. 8 (taken from Ref. 34) we show some results on the excess specific heat of AgI, and in Fig. 9 we show a similar plot for Ag_2Se. The results were interpreted by the polymorphic transition model, using formula (10); the agreement between theory and experiment (for reasonable values of the adjustable parameters) is gratifying.

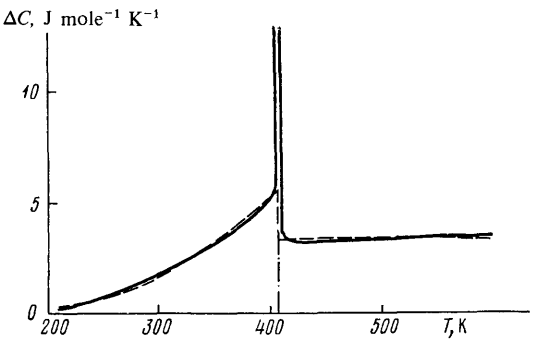

Figure 9. Experimental (full line) and theoretical (broken line) curves for the specific heat of disordering in Ag_2Se.[63]

Anomalies in the temperature dependence $\sigma(T)$ of the ionic conductivity of $RbAg_4I_5$ near the phase transition at $T = 209$ K (a "weak" transition) have been reported[64]. Measurements of the conductivity jump led to values of the thermodynamic parameters ($w = 5.6 \times 10^{-2}$ eV and $\lambda = 9.6 \times 10^{-2}$ eV) close to those previously calculated from specific heat data for the same compound but in a different temperature region ($w = 6 \times 10^{-2}$ eV and $\lambda = 10^{-1}$ eV).

Data[65] on the ionic conductivity of high-temperature solid electrolytes with the fluorite structure (CaF_2, SrF_2, $SrCl_2$) were compared[25,32] with theoretical models of disorder, and satisfactory agreement was obtained.

The dependence of the ionic conductivity of Na_2WO_4 crystals on temperature suggests[66] the existence of two (very close) phase transitions of the first kind accompanied by an increase and by a decrease in ionic conductivity respectively. This behaviour is consistent with the theoretically predicted bitransitions (see Fig. 6*e*). Further experimental evidence of the possible existence of bitransitions was obtained in a study[67] of the temperature dependence of Raman scattering in the solid electrolyte $Ag_{26}I_{18}W_4O_{16}$.

Calculations of the effect of impurities on the thermodynamics of disorder yield a qualitative explanation of changes in transition temperature along a series of isomorphous compounds (in particular, $RbAg_4I_5$, $K_{3/4}Rb_{1/4}$. $.Ag_4I_5$, and KAg_4I_5). Treating the K^+ ions as an impurity, we can calculate the transition temperatures by formula (13): the agreement between theory and experiment (see below) is satisfactory:

Compound	$RbAg_4I_5$	$K_{3/4}Rb_{1/4}Ag_4I_5$	KAg_4I_5
T_{tr}, K (exper)	122	134	137
T_{tr}, K (calc)	122	135.5	140

Experiments on the effect of pressure P on the phase transition temperature T_{tr} in solid electrolytes are reported in Ref. 68. For the compound AgI the function $T_{tr}(P)$ is accurately described by a straight-line dependence corresponding to a decrease in volume of the crystal by ~5.6% during the transition from the low-temperature to the high-temperature phase. In the case of the solid electrolyte $RbAg_4I_5$ we must retain the quadratic terms in P to describe the $T_{tr}(P)$ relationship. We note that the parameters needed to apply formula (14) are not yet known with sufficient precision.

III. BEHAVIOUR OF SOLID ELECTROLYTES IN AN EXTERNAL FIELD. TRANSPORT PHENOMENA

Transport phenomena can be treated by different approaches: one of them (the macroscopic approach) relies on the phenomenological equations of the thermodynamics of irreversible processes, the other (microscopic) relies on concrete microscopic models of the process of interest. The first approach requires very little detail, the properties of the system being described by the phenomenological parameters inserted into the theory. In the present state of development of kinetic models of homogeneous and heterogeneous charge transfer processes in solid electrolytes the phenomenological description offers the best (and sometimes the only) approach.

The electro-diffusion equations applied to transport phenomena in liquid electrolytes and in ionic crystals are based essentially on this phenomenological approach. The same equations (in most cases, unmodified) have been used also to describe the transport of current carriers in solid electrolytes[2-5]. However, solid electrolytes have a number of specific features which are ignored in the standard description, though they may play an important role. The present review is aimed specifically at those features.

The second approach, which should relate the phenomenologically chosen coefficients to the microstructural details and to the dynamic characteristics of the microscopic processes, is still in the formulation stage.

Some aspects of the study of micro-processes and some of the results obtained will be discussed in the following Section.

For relatively small deviations from equilibrium the transport properties of a system are closely related to its thermodynamic properties. Hence, in the phenomenological approach the flows of components (charge carriers) are proportional to the gradients of their electrochemical potentials, which can be obtained from the expression for the free energy F of the system.

For a solid electrolyte with structural disorder and exposed to an external electric field we can write, using the concepts discussed in previous Sections,

$$F(n_1, n_2) = E_1 n_1 + E_2(N_2 - n_2) + e\varphi(n_1 - n_2) - \\ - T \ln \left\{ \frac{N_1!}{(N_1 - n_1)!\, n_1!} \frac{N_2!}{(N_2 - n_2)!\, n_2!} \right\} , \quad (15)$$

where n_1 and n_2 are the concentrations of interstitial ions and of vacancies, E_1 and E_2 are the energies needed to force the ion into an interstitial and to remove it from a lattice site ($E_2 - E_1 = w$), and ϕ is the potential due to the electric field in the crystal. The quantities n_1, n_2, and ϕ usually depend on the spatial coordinates. In Eqn.(15) the terms which allow for changes in the vibrational frequencies due to disorder (vibrational terms) have been omitted to simplify the treatment, and collective interactions have been assumed to have a negligible effect ($\lambda = 0$). The expressions for the electrochemical potentials $\mu_{1,2} = \partial F/\partial n_{1,2}$ of the interstitial ions and of the vacancies are

$$\mu_1 = E_1 + e\varphi + T \ln[n_1/(N_1 - n_1)] \\ \mu_2 = -E_2 - e\varphi + T \ln[n_2/(N_2 - n_2)] . \quad (16)$$

Eqns.(16) can be used to describe both the equilibrium properties of a solid electrolyte in an electric field and the transport phenomena.

1. Equilibrium States in an Electric Field

The concentration distributions of interstitial ions and of vacancies n_1 and n_2 corresponding to thermodynamic equilibrium can be calculated from the conditions of constant chemical potentials and of "chemical equilibrium" ($\mu_1 + \mu_2 = 0$). From (16) we have

$$n_1 = n_0/[\gamma_1 + (1 - \gamma_1)\exp\psi]; \quad n_2 = n_0/[\gamma_2 + (1 - \gamma_2)\exp(-\psi)] . \quad (17)$$

In these expressions $\psi \equiv e\phi/T$, and $\gamma_{1,2} \equiv n_0/N_{1,2}$, where n_0 is the equilibrium concentration of defects in the absence of the electric field, given§ by Eqn.(3). In the limit of $\gamma_1 = \gamma_2 = 0$ Eqn.(17) reduces to the standard Boltzmann distribution: $n_{1,2} = n_0 \exp(\pm\psi)$. However, in the general case the concentrations $n_{1,2}$ are described by distributions of the Fermi type, and at the limit of $\psi \to \pm\infty$ the concentrations n_1 and n_2 reach their maximum allowed values N_1 and N_2. This result demonstrates the lattice saturation effect[69]: the concentrations of interstitial ions and vacancies have an upper limit defined by the specific properties of the crystal. In the simplest case the lattice saturation effect is due to purely structural limitations (the fact that the number of positions available to the ions in the crystal lattice is finite). In the more general case the effect reflects also the interparticle interactions, and the limiting value of $n_{1,2}$ is defined by the appropriate $n_{1,2}^{max}$ value (rather than by $N_{1,2}$), which is a characteristic parameter of the crystal.

§If the neglected terms associated with the entropy of formation of individual defects are retained in (15) and (16) the expressions (17) are unchanged, and the frequency factor χ occurs only in the equation for n_0.

It is interesting to consider the behaviour of $n_{1,2}$ and ϕ near the interface with allowance for the screening effect on the external field due to the redistribution of the charged particles. Within the self-consistent field approximation the potential distribution is given by an equation of the form

$$d^2\varphi/dz^2 = -\frac{4\pi}{\varepsilon_0} e[n_1(\varphi) - n_2(\varphi)] , \quad (18)$$

where z is the coordinate along the axis at right angles to the planar interface, ε_0 is the static dielectric constant of the crystal, and $e > 0$ is the electronic charge. Inserting into Eqn.(18) the Boltzmann distribution for $n_{1,2}$ we arrive at the standard self-consistent equation of the Gouy–Chapman and Debye–Hückel theories[70]. Integration of (18) after using (17) gives the electric field distribution $d\phi/dz$ and the integral charge Q_e of the surface (diffusion) layer. By differentiating the expression for Q_e with respect to potential we obtain the differential capacity C [70] of the diffusion layer:

$$-\frac{d\psi'}{dz} = \varkappa \operatorname{sgn}(\psi') \left[\frac{1}{\gamma_1} \ln \frac{n_0}{n_1} e^{-\psi'} + \frac{1}{\gamma_2} \ln \frac{n_0}{n_2} e^{\psi'} \right] \quad (19)$$

$$C = \frac{C_0}{2} \frac{\operatorname{sgn}\psi' \,[(n_1 - n_2)/n_0]}{\left[\gamma_1^{-1} \ln \frac{n_0}{n_1} e^{-\psi'} + \gamma_2^{-1} \ln \frac{n_0}{n_2} e^{\psi'} \right]^{1/2}} \quad (20)$$

where ψ' is the value of the potential ψ at the edge of the diffusion layer, $\kappa \equiv (8\pi e^2 n_0/\varepsilon_0 T)^{1/2}$, (where κ^{-1} is the Gouy or Debye length), $C_0 \equiv \varepsilon_0 \kappa/4\pi$, $\operatorname{sgn}(\psi') = 1$ for $\psi' > 0$ and $\operatorname{sgn}(\psi') = -1$ for $\psi' < 0$, and the $n_{1,2}$ values are given by Eqn.(17) with $\psi = \psi'$.

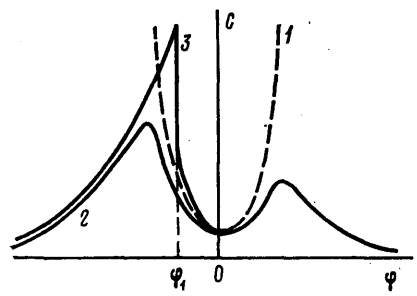

Figure 10. Plots of the diffusion layer capacitance against potential: *1*) $\gamma_1 = \gamma_2 = 0$, *2*) $1 > \gamma_2 > \gamma_1 > 0$, *3*) $\lambda_1 > 0$, $\lambda_2 = \lambda_{12} = 0$, $1 > \lambda_2 > \lambda_1 > 0$.

For $\gamma_1 \to 0$ and $\gamma_2 \to 0$ we obtain from Eqn.(20) $C = C_0 \cosh(\psi'/2)$, which corresponds to the capacity of the diffuse part of the double layer in liquid electrolytes (curve *1* of Fig.10). In the more general case the lattice saturation effect produces two asymmetric maxima in the $C(\psi)$ curve, and far from these maxima (for $|\psi| \to \infty$) we have $C = C_0/(\gamma_{1,2}|\psi|)^{1/2}$ [69] (see curve *2* of Fig.10). A formula similar to (20) is given in Ref.71 for the special case of $\gamma_1 = \gamma_2$. The unipolar model (in which charges of one sign only are redistributed in the field) corresponds to the limit $\gamma_2 = 1$ (or $\gamma_1 = 1$) in Eqns.(19) and (20). Expressions following from (19) and (20) in this model are given in Ref.72.

Thus, because of the lattice saturation effect the capacity of the diffuse part of the double layer in solid electrolytes is quite different from the analogous capacity in liquid

electrolyte systems. We should stress that the experimentally measured capacity is not determined only by the capacitance of the diffusion layer. The surface layer of the crystal may have properties different from those of the bulk (in particular, the energies of defect formation may be different). The influence of the surface layer on the distribution of space charge at the boundary between an ionic crystal and a vacuum is discussed in Refs.73 and 3.

To describe the boundary between a solid electrolyte and a metal we must also allow for the contribution from the fixed part of the double layer (the Helmholtz layer), as in the case of the boundary between a liquid electrolyte and a metal[70]. The effect of the Helmholtz layer, and detailed models of the two surface layers of ions in an ionic crystal, are fully described in Ref.3. We shall not dwell on the expressions obtained for the overall capacity: they are cumbersome, and they contain many parameters which have to be determined experimentally.

A novel effect, associated with the appearance of collective interactions in a crystal exposed to an electric field, is discussed in Ref.74. This effect consists in the stepwise, field-induced generation of disorder. It can be described mathematically as follows[74,75]. The chemical potentials $\mu_{1,2}$ corrected for collective interactions are given by the following expressions [instead of Eqn.(16)]:

$$\mu_1 = E_1 + e\varphi + T\ln n_1/(N_1 - n_1) - T\ln Z_1 - \lambda_1 n_1/N_2 - \lambda_{12} n_2/N_2$$
$$\mu_2 = -E_2 - e\varphi + T\ln n_2/(N_2 - n_2) + T\ln Z_2 - \lambda_2 n_2/N_2 - \lambda_{12} n_1/N_2 \quad (21)$$

In these expressions λ_1, λ_2, and λ_{12} describe respectively the interactions between interstitial ions, the interactions between vacancies, and the interactions between the two types of defect (with $\lambda = \lambda_1 + \lambda_2 + 2\lambda_{12}$); $Z_{1,2}$ are the vibrational partition functions of the ions in interstitials and in lattice sites (with $\chi = Z_1/Z_2$). As a result we obtain from (21) a system of two meshing equations for the dimensionless concentrations $x_{1,2} = n_{1,2}/N_2$ which is parametrically dependent on ϕ and on $x_0 = n_0/N_2$, where n_0 is the value of $n_1 = n_2$ in the absence of an electric field (depending on the difference $E_1 - E_2$ and on the ratio Z_1/Z_2).

The solution of this system over a given range of ϕ values is not unique, and this gives the possibility of phase transitions. The following physical explanation may be suggested. The field causes a redistribution of the charged particles, and the concentration of particles of one kind in the surface layer is increased. The collective interaction energy is itself a function of the concentrations of both kinds of particle. Since a high enough contribution from collective interactions can lead to phase transition, the field can also initiate phase transitions by varying the concentrations of interacting components. In particular, for one of the simplest cases ($\lambda_2 = \lambda_{12} = 0$, $\lambda_1 > 0$, $N_1 = N_2$) we obtain¶ from Eqn.(21)

$$\frac{x_1}{1-x_1} = \frac{x_0}{1-x_0}\exp\left[\frac{\lambda_1(x_1 - x_0) - e\varphi}{T}\right];$$
$$\frac{x_2}{1-x_2} = \frac{x_0}{1-x_0}\exp\left[\frac{e\varphi}{T}\right]. \quad (22)$$

Evidently, when $\lambda_1 > 4T$ the $x_1(\phi)$ curve has an S-shaped portion (see Fig.11), and therefore a change in ϕ must produce a discontinuous jump in x_1. The transition potential ϕ_1 and the discontinuity Δ_1 in the concentration x_1 at the transition are found to be[74]

$$e\varphi_1 = -T\ln(1-x_0)/x_0 + \lambda_1(1/2 - x_0) \quad (23)$$

$$(1+\Delta_1)/(1-\Delta_1) = \exp(\lambda_1\Delta_1/T). \quad (24)$$

¶The case of $\lambda_1 = \lambda_{12} = 0$, $\lambda_2 > 0$ can be treated in a similar way.

In other words, if the potential ϕ varies with the spatial coordinate we obtain a discontinuous change in the concentration x_1 by an amount Δ_1 at the coordinate for which $\phi = \phi_1$. Transitions of this type can give rise to an anomalous charge distribution in the surface layer. By using Eqn.(18) and the solution (22) it can be shown[74] that at high enough potentials an anomalous region of thickness z_* and properties different from those of the bulk material is formed near the surface (see Fig.12). Under these conditions the surface layer can be either enriched or depleted of interstitial ions, depending on the value of x_0, or of vacancies (in the case of $\lambda_1 = 0$, $\lambda_2 > 0$).

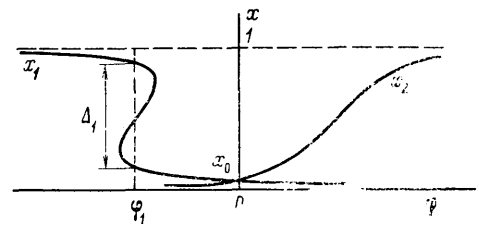

Figure 11. Plots of $x_1(\phi)$ and $x_2(\phi)$ for $\lambda_1 > 4T$ and $\lambda_2 = \lambda_{12} = 0$.

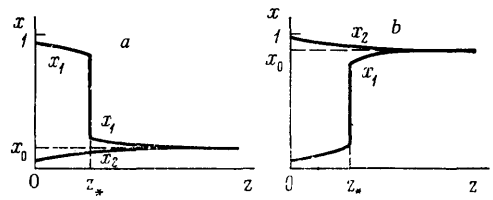

Figure 12. Distribution of x_1 and x_2 in the near-surface region for $\lambda_1 > 4T$ and $\lambda_2 = \lambda_{12} = 0$: (*a*) $x_0 \ll 1$, (*b*) $x_0 \cong 1$.

This effect (the production of a surface layer with anomalous properties whose thickness can be controlled by an applied potential) should be found in all physicochemical processes sensitive to charge distributions near phase boundaries. In particular, if the collective interactions play an important role, and the field can initiate a phase transition, the capacity of the diffusion layer changes suddenly when the transition potential ϕ_1 is reached (curve 3 of Fig.10). The effect can be observed also in studies of ionic surface conductivity, of optical properties of surfaces, and of the current–voltage characteristics of various interfaces (see below). We should stress that surface disorder induced by an electric field may occur also when thermal transitions are excluded by the values of the crystal parameters.

In addition to the surface disorder discussed in Ref.74, an external electric field applied to a crystal can induce disorder (and hence a jump in ionic conductivity) within the volume of the crystal. The theory of discontinuities in bulk ionic conductivity induced by an electric field was developed in Ref.76, and the first experimental data on this effect were reported in Ref.77.

2. Phenomenological Transport Equations

We shall now examine a solid electrolyte with structural disorder whose conductivity is caused by interstitial cations and cation vacancies. There is no difficulty in principle in generalising the discussion to more complex systems. According to the basic principles of irreversible thermodynamics the flows of components (i) can be expressed as[78,79]

$$i_{1,2} = \mp \frac{eD_{1,2}}{T} n_{1,2}(1 - n_{1,2}/n_{1,2}^{\max}) \nabla\mu_{1,2} \ , \qquad (25)$$

where the subscripts 1, 2 refer to interstitial cations and to vacancies, and $D_{1,2}$ are the diffusion coefficients, related to the mobilities $u_{1,2}$ by the Nernst–Einstein relationship $eD_{1,2}/T = u_{1,2}$. Using Eqn.(16) we obtain

$$i_{1,2} = \mp eD_{1,2}[\nabla n_{1,2} \mp eu_{1,2}n_{1,2}(1 - n_{1,2}/n_{1,2}^{\max}) \nabla\varphi] \ . \qquad (26)$$

In the region of $n_{1,2} \ll n_{1,2}^{\max}$ (where the lattice saturation effect is absent) the expressions (26) are indistinguishable from the standard expressions for the currents in systems with low carrier concentrations. Allowing for lattice saturation involves a modification to the transport equations[78,79].

In the absence of current the interstitial ions and the vacancies are in thermodynamic equilibrium†. The flow of current (in general) perturbs the equilibrium. Hence, terms describing the generation–recombination (i.e. the relaxation) processes of the carriers must be included in the transport equations. Thus, the full system of equations for calculating the distribution of the three quantities n_1, n_2, and the potential $\psi \equiv e\phi/T$ is

$$\frac{\partial n_1}{\partial t} = D_1 \frac{\partial}{\partial x}\left[\frac{dn_1}{dx} + n_1\left(\frac{n_1^{\max}}{n_1^{\max} - n_1}\right)^{-1}\frac{d\psi}{dx}\right] + q(n_1, n_2, \psi) \qquad (27)$$

$$\frac{\partial n_2}{\partial t} = D_2 \frac{\partial}{\partial x}\left[\frac{dn_2}{dx} - n_2\left(\frac{n_2^{\max}}{n_2^{\max} - n_2}\right)^{-1}\frac{d\psi}{dx}\right] + q(n_1, n_2, \psi) \qquad (28)$$

$$\frac{d^2\psi}{dx^2} = -\frac{4\pi e^2}{\varepsilon_0 T}(n_1 - n_2) \ . \qquad (29)$$

The relaxation processes in the system are described by the function $q(n_1, n_2, \psi)$. In particular, starting from the law of mass action, and allowing for the lattice saturation effect, we arrive at

$$q = -k_1 n_1 n_2 + k_2(n_1^{\max} - n_1)(n_2^{\max} - n_2) \ ,$$

where $k_{1,2}$ are the rate constants for the recombination and the generation of the carriers. Under steady-state conditions (i.e. $\partial n_{1,2}/\partial t = 0$) the continuity of the total current ($i = i_1 + i_2$) follows from Eqns.(27) and (28).

The above system of non-linear equations is very complex and can only be solved by approximate methods. One of these methods, used in the solution of electro-diffusion problems in liquid electrolytes, is the boundary layer method[80–83], which relies on the fact that the problem includes a small parameter.

The size of the cell L is usually many orders of magnitude greater than the Gouy (or Debye) screening length κ^{-1}, and therefore we can (as in the case of liquid electrolytes) separate the space charge region of thickness l (comparable to κ^{-1}) from the region of electrical neutrality of thickness L, the size ratio of the two regions being $l/L \ll 1$.

In the electrically neutral region $n_1 = n_2$, and the system of three equations (27)–(29) reduces to the two equations (27) and (28) for the two unknowns $n_1 = n_2$ and ψ. Conversely, in the space charge region we can ignore those equations, and confine our analysis to Eqn.(29), by assuming that in this region the n_1 and n_2 concentration distributions are not perturbed by the flow of current. A detailed discussion of this type of problem is given in Ref.81. The equality $n_1 = n_2$ also allows the expression for q to be linearised to $q = (n_0 - n_1)/\tau$, where n_0 is the equilibrium concentration defined by Eqn.(3), and

$$\tau^{-1} \equiv 2k_1 n_0 + k_2[(n_1^{\max} - n_0) + (n_2^{\max} - n_0)]$$

is the reciprocal relaxation time, independent of $n_{1,2}$. Introducing the relaxation length $l_\tau \equiv (D\tau)^{1/2}$, where D is the smaller of the two values D_1 and D_2, we find that different relative values of L, l_τ, and l give rise to different cases, in which the behaviour of the system is qualitatively different:

1) $l_\tau \leqslant l \ll 1$, the fast relaxation case#;
2) $l \ll L \ll l_\tau$, the slow relaxation case;
3) $l \ll l_\tau \ll L$, the intermediate case.

We must stress that, although the above discussion has been aimed specifically at transport and relaxation processes involving carriers of two kinds, the limitation was not implicit in the use of separate electro-neutrality and space charge regions, or in the calculation of generation–recombination effects. In more complex systems several relaxation processes may be taking place simultaneously, and their role has to be analysed specifically for each particular case. Such an analysis is essential in studies of alternating-current processes in solid electrolytes, for example. Theoretical studies of this type are still insufficiently developed[2–5].

From Eqns.(30) and (31) the limiting current $i_{\lim}$ can be calculated directly. In the case of liquid electrolytes $i_{\lim}$ is determined under stationary conditions with only one type of current carrier (n_1, say), so that $n_1(L) = n_2(L) = n_0$, and at the electrode $n_1(0) = 0$. For the same conditions in solid electrolytes (assuming $q = 0$) we obtain[78,82,83]

$$i_{\lim} = i_D[(\gamma_1 + \gamma_2)/\gamma_2 + (\gamma_1 - \gamma_2)\ln(1 - \gamma_2)/\gamma_2^2] \ , \qquad (30)$$

where $i_D \equiv eD_1 n_0/L$. In the limit of $\gamma_{1,2} \to 0$ Eqn.(30) reduces to $i_{\lim} = 2i_D$, the familiar expression for a binary liquid electrolyte[70]. In general we see from Eqn.(30) that $i_{\lim} > 2i_D$, i.e. the lattice saturation effect increases $i_{\lim}$.

We note that allowance for relaxation processes in the linear approximation does not alter the general form of Eqn.(30) for $i_{\lim}$, and only involves re-normalisation of the i_D value.

An effect closely associated with transport phenomena is the development of a potential difference $\Delta\phi$ under open circuit by the application of a temperature difference ΔT between the electrodes. The thermo-electric power θ is defined as the limit

$$\lim_{\Delta T \to 0} \frac{\Delta\varphi}{\Delta T} = \theta \ .$$

If carriers of one kind only are mobile the parameter θ can be expressed, from the basic principles of the thermodynamics of irreversible processes, by the equation

$$\nabla\tilde{\mu} = \theta\nabla T \ ,$$

†The equilibrium concentrations under these conditions are defined by the condition $\mu_1 + \mu_2 = 0$ [see Eqn.(17)].

#In this case l_τ may differ from $(D\tau)^{1/2}$.

where $\tilde{\mu}$ is the electrochemical potential of the mobile carriers. The quantity $\theta = \theta_{hom} + \theta_{het}$ is divided into a homogeneous component $\theta_{hom} = -Q/Te$, where Q is the heat of transport of the ion§, and a heterogeneous component θ_{het}, associated with the temperature dependence of the contact potential differences at the interfaces. If the current is carried by singly charged cations, and local equilibrium is established at the phase boundaries, we can assume that the component θ_{het} is independent of T [84] and write

$$\theta = -Q/Te + \text{const} \quad .$$

Experimental determination of Q from the slope of the linear (θ, T^{-1}) plot yields values close to the activation energy for conduction of the mobile ions. This conclusion is consistent with calculations by the microscopic approach[85-87] (see Section IV).

From measured values of θ we can calculate the thermodynamic characteristics w and λ of the crystal, discussed in Section II. These values are found to agree with those obtained from measurements of the excess specific heat of the disordering process[63].

3. Transport Through a Phase Boundary

Theoretical descriptions of electrode processes are dependent on a correct model of the mechanism by which the current carriers are discharged at the phase boundary. In general, the partial currents i_1 and i_2 at the electrode depend on the carrier concentrations n_1 and n_2 at the discharge plane, and also on the electrode potential ϕ_0 and on the structure of the region adjacent to the electrode. The exact form of the kinetic relationship $i_{1,2} = i_{1,2}(n_1, n_2, \phi_0)$ is largely determined by the chosen microscopic model. The mathematical expressions describing the electrode process can also be used as boundary conditions for the phenomenological transport equations.

A detailed theory of ionic discharge phenomena at a phase boundary, including a solid electrolyte, is not yet available. It is reasonable, therefore, to apply to our system the general model of the slow discharge theory[70], developed for the boundary between a liquid electrolyte and a metal. However, the equations of this theory need some modification. When corrected for the lattice saturation effect and for the contribution of both interstitial ions (cations) and vacancies to the electrode process, the slow-discharge equations for the currents i_1 and i_2 at the electrode–solid electrolyte interface become

$$i_1 = i_{10}\left[\frac{n_1^{max} - n_1}{n_1^{max} - n_1^e}\exp(\beta_1\eta) - \frac{n_1}{n_1^e}\exp(-\alpha_1\eta)\right] \qquad (31)$$

$$i_2 = i_{20}\left[\frac{n_2}{n_2^e}\exp(\beta_2\eta) - \frac{n_2^{max} - n_2}{n_2^{max} - n_2^e}\exp(-\alpha_2\eta)\right] \quad . \qquad (32)$$

In these expressions i_{10} and i_{20} are the exchange currents of interstitial cations and cation vacancies respectively, η is the overvoltage ($\eta \equiv (\psi^0 - \psi^0_e) - (\psi' - \psi'_e)$, where ψ^0 and ψ' are the potentials in T/e units of the electrode surface and of the discharge plane¶ of the ions, $n^e_{1,2}(\psi'_e)$ are the equilibrium values (at $\eta = 0$, or $i_1 = i_2 = 0$) of the surface concentrations $n_{1,2}(\psi')$ which appear in (31) and (32); $\alpha_{1,2}$ and $\beta_{1,2}$ are the transport numbers for the cations and the vacancies ($\alpha_{1,2} + \beta_{1,2} = 1$). The presence of two different exchange currents (for ions and for vacancies) in Eqns.(31) and (32) with a common value of η follows from the principle of detailed balancing. Eqns.(31) and (32) can be used, with (27)–(29), to calculate the polarisation current–voltage characteristics of the system.

If the stationary currents are not large ($i_{1,2} < i_D$) we find that apart from their dependence on the relaxation characteristics (the relative values of l, l_τ, and L) the polarisation curves have similar shapes†, determined by Eqns.(31) and (32) with $n_{1,2}$ and $n^e_{1,2}$ values given by Eqn.(17) and η given by the equation

$$\psi^0 - \psi' = \frac{\varepsilon_0 d}{\varepsilon}\frac{d\psi}{dx}$$

(where d and ε are the thickness and the dielectric constant of the Helmholtz layer). This expression, which is used in the theory of the double layer[70], follows from the condition of continuity of the electrical induction at the phase boundary. An analysis of the system leads to the following conclusions:

1. In the low overvoltage region ($|\eta| \ll 1$) we find an ohmic portion $i = R^{-1}(\phi^0 - \phi^0_e)$, and the resistance of the reaction $R = T/e(i_{10} + i_{20})$ depends on the sum of the exchange currents.

2. In the "intermediate" overvoltage region Tafel's law is obeyed, and at fairly high overvoltages a new law sets in as a result of the lattice saturation effect. In particular, if $i_{10} \gg i_{20}$ and $\psi^0 > 0$ we have[88]

$$\ln i/i_{10} = \beta_1\psi^0 + a, \quad \psi^0 < \psi^0_* \qquad (33)$$

$$\ln i/i_{10} = \beta_1\delta(\psi^0/\gamma_2)^{1/2} + b, \quad \psi^0 > \psi^0_* \qquad (34)$$

where a and b are constants independent of ψ^0, $\delta = \kappa d\varepsilon_0/\varepsilon$, and the potential ψ^0_* of the transition between the laws (33) and (34) is given by

$$\psi^0_* = \ln(\gamma_2)^{-1} + \delta\left(\frac{1}{\gamma_2}\ln 2\right)^{1/2} \quad .$$

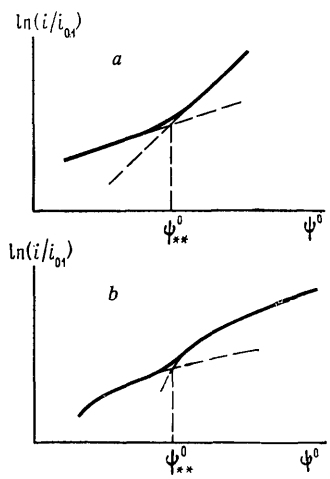

Figure 13. Transitions between different kinetic discharge regimes: (*a*) regimes corresponding to Eqn.(33), (*b*) to Eqn.(34).

§The component θ_{hom} is associated with the cross-over $L_{12} = L_{21}$ coefficient of the phenomenological transport equations of irreversible thermodynamics.

¶This plane is usually identified with the boundary of the diffusion layer (see Section III).

†In the limit of $\tau \to 0$ their shape is the same even for currents $i > i_D$.

3. A transition between different electrochemical reaction regimes is possible: from the discharge of interstitial ions ($i_1 \gg i_2$) to the discharge of ionic vacancies ($i_2 \gg i_1$), or *vice-versa*[82]. The transition may be between current–voltage characteristics of the Tafel type [Eqn.(33)] or of the type of Eqn.(34) (see Fig.13). The potentials of the transitions between regimes (ψ^0_{**}) are given (for $\psi^0 > \psi^0_e > 0$) by the expressions

$$\psi^0_{**} = \psi^0_e + (\beta_2 - \beta_1)^{-1} \ln (i_{10}/i_{20}) \quad (35)$$

$$(\psi^0_{**})^{1/2} = (\psi_e{}^0)^{1/2} + (\beta_2 - \beta_1)^{-1} \gamma_2^{1/2} \delta^{-1} \ln (i_{10}/i_{20}) \quad (36)$$

If the full current i in the system is comparable to i_D the polarisation curves suffer a radical change of shape in the slow relaxation case. The method of calculation and some special cases are discussed in Ref.82.

The polarisation curves may be affected by field-induced phase transitions in the near-surface layer of the solid electrolyte (see Section III). This effect has been shown[89] to lead to a stepwise region ("jump") in the current–voltage characteristic of the system, the potential and the amplitude of the jump being determined by the parameters used above to define the thermodynamic and kinetic properties of the crystal.

The most important of the time-dependent solutions of the transport equations (in relation to studies of electrode processes and of the bulk properties of the system) are those describing the response of the system to small harmonic perturbations. In this case an approximate analytical solution of the system of non-linear equations in partial differentials can be obtained by changing to a system of ordinary linear equations: this change is justified if the amplitude of the harmonic signal is small enough. The method of investigating these systems by studying the relationship between a small harmonic signal and the voltage has been called the impedance method. The application of the impedance method to electrochemical systems is discussed in detail in Ref.90. Within the framework of this method the electrochemical cell is replaced by its corresponding equivalent circuit, in which each element relates to one particular process in the system. The choice of equivalent circuit is not unique, in general. Calculations of the impedance of solid electrolyte cells for different assumed models are described in several papers (see, for example, Refs.91–94).

IV. BASIS OF THE MICROSCOPIC APPROACH. PHYSICAL METHODS OF INVESTIGATION

In this Section we shall examine two groups of problems: 1) some aspects of the microscopic description of ionic transport processes in solid electrolytes, which have been developed in recent years, and 2) the theoretical foundations of the physical methods used experimentally both to justify the choice of microscopic models and to obtain numerical values of the characteristic parameters of the crystals.

The theory of microscopic processes in solid electrolytes is still far behind the stage of development of the theory of transport processes in normal solids. This explains the proliferation of different (and often incompatible) models proposed by various authors. Similarly, the physical methods so far applied to the study of microscopic processes in solid electrolytes have failed, on the whole, to make full use of their implicit possibilities, only a small proportion of the experimental techniques to solid-state physics having been brought to bear.

We shall therefore selectively aim our discussion at those concepts and methods whose value has already been convincingly demonstrated.

1. Microscopic Models of Transport Phenomena

Published theoretical treatments of transport phenomena in superionic crystals by the microscopic approach can be arbitrarily classified into a number of groups.

Many of the papers describe calculations of the diffusion coefficients and mobilities of point defects (interstitial ions or vacancies) under the influence of an externally applied potential. Some of the earlier models have relied on the quasi-free ion concept, analogous to the Sommerfeld–Drude–Lorentz approach to electronic transport phenomena in metals[95,96]. Armstrong and coworkers[97] applied the expressions of the theory of rate processes to a model of thermally activated translation jumps. In this type of calculation the conductivity is expressed, in accordance with experimental data, as $\sigma = \sigma_0 \exp(-E_a/T)$, where the physical significance of σ_0 and that of the activation energy E_a are different in different models. The E_a values for most of the "good" solid electrolytes are relatively small, and similar (~0.1 eV), but the range of σ_0 values extends over several orders of magnitude. Various explanations of this phenomenon have been proposed[98–103] (failure of the simple models when applied to the calculation of the frequency of "attempted jumps" between potential wells, failure to allow for cooperative motion, etc.).

Several papers have dealt with the microscopic calculation of the relationship between the diffusion coefficient and the mobility of the ions allowing for the correlation effects which cause deviations from the Nernst–Einstein relation[104–108].

In another group of papers the properties of the superionic crystal are calculated analytically from a model Hamiltonian[103,109–114]. Some of the earlier attempts[99,100] tried to describe the collective interactions of interstitial ions in superionic crystals by exactly the procedure applied to the electrons in an ordinary ionic crystal (the polaron model). This approach has the advantage of bringing to bear on the problem the well tried mathematical framework of polaron theory. The concept of small polarons was introduced to explain the Hall effect in solid electrolytes[115].

The lattice gas model[85,86,116] is similar to the approach used by Mahan[100]: it assumes the existence of particles described in the secondary quantisation formalism by anti-commutating generation and annihilation operators. The anti-commutation arises because a lattice site (or an interstitial) can be either empty or occupied by a single particle. The Hamiltonian for the sum over the lattice sites includes terms describing the interactions with nearest neighbours, jump terms, and in some treatments terms describing the interaction with phonons. This model has been used[85] in the one-dimensional form to calculate the transport heat Q of the ion, which defines the homogeneous part of the thermo-electric power (see Section III). At relatively low temperatures the parameter Q is found[85] to coincide with the activation energy for conduction E_a, as in the case of non-interacting particles; a three-dimensional treatment of the problem has also been given[86], with allowance for the interaction of the mobile ions with phonons. This interaction causes a small difference between the quantities Q and E_a ($Q < E_a$) due to the energy of formation of the polaron.

Yet another group of papers relies on computer calculations. In the early work of this type[117–119] the interionic interaction potentials were used to calculate the "potential contour" maps for the mobile ions in the crystal and hence

the activation energies, the crystallographic directions of highest ionic conductivity, etc. The energetics of both "shallow" and "deep" levels for ions, their numbers, and their relative position in space have been calculated for specific crystals[120]. This approach helps to determine, in particular, what proportion of the ions is involved in transport phenomena.

Lastly, some of the most recent publications on the theory of solid electrolytes have used the molecular dynamics method (a new method of studying systems of many particles[121]). The development of the molecular dynamics method was made possible by the availability of advanced computer techniques: the method is based on mathematical modelling of the motion of an ensemble of particles subjected to given interaction laws. Numerical solutions of the equations of motion yield the dynamic trajectories of the particles and hence, by applying the ergodic hypothesis, the mean values of the dynamic variables can be obtained. For example, an ensemble consisting of a large number of Ag^+ and I^- ions contained in a cube with periodic boundary conditions has been analysed in this way[122]. From the interaction potentials, whose parameters were chosen from the known ionic radii of Ag^+ and I^-, from the crystal structure of α-AgI, and from diffraction data, the motion of the Ag^+ ions was calculated directly. From results of this type the diffusion coefficient D of the Ag^+ ions (say) can be obtained directly, using the general definition

$$\lim_{t\to\infty}\langle r^2(t)\rangle = 6Dt + \text{const}\ ,$$

where $\langle r^2(t)\rangle$ is the mean-square displacement calculated by the molecular dynamics method#. Similar calculations give the correlation functions of the velocities (u) of the ions: $\langle u(t)u(0)\rangle$. The behaviour of these functions for different values of t characterises the frequency dependence of the conductivity $\sigma(\omega)$. Thus the parameters of the kinetic processes can be expressed through the initial micropotentials of the ionic interactions, which are obtained from independent data.

The molecular dynamics method has been used in studies of the properties of the following solid electrolytes: AgI,[123-127] CuI,[125] CaF_2,[127,128] $SrCl_2$,[129] and γ-Al_2O_3.[79] The characteristics of the superionic crystals which have been calculated include $\sigma(\omega)$, the distribution of the concentration of mobile ions, the diffusion coefficients, and the displacement of the ions in the rigid sublattice. In every case the agreement between calculation and experiment was good. The results also confirm the existence of phase transitions in many solid electrolytes.

2. Interaction with Electromagnetic Radiation

By virtue of its interaction with the individual particles and with the collective excitations present in the crystal, a beam of electromagnetic radiation passing through a solid electrolyte experiences both elastic and inelastic (i.e. accompanied by frequency changes) scattering processes. The inelastic scattering processes are most intimately connected with the microscopic characteristics of the crystal§.

#The result, $D = 2.5 \times 10^{-9}$ m^2 s^{-1}, is close to the value measured experimentally.

§These processes are also called Mandel'shtam–Raman–Brillouin scattering.

The intensity I_R of inelastically scattered radiation of frequency ω is given by the dissipative fluctuation theorem[130] as

$$I_R = A\varepsilon''/[1-\exp(-\hbar\omega/T)]\ , \qquad (37)$$

where $\varepsilon''(\omega)$ is the imaginary part of the complex dielectric constant $\varepsilon(\omega)$, and the quantity A is proportional to the square of the matrix element of the corresponding quantum-mechanical transition. The form of the denominator of Eqn.(37) stems from the fact that the quanta of electromagnetic radiation obey Bose–Einstein statistics.

The frequency-dependent conductivity $\sigma(\omega)$, which describes [like $\varepsilon''(\omega)$] the dissipative processes in the system, is related to ε'' by the expression

$$4\pi\sigma(\omega)/\omega = \varepsilon''(\omega)\ . \qquad (38)$$

If the frequency of the radiation is such that $\hbar\omega \ll T$, and the parameter A is weakly dependent on ω, it follows from (37) and (38) that $\sigma(\omega) \propto \omega^2 I_R$. The last expression shows that the inelastic scattering spectra contain direct information on the microscopic details of the conduction mechanism. Furthermore, independent determinations of the function $\varepsilon''(\omega)$, for example from infrared absorption and reflection data, can also be directly related to the frequency dependence of the conductivity $\sigma(\omega)$. Measurements of this type, using procedures which have become well established in solid-state physics (including dispersion expressions), have been applied to a large number of superionic crystals[131-161].

In one of the simplest models the function $\varepsilon(\omega)$ can be found by examining the frequency of a damped harmonic oscillator in an external electric field E:

$$\ddot{x} + \gamma\dot{x}\omega_0^2 x = zeE/m\ , \qquad (39)$$

where x, Ze, and m are the coordinate, the charge, and the mass (reduced) of the vibrating ion, ω_0 is the vibration frequency in the crystal lattice, and γ is the damping (dissipation) constant. Putting $E = E_0\exp(-i\omega t)$, where $i \equiv \sqrt{-1}$ is the imaginary unit, we can easily calculate from (39) the induced dipole moment $p = ezx$ and hence the polarisability $\alpha(\omega)$ of the system (since $p = \alpha E$). The function $\varepsilon(\omega)$ is then obtained by the formula $\varepsilon(\omega) = \varepsilon_\infty + 4\pi\alpha n$, where n is the number of vibrating ions which scatter radiation per unit volume, and ε_∞ is the value of $\varepsilon(\omega)$ in the limit of $\omega \to \infty$ (in an even more simplified model $\varepsilon_\infty = 1$). The resulting expression for $\varepsilon(\omega)$ is

$$\varepsilon(\omega) = \varepsilon_\infty + S\omega_0^2/(\omega_0^2 - \omega^2 - i\omega\gamma)\ , \qquad (40)$$

where S is a dimensionless constant [according to (39), $S = 4\pi z^2 \cdot e^2 n/m\omega_0^2$]. The function $\varepsilon''(\omega)$, according to Eqn.(40), is given by

$$\varepsilon''(\omega) = S\omega_0^2\omega\gamma/[(\omega_0^2-\omega^2)^2 + (\omega\gamma)^2]\ . \qquad (41)$$

The absorption spectra corresponding to Eqn.(41) should be characteristically bell-shaped (Lorentzian distribution). In spite of its simplicity, the starting model is found to be effective up to frequencies in the infrared region, and the inelastic scattering spectra of many solid electrolytes can be described satisfactorily by Eqns.(37) and (41).[131,133,135]

A direct generalisation of Eqn.(40), applicable to descriptions of the properties of ionic crystals in the infrared spectral region, can be written as

$$\varepsilon(\omega) = \varepsilon_\infty + \sum_j \frac{S_j\omega_{0j}^2}{\omega_{0j}^2 - \omega^2 - i\omega\gamma}\ , \qquad (42)$$

where S_j is the dimensionless oscillator strength for mode j, which characterises the contribution of this mode to the static ($\omega = 0$) dielectric constant: $\sum_j S_j = \varepsilon_\infty - \varepsilon(0)$. The

absorption spectrum corresponding to Eqn.(42) is a set of peaks of the type described by Eqn.(41), usually overlapping.

The specific property of solid electrolytes is the presence of disorder in one of the crystal sublattices, which can manifest itself in a variety of effects associated with the interaction of radiation with matter: different ions, as a result of differences in their coordination, will have different vibration frequencies, and perturbations in the periodicity of the lattice will affect the selection rules, causing distortions in the optical spectra.

Temperature-induced phase transitions in solid electrolytes can also affect the probabilities of optical excitation of different frequencies. This effect is mathematically equivalent to a change in the parameter S_j, i.e. to a variation of the height of the corresponding peaks. If the symmetry of the crystal lattice is changed as a result of the phase transition, the selection rules for optical transitions will also be changed, causing individual peaks in the absorption spectrum to disappear (or appear). These effects have been very convincingly demonstrated experimentally[156,162,163].

Some attempts have been made to generalise the harmonic oscillator ensemble model in a slightly different direction by allowing for the specific features of the motion of ions in solid electrolytes. In particular, a model of an oscillator with a "finite memory" has been proposed[164]: according to this model the force acting on the ion at time t depends on the velocity $\dot{x}$ of the ion at some previous time. Mathematically this assumption involves replacing the term $\omega_0^2 x$ in Eqn.(39) by $\omega_0^2 \int_{-\infty}^{t} M(t-t')\dot{x}(t')dt'$, where $M(t-t')$ is the "memory function". If this function is chosen as

$$M(t-t') = \exp[-(t-t')/\tau_c],$$

where τ_c is the correlation time, in the case of a harmonic signal [$\propto\exp(-i\omega t)$] the above integral is directly calculable, and the final solution is obtained simply by replacing ω_0^2 by $\omega_0^2 i\omega/(i\omega - \tau_c^{-1})$ in Eqn.(40). In this case the conductivity is given by the expression

$$\sigma(\omega) = \frac{z^2e^2n}{m}\,\frac{\tau_c^{-1}(\omega_0^2 - \omega^2 + \gamma\tau_c^{-1}) + \omega^2(\tau_c^{-1} + \gamma)}{(\omega_0^2 - \omega^2 + \gamma\tau_c^{-1})^2 + \omega^2(\tau_c^{-1} + \gamma)^2}\,. \qquad (43)$$

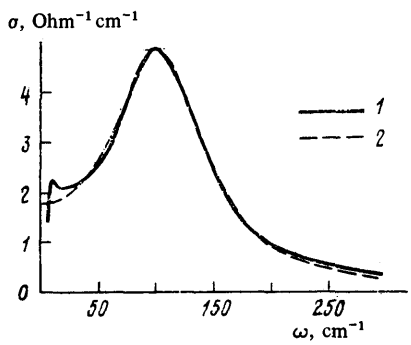

Figure 14. Frequency dependence of the conductivity [$\sigma(\omega)$] for α-AgI at 453 K:[164] *1*) experimental, *2*) calculated by formula (43).

The $\sigma(\omega)$ function calculated by Eqn.(43) for α-AgI with a suitable choice of parameters agrees very well with experiment for $\omega > 20$ cm^{-1} (see Fig.14).

The physical significance of the time τ_c is clear: for $\omega \ll \tau_c^{-1}$ the role of the electric field consists mainly in initiating the diffusional motion of the ion (the term proportional to ω_0^2 is small); conversely, for $\omega \gg \tau_c^{-1}$ the vibrational motion becomes predominant. According to Brüesch and coworkers[164] the characteristic τ_c^{-1} frequency of the transition between these two regimes is ~50 cm^{-1} (~1.5×10^{12} Hz). This value agrees well with that calculated by the formula $\tau_c^{-1} \cong (r_0^2/6D_1)^{-1}$, where r_0 is the distance between potential minima and D_1 is the diffusion coefficient of the interstitial ions.

The frequency dependence $\sigma(\omega)$ in α-AgI at relatively low frequencies ($\omega < 20$ cm^{-1})¶ has been explained[165,166] by allowing for the dependence of the motion of the ion in an alternating field upon the polarisation of the rigid sublattice, using a formalism similar to the above. A system of oppositely charged, interacting ions of two kinds has been discussed[166] by assuming that the ions of one kind can diffuse while those of the other kind are rigidly bound. The solution of the system of two equations obtained shows an apparent change in mass of the diffusion ions with frequency, since the polarisation of the medium (caused by interaction with other ions) either "succeeds" in following their motion or "fails" to do so[166]. Detailed microscopic studies of these phenomena are described in Ref.79.

Correlation effects resulting from the mutual interactions of the mobile ions are discussed in Refs.167–177.

3. Neutron Scattering

The neutron scattering method occupies a special place in the study of the properties of solid electrolytes, because the de Broglie wavelength of thermal neutrons is comparable to the interatomic distances found in typical crystals. At the same time (and unlike X-rays of the same wavelength) these neutrons have an energy comparable to the phonon energy of the crystal. Therefore, valuable information on the vibrational spectrum of the solid can be obtained by measuring the energy spectrum of the scattered neutrons.

Thermal neutrons are scattered by a crystal at a large number of lattice centres simultaneously, and therefore interference of the scattered waves is possible. The part of the scattered radiation affected by interference is called coherent scattering. In addition, different centres can scatter neutrons independently of each other, giving rise to incoherent scattering.

The scattering of neutrons by a system of many interacting particles is directly related to the behaviour of the space- and time-dependent pair correlation function $G(\mathbf{r}, t)$. The differential scattering cross-section within the solid angle $d\Omega$ and the energy range of scattered neutrons $d\mathscr{E} = \hbar d\omega$ can be expressed as

$$\frac{d^2\sigma}{d\Omega d\mathscr{E}} = \frac{a^2}{\hbar}\frac{k}{k_0}S(\varkappa, \omega)\,, \qquad (44)$$

where $S(\kappa, \omega)$ is the Fourier transform of the correlation function $G(\mathbf{r}, t)$ (the dynamic structure factor), $\kappa = \mathbf{k} - \mathbf{k}_0$ (where $\mathbf{k}_0$ and $\mathbf{k}$ are the wave vectors of the incident and of the scattered neutron), the frequencies ω are expressed in terms of the energy changes $\hbar\omega = \hbar^2(k_0^2 - k^2)/2m$ (where m is the mass of the electron), and a is the scattering length.

¶However, we should note that according to Gebhardt and coworkers[154] the conductivity of α-AgI at frequencies between 8×10^9 and 4×10^{10} Hz is described by a simple expression of the Drude type.

Inelastic coherent scattering processes are the most interesting in studies of the dynamic properties of a crystal lattice. Scattering is assumed to take place on nuclei located at lattice sites with a time-dependent displacement determined by the lattice vibrations. The correlation function (for single-phonon scattering) allows for the energy and momentum conservation laws:

$$\hbar^2(k^2-k_0^2)/2m=\hbar\omega_j(\mathbf{q}); \quad \mathbf{k}-\mathbf{k}_0=2\pi\mathbf{b}+\mathbf{q}\,, \qquad (45)$$

where q is the wave vector of the phonon, b is the reciprocal lattice vector, and $\omega_j(\mathbf{q})$ is the frequency of the j-th branch of the normal vibration to which the phonon is assigned. By measuring the one-phonon scattering cross-section of the neutrons we can determine the dispersion laws $\omega = \omega_j(\mathbf{q})$ which characterise the phonon spectrum of the crystal.

Phonon spectra have been obtained experimentally for the following series of solid electrolytes: AgI,[178-181] Ag_3SI and Ag_3SBr,[182] $RbAg_4I_5$,[180,181] BaF_2,[183-185] $SrCl_2$,[183-185] PbF_2,[185,186] Li_2SO_4,[187] $LiAlSiO_4$,[188] and β-Al_2O_3.[189,190] Special attention was paid to the spectral changes accompanying the transition of the superionic crystals into the disordered phase[178,179,182,191]. A study of the dispersion curves of silver iodide at different temperatures[178,191] revealed the loss of one low-energy optical mode during the $\beta \to \alpha$ structural phase transition. This is explained[178] by assuming that a relatively small amount of energy is expended in the rearrangement of the rigid (iodide) anion sublattice attending the transition to the superionic state. Similar results were obtained for the superionic conductors Ag_3SI and Ag_3SBr.[182]

Neutron scattering has been used also to study the behaviour of ions in disordered phases of superionic crystals. A study[96,181] of the quasi-elastic scattering of cold neutrons in the α-phase of AgI may be taken as an example. The experimental results were interpreted on the assumption that scattering occurs exclusively on the silver cations†. The following microscopic model was adopted[96] to calculate the correlation function. The ions take part in two independent types of motion: translational, and local. The translational motion of the ion is described by the hopping mechanism: the particle resides in a fixed position for a time τ_0, after which it jumps (in a time τ_1') to a point a distance l_0 away. The local motion of the ion is treated as the random ("Brownian") motion of particles in some limited regions ("cavities") of the crystal, defined by the geometry of the iodine sublattice.

The best agreement between calculated and experimental curves is obtained for the following values of the parameters: $\tau_0 = 7.5 \times 10^{-12}$ s, $\tau_1' = 16.5 \times 10^{-12}$ s, $l_0 = 5$ Å. The diffusion coefficient of the silver cations D can be calculated by the formula $D = l_0^2/6(\tau_0 + \tau_1')$. Inserting the above values of the parameters we find $D \cong 1.75 \times 10^{-9}$ m^2 s^{-1}, in good agreement with the experimental value $D_{exper} \cong 2 \times 10^{-9}$ m^2 s^{-1}. Detailed studies of the quasi-elastic neutron scattering spectra of α-AgI single crystals[181] have revealed a strong anisotropy in the motion of the Ag^+ ions#.

†The scattering cross-section of iodine is much smaller than that of silver.

#According to Cava and coworkers[192] the average jump length of the cations is $l = 1.79$ Å, but this value is inconsistent with the present result. This problem is examined specifically in Ref. 193.

To conclude this Section we note that the crystal structure of disordered phases in superionic crystals has been studied not only by the quasi-elastic scattering of neutrons, but also by diffuse neutron and X-ray scattering (X-ray and neutron diffraction).[192-211] For example, neutron diffraction experiments with α-Ag_2S have shown[197] that the silver cations are not localised in fixed positions, but behave as a "lattice liquid". The inelastic neutron scattering spectra of $RbAg_4I_5$ are interpreted[103] in terms of a model of the Brownian motion of the diffusing Ag^+ ions in a sinusoidal potential field.

4. Magnetic Resonance

Under NMR conditions, which are highly relevant in studies of superionic crystals[212,213], the system of nuclear spins interacts with an external magnetic field H_0; furthermore, the spins also interact among themselves and with the "lattice".

Let us examine the behaviour of the integral magnetic moment M of a large number of spins (magnetic moments) at a temperature T. Let the external field H_0 be directed along the z axis. In general, the component M_z of the vector M may differ from its equilibrium value M_0, corresponding to a constant field H_0, owing to the fluctuations of the local magnetic field within the crystal. Under these conditions the approach to equilibrium as a result of the interaction of the system of spins with the crystal lattice (in particular, with the phonons) obeys the phenomenological expression (Bloch equation) [214]

$$dM_z/dt=-(M_z-M_0)/T_1\,, \qquad (46)$$

where T_1 has been called the spin–lattice relaxation time.

In discussions of relaxation processes in solid electrolytes the local magnetic field is usually assumed to be produced by the fluctuating magnetic fields of the mobile ions. The time characteristics of the local fields are described in general by the time-dependent pair correlation function $G(t)$, which usually decreases exponentially by the law $\exp(-t/\tau_1)$, where τ_1 is the "relaxation" time of the correlation. Since the nature of the fluctuations changes with temperature, the quantity τ_1 is a function of temperature, and can be expressed as $\tau_1 = \tau_{10}\exp(E_a^*/T)$, where E_a^* is an activation energy and the constant τ_{10} is formally defined as the value of τ_1 at $T \to \infty$.

The relaxation time T_1 is related to τ_1 by the expression[214]

$$\frac{1}{T_1} = B\frac{\tau_1}{1+\omega_0^2\tau_1^2}\,, \qquad (47)$$

where $\omega_0 \equiv \gamma g H_0$ is the precession frequency of the spin in the magnetic field H_0 (the Larmor frequency) and B is a quantity independent of ω_0 and τ_1 and proportional to the intensity of the local magnetic field.

The temperature dependence of the spin–lattice relaxation time T_1 has been studied experimentally at both low and relatively high temperatures in a series of solid electrolytes[215-224]. The activation energies E_a^* obtained from these data by Eqn. (47) for the low-temperature phases of some superionic crystals are satisfactorily consistent with the E_a values calculated from the temperature dependence of the ionic conductivity:

Crystal	PbF_2	$LiAlSiO_4$	CuI
E_a^*, eV	0.7 [217]	0.8 [215]	0.5 [218]
E_a, eV	0.7 [225]	0.7 [226]	0.6 [227]

This agreement between the two sets of activation energy is not surprising, since the transport processes in the low-temperature region occur by jumps of individual ions

between different positions in the crystal. Under these conditions the time τ_1 can be identified with the time between jumps. This agreement is a powerful argument in favour of the validity of the postulates on which these models are based.

Measurements at relatively higher temperatures in the disordered phase (superionic state) have shown that the relaxation rate T_1^{-1} decreases exponentially as the temperature increases[98,219,221]. For $\omega_0\tau_1 \ll 1$, and assuming that the local field (and therefore also the parameter B) is proportional to the concentration of mobile particles $n(T)$, we obtain from (47)

$$T_1^{-1} \propto n(T)\tau_1(T)\,. \qquad (48)$$

In the light of Eqn.(48) the experimental results are readily explained by noting that the quantity $n(T)$ is only weakly dependent on temperature, as discussed in Section II. Thus, the qualitative statements on the "molten" state of one of the sublattices in solid electrolytes[217,218] are experimentally confirmed.

The NMR method has been used in structural studies of superionic conductors, since the local symmetry and the coordination of ions taking part in the transport process can be determined from the NMR spectra of nuclei with a quadrupole moment[228-233]. The method has been found convenient also in studies of phase transitions, especially in $RbAg_4I_5$ [234] and in $Li_{14}Zn(GeO_4)_4$.[235]

However, some results of NMR studies on solid electrolytes are not easily interpreted within the model of independent motion of ions[215,219-221]. These observations suggest the need for many-particle concepts (in particular, allowance for ion correlations) in the description of the transport properties of superionic crystals.

The effect of disorder in one sublattice on the ESR spectra has been demonstrated in solid electrolytes containing paramagnetic ions[236-238]. The ESR method has been used also to study the distribution of impurity ions in superionic crystals[239-243].

* * *

Our analysis of theoretical and experimental results has shown that considerable progress has been made in recent years in understanding the physical basis of the phenomena in solid electrolytes, though many important and interesting problems still await a solution. The set of problems associated with the superionic conduction phenomenon has now been clearly formulated as a self-contained and quite extensive scientific discipline.

The thermodynamics of superionic conduction are closely associated with those of other solid-state phenomena which have been more fully investigated (disorder in alloys, in solid solutions, and in ferroelectrics). We should stress that some of the theoretical results discussed in this review (in particular, the possible existence of bitransitions, and the stimulation of polymorphic transformations in crystalline structures by the presence of disorder in one of the sublattices) are directly relevant to a much wider range of materials.

The discontinuous change in ionic conductivity induced by an external electric field may be found to have practical as well as purely scientific interest.

Ionic transport phenomena in solid electrolytes have a number of specific features whose study offers a better understanding of the analogous phenomena in liquid electrolytes on the one hand and in "normal" ionic crystals on the other hand. We can expect the present intensive studies of the structural, thermodynamic, and kinetic properties of solid electrolytes to lead to a far more detailed knowledge of the behaviour of these materials.

Catalytic Cyclo-oligomerisation Reactions of Lower Olefins and Alkanes with Formation of Aromatic Hydrocarbons

O.V.Bragin

The results of studies devoted to the aromatisation of lower (C_2-C_5) olefins and alkanes in the presence of a number of metal oxide and oxide catalysts are examined. The type of aromatisation discussed constitutes a new potential source of benzene and its nearest homologues, the need for which has been rapidly increasing.
The bibliography includes 70 references.

IV. Oxidative dehydrocyclodimerisation of lower olefins and alkanes 1053

I. INTRODUCTION

The requirement for benzene and its derivatives is at present very great[1-3]. According to Fick[2], the consumption of benzene in the USA will exceed by 1985 the total 1965 requirement by a factor of two for the manufacture of ethylbenzene alone. The overall consumption in 1985 will double compared with the 1976 level, which corresponds to an average annual increment of 7.5%. The great practical value of theoretical and technical developments directed towards the creation of novel processes and the discovery of new possibilities for the synthesis of valuable aromatic hydrocarbons is therefore evident. The important problem of expanding the raw materials base for the manufacture of aromatic hydrocarbons is related to these tasks.

New possibilities for synthesising aromatic hydrocarbons by the dehydrocyclo-oligomerisation of C_2–C_5 light olefins and alkanes[4-15], and in a number of subsequent communications, are of undoubted interest. A characteristic of the cyclo-oligomerisation of C_2–C_3 hydrocarbons is that their aromatisation results in the preferential formation of benzene and toluene[7,11]. It is known that benzene is the primary starting material among aromatic hydrocarbons for industrial organic synthesis and is used to synthesis styrene, cyclohexane, caprolactam, phenol, maleic anhydride, and intermediates for the manufacture of detergents and dyes. Toluene is the starting material for the manufacture of benzene, phenol, benzyl chloride, and various types of varnishes, dyes, and resins.

The synthesis of aromatic hydrocarbons by the dehydrocyclo-oligomerisation of lower olefins and alkanes can be arbitrarily divided into two groups of reactions—non-oxidative and oxidative. The first group includes the conversion of lower (mainly C_2–C_4) olefins into benzene and other aromatic hydrocarbons in the presence of metal-containing and certain oxide catalysts. These reactions have been discussed in the literature under similar names—dehydrocyclo-oligomerisation, cyclodimerisation, cyclotrimerisation, and also aromatisation of lower olefins and alkanes. A distinctive feature of the above group of reactions is that they occur without the supply of gaseous oxygen to the reaction zone and without the participation of oxygen which forms part of the oxide catalyst. In the present review these reactions of lower olefins and alkanes will be referred to as non-oxidative cyclo-oligomerisation. The second groups of reactions includes different versions of the oxidative aromatisation of lower hydrocarbons, which occurs in the presence of various oxide catalysts at 500–600 °C.

The present state of studies on the cyclo-oligomerisation of olefins and the dehydrocyclisation of lower alkanes with formation of benzene and its homologues, mainly in the presence of metal oxides and a number of oxide catalysts, in the non-oxidative and oxidative versions of the reaction is briefly assessed below.

II. DEHYDROCYCLODIMERISATION OF C_3–C_5 OLEFINS AND ALKANES IN THE PRESENCE OF VARIOUS METAL-CONTAINING AND CERTAIN OXIDE CATALYSTS

The first data on the dehydrocyclo-oligomerisation of lower C_3–C_4 olefins with formation of aromatic hydrocarbons were published by Soviet workers[4,5,16-19].

It has been shown[4] that n-butene gives rise to olefins in the presence of an aluminosilicate catalyst at 370 °C; following an increase of temperature to 450–500 °C, aromatic hydrocarbons (benzene, xylenes, and trimethylbenzenes) are formed together with olefins. The polymerisation of isobutene in the presence of an alumina–molybdenum oxide catalyst has been investigated[5] and isomeric xylenes have been detected in the reaction products (400 °C) and isolated. It has been shown[16,17] that aromatic hydrocarbons can be the main products of the conversion of propene over zinc chloride. The polymerisation and aromatisation of propene in the presence of molybdenum/alumina and platinum/alumina catalysts has also been studied[18,19].

The aromatisation of lower C_3–C_5 alkanes in the presence of a number of metal oxides and oxide catalysts was first described by Csicsery in a series of papers[6-10] published in 1969–1970. The dehydrocyclodimerisation of lower alkanes has been studied most thoroughly in relation to butane (and butenes) on platinum/alumina and certain oxide catalysts[6,8,9].

The dehydrocyclodimerisation of propane and propene in the presence of platinum/alumina catalysts, alumina, and mixed oxide catalysts containing bismuth, tin, and nickel oxides as well as a number of others has been studied by Usov and coworkers[20-25].

The dehydrocyclodimerisation of lower C_3–C_5 alkanes takes place at relatively high temperatures. As a rule, the reaction takes place above 430–450 °C. Thus the equilibrium

constants of the reaction 2isobutane ⇌ p-xylene + $5H_2$ at 427° and 527 °C are respectively 16.23 and 1.22×10^4.[6] The reaction takes place successfully in the presence of bifunctional catalysts with the optimum combination of dehydrogenating and acid properties, i.e. having a fairly high dehydrogenating activity and active in acid–base reactions.

A large series of metal oxide and oxide dehydrocyclodimerisation catalysts have been tested[6–10]. Among oxide catalysts, vanadium and chromium oxides are the most active in the reaction discussed; among metals, platinum has proved most successful. The usual overall content of the dehydrogenating component is 0.6–3.0% (for metal oxide catalysts) and 0.3–35% (for complex oxide catalysts) relative to the mass of the carrier. Alumina has been used successfully as the carrier, particularly alumina promoted with a halogen. In addition, amorphous and crystalline aluminosilicates, magnesium oxide, and silicon–magnesium oxides have been used as carriers for catalysts of the dehydrocyclisation of lower alkanes.

The platinum/alumina catalyst proved to be the best of the metal oxide catalysts of the dehydrocyclodimerisation of lower alkanes investigated by Csicsery[6]. Fig.1 shows how the platinum content in the platinum/alumina catalyst affects the degree of conversion of isobutane into aromatic hydrocarbons and the yield of the latter in the dehydrocyclodimerisation reaction. It follows from the results that the active surface of platinum in the catalyst employed (0.5–2.5% Pt/Al_2O_3) is approximately proportional to the platinum content in the catalyst. With increase of the platinum content, the yield of aromatic hydrocarbons falls as a consequence of the considerable intensification of the cracking and coke forming reactions. The author[6] therefore concluded that, under the conditions investigated (the carrier, temperature, space velocity, etc. employed), the optimum concentration of platinum in the catalyst is ~0.8 wt.% or a little less.

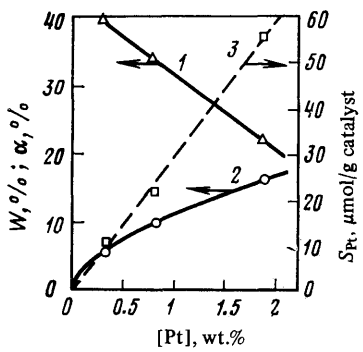

Figure 1. The influence of the concentration of platinum in the Pt/Al_2O_3 catalyst on the dehydrocyclodimerisation of isobutane to aromatic hydrocarbons (560 °C): 1) the yield of aromatic hydrocarbons W; 2) the degree of conversion α of iso-C_4H_{10}; 3) the adsorption capacity of the catalyst[6].

In the presence of this catalyst at 560 °C, C_3–C_5 alkanes undergo a whole series of reactions[6,7]: cracking with formation of methane and other hydrocarbons having a lower molecular weight than the initial compound; dehydrogenation; dehydrocyclodimerisation with formation of aromatic hydrocarbons; coke formation. The yield of aromatic hydrocarbons increases in the sequence propane < butane < pentane and is 9–15, 18–22, and 34–37 wt.% respectively. The main aromatic hydrocarbon obtained as a result of the dehydrocyclodimerisation of propane is benzene[7] the main aromatic compounds obtained as a result of the transformation of butanes are xylenes and toluene; benzene and C_9–C_{10} aromatic hydrocarbons have been detected in much smaller amounts[6]. Pentane gives rise to appreciable amounts of toluene and benzene and also to hydrocarbons with higher molecular weights such as naphthalene, indene, and other condensed compounds[7].

The dependence of the composition of the products of the reaction of isobutane on its contact time with 0.8% Pt/Al_2O_3 has been studied[6]. It follows from Fig.2 that, with increase of contact time, there is a sharp acceleration of the dehydrogenation process accompanied by the formation of butenes, whose amount passes through a definite maximum. The concentration of aromatic compounds in the reaction products increases more gradually. The yield of coke and cracking products increases approximately linearly with increasing contact time. Analysis of the shape of the curves describing the increase of the content of butenes and aromatic compounds led the author[6] to the conclusion that the dehydrocyclodimerisation of isobutane is a consecutive reaction on the assumption that butenes are intermediates in the formation of aromatic hydrocarbons. Rapid skeletal isomerisation was also noted. For longer contact times, the ratio isobutenes: :n-butene approaches the equilibrium value (0.73 at 560 °C). Special experiments showed[6] that the xylenes and ethylbenzene, formed as a result of the dehydrocyclodimerisation of isobutane, undero dealkylation with increase of contact time and are converted into toluene and benzene.

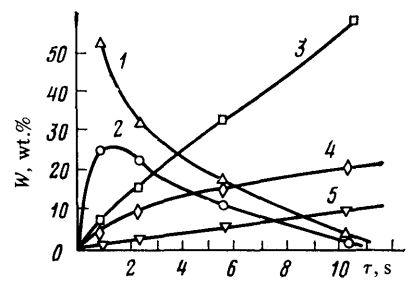

Figure 2. The influence of contact time on the composition of the isobutane dehydrocyclodimerisation products at 560 °C in the presence of 0.8% Pt/Al_2O_3: 1) C_4H_{10}; 2) the sum of C_4H_8 hydrocarbons; 3) the overall yield of C_1 and C_2 hydrocarbons; 4) the sum of aromatic hydrocarbons; 5) coke[6].

An important factor influencing the degree of dehydrocyclodimerisation of lower alkanes and the composition of the aromatic component of the catalytic reaction mixture is the acidity of the catalyst. The latter depends on many factors, including the nature and method of preparation of the carrier, the composition of the compound containing the active component, the method of its deposition, the presence of acid or alkaline additives, etc. Some of these parameters have been varied[6]. An increase of acidity tends to increase the yield of aromatic hydrocarbons.

In the presence of strongly acid catalysts isobutane and n-butane give rise to reaction products with a very similar composition of aromatic hydrocarbons. The latter is apparently due to the fact that the more acid catalyst promotes

the greatest approach of the composition of the initial mixture of isobutenes and n-butenes to the equilibrium composition under the reaction conditions. A definite dependence of the activity of the catalyst in the dehydrocyclodimerisation of isobutane on the acidity of the catalyst has been observed[6], a change in acidity being reflected in the isobutenes:n-butenes ratio in the reaction mixture. Furthermore, in the presence of weakly acid catalyst, n-butane gives rise mainly to ethylbenzene and styrene, while isobutane forms *p*-xylene. At the same time, in the presence of strongly acid catalysts both C_4 alkanes give rise to products with the same composition of the aromatic hydrocarbons.

Interesting data have been published[6] on the reactions of isobutane under dehydrocyclodimerisation conditions over three catalysts: Pt/Al_2O_3; $Pt/Al_2O_3 + Al_2O_3$; $Pt/Al_2O_3 + Al_2O_3 - SiO_2$. In the case of the last two catalysts, used in the form of a mechanical mixture of 0.8% Pt/Al_2O_3 and the "acid component", an appreciable (by a factor of ~2) increase of the yield of aromatic hydrocarbons and a clear decrease of the amount of the products of dehydrogenation of butenes and butadienes were observed.

Csicsery[9] put forward and tested the hypothesis that there is a definite relation between the acidity of the catalyst and its oligomerising activity. It was assumed that olefins are dimerised mainly on acid surface centres. To test this hypothesis, *trans*-but-2-ene was passed over various acid catalysts without a metal. In the presence of alumina and aluminosilicate the butene readily isomerised to a mixture of *cis*-but-2-ene and but-1-ene. A proportion of the butenes were converted into liquid products consisting of linear and cyclic oligomers and also of aromatic hydrocarbons. The concentration of the latter in the catalytic reaction mixtures was appreciably lower than in the presence of corresponding platinum-containing catalysts—Pt/Al_2O_3, and $Pt/Al_2O_3-SiO_2$.

Consequently catalysts not containing the hydrogenating–dehydrogenating component successfully initiate the aromatisation reactions of linear dimers, the disproportionation of polyalkylbenzenes, cracking reactions, etc. but nevertheless to an appreciably small extent than the corresponding metal-containing catalyst. The important role of the acidity of the catalyst has been demonstrated in the study of the reactions of *trans*-but-2-ene over aluminosilicate to which various alkali metals have been added. With increase of the concentration of sodium in the catalyst, the rates of dehydrocyclodimerisation, skeletal isomerisation of olefins, cracking, and coke formation appreciably decreases.

The degree of dehydrocyclodimerisation of butane decreases significantly when the initial hydrocarbon is diluted with hydrogen. It is apparently due to the appreciable acceleration of the hydrogenolysis; in the presence of Pt/Al_2O_3 at 560 °C up to 85% of the butene was converted into methane during the first 10 minutes of the experiment and the main bulk of the aromatic hydrocarbons were demethylated to benzene[6]. In the absence of hydrogen, an increase of the hydrocarbon pressure in the system in the range from 1 to 50 atm entailed an increase of the rate of dehydrocyclodimerisation of the alkane and to a lesser extent an increase of the rate of cracking. Since the dehydrocyclodimerisation of alkanes led to the evolution of a large amount of hydrogen (5 moles of H_2 for 2 moles of the alkane), it is recommended that the initial alkane be diluted with an inert gas.

The question of regeneration of the catalysts of the dehydrocyclo-oligomerisation of lower hydrocarbons has so far been inadequately elucidated. The relatively extensive coke formation on these catalysts necessitates regular and frequent regenerations. Compared with platinum catalysts, the oxide catalysts containing variable-valence elements are much more stable under the conditions of frequent regeneration. It is therefore useful to employ catalysts containing Group V–VII transition metal oxides, which can be usually repeatedly regenerated without significant loss of activity. Vanadium, molybdenum, chromium, tungsten, and manganese oxides deposited on alumina have been investigated[8]; the highest conversion of n-butane was observed in the presence of the first two oxides.

The influence of temperature on the degree of dehydrocyclodimerisation of n-butane in the presence of chromium oxide/alumina catalyst prepared by the method of Pines and Haag[26] has been studied[8], the experiments being performed in the range 490–593 °C. The highest yield of aromatic hydrocarbons was reached at 593 °C. With increase of temperature, an increase of the yields of methane, ethane, ethylene, and coke was noted. The maximum yield of aromatic hydrocarbons, evaluated taking into account the recirculation of the C_3-C_5 hydrocarbons, was observed at 250 °C.

As in the presence of metal-containing catalysts, the acidity of the carrier plays the major role in the case of oxide catalysts. A series of chromium oxide–potassium oxide/alumina catalysts (0.1 wt.% K) with different acid carriers have been studied in relation to the dehydrocyclodimerisation of n-butane[8]. The yield of aromatic hydrocarbons is higher in the presence of catalysts containing η-Al_2O_3 or fluorinated Al_2O_3 (on the latter, the yield of coke is minimal).

The dehydrocyclodimerisation of propane and isobutane on an industrial platinum/alumina catalyst and also the dehydrocyclodimerisation of propene in the presence of alumina specimens of different acidity have been studied in detail[20–25]. The behaviour of propane, propene, and isobutane in the presence of the platinum/alumina catalyst[21,22] and of propene and C_6 hydrocarbons on alumina[23,24], as well as the influence of pyridine and ammonia on the dehydrocyclodimerisation of propane and propene[21,23] have been investigated; finally, alumina specimens of different acidity have been studied by spectroscopic methods[23]. The results enabled the authors to put forward a series of well-founded hypotheses concerning the mechanism of the dehydrocyclodimerisation of propane in the presence of the platinum/alumina catalyst. In particular, it has been shown that, under pulsed conditions in the presence of an industrial platinum/alumina catalyst in the temperature range 560–620 °C, propane undergoes far-reaching transformations in cracking, dehydrogenation, and aromatisation reactions. Depending on the experimental conditions, the yield of aromatic hydrocarbons then amounts to between 0.4 and 17% relative to the propane passed through the system.

The results enabled the authors[21,22] to suggest that propene is an intermediate in the dehydrocyclodimerisation of propane to aromatic hydrocarbons. A similar behaviour has been noted in the reactions of isobutane. The role of olefins in the aromatisation of lower alkanes has been studied in greater detail in relation to the reactions of propene. It was found that in the presence of platinum/alumina catalysts, propene undergoes more far-reaching transformations than propane, particularly with formation of aromatic hydrocarbons.

The same workers[25] described catalytic reactions of the propane–butane fraction of the gas associated with petroleum in the presence of the platinum/alumina catalyst. The transformation of the propane–butane fraction is a complex process consisting of a series of consecutive-parallel reactions, the principal of which are dehydrogenation and cracking of propane and butanes. The olefins formed in the dehydrogenation process subsequently undergo oligomerisation with formation of C_6 and C_8 dimers. The formation of aromatic C_8 and C_9 hydrocarbons, in the first place benzene and toluene, takes place as a result of the C_6-dehydrocyclisation of linear oligomers with the corresponding composition and structure. At the same time benzene (and toluene) are formed as a

result of the demethylation of homologues with a higher molecular weight, as shown by the increase of the concentration of aromatic C_6–C_9 hydrocarbons with increase of temperature and contact time.

In order to elucidate the role of the carrier in the bifunctional platinum/alumina catalyst in the dehydrocyclodimerisation of propane, a study has been made[23,24] of the reactions of propene in the presence of halogenated and alumina not promoted with a halogen. Starting from 250 °C and up to 475 °C, propene dimerises and the concentration of C_6 olefins increases from 3.6 to 16.8%. In the range 520–620 °C propene undergoes far-reaching transformations on fluorinated alumina, the principal reaction being aromatisation.

With increase of the acidity of the catalyst in the sequence γ-Al_2O_3 < γ-Al_2O_3(Cl) < γ-Al_2O_3(F), the overall degree of conversion of propene increases and the yield of aromatic hydrocarbons also rises. In the presence of γ-Al_3O_3(F) isobutene undergoes far-reaching transformations under similar conditions, mainly with formation of aromatic C_8 hydrocarbons.

It has been shown by the pulsed poisoning of fluorinated alumina with ammonia or pyridine that both bases suppress the aromatisation of both propene and C_6 hydrocarbons. It was therefore postulated[23,24] that the dimerising, dehydrocyclising, and dehydrogenating functions of alumina are associated with its acidity. It has been suggested that the first, slowest stage of the conversion of propene is its dimerisation, which can take place on protic acid centres of the catalyst via the carbonium ion mechanism or with participation of Lewis centres via a radical mechanism. The subsequent reactions of the dimers are apparently much faster and involve the formation of five- and six-membered cyclo-olefins and aromatic hydrocarbons and also cracking.

The aromatisation of lower olefins over alumina, aluminosilicates, and activated carbon has been studied[27,28]. The results confirmed that the aromatisation of lower olefinic hydrocarbons is a complex process leading to the formation not only of aromatic hydrocarbons but also of gaseous and liquid aliphatic products and naphthenes. With increase of the number of carbon atoms in the olefin molecule, the degree of conversion of the initial hydrocarbon also increases and the content of aromatic hydrocarbons in the liquid catalytic reaction mixture rises.

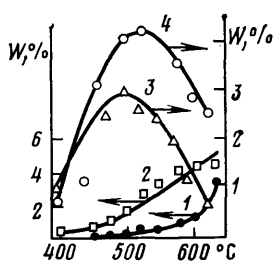

Figure 3. The influence of temperature on the yield of aromatic hydrocarbons W in the aromatisation of C_3H_6 in the presence of Al_2O_3.F: 1) C_6H_6; 2) $C_6H_5CH_3$; 3) aromatic C_9–C_{11} hydrocarbons; 4) xylenes[28].

The data obtained in the presence of fluorinated alumina are presented in Figs.3 and 4. It follows from the results that an increase of the temperature of the dehydrocyclodimerisation of propene and isobutene in the presence of alumina from 300° to 625 °C is accompanied by an increase of the degree of conversion of the initial olefins; aromatic hydrocarbons are formed appreciably only above 500 °C. The greatest selectivity in relation to aromatic hydrocarbons is reached at 550–625 °C. The increase of contact time is accompanied by an appreciable increase of the degree of conversion of the initial olefins but does not have an appreciable effect on the composition of the liquid reaction products and the selectivity of the reaction in relation to aromatisation.

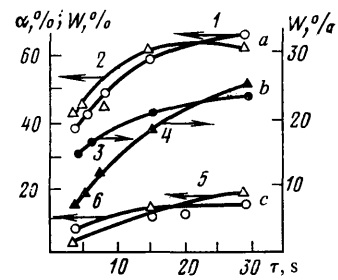

Figure 4. The influence of contact time on the aromatisation of C_3H_6 in the presence of Al_2O_3.F: *a*) the degree of conversion α of C_3H_6; *b*) the yield of aromatic hydrocarbons W relative to C_3H_6 which has reacted; *c*) the yield relative to the C_3H_6 passed through the system; 1), 3), and 5) 600 °C; 2), 4), and 6) 550 °C.[28]

It was noted above that in his study of the dehydrocyclodimerisation of butanes, Csicsery[6] suggested that the given reaction has a consecutive mechanism. In order to elucidate the role of olefins in the dehydrocyclodimerisation of alkanes, a study was therefore made[9] of the conversion of but-2-ene in the presence of the platinum/alumina catalyst. The higher degree of conversion of butene into aromatic hydrocarbons than for butane under similar conditions was established. The but-2-ene conversion products for short contact times proved to be mainly C_6–C_8 olefins and naphthenes. For longer contact times, a relatively larger amount of aromatic hydrocarbons and a much smaller amount of naphthenes were found in the reaction products. This change in the composition of the catalytic reaction mixture shows, according to the author[9], that the dehydrocyclodimerisation of butenes does indeed proceed via the initial formation of C_6–C_8 olefins and naphthenes.

In his treatment of the mechanism of the dehydrocyclodimerisation of butanes in the presence of bi- and polyfunctional catalysts, Csicsery[10] discusses a consecutive scheme consisting of the following stages: (1) dehydrogenation of alkanes to mono- and di-olefins; (2) dimerisation of olefins on acid centres; (3) aromatisation of unsaturated dimers; (4) isomerisation, transalkylation, and dealkylation of the aromatic hydrocarbons obtained initially with formation of a large number of C_8–C_{10} alkyl- and dialkyl-benzenes.

In order to refine the details of the first stage—the formation of olefinic and diolefinic hydrocarbons—experiments with butenes were carried out[9]. The rate of aromatisation of the latter proved to be 2–2.5 times higher than that of butane; the butene ⇌ butadiene equilibrium is established very rapidly; the cracking of butenes is slower and the rate of coke formation is appreciably higher than for butane. It has

been suggested that olefinic and diolefinic hydrocarbons are formed on dehydrogenating catalyst centres:

$$C_4H_{10} \xrightarrow{-H_2} C_4H_8 \xrightarrow{-H_2} C_4H_6 .$$

The second stage—catalytic dimerisation of unsaturated hydrocarbons—occurs mainly on the surface of acid centres on the carrier.

The mode of the third stage—aromatisation of dimerised olefins and diolefins—depends primarily on the experimental conditions and the catalyst. An increase of temperature accelerates the aromatisation of dimers and at the same time favours dealkylation. The latter is apparently responsible for the increase of the yield of benzene and toluene relative to C_9–C_{10} aromatic hydrocarbons. An increase of contact time leads to an increase of the yield of aromatic hydrocarbons compared with naphthenes. Under these conditions, an increase of contact time increases, like the increase of temperature, the contribution of the dealkylation reaction with formation of benzene and toluene. The dimers are aromatised much faster on the dehydrogenating catalyst centres than on the acid centres. However, the latter are also necessary, because, according to the author[9], five-membered naphthenes isomerise to six-membered naphthenes on such centres.

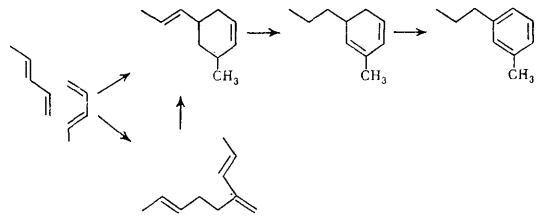
The fourth stage—isomerisation, transalkylation, and dealkylation of primary aromatic hydrocarbons—is accelerated, as noted above, by an increase of the reaction temperature, an increase of contact time, and finally by the acid catalyst centres. As a result of the reactions enumerated above, the n-butane catalytic reaction mixture contains the majority of the possible C_6–C_{10} aromatic hydrocarbons.

With increase of temperature, the cracking and coke forming reactions are accelerated simultaneously. The composition of the butene conversion products suggested[9] that C_3 and C_5 hydrocarbons are formed via the mechanism

$$2C_4H_8 \rightarrow C_8H_{16} \rightarrow C_5H_{10} + C_3H_6 .$$

Above 500 °C, direct cracking of butenes takes place with an appreciable yield:

$$C_4 \rightarrow CH_4 + C_3 \quad \text{or} \quad C_4 \rightarrow 2C_2 .$$



As a result, the following general mechanism has been suggested[10] for the conversion of butanes into aromatic hydrocarbons:

$$\begin{array}{ccccc} C_4H_{10} & \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} & C_4H_8 & \underset{k_{-2}}{\overset{k_2}{\rightleftarrows}} & C_8H_{16} \xrightarrow{k_3} C_6H_4(CH_3)_2 \\ \downarrow k_4 & & & & \downarrow k_5 \\ C_3 + CH_4 & & & & C_3 + C_5 \end{array} .$$

Depending on the rate constant ratios for the above reactions, one or other pathway predominates. It follows from the results that the best catalyst of the dehydrocyclodimerisation of alkanes should have the following properties[10]: (a) it should accelerate the dehydrogenation of alkanes more than the dimerisation of olefins on the acid component ($k_1 > k_2$); (b) it should lead to the aromatisation of the dimers on the dehydrogenating component being much faster than cracking and faster than the dimerisation of the acid component: $k_5 \ll k_3 \gg k_{-2}$; $k_3 > k_2$. The formation of dimers and trimers has also been noted[7] in the dehydrocyclodimerisation of n-pentane. The curve relating the yield of aromatic hydrocarbons to the number of carbon atoms has three maxima: for aromatic hydrocarbons containing 7, 10, and 15 carbon atoms (Fig.5).

The dehydrodimerisation of propene and butadiene over the MoO_3–SiO_2 and WO_3–SiO_2 catalysts has been described[29]. These catalysts exhibited a comparatively high activity in the aromatisation of propene. Thus the selectivity in relation to C_6–C_8 aromatic hydrocarbons reached 33% on the MoO_3–SiO_2 catalyst (treated with HCl) for a propene conversion of 71.4%.

The recently published studies[30,31] whose authors investigated the mechanism of dehydrocyclodimerisation and certain other reactions of piperylene in the presence of modified alumina are of undoubted interest. It was shown that piperylene is converted into n-pentenes as well as alkenylcyclohexenes, C_6–C_9 aromatic hydrocarbons and alkenyl and alkyl derivatives of aromatic C_{10} hydrocarbons on $Al_2O_3.K_2O$ at 500 °C:

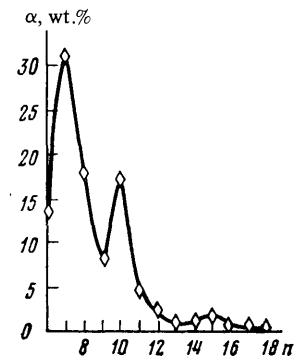


Figure 5. The proportions of aromatic hydrocarbons with different numbers of carbon atoms obtained in the dehydrocyclodimerisation of n-pentane on Pt/Al_2O_3 at 560 °C and for a space velocity of 1.1 h^{-1} (Csicsery[7]); a = overall degree of aromatisation; n = number of carbon atoms in aromatic hydrocarbons.

The activities and selectivities of various oxide catalysts in the dehydrocyclodimerisation of isobutene to *p*-xylene in the non-oxidative version of the reaction have been studied in greatest detail by Japanese workers. Thus the influence of the carrier on the kinetics and mechanism of the vapour-phase dehydrocyclodimerisation of isobutene to xylene over vanadium pentoxide has been studied[32]:

$$2CH_2{=}C\begin{matrix}CH_3\\CH_3\end{matrix} \rightarrow CH_3{-}C_6H_4{-}CH_3 + 3H_2 .$$

In the range 600–800 K at atmospheric pressure the equilibrium constant of this reaction is 4.0–5.4, which corresponds to the equilibrium isobutene conversion in the range 97–100%, i.e. as stated above, the reaction is not limited by the thermodynamic equilibrium.

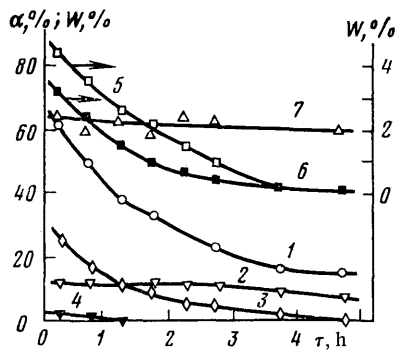
Together with V_2O_5, the following metal oxides have been used as the active phase: Cr_2O_3, MoO_3, Fe_2O_3, WO_3, and Nb_2O_5 deposited on Al_2O_3 in the atomic proportions M : Al ≅

1 : 19, where M is the metal. Apart from Al_2O_3, the carriers used consisted of SiO_2, Ti_2O_3, MgO, and activated carbon. Data concerning the influence of the nature of the carrier on the catalytic properties of various vanadium oxide catalysts in the dehydrocyclodimerisation of isobutene are presented in Table 1. The V_2O_5/Al_2O_3 catalyst showed the greatest activity under these conditions (at 550 °C the yield of xylene was 27.4% for a selectivity of 54.5%).

Table 1. The influence of the nature of the carrier on the activity and selectivity of vanadium oxide catalysts[32].

Carrier	Conversion, %	Selectivity, %			Yield, %	
		toluene	*p*-xylene	*m*-xylene	iso-octane	n-butane
Al_2O_3 *	49.4	3.2	22.7	31.8	12.0	4.8
SiO_2	25.1	4.0	53.4	5.2	6.5	3.5
MgO	10.8	—	73.2	—	3.0	0.8
Carbon	44.7	2.9	36.9	traces	18.8	—
TiO_2	—	—	—	—	—	—

*Selectivity with respect to benzene 0.6%; yield of *o*-xylene—traces.



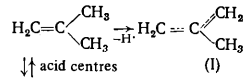


Figure 6. Variation of the degree of conversion α of isobutene (curve *1*) and the yields *W* of *p*-xylene (curve *2*), *m*-xylene (curve *3*), o-xylene (curve *4*), but-2-ene (curve *5*), and but-1-ene (curve *6*) as well as the selectivity in the formation of xylenes (curve *7*) in the presence of the V_2O_5/Al_2O_3 catalyst at 550 °C as a function of the duration of the experiment[32].

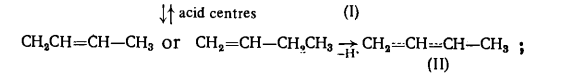
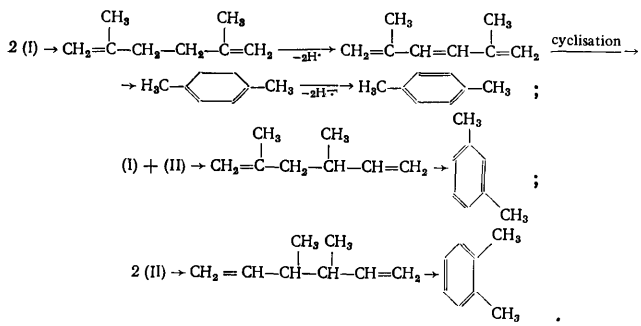


It was established that the catalytic properties of the V_2O_5/Al_2O_3 catalyst change rapidly with time (Fig.6). Thus the *m*- and *o*-xylenes formed in the first hours of the test subsequently disappear and *p*-xylene remains the dominant isomer. The yield of n-butene, formed as a result of the isomerisation of isobutene, also decreases similarly with time, the selectivity of the aromatisation remaining at the same level. Completely different results were obtained in a test of the V_2O_5/MgO catalyst: during the first two hours, the selectivity of the formation of xylene increases from 40 to 75% and remains subsequently at a constant level, the degree of conversion varying only slightly with time and remaining at the level of 10–15%. Skeletal isomerisation does not occur over the catalyst and the only reaction product is *p*-xylene.



The study of the above oxide carriers for V_2O_5 made it possible to divide them into three groups: (a) aluminium and silicon oxides on which all the xylenes as well as small amounts of benzene and toluene are formed; (b) magnesium oxide and activated charcoal on which only *p*-xylene is formed; (c) titanium dioxide on which an inactive catalyst is obtained.

The virtual absence of the isomerisation of xylenes on the V_2O_5/Al_2O_3 specimens shows that *m*- and *o*-xylenes are not formed as a result of the reactions of *p*-xylene but apparently arise from a parallel reaction involving the isomerisation of isobutene to n-butene and the subsequent dehydrocyclodimerisation of the latter.

A mechanism of the dehydrocyclodimerisation of isobutene has been proposed[32], according to which *p*-xylene is formed via 2,5-dimethylhexa-1,5-diene on V^{3+} centres without the involvement of acid centres; at the same time *m*- and *o*-xylenes are formed on acid centres via 2,4- and 3,4-dimethylhexa-1,5-dienes:

The formation of 2,5-dimethylhexa-1,5-diene and *p*-xylene has been established experimentally. It has been suggested that the intermediates in the formation of *m*- and *o*-xylenes are 2-methylhepta-1,5-diene and octa-2,6-diene. It has been found that in the presence of V_2O_5/MgO the kinetic order of the reaction involving the formation of *p*-xylene is 1.1 with respect to the initial isobutene; the activation energy is 31.4 kJ mol^{-1}. It has been suggested that the rate-limiting stage in the formation of *p*-xylene is apparently the interaction of two adsorbed isobutyl radicals (I).

III. DEHYDROCYCLOTRIMERISATION OF ETHYLENE AND ETHANE TO BENZENE AND OTHER AROMATIC HYDROCARBONS

Together with the dehydrocyclodimerisation of C_3–C_5 olefins and alkanes, the catalytic dehydrocyclotrimerisation of ethylene and ethane with formation of benzene and other aromatic hydrocarbons[11–15,33–35], which has been described comparatively recently, is of undoubted interest. It was shown initially[11,12] that the cyclotrimerisation of ethylene takes place successfully in the presence of Pt/Al_2O_3 in the range 500–670 °C. Subsequently, in the study of catalysts containing other Group VIII metals it was observed that rhodium, ruthenium, iridium, and palladium deposited on alumina (0.5–0.6% of the metal) also catalyse this reaction successfully. In contrast to Pt/Al_2O_3, the cyclotrimerisation of ethylene on these catalysts proceeds at lower temperatures

with appearance of benzene in the reaction products in the presence of the Ru–Ir catalysts already at 450 °C and at 350 °C in the presence of the Rh catalyst.

Thermodynamic calculation showed that the cyclo-oligomerisation of lower olefins, including ethylene, can occur over a fairly wide temperature range[12]. Indeed the equilibrium in the ethylene–benzene system in the range from room temperature to 700 °C and above is almost entirely displaced towards the formation of benzene. Here one should note that the content of benzene in the equilibrium mixture decreases somewhat with increase of temperature. The dehydrocyclo-oligomerisation of other lower hydrocarbons is also thermodynamically feasible over a wide temperature range. Indeed the thermodynamic equilibrium in propene–benzene mixtures at 150–700 °C and in propane–benzene mixtures at 450–700 °C is appreciably displaced towards the formation of benzene. Thus, in the above temperature ranges, the cyclotrimerisation of ethylene as well as the cyclodimerisation of propene and propane are thermodynamically favourable. As regards ethane, its actual aromatisation requires a temperature of ~500 °C. The possibility of the aromatisation of ethane in the presence of platinum and palladium catalysts was demonstrated experimentally by the present author[35].

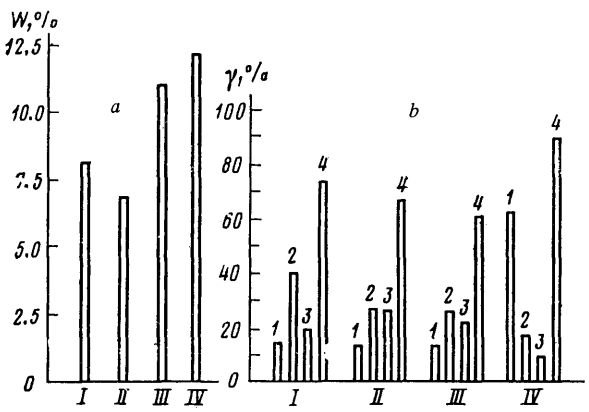


Figure 7. Comparison of the yields (*a*) and selectivities (*b*) in the formation of aromatic hydrocarbons in the presence of a series of catalysts [I) Al_2O_3.F; II) Ru/Al_2O_3.F; III) Pt/Al_2O_3 (AP-56); IV) Rh/Al_2D_3.F] in the cyclotrimerisation of ethylene: 1) benzene; 2) toluene; 3) xylenes; 4) the sum of aromatic C_6–C_8 hydrocarbons; W = overall yield of catalytic reaction products relative to C_2H_4 passed through the system; γ = fraction of aromatic hydrocarbons in the catalytic reaction mixture.

In the course of the study of the cyclotrimerisation of ethylene by a pulsed microcatalytic method platinum/alumina catalysts modified in different ways have been studied in greatest detail[12]. The specimen treated with nitric acid in the course of its preparation proved to be a relatively more active and "low-temperature" catalyst. The yield of aromatic hydrocarbons in its presence reached 9–11% relative to the ethylene passed through the system and 10–14% relative to the ethylene which has reacted. As mentioned above, other Group VIII metals deposited on alumina also exhibited a catalytic activity in the above reaction. The results obtained in the presence of rhodium, ruthenium, and iridium catalysts have been published by Bragin et al.[33] In the course of the application of the first three–four ethylene pulses an increase of the activity of the catalyst was observed; after a definite initiation period the catalytic activity remained close to the maximum in the course of several pulses and then gradually fell.

It has been shown[33,35] that in the presence of M/Al_2O_3 (M = Pt, Ru, Pd, or Ir) catalysts not only ethylene but also ethane undergoes dehydrocyclotrimerisation in the range 550–650 °C with formation of benzene and its homologues. However, the reaction proceeds with somewhat lower degrees of conversion than for ethylene.

The above data refer to the study of the cyclotrimerisation of ethylene under pulsed conditions. Catalysts exhibiting a comparatively high activity and selectivity have also been studied under the conditions of a flow system. Fig.7 presents data[14] referring to the most interesting metal/alumina catalysts. In terms of activity and selectivity, the rhodium- and platinum-containing catalysts proved to be the most effective. The yield of aromatic hydrocarbons in the flow system relative to reacted ethylene reached 18–22%. The presence of C_3–C_6 olefins in the catalytic reaction mixture is striking. It is noteworthy that, in the presence of the rhodium catalyst, cyclotrimerisation takes place at a temperature lower by 80–100 K than on other catalysts; the Rh/Al_2O_3 catalyst has yet another important quality—it exhibits the highest selectivity with respect to the formation of benzene.

It follows from the results of Bragin et al.[14] that in the presence of the 0.6% Rh/Al_2O_3 catalyst the benzene content in the catalytic reaction mixture was 63% and the sum of C_6–C_8 aromatic hydrocarbons was 91%. Specimens with another rhodium content are somewhat less active and are less selective by a factor of 1.5 with respect to the formation of benzene. Nevertheless they are 3–8 times more selective than other metal/alumina systems and Al_2O_3 itself. The distinctive properties of rhodium catalysts discussed above are apparently primarily related to the catalytic properties of rhodium itself, because it is well known that rhodium-containing catalysts are widely used for the demethylation of alkylbenzenes to benzene.

A rhodium/alumina catalyst with a relatively high catalytic activity has been studied by X-ray photoelectron spectroscopy[13]. The state of the metal in the Rh/Al_2O_3 specimen containing 3.5 wt.% of rhodium was investigated as a function of the conditions of the preliminary treatment and the catalytic reaction. It was established that the spectroscopic characteristics of rhodium in the initial non-reduced specimens and in catalysts after oxidative regeneration correspond to the Rh^{3+} state. In the latter case line broadening was observed, which apparently indicates a stronger interaction of rhodium with the carrier.

When the catalyst is treated with hydrogen and also in a hydrocarbon medium, Rh^{3+} is almost completely reduced to zerovalent rhodium. This transition is accompanied by a shift of the spectrum towards lower energies by 3 eV. It has also been noted that the spectrum of reduced rhodium is somewhat broadened compared with that of metallic foil. An important factor is the positive charge observed in the Rh–Al_2O_3 system, appearing when the catalyst interacts with ethylene and its reaction products. It was noted that, under the influence of the reaction medium, the rhodium catalyst is activated in the dehydrocyclotrimerisation of ethylene and that the electronic state of rhodium is then altered. In the course of the activation of the catalyst a positive charge arises on the Rh clusters (formally rhodium passes to the +1 oxidation state); the subsequent decrease of the catalytic activity is accompanied by the return of rhodium to a nearly zerovalent state.

Comparison of the results presented above with the literature data suggested that under certain conditions ethylene can be converted into aromatic hydrocarbons not only in the presence of metal/alumina catalysts but also on alumina itself. Indeed experimental data[33] confirmed this hypothesis. Experiments performed on different γ-Al_2O_3 specimens with different specific activities and also on specimens with and without halogen showed that the cyclotrimerisation of ethylene takes place successfully in the range 500–650 °C. The yield of aromatic hydrocarbons on catalysts with a high acidity is then appreciably higher, which is consistent with the results of a study[23] devoted to the aromatisation of propene in the presence of alumina. Apart from aromatic hydrocarbons, considerable amounts (>25%) of unsaturated aliphatic C_3–C_6 hydrocarbons were detected in the ethylene catalytic reaction mixture. This finding is important for the understanding of the mechanism of the cyclo-oligomerisation of ethylene in the presence of alumina and the above metal oxide catalysts. Studies performed with different alumina specimens free from metal showed that, under the conditions of a flow system, the best results are obtained at 550 °C in the presence of the γ-Al_2O_3 specimen containing 3.4% of fluorine and having a specific surface of 180 $m^2\ g^{-1}$.[33]

The problems of the stability and regeneration of catalysts of the cyclotrimerisation of ethylene merit special attention. An attempt has been made[14] to obtain certain data on the stability of catalysts in a flow system and to determine the conditions for their regeneration. It has been observed that treatment of the catalyst with air for 2 h at 400–450 °C restores its initial activity and selectivity. The catalyst treated periodically in this way after being used for 4–5 h retains its initial activity in the course of 20–30 h. However, it was noted that not all the catalysts investigated are sufficiently stable. Thus the Rh/Al_2O_3 and Pt/Al_2O_3 catalysts are the most stable, while Al_2O_3 itself and Ru/Al_2O_3 are much less stable and somewhat less active after regeneration. The mechanism of the regeneration of catalysts of the cyclotrimerisation of ethylene is so far obscure, but, in conformity with the literature[14,36], one can assume that the regeneration of the metal/alumina catalysts with air consists in burning off and removing from their active surfaces carbon deposits formed on the catalyst in contact with ethylene at 450–550 °C. However, one cannot rule out the possibility that the regeneration of the metal oxide catalyst with air is also associated with a change in the valence state of the active metallic phase.

The mechanism of the formation of aromatic hydrocarbons from ethylene is apparently fairly complex. One of the possible variants is a two-dimensional termolecular reaction on the surface of the catalyst in which a single benzene molecule is formed from three ethylene molecules. An alternative pathway is one in which the formation of aromatic hydrocarbons is preceded by a series of preliminary stages and the cyclotrimerisation reaction is a complex consecutive process. The final answer to these questions is as yet impossible, although the results obtained already constitute definite evidence in support of the second pathway.

The first indication of the course of the reaction is provided by the set of products, indicated above, formed as a result of the cyclotrimerisation of ethylene. Virtually all the catalytic reaction mixtures contain propene and C_4–C_6 aliphatic hydrocarbons; the amount of the latter increases with temperature and with increase of contact time, which is particularly notable on passing from a pulsed to a flow system. Special series of experiments with the initial propene showed that propene is one of the possible intermediates in the aromatisation of ethylene. The yield of aromatic hydrocarbons increased by a factor of ~1.5 when ethylene was replaced by propene[12]. A still more distinctive picture was obtained in a study of the cyclo-oligomerisation of ethylene–butene mixtures (Fig.8) containing 0, 12.5, 25, 50, and 100% of butene in the presence of platinum on fluorinated alumina as the catalyst.

Fig.8 shows that initially the yield of aromatic hydrocarbons, in the first place benzene and toluene, increases appreciable when ethylene is partly replaced by butene, which shows that the formation of butene is apparently an intermediate stage in the cyclotrimerisation of ethylene. The extremum in the dependence of the yields of benzene and toluene on the composition of the reacting gas is consistent with this hypothesis. Presumably, when butene greatly predominates in the initial gaseous mixture, it is converted mainly into xylenes and hydrocarbons with higher molecular weights.

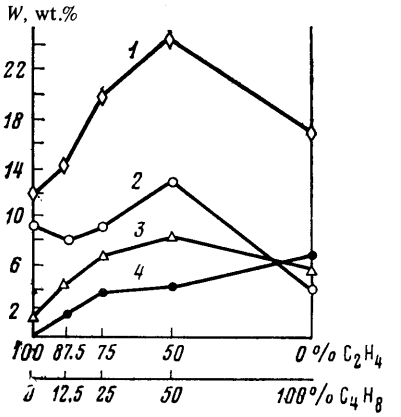

Figure 8. The results of the dehydrocyclo-oligomerisation of ethylene, butene, and their mixtures in the presence of 0.6% Pt/Al_2O_3.F at 559 °C: 1) the overall yield W of aromatic C_6–C_8 hydrocarbons; 2) benzene; 3) toluene; 4) xylenes.

Thus the results support the hypothesis of the preliminary linear oligomerisation of ethylene with formation of C_6 and higher fragments, which is followed by their cyclisation and aromatisation. The proposed mechanism of the cyclotrimerisation of ethylene is also supported by the results obtained independently in a study of the interaction of hydrocarbons with different structures on the surface of fluorinated Al_2O_3 with the aid of diffuse reflectance spectra[37]. Al_2O_3.F, which the present author used previously both as an independent catalyst and as a carrier for various metal/alumina catalysts (M = Pt, Rh, and others) in the cyclotrimerisation of ethylene, was applied. The nature of the spectra and particularly the appearance of a band in the region of 354 nm lead to the hypothesis that surface compounds with conjugated double bonds are formed on alumina. This hypothesis is consistent with the dimerisation of lower olefins on the Al_2O_3 surface with simultaneous evolution of hydrogen known from the literature[38]. These data can be accounted for by the formation of a linear dienyl carbonium ion on the surface; for example, in the case of propene we have

$$H_2C=CH-CH_3+CH_3-CH=CH_2 \rightarrow H_2C=CH-\overset{+}{C}H-CH_2-CH= \\ =CH_2+\bar{H}+H_2\ .$$

The above results permit the conclusion that linear and cyclic oligomerisation of lower olefins, preceding their aromatisation, take place on the surface of Al_2O_3 and even

more so on metal/alumina catalysts. According to this concept, one can assume that the cyclotrimerisation of ethylene consists of a series of consecutive reactions; one of these is the formation of butene and also propene, which undergo oligomerisation, codimerisation, C_5- and C_6-cyclisation, cracking, disproportionation, etc. At the same time one must emphasise that all the above evidence in support of the consecutive ethylene cyclotrimerisation mechanism does not rule out other reaction pathways which apparently make a smaller contribution to the overall ethylene aromatisation process under the conditions which we investigated. The C_6-dehydrocyclisation of long-chain ethylene oligomers formed in the course of the reaction as well as the termolecular catalytic formation of benzene from ethylene, already mentioned above, may be indicated as possible parallel pathways.

Depending on the experimental conditions (and in the first place on the catalyst used), the benzene and its homologues formed in the cyclotrimerisation of ethylene can undergo further reactions For example, a proportion of the toluene and xylenes detected in the catalytic reaction mixture are obtained by the methylation of benzene. The latter can be obtained in its turn by the catalytic demethylation of toluene and xylenes. This possibility has been tested[13] in relation to the platinum and rhodium catalysts as well as Al_2O_3.F and has been confirmed experimentally.

At the same time one can put forward certain considerations also concerning cyclotrimerisation catalysts. As shown above, metal/alumina catalysts, and in the first place those containing platinum and rhodium, proved to be the most effective. The results obtained, and particularly the occurrence of cyclotrimerisation on the surface of alumina itself, indicate a significant influence of the carrier on specific stages of the reaction. Indeed, on the basis of studies of both catalytic and spectroscopic properties of Al_2O_3, one can postulate that the dimerisation and oligomerisation of lower olefins proceed mainly on the acid centres of alumina. These centres are apparently responsible for isomerisation, polymerisation, and also may be partially responsible for coke formation.

Table 2. The results of the conversion of propene on various metal phosphate catalysts.[41]

Catalyst	Conversion of propene (%) with formation of different products		
	CO_2	C_3H_4O	C_6H_6
$Ca_3(PO_4)_2$	17.1	0	0
$CrPO_4$	5.2	0	0
$FePO_4$	31.9	8.5	0
$Co_3(PO_4)_2$	4.8	0	0

*Obtained at a high temperature.
**A type of monazite.

It is known that, when fluorine is introduced into Al_2O_3, the catalytic activity of the latter increases in a whole series of reactions, which is as a rule attributed to the appearance of strong protic centres on the Al_2O_3 surface[39]. It is also known that Al_2O_3 (particularly "acid" alumina) exhibits an appreciable catalytic activity in the cyclisation of olefins and dienes with formation of the corresponding cyclanes and cyclenes. Furthermore, Al_2O_3 is also a dehydrogenating agent albeit a relatively weak one. The dehydrogenation reaction on Al_2O_3 is apparently associated with its aprotic centres, capable of abstracting H atoms from the hydrocarbon molecule. The trienes formed as a result of the consecutive dehydrogenation can then undergo further thermal cyclisation.

At the same time the main dehydrogenating component in the metal/alumina catalysts used is undoubtedly the metal and in the first place platinum. Evidently vigorous dehydrogenation of olefins to dienes and of cyclenes to aromatic hydrocarbons respectively takes place on metallic centres. Furthermore, the metallic centres of the catalyst promote a more far-reaching and more selective dehydrocyclisation. The introduction of a metal (platinum and particularly rhodium) into the catalyst increases the hydrocracking properties of the latter. This is apparently the reason (the formation of smaller "fragments" from aliphatic compounds and dealkylation of alkyl- and polyalkyl-benzenes among aromatic hydrocarbons) why the selectivity of the reaction with respect to the formation of benzene and toluene increases appreciably.

IV. OXIDATIVE DEHYDROCYCLODIMERISATION OF LOWER OLEFINS AND ALKANES

This section deals with the second type of dehydroaromatisation of lower olefins and alkanes—the oxidative version with participation of atmospheric oxygen or oxygen forming part of the catalyst. Various compounds, particularly bismuth phosphate, arsenate, and antimonate, as well as the binary mixture of the oxides Bi_2O_3 and SnO_2 are used as catalysts of the oxidative dehydroaromatisation of olefins in the presence of oxygen[40-42]. Instead of the last oxide, one can also use magnesium, titanium, chromium, manganese, iron, cobalt, nickel, copper, zinc, arsenic, zirconium, niobium, silver, silicon, or lead oxides[41,43]. Alkali metal compounds in the form of oxides, hydroxides, or weak acid salts are used as promoting agents. The above oxides can also be employed as deposited catalysts on alumina, carborundum, silica, pumice, graphite, etc. as carriers.

Oxygen-containing and aromatic compounds are formed in the oxidative catalytic dehydroaromatisation of olefins with participation of oxygen in the range 300–600 °C. Propene is then converted into acrolein and benzene; this is accompanied by the formation of CO_2 as well as small amounts of CO, acetaldehyde, and hexa-1,5-diene. Butene gives rise to 2,5-dimethylhexa-1,5-diene, CO, and CO_2; isobutene and butadiene are converted mainly into *p*-xylene.

The oxidative dehydrodimerisation and aromatisation reactions have been used successfully not only in reactions involving olefins but also in those with their functional derivatives, particularly halogenoalkanes, unsaturated amines, cyanides, and alcohols[44]. The reactions can occur in both oxidising and reducing media. The process is usually carried out in a reducing medium when the required products are olefin dimers. We may note that, with increase of the partial pressure of oxygen in the mixture of reacting compounds, the selectivity in the formation of linear and cyclic olefin dimers is appreciably reduced.

The dehydroaromatisation of propene has been studied[41] in the presence of various metal phosphates. Table 2 presents the results of these experiments carried out at 500 °C with a mixture of 9% of propene 18% of oxygen. It is seen from the data in Table 2 that the activities of various phosphates differ markedly. The highest degrees of conversion of propene were achieved in the presence of Bi^{3+} ions. The maximum

yield of aromatic hydrocarbons was reached for the Bi:P = 2:1 ratio; at 500 °C and for the oxygen:propene ≅ 2:1 ratio, ~36% of propene is converted into benzene.

Different temperatures and catalysts apparently have different effects on the selectivity of the reaction. Thus at 300–450 °C in the presence of bismuth arsenate and basic bismuth sulphate, propene gives rise mainly to acrolein while in the range 400–550 °C benzene predominates. Bismuth phosphate, arsenate, and antimonate as well as bismuth titanate and sulphate exhibit a relatively high selectivity with respect to the formation of benzene, while bismuth molybdate is more selective in the reaction involving the conversion of propene into acrolein.

The influence of basic promoting agents on the catalytic properties of tin oxide is significant in the oxidative dehydroaromatisation of propene. Thus oxides with basic properties increase the yield of benzene, while modification of the catalysts by acid oxides favours the formation of acrolein with a simultaneous decrease of the overall activity. The influence of various oxide additives on the catalytic activity of tin oxide in the oxidative dehydroaromatisation of propene at 550 °C has been studied[41].

The study of binary oxide systems such as $Bi_2O_3 + P_2O_5$, $Bi_2O_3 + As_2O_5$, and $Bi_2O_3 + TiO_2$ showed[41] that weakly acid catalysts promote the formation of benzene, while strongly acid catalysts promote the formation of acrolein. The latter include, for example, bismuth molybdate. The following mechanism of the aromatisation of propene has been proposed for the bismuth phosphate catalytic system[40]:

$$2CH_3{=}CH{-}CH_3 \xrightarrow[-2H]{} \underset{(A)}{2CH_2{=}CH{-}CH_2} \xrightarrow[-4H]{} C_6H_6 ,$$

where (A) is an intermediate π-allyl complex. This mechanism is consistent with data[45–47] according to which acrolein and hexa-1,5-diene are also formed (from propene on the acid Bi–P catalyst, Cu_2O, and Ag) via an intermediate π-allyl complex adsorbed on the surfaces of the above catalyst.

The oxidative dehydroaromatisation and dimerisation of propene have also been investigated in other studies[48,49]. The conditions for the dimerisation and aromatisation of propene and isobutene in the presence of the In_2O_3/pumice catalyst in the range 440–550 °C have been described[48] and it has been shown[49] that the dehydrodimerisation of propene to diallyl on lead oxides depends on the composition of the reaction mixture and takes place in a reducing medium. In a reducing medium lead oxides are unstable and they are reduced during the period of the experiment. The reduction of the oxide has a positive effect on the process selectivity. The highest selectivity is shown by the catalyst consisting of PbO and metallic lead in the stationary state.

The metal oxides investigated in the oxidation reactions of lower olefins have been divided[43,50] into four conventional groups. They are represented below by series with decreasing activities:

(1) oxides favouring the formation of acrolein:

$$MoO_3 > Sb_2O_3 > V_2O_5 > TiO_2 = Fe_2O_3 > SiO_2 > WO_3, Al_2O_3;$$

(2) oxides favouring the formation of benzene or hexa-1,5-diene:

$$ZnO > Bi_2O_3 > In_2O_3 > SnO_2 > CdO;$$

(3) oxides favouring the formation of CO_2:

$$CuO = Co_3O_4 > NiO > Cr_2O_3 > MnO_2 = GeO_2;$$

(4) oxides weakly favouring the formation of CO_2:

$$CaO, MgO\ GeO_2, PbO_4, Te_2O_3.$$

Within the framework of this classification, it was noted that the majority of the oxides of the first and second groups are *n*-type semiconductors, while those in the third group are *p*-type semiconductors.

The $Bi_2O_3–Al_2O_3$ catalyst mainly promotes the linear dimerisation of propene and isobutene at 540 °C; the addition of $Cr_2O_3–Al_2O_3$ to the above catalyst promotes the dehydrocyclisation of the dimers formed initially, giving rise to aromatic hydrocarbons. The oxidative dehydrocyclodimerisation of propene to benzene on the following catalysts has also been described: $Bi_2O_3–ZnO$, $Bi_2O_3–WO_3$, and $Bi(SnO_3)_3$. It was assumed[43] that hexa-1,5-diene and cyclohexa-1,3-diene are intermediates in the reaction.

Trimm and coworkers[51–53] described the reactions of propene and isobutene in the presence of indium and thallium oxides. In the presence of the above catalysts, propene is converted into acrolein, hexa-1,5-diene, benzene, and carbon dioxide, while methacroleine, 2,5-dimethylhexa-1,5-diene, *p*-xylene, benzene, toluene, traces of *o*- and *m*-xylenes, and carbon dioxide are formed from isobutene. According to the authors[51–53], benzene and toluene are secondary xylene conversion products. The selectivity in the formation of aromatic hydrocarbons hardly changed with increase of temperature from 480° to 530 °C; at the same time the selectivity in the formation of 2,5-dimethylhexa-1,5-diene increased appreciably under these conditions. The yield of aromatic hydrocarbons can be increased by modifying the catalysts with indium and thallium oxides (already mentioned) or by cyclising the diene formed initially in an additional reactor in the presence of a dehydrocyclising catalyst, for example, chromium oxide.

The study of the reactions of propene and isobutene in the presence of indium oxide in the range 420–500 °C for different ratios of the initial olefin and oxygen showed[52,53] that the proportions of the reaction products depend significantly on the ratio of the hydrocarbon and oxygen. The maximum yield of benzene and hexadiene from propene is attained for the molar ratio $O_2 : C_3H_6 \cong 0.2–0.3$. It has been suggested that hexa-1,5-diene can be formed both on the catalyst surface and in the gas phase at a higher temperature. It has been shown that acrolein and hexadiene inhibit the dehydrocyclodimerisation reaction, while benzene does not have an appreciable influence on the reactions of propene. These findings support the view that the adsorption of propene, acrolein, and hexadiene apparently takes place on centres of the same type, while the dehydrocyclisation of hexadiene to benzene occurs on centres of another type[54]. It has been shown[52,53] that the toluene and benzene formed in the reaction of isobutene are the products of the subsequent transformations of dimethylhexadiene and *p*-xylene. The kinetics of the formation of diene and *p*-xylene in the range 460° to 495 °C have been investigated and virtually identical activation energies, amounting to 126–130 kJ mol^{-1}, have been obtained.

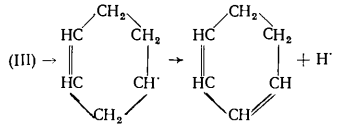
It has been established experimentally[52] that hexadiene and acrolein are the primary reaction products in the formation of benzene and carbon dioxide respectively from propene. According to the authors[52], the above reactions can be described overall by the following stoichiometric equations:

$$2CH_3{-}CH{=}CH_2 + 1/2O_2 \rightarrow CH_2{=}CHCH_2CH_2CH{=}CH_2 + H_2O,$$
$$CH_2{=}CHCH_2CH_2CH{=}CH_2 + O_2 \rightarrow C_6H_6 + 2H_2O,$$
$$CH_3CH{=}CH_2 + O_2 \rightarrow CH_2{=}CH{-}CHO + H_2O.$$

The oxidative dehydrodimerisation of isobutene in the presence of indium oxide proceeds, according to Parera and Trimm[53], with formation of an intermediate π-allyl complex, which dimerises to a diolefin with subsequent cyclisation and aromatisation.

The oxidative dimerisation of propene in the presence of bismuth oxide without the supply of oxygen to the reaction mixture has been studied[55]. The starting materials was a mixture of propene and nitrogen in molar proportions of 2 : 1 at an experimental temperature of 475–560 °C. An increase of temperature entails a decrease of selectivity with respect to hexa-1,5-diene and an increase of selectivity with respect to benzene and CO_2. The hypothetical pathways leading to the formation of hexa-1,5-diene and acrolein from propene have been studied using bismuth oxide and molybdate as oxidants[56]. The authors concluded that bismuth oxide forms surface complexes with propene, which then decompose to hexa-1,5-diene and bismuth compounds.

It has been suggested[55] that propene interacts directly with the oxygen of the crystal lattice of the oxide with formation of water and the reduction of the oxide to the metal. The overall equation is as follows:



$$2CH_2=CHCH_3+1/2O_2\rightarrow CH_2=CHCH_2CH_2CH=CH_2+H_2O$$

or

$$6C_3H_5\,(g)+Bi_2O_3\rightarrow 3C_6H_{10}\,(g)+2Bi\,(s)+3H_2O\,(g)\,.$$

According to the authors[55], the first stage consists in the formation of a C_3 allyl radical, which then interacts with the oxygen of the lattice after being adsorbed; the subsequent stage involving the dehydrocyclisation of hexa-1,5-diene to cyclodiene takes place with formation of C_6 radicals, which exists in forms (III) and (IV):

$$\underset{\text{(III)}}{CH_2=CH-CH_2-\dot{C}H-CH=CH_2} \rightleftarrows \underset{\text{(IV)}}{\dot{C}H_2-CH=CHCH_2CH=CH_2}\ ;$$

An alternative pathway leading to the formation of hexa-1,5-diene was studied at the same time, taking into account the possibility of the formation of allyl radicals in the pyrolysis of propene. Here two variants are possible (a) the interaction of two allyl radicals on the surface or in the gas phase with formation of hexa-1,5-diene ($2CH_2=CH-\dot{C}H_2 \rightarrow CH_2=CH-CH_2CH_2CH=CH_2$) and (b) the interaction of the allyl radical with propene involving the loss of hydrogen and formation of n-hexenyl or isohexenyl radicals, which then cyclise to methylcyclopentene:

$$CH_2=CH-\dot{C}H_2+CH_2=CH-CH_3\rightarrow\begin{cases}\rightarrow CH_2=CH-CH_2-CH_2-\dot{C}H-CH_3\\ \rightarrow CH_2=CH-CH_2-\underset{CH_3}{CH}-\dot{C}H_2\end{cases}.$$

Analysis of the reaction products enabled the authors[55] to exclude the latter variant of the formation of hexa-1,5-diene, where the allyl radicals adds directly to the propene.

The catalysts of the oxidative dehydroaromatisation of lower olefins (bismuth phosphates) have been studied by X-ray diffraction after their reduction by propene.[57] The main propene reaction products on these catalysts are the same as for the reaction of propene in the presence of oxygen; benzene was obtained in a yield of ~20%. The study of the catalysts showed that after reduction the specimens consist of a mixture of metallic bismuth and bismuth phosphate ($BiPO_4$).

The oxidative dehydrodimerisation and aromatisation of propene in the presence of the individual oxides SnO_2 and Bi_2O_3 as well as the binary oxide system SnO_2–Bi_2O_3 have been recently described[58,59]. The experiments were performed in the absence of oxygen from the gas phase and the oxidative reactions of the hydrocarbons occured with participation of the oxygen in the oxide. It was established that Bi_2O_3 promotes the oxidative dimerisation of propene to hexadiene with a low conversion but with a fairly high selectivity. At the same time SnO_2 exhibits an appreciable catalytic activity in the oxidative dimerisation of propene to hexadiene and the subsequent dehydrocyclisation of hexadiene to benzene in the initial stage of the reduction of the surface of the oxide. The addition of small amounts of one oxide to another increases the oxidising capacity of the catalyst.

The mixed oxide with the ratio Bi : Sn ≈ 1 : 1 exhibits the most effective oxidising properties in the propene dehydrodimerisation and aromatisation reactions. Trimm and Doerr[52] discussed a similar mechanism of the oxidative dimerisation of propene on the SnO_2 surface in terms of the mechanism of the dimerisation of propene in the presence of In_2O_3 on the basis of their experimental data.

The results of a study of the oxidative conversion of propene on a series of individual oxides (copper, nickel, vanadium, cobalt, cadmium, zinc, titanium, iron, antimony, tin, indium, and bismuth oxides) and some of their binary mixtures and also on oxide systems promoted by alkali metal compounds and ammonia have been published[20]. All the above oxides with the exception of Sb_2O_3, SnO_2, and Bi_2O_3 exhibit a high selectivity in the extensive oxidation of propene; copper, nickel, vanadium, cobalt, and iron oxides catalyse the above reactions under the conditions investigated with 100% conversion. On cadmium and antimony oxides, the formation of CO and CO_2 was found to be accompanied by the dehydrodimerisation of propene to diallyl, while on indium oxide propene was dehydroaromatised to benzene, as mentioned above. Bi_2O_3 and SnO_2 are active in both reactions.

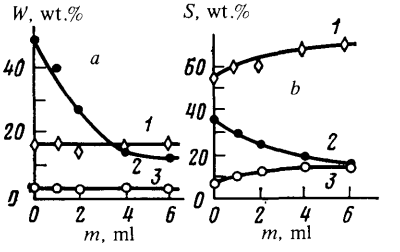


Figure 9. *a*) The influence of the amount of NH_3 (*m*) on the composition of the products (*W*) of the reaction of propene; *b*) the selectivity *S* of the process in the Bi–Ni system at 560 °C; 1) benzene; 2) CO + CO_2; 3) hexa-1,3-diene[20].

In the study of the promoting effect of ammonia and alkali metal compounds on the activity of the bismuth–nickel catalyst it was shown that basic additives appreciably suppress the extensive oxidation reaction and increase the selectivity in the formation of benzene and hexa-1,5-diene. The highest selectivity with respect to benzene is observed when the catalyst is promoted by sodium and rubidium compounds and that with respect to hexa-1,5-diene is attained in the presence of lithium and potassium compounds. Ammonia hardly affects the concentration of benzene and hexa-1,5-diene in the catalytic reaction mixture, but tends to increase appreciably the selectivity in their formation, which rises with increase of the amount of ammonia in the reaction zone with a simultaneous decrease of the amounts of carbon monoxide and dioxide (Fig.9).

Thus it follows from the data presented above that, in the region of the oxidative dimerisation and aromatisation of C_3–C_4 olefins, the reactions of propene and isobutene on indium and bismuth oxides have been studied in greatest detail and most completely and a high activity of the binary oxide catalysts has been discovered. The oxidative conversion of olefins under the conditions of a reducing medium, the influence of promoting additives on the activity of catalysts and the selectivity of their action, and the mechanism of the action of promoting agents have been studied in much less detail.

---o0o---

During the preparation of the review for the press, a series of studies by foreign[60–65] and Soviet[66–70] workers, devoted to the aromatisation of hydrocarbons (including lower hydrocarbons) in the presence of high-silicon ZSM zeolites, were published. The zeolites, which exhibit a high activity and selectivity in the given process, constitute a new promising generation of zeolite-containing catalysts of the reactions of hydrocarbons and many of their functional derivatives.

Cytochrome P-450—An Effective Catalyst of the Oxidation of Organic Compounds by Peroxides

D.I.Metelitsa

Experimental data on the oxidation of organic compounds by peroxides and other oxidants with participation of cytochrome P-450 from different natural sources are described sytematically and critically. The role of cytochrome P-450 in the oxidative dealkylation of *N*-alkylamines and ethers by hydroperoxides and also its involvement in the peroxide oxidation of aromatic compounds, saturated aliphatic acids, steroids, and other substrates is discussed. Attention is concentrated on the comparison of the mechanism of the oxidation of organic compounds in the complete liver enzyme system, incorporating cytochrome P-450, cytochrome P-450 reductase, and phospholipids as well as NADPH and O_2, and the mechanism of the oxidation of organic compounds by hydroperoxides with participation of cytochrome P-450 alone.
The bibliography includes 147 references.

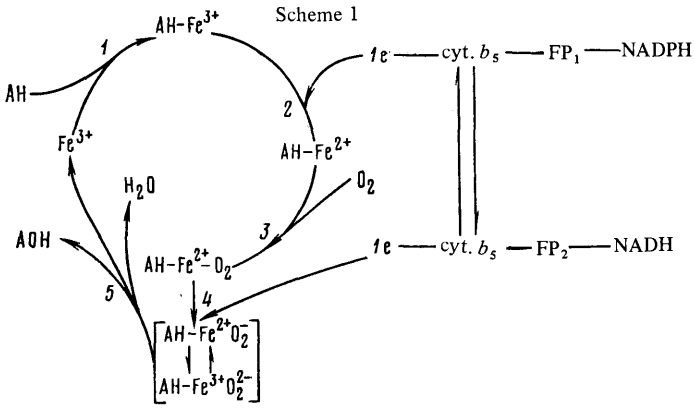
I. INTRODUCTION

In 1978, 20 years elapsed since the discovery by Garfinkel[1] and Klingenberg[2] of a unique haemoprotein—cytochrome P-450. This haemoprotein is widely distributed in nature and is a component of enzyme systems belonging to the class of oxidoreductases which have been called mono-oxygenases or mixed-function oxidases. Three years after the discovery of cytochrome P-450 Mason et al.[3] and Hayashi et al.[4] independently discovered a new type of oxidoreductases which obligatorily require the presence of reduced pyridine-nucleotides (NADPH or NADH) and which oxidise various substrates, inserting one oxygen atom in the latter and reducing the other to water:

$$AH + NADPH + H^+ + O_2 \rightarrow AOH + NADP + H_2O ,$$

where AH is the substrate and AOH the substrate oxidation product. In 1964 Omura and Sato[5,6] established that cytochrome P-450 is a *b*-type haemoprotein and is characterised by an atypical absorption band of the carbonyl complex in the reduced state at 450 nm, which gave rise to the name of the protein.

During two decades, considerable advances have been made in the study of mono-oxygenases, their composition, properties, function, and structure. These achievements have been reflected in monographs, collections of papers, reviews, and conference proceedings[7-16]. It is now well known that enzyme systems containing cytochrome P-450 enter into the composition of the microsomal fraction of human and mammalian liver cells and are responsible for the metabolism of steroids, prostaglandins, and an enormous number of xenobiotics—foreign substances entering the organism from the environment, among which there are carcinogens, medicinal drugs, and other substances. A steroid hydroxylating system, similar in properties to the microsomal hydroxylating system of the liver, is localised in the mitochondria of the adrenal cortex and is responsible for key stages in the biosynthesis of steroid hormones in man and mammals. Many strains of bacteria contain hydroxylating enzyme systems with cytochrome P-450 as the terminal oxidase and are capable of oxidising hydrocarbons, heterocycles, and compounds of other classes.



The microsomal hydroxylating system of the liver has particularly attracted the attention of investigators in connection with the significant role of its functions from the point of view of pharmacologists, toxicologists, specialists in chemical carcinogenesis, biochemists, and biophysicists. The microsomal hydroxylating system of the liver consists of three components, each of which has now been isolated and fairly completely characterised[12]: NADPH-cytochrom P-450 reductase (EC 1.6.2.4.), cytochrome P-450 [aryl 4-monoxygenase] (EC 1.14.14.1), and phospholipids. The steroid hydroxylating system from the mitochondria of the adrenal cortex also consists of three main components: adrenodoxin-reductase (EC 1.6.7.1), ferredoxin (adrenodoxin), and cytochrome P-450. The bacterial camphor hydroxylating system also incorporates three enzymes[8]: putidaredoxin reductase, putidaredoxin, and cytochrome P-450_{cam}†.

The mechanism of the action of all three systems is complex and includes many stages. Scheme I presents the sequence of stages in the enzymatic oxidation in the microsomal liver system proposed by Estabrook et al.[17] The majority of these stages have been studied by the methods of stationary and rapid kinetics[18]. The first stage consists in the interaction of the substrate with the oxidised form of cytochrome P-450. The rate constants for this reaction are high and lie in the range 10^2–10^5 litre mol^{-1} s^{-1}.[18] The formation of the enzyme-substrate complex is accompanied by the transition of the

†The following abbreviations have been adopted: cytochrome P-450_{cam} = cytochrome P-450 of camphor hydroxylating bacteria; cytochrome P-450-LM_2 = the form of cytochrome P-450 from the livers of rabbits receiving phenobarbital sodium; PB = phenobarbital sodium; 3-Mech = 3-methylcholanthrene; CHP = cumenyl hydroperoxide; TBHP = t-butyl hydroperoxide; NADPH and NADH can be omitted as they are terms in universal use. AH = substrate in the reduced form.

haem iron from the low-spin to the high-spin state for substrates of type I—hydrocarbons, fully alkylated amines, and unsaturated compounds[19]. The second stage is the reduction of the enzyme–substrate complex by the first electron arriving from the NADPH of the NADPH-specific transport chain via the flavoprotein FP_1 with the possible participation of cytochrome b_5 contained in the membranes of the endoplasmic reticulum of the liver. The second stage consists of two phases: the first phase is characterised by rate constants of 0.2–1 s^{-1} for different substrates and the second (slow) phase is characterised by rate constants in the range 0.09–0.31 s^{-1}.[18]

Scheme 1

The third stage is the formation of the $HA-Fe^{2+}-O_2$ ternary complex. Oxygen adds to the reduced enzyme–substrate complex at high rates of approximately 10^6 mol litre^{-1} s^{-1}.[20] The fourth stage is the reduction of the ternary complex $HA-Fe^{2+}-O_2$ by the second electron, which is believed to be supplied by the NADPH-specific transport chain incorporating the flavoprotein FP_2 and cytochrome b_5. At the present time this reduction stage has not so far been resolved into individual steps for microsomal systems and its rates have not been measured. The fifth stage, which can also be a complex process and can consist of several steps, is characterised by intramolecular reactions of the reduced ternary complex and its decomposition with liberation of a water molecule and a hydroxylated derivative. Cytochrome P-450 is reconverted into the initial form in the fifth stage. Thus the activation of the molecular oxygen in the ternary complex takes place as a result of its reduction by two electrons. The nature of the active form of oxygen responsible for the hydroxylation of chemical compounds of different structure has not so far been established and is controversial.

The mechanism of hydroxylation in the steroid oxidising system and in the camphor hydroxylating bacterial system has, on the one hand, features in common with the oxidation in microsomes and, on the other hand, is characterised by an appreciable difference from the microsomal system[10,11].

The possibility of using organic hydroperoxides for the oxidation of *N*-alkylamines with participation of only cytochrome P-450 in the oxidised form, first discovered by Kadluvar et al.[21], is very important for the study of the mechanism of the activation of molecular oxygen by cytochrome P-450. The use for the hydroxylation of the organic compounds of oxidants containing oxygen already reduced by two electrons (hydroperoxides), $NaIO_4$, $NaClO_2$, and hydrogen peroxide obviates the necessity for the complex electron transport system consisting of macromolecular biocomponents—FP_1, FP_2, and cytochrome b_5.

Thus a possibility arises for simplifying the hydroxylating enzyme system of microsomes by replacing complex components which are difficult to isolate by readily available oxidants. This may be of great importance for the practical application of this unique biocatalyst in the hydroperoxide oxidation of compounds important for pharmacology and medicine. The high capacity of variable-valence metal complexes for the catalytic hydroperoxide oxidation of unsaturated compounds is well known[22,23]: the hydroperoxide oxidation of olefins catalysed by molybdenum complexes constitutes the basis of a familiar method of synthesising epoxypropane developed by the HALCON Company[24].

The aim of the present review is to give a systematic and critical account of reactions involving the oxidation of organic compounds by peroxides with participation of cytochrome P-450 and certain other haemoproteins—haemoglobin, catalase, and cytochrome *c*. We do not consider it necessary to examine here the oxidation of organic compounds by hydrogen peroxide with participation of peroxidases, since peroxide oxidation has been examined in detail in thorough reviews[25,26].

II. OXIDATIVE *N*-DEALKYLATION OF *N*-ALKYLAMINES

The oxidative *N*-dealkylation of alkylamines is one of the commonest reactions catalysed by the microsomal enzyme system. It is believed that this reaction proceeds in two stages, the first of which consists of the insertion of an oxygen atom in a C–H bond of an alkyl substituent with formation of an intermediate hydroxylated compound, which decomposes with liberation of the free amine and formaldehyde:

Table 1. The rates of oxidation of amines by pig liver microsomes with participation of cofactors, CHP, and bovine catalase (the rates are given in nanomoles of formaldehyde per minute per miligram of microsomal protein)[21].

Amine	Microsomes, NADPH, O_2	CHP	
		microsomes	catalase
Dimethylaniline	3.4	35.1	451
Aminopyrine	3.5	5.8	312
Benzphetamine	3.3	4.2	10
Propoxyphene	4.7	3.3	0
Ethylmorphine	6.3	2.2	0
Metamphetamine	2.0	0.4	0

The oxidation of aminopyrine, benzphetamine, dimethylaniline, ethylmorphine, and other alkylamines by various peroxides with participation of various animal liver microsomes and highly purified cytochrome P-450 has been investigated[21,27–31]. Table 1 presents data for the oxidation of various amines by cumenyl hydroperoxide (HP) with participation of pig liver microsomes or bovine catalase and compares them with data for the microsomal oxidation of the same substrates in the complete enzyme system containing all the components, NADPH, and O_2.[21] The replacement of the cofactors—NADPH and O_2—by CHP ensures the oxidation of all the amines investigated at rates which in many instances exceed the rate of oxidation in the complete sys-

tem (dimethylaniline and aminopyrine). Catalase is effective only in the oxidation of the first three substrates under the influence of CHP.

The comparison of the efficiencies of various peroxides in the oxidation of the same substrate is of interest (Table 2). The most effective oxidant is CHP. The generation of H_2O_2 in a system containing glucose and glucose oxidase does not ensure high rates of oxidation of aminopyrine. However, comparatively high rates of oxidation of aminopyrine as well as benzphetamine and *p*-nitroanisole by microsomes have been observed in the electrolytic generation of H_2O_2 (or HO_2^-).[28] The participation of cytochrome P-450 in the peroxide oxidation of all amines and many compounds of other classes does not give rise to any doubts. Its involvement has been confirmed by the inhibiting effect of detergents, which convert cytochrome P-450 into the inactive form P-420 (SKF-525A, potassium deoxycholate, etc.)[21] and by the increase of the rate of oxidation of aminopyrine when the microsomes of animals administered phenobarbital are used, since in this case the content of P-450 in the microsomes is significantly increased. The rate of oxidation of aminopyrine by CHP increases in proportion to the cytochrome P-450 concentration. The most convincing demonstration of the direct involvement of cytochrome P-450 in the oxidative dealkylation of amines by peroxides is provided by experiments on the oxidation of benzphetamine involving CHP and highly purified cytochrome P-450 in one of its forms (LM_2) produced in rat liver after induction with phenobarbital[31]. Highly purified cytochrome P-450 is free from reductase, cytochrome b_5, and other components of the microsomal electron transport chains and exhibits a high catalytic activity, which is equal to or exceeds the activity of cytochrome P-450 in microsomes[31].

Table 2. Oxidation of aminopyrine by various peroxides with participation of pig liver microsomes or bovine catalase[21].

Peroxide	Microsomes	Catalase
Cumenyl hydroperoxide	10.8	312
t-Butyl hydroperoxide	3.8	165
Geraniol hydroperoxide	2.0	89
Linoleic acid hydroperoxide	0.7	11
Pregnenolone 17α-hydroperoxide	0.4	8
Di-t-butyl peroxide	0.2	14
H_2O_2-generating system	0.1	0

A detailed kinetic study of the demethylation of many amines by hydroperoxides in the range 20–37 °C has been carried out in our laboratory[27,29,30]. Assuming that the step involving the insertion of activated oxygen in the substrate–cytochrome P-450–ROOH ternary system is rate limiting in the hydroperoxide oxidation of amines and that the subsequent stages involving the liberation of the reaction products are much faster, it is possible to regard the catalytic rate constant as a quantitative characteristic of the decomposition of the ternary complex (Table 3). It follows from Table 3 that the activation energies for the oxidation of amines in hydroperoxide systems (E) are close to the values obtained in the same temperature range and under the same conditions for the complete microsomal system with the cofactors (E^*). The difference between them is within the limits of the error of the determination of the activation energy in a narrow temperature range. The oxidation of amines by hydroperoxides with participation of cytochrome P-450 is characterised by a compensation effect which is described by an equation relating the activation characteristics for the decomposition of the substrate–enzyme–hydroperoxide ternary complex: $\Delta H^*(\text{kcal mol}^{-1}) = 18.7 + 333\Delta S^*$. The compensation effect is characterised by the quantity $\alpha = 333/T_{av} = 1.11$, where T_{av} is the average temperature of the experiments.

Table 3. Parameters of the activation of the enzyme–substrate complexes in the hydroperoxide oxidation of amines with participation of microsomal cytochrome P-450.[29,30]

System	Pre-exponential factor, s^{-1}	E, kcal mol^{-1}	E^*, kcal mol^{-1}	ΔE^a, kcal mol^{-1}
1,2,7-Trimethyldeca-hydro-4-quinolone + CHP	$6.45 \cdot 10^9$	13.7	14.2	+0.5
Dimethylaniline + TBHP	$7.76 \cdot 10^{10}$	15.8	—	—
Aminopyrine + CHP	$1.12 \cdot 10^9$	12.7	13.4	+0.7
Aminopyrine + CHP[b]	$3.30 \cdot 10^8$	12.0	—	—
Monomethylaniline + CHP	$1.95 \cdot 10^{11}$	16.1	16.6	+0.5
Dimethylaniline + CHP	$5.12 \cdot 10^8$	12.2	13.4	+1.2

Note. [a] $\Delta E = E^* - E$; [b] experiments performed with microsomes of rats receiving phenobarbital.

III. THE HYDROPEROXIDE *O*-DEALKYLATION OF ETHERS

The complete microsomal hydroxylating system in the presence of the cofactors NADPH and O_2 catalyses the oxidative *O*-dealkylation of ethers via the mechanism

$$R{-}OCH_3 \xrightarrow{O_2} R{-}OCH_2OH \rightarrow R{-}OH + HCOH \ .$$

In peroxide systems these reactions are carried out by microsomes in the absence of NADPH and O_2.[32–35]

Table 4. Comparison of the rates of the NADPH-dependent and CHP-dependent *O*-dealkylation in catalysis by rabbit PB-microsomes at 22–25 °C (the rates are expressed in nanomoles of aldehydes per minute per milligramme of microsomal protein)[35].

Substrate	With participation of NADPH and O_2	With participation of CHP
7-Ethoxycoumarin	1.5	3.6
p-Nitroanisole	2.3	12.0
Norcodeine	6.2	6.2
Phenacetine	2.3	2.7

Cumenyl hydroperoxide is effective in the *O*-dealkylation of many substrates (Table 4) and in the oxidation of *p*-nitroanisole the rate of reaction exceeds by a factor of 6 the rate of oxidation in the complete system. *O*-Dealkylation is greatly inhibited by sodium dodecyl sulphate and 1-(2-isopropylphenyl)imidazole[32]. Superoxide dismutase hardly affects the rate of *O*-dealkylation, i.e. the reaction does not involve the active radical-anions O_2^-. It is extremely important that haemin, catalase, horseradish peroxidase, and myoglobin are completely inactive in the reactions involving *O*-dealkylation by hydroperoxides[32].

A detailed kinetic study of the *O*-dealkylation of 7-ethoxycoumarin in the range 0–45 °C and of anisole and *p*-chloroanisole in the range 20–37 °C with participation of CHP and microsomes has been carried out[34,35] (Table 5).

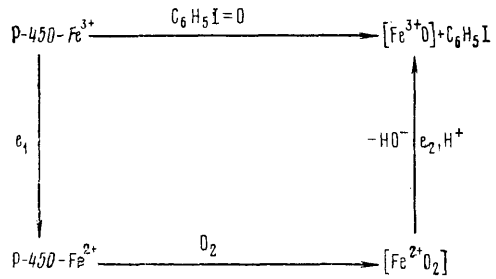


Table 5. Characteristics of the *O*-dealkylation of ethers by cumenyl hydroperoxide[34,35].

Substrate	System	k_0, s^{-1}	E, kcal mol^{-1}	Refs.
Anisole	CHP + intact microsomes	$2.0 \cdot 10^7$	11.4	[34]
p-Chloroanisole	CHP + intact microsomes	$5.5 \cdot 10^7$	11.8	[34]
7-Ethoxycoumarin	CHP + PB-microsomes	—	17.0	[35]

The hydroperoxide oxidation of the same substrate can be achieved via two pathways[34]: TBHP and microsomes demethylate anisole (20%) and at the same time hydroxylate it in the *p*-position (80%) with formation of *p*-methoxyphenol.

For the understanding of the mechanism of oxidation with participation of peroxides and cytochrome P-450, it is of interest that 7-ethoxycoumarin can be *O*-dealkylated by iodosobenzene with participation of microsomes[33], since iodosobenzene contains only one oxygen atom. Presumably the active species attacking the substrates contains only one oxygen atom. Such a species can be the oxenoid complex $[FeO]^{3+}$ (Scheme 2). Scheme 2 illustrates the pathways leading to the formation of the $[FeO]^{3+}$ species by the reaction with iodosobenzene and also in the complete microsomal system.

Scheme 2

IV. HYDROXYLATION OF AROMATIC COMPOUNDS AND EPOXIDATION OF CYCLOHEXENE

A number of studies have been made of the hydroxylation of aromatic compounds by hydroperoxides with participation of liver microsomes and highly purified cytochrome P-450 [36–46] (Table 6).

The hydroxylation of aromatic compounds is accompanied by the decomposition of CHP with formation of cumenyl alcohol. It has been shown[36] that one *p*-aminophenol molecule is formed for each CHP molecule decomposing in the oxidation of aniline. Haemin, catalase, horseradish peroxidase, myoglobin, cytochrome b_5, and cytochrome P-420 are ineffective in the hydroxylation of aniline by cumenyl hydroperoxides[36].

The kinetic characteristics of the hydroxylation of naphthalene by cumenyl hydroperoxide with participation of different enzyme systems have been compared quantitatively[38]. The rate of reaction in the presence of the enzyme system induced by phenobarbital sodium increases in proportion to the increase of the concentration of cytochrome P-450. The catalytic rate constant in induction by 3-methylcholanthrene is reduced by a factor of two compared with the intact systems due to the formation of a new form of haemoprotein (cytochrome P-448) in 3-Mech-induced systems.

Table 6. Comparison of the rates of oxidation of aromatic substrates in the presence of NADPH and O_2 as cofactors and CHP (the rates are expressed in nanomoles of reaction products formed per minute in miligrams of microsomal protein).

System	Substrate	NADPH and O_2 cofactors	CHP
Rat liver microsomes	biphenyl	0.60	1.70
Rat liver microsomes	benzopyrene	0.78	0.89
Rabbit liver PB-microsomes	coumarin	0.062	0.055
Rabbit liver-3- Mech-microsomes	aniline	0.51	50.0

Table 7. The energy characteristics of the oxidation of naphthalene, aniline, and cyclohexene by hydroperoxides.

System	t, °C	E, kcal mol^{-1}	Refs.
Naphthalene			
Male rat PB-microsomes + CHP	5–40	18.8	42
Highly purified rabbit liver cytochrome P-450 (13 nmol/mg of protein) + CHP	5–38	17.2	42
Aniline			
Intact male rate microsomes + CHP	10–40	18.1	42
Male rat PB-microsomes + CHP	5–36	21.3	42
Intact female rat microsomes + CHP	15–37	15.3	40, 41
Intact female rat microsomes + TBHP	15–37	14.5	40, 41
Rat liver cytochrome P-450 (4.4 nmol/mg of protein) + CHP	14–37	15.8	39
Cyclohexane			
Intact male rat liver microsomes + TBHP	20–37	8.15	29

The kinetics of the hydroxylation of naphthalene and aniline by hydroperoxides over a wide temperature range and of the epoxidation of cyclohexene by cumenyl hydroperoxide have been studied in detail[29,37–46]. All the experiments were performed under the conditions involving saturation with respect to the hydroperoxide. The temperature variation of the maximum rates of oxidation of aniline, naphthalene, and cyclohexene obeys the Arrhenius equation, from which the process activation energies were calculated (Table 7). The activation energies for the oxidation of naphthalene by microsomes and highly purified cytochrome in the reaction with the same hydroperoxide are similar. The activation energies for the oxidation of aniline to *p*-aminophenol catalysed by male rat microsomes and purified cytochrome P-450 also differ a little—15.3 and 15.8 kcal mol^{-1}.[39,40,41] Induction by phenobarbital hardly affects the energy characteristics of the oxidation of naphthalene and aniline by cumenyl hydroperoxide[42].

Thus cytochrome P-450 in microsomes and highly purified cytochrome P-450 in solution do not exhibit energy differences in reactions involving the oxidation of the same substrate (naphthalane or aniline) by hydroperoxides. It is therefore of interest to investigate the influence of individual phospholipids on the reactivity of highly purified cytochrome P-450 in the hydroperoxide oxidation of aromatic compounds[43-46], since phospholipids are components of microsomal membranes and are necessary for the reconstruction of the microsomal system for the restoration of its full activity.

The hydroxylation of naphthalene and aniline by cumenyl hydroperoxide with participation of the highly purified LM_2 form of cytochrome P-450 from rabbit liver PB-microsomes (16.8 nmol/mg of protein) has been studied in the presence and absence of various phospholipids[44-46] and it has been shown that the total microsomal phospholipids (TPL), phosphatidylinositol (PI), and lysophosphatidylcholine (LPC) increase the rate of oxidation of naphthalene in the reaction with CHP by a factor of 3–4 when the molar ratio lipids : cytochrome P-450 is 30 and more. Phosphatidylcholine (PC) and sphingomyelin (SM) hardly affect the oxidation of naphthalene up to lipid : cytochrome P-450 ratios of 200–300. The addition of aliphatic acids to the incubation mixture retards the oxidation of naphthalene by cumenyl hydroperoxide.

The addition of TPL, PI, PC, and LPC increases also the rate of oxidation of aniline in the reaction with CHP by a factor of two, PC and SM do not influence the oxidation of aniline, while aliphatic acids retard this process. Thus acid phospholipids (PC, PI, and TPL), containing acid lipid components, activate cytochrome P-450 in the hydroperoxide oxidation of naphthalene and aniline, while lipids existing in the zwitterionic form do not affect the rate of oxidation of a type I substrate (naphthalene) and a type II substrate (aniline)[44-46]. Thus the interaction of cytochrome P-450 with acid lipids affects the rates of hydroperoxide oxidation of aniline. Phosphatidylcholine—the principal component of the microsomal membrane—hardly affects this process. It may be that this factor actually explains the absence of a difference between the activation energies for the hydroperoxide oxidation of naphthalene and aniline with participation of highly purified cytochrome P-450 and membrane-bound cytochrome P-450.[39-42]

The activation of cytochrome P-450 by acid phospholipids in the hydroperoxide oxidation reaction can be accounted for by the stabilisation of the active conformation of the haemoprotein in solution when the lipid molecules are immobilised on the surface of the protein. Coon et al.[47] showed that the interaction of the LM_2 form of cytochrome P-450 with phospholipids is accompanied by an increase of the α-helix content. The spectroscopic changes recorded by differential spectrophotometry in the interaction of LM_2 cytochrome P-450 with phospholipids at different temperatures permit the conclusion that phospholipids can influence the equilibrium involving the spin forms of cytochrome P-450 differing in their ability to interact with substrates of this enzyme[48]. The general considerations concerning the stabilisation of the cytochrome P-450 conformation on interaction with phospholipids can be made specific: cytochrome P-450 assumes the α-helix conformation and can undergo a change in the spin state as a result of conformational rearrangements.

V. OXIDATION OF SATURATED COMPOUNDS AND STEROIDS

Microsomal hydroxylating systems of the liver and kidney, incorporating cytochrome P-450, are known to catalyse the ω-oxidation of aliphatic acids[49,50], the oxidation products being ω1- and ω2-hydroxy acids[50,51]. It has been suggested that liver microsomes contain a highly specific cytochrome P-450 responsible solely for the oxidation to ω1-hydroxy-derivatives, as well as another non-specific cytochrome P-450 which catalyses the ω2-oxidation of aliphatic acids and the hydroxylation of many medicinal drugs and other xenobiotics[51-54]. Kidney microsomes probably contain only one form of cytochrome P-450, which is responsible for both ω1- and ω2-oxidation of aliphatic acids[55,56]. The ratio of the ω1- and ω2-oxidation products is determined by the length of the alkyl substituent in aliphatic acids.

Table 8. Hydroxylation of steroids with participation of rat liver microsomes and different oxidants[60].

Main reaction products	Reaction rates*		
	NADPH, and O_2	$NaIO_4$	CHP
Androstenedione			
6α-OH	0.58	3.97	0.85
7α-OH	0.13	7.13	0.65
15-OH	0.13	0.90	0.12
16α-OH	0.27	0.58	0.43
17β-hydroxy-4-androstene-3,16-dione	0.12	0.70	0.10
Total	1.23	13.28	2.15
Testosterone			
6β-OH	0.74	2.20	1.22

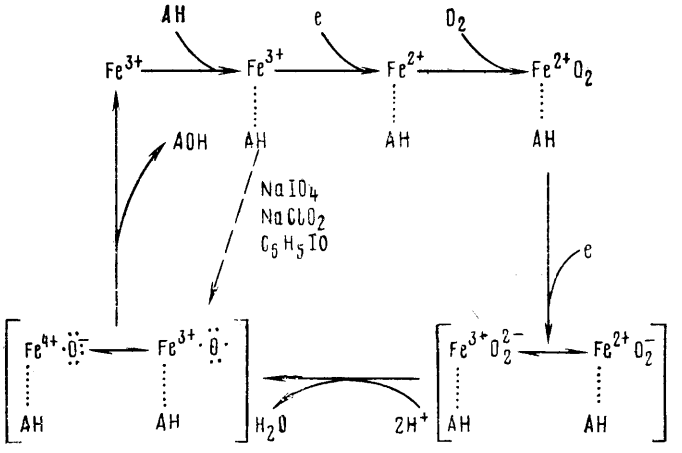
Cumenyl hydroperoxide and liver microsomes ensure the oxidation of lauric acid to an ω2-hydroxyacid, the ω1-hydroxy-derivative not being formed in detectable amounts[57], while in the complete system containing the cofactors NADPH and O_2 the formation of ω1- and ω2-hydroxy-derivatives in proportions of 1 : 5 is observed. Kidney microsomes and CHP ensure the ω2-oxidation of lauric acid at low rates, but ω1-hydroxy-lauric acid was not detected in this instance[57]. Thus oxidation of lauric acid by CHP with participation of liver and kidney microsomes can yield the same product in both instances—ω2-hydroxylauric acid. This fact confirms the existence in the liver microsomal fraction of two or more forms of cytochrome P-450 responsible for the ω-oxidation of aliphatic acids. Presumably cytochrome P-450 responsible for the ω2-oxidation of aliphatic acids by cumenyl hydroperoxide is identical in liver and kidney microsomes[57].

Rat liver microsomes catalyse the oxidation of aliphatic acids by oxidants such as sodium chlorite, sodium periodate, iodosobenzene, and iodosobenzene diacetate[58]. The oxidants employed hydroxylate aliphatic acids only in the ω2-position

and are much more effective than NADPH and O_2 in the complete microsomal system; iodosobenzene diacetate is the most effective substance. The ω2-oxidation of laurate with participation of liver microsomes is inhibited by a substrate of the microsomal system (aniline), which fully arrests the process[58].

A number of studies have been made on the peroxide oxidation of steroids with participation of cytochrome P-450-containing systems[59-65]. The peroxide oxidation of steroids can be catalysed by liver microsomes[60], cytochrome P-450 from adrenal cortex mitochondria[62], and cytochrome P-450 from liver microsomes[59,63]. Table 8 presents data on the oxidation of steroids in the full microsomal system and also in the presence of $NaIO_3$ and CHP.[60] Evidently the use of $NaIO_3$ and CHP in combination with liver microsomes does not ensure the selective oxidation of steroids, which can be attributed to the presence of many forms of cytochrome P-450 in liver microsomes or to the possible role of radicals in the oxidation, which frequently leads to the absence of selectivity. $NaIO_3$ is the most effective oxidant for steroids[60]; $NaClO_2$, CHP, pregnenolone 17 α-hydroperoxide, t-butyl hydroperoxide, and linoleic acid hydroperoxide give rise to lower rates of oxidation than in the complete system with participation of NADPH and O_2. Oxidants such as H_2O_2, $K_2Cr_2O_7$, CrO_3, $KClO_4$, $KBrO_3$, K_2IrCl_6, and $NaIO_3$ exhibit no activity in the oxidation of steroids with participation of liver microsomes[60].



The partly purified cytochrome P-450 from rat liver microsomes oxidises androstenedione when $NaIO_4$, $NaClO_2$, H_2O_2, and organic hydroperoxides are used[59]. Sodium periodate is the most effective oxidant. It is noteworthy that horseradish peroxidase, catalase, and metmyoglobin do not exhibit catalytic properties in the oxidation of steroids by various peroxides[59].

The study of the oxidation of androstenedione by various iodobenzene derivatives with participation of cytochrome P-450 from liver microsomes showed[64] that the effectiveness of the oxidant diminishes in the sequence 2-nitroiodosobenzene diacetate > 2-chloroiodosobenzene diacetate > 2-methoxyiodosobenzene diacetate 4-methyliodosobenzene > iodosobenzene. The effectiveness of the oxidant is determined by several factors: the tendency towards its oligomerisation, which diminishes when the oxidant is coordinated to haem iron, the presence of substituents in the 2-position, and the electron-donating capacity of the substituents. The rates of 7α-, 6β-, and 16α-hydroxylation of androstenedione by 2-nitroiodosobenzene diacetate are higher by factors of 108, 130, and 167 than the corresponding values for the oxidation of this substrate in the same positions in the complete microsomal system. The authors[64] believe that this finding supports the view that there are different rate-limiting stages in the oxidation of androstenedione in the complete microsomal system and in the reaction involving peroxides.

The majority of oxygen donors used in the oxidation of steroids do not ensure process selectivity, in contrast to the observations made in the ω-hydroxylation of saturated aliphatic acids[57,58]. However, in the oxidation of cholesterol by $NaIO_4$ and CHP in the presence of liver microsomes, exceptional selectivity is observed: both oxidants ensure the exclusive 25-hydroxylation of cholesterol[65]. It is of interest to note that, in the oxidation of cholesterol in the complete microsomal system with participation of NADPH and O_2, hydroxylation takes place in the 6β-, 7α-, 12α-, 25-, and 26-positions[65]. In this case the transition to peroxide oxidation is characterised by a greater reaction selectivity. This finding is difficult to account for unambiguously, although one can postulate that competition between the oxidants and cholesterol for binding to cytochrome P-450 renders all the substrate positions except the 25-position inaccessible to attack by the hydroxylating agent. The effectiveness of highly purified cytochrome P-450 in the oxidation of androstenedione by sodium periodate increases following the addition of phosphatidylcholine: the rate of 6β-hydroxylation of this substrate increases by a factor of 2.5 for a cytochrome P-450 : lipid ratio of approximately 10.[63] Detergents such as Triton X-100 also exert an activating effect on cytochrome P-450 in the oxidation of androstenedione by sodium periodate[63].

Hrycay and coworkers[59-62] believe that the active oxidant in the hydroxylation of steroids by various peroxides is the same species, namely the ferryl ion $[Fe^{4+}O^-]$, which is formed when oxygen donors (ROOH, $NaIO_4$, $NaClO_2$, etc.) interact with oxidised cytochrome P-450 (Scheme 3). The postulated species is analogous to the well known complex I (see Scheme 3) formed in the interaction of hydrogen peroxide with peroxidases or catalases[25,26].

Scheme 3

One of the alicyclic compounds oxidised by hydroperoxides with participation of microsomes or purified cytochrome P-450 is cyclohexane[66,31]. In this case the hydroperoxide system (TBHP) is less effective than the complete microsomal system. The affinity of cyclohexane for cytochrome P-450 in the presence of TBHP decreases by a factor greater than 2 and the rate of oxidation falls by a factor of approximately 10.[66]

In conclusion of this section of the review, one should note that both liver microsomes and pure cytochrome P-450 are effective catalysts of the oxidation of saturated compounds such as aliphatic acids and cyclohexanes. It is significant that these compounds are not oxidised at appreciable rates at temperatures close to physiological values by oxidants such as hydroperoxides, hydrogen peroxide, and $NaClO_2$. Cytochrome P-450 accelerates the oxidation of saturated compounds by peroxides. This finding is particularly important from the standpoint that the strength of the C–H bonds at which oxidation occurs is high compared with compounds of other classes (90–95 kcal mol^{-1}). Nevertheless the oxidation of saturated compounds by readily available oxidants with participation of cytochrome P-450 at 20–37 °C is strikingly easy.

VI. PEROXIDASE REACTIONS OF CYTOCHROME P-450

Reactions catalysed by peroxidases are characterised by the following stoichiometry:

$$AH_2 + XOOH \rightarrow A + H_2O + XOH ,$$

where AH_2 is the hydrogen donor and XOOH the peroxy-compound. In 1972 Hrycay and O'Brien[67] showed that cytochrome P-450 exhibits the properties of peroxidases and reduces steroid hydroperoxides to the corresponding alcohols in the presence of a hydrogen donor such as *N,N,N',N'*-tetramethyl-*p*-phenylenediamine (TMPPD). The peroxidase activity of rat liver and borine adrenal cortex microsomes in relation to steroid peroxides is analysed in Table 9.[67] In all cases the rat liver microsomes are more active than the bovine adrenal cortex microsomes.

Table 9. The peroxidase activity of microsomes in relation to steroid hydroperoxides*[67].

Hydroperoxide	Rat liver microsomes	Bovine adrenocortical microsomes
Progesterone 17α-hydroperoxide	92	31
Pregnenolone 17α-hydroperoxide	80	30
Allopregnanolone 17α-hydroperoxide	76	27
Linoleic acid hydroperoxide	75	25
Cumenyl hydroperoxide	34	12
Cholesterol 7β-hydroperoxide	30	17
Cholest-4-en-3-one 6β-hydroperoxide	30	10
Cholesterol 7α-hydroperoxide	22	9
Cholesterol 25-hydroperoxide	17	9
Cholesterol 26-hydroperoxide	15	9
Cholesterol 20α-hydroperoxide	12	5

*The peroxidase activity was measured at 23 °C in 3 ml of phosphate buffer (pH 7.5) containing 0.2×10^{-3} M TMPD, 2 mg of microsomal protein, 0.05×10^{-3} M hydroperoxides, and 1.5×10^{-3} M EDTA.

The peroxidase activity is not influenced by CO, nitrogen, EDTA, and 2-phenyl-2-propanol. Sodium azide has a slight inhibiting effect (20%). The peroxidase activity diminishes by 95% when the microsomes are heated to 80 °C. Substrates of the microsomal enzyme system exert an effective inhibiting influence on the peroxidase reactions of liver microsomes[67]: type I substrates—androstenedione, testosterone, 17β-oestradiol, aminopyrine, hexabarbital, and linoleic acid—inhibit the peroxidase reactions by 65–34%, while type II substrates—aniline, imidazole, pyridine, cyanide, corticosterone, and n-octylamine—inhibit the peroxidase activity by 83–50%. This confirms that cytochrome P-450 is involved in the peroxidase reactions in the oxidised form. The peroxidase activity of cytochrome P-450 from adrenal cortex microsomes is also largely inhibited by substrates of microsomal systems of both types[67].

In the peroxidase reactions of cytochrome P-450, NADH and NADPH can function as hydrogen donors[68]. The combined experimental data[67,68] show that the peroxidase activity is characteristic of the oxidised form of P-450: CO does not inhibit the peroxidase reactions of cytochromes P-450, because it forms a complex solely with the reduced form of this haemoprotein. It has been suggested that, when cytochrome P-450 reacts with hydroperoxides, a complex is formed[25,26] in which the haem iron can exist in a high oxidation state:

$$\text{P-450—Fe}^{3+} + \text{ROOH} \rightarrow \text{P-450—Fe}^{5+} + \text{ROH} .$$

It is known that primary aliphatic alcohols are not substrates of peroxidases[69]. However, rate liver microsomes and highly purified cytochrome P-450 catalyse the oxidation of primary aliphatic alcohols to aldehydes[70]. The susceptibility of alcohols to oxidation by cumenyl hydroperoxide with participation of cytochrome or catalase diminishes with increase of the size of the aliphatic group[70].

Cytochrome P-450 is the most effective catalyst of the oxidation of ethanol by cumenyl hydroperoxide, while cytochrome *c*, haemoglobin, and peroxidase hardly catalyse the oxidation of alcohol. The induction of microsomes by phenolbarbital sodium increases by a factor of almost 5 their catalytic activity in the oxidation of ethanol by CHP.[70] The mechanism of the oxidation of aliphatic alcohols with participation of cytochrome P-450 and hydroperoxides is controversial: alcohols can behave as hydrogen donors and can be oxidised via the peroxidase mechanism, which has already been discussed in this section; the second possibility in the oxidation of alcohols is associated with the monooxygenase activity of cytochrome P-450—the insertion of an activated oxygen atom from the P-450–ROOH complex in an alcohol molecule with subsequent decomposition of the unstable intermediate to acetaldehyde and water:

$$CH_3CH_2OH \xrightarrow{\text{cytochrome P-450-ROOH}} \rightarrow \left[CH_3—\underset{\displaystyle OH}{\underset{|}{CH}}—OH \right] + \text{P-450} + \text{ROH}$$
$$\downarrow$$
$$CH_3CHO + H_2O .$$

The mechanism of the oxidation of alcohols by hydroperoxides with participation of cytochrome P-450 has never been studied. The reduction of steroid hydroperoxides by cytochrome P-450 is of great interest for the elucidation of the mechanism of the oxidation of steroids by liver microsomes and in their biosynthesis with participation of mitochondrial cytochrome P-450 from adrenal cortex, since steroid hydroperoxides can behave as intermediates which are then converted into hydroxy-derivatives with participation of cytochrome P-450.

An undesirable side process accompanying the hydroperoxide oxidation of the majority of substrates is the degradation of cytochrome P-450 by hydroperoxides[43–45,71,72]. It has been shown[72] that CHP and TBHP decompose not only cytochrome P-450 but also cytochrome b_5, which plays an important role in electron transport in microsomal chains. The hydroperoxide of linoleic acid decomposes cytochrome P-450 in the microsomal form when this haemoprotein has not been induced, or has been induced by phenobarbital or 3-methylcholanthrene[71]. According to Jeffery et al.[71], two phases—rapid and slow—can be observed in the degradation of microsomal cytochrome P-450. A detailed kinetic study of the degradation of cytochrome P-450 by cumenyl hydroperoxide in microsomes and after purification to different extents in solution has shown that this process is complex and consists of three stages[43–45]. Under the conditions of an excess of CHP, the degradation of cytochrome P-450 can be characterised in terms of bimolecular rate constants for each degradation stage. The extent of the first stage in the degradation of cytochrome P-450 depends on the initial concentration of the hydroperoxide and on the duration of the degradation process regardless of the degree of integration of the cytochrome (microsomes or solubilised cytochrome P-450).[43–45]

Table 10 presents the kinetic parameters characterising the degradation of cytochrome P-450 and its reaction with CHP at different stages of this process. The rate constant k_0 (s^{-1}) characterises the degradation of cytochrome P-450 in the absence of hydroperoxide. This reaction is observed at 25 °C in only one case—for cytochrome P-450 in the LM_2

form when its specific content is 12.0 nmol/mg of protein. The substrates of the microsomal system (aniline and others) greatly inhibit the degradation of cytochrome P-450 by hydroperoxides. The introduction of a radical process inhibitor (1-naphthol) into the incubation mixture entails its consumption and marked inhibition of the degradation process. The inhibiting effect of this antioxidant confirms the radical mechanism of the degradation of cytochrome P-450. The complex of the hydroperoxide and cytochrome P-450, whose structure will be discussed in the next section of the review, decomposes with formation of active radicals:

$$[P-450-Fe^{3+}\ldots OOR] \rightarrow [P-450-Fe^{2+}] + \dot{O}OR + H^+ ;$$
$$[P-450-Fe^{2+}] + ROOH \rightarrow [P-450-Fe^{3+}] + HO^- + RO^\cdot .$$

The radical species RO· and RO_2^- formed attack the porphyrin ring of the cytochrome P-450 haem and the apoenzyme, decomposing the latter.

VII. CATALYSIS OF THE PEROXIDE OXIDATION BY OTHER HAEMOPROTEINS (HAEMOGLOBIN, CATALASE, AND CYTOCHROME *c*)

The elucidation of the catalytic activities of other haemoproteins in the peroxide oxidation is of great interest. Cytochrome P-450 cannot be replaced in all cases by other more readily available haemoproteins: the oxidative dealkylation of *N*-alkylamines is catalysed by horseradish peroxidase in combination with H_2O_2,[73] and by haemoglobin and catalase in combination with CHP or H_2O_2;[74] the oxidation of aniline by cumenyl hydroperoxide is catalysed by haemoglobin[75] and cytochrome *c*;[76] haemoglobin exhibits a peroxidase activity in the presence of H_2O_2 in relation to phenylhydrazine[77].

Data on the catalytic activity of haemoproteins in various reactions are summarised in Table 11. Only cytochrome P-450 is catalytically active in all the reactions, while other haemoproteins can catalyse only one or several peroxide oxidation reactions. None of the haemoproteins, except cytochrome P-450, is capable of catalysing the peroxide *O*-dealkylation of ethers[32] and the oxidation of steroids[59]. Catalase participates in the oxidation of alcohols[70] and in the *N*-dealkylation of amines[21]. Cytochrome P-420 does not exhibit an activity in any of the reactions[32]. It is important to note that the mechanisms of reactions with participation of cytochrome P-450 and other haemoproteins are as a rule different. Hitherto radicals have not been detected directly in any of the peroxide oxidation reactions involving cytochrome P-450. On the other hand, the reactions involving the oxidative *N*-dealkylation of amines in the H_2O_2–peroxidase[73], CHP–catalase, and CHP–haemoglobin[74] systems are accompanied by the formation of radicals. Radical process inhibitors (1-naphthol and others) retard the oxidation of aniline in the haemoglobin–CHP and cytochrome *c*–CHP systems[75,76], which indicates the presence of radical stages in these instances.

Table 11. Catalytic properties of haemoproteins in the oxidation of the organic compounds by peroxides and certain other non-peroxide oxidants.

Reaction	Haemoproteins with catalytic activity*	Refs.	Haemoproteins without catalytic properties	Refs.

Cytochrome P-450 in microsomes (1.25×10^{-6} M) + CHP (0.001 M)	8.20

*Initial rate of reaction.

In the oxidative dimethylation of aminopyrine in the H_2O_2–peroxidase system radical species have been detected by EPR and are apparently aminopyrine radical-cations[73]. The oxidation of aminopyrine by peroxidase in combination with H_2O_2 is the most effective method for transforming this compound compared with other systems.

The efficiencies of various haemoproteins in the peroxide oxidation of dimethylaniline are compared in Table 12.[74] Catalase is most effective in the peroxide oxidation of dimethylaniline. The inhibiting effect of 1-naphthol has been observed only in reactions involving cytochrome P-450.[74]

At 37 °C in a phosphate buffer (pH 7.4) aniline is hydroxylated to *p*-aminophenol in the haemoglobin–CHP system. Kinetic[75] and spectroscopic[78,79] data show that the hydroxylation of aniline entails the formation of a complex of haemoglobin with aniline and the hydroperoxide: difference spectra of the aniline–haemoglobin system are characterised by an absorption maximum at 425 nm and a minimum at 405 nm.[78] Identical differential spectra have been observed in the interaction of haemoglobin with CHP. The reaction involving the insertion of activated oxygen takes place in the aniline–haemoglobin–CHP ternary complex. A side reaction involving the degradation of haemoglobin by cumenyl hydroperoxide is observed in the course of the process[75].

At 0 °C cytochrome *c* catalyses in combination with CHP the oxidation of aniline to *p*-aminophenol. Aniline forms a complex with cytochrome *c* characterised by an absorption maximum at 420 nm and a minimum at 401 nm at pH 5.8 in a phosphate buffer. Complexes of CHP with cytochrome *c* are formed, which is reflected in the difference absorption spectra, having a maximum at 433 nm and a minimum at 413 nm.[76] 1-Naphthol inhibits the oxidation of aniline by cumenyl hydroperoxide with participation of cytochrome *c*,[76] but does not arrest it completely.

The ability of haemoglobin in combination with H_2O_2 to exhibit a peroxidase activity has been demonstrated[77] in relation to the oxidation of phenylhydrazine in this system. It has been suggested that oxidised haemoglobin (Hb^{3+}) forms a complex with H_2O_2, which decomposes and generates ferrylhaemoglobin, the latter oxidising phenylhydrazine:

$$Hb^{3+} + H_2O_2 \rightarrow [HbO]^{4+} + H^+ + {}^1/_2H_2O_2,$$
$$2[HbO]^{4+} + C_6H_5NH{-}NH_2 \rightarrow 2Hb^{3+} + C_6H_5{-}N{=}NH + H_2O.$$

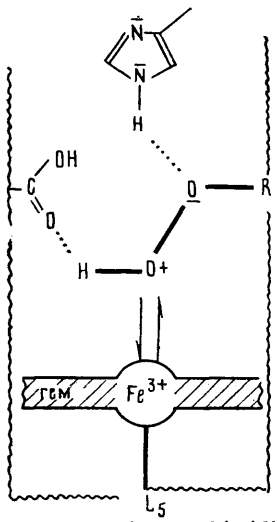
The haemoprotein recently isolated from peas differs from cytochrome P-450 and oxidises a number of substrates via the peroxidase mechanism in the presence of hydroperoxides and H_2O_2: indole is oxidised to indoxyl, phenol is oxidised to hydroquinone, α-naphthol is oxidised to α-naphthohydroquinone, and aniline is oxidised to phenylhydroxylamine[80]. The oxidation of indole in the presence of this haemoprotein is slightly inhibited by KCN and NaN_3, but is very markedly retarded by α,α′-bipyridyl, aniline, and *N*,*N*-dimethyl-*p*-phenyldiamine. The new catalyst, was called the "H_2O_2 reducing haemoprotein[80]. The products formed in the oxidation of the substrates enumerated above with participation of this haemoprotein differ greatly from the products of the microsomal oxidation of the same substrates, which confirms the difference between the new haemoprotein and cytochrome P-450.

In conclusion of this section, it must be emphasised yet again that all the reactions catalysed by cytochrome P-450 are accelerated by other haemoproteins. The most significant difference between the catalytic activities of cytochrome P-450 and other haemoproteins is the absence of radical stages in the case of cytochrome P-450 and their presence in the reactions involving other haemoproteins. Peroxides form complexes not only with cytochrome P-450 but also with other haemoproteins; however, the complexes of cytochrome P-450 and other haemoproteins react via different pathways.

VIII. THE MECHANISM OF THE ACTION OF CYTOCHROME P-450 IN THE PEROXIDE OXIDATION OF ORGANIC COMPOUNDS

Cytochrome P-450, haemoglobin, and cytochrome *c* form complexes on interaction with hydroperoxides[81–84]. The formation of complexes by cytochrome P-450 in a microsomal suspension with cumenyl hydroperoxide was first demonstrated spectrophotometrically[81]. When CHP was mixed with liver microsomes from rabbits receiving phenobarbital, difference absorption spectra were recorded at 5 °C with maxima at 441 and 535 nm and minima at 422 and 579 nm. Analogous spectral changes were observed also in the interaction of microsomes with t-butyl and tetralyl hydroperoxides[82] and also in the interaction of purified cytochrome P-450 with CHP.[39]

The interaction of hydroperoxides and peracids with the highly purified LM_2 form of cytochrome P-450 from rabbit liver microsomes has been studied spectrophotometrically in combination with the stopped flow method[83,84]. Difference absorption spectra were obtained with maxima at 370, 436, and 540 nm and a minimum at 421 nm. The interaction of CHP with P-450-LM_2 is described schematically as follows:



$$P{-}450{-}LM_2 + CHP \underset{k_2}{\overset{k_1}{\rightleftharpoons}} C \underset{k_4}{\overset{k_3}{\rightleftharpoons}} D,$$

where C is the Michaelis complex between CHP and P-450, and D is the spectroscopically detectable species, which can be an oxyferryl derivative of cytochrome P-450. The interaction of CHP and P-450 is very rapid: $k_1 = 5000$ litre $mol^{-1} s^{-1}$. The rate constants for the reverse reaction are $k_2 = 50\ s^{-1}$, $k_3 = 1.3\ s^{-1}$, and $k_4 = 0.009\ s^{-1}$.[83] The kinetic parameters determined for this reaction depend little on the pH and on the addition of phospholipids.

Similar spectra characteristics have been obtained in the study of the products of the reaction of P-450-LM_2 with peracetic, *m*-chloroperbenzoic, and *p*-nitroperbenzoic acids as well as other peroxides. The fact that different peroxycompounds form complexes with P-450 having analogous spectroscopic characteristics suggests that the active species arising on complex formation is similar for different oxidants. The spectroscopic parameters of the complexes of haemoproteins with hydroperoxides are presented in Table 13. According to the author, the formation of complexes by hydroperoxides takes place as shown in Scheme 4. The complex is formed by the undissociated form of the hydroperoxide, one oxygen atom of which (from the HO group) is bound to the haem iron, while the other atom forms a hydrogen bond with histidine; the alkyl residue of the peroxide interacts with the apoenzyme via hydrophobic binding. The distal histidine is probably involved in the stabilisation of the haemoglobin complex. Complexes of haemoglobin with

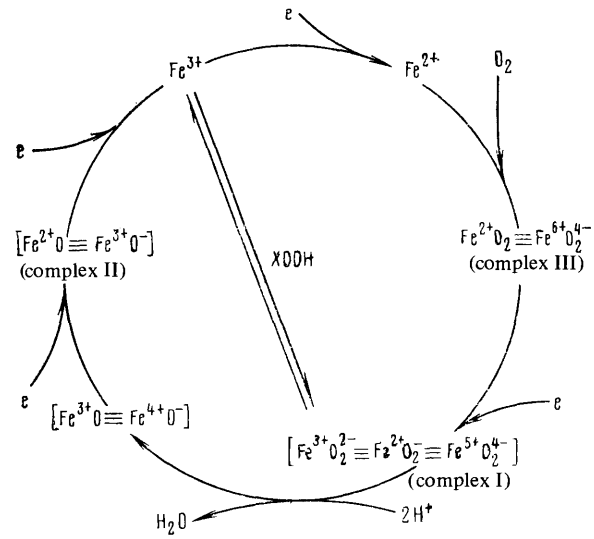
molecular oxygen are known to be stabilised by the distal histidine[85,86].

Scheme 4

L_5 = cysteinyl or histidinyl.

The spectroscopic characteristics (Table 13) probably refer to the product of the conversion of the complex illustrated in Scheme 4 into the oxyferryl derivative, formed as a result of the dissociation of the –O–O– bond and analogous to complex I, known to occur in the reactions of peroxidases:

$$[Fe^{3+}\cdot\ddot{O}\cdot] \rightleftharpoons [Fe^{4+}\ddot{O}:] \xrightarrow{H^+} Fe^{4+}OH\ .$$



In the interaction of CHP with cytochrome P-450 a signal with a *g*-factor of approximately 2.0, analogous to the EPR signal arising in the interaction of H_2O_2 with metmyoglobin or with cytochrome *c* peroxidase[87,88], was recorded by EPR.[81] It is suggested that this EPR signal is associated with the highest valence states of haem iron, for example, the ferryl 4+ state. When CHP or H_2O_2 is added to metmyoglobin, an EPR spectrum similar to that recorded in the microsomes–CHP system is observed[81]. Yamazaki et al.[89] suggested an overall mechanism which describes the oxidation-reduction reactions of haemoproteins and is distinguished by five valence states of haem iron. This mechanism describes the results obtained in the study of peroxidase and catalase and agrees with the results of the study of the interaction of peroxides with metmyoglobin[90,92].

Scheme 5 illustrates the successive formation of various oxygen-containing species in the functioning of cytochrome P-450 and draws an analogy with the species formed in the functioning of peroxidases. The ternary complex comprising reduced cytochrome P-450, the substrate, and oxygen is equivalent to complex III of peroxidases, as suggested by Ulrich and Staudinger[93]. The valence state of the iron in this complex depends on the distribution of electrons between the oxygen and the iron ion. The one-electron reduction of this complex leads to the formation of complex I or the perferryl ion[89]. The complex I formed can be reduced by a single electron to complex II or simultaneously by two electrons to the initial state (Fe^{3+}–P-450).

Thus the active species formed in the interaction of oxidised cytochrome P-450 with peroxides or in the successive reduction of the substrate–cytochrome P-450–O_2 ternary complex by two electrons can be the same as complex I, which is characterised by a high degree of oxidation of the iron ion.

Complex I can react, receiving in succession one electron from the substrate and being reconverted into the initial form Fe^{3+}–P-450. This peroxidase reaction pathway is characterised by the intermediate formation of complex II. In other cases complex I can obtain immediately two electrons from the substrate and be reconverted into the initial form Fe^{3+}–P-450. This pathway obtains in hydroxylation reactions believed to involve an oxenoid mechanism[93]. The relative contributions of the peroxidase and oxenoid reactions of complex I are determined primarily by the nature of the haemoprotein. In reactions involving hydroperoxides, haemoglobin and cytochrome *c* react via the peroxidase pathway with the intermediate formation of radicals, which has been confirmed by the retarding effect on these reactions by radical process inhibitions. The oxenoid or hydroxylase mechanism is characterised by the absence of radical stages, which is confirmed by the effect of the same inhibitors in hydroxylase reactions[74].

Scheme 5

Complex I, which exists in different forms ($Fe^{2+}O_2^-$, $Fe^{3+}O_2^{2-}$, $Fe^{3+}O$, $Fe^{4+}O^-$) contains oxygen in the triplet or singlet state. The singlet oxenoid inserts an oxygen atom into the substrate via a three-centre synchronous mechanism with formation of a singlet reaction product:

$$\rangle C{-}H + [:\ddot{O}\,Fe^{3+}] \rightarrow \left[\rangle C\overset{OFe^{3+}}{\cdots}H\right] \rightarrow \rangle C{-}OH + Fe^{3+}\ .$$

If the oxenoid is in the triplet state, then the direct insertion of oxygen in the substrate is impossible, because this reaction would be spin-prohibited. In this case oxidation proceeds via the "abstraction of a hydrogen atom–recombination" mechanism or via a latent radical mechanism, which may not be sensitive to the action of radical process inhibitors:

$$\rangle C{-}H + [\cdot\ddot{O}\cdot Fe^{3+}] \rightarrow \rangle C^{\cdot} + [H\ddot{O}\cdot Fe^{3+}] \rightarrow \rangle C{-}OH + Fe^{3+}\ .$$

The different states of the oxygen in complex I can be determined by the nature of the fifth ligand of the haem iron in haemoproteins. The presence of histidine in the fifth position in haemoglobin and cytochrome *c* probably determines significantly the peroxidase reaction pathway with participation of these haemoproteins and hydroperoxides. The cysteinyl group in the fifth position of cytochrome P-450

is responsible for the difference between the spectra of the complexes of this haemoprotein with hydroperoxides and the spectra of the complexes of other haemoproteins (Table 13) and for the hydroxylase reaction pathway.

We shall now consider the possible reaction pathways for the complexes of haemoproteins with hydroperoxides. As a result of the interaction of haemoproteins with hydroperoxides, a Michaelis complex C is formed in which the hydroperoxide is coordinated to the central iron ion via the oxygen atom of the hydroxy-group (see Scheme 4). Evidence for the involvement of the HO groups of cumenyl hydroperoxide in coordination to cobalt and nickel chelates has been obtained by NMR from the chemical shifts of the HO protons in the hydroperoxide[94]. The Michaelis complex C decomposes via reaction (2) with formation of an oxenoid complex or an oxyferryl derivative analogous to complex I. Complex I can react via the hydroxylase mechanism [reaction (3)]. It can receive two electrons in succession from a suitable substrate: the reduction by the first electron leads to the formation of complex II via reaction (4). The Michaelis complex C can decompose in the absence of the substrate with formation of the peroxy-radical $RO_2^{\cdot}$ [reaction (5)]. In this reaction the hydroperoxide behaves as a reductant#:

$$L_5Fe^{3+} + ROOH \rightleftharpoons [L_5Fe^{3+}\ldots \underset{H}{OOR}] \quad (1)$$

(complex C)

$$C \rightarrow [L_5Fe^{3+}O] + ROH \quad (2)$$

(complex I)

$$[L_5Fe^{3+}O] + AH \rightarrow L_5Fe^{3+} + AOH \quad (3)$$

$$[L_5Fe^{3+}O] + AH \rightarrow [L_5Fe^{2+}O] + A^{\cdot} + H^+ \quad (4)$$

(complex II)

$$[L_5Fe^{3+}\ldots \underset{H}{OOR}] \rightarrow L_5Fe^{2+} + H^+ + RO_2^{\cdot} \quad (5)$$

$$L_5Fe^{2+} + ROOH \rightarrow L_5Fe^{3+} + RO^{\cdot} + HO^- , \quad (6)$$

where AH is the substrate and L_5 is the axial ligand in the fifth position.

The reduced form of the haemoprotein is oxidised by another hydroperoxide molecule with formation of the radical $RO^{\cdot}$ [reaction (6)]. Reactions (5) and (6) are well known in the interaction of CHP with metal ions and metal complexes as the Haber–Weiss reactions[95]. The ratios of the rates of reactions (3)–(6) are determined by the nature of the haemoprotein, particularly by the nature of the axial ligand in the fifth position, by the presence or absence of substrates, by the nature of the oxidised substrate, and by other factors. Complex I, formed in the interaction of cytochrome *c* or haemoglobin with cumenyl hydroperoxide, reacts mainly via the peroxidase pathway [reaction (4)], while complex I of cytochrome P-450 reacts mainly via the hydroxylase pathway [reaction (3)]. It is noteworthy that the Michaelis complex C, which is capable of oxidising the substrate in a single stage on interaction with the latter, can serve as the hydroxylating agent. The study of model systems has shown that two hydroxylation mechanisms are possible—consecutive two-state hydroxylation [reactions (2) and (3)] or a single-stage transfer of active oxygen to the substrate[96,97] with the aid of complexes analogous to the Michaelis complex C.

In the presence of substrates or radical process inhibitors, reactions (5) and (6), initiating the degradation of haemoproteins, take place at lower rates. In the absence of substrates or inhibitors, the radicals $RO^{\cdot}$ and $RO_2^{\cdot}$ attack the haem and the apoenzyme and irreversibly decompose them.

The oxygenated form of reduced cytochrome P-450 from liver microsomes was first detected spectrophotometrically by Estabrook et al. in 1971.[17] Gunsalus et al.[98] and Ishimura et al.[99] demonstrated spectroscopically the formation of a complex of molecular oxygen with reduced cytochrome $P\text{-}450_{cam}$, which hydroxylates camphor. The camphor–cytochrome $P\text{-}450_{cam}$–O_2 and reduced cytochrome $P\text{-}450_{cam}$–O_2 complexes have been isolated chromatographically[100,101] below 0 °C in mixed aqueous organic solvents and have been characterised spectroscopically and kinetically. The camphor–cytochrome $P\text{-}450_{cam}$–O_2 ternary complex undergoes autoxidation; the activation energy for this process is 18 kcal mol^{-1} in water and 19 kcal mol^{-1} in an aqueous organic medium[100].

Using the stopped flow method, the formation of a complex of highly purified cytochrome P-450 from liver microsomes with molecular oxygen was investigated spectrophotometrically[102]. In the presence of benzphetamine, this reaction is characterised by two phases: complex A—an oxygenated complex of cytochrome P-450 having maxima at 430 and 450 nm in the difference spectrum—is formed initially. The short-lived complex A is then converted into complex B with a maximum at 440 nm. The formation of complexes of O_2 with reduced cytochrome P-450, can be described schematically as follows:

$$P\text{-}450^{red} + O_2 \overset{k_1}{\rightarrow} \text{complex A} \overset{k_2}{\rightarrow} \text{complex B} \overset{k_3}{\rightarrow} P\text{-}450^{ox}.$$

Complex B has spectroscopic characteristics close to those of complex I and is probably similar to the latter. The reactants are characterised by the following Soret bands: $P\text{-}450^{red}$—424 nm, $P\text{-}450^{ox}$—418 nm, complex A—423 nm, and complex B—421 nm.[102] The rate-limiting stage of the process is the oxidation of cytochrome P-450 in the ternary complex accompanied by the hydroxylation of the substrate. The addition of cytochrome b_5 to the system increases the rate constant k_3, i.e. cytochrome b_5 plays the role of an effector in the reaction.

Thus an oxygenated complex of cytochrome P-450 with properties similar to those of complex I is formed in the complete microsomal system as a result of a series of steps (see Schemes 2, 3, and 5). This complex can transfer an oxygen atom to the substrate with a simultaneous liberation of a water molecule or can initially abstract a water molecule and be converted into the ferryl derivative [$Fe^{3+}O \rightleftharpoons Fe^{4+}O^-$], which transfers an oxygen atom to the substrate.

It is of great interest to elucidate the nature of the rate-limiting stage in the oxidation of substrates in the complete microsomal system. This complex process consists of at least five steps (see Schemes 1 and 5). A kinetic analysis of each of the five steps has been carried out in a review[18], where data obtained in several laboratories were surveyed. Direct measurements of the rate constants for the interaction of substrates with cytochrome P-450, for the reduction of the enzyme–substrate complex by the first electron, and for the formation of the ternary complex comprising reduced cytochrome P-450, the substrate, and oxygen have shown that all three steps are characterised by high rate constants and cannot be rate limiting in the oxidation reaction in the complete system[18].

The rate of this process can be limited either by the reduction of the ternary complex by the second electron or by the step involving the insertion of activated oxygen in the substrate, which is accompanied by the rupture of the attacked bond and subsequent rapid liberation of the reaction product.

#It is noteworthy that the peroxy-radical $RO_2^{\cdot}$ may be bound in a complex, as shown[23] for the decomposition of complexes of hydroperoxides with molybdenum(VI):

$$[Mo^{6+}\ldots \underset{H}{OOR}] \rightarrow [Mo^{5+}\ldots {}^{\cdot}OOR] + H^+ .$$

Hitherto the conversion of the ternary complex, involving its reduction by the second electron and the subsequent decomposition with formation of the reaction product, has not been resolved into individual stages. However, there are experimental facts showing that the rate-limiting stage of the reaction involves the dissociation of the attacked C–H bond in the substrates. The primary isotope effects in the oxidation of substrates in the complete microsomal system have been measured in a number of studies[103–117]; the results are summarised in Table 14. As a rule, high primary isotope effects are observed except for the oxidation of deuterated cyclohexane, for which an isotope effect has not been observed[105]. Studies in which an intramolecular determination has been made of isotope effects involving substrates which are symmetrical and contain simultaneously non-deuterated and deuterated C–H bonds attacked in the oxidation process, such as, for example, 1,3-diphenylpropane-1,1-d_2, are of special interest[114]. In this case the isotope effect is 11. The same value was obtained in the hydroxylation of norbornane in a reconstructed enzyme system of rabbit liver microsomes[117]. The isotope effects obtained leave no doubt that the rate-limiting stage of the oxidation reaction involves the dissociation of the attacked C–H bond, which supports the "abstraction–recombination" mechanism.

Table 14. The primary isotope effects in the microsomal oxidation of various substrates.

Substrate	Isotope effect	References
CD_3-morphine	1.4	103
[α-D_2]Ethylbenzene	1.8	104

Biphenyl	1.4	115
N,N'-Dimethylphentermine	1.4	116
Norbornane	11.5	117

Another piece of evidence for the decisive role of the strength of the bond ruptured in the oxidation process is the existence of the so-called uncoupling compounds—fully fluorinated hydrocarbons which interact with cytochrome P-450 but are not oxidised, since the strong C–F bond cannot be ruptured by the oxidising species[118–121].

Comparison of the energy characteristics of the oxidation of the same substrates in the complete microsomal system and in systems containing only cytochrome P-450 and hydroperoxides showed that in both cases the activation energies for the same substrate are similar or identical (see Table 3 and Akhrem and coworkers[29,30]). This comparison, carried out under rigorously identical conditions for both systems (complete and shunted), supports the occurrence of the same rate-limiting stage in the process in both instances. In the hydroperoxide system there is no need for the transfer of the second electron to the enzyme–substrate–hydroperoxide complex, since the oxygen in this complex is already activated by two electrons, i.e. the ternary complex is not reduced in this case and the rate-limiting stage of the reaction can be only the insertion of an oxygen atom with dissociation of the bond in the substrate oxidised. Consequently the same rate-limiting stage of the process can be postulated in the hydroperoxide system and in the complete microsomal system, namely the insertion of active oxygen in the substrate with subsequent rapid decomposition of the complex and liberation of the reaction product.

Data have been obtained[58–62] showing that the use of oxidants ($NaIO_4$, $NaClO_2$, and iodosobenzenes) in combination with cytochrome P-450 makes it possible to increase the rate of transformation of substrates compared with those attained in the complete system. This led the authors to the view that the rate-limiting stages in the two systems are different[58–62]. Here one should note that the difference between the rates of oxidation can be accounted for not by the difference between the rate-limiting stages in the two cases but by different concentrations of the active oxidising species, which is due to the different affinities of molecular oxygen and the oxidants used for cytochrome P-450.

Naturally the most convincing evidence for the nature of the rate-limiting stage in the oxidation process in the complete microsomal system may be provided by the direct measurement of the rates of all the stages of the process by high-speed kinetic methods. Such a study has been performed for the demethylation of benzphetamine in a reconstructed microsomal system[122]. The rate-limiting stage in the oxidation of benzphetamine may be associated with the reduction of the ternary complex by the second electron or with any process involving the transformation of the ternary complex after its reduction, since all the preceding stages are much faster than the accumulation of the reaction products[122,123].

It is noteworthy that under certain conditions in the microsomal membrane the reduction of cytochrome P-450 by the first electron may be the rate-limiting stage of the oxidation reaction. Below 18–20 °C, the interaction of cytochrome P-450 in microsomes with its reductase (flavoprotein I) is hindered due to a change in the phase state of the phospholipids of the microsomal membranes from the liquid crystal state above 18–20 °C to the crystalline state below these temperatures. The phase transition of the membrane phospholipids is reflected in the activation energy for the oxidation of substrates in the complete system: at 18–20 °C a break is observed in the Arrhenius relation for the maximum rates of oxidation or for the catalytic constants[35,42,124]. The activation energy for the oxidation of substrates of the first type above 18–20 °C is 8–12 kcal mol^{-1} and probably refers to the transformation of the ternary complex; the activation energy below 18–20 °C is 18–24 kcal mol^{-1} and refers to another rate-limiting stage, which may be the reduction of cytochrome P-450 by its reductase under the conditions of hindered contact between them. This contact is facilitated when the state of the membrane changes above 18–20 °C as a result of the possibility of the lateral mobility of its components.

IX. PROSPECTS FOR PRACTICAL UTILISATION

In view of the important functions of hydroxylating enzymes it is desirable to search for ways of using them in practice. At the present time only the first attempts have been made at the practical application of monooxygenases containing cytochrome P-450. The region where cytochrome P-450 and its analogues can be used is extremely wide. The enzyme systems of micro-organisms and yeasts containing

cytochrome P-450 can oxidise virtually all hydrocarbons to alcohols: the American firm Mobil Oil took out a patent in 1967 for the oxidation of petroleum hydrocarbons of all classes by monooxygenases present in bacteria of different strains[125].

"Metabolic reactors" for the investigation of the optimisation of medicinal preparations and also for the extracorporeal detoxidation of blood by oxidising the impurities contained in it can be created on the basis of immobilised cytochrome P-450.[126-128] The cytochrome and its analogues in the immobilised state can be used for the selective oxidation of physiologically active compounds, in the first place steroids and certain amines[129]. It is already possible to quote an example of the successful application of monooxygenases in the sphere of traditional applications of the activity of microbial cells—steroid chemistry; thus Mosbach[130,131] converted Reichstein's substance "S" into prednisolone with the aid of a two-stage system. In the first stage substance "S" is hydroxylated in the 11β-position with formation of cortisol by the mycelium of the fungal culture of *Curvulatia lunata* immobilised in a polyacrylamide gel and the cortisol is converted into prednisolone in the second stage in a column filled with immobilised steroid Δ^{1-2}-dehydrogenase from *Corynebacterium simplex*.

Workers in the German Democratic Republic devised an enzyme electrode based on cytochrome P-450.[126,132] With its aid, it is possible to detect low concentrations of many substrates of cytochrome P-450 by following the consumption of hydrogen peroxide in the reaction with the aid of a sensor electrode.

The practical employment of hydroxylating enzyme systems involves the solution of several complex problems, since such systems consist of multienzyme complexes and require the use of cofactors. Cytochrome P-450 and other components of the system are unstable and expensive. It is therefore necessary to solve the following problems on the way to the practical utilisation of cytochrome P-450 containing monooxygenases:

(1) Simplification of the involved multienzyme complex by decreasing the number of its components and by replacing biomolecules which are difficult to isolate by simpler and more readily available analogues;

(2) stabilisation of cytochrome P-450 by immobilising microsomes or isolated components of the hydroxylating complex[133-139];

(3) practical utilisation of simpler analogues of cytochrome P-450, which retain its function;

(4) immobilisation of micro-organism cells containing hydroxylating complexes[130,141,140].

One of the ways of solving the first problem was proposed by ourselves[29]: the complex electron transport chain of microsomes is replaced by organic hydroperoxides, whose combination with one component of the system (oxidised cytochrome P-450) effects all the reactions characteristic of the complete system. This simplification of the hydroxylating complex greatly decreases the cost of the catalytic system and makes it possible to reduce the involved task of immobilising the entire multienzyme complex to the immobilisation of one of its components—cytochrome P-450.

Further advances in the utilisation of hydroperoxide systems require a successful immobilisation of cytochrome P-450 and its stabilisation with respect to the second component—the organic hydroperoxide. In many laboratories attempts have been made to immobilise cytochrome P-450 from liver microsomes and other natural sources[127,129,133-139] In all cases cytochrome P-450 partly retained its activity, but, after several hours or days, the activity of the immobilised haemoprotein decreases significantly. The task of increasing the stability of the immobilised cytochrome P-450 and of simplifying its immobilisation therefore still remains urgent. It is known that the stability of certain enzymes can be significantly increased by their immobilisation not directly on a matrix but via binding it to an inert protein, which is then in its turn immobilised on a support. In particular such an inert protein may be serum albumin. Berezin and coworkers[142,143] showed that the immobilisation of peroxidase on BrCN-Sepharose, subjected to a preliminary modification with albumin, or the immobilisation of oligomers obtained by the interaction of peroxidase with albumin in the presence of glutaraldehyde leads to a significant stabilisation of peroxidase. The present author and his coworkers[136] immobilised highly purified cytochrome P-450 from rabbit liver microsomes on a modified albumin Biogel P-300 and investigated its activity in the hydroxylation of aniline by cumenyl hydroperoxide. This immobilisation method increases significantly the thermal stability of cytochrome P-450 and ensures the oxidation of aniline to *p*-aminophenol with kinetic characteristics close to those of the same reaction involving non-immobilised cytochrome P-450. After immobilising cytochrome P-450 by sorption on polyamide or nylon-6, specimens of a "dry" catalyst, retaining a high activity for 19 days, were obtained[138].

A detailed study of the degradation of cytochrome P-450 by hydroperoxides suggests that it can be prevented[45,144] by introducing radical reaction inhibitors into the system. The necessity to increase the thermal stability of cytochrome P-450 entails a complex problem. Systematic study of the thermal inactivation of cytochrome P-450 from rabbit liver showed that the stability of the haemoprotein increases significantly when 20% of glycerol is added to the solution and also for certain ways of immobilising cytochrome P-450.[145] According to the present author, further advances in the application of cytochrome P-450 will be achieved using certain new procedures for the stabilisation of enzymes developed by Berezin and Martinek[146,147]: by carrying out the reactions in two-phase "water–water-immiscible organic solvent" systems, by incorporating the enzyme in inverted surfactant micelles in organic solvents, etc.

The studies on the practical utilisation of the unique properties of cytochrome P-450 are only beginning. However, certain advances have already been achieved in this field, but their number is still small. There is no doubt that enzyme reactors and selective oxidation processes will be devised on the basis of cytochrome P-450 and its analogues.

Copper Salts in Catalytic Reactions of Organic Compounds

Sh.O.Badanyan, M.G.Voskanyan, and Zh.A.Chobanyan

The reactions of copper complexes and organocopper compounds are examined and described systematically. Attention is concentrated on the reactions of copper complexes leading to the formation of carbon-carbon bonds. The influence of various parameters on the mode and mechanism of cuprocatalytic reactions is discussed.
The bibliography includes 343 references.

I. INTRODUCTION

The study of catalytic processes involving unsaturated systems and the search for ways of their practical utilisation constitute one of the most rapidly developing fields of organic chemistry. Syntheses using catalysts based on copper salts or organocopper compounds are very common[1-12]. By virtue of their unusual and to some extent unique catalytic properties, copper salts have long attracted the attention of many investigators; thus copper(I) chloride is used as the catalyst in numerous important industrial processes—the synthesis of vinylacetylene, acrylonitrile, vinyl chloride, acetaldehyde, etc.

In assessing the reactions occurring in the presence of organocopper catalysts, one may say that they continue to serve as some of the fundamental synthetic methods in modern organic chemistry whereby one can obtain compounds of various classes[8,9,13]. Despite the fact that the first reaction involving organocopper compounds was achieved as early as 1869 by Glaser, the chemistry of these reactions has undergone particular development in the last two decades. Thus, up to the 60's of the present century, only six reactions based on organocopper compounds [reactions (1)–(6)] were known[13-18].

A. Substitution reactions

1. Symmetric oxidative coupling reactions:
(a) the Glaser reaction[15,16]:

$$2RC{\equiv}CCu \xrightarrow{\text{oxidation}} RC{\equiv}CC{\equiv}CR\ ; \quad (1)$$

$$2N{\equiv}CCu \xrightarrow{\text{oxidation}} N{\equiv}CC{\equiv}N\ ; \quad (2)$$

(b) the Ullmann synthesis of biaryls[15,17]:

$$2Ar{-}X \rightarrow Ar{-}Ar\ . \quad (3)$$

2. Asymmetric oxidative coupling reactions:
(a) the Rosenmund synthesis of nitriles[15]:

$$N{\equiv}CCu \xrightarrow{N_2^+Ar} N{\equiv}CAr\ ; \quad (4)$$

(b) the Gattermann synthesis of nitriles[15]

$$N{\equiv}CCu \xrightarrow{N_2^+Ar} NCAr\ . \quad (5)$$

B. Addition reactions

The Straus reactions[18]:

$$RC{\equiv}CCu \xrightarrow{HC{\equiv}CR} RC{\equiv}CCH{=}CHR\ . \quad (6)$$

In the course of the last twenty years a further six new reactions [reactions (7)–(12)] were discovered on their basis[4,5-28].

A. Substitution reactions

1. Symmetrical oxidative coupling reactions:
(a) reactions of vinyl derivatives of organocopper compounds[19-22]:

(7)

(b) oxidative coupling of copper *at*-complexes[23]:

$$[Alk{-}Cu{-}Alk]^-Li^+ \xrightarrow{\text{oxidation}} Alk{-}Alk\ . \quad (8)$$

2. Asymmetric oxidative coupling reactions:
(a) reactions of copper acetylides with aryl halides[5,6,24,25]:

$$RC{\equiv}CCu \xrightarrow{IAr} RC{\equiv}CAr\ ; \quad (9)$$

(b) synthesis of hydrocarbons from copper *at*-complexes and aryl halides[26]:

$$[CH_3CuCH_3]^-Li^+ \xrightarrow{IAr} CH_3Ar\ . \quad (10)$$

B. Addition reactions of copper *at*-complexes

(a) Addition to a double bond[27]:

$$[CH_3{-}Cu{-}CH_3]^-Li^+ \xrightarrow{\overset{CO-}{=}} CH_3{-}\underset{|}{\overset{|}{C}}{-}\underset{|}{\overset{|}{C}}{-}CO{-}\ ; \quad (11)$$

(b) addition to a triple bond[28]:

$$[CH_3{-}Cu{-}CH_3]^-Li^+ \xrightarrow{\overset{CO_2CH_3}{=}} \diagdown\!\!=\!\!\diagup_{CO_2CH_3}\ . \quad (12)$$

If we add to the above the fact that organocopper compounds catalyse also the coupling of organomagnesium compounds with various halides[29,30] or the dimerisation of alkyl, alkenyl, or alkynyl groups[29-32] starting with Grignard complexes

$$R{-}MgX \rightarrow R{-}R$$

as well as the use of complex copper salts as oxidants, (Benedict's, Barfoed's, Fehling's, Pavy's, etc. reagents)[33], etc., then the wide spectrum of the action of organocopper complexes and organocopper compounds in organic chemistry will become clear.

Simultaneously with the vigorous research into cuprocatalysis, elegantly written reviews have appeared in recent years in the literature[8-14,17], whose authors discuss mainly the reactions of homo- and hetero-cuprates and devote less attention to the reactions proceedings via organocopper complexes[34-36]. In order to survey the available literature data on numerous reactions with organocopper compounds and copper complexes, in the present review an attempt was therefore made to give a systematic account of the extensive experimental data on reactions involving organocopper complexes; attention is concentrated on the catalytic reactions of unsaturated compounds in the presence of copper salts.

Among organocopper compounds, one usually distinguishes homocuprates, heterocuprates, and copper π-complexes with organic compounds. However, the reactions of copper complexes and cuprates, particularly heterocuprates, are frequently difficult to distinguish from the reactions of pure organocopper compounds. Following the example of many investigators who have already surveyed various aspects of the reactions of organocopper compounds, we shall also consider these reactions together for the sake of convenience and when dictated by necessity.

II. ADDITION REACTIONS

1. Halogenation

A hydrochloric acid solution of copper chlories is an effective chlorinating agent whereby acetylene can be converted into *trans*-dichloroethylene[37-48]. Similarly a mixture of copper(I) and copper(II) bromides brominates acetylene to dibromoethylene[42]. It has been reported[43] that the chlorination reaction also yields 1,1-dichloroethylene[43]. According to certain data, when the chlorination[49,50] as well as the bromination[51] reaction is carried out in less acid media and in the presence of an excess of copper salts, tri- and tetrahalogenoethylenes are formed[49,50,52]:

$$HC{\equiv}CH \rightarrow HCX{=}CX_2\ ;$$
$$HC{\equiv}CH \rightarrow CX_2{=}CX_2\ ;$$
$$X = Cl, \text{ or } Br.$$

Copper(II) halides convert cyanoacetylene almost quantitatively into dihalogenoacrylonitrile[53]:

$$HC{\equiv}CCN \rightarrow HCX{=}CXCN\ ;$$
$$X = Cl \text{ or } Br.$$

A mixture of copper(I) and copper(II) salts was subsequently widely used in the halogenation of vinylacetylene[38,44,54], phenylacetylene[44], diacetylene[54,55], divinylacetylenes[56], as well as acetylenic[57-61] and diacetylenic[62,63] compounds with functional groups. It is remarkable that only the triple bond is then halogenated:

$$RC{\equiv}CH \rightarrow RCX{=}CXH\ .$$

Various workers have frequently dealt with the problem of the elucidation of the mechanism of the halogenation of multiple bonds[3,4,39,57,64-69]; attempts were made to provide an experimental basis for and to relate all the processes occurring in cuprocatalytic solutions[3,4,57,65,70]. However, at present it is impossible to give an exhaustive answer to numerous questions arising in the discussion of the mechanism of these reactions.

The halogenation of acetylene and its derivatives is usually carried out in aqueous or aqueous alcoholic solutions; dimethylformamide (DMF), dioxan, etc. are also used as solvents. However, under analogous conditions alkenes or alkadienes do not interact with bivalent copper salts. Thus it has been shown that the chlorination of butadiene can be achieved only with the aid of copper chloride melts[71-73] or in a fluidised catalyst bed[74]. In all the instances indicated the main reaction products were 3,4-dichlorobut-1-ene and a mixture of *cis*- and *trans*-1,4-dichlorobut-2-enes:

$$CH_2{=}CHCH{=}CH_2 \rightarrow \begin{cases} \rightarrow ClCH_2CH(Cl)CH{=}CH_2 \\ \rightarrow ClCH_2CH{=}CHCH_2Cl\ . \end{cases}$$

Subsequently it proved possible to halogenate various diolefins by adding various ligands and reducing agents[75-79]. Among these processes, the reaction in which butadiene is converted into a mixture of 1- and 2-chlorobutadienes is of particular interest[75]:

$$CH_2{=}CHCH{=}CH_2 \rightarrow \begin{cases} \rightarrow CH_2{=}CClCH{=}CH_2 \\ \rightarrow ClCH{=}CHCH{=}CH_2\ . \end{cases}$$

Finally, one should note that copper(II) chloride has also been used to halogenate alkenes and cycloalkenes[61]. As was to be expected, this reaction is less successful than for alkynes.

2. Hydrohalogenation and Addition of Hydrocyanic Acid

One of the most important fields of application of copper salts involves their use as catalysts of the hydrohalogenation of acetylene[80] and vinylacetylene[81]:

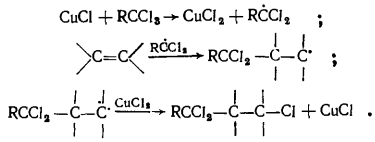
$$HC{\equiv}CH \xrightarrow{HX} CH_2{=}CHX\ ;$$
$$H_2C{=}CHC{\equiv}CH \xrightarrow{HX} CH_2{=}\underset{X}{C}{=}CHCH_2X \rightarrow$$
$$\rightarrow CH_2{=}\underset{|}{C}CH{=}CH_2\ .$$

Vinyl chloride and chloroprene continue to be synthesised in many countries on the basis of these reactions. Various alkynes, alkenynes, and their derivatives also enter into this reaction. Studies in this field have been frequently discussed and surveyed by various workers[81-83].

It has been found[84] that the triple bond activated by complex copper salts combines with hydrogen cyanide:

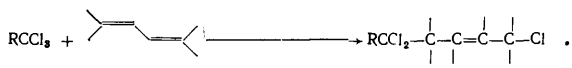
$$RC{\equiv}CH \xrightarrow{HCN} RHC{=}CHCN\ .$$

This method is still one of the most acceptable procedures for the synthesis of acrylonitrile, which is an extremely important monomer and reagent in organic chemistry.

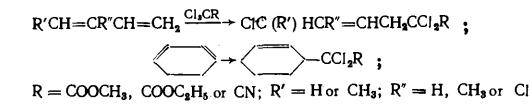


3. The Asscher–Vofsi Addition

Another important application of copper salts involves their use as catalysts of the alkylation of unsaturated systems by organic polyhalogeno-compounds. Thus Asscher and Vofsi[85-87] showed that, in the presence of copper ions, chloroform,

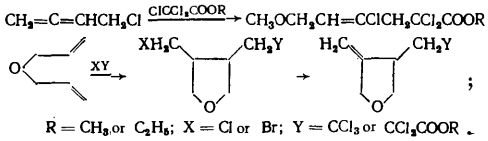


carbon tetrachloride, bromotrichloromethane, and sulphonyl chloride add smoothly to alkenes:

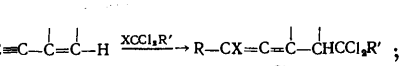


It is of interest that under these conditions a copper(I) salt is an effective catalyst of the chloroalkylation of olefins[88,89], the radical being regenerated via the following mechanism in its presence:

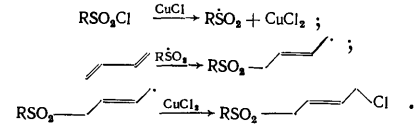
Analogous results have been obtained by other workers in the reaction of alkenes and styrene, on the one hand, and carbon tetrachloride, trichloroacetonitrile, and dichloroacetonitrile, on the other[90-92]. Copper(I) salts have been used successfully also for the halogenoalkylation of various dienes with chloroform, carbon tetrachloride, and bromotrichloromethane[85,88,93]:



From the preparative point of view, together with the reaction described above, the alkylation of butadiene, isoprene, piperylene, cyclohexadiene, chloroprene, and other halogenodienes with trichloroacetate esters and trichloroacetonitrile in the presence of copper(I) oxide is of considerable interest[94-97]:

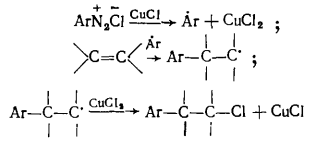


It is remarkable that, when the reaction is carried out in protic solvents, copper(I) salts promote the solvolysis of the allylic halogen generated in the process with formation of an ether[95,96]:

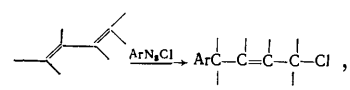


This catalyst has been used successfully for the addition of polyhalogeno-derivatives of organic compounds to cumulated and isolated dienes[94,98]:

It has been shown recently that copper(I) oxide is an effective catalyst of the addition of bromotrichloromethane, trichloroacetate esters, and trichloroacetonitrile to vinyl-, isopropenyl-, and cyclohexenyl-acetylenes and their functional derivatives and satisfactory yields of various allene derivatives have been obtained[94,97,98]:

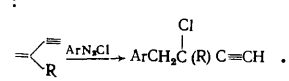


The interaction of various sulphonyl chlorides with dienes also takes place successfully in the presence of copper salts[88,100-103]. The occurrence of the reaction via the following mechanism is usually postulated:



The chlorides of organic sulphonic acids add smoothly under analogous conditions, i.e. in the presence of copper(II) chloride, to vinylacetylenic hydrocarbons[104,105], as well as their silicon-substituted analogues[106,107]. It has been shown that, in the case of hydrocarbons with the normal structure of the enyne residue, the addition is to the double bond whereas in the case of the silicon-containing analogues 1,4-addition is also observed. Thus the Asscher–Vofsi reaction makes it possible to synthesise various organoelemental compounds from ethylene, acetylene, and their derivatives.

4. The Meerwein Arylation



Copper(I) salts have been used successfully in the arylation of alkenes and their derivatives by diazonium chlorides via the Meerwein reaction[108-110]:

Various dienes[109,111], alkynes, enynes[109,112,113] also undergo the Meerwein arylation. Interesting features of the coupled addition of the aryl residue and the halogen to dienes and particularly to enyne systems have been discovered. In the first place one should mention the ability of diazonium salts to arylate conjugated dienes in the 1,4-positions[109,111,113]:

and also the arylation of conjugated enyne compounds at the double bond[81,82,114]:

The characteristics of the reaction associated with the influence of neighbouring groups in unsaturated systems, the presence of substituents in the aromatic ring of diazonium salts, the pH of the medium, the nature of the solvents, the role of the catalyst, etc. are likewise noteworthy and exhaustive information about them can be obtained from elegantly written reviews of the Meerwein reaction[108,109]. It is remarkable that various polyfunctional compounds which are difficult to obtain by othe procedures have been synthesised by the above reaction.

5. The Reppe–Jones Alkynol Synthesis

It has been established that the complex catalyst based on copper salts is effective in the condensation of acetylene with formaldehyde not only under pressure[115-124] but also

without it[124-132]:

$$HC{\equiv}CH \rightarrow HOCH_2C{\equiv}CCH_2OH \ .$$

The reaction takes place more successfully with other aldehydes[115] and with terminal vinylacetylenes[133].

It has been reported quite recently that copper(II) ions catalyse effectively the aldol condensation reaction[134,135]:

$$ArCHO \xrightarrow[Cu^{2+}]{R'CH_2COR} ArCH{=}\overset{R'}{\underset{|}{C}}{-}COR \ .$$

6. Generation of Carbenes

Among cuprocatalytic reactions, the application of complex catalysts based on copper salts in the generation of carbenes is of considerable interest. The characteristic features of the behaviour of the carbenes, obtained in the presence of copper ions, in addition reactions, rearrangements, etc. have been investigated[136-140].

III. SUBSTITUTION REACTIONS

Copper salts have found extensive applications as successful catalysts also in substitution reactions.

1. Solvolytic Reactions

It has been shown[141] that the hydrolysis of allyl chloride is accelerated when a hydrochloric acid solution of copper hemichloride is added to the reaction medium. On the basis of kinetic studies, the authors[141] concluded that the rate of hydrolysis is determined by the stage involving the ionisation of allyl chloride bound in a complex:

$$CuCl + Cl^- \rightarrow \widetilde{CuCl_2} \ ;$$
$$CH_2{=}CHCH_2Cl + CuCl_2^- \rightarrow [CH_2{=}CHCH_2Cl \cdot CuCl_2]^- \ ;$$
$$[CH_2{=}CHCH_2Cl \cdot CuCl_2]^- \rightarrow [CH_2{=}CHCH_2 \cdot CuCl_2] + Cl^- \ ;$$
$$[CH_2{=}CHCH_2CuCl_2] + \overline{OH} \rightarrow CH_2{=}CHCH_2OH + \widetilde{CuCl_2} \ .$$

Continuing the study of the solvolysis of substituted allyl halides in relation to individual stereoisomers, the same workers concluded that the $CuCl_2^-$ ions behave as the catalyst in these reactions[142-144]. The catalytic effect of copper salts on the hydrolysis of allyl chloride in an alkaline medium has also been confirmed in another study[145].

It is noteworthy that another group of investigators demonstrated the possibility, in principle, of the catalysis by copper salts of the reverse reaction, i.e. the formation of allyl chloride from allyl alcohol[146-148]:

$$CH_2{=}CHCH_2OH \xrightarrow[CuCl]{HCl} CH_2{=}CHCH_2Cl \ .$$

2. The Exchange of a Halogen

It has been established recently that copper(I) and copper(II) salts catalyse the exchange of the halogen in allyl halides[149-151]:

$$RR'C{=}CHCH_2Cl \xrightarrow[Cu^+/Cu^{2+}]{HX} RR'C{=}CHCH_2X \ ;$$
$$X = Cl \text{ or } Br.$$

It is of interest that in the case of substituted allyl halides the migration of the reaction centre is observed simultaneously[150]:

$$CH_2{=}CHCCl_3 \rightarrow BrCH_2CH{=}CCl_2 \ ;$$
$$CH_2{=}CHC(Cl)RR' \rightarrow RR'C{=}CHCH_2Br \ .$$

3. Mixed Reactions

Certain examples available at the present time in the literature show that substitution of the allyl chlorine[152] or hydroxyl[153] by a weak nucleophile such as the cyanide ion can also be successfully catalysed by a copper halide:

$$ClCH_2CH{=}CHCH_2Cl \xrightarrow[Cu^{2+}]{KCN} NCCH_2CH{=}CHCH_2CN \xrightarrow[Cu^{2+}]{HCN} HOCH_2CH{=}CHCH_2OH \ .$$

It is striking that, when crotyl chloride is involved in the reaction, dehydrocondensation via the hydrogen atoms of the methyl group takes place simultaneously[154].

Copper salts are likewise effective catalysts of the interaction of the allylic halogen with ammonia and primary and secondary amines[155]:

$$CH_2{=}CHCH_2Cl \xrightarrow[Cu^+/Cu^{2+}]{HNRR'} CH_2{=}CHCH_2NRR' \ ;$$
$$R = H \text{ or Alk}; \ R' = Alk \ .$$

According to patent data[156], copper or its salts can be used as catalysts for the synthesis of unsaturated amines via the mechanism

$$ClCH_2CH(Cl)CH_2Cl \xrightarrow{H_2NR} CH_2{=}C(Cl)CH_2NHR \ .$$

Polyhalogenoalkenes have also been made to react with amines in the presence of copper(II) salts[157]. There have been a number of reports concerning the application of copper(II) salts as catalysts in the reaction of aryl halides with ammonia or amines, leading to the formation of aniline derivatives[158-163].

4. Substitution of the Hydrogen in C–H Acids

(a) For a halogen. According to the available literature data, copper salts promote both the substitution of hydrogen by a halogen in alkanes, aldehydes, and ketones and the dehydrohalogenation of halogenoalkanes[164-173]. They have been used successfully for the synthesis of α-halogenoalkynes from terminal acetylenic compounds[61,174] and for the chlorination of butadienyl sulphone to 1,1,4,4-tetrachlorobuta-1,3-diene.[175]

(b) For dialkylamino-groups. It is also well known that copper salts catalyse the Mannich reaction, in particular the substitution of active acetylenic hydrogen for a dialkylamino-group[176,177]:

$$R{-}C{\equiv}CH \xrightarrow{R'CHO,\ HNR'R''} R{-}C{\equiv}C{-}C(R')HNR'R'' \ .$$

5. The Sandmeyer Reaction

The conversion of diazonium compounds into aryl halides by the substitution of diazo-groups by chlorine via the Sandmeyer reaction, where copper(I) salts are again used as catalysts, can serve as an interesting example of cuprocatalysis[178]. According to Kochi[179], the reaction can be represented schematically as follows:

$$ArN_2Cl \xrightarrow{CuCl} \overset{+}{ArN_2}Cu\overline{Cl_2} \ ;$$
$$\overset{+}{ArN_2}Cu\overline{Cl_2} \rightarrow \dot{A}r + CuCl_2 + N_2 \ ;$$
$$\dot{A}r \xrightarrow{CuCl_2} ArCl + CuCl \ .$$

IV. ALKYLATION, ARYLATION, AND ACYLATION

1. The Colonge–Korts Alkylation

Copper(I) salts are used as catalysts of the alkylation of terminal acetylenes with allyl halides[180–188]:

$$RC{\equiv}CH \xrightarrow{XCH_2C(R'''){=}CR'R''} RC{\equiv}CCH_2C(R'''){=}CR'R''.$$

Allylacetylenes, allylacetylenic alcohols, etc. have been synthesised in this way. A catalytic amount of copper(I) chloride is usually sufficient for the reaction. It is striking that under analogous conditions propargyl chlorides react mainly with inversion of the reaction centre[189,190]:

$$RC{\equiv}CH \xrightarrow{ClCH_2C{\equiv}CH} RC{\equiv}CCH{=}C{=}CH_2 .$$

We may note that allenyl halides with the halogen at an sp^2-hybridised carbon atom enter into this reaction[191]:

$$RC{\equiv}CH \xrightarrow{ClCH{=}C{=}CR'R''} RC{\equiv}CCH{=}C{=}CR'R'' .$$

The alkylation of cyanoacetic ester by propargyl halides in the presence of zerovalent and univalent copper are closely related to the above reaction[192]:

$$HC{\equiv}C{-}\underset{Cl}{\underset{|}{C}}RR' \xrightarrow{NCCH_2CO_2C_2H_5} HC{\equiv}CC(RR')\underset{CN}{\underset{|}{C}}HCO_2C_2H_5 .$$

Finally copper(I) oxide has been used successfully for the alkylation of allylisonitrile with allyl bromide via the mechanism[193]

$$CH_2{=}CHCH_2NC \xrightarrow{BrCH_2CH{=}CH_2} \begin{cases} \rightarrow CH_2{=}CHCH(\underset{CN}{\underset{|}{}})CH_2CH{=}CH_2 \\ \rightarrow CH_3CH(\underset{CN}{\underset{|}{}})C{-}CH_2CH{=}CH_2 \end{cases} .$$

2. The Sladkov–Castro Arylation, Alkylation, and Acylation

The arylation of ethynylcopper compounds by aryl halides constitutes yet another important field of application of organocopper compounds[5,6,24,25,186,194–197]:

$$RC{\equiv}CCu + ArX \rightarrow RC{\equiv}C{-}Ar ;$$

R = Ar, furyl, etc.; X = I or Br.

Subsequently this method was extended to many classes of organic compounds. Studies in this field have been examined systematically and in detail by Sladkov, Ukhin, and Gol'ding[5,6].

Copper acetylides are smoothly alkenylated by compounds containing an allylic halogen atom[198–200]:

$$RC{\equiv}CCu + XCH_2C(R'){=}CR''R''' \rightarrow RC{\equiv}CCH_2C(R'){=}CR''R''' .$$

Studies by a number of workers have shown that vinyl halides are also capable of reacting with copper acetylides[189, 200,201]; furthermore, the involvement of α-halogenoketones in the above reaction made it possible to develop a fairly convenient method of synthesis of furan derivatives[200]:

$$PhCOCH_2Br \xrightarrow{CuC{\equiv}CR} Ph{-}\underset{O}{\langle\!\rangle}{-}R .$$

The Sladkov–Castro reaction has also been used successfully to synthesise important natural products, particularly pheromones[202]. The reaction of copper acetylides with acid halides shown below is also of interest[199,203]:

$$RC{\equiv}CCu \xrightarrow{R'C(=O)Cl} RC{\equiv}CCOR' .$$

V. REARRANGEMENTS

1. Allyl Halides

The very wide variety of the catalytic properties of copper(I) and copper(II) salts has led to the possibility of using them in the anionotropic rearrangements of unsaturated systems. Such rearrangements are usually characteristic of allyl and propargyl halides. As an illustration, one may quote the isomerisation of 1,4-dichlorobut-2-ene to 1,2-dichlorobut-3-ene in the presence of copper halides on heating[204,205]:

$$ClCH_2CH{=}CHCH_2Cl \rightarrow ClCH_2CH(Cl)CH{=}CH_2 .$$

According to other data[206], 1,4-dichlorobut-2-ene is converted into 1,1-dichlorobut-3-ene under the influence of copper or copper(I) oxide:

$$ClCH_2CH{=}CHCH_2Cl \rightarrow Cl_2CHCH{=}CH_2 .$$

In recent years the synthesis of chloroprene from butadiene has assumed great practical importance. This largely accounts for the attempts by a number of workers to elucidate the possibility of the interconversion of the butadiene chlorination products and to establish their configuration. It was found[207] that, in the presence of copper(I) salts at 35° to 90 °C, an equilibrium mixture of *cis*-1,4-dichlorobut-2-ene (5–6%), *trans*-1,4-dichlorobut-2-ene (70–80%), and 1,2-dichlorobut-3-ene (15–20%) is obtained. Next it was shown that 1,4-dichlorobut-2-ene readily isomerises to 1,2-dichlorobut-3-ene on refluxing in the presence of $CuCl_2$:[208]

$$ClCH_2CH{=}CHCH_2Cl \rightarrow CH_2{=}\underset{Cl}{\underset{|}{C}}HCH_2Cl .$$

One should note particularly that copper naphthenates[209,210] and acetylacetonate[211] have been used as catalysts for the anionotropic isomerisation of allylic halides:

$$CH_3\underset{Cl}{\underset{|}{C}}HCH{=}CH_2 \rightarrow CH_3CH{=}CHCH_2Cl .$$

Cuprocatalysis also occurs in the conversion of 4-chlorobuta-1,2-diene into chloroprene[212]:

$$ClCH_2CH{=}C{=}CH_2 \rightarrow CH_2{=}CClCH{=}CH_2 .$$

2. Propargyl Halides

The conversion of dichlorbutyne into a diene dihalide in the presence of copper(I) chloride and ethylamine hydrochloride in DMF is of great interest[213]:

$$ClCH_2C{\equiv}CCH_2Cl \rightarrow CH_2{=}CClCCl{=}CH_2 .$$

It is known that propargyl halides isomerise to halogenoallenes under the influence of copper(I) salts[214,215]:

$$RR'C(\underset{X}{\underset{|}{}}){-}C{\equiv}CH \rightarrow RR'C{=}C{=}CHX ;$$

X = Cl or Br.

When copper salts were used in reactions involving substitution of a hydroxyl for hydrogen in hydrogen halide solutions it was found that, together with acetylenic halides, halogenoallenes are also obtained[216,217]:

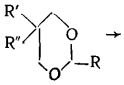
$$RR'C(\underset{OH}{\underset{|}{}}){-}C{\equiv}CR'' \rightarrow RR'CC{\equiv}CR + RR'C(\underset{X}{\underset{|}{}}){=}C{=}CR'' .$$

A comprehensive study of this reaction showed that allenic compounds are products of the isomerisation of acetylenic halides catalysed by copper salts[216,217]:

$$RR'C(X)-C\equiv CR'' \rightarrow RR'C=C(X)=CR''$$

Studies in this field have been surveyed in reviews by Vartanyan and Badanyan[216], Wotiz[217], and others[218-220], in which the available extensive literature data on this field are examined in detail and described systematically.

3. Rearrangements of Other Systems



It has been established that copper-based catalysts are used successfully for the rearrangement of α,β-unsaturated alcohols to aldehydes and ketones[221,222]. Here it is important that the latter are formed via the hydrogenation of the intermediate α,β-unsaturated carbinols:

$$RCH=CH-CH(OH)R' \rightarrow RCH=CHCOR' \rightarrow RCH_2CH_2COR' .$$

More detailed data on the anisotropic transformations of alkenes and alkynes can be found in a collection of articles[223] and in a review[218].

In many instances copper complexes are used for prototropic isomerisations[224,225], *cis–trans* transformations[225], the Wolff rearrangement[227], the synthesis of polycyclic compounds[228], the disproportionation of substituted benzenes[229], and for other purposes[230].

Finally one should note the rearrangement of *m*-dioxans to β-alkoxyaldehydes in the presence of copper–silver catalysts[231]:

$$\rightarrow ROCH_2C(R'R'')CHO .$$

VI. DIMERISATION REACTIONS

1. Oxidative Dimerisation

(a) The Glaser and Cadiot–Chodkiewicz oxidative dimerisation of acetylenes. Oxidative coupling reactions of various acetylenes in the presence of copper(I) salts are known in the chemical literature. Here in the first place mention should be made of the Glaser reaction[232] and its modification by Eglinton[238] and also the Cadiot–Chodkiewicz method[234,235] whereby asymmetrically substituted diacetylenes can be obtained.

Recently studies in this field have been surveyed by Eglinton and McCrae[236,237] and other workers[238,239]. The applications of the above reactions and the influence of various factors on the yield and direction of the process are examined and the pathways via which they occur are discussed in these reviews.

(b) Dimerisation of other C–H acids. It has been found[240] that, in the presence of copper(I) salts in pyridine, phenyl-substituted acetonitriles are converted by atmospheric oxygen or various peroxide compounds into adiponitrile derivatives[240]. Ketonitriles behave similarly[241,242]. Studies on the oxidative coupling of other C–H acids (arenes, aryl halides, thiophen and its derivatives, etc.) via organocopper compounds with formation of a carbon–carbon bond have been widely developed and have been the subject of a special discussion[13,14].

The catalytic properties of copper salts have been used successfully by a number of investigators for the oxidative polymerisation of aromatic hydrocarbons[243,246]. Copper salts can be used for the oxidative dehydrodimerisation of hydrogen cyanide[247]:

$$N\equiv CH \rightarrow N\equiv C-C\equiv N .$$

It is remarkable that copper(I) and copper(II) oxides as well as various copper(II) salts catalyse the dimerisation–addition of α,β-unsaturated carbonyl compounds—nitriles, esters, and ketones[248-252]:

$$R'CH=CHR- \begin{cases} \rightarrow R'CH=C(R)C(R')HCH_2R \\ \xrightarrow{R'=H} RCH_2CH=CHCH_2R \\ \xrightarrow{CH_2=CHR} R'CH=C(R)CH_2CH_2R \end{cases} ;$$

R = COAlk, COOAlk or CN .

The above reaction is regarded[248-252] as a special type of the Michael addition. A good example of the dehydrocondensation is also the dimerisation of acrylonitrile in the presence of copper(II) ions, which leads to the nitrile of hexenedicarboxylic acid[253]:

$$2CH_2=CHCN \rightarrow NCCH_2CH=CHCH_2CN .$$

(c) Dimerisation of organometallic compounds. The cuprocatalytic dimerisation reactions of Grignard reagents with alkyl halides, which made it possible not only to increase the rate of coupling of the alkyl residues of the above class of compounds but also to apply the method successfully to other syntheses, proved to be particularly productive. Studies in this field have been surveyed by Tamura and Kochi[254]. Analogous question have been partly dealt with in the reviews of Schlosser[255], Posner[11,12], and Normant[8], who considered the problems of the formation of a C–C bond with the aid of organometallic reagents. Another important method of synthesis of various hydrocarbons is the coupling reaction of alkyl, alkenyl, and alkynyl derivatives of lithium, magnesium, zinc, and aluminium, as well as other organometallic compounds in the presence of copper salts[11-14,17,254-257].

2. The Straus–Neuland Dimerisation of Acetylenes

Straus showed that the copper derivative of phenylacetylene dimerises to 1,4-diphenylbut-3-ene-1-yne on heating with acetic acid[258]:

$$C_6H_5C\equiv CCu \rightarrow C_6H_5C\equiv CCH=CHC_6H_5 .$$

Subsequently other workers extended the above reaction to various terminal acetylenes[259-261]. However, the most important result of these studies was the finding that an acid medium promotes the dimerisation of acetylenes, as a result of which cuprocatalytic methods were successfully applied to the dimerisation of acetylene and its monosubstituted homologues to vinylacetylene and its derivatives[2,3,4,80,81,262]:

$$2RC\equiv CH \rightarrow RCH=CHC\equiv CR .$$

The process is usually carried out in a hydrochloric acid solution of copper(I) chloride and is still used in the manufacture of chloroprene from acetylene[80,81,263].

3. Reductive Dehalogenodimerisation Reactions

(a) The Ullmann dehalogenodimerisation of aryl halides. The Ullmann reaction, which consists in the reaction of aryl halides with powdered copper at a high temperature, has

already been widely used for the synthesis of a wide variety of aromatic systems in the course of several decades[264,265]:

$$Ar{-}X \xrightarrow{Cu} Ar{-}Ar + CuX_2 \ .$$

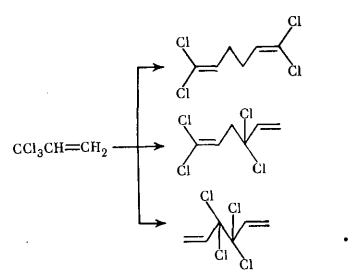
The available literature data on this reaction have been frequently described in reviews[264,265], in which the present limits of the applicability of the reaction, its conditions, and the influence of various substituents and the solvent, as well as the question of the application of a series of copper compounds [copper(I) oxide and copper(I) and copper(II) salts] as additives or independent catalysts are clearly defined; the kinetics of the reaction have been examined in detail and its probable mechanisms have been put forward.

It is appropriate to mention that metallic copper or copper salts in various oxidation states are used successfully also in the so called Ullmann condensation, i.e. in the reaction of aryl halides with anilines[265]:

$$ArCl \xrightarrow{Ar'\text{-}NH_2} ArNHAr' \ .$$

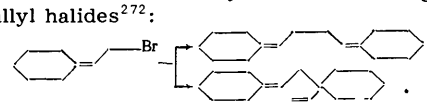
In their studies of the influence of various added copper(I) and copper(II) salts on the Ullmann condensation, some workers[266,267] concluded that copper(I) ions are the catalytically active form for this reaction and that the application of bivalent copper must be accompanied by reducing agents[268].

(b) The dehalogenodimerisation of α-halogenoethers and allyl, propargyl, and benzyl halides. There has been a recent growth of interest in the so-called dehalogenodimerisation reactions of organic halogeno-compounds, which occur in the presence of zerovalent or univalent copper. One of the first reports on this field[269] showed that, on refluxing with metallic copper, various α-chloroethers are converted into ethylene glycol derivatives in high yields:



$$RCOCH_2Cl \rightarrow ROCH_2CH_2OR$$
$$R = CH_3,\ ClCH_2CH_2 - \text{etc.}$$

A little later data were published on the dehalogenodimerisation of allyl halides. Thus Yagupol'skii and Chaika[270] showed that trichloromethylalkenes give rise to chloro-substituted bisallyls and trienes in pyridine in the presence of copper via the mechanism



$$RCH{=}CHCCl_3 \rightarrow RCH{=}CHCCl_2CCl_2CH{=}CHR \rightarrow RCH{=}CHCCl{=}CClCH{=}CHR$$
$$R = H,\ C_6H_5,\ COOH,\ COOCH_3 \text{ or } COC_6H_5 \ .$$

It was established that the yield of trienes greatly increases when the reaction is carried out in acetonitrile.

In a somewhat later study it was reported that, in the presence of copper powder in pyridine, trichloromethylethylene dehalogenodimerises to a mixture of all the expected hexadienes[271].

It is of interest that the organocopper complexes obtained from alkyl-lithium and copper iodide in the presence of dialkylamines are effective catalysts of the dehalogenodimerisation of allyl halides[272]:

The results showed that the dehalogenodimerisation reaction is specific only to compounds containing a mobile halogen atom. A study by Japanese workers on the dehalogenodimerisation of allyl and benzyl halides[273,274] provides a good illustration of this postulate. It was observed that both allyl and benzyl chlorides give rise to high yields of dimers in the presence of the copper(I) cation in ethylenediamine, diethylenetetramine, triethylenetetramine, acetylacetone, and ethylenediaminetetra-acetic acid (EDTA):

$$\overset{I}{CuCl} + n\,(en) \rightarrow \overset{I}{Cu}\,(en)_nCl \ ;$$
$$RCH_2Cl + 2\overset{I}{Cu}\,(en)_nCl \rightarrow RCH_2CH_2R + 2\overset{II}{Cu}\,(en)_nCl_2 \ .$$

The replacement of the above solvents by ethanolamine, pyridine, bipyridyl, phenanthroline, or triphenylphosphine suppresses the reaction.

In the presence of the above catalysts [$Cu^I(en)_nCl$] benzyl chloride derivatives (trichloromethylbenzyl, dichlorodiphenylmethane, and chlorodiphenylmethane) behave similarly, with the sole difference that the resulting chloroethanes are then converted into stilbenes[275,276]:

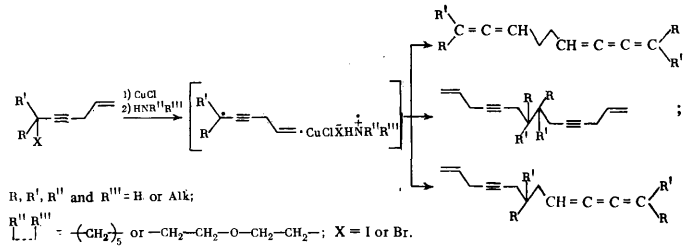
$$C_6H_5C\,(R)\,Cl_2 \rightarrow C_6H_5\overset{R}{\underset{|}{C}}Cl{-}\overset{R}{\underset{|}{C}}ClC_6H_5 \rightarrow C_6H_5\overset{R}{\underset{|}{C}}{=}\overset{R}{\underset{|}{C}}C_6H_5 \ ;$$
$$(C_6H_5)_2C\,(R)\,Cl \rightarrow (C_6H_5)_2\overset{R}{\underset{|}{C}}{-}\overset{R}{\underset{|}{C}}\,(C_6H_5)_2 \xrightarrow{R=Cl} (C_6H_5)_2C{=}C\,(C_6H_5)_2 \ .$$

We may note that this reaction is also catalysed by iron(II) salts.

The available literature data show that the dehalogenation of halogenoalkanes in the presence of both copper salts[276] and zerovalent copper[278-284] is accompanied by partial dehalogenodimerisation with formation of halogenoalkene derivatives.

We believe that, among all the existing ideas concerning the mechanism of the dehalogenodimerisation of allyl systems[271,274], the most likely is the view of Hashimoto and coworkers[274], according to which all these reactions can be interpreted as oxidation-reduction processes via the mechanisms:

$$\overset{I}{Cu} + n\,(en) \rightarrow \overset{I}{Cu}\,(en)_n \ ;$$
$$RCH_2Cl \xrightarrow{\overset{I}{Cu(en)_n}} RCH_2CH_2R + \overset{II}{CuCl_2} \ ,$$



or

$$2RCH_2Cl \xrightarrow{\overset{I}{CuCl}} 2\,[RCH_2Cl \ldots CuCl \leftrightarrow R\dot{C}H_2\overset{II}{Cl}\overset{I}{Cu}Cl] \rightarrow RCH_2CH_2R + \overset{II}{CuCl_2} \ ,$$

or

$$RCH_2Cl \xrightarrow{\overset{I}{CuCl}} RCH_2ClCuCl \xrightarrow{\overset{I}{CuCl}} RCH_2\overset{I}{Cu}Cl + CuCl_2 \ ;$$
$$2RCH_2\overset{I}{Cu}Cl \rightarrow RCH_2CH_2R + 2\overset{I}{CuCl} \ .$$

Badanyan showed recently that vinylpropargyl halides are converted into a mixture of unsaturated hydrocarbons in the presence of copper(I) salts and amines (primary or secondary) via dehalogenodimerisation[285-295]. The authors believe that the process proceeds via the mechanism

It was shown that complexes of copper salts with amines containing hydrogen attached to the nitrogen atom exhibit a catalytic activity, the yield of product depending greatly on the ionisation potential of the amines[288,293,295].

The study of the influence of substituents in various positions in the system revealed certain regularities. Thus it has been found that an increase in the bulk of the alkyl groups at the carbon atom attached to the halogen in vinylpropargyl halides not only decreases the overall yield of hydrocarbons but also increases the fraction of anomalous dehalogenodimerisation products—unsaturated hydrocarbons with cumulated multiple bonds[286,288,295].

An interesting picture was observed when vinylpropargyl halides with substituents at the double bond were introduced into the reaction. Thus in the case of vicinal substitution (at the double bond) of the halides, the yield of the anomalous dehalogenodimerisation products increases; in contrast, geminally substituted or trisubstituted unsaturated halides give rise only to dienediyne hydrocarbons[290,291]:

$$RR'C(X)C{\equiv}CC(CH_3){=}CHR'' \rightarrow HC(R'){=}C(CH_3)C{\equiv}CC(RR')C(RR')C{\equiv}CC(CH_3){=}CHR'';$$

R, R′, and R″ = H or alkyl.

The different types of behaviour of the systems investigated can be readily accounted for within the framework of the electronic effects of the substituents and the steric hindrance generated by them. In the study of the effect of the medium and also of various additives on this reaction, it was concluded[293,295] that the reaction proceeds via the formation of radical intermediates. Here it is important that, when a reducing agent (hydroxylamine hydrochloride), is introduced into the reaction medium, the reaction becomes catalytic[295].

It is noteworthy that, under the conditions of the dehalogenodimerisation of vinylpropargyl halides, allyl chlorides containing electron-accepting substituents also enter into this reaction[292]:

$$RR'C{=}C(R'')CH_2Cl \rightarrow RR'C{=}C(R'')CH_2CH_2C(R''){=}CRR'';$$
R, R′ and R″ = H or Cl.

There are literature data concerning the reductive dimerisation of ethers of acetylenic carbinols[296], allenic halides[297], and other systems[298] catalysed by copper or its salts.

It has been reported that in the presence of metallic copper trichloromethylbenzene dehalogenodimerises to dichlorostilbene[299]:

$$C_6H_5CCl_3 \rightarrow C_6H_5CCl{=}CClC_6H_5.$$

The dehalogenodimerisation of α-halogenoacids[300]

$$RR'CBrCOOR'' \rightarrow RR'C(COOR'')-CRR'(COOR'')$$

and of acid chlorides[301]

$$RCOCl \rightarrow RCOCOR$$

is of interest from the practical point of view.

Finally one should note that the amine complexes of copper(I) salts catalyse the intramolecular cyclisation of propargyl ethers[302].

---o0o---

It is evident from the above that during recent years definite advances have been made in the field of cuprocatalytic reactions on the basis of which methods of synthesis of many types of organic compounds have been developed. These processes are undoubtedly still of enormous interest, as shown by the vigorous present development of homogeneous cuprocatalysis based on isonitrile complexes of copper and its salts. The above catalysts are used widely for the synthesis of derivatives of cyclopropane, cyclobutane, cyclopentane, oxazoline, oxazine, imidazoline, thiazole, pyrroline, etc. Earlier data on this field have been surveyed[303]. Synthetic studies on these lines are being continued[304-312]. It is remarkable that copper complexes of the above type catalyse the insertion of isonitriles in the heteroatom—hydrogen bond in amines[311,313,314], alcohols[308,315,316], thiols[317,318], phosphines[319], and silanes[330] and also the esterification of alkanoic, halogenoalkanoic, and halogenoarenoic acids and their anhydrides[321-323]. Isonitrile complexes of copper are used in the binding of carbon dioxide[324-329] and in prototropic[314] and *cis–trans*[323,330] isomerisations. It is extremely important that they catalyse the Michael, Tishchenko, Meerwein–Ponndorf, and analogous reactions[251,330-338], the dimerisation of α,β-unsaturated nitriles and carbonyl compounds[248,249,330-332,339], and the polymerisation of alkenes and their derivatives[340-343]. There is no doubt about the prospects for the further development of both the theoretical and practical aspects of cuprocatalytic reactions; a more profound understanding of their essential features and their control are the tasks for the immediate future.

Advances in the Chemistry of Isoindole

F.S.Babichev, V.A.Kovtunenko, and A.K.Tyltin

Data on the synthesis and physical and chemical properties of isoindoles published in 1968-1978 are examined and problems of the aromaticity of *o*-quinonoid heterocycles (isobenzofuran, isothionaphthene, and isoindole) are discussed. The bibliography includes 214 references.

I. INTRODUCTION

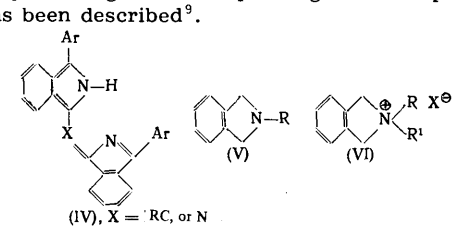
The annelation of benzene and aromatic five-membered heterocycles containing one heteroatom (pyrrole, furan, and thiophen) leads to two classes of bicyclic compounds isoelectronic with naphthalene. If the annelation takes place along the *b* side, the products are the so-called normal isomers or, according to recent chemical usage, type (I) Kekulé isomers: indole (X = NH), benzofuran (X = O), and thionaphthene (X = S). Annelation along side *c* of the five-membered ring leads to isomeric *o*-quinonoid heterocycles of type (II): isoindole (III), isobenzofuran (X = O), and isothionaphthene (X = S). These two classes of heterocycles exhibit fundamental differences of their electronic structure and properties.

Heterocycles of type (I) have been known for more than 100 years and comprise thoroughly investigated stable compounds. Their type (II) isomers have been obtained only comparatively recently after numerous unsuccessful attempts; they proved to be extremely reactive. Among these compounds, isoindole is particularly interesting.

(I) (II) (III)

Since the publication of the first review[1] on the isoindole chemistry, more than 10 years have elapsed. During this period, the parent compound (III) has been synthesised, new methods have been developed for the synthesis of isoindoles, their chemical properties have been investigated in detail, and practical applications have been found for isoindole derivatives. Certain new data on individual aspects of the isoindole chemistry have been described in reviews[2,3], but the information concerning isoindoles in monographs on the chemistry of benzopyrroles[4-7] does not go beyond the information contained in the review of White and Mann[1].

This survey includes all studies on the chemistry of isoindole mentioned in Chemical Abstracts during the last 10 years. It does not deal with condensed isoindoles, tetrahydroisoindoles, isoindolines, and also compounds of type (IV) (X = RC); Svirevski's review is devoted to compounds of the last type[8].



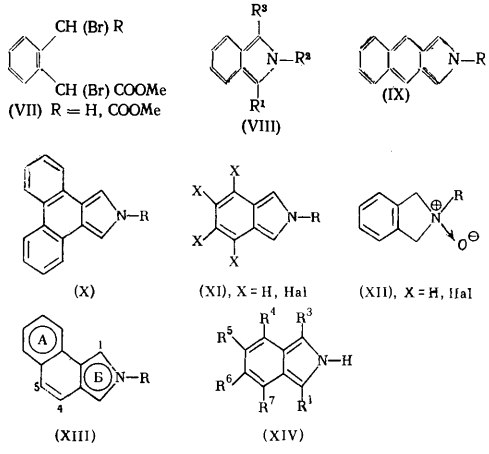
II. METHODS OF SYNTHESIS OF ISOINDOLES

1. Synthesis of Isoindoles from Isoindolines

Two ways of converting isoindolines (V) into isoindoles are possible: (a) the elimination method and (b) the oxidation method. In view of the lack of thoroughly developed methods for the single-stage mild oxidation of compounds (V), the elimination method is preferable.

(a) The Elimination Method

The Wittig method, which consists in treating quaternary ammonium salts (VI) (R = R^1 = alkyl) with strong bases, is not nowadays widely used. Only the synthesis of 2-methylisoindole by treating the corresponding salt with phenyllithium has been described[9].



(IV), X = RC, or N (V) (VI)

A method has been proposed recently[10] for the synthesis of 2-substituted isoindoles from hydrazinium salts (VI, R^1 = NHR^2) by treatment with an excess of alkali or a base; compound (V, R = $BuOOCNCH_2CH{=}CH_2$) and not 2-allylisoindole is formed from the salt (VI, R = $CH_2CH = CH_2$, R^1 = NHCOOBu) under these conditions. The initial salts (VI, R^1 = NHR^2) need not necessarily be isolated in a pure state from the reaction mixture in their synthesis from 1,2-bis(bromomethyl)benzenes and hydrazines[10]. Large series of 1,2,3-trialkylisoindoles have been synthesised by this method[14].

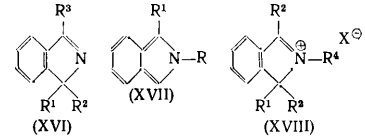
It has been shown that isoindoles are formed in a single stage from the esters (VII) with R = H[12,13] and R = COOMe[11,12] and the corresponding hydrazines with subsequent elimination of ammonia from the intermediate salt of type (VI). It was impossible to make hydrazine hydrate react with the dibromo-derivatives (VII) and obtain isoindoles (VIII, R^2 = H). The interaction of compound (VII) with phenylhydrazine is more complex, but in this case too it is possible to isolate the isoindoles (VIII, R^2 = Ph).[13] Isoindoles (IX) and (X)

with R = Me have been synthesised by the same method from 2,3-bis(bromomethyl)naphthalene and 9,10-bis(bromomethyl)-phenanthrene[15].

Isoindoles (XI, R = alkyl, X = Br) have been obtained in high yields by the acetolysis of the amine oxides (XII) on treatment with a mixture of acetic anhydride and triethylamine[16]. A somewhat different method has been used[17] to synthesise isoindoles (XI, X = H). For the mechanism of the acetolysis of amine oxides, see von Volz and Ruchti[18]. Pyrolysis of amine oxides (XII) is also used to obtain isoindoles[19,20].

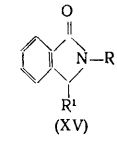
Benzoisoindoles (X, R = H)[22] and (XIII, R = H)[23] have been obtained by treating substituted 2-tosylisoindolines with strong bases. It has been shown[24-26,177] that isoindoles (XIV) can be synthesised successfully from 2-methanesulphonyliso-indolines, which are treated with an excess of potassium t-butoxide in DMSO[21-25,28] or of sodionaphthalene[22] in dimethoxyethane (XXII).

The parent isoindole (III) was first obtained by Bonnett et al.[20,27] in 1972 by the pyrolysis of isoindoline (V, R = OCOOMe). Thermal decomposition of the same isoindoline in a solvent also gives rise to isoindole, which has been demonstrated by the formation of an adduct with *N*-phenylmaleimide[20]. The formation of isoindole from 2-hydroxyisoindoline when the latter is treated with acetic anhydride is indicated by the isolation of the same adduct[20].



(b) The Oxidation Method

The method involving the direct single-stage oxidation of *N*-substituted isoindolines (V) for the synthesis of the corresponding isoindoles began to develop only recently. It has been shown[17] that the self-oxidation of 2-butyliso-indoline depends on the nature of the solvent and is a free-radical process. 1,3-Dimethoxycarbonylisoindole and *N*-alkyl derivatives have been obtained by oxidising the corresponding isoindolines at room temperature with atmospheric oxygen. 1,3-Disubstituted isoindolines having the *cis*-configuration are oxidised to isoindoles much more readily than their *trans*-isomers[21].



2-Arylisoindolines are entirely stable in air at the usual and elevated temperatures and other oxidants must be used to obtain isoindoles from them[21]. Thus the oxidation of compounds (V, R = Ar) to the corresponding isoindoles can be achieved with the aid of chloranil in high-boiling solvents. A heterolytic reaction mechanism, initiated by hydride transfer, is then postulated[29]. The aromatisation of isoindolines using chloranil has been used to synthesise a number of isoindoles (VIII) and gave various yields (23–80%)[13]. The use of 2,3-dichloro-5,6-dicyano-1,4-benzoquinone and the synthesis of 4- and 5-azaisoindoles from the corresponding azaisoindolines have been described[30].

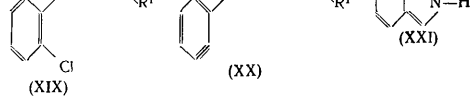
2. Syntheses of Isoindoles via Phthalimidines

Phthalimidines (XV) are structurally similar to isoindoles. Judging from ^{1}H NMR spectra[21], they do not show a tendency towards formation of one of the possible tautomeric lactim forms (XVI, R^3 = OH) or (XVII, R^1 = OH), but Wittig showed[1] that they can be successfully converted into isoindoles either by treatment with organolithium compounds or by reduction. Isoindoles (VIII) are formed in high yields when phthalimidines are treated with a solution of methyllithium[14,32]. 2-, 3-, and 6-Substituted phthalimidines have been used as starting materials in the reaction with methyllithium.

Together with methyl-lithium, ethyl-, butyl-, or vinyl-lithium can be employed in this reaction[14].

Previously Wittig obtained 2-methyl- and 2-phenyl-isoindoles by treating the corresponding phthalimidines with $LiAlH_4$ in ether and subsequent pyrolysis of the intermediate lithium alkoxide. In the case of 2-benzylphthalimidine the corresponding isoindole could not be obtained. The replacement of $LiAlH_4$ by sodium bis(2-methoxyethoxy)aluminium hydride (SBMAH)[33] gives a 60% yield of 2-benzylisoindole. In addition it has been found that the same isoindole can be obtained from *N*-benzylphthalimidine when the latter is treated with SBMAH, while the use of $LiAlH_4$ gives rise solely to the isoindoline (V, R = CH_2Ph).[33]

A new method of synthesising isoindole derivatives involving the use of the Vilsmeier reagent has been developed recently[34,35]. When phthalimidines (XV, R^1 = H) are treated with twice the amount of dimethylformamide (DMF) and $POCl_3$, the salt (XVIII, $R^1 + R^2 = CHNMe_2$, R^3 = Cl) is formed and on heating with alkali is converted into the isoindole (VIII, R^1 = Cl, R^3 = CHO). Treatment of the salts (XVIII, $R^1 + R^2 = CHNMe_2$, R^3 = Cl or Br, R^4 = H) with bases gives rise to the isoindolenine (XVI, $R^1 + R^2 = CHNMe_2$, R^3 = Cl or Br), which can also be converted in its turn into an isoindole of type (XIV)[34]. If the substrate : reactant ratio is altered to equivalent proportions, the reaction product is tris(1-oxoisoindolino)methane. The use of Vilsmeier reagents for the synthesis of azaisoindoles has also been described[36,171].



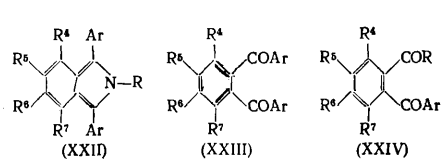
When phthalimidines (XV, R = H) were treated with cyclic immonium salts (formed on mixing pyridine, quinoline, or isoquinoline with benzoyl chloride), isoindoles (VIII) containing the residues of these heterocycles in the 1- and 3-positions were obtained[37]. Phthalimidines (XV), where $R^1 = CH_2Ar$ and R = H, can be aromatised in a similar manner. The reaction of cyclic immonium salts with phthalimidines is one of the examples of the heterylation reaction, the mechanism of which has been described[38].

The lactim forms (XVI, $R^3 = OH$) and (XVII, $R^1 = OH$) can be stabilised by their *O*-alkylation. This reaction has been known for a long time, but interest in 1-alkoxyisoindolenines has increased recently in connection with their use in the synthesis of various nitrogen-containing isoindole derivatives[39-42]. The *O*-alkylation of phthalimidines takes place at room temperature on mixing solutions of phthalimidine and trialkyloxonium fluoroborates in inert solvents. The resulting salts (XVIII, $R^3 = OR$) are converted into 1-alkoxyisoindoles on treatment with strong bases[39-42]. The reaction of Meerwein reagents with 2-methyl- and 2-ethyl-phthalimidines also takes place smoothly, but with formation of salts giving rise to isoindoles (XVII, $R^1 = OAlk$) on treatment with bases[43].

The formation of aza-derivatives of isoindole (XVII, $R^1 = OAlk$) has been described[171].

3. Syntheses of Isoindoles via *o*-Disubstituted Benzenes

Heterocyclisation processes involving dehydrobenzene are known[44], but, when molecules with a potential aryne functional group (for example, a chlorine atom in an aromatic ring) have a side chain exhibiting nucleophilic properties [as in *o*-chlorobenzylamines (XIX)], then intramolecular cyclisation is possible at an intermediate stage in the generation of the aryne (XX). An example of such heterocyclisation is provided by the elegant synthesis of 2-methylisoindole from the amine (XIX, R = H, $R^1 = CN$) and potassium amide in liquid ammonia (89%)[44,45]. Isoindoles (XVII, R = Me, $R^1 = COOR^2$, $CONH_2$, or COPh) have also been obtained by this procedure in very low yields. The mechanism of the reaction (XIX) → (XVII) is still not altogether clear[46].



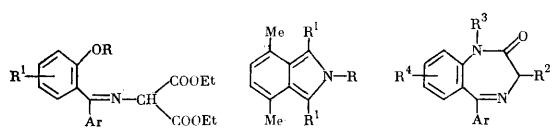
A very simple method of synthesising aminoisoindole (XXI, $R = NH_2$) from the dinitrile of phthalic acid by reduction with $LiAlH_4$ has been proposed[47,48]. The same isoindole can be obtained by the catalytic hydrogenation of *o*-azidomethylbenzonitrile[56].

Babichev and Tyltin[49,55] found that the reaction of *o*-chloromethylbenzonitrile on heating with amines produces in a single stage derivatives of aminoisoindole (XVII, $R^1 = NH_2$) and not benzylamine derivatives, as claimed previously[50], and not 2-substituted phthalimidines, as described in patents[51,183]. A series of similar compounds have also been obtained in other studies[52-54,57] as a result of the interaction of *o*-chloro(bromo)methylbenzonitriles with various primary amines. The corresponding bis-compounds have been obtained from *m*- and *p*-phenylenediamines[55].

Phthalonitrile and its substituted derivatives react with organomagnesium compounds to form red-violet compounds with structure (XIV, X = N); the isoindoles (XVI, R^1 + R^2 = NH) are intermediates in this reaction[58].

1,3-Diphenylisoindoles (XXII) can be obtained by condensing *o*-diacylbenzenes (XXIII) with primary amines or ammonium acetate[59,60].

This method[1], devised by Emmet, was developed further in other investigations[61-66]. The process can be regarded as a modified Leuckart reaction; when applied to compounds (XXIV), it leads to low yields of isoindoles[1,67]. In order to increase the yield, it has been suggested[63] that an alcoholic solution of methylamine be used and that sodium tetrahydroborate be added to the reaction mixture. A number of biologically active isoindoles have been obtained from the benzophenones (XXIV, R = COOEt or $CONR_2^1$)[65,66] on treatment with diethylaminoethylammonium formate.



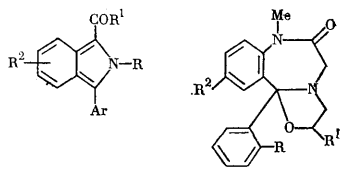
Maekawa and coworkers investigated the reaction of *o*-acylbenzophenones with ammonia[61,62] and primary amines[64,117]. Whereas the interaction of compound (XXIV, R = Ar) with ammonium formate leads to isoindoles, as shown above, the reaction of compound (XXIV, R = Me or Et) under these conditions results in the formation of low yields of isoindole self-condensation products—stable dark-blue pigments (IV, X = RC). Depending on the conditions, three types of compounds can be obtained in the reaction of compound (XXIV, R = Me) with primary alkylamines[64,117].

It follows from the study of Do Minh et al.[68] that none of the products of the interaction of *o*-phthalic aldehyde with ammonia and amines is an isoindole. On the other hand, a mixture of *o*-phthalic aldehyde and β-mercaptoethanol is a familiar and widely used biochemical reagent for the spectofluorimetric determination of aminoacids and proteins[69]. Simons and Johnson[70] suggested that the fluorescent products of the reaction of the above reagent with the *N*-terminal groups of aminoacids and proteins are isoindoles (XVII, $R^1 = SAlk$). To test this hypothesis, *o*-phthalic aldehyde was condensed with n-propylamine in the presence of ethanethiol, β-mercaptoethanol[70], t-butanethiol[71], thiophenol[72], and other thiols. Isoindoles have been isolated in the pure form only in the case of t-butanethiol and ethanedithiol. The formation of isoindoles (XVII, $R^1 = SAlk$) in alcoholic solutions has been investigated[72] by ultraviolet spectroscopy and NMR. The condensation products exhibit a strong fluorescence, which in general confirms the above hypothesis.

It has been shown[73] that, when *o*-acetylphenylacetic acid is condensed with hydroxylamine, the isoindole (XIV, R^1 = Me, R^3 = COOH) is formed in a high yield. A novel method of synthesising isoindoles has been described in a patent[74]. On heating with a large excess of imidazole (or alkylimidazoles), compounds (XXV) give rise to isoindoles (XIV, R^1 = Ar, R^3 = COOEt) in 16–60% yields; in the absence of imidazoles, the reaction does not take place.

On condensation with 1,2-dicyano- or 1,2-dibenzoylethanes, 3,4-diformyl-1,2,5-trimethylpyrrole gives rise to 5,6-dicyano(dibenzoyl)-1,2,3-trimethylisoindoles[75]. Derivatives of 5-aza- and 5,6-diaza-isoindoles have also been obtained from this pyrrole[75].

4. Condensation of 1,4-Diketones with Amines or Pyrroles



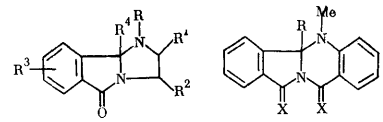
If both α-positions of the pyrrole ring are occupied, as, for example, in 2,5-dimethylpyrrole, then condensation with 1,4-diketones results in the formation of isoindole derivatives (XXVI)[1]. When a mixture of 1-R-2,5-diphenylpyrrole[19] or 1-R-2,5-dimethylpyrrole[19,28,76] and hexane-2,5-dione is refluxed in acetic acid, the corresponding isoindoles (XXVI)

are formed. The isoindole (XXVI, R = Me) was obtained in a single stage from methylamine and hexane-2,5-dione[19,76]. It was shown[28] that refluxing of a solution of 2,5-dimethylpyrrole in aqueous acetic acid results in the formation of the isoindole (XXVI, R = H) in 82% yield as a result of self condensation. This finding is of interest, because it had been observed earlier[1] under similar conditions that 2,5-dimethylpyrrole undergoes reductive self condensation with formation of a mixture of *cis*- and *trans*-1,3,4,7-tetramethylisoindolines.

5. Isoindoles as Products of the Isomerisation of 1,4-Benzodiazepinones

The rearrangement of 1,4-benzodiazepinones to isoindoles, noted by White and Mann[1], has been used to obtain several series of biologically active isoindoles[65,66,77]. Thus 1,4-benzodiazepinones (XXVII) give rise to a high yield of the amides (XVIIIa, R = H) on treatment with NaH in DMF[65,66,77]. A rearrangement of the above type also takes place with thioanalogues of compounds (XXVII), which gives rise to high yields of thioamides[77].

(XXVIII) (XXIX)



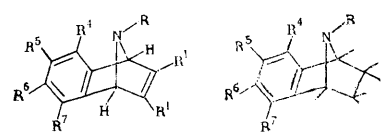
(a) R^1 = NHMe; (b) R^1 = OR^3

It has been shown[65,66] that, if the isomerisation is carried out in the presence of carbonic acid esters, then, instead of amides, the products are the esters (XXVIIb). A method of carrying out the single-stage transformation (XXVII) → (XXVIIIb, $R^3 = CH_2CH_2NEt_2$) has been described in a patent[65].

Like 1,4-benzodiazepin-2-ones, the esters (XXVII, R^2 = COOR) can be converted into isoindoles; the products are the isoindoles (XXVIIIb, R = H). An interesting difference in the behaviour of condensed benzodiazepinones (XXIX) under the conditions of isomerisation to isoindoles has been discovered[78]. It was found that compound (XXIX, R = Cl) isomerises to the corresponding isoindole, while compound (XXIX, R = H) gives rise to other products.

6. Reduction of Condensed Isoindoles with $LiAlH_4$

According to Sulkowski et al.,[80] treatment of imidazoisoindoles (XXX) with $LiAlH_4$ in diethyl ether yields 2,5-benzodiazocines. However, it has been shown[81-85,178] that, in the presence of an excess of $LiAlH_4$ and after prolonged refluxing of the reaction mixture, 2-(*N*-alkylaminoethyl)isoindoles are formed together with the corresponding diazocines. Under identical conditions, pyrimidoisoindoles are reduced by $LiAlH_4$ to 2-(aminopropyl)isoindoles[81,83,84] with high yields, while 1-methyl-1,3,4,10*b*-tetrahydro-2*H*-pyrimido[2,1-*a*]isoindol-6-one is reduced to the isoindole [XVII, R = $(CH_2)_3NHMe$].[86] The reduction of the benzo-analogue (XXX, R = R^3 = H) with an excess of $LiAlH_4$, followed by treatment with alcohol, gives rise to the isoindole (XVII, R = 2′-$C_6H_4NH_2$).[83]



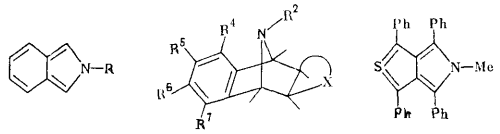
(XXX) (XXXI)

A pattern, which is similar in broad outline, is observed in the reduction of compounds of type (XXXI, X = O) with $LiAlH_4$. The reduction product is compound (XXXI, X = H_2) which isomerises during chromatography to the isoindole (XVII, R = 2′-$CH_2C_6H_4NHMe$).[83,87]

7. Synthesis of Isoindoles by the Diels–Alder Retro-Reaction

The study of the Diels–Alder retro-reactions, taking into account their similarity with mass-spectrometric, thermal, and photochemical processes, contributed much new information to the chemistry of simple isoindoles and isobenzofurans and yielded extremely useful results[88]. The first data on the thermal decomposition of derivatives of 7-azabenzonorbornadiene (XXXII) were obtained as early as 1963 by Wittig[89], who isolated α-naphthylamine in the thermolysis of the hydrobromide of compound (XXXII, R = R^{4-7} = H). In 1966 Carpino and Barr[90] obtained similar results.

The first evidence for the possibility of obtaining isoindoles from compounds (XXXII) was obtained by Coe and Uff[91]. Subsequently it was found that the loss of ethylene in the mass-spectra of 7-azanorbornenes (XXXIII) constitutes the principal type of fragmentation of the molecular ion (XXXIII, R = Me, R^{4-7} = F), and the isoindole (XI, R = Me, X = F) was isolated quantitatively in the thermolysis of the above compound at a temperature as low as 120 °C.[88] The essential feature of the Diels–Alder reaction consists in the thermolysis of the products (XXXII) and (XXXIII) obtained initially by the Diels–Alder reaction. An example of the direct conversion of compound (XXXII, R = R^{4-7} = H) into isoindole with elimination of acetylene has been described[92,187].



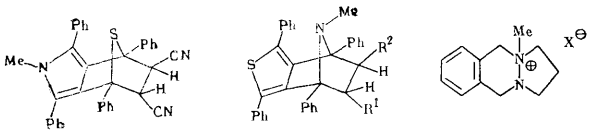
(XXXII) (XXXIII)

Thermolysis of derivatives of compound (XXXIII) leads to the loss of an ethylene molecule and the formation of the corresponding isoindole. The isoindoles obtained by the Diels–Alder retro-reaction are very pure. The isoindoles (XXIV)[93], (XI, R = H, Me, or CH_2Ph, X = F),[94,95] and benzo[*f*]isoindole[95,176] have been obtained by this method.

An interesting version of the Diels–Alder retro-reaction has been proposed in a study[96] where it was shown that the derivatives (XXXII) readily undergo the [2 + 4] cycloaddition reaction with 3,6-dipyridyl-*sym*-tetrazine to form the 1,1-adducts [XXXV, X = C(α–Py) = N–N = C(α–Py)], whose thermolysis gives rise to a mixture of isoindole and 3,6-di-α-pyridylpyridazine. This procedure was used by Anderson[97] to obtain isoindoles, but the adduct [XXXV, X = –NPh–N= C(Ph)–] then undergoes pyrolysis.

The synthesis of the isoindole (III) by the high-vacuum pyrolysis of compound (XXXIII, R = COOBu) has been described[98]. 1-Methyl- and 1,3-dimethyl-isoindoles have

been obtained by this method from the corresponding derivatives (XXXIII). It has been established in relation to the Diels–Alder retro-reaction for 7-azabenzonorbornene (XXXIII) and 7-azanaphtho[2,3]norbornene that the pyrolysis of both compounds at 125 °C leads exclusively to deamination (i.e. results in the formation of naphthalene and anthracene respectively); the relative yield of isoindole increases with increase of the pyrolysis temperature and reaches a maximum at 700–800 °C.[99]



(XXXIV) (XXXV) (XXXVI)

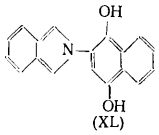
The 1:1 adducts of the Diels–Alder reactions with condensed thiophens (XXXVI) are capable of giving rise to isoindoles under the conditions of the Diels–Alder retro-reaction[100,101]. Thus, when a mixture of equimolar amounts of compound (XXXVI) and fumaronitrile is refluxed in xylene for 12 h, the isoindole (XXII, $R^{4,7}$ = Ph, R = Me, $R^{5,6}$ = CN) is formed in 53% yield. On being refluxed in toluene for 12 h, fumaronitrile and compound (XXXVI) form compound (XXXVII) in 67% yield, while refluxing in benzene for 1 h gives a 63% yield of compound (XXXVIII). Both compound (XXXVII) and compound (XXXVIII) are capable of being converted into the above isoindole in a high yield on being refluxed in xylene. The adduct (XXXVII) can be converted into isoindole also on mixing its solution in methanol with sodium methoxide. The thienopyrrole (XXXVI) undergoes similar reactions with acrylonitrile and ethyl acrylate[100,101].

8. Synthesis of Isoindoles by the High-Vacuum Pyrolysis of Heterocyclic Compounds

High-vacuum pyrolysis—one of the modern methods of synthesising new heterocyclic systems[102]—has also been used to obtain isoindoles. Thus it has been shown[103] that isoindole derivatives can be obtained by the vacuum flash pyrolysis of phenyl-1,2,4-triazoles. The possible mechanism of the formation of isoindole in the thermolysis of triazoles includes the 1,5-sigmatropic shift of the *N*-phenyl group and the formation of a non-aromatic intermediate, the elimination of molecular nitrogen, and the cyclisation of the iminocarbene (or the 1,3-biradical) to 1,3-diphenylisoindole[103].

(XXXVII) (XXXVIII) (XXXIX)

The vacuum pyrolysis of *N*-(2-hydroxy-3-isoquinolinyl)-urethane at 600 °C affords 1-cyanoisoindole in quantitative yield[104,105,179]. It has been mentioned in patents[105,179] that this method can be used to synthesise also 1-cyanoisoindoles substituted in the benzene ring. The necessary condition is then the stability of the substituent on pyrolysis; the most suitable substituents proved to be the fluorine and chlorine atoms and the Me and CN groups[179].



9. The Formation of Isoindoles in the Isomerisation of Heterocyclic Compounds

The rearrangement of 1-(4′-chlorophenyl)-2,5-benzodiazocine to derivatives of 2-aminoethylisoindole under the influence of strong bases is a familiar example[82,85]. The isomerisation is accompanied by the dehydrochlorination of the initial compound and, if there is no chlorine atom in the *p*-position in the benzene ring, which corresponds to the 1-position in benzodiazocine, then the product is 2-(β-aminoethyl)-1-phenylisoindoline[82].

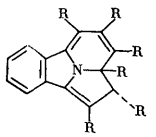
A study of the reactions of isoquinoline derivatives with nucleophiles yielded interesting results for the chemistry of isoindole[106,107]. Thus it has been found that the amination of 3-amino-4-bromoisoquinoline with potassium amide in liquid ammonia gives rise to a mixture of 1-cyanoisoindole and 3-aminoisoquinoline[106]. The condensed hydrazinium salt (XXXIX) gives rise to 2-(3-methylaminopropyl)isoindole on treatment with potassium t-butoxide[86].

10. Other Methods of Synthesis of Isoindoles

When a benzene solution of *N*-(2-naphthoquinonyl)isoindoline is irradiated with light from a mercury lamp, an intramolecular oxidation–reduction reaction takes place with formation of the isoindole (XL).[108]

(XL)

Together with other products, the addition of di-t-butylthioketen to benzophenone methylimine results in the formation also of the isoindole (XVII, R = $CHPh_2$, R^1 = Ph).[109]



The oxidation of *N*-aminophthalimide produces phthalimidonitrene, while the reaction of the latter with isobenzofuran derivatives has been shown[110] to constitute a pathway leading to a high yield of 2-phthalimidoisoindole.

The two-electron polarographic reduction of 1,2-dihydrophthalazines in an acid medium initially produces isoindole and then isoindoline[111].

III. PHYSICAL PROPERTIES

1. Bond Orders and Lengths

There are no literature data on the X-ray diffraction analysis of isoindole derivatives. The geometrical parameters of compound (XLI), whose structural element is an isoindoline fragment, are known[112].

(XLI)

The bond orders and lengths in isoindole, 1-phenylisoindole[114], 2-phenylisoindole, 1,3-diphenylisoindole[114], benzo[*f*]isoindole[15,114], benzo[*e*]isoindole[114,115], and dibenzo[*e*,*g*]-isoindole[14,114] have been calculated by the SCF MO[15,113–115] and *ab initio*[116] methods. It has been noted[115] that the calculated bond lengths in benzo[*e*]isoindole (XIII, R = H) indicate an appreciable localisation of the bonds between the (A) and (B) ring systems (see Section II, 1a).

2. Distribution of π-Electron Density and Dipole Moments

The results of the calculations of the distribution of π-electron density in the isoindole molecule and the calculated dipole moments have been published (Table 1)[15,115,116,118-120]. Analysis of these data indicates unambiguously the order in the variation of the π-electron density in isoindole (III): $q_1^\pi > q_{3a}^\pi > q_5^\pi > q_4^\pi$. According to the above sequence in the variation of the π-electron density, assignments were made to the corresponding protons in the ^{1}H NMR spectrum of 2*H*-isoindole[27]. The calculations showed that the effective π-electronic charges on the carbon atoms of the pyrrole ring in 1-phenylisoindole are greater, as in benzo[*e*]isoindole (XIII, R = H), than on the remaining carbon atoms[114]. The following sequence in the distribution of π-electron density holds for compound (XIII): $q_3^\pi > q_1^\pi \gg q_5^\pi$.

Table 1. The distribution of electron density in isoindole (III).

* 2-Phenylisoindole. Calculation carried out by V.I.Minkin.
** 2-Methylisoindole.

The data on the distribution of π-electron density make it possible to attempt an approach to its quantitative estimation in the series of *o*-quinonoid heterocycles (II) and their isomers (I) on the basis of the concept of the excess π-electron density in heterocycles. According to Pozharskii[121], the average negative charge per carbon atom of the heterocyclic system can serve as a measure of the excess π-electron density. Thus, according to the results of calculations[114], the average effective π-electronic charges on all the carbon atoms of pyrrole, isoindole, indole, and carbazole are respectively −0.040, and −0.024, −0.015, and −0.008, while on the carbon atoms of the pyrrole ring in the above compounds they are −0.040, −0.044, −0.024, and −0.013 respectively. The above results indicate a higher excess π-electron density in isoindole compared with indole.

The same conclusion can be arrived at by comparing the distribution of π-electron densities in the above compounds, obtained from SCF MO[115,118] and *ab initio*[120] calculations. Comparison of the effective π-electronic charges on the carbon atoms of the pyrrole ring in the above benzopyrroles and the parent compound indicate a higher excess of π-electron density in isoindoles (III) even by a comparison with pyrrole. Similarly the results of calculation[114] permit the conclusion that the excess π-electron density in isobenzofuran (II, X = O) is greater than in benzofuran (I, X = O); the results of calculations of the distribution of π-electron density in compounds (II, X = NH, S, or O)[116] when the latter are examined from the standpoint of effective π-electronic charges of the carbon atoms indicate a comparatively greater excess of π-electron density in isoindoles (III) compared with the remaining *o*-quinonoid heterocycles.

3. The Reactivity Indices of Isoindoles

Qualitative conclusions concerning the direction of electrophilic and nucleophilic attack as well as addition reactions have been reached on the basis of the calculated charge densities within the framework of the isolated molecule approximation[115]. The 1(3)-position in *o*-quinonoid heterocycles (II) is most likely to undergo electrophilic attack, while the 4(7)-position is most favourable for nucleophilic attack. Analysis of the bond orders of *o*-quinonoid heterocycles (II) led to the conclusion that the $C_{(4)}-C_{(5)}$ (or $C_{(6)}-C_{(7)}$) bond should be most reactive in addition reactions[115]. The calculated free valence indices of the above compounds made it possible to determine the preferential direction of attack in free-radical reactions; for all the *o*-quinonoid heterocycles, these are the $C_{(1)}-C_{(3)}$ atoms. According to Klasinc et al.,[115] in benzo[*e*]isoindole the $C_{(4)}$ atom is subjected to electrophilic attack, while nucleophilic and radical attack is directed to the $C_{(3)}$ atom. It is noteworthy that these conclusions[115] are inconsistent with the results of the determinations and calculations of the electron density in the molecule of compound (XIII).[114]

4. The NMR Spectra of Isoindoles

The first calculation of the chemical shifts of isoindoles (III) was carried out by Black et al.[122] With the aid of a modified VESCF method, the authors calculated the delocalised contribution (the contribution of ring currents) to the diamagnetic anisotropy $\Delta\chi$ of heteroaromatic molecules.

Heterocycle	$-10^6\,\Delta\chi$
Indolisine	39.39 — 39.58
Isoindole	43.76 — 44.94
Indole	45.12 — 45.83
Isobenzofuran	40.68 — 41.78

Calculation of the chemical shifts of the isoindole protons[122] led to the following sequence: $\delta_{4,7\text{-H}} > \delta_{1,3\text{-H}} > \delta_{5,6\text{-H}}$. Later the same sequence was established experimentally.[20,27,93] Recently attempts have been made to relate the ring current data to the degree of aromaticity of the entire molecule itself. Corradi et al.[119] calculated the contributions of the ring currents to the shielding constants. The results of the calculations support the idea of a limited degree of aromaticity of the above compounds. The conversion of the five-membered heterocycles into their benzo-derivatives results in an increase of the ring current effects relative to the sum of the currents of the individual constituent rings. The annelation of the benzene ring to the *b* side of the five-membered heterocycle [the Kekulé structure (I)] has been shown by calculation[119] to entail a greater delocalisation of electrons than the annelation to the *c* side [the *o*-quinonoid heterocycle (II)].[119]

Analysis of the ^{1}H NMR spectra of substituted isoindoles showed that, following the absorption of resonance energy by the protons, the following sequence obtains: $\delta_{4,7\text{-H}} > \delta_{1,3\text{-H}} > \delta_{5,6\text{-H}}$, although it can break down in certain cases for $\delta_{1,3\text{-H}}$, depending on the nature of the substitution in the system. For the chemical shifts of the protons of the methyl groups in 2*H*-isoindole derivatives, it is more difficult to observe a similar rule; however, the relation $\delta_{1,3\text{-Me}} > \delta_{4,7\text{-Me}}$ holds at least in many instances.

The ^{1}H NMR spectrum of the parent isoindole (III) has been obtained quite recently[20,27,93]. The four-spin system of the AA'BB' spectrum, corresponding to the spin—spin interaction of the protons in isoindole, has been analysed[15,116,123,125] with the aid of the LAOCN3[123-125], LAOCOONII[15],

LAMS[116], and NMRIT[125] programmes. In the first stage of the computations based on the LAMS programme calculations were made for the four-spin system AA'BB' (protons in the 4-, 5-, 6-, and 7-positions) and then for the six-spin system of the AA'BB'XX' spectrum (i.e. for additional H in the 1- and 3-positions). In order to determine the accurate spin–spin interaction constants (SSIC) of isoindoles, the results of the calculation were compared with experiment. The SSIC of isoindoles are compiled in Table 2. The ^{19}F NMR spectrum of 4,5,6,7-tetrafluoroisoindole has been recorded[97].

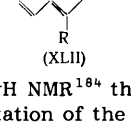

Table 2. The spin–spin interaction constants (SSIC) (J_{H-H}, Hz) of isoindoles.

Isoindole	$J_{4,5}=J_{6-7}$	J_{5-6}	$J_{4-6}=J_{5-7}$	J_{4-7}	Refs.
(III)	8.49	6.29	0.89	0.98	[123, 124]
(XXXIV) (R=Me)	8.60	6.28	0.86	0.98	[15]
ditto	8.690	6.456	0.899	0.790*	[116]
(VIII) (R^1=R^3=Ph, R^2=Me)	8.63	6.35	0.98	1.02	[15, 125]

* In addition, the transannular constants $J_{1-4} = 0.457$, $J_{1-6} = -0.070$, $J_{1-7} = -0.081$, and $J_{1-5} = 0.070$ are presented.

Data have been published[116,188] on the ^{13}C NMR spectrum of 2-methylisoindole. The similarity of the resonance absorption of energy by different carbon atoms is striking. The most characteristic feature of the 2-methylisoindole spectrum is the overall upfield shift of the absorption due to the carbocyclic ring carbon atoms (by ~ 6 p.p.m.); an even greater shift is observed for the $C_{(1)}$, $C_{(3)}$ atoms of isoindole, particularly in relation to the corresponding $C_{(2)}$ atoms of pyrrole or indole.

The ^1H NMR method combined with the shift reagent method [Eu(DPM)$_3$][126] made it possible to determine the structure of the preferred conformer of acyl derivatives of the isoindole (XLII, R = COR^1, R^1 = H or Me). In both cases the phenyl substituent in the 2-position is displaced from the ring of the bicyclic system, while the carbonyl group is located in space in such a way that it influences the resonance absorption of the $H_{(4)}$ proton due to a non-bonding interaction. The signal of the $H_{(4)}$ proton is displaced downfield, the strongest signal (~ 1 p.p.m.) being observed for the formyl derivative[126].

(XLII)

It has been shown by ^1H NMR[184] that even at very low temperatures the free rotation of the dimethylamino-group of the isoindole (XLII, R = H) is unhindered.

5. Photoelectron Spectra

A correct method for estimating the energy of the highest occupied molecular orbital (HOMO) may be based on the first ionisation potential (IP) of the molecule. Information about the ionisation potential can be obtained from photo-electron spectra. The photoelectron spectra of isoindole and other *o*-quinonoid heterocycles were determined in 1976 by three groups of investigators[15,116,127]. In all cases a helium lamp served as the source of radiation. Inspection of the experimental and calculated Franck–Condon (vertical) values of IP[114,124] shows that not all methods of calculation yield satisfactory results.

The method of structural representations for the theoretical description of electronic spectra, the foundations of which were laid by Simpson[130], has been used successfully to predict the IP in studies by Koenig and coworkers[127,131,185]. The method has been used[127] to calculate the IP of 2-methylisoindole.

Inspection of the data in Table 3 permits the following conclusions.

(1) the IP diminishes successively in the series pyrrole–indole–isoindole, i.e. an increase in the size of the aromatic system entails an increase of the HOMO energy.

(2) The nitrogen-containing heterocycles (I), (II), and (LVII) have more marked π-donor properties than their oxygen and sulphur analogues.

(3) the benzo[*c*]-derivatives of the monocyclic compounds (LVII) have lower IP (higher HOMO) than the benzo[*b*]-derivatives, i.e. the heterocycles with the *o*-quinonoid structure have a more pronounced π-donor capacity than their positional isomers.

Table 3. The first ionisation potentials (IP, eV) of *o*-quinonoid heterocycles, their positional isomers, and the monocyclic compounds.

X			
>N—CH$_3$	7.95 [127]	7.87 [127]	7.2 [116]
—S—	8.86 [129]	8.47 [121]	7.7 [116]
—O—	8.89 [129]	8.29 [121]	8.0 [116]

Note. The numbers in square brackets denote references (Ed. of Translation).

The capacity of isoindoles for the formation of charge-transfer complexes (CTC) on interaction with electron acceptors may be regarded as confirmation of the existence of the π-donor capacity. A stable complex of 2-methylisoindole with trinitrobenzene has been described[14]. Similar complexes had been obtained earlier for pyrrole, indole, and other heteroaromatic compounds.

6. Electronic Spectra

The above photoelectron spectroscopic data show that the *o*-quinonoid heterocycles require less excitation energy than their structural isomers. This conclusion is also confirmed by a comparison of the electronic spectra of indoles and isoindoles. Whereas the long-wavelength absorption maximum in the spectra of indoles is displaced towards shorter wavelengths compared with that in the naphthalene spectrum, in the spectra of isoindoles it is actually at longer wavelengths. Analysis of the ultraviolet spectra of isoindoles permits certain generalisations. Three regions of absorption in the ultraviolet are characteristic of 2*H*- and 2-alkyl-isoindoles:

(a) Band *A* (230 ± 5 nm) with an intensity lg ε = 4.2–4.5 (one maximum);

(2) band *B* (260–290 nm) with an intensity lg ε = 3.1–3.3 (from one to three maxima);

(3) band *C* (320–350 nm) with an intensity lg ε = 3.6–3.7; solutions of isoindoles in n-hexane absorb in region *C* in the form of several closely spaced maxima, which is associated with the vibronic interactions.

A bathochromic shift of bands *A*, *B*, and *C* has been observed for 2-arylisoindoles compared with 2-alkyl-substituted derivatives. The intensity of the bands in regions *A* and *C* does not then change, while the intensity of the *B* band increases somewhat. The introduction of phenyl substituents in the 1,3-positions of isoindole results in a bathochromic shift of the absorption in region *C* accompanied by a slight hyperchromic effect for bands *B* and *C* compared with the parent isoindole and 2-alkylisoindoles.

The absorption spectra of benzoisoindoles are determined by the type of annelation of the benzene ring. Thus benzo[*e*]- and dibenzo[*e*,*g*]-isoindoles[15] absorb in the same region of the ultraviolet spectrum as the parent isoindole, while the long-wavelength absorption maximum in the spectrum of benzo[*f*]isoindole is displaced to the visible region[15]. Furthermore, the intensity of the *B* band is much higher in the spectra of benzoisoindoles.

Calculations of the energies of the singlet–singlet transitions for isoindole and its benzo-derivatives have been made by semiempirical methods in the π-electron approximation[15, 113,115,118,134]. Calculated data closest to the experimental values have been obtained by Rettig and Wirz[15] and Klasinc et al.[115] The directions of polarisation of the absorbed light in the transitions to the S_1 and S_2 states of the isoindoles (XXXIV, R = Me) and (IX, R = Me) have been predicted on the basis of calculations[15] and then confirmed experimentally. Tests showed that the $S_0 \rightarrow S_2$ transitions in the above compounds are polarised along the major molecular axis, while the $S_0 \rightarrow S_1$ transition, which should have been polarised along the short molecular axis, in fact exhibits a mixed polarisation due to the excess vibrational energy, which the molecule receives on excitation[15].

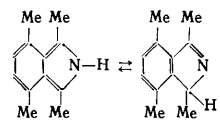
A phenomenological approach to the analysis of the electronic spectra of isoindoles has been made[118] on the basis of the indene anion model as a general perturbed system. An intense fluorescence corresponds to the long-wavelength absorption band of isoindoles. It has been shown[15] that in 2-methylisoindole 8% of the excitation energy is emitted in the form of phosphorescence with a lifetime of 0.4 s, and that its first triplet level is lower relative to naphthalene, for which E_T = 21266 cm^{-1} according to Gordon and Ford[129].

The mechanism of the spectral chemiluminescence of two arylisoindoles has been investigated[135]. The authors concluded that a cooperative effect is responsible for the excitation of electrochemiluminescence.

7. Infrared Spectra of Isoindoles

No systematic studies have been made of the infrared spectra of derivatives of isoindoles in order to discover and assign their characteristic absorption bands. Within the framework of a study of the tautomerism and association of cyclic amidines, their infrared spectra, including those of 1-aminoisoindole, have been obtained[48]. Theoretically, three tautomeric structures are possible for 1-amino-isoindoles, but, according to the results of the study of its infrared spectra in the solid state and in solution, it exists mainly in the form (XVI, $R^1 = R^2 = H$, $R^3 = NH_2$).

8. Mass Spectra of Isoindoles



A general characteristic feature of all the known data for the mass-spectra of isoindoles may be noted, namely the fact that the most intense peak in the spectrum is that of the molecular ion M^+. In the majority of studies of isoindole the mass-spectrometric data are confined to those for M^+. The complete set of mass-spectrometric data is available for the following isoindoles: compound (III)[20,27], 2-methylisoindole[44], compound (IX)[15], compound (X)[15], 2-butylisoindole[20], and 2-ethyl-1,3,4,7-tetramethylisoindole[76]. The fragmentation of 1,3-diphenylisoindole and 1,3-diphenylisobenzofuran has been analysed in detail in only one study[136].

9. The Tautomerism of Isoindoles

One of the most characteristic features of isoindole (III) is its ability to undergo rapid tautomeric transformations into the corresponding 1*H*-isoindoles (isoindolenines) (IIIa). Since the *o*-quinonoid structure (III) and the isoindolenine structure (IIIa) differ insignificantly in their thermodynamic stabilities, which precludes the isolation of the tautomeric forms in a pure state, the equilibrium (III) ⇌ (IIIa) was investigated by ultraviolet and infrared spectroscopy and mainly by NMR.

The first studies[20,27,94] on the NMR spectra of isoindole (III) at low temperatures (−40 °C) showed that this compound is a mixture of tautomers (III) and (IIIa) with the *o*-quinonoid structure predominating in the equilibrium. However, it was found later[123] that, when a mixture of compounds (III) and (IIIa) is dissolved in solvents of different polarity, the content of compound (III) in solution increases with time, its accumulation obeying a kinetic first-order law ($T_{1/2}$ = 16 min). It has been established by ^{1}H NMR that the content of the *o*-quinonoid structure (III) increases at −40 °C in initial mixtures in solvents of different polarity. In all cases the NMR signals corresponding to the isoindolenine structure (IIIa) disappear altogether after a definite time interval, i.e., regardless of the polarity of the medium, the process stops only when the isoindolenine form (IIIa) is completely (or almost completely) converted into the thermodynamically more favourable *o*-quinonoid structure (III).

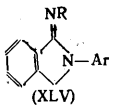
1-Methyl-, 1,3-dimethyl-, and 1,3,4,7-tetramethyl-isoindoles as well as the parent isoindole (III) exist in solution in equilibrium with their isoindolenine tautomers and the equilibrium position depends significantly on the nature of the solvent employed[98]. The study of deuterium exchange for 1-phenylisoindole confirmed unambiguously the earlier observation of equilibrium between isoindole and its isoindolenine tautomer[98,123]:

(XLIII) (XLIV)

It has been shown with the aid of infrared, ultraviolet, and ^{1}H NMR spectra that the isoindole (XLIII) exists in solution as well as in the solid state in a mixture with its tautomer (XLIV) with the latter predominating[28]. It has been found that the state of tautomeric equilibrium is greatly influenced by the ability of solvents to form intermolecular hydrogen bonds with compound (XLIII).

The position of the isoindole–isoindolenine equilibrium depends on two effects[137]—electronic and steric. Electron-donating groups in the 1- and 3-positions of the bicyclic system stabilise the isoindolenine tautomer. For example,

the amount of the isoindolenine tautomer in deuterochloroform is 9% for compound (XXI, R = Ph), 31% for (XXI, R = 4′MeOC$_6$H$_4$), and 100% for (XXI, R = OEt). On the other hand, electron-accepting groups increase the content of the *o*-quinonoid structure in the tautomeric mixture in deuterochloroform. 5-Methyl-1,3-diphenylisoindole[60], 1-cyanoisoindole[104], 1-methoxycarbonylisoindole[13], and 1,3-dimethoxycarbonylisoindole[11] have the 100% *o*-quinonoid structure. On the other hand, the steric effect is manifested in compounds (XLIII), where there are two peri-interactions involving the methyl groups in the 1,7- and 3,4-positions and exerting a destabilising influence. In the tautomeric form (XLIV) one of these interactions has been eliminated which is undoubtedly associated with a considerable energy gain[137].



The type of annelation of benzene rings to the isoindole molecule influences significantly the position of the tautomeric equilibrium. In agreement with quantum-chemical calculations[1], the isoindoles (X, R = H)[22] and (XIII, R = H)[23] exist exclusively in the *o*-quinonoid form, while benzo[*f*]-isoindole (IX, R = H) exists preferentially in the corresponding tautomeric isoindolenine form (IXa), but the formation of an adduct with *N*-phenylmaleimide confirms the presence of a certain amount of the tautomer having the isoindole structure (IX)[176]. Halogen (fluorine[94,95,97], chlorine[25], and bromine[24]) atoms in the isoindole ring suppress the formation of the isoindolenine tautomer and stabilise the system as a whole compared with the parent compound. The presence of the isoindolenine tautomer has not been observed for any of the halogenoisoindoles. We mentioned above the unsuccessful attempt to isolate both tautomeric forms of isoindoles. However, in the case of compound (XXVI, R = H) each tautomeric form was obtained in a pure state. When a solution of the methylamide (XXVIII, R = H) in DMF is treated with sodium carbonate, the isoindolenine (XVI, R^1 = CONHMe, R^2 = H, R^3 = Ph) is formed. On treatment with acid, this compound is converted into the tautomer with the isoindole structure[77].

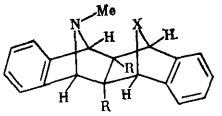
IV. CHEMICAL PROPERTIES

1. Alkylation of Isoindoles

The alkylation of isoindoles unsubstituted at the nitrogen atom can proceed in two ways: either at the N$_{(2)}$ atom with formation of 2-R-isoindoles or at the C$_{(7)}$ (or C$_{(3)}$) atom of the pyrrole component of the bicyclic system. Thus methylation of 1,3-dimethoxycarbonylisoindole with diazomethane in ether gives a high yield of the *N*-methyl derivative[21]. Alkylation of aminoisoindole with phenacyl bromide also involves the N$_{(2)}$ ring nitrogen atom with formation of the salt (XVIII, R^3 = NH$_2$, R^4 = CH$_2$COPh)[138].

Interesting results have been obtained[49,139] in the alkylation of cyclic amidines having the general formula (XLV, R = H) with dimethyl sulphate (DMS). The interaction of compound (XLV) with DMS gives rise to the corresponding *N*-methylisoindolenine methosulphates (XLV, R = Me). The bases (XLV, R = Me) react with DMS to form salts, which are converted into the isoindoles (XLII, R = H) on treatment with bases[139]. 1,3- and 1,4-Bis(1-dimethylamino-2-isoindolyl)benzenes have been obtained similarly from the corresponding cyclic amidines[55]

(XLV)



The alkylation of 1-alkoxyisoindolenines[43,56] with trialkyloxonium fluoroborates involves the nitrogen atom N$_{(2)}$ with formation of the salts (XVIII, R^3 = OAlk), from which the isoindoles (XVII, R^1 = OAlk) can be obtained by treatment with bases. The vast majority of instances of the alkylation of isoindoles unsubstituted at the N$_{(2)}$ atom involve the preliminary generation of isoindole anions with the aid of alkali metal hydrides[28,65,66,94,140,141], alkoxides[77,78], or hydroxides[58] in suitable solvents. Thus the alkylation of the esters (XXVIIIb, R = H) and the amides (XXVIIIa, R = H) at the ring nitrogen atom has been described in patents[65,66].

The alkylation of the 3-(4′-chlorophenyl)-1-ethoxyisoindole anion with alkyl halides[42,141] or bromoacetic esters[140,180–182] involves the C$_{(3)}$ carbon atom with formation of racemic isoindolenines of the type (XVI, R^3 = OEt). On alkylation with benzyl bromide, the anion of the isoindole (XLIII) yields 1-benzyl-1,3,4,7-tetramethyl-1*H*-isoindolenine[28]. The anions of the methylamides (XXVIIIa, R = H) are alkylated with ethylene bromohydrin[78] and methyl iodide[77] at the N$_{(2)}$ ring nitrogen atom, but in the latter case the *C*-alkylation product is also isolated. More complex compounds containing the ring of the isoindole (IV) are alkylated by dialkyl sulphates at the N$_{(1)}$ atom in the presence of bases[58].

2. The Diels–Alder Reactions

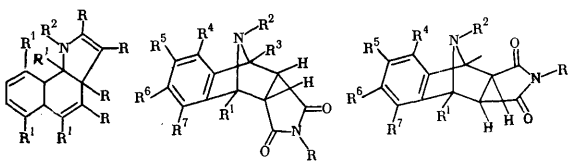
(a) The Addition of Dimethyl Acetylenedicarboxylate (DMAC)

Isoindoles combine extremely readily with DMAC to form products with different proportions of isoindole and DMAC[2]. Thus Wittig showed[1] that 2-methylisoindole forms a 2:1 adduct (XLVI) with DMAC. However, the majority of isoindoles give rise to 1:1 adducts (XXXII, R^1 = COOMe), i.e. substituted 7-azabenzonorbornadienes[92,187].

(XLVI)

The reactions of isoindoles with DMAC are exothermic. An increase of the temperature of the reaction mixture in the presence of an excess of DMAC can entail the deamination of 7-azabenzonorbornadiene and the formation of the corresponding naphthalene, which has been observed[108,142]. On reaction with DMAC, certain 2*H*-isoindoles form 1:2 adducts with the structure (XXXII, R = MeOOCC = CHCOOMe, R^1 = COOMe). This applies particularly to tetrachloro-(bromo)isoindoles. The isoindole (XLIII) reacts with DMAC at room temperature to form a 1:1 adduct of the type (XXXII), which rearranges to a 1:2 adduct of the type (XLVII) on refluxing with DMAC in benzene. *N*-Ethyl- and *N*-n-butylisoindoles react with DMAC at 0 °C to give the corresponding compounds (XLVII), the mechanism of the formation of which has been described[137]. Ethyl propiolate does not form adducts with isoindoles[19].

(b) The Addition of Dehydrobenzenes to Isoindoles



Isoindoles readily combine with dehydrobenzene to form derivatives of 7-azadibenzonorbornadienes. Wittig showed for the first time[1] that *N*-methyl- and *N*-phenyl-isoindoles react with dehydrobenzene to form the adducts [XXXII, R^1 + R^1 = (CH = CH)$_2$], which can react further with an

excess of dehydrobenzene to form anthracene derivatives[1]. Dehydrobenzene, generated in different ways, reacts with 2-methyl-1,3-diphenylisoindole to form adducts of the above type[143]. The reaction of 2,4,7-trimethyl-1,3-diphenylisoindole with dehydrobenzene gives rise to the corresponding derivatives of 7-azadibenzonorbornadiene[144].

A new method of generating dehydrobenzene from chlorobenzene and the lithio-derivatives of tetramethylpiperidine has been tested in relation to the synthesis of 7-methylazadibenzonorbornadiene from 2-methylisoindole[145]. A large group (more than 40 compounds) of substituted 7-azadibenzonorbornadienes have been obtained from substituted isoindoles and dehydrobenzenes (15 types), dehydronaphthalenes, and heteroarynes (8 types)[14]. A series of new adducts of isoindoles with dehydrobenzene and dehydronaphthalene have been used in the oxidative deamination reaction in order to obtain new derivatives of anthracene and benzanthracene which are otherwise difficult to synthesise[146]. Krick and Vernon[144] explained the extremely unusual result of the reaction of 2-benzyl-1,3,4,7-tetramethylisoindole with dehydrobenzene by the deamination of the 7-azadibenzonorbornadiene derivative, the formation of the corresponding anthracene, and the subsequent cycloaddition of dehydrobenzene in the 9,10-positions of the latter.

(c) The Addition of Maleic Acid Derivatives to Isoindoles

The formation of an adduct with *N*-phenylmaleimide is the usual method of identifying isoindole[93,103]. The addition of *N*-phenylmaleimide to isoindoles can theoretically lead to two products: the *endo*-product (XLVIII) and the *exo*-product (XLIX). One of the most correct methods of determining the configuration of the adducts is ^{1}H NMR, since the patterns of the signals due to the protons in the 1-, 4-, 5-, and 6-positions in these compounds are significantly different[20,96]. A mixture of compounds (XLVIII) and (XLIX), with the *exo*-adduct predominating, is obtained from isoindole and *N*-phenylmaleimide. If this mixture is heated in xylene, then the *endo*-adduct is transformed into the thermodynamically more stable *exo*-isomer[20,27].

(XLVII) (R=COOMe) (XLVIII) (XLIX)

Benzo[*e*]isoindole, benzo[*f*]isoindole, and dibenzo[*e*,*g*]isoindole also form an adduct with *N*-phenylmaleimide[22,23,96], although, according to spectroscopic data, benzo[*f*]isoindole has the isoindolenine structure[95]. The geometry of the adduct of isoindole (X, R = H) with *N*-phenylmaleimide precludes its assignment to a definite type, since it dissociates in concentrated solutions and the ^{1}H NMR spectrum reflects a mixture of the initial substances[22].

4,5,6,7-Tetrafluoro-[94] and 4,5,6,7-tetrachloro-isoindoles[25] react with *N*-phenylmaleimide to form the corresponding exo-adducts, while the π-electron system of tetrabromoisoindole is so deactivated that it does not form an adduct with maleic anhydride[24]. It has been shown[97] that treatment of tetrafluoroisoindole with *N*-phenylmaleimide gives rise to a mixture of the *exo*- and *endo*-adducts, which can be separated by column chromatography on silica gel. This is perhaps the only example where the *exo*- and *endo*-adducts were isolated in a pure state.

The isoindole (XLIII) and maleic anhydride form an adduct, which has the structure (XLVIII) or (XLIX) in the solid state; however, in solutions the adducts associate into the initial substances, which react anew but now with formation of adducts of the Michael type[137]. The cyclic 1:1 adduct of the isoindole (XI, X = Cl) with 4-phenyl-1,2,4-triazoline-3,5-dione has been described[25]. 2R-Isoindoles form adducts with dienophiles just as readily as the 2*H*-derivatives.

N-Methylmaleimide reacts with 2-ethoxycarbonylisoindole and 2-methyl-4,5,6,7-tetrafluoroisoindole to give a mixture of *exo*- and *endo*-adducts according to ^{1}H NMR data[96]. Mixtures of the same composition are also formed by the reaction of *N*-phenylmaleimide with the isoindole (XI, R = Me, X = F)[88]. Adducts of the isoindoles (XI, X = Br, R = Me) with *N*-phenylmaleimide could not be obtained[16]. 2-Acetylisoindole *in statu nascendi* reacts with *N*-phenylmaleimide to produce a low yield of the *exo*-adduct[20]. The isoindole (XI, X = F, R = CH_2Ph) reacts with *N*-phenylmaleimide at 0 °C to form the adduct (XLVIII). A series of endo-adducts have been obtained from the isoindole (XL) by the reaction with *N*-methyl- and *N*-phenyl-maleimides and also with 1,4-benzoquinone[108].

The isoindole (XLII) reacts readily with maleimide and *N*-phenylmaleimide to give high yields of adducts, which we assign to the *endo*-series on the basis of the ^{1}H NMR spectra quoted in the relevant communication[147]. 1-Alkoxy-2-methyl-isoindoles react with maleimide derivatives to form 1:2 *exo*-adducts; initially electrophilic addition probably takes place at the free $C_{(3)}$ position in the isoindole and then the usual addition at the $C_{(1)}$ and $C_{(3)}$ carbon atoms[43]. The addition of 1,4-epoxy-1,4-dihydronaphthalene to 2-methylisoindole gives rise to the isomeric *exo-exo*-adduct (XLVI, X = O) and *exo-endo*-adduct, which were separated chromatographically[9].

3. Isoindoles under the Conditions of Attack by an Electrophile

(a) Electrophilic Addition Involving Isoindoles

The protonation of isoindoles—the simplest example of the electrophilic addition reaction—takes place at the $C_{(1)}$ or $C_{(3)}$ carbon atom in view of their symmetrical structure. The ionisation constants of the two isoindoles (XXII, R = R^5 = Me) and (XXII, R = Ph, R^4 = Me) have been determined spectrophotometrically[148]. The greater basicity of isoindole derivatives compared with that of the corresponding *N*-methyl- and *N*-phenyl-indoles can be accounted for by the greater resonance stabilisation of the latter. There are virtually no data on the protonation of the asymmetrically substituted isoindole (VIII). On protonation, the isoindoles (XLII, R = H)[139] and (XVII, R^1 = OAlk) form cations with the structures (XVIII, R^3 = NMe_2 or OAlk) respectively. This has been confirmed by ^{1}H NMR.

Comparison of the ultraviolet spectroscopic data for tetra- and penta-substituted isoindoles (XXII) in neutral and acid media revealed interesting features[60]. It was found that the methyl group in the 4-position in isoindole promotes the formation of the cation. The transition of the $C_{(1)}$ or $C_{(3)}$ atom from trigonal to tetrahedral hybridisation enables one of the phenyl substituents to deviate from the plane in which the methyl group at the $C_{(4)}$ or $C_{(7)}$ atom is located, which entails a decrease of steric strain, favouring an increase of the fraction of the isoindolenine form of the cation[60].

Examples of reactions involving electrophilic addition to isoindoles have been published[25,55,70,77,139]. It was found that, as a result of electrophilic addition, the reaction of

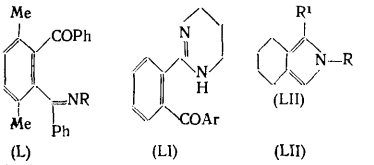
DMAC with isoindoles of the type (XVII, R^1 = SAlk) gives rise to the product (VIII, R^1 = SAlk, R^3 = MeOOCC = CHCOOMe)[70]. An analogous type of addition has been observed[25] in the reaction of azodicarboxylate esters with tetrachloroisoindole. The isoindoles (XLII, R = H) readily add to phenyl isocyanates and isothiocyanates, giving rise to high yields of the corresponding 3-substituted derivatives[55,139]. The reaction of 2-methyl-1-phenylisoindoles with methyl isocyanate leads to the methylamide of 2-methyl-3-phenylisoindole-1-carboxylic acid[77].

(b) Electrophilic Substitution Reactions of Isoindoles

The rates of the simplest electrophilic substitution reaction (deuterium exchange) in the series of bicyclic 10-π-electron compounds have been determined[149] and it was found that 2-methylisoindole is more reactive by four orders of magnitude than 1-methylindole.

The available information about the electrophilic substitution reactions of isoindoles is scanty. Thus the treatment of the isoindoles (XLII) with acetic anhydride or benzoyl chloride leads to acyl derivatives as a result of the electrophilic substitution reaction[139]. Interesting compounds have been obtained via the electrophilic substitution mechanism from 1,2-disubstituted isoindoles and the trimethylsilyl ester of 6-isocyanatopenicillanic acid[150]. 2-Benzyl-1-methoxycarbonylisoindole does not undergo the electrophilic substitution reactions (the Mannich reaction and acetylation)[13].

4. Isoindoles under the Conditions of Attack by a Nucleophile



Nucleophilic substitution of isoindoles has been mainly studied for 1-alkoxyisoindoles having the structure of isoindolenines and structurally similar to the iminoesters of carboxylic acids. All the reactions described below can be readily understood and accounted for from this point of view. Thus the reaction of 1-ethoxyisoindole with primary aromatic and heterocyclic amines involves the substitution of the ethoxy-group by an arylamino-group[151]. More than 40 compounds have been obtained in this way. Benzylamine[152] and its substituted derivatives[151-152] as well as 2-(β-dialkylamino)-ethylamine[152] react with salts of 1-ethoxyisoindole to form the same products as in the reactions with the bases, but the yields are higher[56]. The reaction of 1-ethoxyisoindole with hydrazine produces 1-hydrazinoisoindole[56,152], while 3-aryl-1-ethoxyisoindole gives a high yield of aminophthalazines[42]. Phenylhydrazine and hydroxylamine are also capable of substituting an alkoxy-group in the 1,3-positions of the bicyclic system[56]. On being refluxed with aziridinium tetrafluoroborate in toluene, 1-ethoxyisoindoles give rise to the derivatives of imidazo[2,1-*a*]isoindole as a result of the nucleophilic substitution of the ethoxy-group and simultaneous cyclisation[40,41].

5. Heterocyclisation Based on Isoindole Derivatives

1-Amino-2-phenylisoindole and its hydrobromide are converted into 2-phenyl-5*H*-imidazo[2,1-*a*]isoindole on heating[138]. On heating in acetone, 2-aminoethylisoindoles cyclise to pyrazinoisoindoles[82,85]. On condensation with α-acetyl-γ-butyrolactone in acid, 1-aminoisoindole gives rise to a mixture of isomeric condensed pyrimidoisoindoles[153]. When a solution of 3-phenylisoindole-1-carboxamide in acetic anhydride was stirred with boron trifluoride etherate, an orange product, consisting of a derivative of imidazo[5,1-*a*]isoindole was isolated[77]. On prolonged refluxing with orthoesters in isopropyl alcohol, 1-hydrazinoisoindole forms triazoloisoindoles in moderate yields[154]. Tetrazoloisoindole is formed from 1-hydrazinoisoindole and nitrous acid in a high yield at a low temperature[155].

6. Oxidation of Isoindoles

Isoindoles are extremely sensitive to the action of atmospheric oxygen. Isoindoles unsubstituted at the $N_{(2)}$ atom can give rise to two types of products on mild oxidation: compounds containing two residues of the corresponding phthalimidine, which is observed in the oxidation of 1-methoxycarbonylisoindole[13], and tertiary alcohols of the type (XVI, R^1 = OH), with formation of a hydroperoxide of the type (XVI, R^1 = OOH) as an intermediate in the latter case[156]. The oxidation of isoindoles gives rise to a wide variety of products whose structure depends on the reagents employed and the reaction conditions. The reactions of permanganate in an alkaline medium with 1-cyanoisoindole[105] and 1,3,4,7-tetramethylisoindole[28] or of hydrogen peroxide in acetic acid[157] (or in alcohol[77]) with the isoindoles (IV, X = HC) and (XXVI, R = H) give rise to phthalic acid derivatives. Treatment of the isoindole (IV, X = HC) with chromium trioxide in an acid medium leads to *o*-benzoylbenzoic acid[157], while nitrous acid converts compound (XXII, R^4 = R^7 = Me) into 1,2-dibenzoyl-3,6-dimethylbenzene[156].

(L) (LI) (LII)

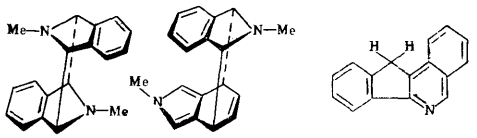
The self-oxidation of 1,2,3,4,7-pentamethylisoindole produces the corresponding phthalimide[76]. Benzophenones (L) are obtained by the self-oxidation of the isoindoles (XXII, R^4 = R^7 = Me, R^5 = R^6 = H). On the other hand, in the case of the isoindole (XXII, R = Ph) self-oxidation is achieved following additional irradiation with ultraviolet light and the imine (L) formed initially is converted subsequently under the experimental conditions into a phenanthridine derivative[156]. In the absence of oxygen the above isoindoles are entirely stable on both heating and irradiation. Oxidation of the isoindoles (XVII, R^1 = COOMe) with oxygen gives rise to the corresponding phthalimidines (XV)[13]. Irradiation of a solution of isoindole (XXVIIIa, R = Me) with access of air leads to a mixture consisting of the phthalimidine (XV, R^1 = Ph) and its 3-hydroxy-derivative[77]. Prolonged oxidation of solutions of 2-(γ-aminopropyl)isoindoles with oxygen and sometimes with $K_2Cr_2O_7$, $KClO_3$, and H_2O_2 leads to pyrimidoisoindoles and not to benzophenones (LI), as believed previously[166]. More than 40 compounds of this series have been described in a number of patents[158,165].

7. Reduction of Isoindoles

The catalytic hydrogenation of isoindoles in the presence of 10% Pd/C in ethanol[13] or in acetic acid[84] at a pressure of 3–5 atm gives rise to products of the addition of hydrogen to the pyrrole component of the molecule. Thus 1-methoxycarbonyl-2-phenylisoindole[13] and 2-γ-aminopropyl-1-arylisoindoles[84] form racemic mixtures of isoindolines under these conditions. Under the same conditions, the isoindole (VIII,

$R^1 = R^3 = COOMe$, $R^2 = Ph$) forms three products: the meso- and *d,l*-forms of the corresponding isoindolines[13]. The catalytic hydrogenation of the isoindoles (XXVIII, R^2 = 5-H or 5-Cl) in the presence of palladium chloride produces the same isoindoline[77]. Hydrogen adds readily only to the double bond of 2-vinylisoindoles on catalytic hydrogenation[79]. The use of Raney nickel as the catalyst of the hydrogenation of 2-(γ-methylaminopropyl)isoindole yields results similar to those of the catalytic hydrogenation on Pd/C, i.e. hydrogen adds to the pyrrole component of the molecule[86].

The final result of the hydrogenation reaction probably depends to a large extent on the nature of the substituents in the pyrrole component of the bicyclic system. Thus the hydrogenation of the isoindoles (XVII, $R^1 = COOMe$) yields products of the addition to the carbocyclic moiety with formation of compounds (LII), in contrast to 1-methoxycarbonyl-2-phenylisoindole mentioned above. A similar result has been obtained[167] in the hydrogenation (in the presence of the $Pd/BaSO_4$ catalyst) of the isoindole (VIII, $R^1 = CHO$, $R^2 = CH_2CH_2Ph$, $R^3 = Cl$)—the pyrrole (LII, $R^1 = CH_2OH$, $R = CH_2CH_2Ph$) was isolated as the hydrogenation product.



In all the known instances of the reduction of isoindoles with zinc dust in acetic acid, the corresponding isoindolines were obtained. This reduction method has been used for 4,5,6,7-tetrafluoroisoindole[94,95], benzo[*e*]isoindole[23], dibenzo-[*e,g*]isoindole[22], and 1,2-dimethyl-3-phenylisoindole[32]. It is of interest to note that in the latter case the mixture of diastereoisomers formed as a result of the reaction was resolved. Similarly the reduction of the isoindole (XLIII) with zinc dust in acetic acid yielded the isomeric *trans*- and *cis*-iso-indolines, which were separated. The catalytic hydrogenation of compound (XLIII) in the presence of PtO_2 in alcohol gives rise to mixtures of isoindolines with similar compositions[28].

8. Other Reactions of Isoindoles

Isoindoles are known to undergo reactions involving a functional group but not the ring. Thus the nitrile of isoindole-1-carboxylic acid is smoothly converted into the amide on treatment with 10% alkali[104]. The phthalyl protecting group is removed almost quantitatively from the isoindole (VIII, $R^1 = R^3 = Ph$, $R^2 = NCOC_6H_4CO$) on treatment with hydrazine[110]. The isoindole (XXVI, $R = CH_2CH_2OH$) is acetylated under different conditions, with the preferential formation of diacetyl derivatives—the products of the reaction involving the oxygen atom of the alcoholic group and the nitrogen atom of the *N*-methylcarbamoyl group[78,79]. On hydrogenation in methanol with added sodium methoxide and in the presence of the $Pd/BaSO_4$ catalyst, the isoindoles (VIII, $R^1 = CHO$, $R^3 = Cl$) retain the isoindole structure but lose chlorine atoms, forming 1-formyl-2R-isoindoles in 80% yield[167]. The isoindole (XXVIIIa, $R^2 = Cl$) is dehydrochlorinated similarly[77]. On being refluxed with an excess of hydrazine in ethanol for 2 h, the 5,6-dibenzoyl-1,2,3-trimethylisoindole gives rise to derivatives of 6,7-diazabenzo-[*f*]isoindole[75].

A number of coloured products (IV, X = RC) are formed on condensation of 1-phenylisoindole with aldehydes in pyridine with very low yields[62,169]. When the isoindole (XLIII) is heated with metal (copper, nickel, manganese, etc.) acetates, the corresponding coloured octamethyltetrabenzoporphyrins are formed. Similar molybdenum and cobalt compounds have been isolated in the form of complexes in which the central metal atom coordinates additionally other ligands (for example, pyridine, etc.)[137,169].

Under the conditions of the Vilsmeier reaction, the isoindole (XXVIIIa) forms 5-chloro-1-dimethylaminomethylene-3-phenyl-1*H*-isoindole, i.e. the carbamoyl group is eliminated and the $C_{(1)}$ atom is formylated[77].

(LIII) (LIV) (LV)

The photolysis of a solution of the isoindole (XXXIV, R = Me) leads to a 60% yield of the $[{}_{\pi}4_S + {}_{\pi}4_S]$ photodimer (LIII). Together with compound (LIII), the isomeric dimer (LIV) was isolated in 7% yield. When both dimers are irradiated with ultraviolet light at 254 nm, they dissociate and the initial isoindole is formed. Pyrolysis converts the isoindole (XXXIV, R = Me) into a condensed isoquinoline (LV)[170].

9. Practically Useful Properties of Isoindoles

In patents there are indications of the possibility of practical applications of isoindole derivatives, particularly in medicine. Thus antihypertonic[152], anti-inflammatory[152], contraceptive[138], and anorectic[65,66] effects and the sedative[87] and stimulating[81,84] influences on the central nervous system by various isoindole derivatives have been reported.

A series of preparations have been tested in electroluminescent systems[67] and as agricultural fungicides[85].

V. AROMATICITY OF *o*-QUINONOID HETEROCYCLES

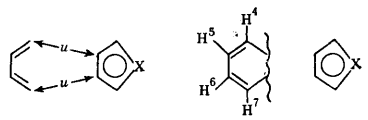
The data on the physical and chemical properties of isoindole discussed above indicate a number of characteristic features of this system and other *o*-quinonoid heterocycles of type (II). In the discussion of the differences between the properties of indole and isoindole, attention must be concentrated on the differences between the degrees of their aromaticity.

A common characteristic of indole and isoindole is the presence of the 10-π-electron cloud and the identity of the electronic configurations of the atoms. The only difference, which determines the entire set of the physicochemical properties of systems (I) and (II), is that between the positions of the heteroatom in the 10-π-electron cloud and the consequent difference between the perturbations in the two cases.

Isoindole derivatives are more reactive than the corresponding indoles; isoindole itself is an extremely unstable readily polymerisable compound, i.e. its chemical behaviour does not indicate its aromaticity. Nevertheless, according to data obtained by various quantum-chemical computational methods[114,132,133,172,173], isoindole possesses a significant resonance energy, although it is smaller than that of indole (Table 4).

The resonance stabilisation of isoindole is indirectly confirmed by the spontaneous and irreversible transformation of the isoindolenine form into the isoindole form[123].

Consequently it is necessary to explain two mutually exclusive facts, namely why is isoindole so reactive if it is at the same time aromatic in the usual sense of the term.



We may point to several studies[15,116,123,124,175] whose authors noted the above contradiction and attempted to resolve it. Apparently the best founded hypothesis,

capable of reconciling the high reactivity of *o*-quinonoid heterocycles with their aromaticity, is that put forward by Bornstein and coworkers[124], according to which the *o*-quinonoid heterocycles (II) consist of adjacent but in essence non-interacting π-electron systems and therefore possess a wide region of aromaticity due to the presence of the five-membered heterocyclic rings together with the reactivity imparted to the bicyclic system (II) by the adjacent butadiene component.

Table 4. The resonance energies of indole (I, X = NH) and *o*-quinonoid heterocycles (II).

Heterocycle	In units of β (Ref.172)	In units of β (Ref.173)	in kcal mol^{-1} (Ref.114)
(II) (X = NH)	0.29	0.32	11.6
(II) (X = S)	0.25	0.29	9.3
(II) (X = O)	0.02	0.11	2.4
(I) (X = NH)	0.47	0.38	23.8
(XLIV) (X=NH)	—	—	8.4

As a structural equivalent of the above hypothesis, it has been suggested[124] that *o*-quinonoid heterocycles be represented with the aid of formulae of type (LVI). The above structural ideas were first used[127] to calculate the ionisation potential of 2-methylisoindole. They have been confirmed primarily by the spin–spin interaction constants for isoindole and other *o*-quinonoid heterocycles[15,115,123–125]. According to Crews et al.,[125] the spin–spin interaction constants of the $H_{(4)}$–$H_{(7)}$ vinyl protons, obtained for various *o*-quinonoid systems (LVII), or more precisely the ratio $J_{rel} = J_{H_{(5)}-H_{(6)}}/J_{H_{(4)}-H_{(5)}}$, can serve as a characteristic of the degree of delocalisation of electrons in the butadiene fragments indicated.

(LVI) (LVII) (LVII)

Analysis of the data in Table 5 shows that, if the degree of delocalisation of electrons can indeed be estimated with the aid of J_{rel}, the implication is that the electron distribution in the carbocyclic component of *o*-quinonoid heterocycles is insensitive to perturbations in the five-membered rings. Consequently the constancy of J_{rel} for systems with such a widely variable stability (from the extremely unstable isobenzofuran to the comparatively stable isothionaphthene) can be understood only on the basis of the structural representations (LVI).

The subsequent discussion will be based on the resonance energies of structures (I), (II), and (LVII) calculated by Dewar. According to Dewar[128], the resonance energy of butadiene is zero. Consequently the difference between the calculated Dewar resonance energies of isoindole and pyrrole makes it possible to estimate the degree of stabilisation (annelation energy) as a result of the interaction in compound (LVII) between the butadiene and the five-membered heterocycle along side c. The annelation energy of butadiene and the five-membered heterocycle corresponding to the interaction along side *b* can be determined similarly.

Analysis of experimental data shows that, in contrast to heterocycles with the Kekulé structure, in which the annelation energy is ~15.4–18.8 kcal mol^{-1} (*o*-quinonoid heterocycles have an extremely insignificant annelation energy of 0.8–3 kcal mol^{-1}), annelation along side c of the second ring in compound (LVII) leads to only a very slight stabilisation of the system as a whole.

The structural representations (LVI) can be confirmed by comparing the bond orders of indole and isoindole. In the carbocyclic part of isoindole they are in essence the same as in acyclic polyenes, whereas the bond orders in the five-membered ring are close to those found for the monocyclic compounds (LVII).

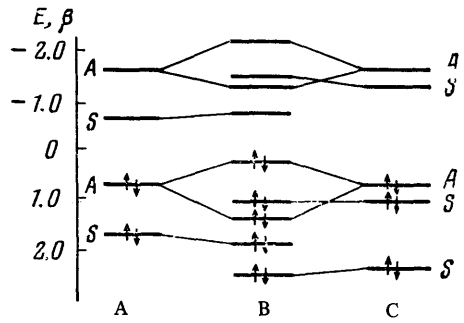
Table 5. The spin–spin interaction constants (SSIC) for a series of derivatives of *o*-quinonoid heterocycles.

SSIC, Hz	(II) (X = NH) [123–124]	(XXXIV) (R = Me) [15]	(VIII) (R^1=R^2=Ph, R^3 = Me) [125]	(II) (X = O) [116]	(II) (X = S) [116]	(II) (X = Se) [124]
$J_{H(5)-H(6)}$	6.29	6.28	6.39	6.22	6.35	6.79
$J_{H(4)-H(5)}$	8.49	8.60	8.63	8.52	8.64	9.16
J_{rel}	0.74	0.73	0.74	0.70	0.72	0.74

Note. The numbers in square brackets denote references (Ed. of Translation).

If the above considerations are valid, then one must explain from the above standpoints the entire set of properties of *o*-quinonoid heterocycles, particularly isoindole. This can be done within the framework of the method of perturbed molecular orbitals (the PMO method)[128], in which *o*-quinonoid heterocycles are treated as combined residues of butadiene and the monocyclic π-system along side c in (LVI).

The diagram for the interaction of the molecular orbitals of butadiene and pyrrole, leading to the formation of the π-electron system of isoindole, obtained as a result of such treatment, is illustrated in the Figure taking into account the first- and second-order perturbations.



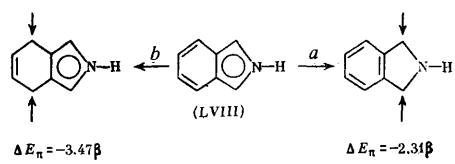


Diagram illustrating the interaction of the orbitals in the formation of the π-electron system of isoindole (B) by combining butadiene (A) and pyrrole (C).

When the residues of butadiene and of the monocyclic π-electron system of pyrrole are combined, two types of interaction are observed.

(1) Interaction between the highest occupied molecular orbitals (HOMO) of butadiene and pyrrole with the same energies, which leads to a decrease of the difference between the energies of the HOMO and the lowest unoccupied molecular orbitals (LUMO), i.e. is responsible for the low value of the first-ionisation potential and the long-wavelength absorption maximum; this type of interaction does not entail an energy gain (i.e. the stabilisation of the compound). Since the HOMO is antisymmetric in the symmetry plane $\sigma_v(y)$ and the energy of the interaction under consideration is independent of the nature of the heteroatom, all the *o*-quinonoid heterocycles exhibit a similar reactivity.

(2) Interaction with unfilled molecular orbitals, which leads to a slight decrease of the lowest occupied (symmetrical) molecular orbital of both butadiene and the monocyclic compound; this interaction depends on the nature of the heteroatom and is responsible for the annelation energy. In other words, the nature of the "aromaticity" of *o*-quinonoid heterocycles (II, X = NH, O, or S) is the same as that of the corresponding monocyclic compounds.

The structural ideas examined above should also account for the exclusively high reactivity of the *o*-quinonoid heterocycles (II) and in the first place for their tendency to enter into the Diels–Alder reaction. According to the structural representation (LVIII), there is a possibility of two types of cycloaddition reactions: to the pyrrole ring and to the carbocyclic part of the molecule. The energy of activation of π electrons (ΔE_π) in the molecule or, in other words, the reactivity of the molecule is determined mainly by the difference between the energy of the π electrons in the transition state and the energy of the π electrons of the reactants[128]. The formation of transition states in the above instances is illustrated graphically below (the arrows indicate the direction of cycloaddition) together with the calculated energies of activation of π electrons; the complete absence of interaction between the butadiene and pyrrole π-systems is postulated:

(LVIII)

$\Delta E_\pi = -3.47\beta$ $\Delta E_\pi = -2.31\beta$

Both values of ΔE_π presented are significantly smaller than for pyrrole itself and indicate an appreciable increase of the reactivity of isoindole.

Special mention should be made of the fact that the calculated activation energy for pathway *a* is smaller than that necessary for attack on the isolated butadiene fragment (pathway *b*). The activation energy in Diels–Alder reactions in relation to *o*-quinonoid heterocycles can be regarded as comprising two contributions: (1) the endothermic contribution due to the decomposition of the π-electron system of the five-membered ring and (2) the exothermic contribution due to the formation of the benzene ring on cycloaddition. The ratio of these two contributions is determined by the height of the activation barrier and, when account is taken of the considerations adduced above, it is clear that the higher resonance stabilisation of the "parent" five-membered heterocycle entails a corresponding decrease of the reactivity of the *o*-quinonoid heterocycle. Thus isobenzofuran, derived from the "weakly aromatic" furan, is much more reactive than isothionaphthene or isoindole, which are derived from more aromatic monocyclic compounds.

During the preparation of the manuscript for printing, a number of studies on the chemistry of isoindole were published. Thus-2-t-butylisoindole[208,213], 2-methylbenzo[*f*]isoindole[192,195], 4,7- and 5,6-dimethylisoindoles, 4,5,6,7-tetramethylisoindole[202], as well as substituted 2-methylisoindole[201], 1-methylisoindole[209], 1-azidoisoindole[203], 2-methyl-5-azaisoindole[210], 2-arylisoindole[211], and 2-(4′-pentenyl)isoindole[212] were obtained. The relevant calculations were made[190,193,200] and the ^{14}N NMR spectrum of 2-methylisoindole was measured[189,196]. The radical-cation derived from 1,3,4,7-tetramethyl-2-(4″-tolyl)isoindole was detected in the EPR spectrum[194]. Diels–Alder adducts involving isoindole derivatives[192,195,201,202,209,212,214], electrophilic reactions[213], and alkylation[197,204,207] have been studied for the isoindole series. The condensation of 1-aminoisoindole with β-diketones has been investigated[206]. The anorectic effect of substituted indoles has been observed[197,204,207]. Spectrofluorimetric methods for the determination of the lowest concentrations of aminoacids and proteins, by converting them into 1-thioisoindole derivatives, have been proposed[191,198,199,205].

Semiconducting Pyropolymers

M.A.Magrupov

Model structures which explain the electrical and the paramagnetic properties of semiconducting pyropolymers are proposed. The development of paramagnetic clusters during the formation of these polymers is demonstrated, and the generality and the thermodynamic efficiency of this process are stressed. The problems encountered when applying the theory of electrical conduction in heterogeneous materials and the theory of flows to semiconducting pyropolymers are discussed. Transport phenomena involving the charge carriers in these polymers are analysed by the theory of electronic states in disordered systems. The temperature dependence of the electrical conductivity is shown to obey Mott's law over a wide range of temperature. Quantitative relationships for the pressure dependence of the electrical parameters of powdered semiconducting pyropolymers are obtained, and the influence of the structure of these materials on their electrical and paramagnetic properties is examined. 103 references.

I. INTRODUCTION

Many polymers showing semiconducting properties have been synthesised and investigated[1-14]. Their electrical[1-7], photoelectric[1-4,10,13,14], catalytic[1-3,15,16], and paramagnetic properties[1-3,7,16-22] have been highlighted, and the materials have been used in optical information storage systems[13,14]. The practical realisation of superconductivity with a high critical temperature by using polyconjugated polymers has been predicted[23], and though the prediction has not yet been proved correct it has made a very important contribution to the development of the physics and chemistry of molecules with conjugated bonds[16], whose photochemical and radiation-chemical stability is discussed in detail in Ref. 24.

Comprehensive theoretical studies[16,18-31] of the electronic structure and of the paramagnetism of polymers with conjugated bonds have been carried out, the properties of their molecules have been broadly characterised, and experimental observations of their optical spectra have been explained. In this context the work of Ovchinnikov[30,31] deserves special mention for combining a physical demonstration with a theoretical proof of the development of ferromagnetism in alternant organic systems. In spite of these achievements, however, a general theory of the physical properties of polymeric semiconductors is still awaited. The need for a special theory has even been questioned: as an alternative, the properties of these polymers could be described in terms of the theory of disordered systems[32-42].

In this review we shall examine from the standpoint of the theory of the electrical properties of disordered systems the relationship between the electrical conductivity (or the paramagnetism) and the structure of semiconducting pyropolymers, prepared mainly from polyacrylonitrile (PAN). The choice of these materials was dictated by the abundance of the data on the thermal transformations of PAN,[1,8,12,43-51] and by the recent publication of monographs dealing with the semiconducting properties of the PAN pyropolymers[1,2,7].

No attempt will be made to include the whole of the information on the thermal reactions of PAN and on the properties of the semiconducting products of these reactions. Published work will be mentioned only if it contains data on the structural, electrophysical, or paramagnetic properties of these materials, or if it can help to build a concrete model of the structure of semiconducting pyropolymers.

II. STRUCTURAL FEATURES AND ELECTRICAL CONDUCTIVITY OF PYROPOLYMERS

Semiconducting pyropolymers can be treated as microheterogeneous systems consisting of electrically conducting polyconjugation regions separated by barrier layers[1-3,7]. The volume fraction of the polyconjugation regions is determined by the technological conditions used in the preparation of the pyropolymer: it increases monotonically with the temperature of heat treatment, and thus it affects very markedly the interactions between these regions[52,53]. For this reason semiconducting pyropolymers prepared under different conditions cannot be described by the same type of heterogeneous model.

In order to produce a concrete model of the structure of the heterogeneous system we must first of all determine the volume fractions, the size, the types of interaction, and the distribution of the components. So far this information is available only for semiconducting pyropolymers based on PAN.[52-55]

1. Determination of the Concentration of the Polyconjugation Regions and of the Structural Parameters of Semiconducting Pyropolymers

The concentration of the components of heterogeneous semiconducting pyropolymer systems is determined by monitoring the change in an extensive factor with heat treatment temperature (T_{form}). The most convenient and easily measured extensive factor in these systems is the density, which increases with the T_{form} value of the semiconductor[53]. This suggests that the polyconjugation regions are relatively dense, and the interlayers between these regions relatively loose.

The density γ of a heterogeneous system is defined by the expression

$$\gamma = \sum_i V_i \gamma_i , \qquad (1)$$

where V_i is the volume fraction and γ_i is the density of the i-th phase. In the case of two-component systems, to which semiconducting pyropolymers can be assigned to a first

approximation, Eqn.(1) takes the form

$$\gamma = V_1\gamma_1 + (1-V_1)\gamma_2 , \qquad (2)$$

where γ_1 and γ_2 are the densities of the conducting and the non-conducting component respectively, and V_1 is the volume fraction of the polyconjugation regions. Obviously, $V_2 = 1 - V_1$ is the volume fraction of the non-conducting component. Solving Eqn.(2) for V_1 we obtain

$$V_1 = \frac{\gamma - \gamma_2}{\gamma_1 - \gamma_2} . \qquad (3)$$

In the case of PAN semiconductors the volume fraction V_1 has been determined[52,53] by formula (3) by arbitrarily identifying γ_1 with the density of the sample obtained at 1100° (assumed to consist almost exclusively of fully developed polyconjugation regions), and γ_2 with the density of the sample obtained at 200° (in which the amount of polyconjugation is negligible). This involves the assumption that the densities of the conducting and of the non-conducting component are independent of the heat-treatment temperature (T_{form}) of the sample, i.e. that only the relative amounts of the two components are affected by the pyrolysis temperature. This hypothesis is supported by studies of the frequency dependence of electrical conductivity[56] and of the frequency spectrum of the current noise[57] in pyrolysed PAN: the results confirm that the basic structure of the polyconjugation regions is unchanged by an increase in the pyrolysis temperature of the initial polymer. Though an analysis of the formation of semiconducting pyropolymers suggests[44-51] that both γ_1 and γ_2 should increase slightly with pyrolysis temperature, the inequality $\gamma_1 > \gamma > \gamma_2$ must always be satisfied, and therefore the volume fractions calculated by formula (3) cannot be greatly in error.

Table 1. Effect of the formation temperature T_{form} of PAN on the concentration of PMC, on the distance d between them, on the volume fraction V_1, the average volume $\bar{v}$, and the average linear size L of the polyconjugation regions, and on the average distance S between the "surfaces" of these regions (measurements in air)[53].

T_{form}, °C	$10^{-19}N$, spins cm^{-3}	V_1	$\bar{v}$ (Å)³	L, Å	S, Å	d, Å
300	$9.5\cdot10^{-2}$	0.07	$7.7\cdot10^{4}$	42.5	60.8	103.3
350	$3.3\cdot10^{-1}$	0.16	$5.0\cdot10^{4}$	36.9	30.7	67.5
400	1.1	0.24	$2.3\cdot10^{4}$	28.4	17.0	45.4
450	2.6	0.30	$1.2\cdot10^{4}$	22.8	11.1	33.9
500	6.7	0.38	$5.7\cdot10^{3}$	17.9	6.7	24.6
550	1.1·10	0.44	$4.0\cdot10^{3}$	15.9	4.9	20.8
600	1.5·10	0.51	$3.4\cdot10^{3}$	14.9	3.8*	18.7
650	1.7·10	0.58	$3.3\cdot10^{3}$	15.0	3.0*	18.0
700	1.3·10	0.62	$5.4\cdot10^{3}$	17.5	2.9*	20.4
750	5.1	0.72	$1.4\cdot10^{4}$	24.2	—	27.0
800	1.4·10	0.81	$5.8\cdot10^{5}$	83.4	—	89.3
850	$5.2\cdot10^{-2}$	0.85	$1.6\cdot10^{6}$	117.7	—	124.4
900	$2.1\cdot10^{-2}$	0.88	$4.1\cdot10^{6}$	161.5	—	168.3
1000	$1.5\cdot10^{-2}$	0.95	$6.3\cdot10^{6}$	185.7	—	188.7

*These values have no real physical significance.

Table 1 (taken from Ref.53) shows the volume fractions of polyconjugation regions in PAN pyropolymers, calculated by formula (3) as a function of the thermolysis temperature. The Table also shows the average effective volume corresponding to one paramagnetic centre (PMC)

$$\bar{v} = V_1/N , \qquad (4)$$

where N is the number of PMC in 1 cm^3, and the average linear size

$$L = (V_1/N)^{1/3} \qquad (5)$$

of the polyconjugation regions. On the assumption that the unpaired electrons are uniformly distributed throughout the sample, and localised on specific atoms or within their coordination sphere, we can use the expression

$$d = N^{-1/3} \qquad (6)$$

for the average distance between PMC. On the additional assumption that the distribution of polyconjugation regions over the sample is uniform and random, and using Eqns.(4) to (6), we can define an average effective distance S between the "surfaces" of the polyconjugation regions as

$$S = \frac{1 - V_1^{1/3}}{N^{1/3}} \quad \text{or} \quad S = d - L . \qquad (7)$$

Since the parameter N is affected by atmospheric oxygen, all the quantities calculated by Eqns.(4)–(7) (i.e. $\bar{v}$, L, d, and S) also depend on the conditions under which N was determined. We should note that V_1 and N (and therefore also $\bar{v}$, L, d, and S) are parameters of the structure of the semiconducting pyropolymers: the change in these parameters during the formation of the polymer reflects the growth of the polyconjugation regions in relation to the external factors. This is illustrated by the data in Table 1, from which it is clear that as the heat treatment temperature of the PAN is increased the volume fraction of the polyconjugated regions also increases to a value in excess of 50% at temperatures above 600°, and the distance between polyconjugation regions becomes shorter.

The variation of L with the thermolysis temperature of the sample yields valuable information on the growth of the polyconjugation regions during the formation of the semiconducting pyropolymers. At first sight the decrease of L with increase in heat treatment temperature (to 600°) appears inconsistent with studies of the absorption[43] and fluorescence[51] spectra of PAN at various stages of heat treatment. According to those studies more intensive thermolysis causes cross-linking of the continuous conjugation regions, reflected by a shift in the fluorescence spectrum in the near i.r. and by an increased absorption in the long-wavelength tail of the spectrum, i.e. by an increase in the length of the polyconjugation blocks. However, this apparent contradiction is easily dismissed if we consider the mechanism of thermolysis of PAN [46,51] to give polyconjugated systems with a wide distribution in size of the polyconjugation blocks[8]. Obviously, the rate of formation of these blocks (after an initial stage in the formation of the semiconducting pyropolymers) increases with the formation temperature T_{form} more rapidly than their rate of growth and coalescence, causing N to increase and L to decrease. At this stage in the heat treatment the pyropolymer is enriched in polyconjugation regions mainly through an increase in their number. On the other hand, at temperatures $T_{form} > 600°$ the polyconjugation regions can also grow and coalesce, and the number of PMC decreases (see Table 1).

Information on the electronic states of semiconducting pyropolymers and on the distribution and interaction of their components over microscopic volumes can be obtained from the ESR spectra. The ESR lines of PAN semiconductors with formation temperatures $T_{form} \leqslant 300°$, $300° < T_{form} < 600°$, and $T_{form} \geqslant 600°$ have a Gaussian, a mixed, and a Lorentzian form respectively[55]. The line width and the spin–lattice relaxation time T_1 decrease as T_{form} increases[58]. By studying samples containing different numbers of PMC a strong concentration dependence of the rate of spin–lattice relaxation was observed[58] (see Table 2), as in polyphenylacetylene

samples thermolysed at different temperatures[59,60]. This indicates exchange interaction between the PMC in thermolysed PAN for $T_{form} > 300°$, increasing with the thermolysis temperature of the polymer. We know[61] that the intensity of the exchange interaction is very sensitive to the distance between the PMC, the effect being strong at distances <10 Å. Thus we may conclude that the distance between some of the PMC in PAN pyropolymers with $T_{form} > 300°$ is less than 10 Å.

Table 2. Effect of the formation temperature T_{form} of PAN on the concentration N of PMC, on the width ΔH of the ESR line, on the average distance d between PMC, on the average number K of PMC in each cluster, and on the time T_1 (measurements in vacuum).[58]

T_{form}, °C	$10^{-19}N$, spins cm^{-3}	ΔH, Oe	d, Å	K	T_1, s
300	$9.7\cdot10^{-1}$	16	46.9	2.2	$1.1\cdot10^{-2}$
400	6.0	15	26.5	36	$3.4\cdot10^{-3}$
500	$2.0\cdot10$	4.1	17.1	238	$2.1\cdot10^{-4}$
600	$2.9\cdot10$	1.8	15.1	753	$3.9\cdot10^{-5}$

If the true distance between the PMC is calculated by formula (6) it becomes impossible to account for the observed exchange interaction, since at the maximum PMC concentration this formula gives $d \geq 18$ Å (Table 1). We must assume that in the samples prepared at $T_{form} > 300°$ the unpaired electrons are delocalised within the separate polyconjugation regions, i.e. they are π-electrons. Under these conditions the distance between the unpaired electrons of neighbouring polyconjugation regions (at the moment of nearest approach) is the quantity S, given by formula (7). But even in this case the presence of exchange interaction between the PMC in samples containing less than 5×10^{19} spins cm^{-3} cannot be accounted for. To resolve these inconsistencies we must postulate the formation of clusters (swarms) within which the distance between PMC is <10 Å in PAN pyropolymers formed at $T_{form} > 300°$: under these conditions the exchange integral becomes large. The formation of paramagnetic clusters during the preparation of semiconducting pyropolymers is a direct consequence of the local activation effect[62], which causes PMC to be formed preferentially near other PMC. The same effect has been used[63] to explain the deviation from a uniformly random distribution of the PMC in poly(vinyl chloride) samples with a modified surface.

The average number of PMC in separate paramagnetic clusters can be estimated by the method developed by Vannikov and coworkers[2,7] to determine the average number of polyconjugation regions per unit length from the current–voltage characteristic (CVC) of the sample. The method is based on the theory[64] of the CVC of heterogeneous systems consisting of layers with good and with poor electrical conductivity connected in series, the poorly conducting layers acting as barriers to the charge carriers. Ignoring the resistance of the polyconjugation regions, we can express the density j of the current flowing through the barriers as a function of the applied potential by the Petritz formula[2]

$$j = Mep\left[\exp\left(-\frac{\varphi}{k_BT}\right)\right]\left[\exp\left(\frac{e\Delta V}{k_BT}\right) - 1\right], \quad (8)$$

where p is the average concentration of the majority carriers in the polyconjugation regions, ϕ is the height of the potential barrier, ΔV is the potential step at each barrier, k_B is Boltzmann's constant, T is the absolute temperature, M is a parameter independent of ϕ and of the same order as the thermal velocity of the current carriers, and e is the electronic charge. In the low-field region we have $\Delta V \ll k_BT/e$, and Eqn.(8) becomes[2]

$$j = \frac{Mpe^2\Delta V}{k_BT}\exp\left(-\frac{\varphi}{k_BT}\right).$$

Let n_1 be the number of polyconjugation regions per unit length connected in series. The potential step ΔV then becomes[2]

$$\Delta V = V/n_1 l = E/n_1, \quad (9)$$

where V is the voltage applied to the sample, E is the field strength, and l is the thickness of the sample. In the strong field region we have $e\Delta V \gg k_BT$, and by combining (8) and (9) we obtain[2]

$$j = Mep\exp\left(-\frac{\Delta E}{k_BT}\right), \quad (10)$$

where $\Delta E = \phi - BV$, and $B = e/n_1 l$. Thus the parameter B can be obtained from the current–voltage characteristic, and used to calculate n_1.

The exchange interaction arises because of the overlap of the π-electron clouds in the polyconjugation regions responsible for the PMC clusters. In the presence of strong exchange interaction the individual PMC clusters behave as single spin-systems: within each paramagnetic cluster the barriers are practically transparent to the charge carriers, and the reistance of the cluster can be neglected in comparison to that of the layers which separate the clusters. Therefore the CBC can be used to determine effectively the number of PMC clusters per unit length. The ratio

$$k = N/n_1^3 \quad (11)$$

defines the average number of polyconjugation regions forming separate clusters, i.e. the structural parameter responsible for the mechanism of electrical conduction and of paramagnetic relaxation in these materials.

As Table 2 shows, the size of the paramagnetic clusters (characterised by the parameter k) increases with T_{form}; at the same time the spin–lattice relaxation time T_1 decreases. These results suggest that (as in the case of thermolysed polyphenylacetylene[59]) the paramagnetic relaxation occurs through the clusters. The increase in k with T_{form} also shows that in PAN semiconductors with $T_{form} < 350°$ exchange interaction occurs through nearest-neighbour PMC, whereas in samples with $T_{form} > 350°$ the interaction also involves PMC at distances much greater than the radius of the coordination sphere. This conclusion is confirmed by the gradual disappearance of the saturation effect on the ESR line as T_{form} is increased, the PAN semiconductor becoming non-saturable for $T_{form} > 600°$.[58] This observation shows that when $T_{form} > 600°$ exchange interaction between the paramagnetic clusters sets in.

The organisation of PMC into clusters during the formation of semiconducting pyropolymers enhances the degree of delocalisation of the π-electrons, and this should lead to a decrease in the internal energy of the system: in other words, cluster formation is a thermodynamically favourable process. Cluster formation of the PMC is, essentially, the first step in the formation of graphitisation nuclei, and can be treated as a self-organisation process: the formation of ordered structures in disordered systems. A recent monograph[65] is devoted to self-organisation processes in a wide variety of systems.

Thus, the above results lead to the conclusion that semiconducting pyropolymers can be treated (with adequate precision) as micro-heterogeneous, two-component, electronically

non-uniform systems consisting of regions with high and with low electrical conductivity. We can therefore attempt to apply the theory of heterogeneous materials to a description of the electrical conductivity of these polymers.

2. Theory of the Electrical Conductivity of Disordered Systems and Electrical Conductivity of Semiconducting Pyropolymers

The effective medium method has been used[66,67] in a theoretical calculation of the electrical conductivity σ of two-component (composite) systems in which one of the phases forms a matrix at all finite concentrations, and also of random mixtures in which the particles are fully disordered and do not form any regulating structure. Formulae (12) and (13) were obtained[66,67] for the matrix systems and for the random systems respectively:

$$\sigma(V_1) = \sigma_2\left[1 + \frac{V_1}{(1-V_1)/3 + \sigma_2/(\sigma_1-\sigma_2)}\right] \qquad (12)$$

$$\sigma(V_1) = \frac{(3V_1-1)\sigma_1 + (3V_2-1)\sigma_2}{4} + \left[\frac{[(3V_1-1)\sigma_1 + (3V_2-1)\sigma_2]^2}{16} + \frac{\sigma_1\sigma_2}{2}\right]^{1/2}, \qquad (13)$$

where σ_1, σ_2, V_1, and V_2 are the electrical conductivities and the volume fractions, respectively, of the conducting and of the non-conducting component of the heterogeneous system.

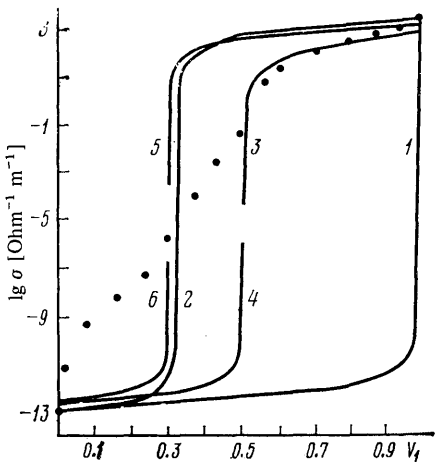

Figure 1. Electrical conductivity against volume fraction of polyconjugation regions in PAN semiconducting pyropolymers. The points are experimental, the full lines are calculated by: *1*) Eqn.(12), *2*) Eqn.(13), *3*) Eqn.(15) with $V_1 = 0.5$, *4*) Eqn.(17) with $V_c = 0.5$, *5*) Eqn.(15) with $V_c = 0.3$, *6*) Eqn.(17) with $V_c = 0.3$.

Some corrections are needed before Eqns.(12) and (13) can be used to describe the concentration dependence of the conductivity of micro-heterogeneous semiconducting pyropolymers, because these equations were derived for systems of chemically non-interacting macroscopic regions (densely compressed mixtures of particles) of high and of low conductivity. However, information on the structural details of the heterogeneous materials can be obtained from the deviation of the experimental $\sigma(V_1)$ dependence from the dependence calculated by Eqns.(12) and (13). This is illustrated in Fig.1 by curves plotted from the data of Table 1.

We note the substantial difference between the experimental $\sigma(V_1)$ plot and that calculated by formula (12) for semiconducting PAN pyropolymers. Hence, the structural model of a two-component matrix system with equally spaced inclusions of equal size, for which Eqn.(12) was derived, is not applicable to semiconducting pyropolymers. The $\sigma(V_1)$ dependence calculated by formula (13), however, is close to the experimental curve for $V_1 \geq 0.5$.

As Fig.1 shows, formula (13) predicts a critical concentration ($V_c \approx 0.333$) of the electrically conducting component at which the conductivity of the two-component system begins to rise steeply. This means that in a system with $V_1 > V_c$ we expect clusters of particles of the conducting component to permeate the whole system. Thus, Odelevskii's generalised conductivity theory[67] for random two-component mixtures implies the important concept of a critical (threshold) concentration V_c:

$$\sigma(V_c) = \frac{\sigma_2 + \sqrt{\sigma_2^2 + 8\sigma_1\sigma_2}}{4}. \qquad (14)$$

A strict mathematical definition of the threshold concentration (flow threshold), given in Ref. 68, laid the foundations of the theory of flows. A detailed analysis of the basis of this theory and of its application to the calculation of the electrical parameters of highly inhomogeneous media can be found in earlier reviews[35,36]. The flow thresholds calculated for the covalent bond problem (diamond type lattice) and for the lattice site problem (simple cubic lattice) are close to the values given by formula (13) (see Table 5.1 of Ref.36).

The following dependences have been obtained[37,38,40] by the theory of flows: for $V_1 \geq V_c$

$$\sigma(V_1) = \sigma_1(V_1 - V_c)^t \qquad (15)$$

$$\sigma(V_c) = \sigma_1(\sigma_2/\sigma_1)^s = \sigma_1 h^s; \qquad (16)$$

and for $V_1 < V_c$

$$\sigma(V_1) = \sigma_2(V_c - V_1)^{-q} = \sigma_1 h(V_c - V_1)^{-q}. \qquad (17)$$

In these expressions t, s, and q (for three-dimensional systems) have the following values[38]: $t = 1.6$, $s \approx 0.62$, and $q = t/s - t$; σ_1, V_1, and V_c are the electrical conductivity, the volume fraction, and the threshold concentration of the metallic component of the two-component system, σ_2 is the electrical conductivity of the dielectric component. If the parameter $h = \sigma_2/\sigma_1$ is very small but finite the dielectric components begin to shunt the conducting cluster when the difference $V_1 - V_c$ is small enough; under these conditions the singularity of the function $\sigma(V_1)$ at $V_1 = V_c$ disappears, and $\sigma(V_1)$ becomes a smooth function increasing monotonically from σ_2 to σ_1.[38] In the immediate vicinity of V_c Eqns. (15) and (17) are not valid, and become indistinguishable[38]. It has been suggested[37,38] that in the transition region the $\sigma(V_1)$ dependence is determined by the parameter $\Delta = h^m$ (where $m = s/t$), called the width of the transition.

Formulae (15) and (17) accurately describe the electrical conductivity of two-component systems consisting of materials with widely different conductivities. Typical examples of these systems are the cermets, and substances which undergo dielectric—metal phase transitions of the first kind at a particular temperature (for example, transition-metal oxides)[38]. The transition can be "smeared out" by inhomogeneities in the material, and extend to relatively low temperatures. As a result, a metallic phase is formed within the dielectric matrix, the volume fraction being determined (between zero and unity) by the heat treatment temperature[69].

An analogous description can be given to the formation of polyconjugation regions (the "metallic phase") in a matrix of the initial polymeric dielectric (such as PAN, poly(vinyl chloride), poly(vinyl acetate), oxidised and cross-linked polyolefins, and some resins) during heat treatment. Indeed, from the standpoint of the structure of the final product the formation of semiconducting pyropolymers and the dielectric–metal transition have a great deal in common. However, when using this analogy the essential difference in nature between these two transitions should be remembered: the phase transition is a physical transformation, but the formation of semiconducting pyropolymers is a chemical transformation. Furthermore, in metals the motion of the delocalised electrons is three-dimensional (though it may be effectively two-dimensional in very thin layers), whereas in the chains of polyconjugation blocks it is one-dimensional[27]. (The existence of one-dimensional metals has been shown[70] to be impossible.) Therefore, the problem of one-dimensional conduction in long conjugated molecular chains is still unresolved[27,39].

As Fig.1 shows, the experimental curve almost coincides with that calculated by formula (15) in the range beginning at $V_1 \cong 0.5$. Hence, for our samples[53] of heat-treated PAN we can assume $V_C \cong 0.5$, which corresponds to $T_{form} \cong 600$ °C. The reality of the high-concentration threshold predicted by the flow theory is consistent with a high level of asymmetry in the configuration of the conducting and the non-conducting regions[40].

The deviation at $V_1 < V_C$ of the experimental $\sigma(V_1)$ plot from the curve calculated by Eqn.(17) is probably due to tunnelling of the electrons through the layers of dielectric material.

We should note that the $\sigma(V_1)$ relationships calculated by Eqns.(13), (15), and (17) and $V_C \cong 0.333$ are practically identical (the width $\Delta = h^m$ of the transition between (15) and (17) is fairly small for semiconducting pyropolymers). This allows us to compare (14) and (16), which leads to the expression

$$h^s = \frac{h + \sqrt{h^2 + 8h}}{4} \quad . \tag{18}$$

The quantity s calculated by Eqn.(18) for h values between 10^{-4} and 10^{-16} lies in the range 0.57–0.51, i.e. it increases very slowly with h.

Thus, the electrical conductivity of semiconducting pyropolymers in which the volume fraction of polyconjugations ("metallic phase") regions is $V_1 > 0.5$ can be described by the theory of flows. From this we may conclude that our proposed method[53] of determining the volume fraction of polyconjugation regions correctly represents the structural features of this type of material.

Useful information on the conduction mechanism has been obtained from the temperature dependence of the conductivity in semiconducting pyropolymers[1–7,71–73]. Most of the experimental results (with a few exceptions) lie on straight-line plots of lg σ against T^{-1}. In some cases these plots include breaks. For example, a study[72] of the temperature dependence of the conductivity of thermolysed PAN samples between 1.7 and 700 K has revealed five linear regions, the activation energy for conduction decreasing with decrease of temperature. This type of change in conductivity with temperature has been discussed[74–76] in terms of the electronic theory of disordered materials[35,36].

We know[35] that the temperature dependence of hopping conduction in the constant activation energy regime is

$$\sigma = \sigma_3 \exp\left(-\frac{\varepsilon_3}{k_B T}\right) \quad . \tag{19}$$

The activation energy (ε_3) for a given temperature is defined by the differential $[d(\ln \sigma)/d(k_B T)]^{-1}$. Hence, using Mott's law

$$\sigma = \sigma_0 \exp[-(T_0/T)^{1/4}] \quad , \tag{20}$$

where T_0 and σ_0 are parameters of the chosen model, we find that ε_3 can be expressed as

$$\varepsilon_3 = \frac{1}{4} T_0^{1/4} k_B T^{3/4} \quad , \tag{21}$$

and therefore decreases monotonically (as $T^{3/4}$) when the temperature is lowered.

Mott[41] gives the following expressions for T_0 and σ_0:

$$T_0 = \frac{\beta}{k_B g(\mu) a^3} \quad , \tag{22}$$

$$\sigma_0 = \frac{3 e^2 \nu \Phi_0}{2} \left(\frac{g(\mu) a}{2\pi k_B T}\right)^{1/4} \quad , \tag{23}$$

where a is the radius of the localised states close to the Fermi level, $g(\mu)$ is the density of states at the Fermi level, e is the electronic charge, ν is the phonon frequency, $\Phi_0 \cong 1$ is a constant, and $\beta = 21.2 \pm 1.2$ is a coefficient calculated by the theory of flows[36].

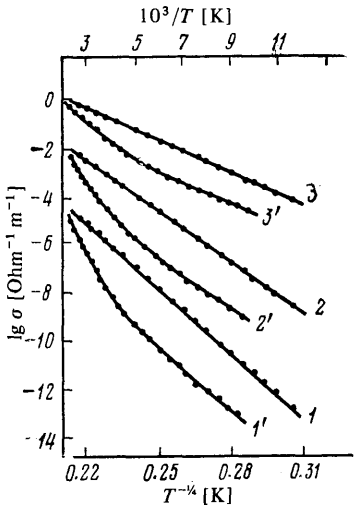

Figure 2. Temperature dependence of the electrical conductivity of PAN semiconducting pyropolymers prepared at different temperatures: *1*) and *1'*) 400°, *2*) and *2'*) 500°, *3*) and *3'*) 600°; *1*), *2*), and *3*) are in lg σ–$T^{-1/4}$ coordinates, *1'*), *2'*), and *3'*) in lg σ–T^{-1} coordinates[74].

The temperature dependence of the electrical conductivity is accurately described by straight lines (Fig.2) between 100 and 450 K when plotted as lg σ against $T^{-1/4}$, confirming that Mott's law (20) is obeyed.

Simultaneous solution of Eqns.(22) and (23) using data from Fig.2 gives unreasonable values of a and of $g(\mu)$ (see Table 3 [74]). Similar results were obtained with polyacene copolymers of the quinone radical type[77]. Therefore $g(\mu)$ was calculated by taking a as one-half of the average distance between polyconjugation regions determined by formula (7). This gave entirely reasonable values of $g(\mu)$ when Eqn.(22) was used, but calculations by Eqn.(23) gave physically

meaningless results (see Table 3). Hence, Eqn.(23) is not applicable to polymeric semiconductors. We note from Fig.2 that the temperature dependence of the conductivity is linear in lg σ against T^{-1} coordinates over relatively narrow temperature ranges, and the ε_3 values for these ranges decrease monotonically as the temperature decreases (see Table 4) [75] in accordance with Eqn.(21).

The temperature dependence of the electrical conductivity of semiconducting pyropolymers reflects the structure of these materials. As stated above, pyropolymers can be treated as micro-heterogeneous systems consisting of electrically conducting polyconjugation regions separated by layers of dielectric material. The distance between the polyconjugation regions (and between their clusters) can take a set of values, since their nucleation during pyrolysis is a random process. These inhomogeneous systems can be described by Miller and Abrahams' random resistance network model[35,36], in which the polyconjugation regions are treated as the analogues of donors, and the dielectric layers as analogues of the resistance to the transfer of current carriers between donors. At low temperatures the main contribution to the conduction is that of barrier layers with low values of ε_3. On raising the temperature the contribution from layers with relatively high values of ε_3 becomes significant.

The general definition of electrical conductivity is

$$\sigma = en\mu , \qquad (24)$$

where n and μ are the concentration and the mobility of the current carriers respectively. In the case of semiconducting pyropolymer the parameter n denotes the average number of polyconjugation regions in each cluster, within which the barriers are almost transparent to the current carriers, and therefore $n < N$. Electrical conduction arises mainly from jumps of the current carriers between the polyconjugation regions and between their clusters.

In semiconductors of this type the increase in conductivity with temperature is usually ascribed to an increase in μ;[1-4,7,73] we can therefore write

$$\mu = \mu_0 \exp[-(T_0/T)^{1/4}] \qquad (25)$$

$$\sigma_0 = en\mu_0 , \qquad (26)$$

where μ_0 is a constant, independent of the measurement temperature. The n values, determined by formula (10) from the CVC, are given in Table 3 together with the μ_0 values. We see from Fig.3 that μ increases with the heat treatment temperature. Thus semiconducting pyropolymers are strongly inhomogeneous systems in which electrical conduction is by jumps of variable length over a wide range of temperature. The temperature dependence of the average jump length $\bar{r}$ is given by the expression[36]

$$\bar{r} = \frac{1}{2.73}\, a\,(T_0/T)^{1/4} .$$

The average jump length decreases as T_{form} increases (Fig.4). From Fig.3 and Table 4 we conclude that higher values of mobility correspond to higher values of the activation energy.

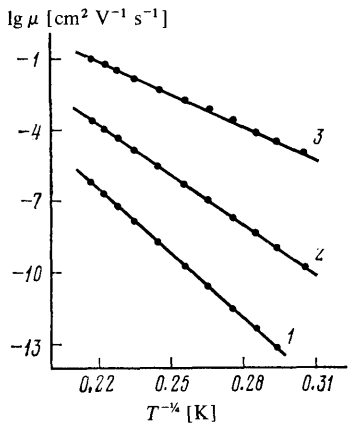

Figure 3. Temperature dependence of the mobility of the charge carriers μ in PAN semiconducting pyropolymers prepared at: *1*) 400°, *2*) 500°, and *3*) 600°.[75]

The current carriers in semiconducting pyropolymers have very low mobilities (Fig.3). Ioffe and Regel'[32-34] tried to explain the low mobilities in amorphous and in liquid semiconductors of various types, but they met some fundamental difficulties, which we shall examine below.

The mobility μ and the coresponding mean free path l of the current carriers with an effective mass m^* at room temperature are interrelated by the expression[33,34]

$$l \simeq 10^{-8} \mu (m^*/m)^{1/2} ,$$

where m is the mass of the electron. In the case of electronic semiconductors the mean free path has been shown[33,34] to lie between 10^{-9} and 10^{-4} cm. In these materials the interatomic distances are $r \cong (3-5) \times 10^{-8}$ cm, and the wave length of

the free electrons and holes moving with thermal velocity at room temperature is $\lambda \cong 7 \times 10^{-7}$ cm. It is found that $l < \lambda$ for all semiconductors with a mobility $\mu < 100$ cm^2 V^{-1} s^{-1}, and $l < r$ for $\mu < 5$ cm^2 V^{-1} s^{-1}. However, free motion of the carriers at some average velocity is possible only at a distance l. Therefore it is clear that the concept of a carrier velocity becomes meaningless for all semiconductors with $\mu < 100$ cm^2 V^{-1} s^{-1}.[33,34] As Ioffe and Regel' have pointed out, the mean free path and the mobility of the charge carriers also become meaningless for semiconductors in which $l < \lambda$ (and especially when $l < r$), since in the quantum-mechanical model the electron is "smeared out" over a region of length λ.

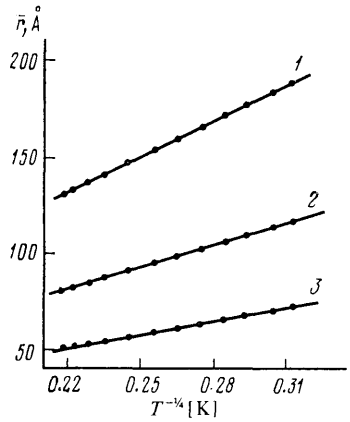

Figure 4. Temperature dependence of the average jump length of the charge carriers in PAN semiconducting pyropolymers heat treated at: *1*) 400°, *2*) 500°, and *3*) 600°.[75]

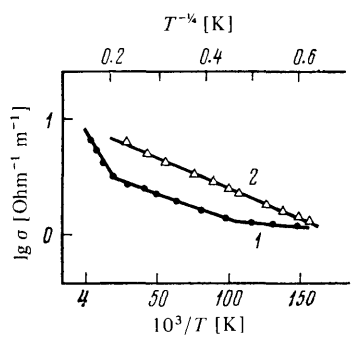

Figure 5. Temperature dependence of the electrical conductivity of a copolymer of cyano-acetylene and acetylene, plotted as: *1*) lg σ against T^{-1} (after Ref.6), and *2*) lg σ against $T^{-1/4}$.

In their treatment of the charge transport phenomenon as a special type of chemical reaction with an activation energy E Ioffe and Regel' expressed the temperature dependence of the carrier mobility (for low applied electric fields) as

$$\mu \propto \exp(-E/k_B T).$$

According to this expression the parameter μ increases exponentially with temperature in semiconductors with a low mobility of charge carriers. A low mobility, increasing with temperature, is consistent with an activational mechanism for the transfer of charge carriers through potential barriers.

The work described in Refs.32–34 laid the foundations for the development of extensive studies of the physical properties of disordered systems, such as amorphous or liquid semiconductors, in which the short-range structural order plays the key role in the formation of the electron energy spectrum and determines the localisation of the electronic states attending an increase in the structural disorder factor[42]. It has been suggested[33,34] that in low-mobility semiconductors the term "mobility" should be replaced by the concept of a frequency of transitions between localised states. The results discussed above show that an increase in temperature increases the frequency of the transition (the transition probability) of the charge carriers between the polyconjugation regions and between their clusters in semiconducting pyropolymers.

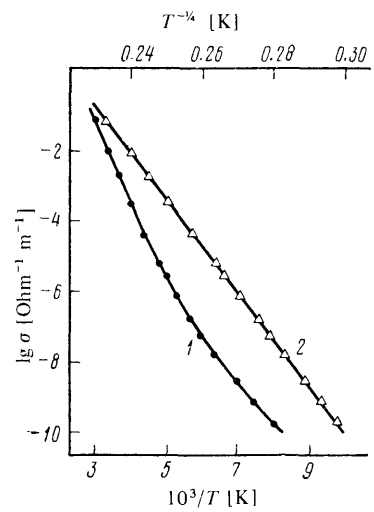

Figure 6. Temperature dependence of the electrical conductivity of thermally- and radiation-modified polyethylene, heat treated at 445° and exposed to iodine at 240°: *1*) plotted as lg σ against T^{-1}, *2*) same data, plotted as lg σ against $T^{-1/4}$.

The above interpretation of the temperature dependence of electrical conductivity applies to all semiconducting polymers. As an illustration we have plotted a large amount of published data[6,7,72,73] according to Mott's law [Eqn.(20)]. As Figs.5–8 show, the curves of electrical conductivity against temperature are linearised in many cases when plotted as lg σ against $(1/T)^{1/4}$.

We should stress that the presence of empty donors is a necessary condition for hopping conduction: in the case of semiconducting pyropolymers free sites must be available in the blocks or in the polyconjugation regions. This condition implies compensation in the semiconductor[35,36]. Hence, the report[77] that the formation of semiconducting pyropolymers is accompanied by substantial compensation appears to be correct.

In conclusion we should note that in our model the density of localised state is independent of energy. In this model the region in which Mott's law (20) applies has neither an upper nor a lower temperature limit[36]. As we see from Figs. 2 and 6–8, Mott's law is obeyed over a wide temperature range (10–600 K). Hence we may conclude that in semiconducting pyropolymers the density of states may be treated as constant over a wide temperature range.

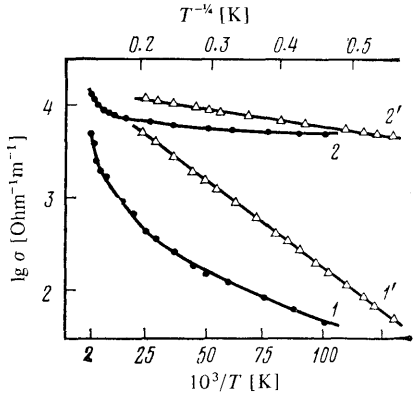

Figure 7. Temperature dependence of the electrical conductivity of PAN thermolysed at *1*) 800° and *2*) 850°: *1*) and *2*) after Ref. 72, plotted as lg σ against T^{-1}, *1'*) and *2'*) same data, plotted as lg σ against $T^{-1/4}$.

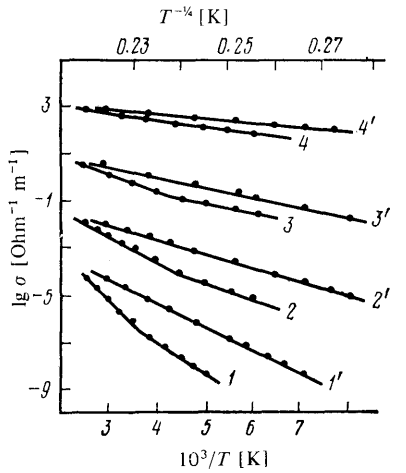

Figure 8. Temperature dependence of the electrical conductivity of PAN thermolysed at *1*) 400°, *2*) 500°, *3*) 600°, and *4*) 700°: *1*), *2*), *3*), and *4*) after Ref. 73, plotted as lg σ against T^{-1}; *1'*), *2'*), *3'*), and *4'*) same data, plotted as lg σ against $T^{-1/4}$.

Thus, from the standpoint of a concrete structural model the semiconducting pyropolymers can be divided into three groups. The first group includes the semiconducting pyropolymers in which polyconjugation regions at different distances are gradually converted (as the thermolysis temperature is increased) from isolated states into a state which can support weak exchange interactions, without formation of a joined, continuous phase. Under these conditions the Gaussian shape of the ESR line changes to a mixed shape: Lorentzian in the centre, Gaussian at the tails, and showing a saturation effect. The concentration by volume of polyconjugation regions is ~40–50% towards the upper limit of the formation temperatures of the semiconducting pyropolymers, which depends on the nature and structure of the initial component as well as on the thermolysis conditions. In the case of PAN the semiconductors prepared by thermolysis below 600° belong to the first group. According to our model the materials in this group (which have a fairly high resistance) can be treated as two-component systems in which the polyconjugation regions (or their clusters) behave as electrically conducting inclusions while the insulating component forms the continuous matrix. The distance between polyconjugation regions, i.e. the thickness of the poor conductor, has a real physical significance and determines the height of the potential barrier opposing the motion of the current carriers.

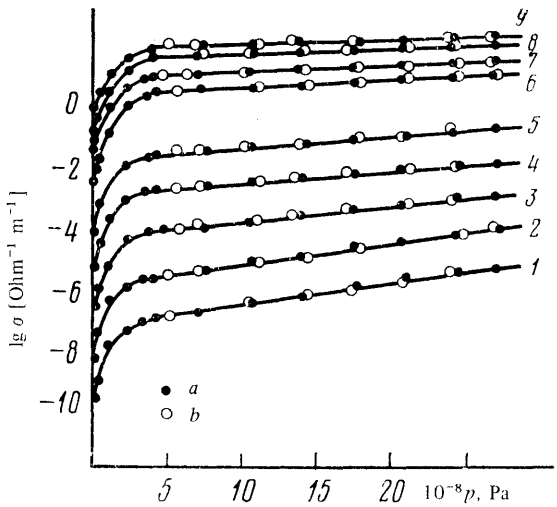

Figure 9. Electrical conductivity σ against pressure p for powdered PAN semiconductors prepared at: *1*) 400°, *2*) 450°, *3*) 500°, *4*) 550°, *5*) 600°, *6*) 650°, *7*) 700°, *8*) 750°, and *9*) 800°; (*a*) and (*b*) denote increasing and decreasing pressure runs respectively.

The second group consists of the semiconducting pyropolymers prepared at temperatures corresponding to extrema in the dependence of the number of PMC on the thermolysis temperature. The ESR line of these semiconductors is Lorentzian, and does not show a saturation effect. In the preparation of PAN semiconductors this temperature region is found between 600 and 700° (Table 1). The samples prepared at these temperatures can be described as a random mixture of a conducting and an insulating component, both components forming continuous phases. In other words, at the lower end of this range of formation temperatures the conducting component just begins to form an infinite cluster, i.e. for temperatures $T_{form} \geq 600°$ we have $V_1 > V_c$. This conclusion is confirmed by the low value of the activation energy for conduction for relatively high values of the resistivity[53]. The *S* values for these samples (denoted by an

asterisk in Table 1) are physically meaningless: they define the effective distances between polyconjugation regions for samples in which these regions are uniformly embedded in a poorly conducting matrix.

The third group includes the semiconducting pyropolymers with strong interactions between the polyconjugation regions, which occupy most of the available volume and form a continuous phase (infinite cluster). Pyropolymers of this group are formed at temperatures above the level corresponding to a decrease in the number of PMC with increase of T_{form}. Materials in this group can be treated as matrix systems, the matrix consisting of polyconjugation regions developed in three dimensions with random microscopic inclusions of a resistive component, whose volume fraction decreases as T_{form} increases. The resistive inclusions could be dielectric impurities, defects, and pores, formed during the thermolysis of the initial polymer. In these samples the distance between resistive inclusions is more meaningful than the parameter S. If the number of resistive inclusions is of the same order as the number of PMC the distance between the inclusions is of the same order as the parameter L.

We should note that the transition of semiconducting pyropolymers between these groups occurs at temperatures depending on the structure of the initial polymer and on the pyrolysis conditions. For example, inorganic substrates can lower the transition temperature of PAN semiconductors by 100–150 K.[78]

III. PRESSURE DEPENDENCE OF THE ELECTRICAL CONDUCTIVITY

If the above heterogeneous models of the structure of semiconducting pyropolymers are correct the dependence of the electrical conductivity (σ) on pressure (p) should become less marked as the pyrolysis temperature of the polymer increases, i.e. as the concentration of polyconjugation regions in the sample increases, because the latter are denser than the resistive layers between them. In other words, for the three groups of semiconducting pyropolymers defined above the pressure sensitivity should decrease in the order group I > group II > group III. This conclusion will prove correct only if the height of the potential barriers between the regions of delocalised electrons[79,80] is affected by the pressure.

Studies of the effect of pressure on the electrical conductivity of semiconducting pyropolymers are needed not only to provide an answer to this type of question but also to establish the possibility of using these materials as the sensitive element of pressure transducers, and to allow for contact phenomena between the particles of powdered samples in the measurement and interpretation of their electrical properties. The latter aspect is quite important, because many semiconducting polymers are available only as powders which cannot be pelleted. Therefore it important to know the pressure at which the powdered sample behaves as a monolithic sample, and the way to determine the electrical parameters corresponding to the monolithic state at $p \to 0$ (or at atmospheric presure), so as to obtain the electrical conductivity of individual particles of the powder.

The effect of hydrostatic compression on the electrical conductivity and thermo-electric power of PAN fibre heat-treated at 600 and 650° has been reported[79,80]. Powdered samples are thought[79] to be unsuitable for this work, because their resistance depends on contacts between particles, whereas fibres behave as monolithic specimens. However, fibres cannot be used to study carrier transport over a wide range of pressure, because they break at loads >8 kbar.[1] We have therefore studied[81,82] the effect of quasi-hydrostatic pressures between atmospheric and 30 kbar on the electrical conductivity parameters of powdered semiconducting pyropolymers based on PAN and thermolysed at 300–900°. This work has produced convincing answers to some of the questions formulated above, and will be reviewed in some detail.

In Fig.9, taken from Ref.82, two regions can be distinguished: in the first σ rises very steeply as p is raised to 3.4×10^8 Pa, suggesting densification of the powdered sample and an increase in the area of contact between the particles. We know[83] that the average porosity of a compressed powder decreases monotonically as a function of the applied pressure, and vanishes at a specific pressure, when the density and the conductivity of the sample become equal to those of the individual particles of the power. We see from Fig.9 that for heat-treated PAN powders this pressure lies in the region of 3500–4000 kg cm^{-2}. Beyond these pressures we observe the second region, in which the experimental points (plotted as lg σ against p) are almost indistinguishable from the straight lines

$$\sigma = \sigma_{p=0} \exp\left(\frac{ap}{k_B T}\right), \qquad (27)$$

where a is a constant.

Table 5. Dependence of $\sigma_{p=0}$ and of the parameter a on the heat treatment temperature (T_{form}) of PAN.[82]

T_{form}, °C	$\sigma_{p=0}$, Ohm^{-1} cm^{-1}	$10^{-4}a$, eV cm^2 kg^{-1}	T_{form}, °C	$\sigma_{p=0}$, Ohm^{-1} cm^{-1}	$10^{-4}a$, eV cm^2 kg^{-1}
400	$3.97 \cdot 10^{-10}$	4.2	650	$3.97 \cdot 10^{-3}$	1.1
450	$1.41 \cdot 10^{-8}$	3.68	700	$1.58 \cdot 10^{-1}$	0.9
500	$6.25 \cdot 10^{-7}$	2.65	750	$8.85 \cdot 10^{-1}$	0.6
550	$1.77 \cdot 10^{-5}$	1.84	800	1.77	0.36
600	$2.94 \cdot 10^{-5}$	1.69			

The pre-exponential term $\sigma_{p=0}$ for a monolithic sample corresponds to the electrical conductivity in the absence of pressure[79]. In the case of a powdered sample $\sigma_{p=0}$ defines the electrical conductivity at zero pressure but assumed independent of the contact between the particles, i.e. $\sigma_{p=0}$ corresponds to the monolithic state of the powder at $p = 0$. The true value of $\sigma_{p=0}$ for a powder is determined by extrapolating to $p = 0$ the linear portion of the lg σ against p plot. Values of $\sigma_{p=0}$ obtained in this way and values of a calculated by Eqn.(27) for PAN samples heat-treated at different temperatures are given in Table 5 (taken from Ref.82). As T_{form} is increased the constant a decreases, and $\sigma_{p=0}$ increases. This quantity is identical to the value $\sigma_{20°}$ obtained from the plots of lg σ against T^{-1} at a pressure of 3500 kg cm^{-2}. Hence, and in the light of the above definition of $\sigma_{p=0}$, we can write

$$\sigma_{p=0} = \sigma_3 \exp\left(-\frac{\varepsilon_3}{k_B T}\right), \qquad (28)$$

where ε_3 is the thermal activation energy for conduction at zero pressure. Thus Eqn.(28) describes the temperature dependence of the hopping conduction in the constant activation energy regime at zero pressure.

From formulae (27) and (28) we obtain the following expression for the temperature dependence of the electrical conductivity in the presence of an applied pressure:

$$\sigma = \sigma_3 \exp\left(-\frac{\varepsilon_3 - ap}{k_B T}\right). \qquad (29)$$

It follows from this expression that a is a quantity (depending on the nature of the sample) which describes the decrease in the activation energy for electrical conduction in semiconducting pyropolymers brought about by the application of unit pressure, i.e.

$$\varepsilon_3'-\varepsilon_3''=-a(p_1-p_2) \quad \text{or} \quad \Delta\varepsilon=-a\Delta p\,, \tag{30}$$

where ε_3' and ε_3'' are the activation energies for conduction at pressures p_1 and p_2 respectively. As Table 6 shows[82], the activation energy for conduction decreases linearly with increase of pressure, as required by Eqn.(30). Extrapolation to zero pressure gives the activation energy for conduction in the "monolithic" state of the powder in the absence of pressure. The activation energies for conduction obtained in this way are 0.01–0.02 eV lower than the values for powder samples densified by vibration.

Table 6. Electrical conductivity parameters of heat-treated PAN at different pressures.

*These data refer to a powder densified by vibration in a quartz cylinder at atmospheric pressure.

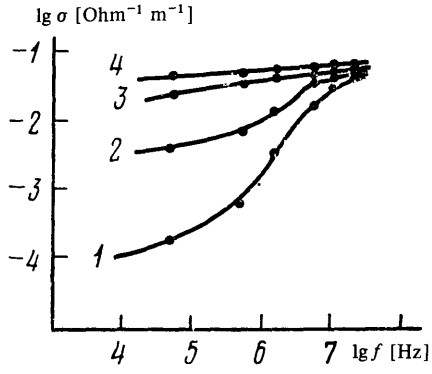

Figure 10. A.c. conductivity against frequency at different pressures for a sample of PAN heat treated at 600°: *1*) atmospheric pressure, *2*) 1.0×10^3, *3*) 3.5×10^3, *4*) 1×10^4 kg cm^{-2}.[82]

We would stress that in the linear region of the plots of lg σ against p the change of σ with pressure is reversible (see Fig.9), and therefore in this region (at $p \geq 3500$ kg cm^{-2}) the properties of the powdered semiconducting pyropolymer samples are indistinguishable from those of monolithic specimens. Measurements of the a.c. conductivity under pressure have confirmed this view. Since the conductivity of a fibre (monolithic specimen) of thermolysed PAN is independent of frequency[79], the gradual decrease in the frequency dependence of conductivity with increase of pressure (Fig.10) confirms the above conclusion.

In 1960 Tal'roze and Blyumenfel'd[84] observed a linear dependence of lg σ_3 on ε_3 (i.e. a compensation effect) in a wide range of polymeric semiconductors. A detailed analysis of various aspects of this phenomenon from the point of view of the chemical physics of the solid state is given in Ref.85. As Fig.11 shows, a linear relationship is observed also between lg $\sigma_{p=0}$ and a, which vary in opposite senses, i.e. according to the equation

$$a=b+c\lg\sigma_{p=0} \tag{31}$$

whose coefficients b and c (calculated by least squares) are 0.456×10^{-6} and -0.382×10^{-6} respectively.

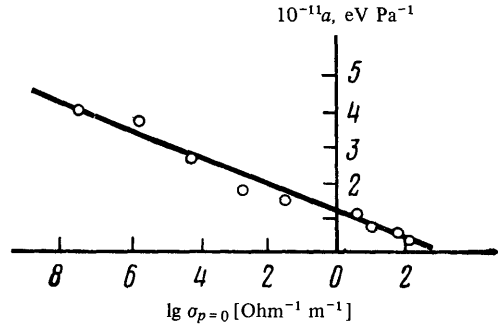

Figure 11. Pre-exponential factor $\sigma_{p=0}$ in Eqn.(27) against the constant a for heat-treated PAN samples[82].

From the lack of dependence of the pre-exponential factor σ_3 on p in the linear part of the lg $\sigma(p)$ function (see Fig.9 and Table 6) and from the inverse variation (31) between $\sigma_{p=0}$ and a we may conclude that the main effect of pressure is an increase in the mobility of the charge carriers, the concentration of the carriers being unaffected by the pressure. The same conclusion was reached[80] from an observation of the pressure-independence of the thermo-electric power of pyrolysed PAN fibre, coupled with a decrease in the activation energy for electrical conduction with increase of pressure.

However, we should point out that Shimamura and coworkers[86,87] concluded from a study of the electrical conductivity of polyacetylene at pressures up to 108 kbar between room temperature and liquid-nitrogen temperature that the concentration of current carriers increases with pressure. This conclusion is incorrect, because the pre-exponential factor is sensitive to changes in the density of charge carriers[4], and therefore constancy of this factor coupled with a decrease in the activation energy for conduction with increase of pressure implies that the main influence of pressure on the electrical conductivity of polymeric semiconductors is to increase the mobility of the carriers by lowering the potential barriers.

From Tables 5 and 6 and Fig.9 we note that the pressure dependence of the electrical conductivity decreases as T_{form} increases, i.e. as the volume concentration of polyconjugation regions increases. These results indicate that the structural features of the pyropolymers and their changes with thermolysis temperature are correctly reflected, on the whole, by the heterogeneous models discussed above. They also show that the main effect of pressure is on the potential

barriers which separate the regions containing delocalised electrons. In other words, the insulating inter-layers are more compressible than the polyconjugation regions. The semiconducting pyropolymers of group I are the more pressure-sensitive, and they can be used as the sensing element in pressure transducers. A detailed analysis of the advantages of polymeric semiconductors as materials for pressure transducers will be found in Ref.88.

IV. RELATIONSHIP BETWEEN THE NUMBER OF PARAMAGNETIC CENTRES AND THE ELECTRICAL CONDUCTIVITY

A large volume of work, reviewed in Refs.1, 2, and 7, suggests the existence of a definite relationship between the electrical and the paramagnetic properties of polymeric semiconductors. However, different points of view have been put forward in the interpretation of this phenomenon. For example, some workers[89,90] consider that at high enough levels of conjugation (i.e. under conditions of eka-conjugation) the electronically excited state can exist at room temperature because the distance between the ground and the triplet state is small, and charge carriers formed by the scheme

$$R + \ddot{R} \rightleftarrows R^+ + R^-$$

are recorded in the ESR spectra. The authors[89,90] used the theory of rate processes to explain the relationship between conductivity and paramagnetism in polymers with conjugated bonds.

Vlasova and coworkers[91,92] conclude from the good agreement between experimental values of the thermoelectric power of thermolysed PAN and polypyridine and the values calculated by the band theory of solids that the PMC behave as donor impurities in these materials. This work suggests (implicitly) that the unpaired electrons transferred to the conduction band by the ionisation of the donors give the same ESR signal as the electrons still in the filled donors[2]. Further work is needed to confirm this conclusion.

An analysis of the electrical and paramagnetic characteristics of polymeric semiconductors led Vannikov and Boguslavskii[2] to conclude that in most cases a direct link between the electronic states which control the electrical and the paramagnetic properties cannot be established. If such a link exists, it can only be discovered by detailed studies and comparisons of the electrical and paramagnetic properties over a wide range of experimental conditions and of chemical composition and structure of the sample[2]. We note in this connection the work of Volod'ko and coworkers[93], who obtained an expression directly relating the electrical conductivity and the number of PMC by using the hopping model of conduction. According to that model the mobility is expressed by the formula[4]

$$\mu = \frac{fSeN_s(k_BT)}{h^2\nu^2}\exp\left(-\frac{\varepsilon_s}{k_BT}\right), \qquad (32)$$

where f is the average angle between the jump direction and the vector of the electric field, S is the distance between molecules, N_S is the number of neighbouring molecules, ν is the vibration frequency of the activated complex in a plane normal to the direction of motion of the charge carriers, ε_S is the height of the barrier, and h is Planck's constant. In the case of semiconducting pyropolymer S is interpreted as the distance between polyconjugation regions, and N_S as the number of adjacent polyconjugation regions.

Eqn.(32) has no practical applications, because it contains quantities which cannot be measured experimentally. Therefore, introducing the substitutions

$$S=\xi_1 N^{-1/3};\ f=a_0N^{1/3}/\xi_1;\ N_s=R^3N;\ \varepsilon_s=\varepsilon_3;\ \nu=\varepsilon/\hbar;\ n=N\xi, \qquad (33)$$

where a_0 is the mean radius of the molecule, R is the mean intermolecular interaction radius, ξ is a quantity depending on N, ξ_1 is a constant, and ε_3 is the activation energy for hopping conduction, Volod'ko and coworkers[93] obtained from (24) and (32) the expression

$$\sigma=\alpha_1\varphi(N)N^{5/3}(k_BT/\varepsilon_3)^2\exp\left(-\frac{\varepsilon_3}{k_BT}\right), \qquad (34)$$

where $\phi(N)$ is a function of N, and

$$\alpha_1=e^2a_0\xi_1R^3/\hbar. \qquad (35)$$

Formula (34) accurately describes the electrical conductivity of polymers with a polyconjugated system if the following condition applies[93]:

$$\varphi(N)=\varphi_0\exp\left(-\beta\frac{N^{1/3}}{\gamma+N^{1/3}}\right). \qquad (36)$$

Inserting (36) into (34) gives

$$\sigma=\alpha N^{5/3}\left(\frac{k_BT}{\varepsilon_3}\right)^2\exp\left[-\frac{\varepsilon_3}{k_BT}-\beta\frac{N^{1/3}}{\gamma+N^{1/3}}\right], \qquad (37)$$

where $\alpha = \alpha_1\phi_0$, β, and γ are constants; the values $\ln\alpha = -44.7$, $\beta = 40$, and $\gamma = 1.3\times10^6$ were obtained[93] by least squares.

Satisfactory agreement was obtained in a comparison[93] of experimental electrical conductivity data for 44 polymeric semiconductors with the values calculated by formula (37). Differences of an order of magnitude between calculated and experimental conductivities are ascribed to errors in the measurement of the activation energy for conduction and of the concentration of PMC. However, in some samples discrepancies as high as 1.4–7 orders of magnitude were obtained[93]: no attempt was made to explain these large errors.

In spite of the satisfactory results given by formula (37) for most of the materials studied by Volod'ko and coworkers[93], the extent to which this formula is universal remains to be established. To solve this problem we need first of all to demonstrate the universality of the constants α, β, and γ which appear in formula (37), and the lack of dependence of the results upon the type of interaction between the PMC.

Comparing the first of the substitutions (33) with Eqn.(7) we can write, for the case of semiconducting pyropolymers,

$$\xi_1=1-V_1^{1/3}=1-LN^{1/3}, \qquad (38)$$

i.e. ξ is the linear fraction of dielectric inter-layers between polyconjugation regions. Inserting (38) into (35) we obtain

$$\alpha=\frac{e^2a_0(1-V_1^{1/3})R^3}{\hbar}\varphi_0=\frac{e^2a_0(1-LN^{1/3})R^3}{\hbar}\varphi_0. \qquad (39)$$

In the case of semiconducting pyropolymers a_0 and R are interpreted as $L/2$ and $S/2$ respectively, i.e. within the definition of the structure parameters given in Section II $a_0 = L/2$ and $R = S/2$. Hence, when applied to semiconducting pyropolymers Eqn.(39) becomes

$$\alpha=\frac{e^2L(1-V_1^{1/3})S^3}{16\hbar}\varphi_0. \qquad (40)$$

Clearly, the quantity α depends on the nature and on the structure parameters of the polymeric semiconductor, i.e. it takes a different value for each polymer. Therefore the use[93] of a single value (ln

($\ln\alpha = -44.7$) to calculate the electrical conductivity of polymeric semiconductors by Eqn.(37) is unjustified. This is

probably one of the main reasons for the discrepancy between experimental conductivities and those calculated by Eqn.(37). Nothing has been said about the universality of the constants β and γ, since there is no physical justification for the choice of the function (36), which appears to have been purely empirical. Nevertheless this function shows how complex is the relationship between the concentration and mobility of the charge carriers and the number of PMC in the polymer.

The reason why formula (37) with the constants α, β, and γ given in Ref.93 can be used for semiconducting pyropolymers according to the nature of the interactions between PMC was discussed in Ref.54. It was shown that the electrical conductivity of semiconducting pyropolymers of group I (see Section II), in which the polyconjugation regions and their clusters do not merge into a continuous phase, i.e. in which the interaction between these regions are weak, are most accurately described by formula (37). The largest deviations occur with samples from group II, prepared at temperatures corresponding to extrema in the dependence of the number of PMC on the thermolysis temperature of the initial polymer. The same conclusion follows from Eqn.(40), since in semiconductors of groups II and III the parameter S has no real physical meaning (see Section II).

To conclude this Section we should stress the following aspect. By comparing Eqn.(29) for $p = 0$ with Eqn.(37) we obtain

$$\sigma_3 = \alpha N^{2/3} \left(\frac{k_B T}{e_3}\right)^2 \exp\left(-\frac{\beta N^{1/3}}{\gamma + N^{1/3}}\right) . \qquad (41)$$

Though this comparison of the universal (over a narrow temperature range) equation (29) at $p = 0$ with an expression [Eqn.(37)] whose universality remains to be proved is not entirely justified, it nevertheless allows us to highlight some special features of the quantities ϕ_3, α, β, and γ. Eqn.(41) relates the pre-exponential factor ϕ_3 (which appears in formula (19) for the hopping conductivity in the constant activation energy regime) to the number of PMC. Hence, the relationship between the electrical conduction and the paramagnetic characteristics of semiconducting pyropolymers takes place mainly through the parameter ϕ_3.

We have shown (see Section III) that in the region of reversible pressure effects on the conductivity the pre-exponential factor ϕ_3 in Eqn.(29) is independent of pressure. From this we may conclude that the effects of pressure on the quantities which appear in Eqn.(41) must be mutually compensating. The activation energy for conduction decreases as the pressure increases, in accordance with Eqn.(30). It is evident from Eqn.(40) that the quantity α also should decrease with pressure, since it is proportional to S^3, where S is the thickness of the resistive layers between polyconjugation regions, to which the pressure is effectively applied. The changes in α and in ε_3 brought about by pressure may largely cancel out. A change of N with pressure seems unlikely in the region of reversible pressure dependence of the electrical conductivity of semiconducting pyropolymers. Therefore we are led to the conclusion that β and γ are unaffected by pressure, or that their pressure changes are mutually compensating.

V. CONCLUSIONS

Research into the preparation, properties, and applications of micro-heterogeneous semiconducting pyropolymers may develop in a number of new directions. The structural models of these polymers discussed above suggest the possibility of modifying their properties merely by controlling the degree of interaction between the polyconjugation regions in the system. The gradual change in properties of the initial polymer caused by increasing the thermolysis temperature can be classified as a thermal modification process. However, controlled changes in the properties of semiconducting pyropolymers by the addition of various compounds are also possible. For example, the controlled modification of the paramagnetic and of the adsorption properties of PAN semiconductor pyropolymers by doping with anthracene has been demonstrated[94-96]. The effect of additions of nickel during the pyrolysis of PAN on the electrical properties of the product has been investigated[97,98]. Metal-containing polymeric semiconductors of this type are potentially interesting as selective catalysts based on polyconjugated matrices, and also as materials for switching applications.

We believe that one of the most promising new developments will be the modification of fillers by semiconducting pyropolymers. This area of work includes methods of controlling the grafted polymerisation of acrylonitrile, vinyl acetate, and vinyl chloride on the surface of ordinary cheap fillers. Heat treatment of fillers modified in this way should give electrically conducting fillers for plastics with entirely new properties[99-103]. The work must include a study of the formation of semiconducting pyropolymers on the surface of cheap mineral filler particles, and of the effect of the fillers modified in this way on the physicochemical properties of the polymeric binders. All these problems need to be studied in detail.

Metal Ions in Unusual and Unstable States of Oxidation and the Steps of Electrochemical Reactions

B.G.Ershov

Problems associated with the steps of electrochemical discharge and ionisation reactions of metals in aqueous solutions are discussed. Data on the radiation-chemical preparation of metals in unusual and unstable states of oxidation are reported. The results of studies of the physicochemical properties of these species in aqueous solutions and of their reactions with organic and with inorganic compounds are generalised. The effect of metal ions in unusual and unstable states of oxidation on the elementary steps of electrode reactions is discussed. 162 references.

I. INTRODUCTION

It is generally assumed[1-3] that complex electrochemical oxidation–reduction reactions consist of several elementary (one-electron) electrochemical acts. The intermediate steps of these reactions (for example, the anodic dissolution or the cathodic deposition of metals) give ions in unusual and unstable states of oxidation. Since the direct experimental observation of these short-lived intermediate species is impossible at present, any conclusion as to the steps involved in an electrochemical reaction must be based on an analysis of the kinetics of the process. However, the criteria used to identify the steps cannot usually yield an unambiguous description of the overall mechanism of the process. Nevertheless metal ions in unstable states of oxidation have been obtained by radiation-chemical methods (mainly in aqueous solutions), and their properties have been studied in fair detail. It could be useful to review and discuss these results from the standpoint of a more fundamental understanding of the mechanism of the multi-step discharge and ionisation reactions of metals.

II. STEP REACTIONS IN ELECTROCHEMICAL KINETICS

The theory of multi-step electrode processes is based on the proposition that the transfer of several electrons in a single elementary discharge (or metal ionisation) act is less probable than the sequential transfer through one-electron intermediate steps. Thus a multi-step electrochemical reaction presupposes the formation of metal ions having intermediate valencies.

The fullest discussion of multi-step electrochemical processes can be found in papers[4,5] describing the anodic dissolution of iron in alkaline solutions by the overall reaction

$$Fe + 2OH^- \rightleftarrows Fe(OH)_2 + 2e .$$

The experimental results were explained by postulating the formation (in a one-electron process) of the intermediate surface compound Fe(OH)(ads):

$$Fe + OH^- \rightleftarrows Fe(OH)(ads) + e$$

followed by the slow step

$$Fe(OH)(ads) + OH^- \rightarrow FeO(ads) + H_2O + e$$

and by the fast reactions leading to the formation of the final product

$$FeO(ads) + OH^- \rightleftarrows HFeO_2^- ,$$
$$HFeO_2^- + H_2O \rightleftarrows Fe(OH)_2 + OH^- .$$

The mechanism of a multi-step electrode process on a solid electrode is difficult to study because of the imperfection of real surfaces, and also because the electrochemical discharge (ionisation) reaction is often accompanied by other steps such as diffusion of the species being discharged to crystallisation sites, their incorporation into the lattice, etc. The amalgam electrode is more convenient for theoretical and experimental studies of step reaction mechanisms, and it offers some important advantages over solid electrodes. We shall therefore confine this discussion mainly to data obtained for multi-step electrode processes on amalgams.

1. Criteria of Step Mechanism

The recognition of a step mechanism in an electrochemical reaction is usually based on an analysis of the reaction kinetics. Theoretical rules developed for this purpose[2,3,6-9] have been called the "criteria of step mechanism": they are discussed in detail in Ref. 3.

The step mechanism of a complex electrochemical reaction can be demonstrated by studying the kinetics of the cathodic and of the anodic process. Consider the overall discharge (metal ionisation) reaction

$$M \rightleftarrows M^{n+} + ne \qquad (1)$$

whose rate is limited by the slow step

$$M^{(m-1)+} \underset{k_{cm}}{\overset{k_{am}}{\rightleftarrows}} M^{m+} + e . \qquad (2)$$

According to the slow discharge theory[10], the rates of the anodic and of the cathodic process are given by

$$i_{am} = k_{am}[M^{(m-1)+}]_s \exp\left(\frac{\beta_m F(\varphi - \psi_1)}{RT}\right) , \qquad (3)$$

$$i_{cm} = k_{cm}[M^{m+}]_s \exp\left(-\frac{\alpha_m F(\varphi - \psi_1)}{RT}\right) , \qquad (4)$$

where ψ_1 is the potential at a point one ionic radius away from the electrode surface measured from the potential in the volume of the solution, and α_m and β_m are the true transfer coefficients of the m-th step, for which we can write

$$\alpha_m + \beta_m = 1 . \qquad (5)$$

By using the Nernst equation we can determine the concentrations of intermediate species $M^{(m-1)+}$ and M^{m+}, and thus we can replace Eqns.(3) and (4) (using the subscripts s and v to denote surface and volume concentrations respectively) by

$$i_{am} = k_{am}[M^{(m-1)+}]_v \exp\left(\frac{\beta_m F\varphi}{RT}\right) \exp\left[-\frac{(m-1+\beta_m)F\psi_1}{RT}\right] , \qquad (6)$$

$$i_{cm} = k_{cm}[M^{m+}]_v \exp\left(-\frac{\alpha_m F\varphi}{RT}\right) \exp\left[-\frac{(m-\alpha_m)F\psi_1}{RT}\right] . \qquad (7)$$

The apparent transfer coefficients of the anodic (β) and of the cathodic (α) process are related to the true coefficients β_m and α_m by the expressions

$$\begin{gathered}\beta = m - 1 + \beta_m , \\ \alpha = n - m + \alpha_m , \\ \alpha + \beta = n .\end{gathered} \qquad (8)$$

The criteria for the presence of steps can be formulated by analysing the kinetic features of the electrode process. In the case of a single rate-limiting step the criterion for a step mechanism is the dependence of the ratio of the apparent transfer coefficients (defined by the slopes of the anodic and the cathodic curve) on the number m of the limiting step:

$$\beta/\alpha = (m - 1 + \beta_m)/(n - m + \alpha_m) \qquad (9)$$

and also the fact that the sum of these coefficients is equal to the total number of electrons taking part in reaction (1) [as required by Eqn.(8)].

If in a two-step process the first step is rate-limiting, and the second is a disproportionation reaction, the kinetic equations for the cathodic and the anodic process will be the same as for one-electron reactions. Lastly, if successive steps in a process have comparable rates we observe a discrepancy between the sum of the apparent transfer coefficients and the total number of electrons taking part in the reaction (i.e. $\alpha + \beta < 2$). In this case the most important criteria for a step mechanism are the difference between the exchange currents obtained from the anodic and the cathodic Tafel plot and the difference between the true and the extrapolated value of the exchange current.

The methods of analysing polarisation curves in order to identify the step mechanism of electrochemical processes have been improved. Thus, a computer-aided approach to the analysis of the transition regions of polarisation curves has been developed[11] for studies of fast electrode reactions. Characteristic changes in shape have been established also for the differential curves in the case of a simple one-step process or for two consecutive processes having comparable rates. These changes are found to be adequate criteria for the recognition of step mechanisms.

2. Step Reactions

We shall illustrate the application of the step mechanism criteria to the study of electrochemical processes, and the demonstration of the participation (as intermediates) of metals in unusual states of oxidation, by examining briefly a few specific examples. Studies of the polarisation curves of a labelled zinc amalgam (0.4 M) in 0.1 M $ZnSO_4$ + 0.01 N H_2SO_4 have shown[12,13] that the sum of the apparent transfer coefficients at potentials close to the equilibrium value is approximately 2, and their ratio is approximately 1.6. Similar results were obtained for an indium amalgam in the presence of an excess of $NaClO_4$ [14,15] (found, $\alpha + \beta \cong 3.1$ and $\beta/\alpha \cong 2.4$). It follows from the step mechanism criteria that in both cases we are dealing with a complex electrochemical process in which the rate-limiting step is the removal of the last electron (for the anodic process) or the

addition of the first electron (for the cathodic process), i.e. the results are consistent with the electrochemical formation and with the existence of the ions Zn^+ and In^{2+} in aqueous solutions.

Published data (reviewed in Refs.1–3) clearly show that a substantial difference between the apparent transfer coefficients of the anodic and of the cathodic process is a common feature of all multi-electron discharge (metal ionisation) processes: as a rule, $\beta > \alpha$. For example, for cadmium amalgams β is 1.36–1.78 [16–19] and α lies in the range 0.24–0.28 [20,21], for copper amalgam $\beta = 1.60$ and $\alpha = 0.41$,[22] and for gallium, tin, and lead amalgams α values of 0.23,[23] 0.4–0.6,[24] and 0.5 [25] have been reported, with $\beta = 1.3$–1.6.

An example of a stepwise redox reaction with two consecutive steps taking place at comparable rates is

$$Tl^+ \rightleftarrows Tl^{3+} + 2e\,.$$

The kinetics of this reaction in 15 *N* H_2SO_4 have been studied on a platinum electrode: after being corrected for diffusion the polarisation curves show linear regions corresponding to $\beta = 0.64$ and $\alpha = 0.36$, i.e. $\alpha + \beta < 2$.[26] Extrapolation of these regions to the equilibrium potential gives very different exchange currents, indicating the presence of one-electron ionisation reactions having comparable speeds:

$$Tl^+ \rightleftarrows Tl^{2+} + e\,,$$
$$Tl^{2+} \rightleftarrows Tl^{3+} + e\,.$$

Similar results have been reported for polarisation measurements in the $Pb^{2+} \rightleftharpoons PbO_2 + 2e$ system in concentrated solutions of $HClO_4$.[27] Here $\alpha = 0.86$, $\beta = 0.24$, and the exchange current found by extrapolating the Tafel portion of the anodic branch of the polarisation curve is higher than the exchange current given by the cathodic branch. These results can be explained by postulating the formation of tervalent lead in an intermediate step of the electrochemical process.

The rate of discharge (or ionisation) of many metals is a sensitive function of pH. One possible explanation assumes that the electrode process is stepwise, and that the rates of the various steps are affected to different extents by the concentration of H^+ ions. Exactly the same explanation has been proposed for the decrease in the rate of the electrode process with increase in the acidity of the medium in the case of an indium amalgam[28,29]. The rate-limiting step does not involve simple In^{2+} ions, but ions which have been partially hydrolysed,

$$InOH^+ \rightleftarrows InOH^{2+} + e\,,$$

this reaction being preceded by the hydrolysis step

$$In^{2+} + H_2O \rightleftarrows InOH^+ + H^+$$

and followed by the chemical step

$$InOH^{2+} + H^+ \rightleftarrows In^{3+} + H_2O\,.$$

The difference in rate between the anodic and the cathodic discharge (or ionisation) of bismuth has also been explained by postulating a step mechanism and by allowing for the hydrolysis of bismuth in intermediate states of valency[30]. The rate of the electrode reactions is affected also by the nature and concentration of the anions present in solution, suggesting complex formation during the intermediate steps of the electrode process, anion effects on the electron transfer conditions, or adsorption of the anions on the electrode[29].

The strongly inhibiting effect of surface-active substances (SAS) on the discharge (or ionisation) of multivalent metals (as compared with the corresponding effect on univalent metals) has been known for a long time[31,32]. This is another indication of a step mechanism, the various steps being affected by the SAS to different extents. The kinetics of electrode processes on a tin amalgam in the presence of camphor (SAS) have been studied in detail[33–35]. Evaluation of the polarisation and adsorption measurements on a computer showed that camphor causes a ~70-fold decrease in the rate of the redox step

$$Sn^+ \rightleftarrows Sn^{2+} + e\,,$$

whereas the rates of formation and of discharge of the singly charged cations,

$$Sn \rightleftarrows Sn^+ + e\,,$$

are decreased only 5-fold. The difference in the effects of the SAS on the different steps is due to the difference in nature of these steps and to the differences in hydration energy of the various steps.

A retardation by SAS in various potential regions (corresponding to different rate-limiting steps) has been observed in a study of the stepwise discharge (ionisation) of bismuth on an amalgam electrode in the presence of hydroquinone[36]. A study of the discharge (ionisation) mechanism of copper[37–39] has revealed the two sequential steps

$$Cu \rightarrow Cu^+ + e\,,$$
$$Cu^{2+} + e \rightharpoonup Cu^+\,.$$

The rate of both these steps is affected by the nature of the solvent (aqueous 2M $HClO_4$ solution, CH_3OH, or glacial acetic acid).

We should stress that the stepwise mechanism criteria are not unambiguous, because they are often based on a large number of assumptions (that the one-electron steps are first-order reactions, and purely electrochemical, i.e. that no additional chemical steps are present; also, that parallel electrochemical reactions are absent, that specific adsorption of the initial, intermediate, and final products is negligible, and that diffusional rate limitation can be ignored). Hence it is very important to establish additional criteria and other methods of studying multi-step electrochemical reactions. For example, electrochemical measurements have been used successfully in conjunction with radiochemical measurements[3] to study isotope exchange effects in a multi-step electrode process[40].

More recently the rotating disk electrode with guard ring[41] has been used increasingly in studies of the multi-step anodic dissolution or cathodic deposition of metals, with identification of the unstable intermediate species involved. The multi-step electrode reaction takes place on the central (disk) electrode, and the current i_D is measured as a function of ϕ_D for this electrode. The products of the intermediate steps diffuse from the disk towards the ring, where they react, producing a current i_R. By studying the dependence of i_R on i_D for different speeds of rotation of the disk we can determine the kinetic characteristics of the individual steps in a complex electrode process.

However, in most cases this method also fails to identify the intermediate products directly, and the mechanism of the electrode process has to be inferred from assumed kinetic schemes for the separate reactions. Nevertheless by exploiting recent advances (including progress in computing techniques) we are able to identify the mechanism of the individual steps and the nature of the short-lived intermediate products in a number of electrode processes. For example, evidence has been obtained for the formation of the following lower-valency ions: Al^+ (in the dissolution of aluminium in anhydrous acetic acid[42]), and Be^+ in the dissolution of beryllium[43,44]. An interesting feature of the

dissolution of beryllium is the possibility of a two-electron mechanism (giving Be^{2+}) in parallel with the one-electron mechanism (giving Be^{+}). The lifetime of Be^{+} in solution is $\sim 10^{-2}$–10^{-1} s.

However, the formation of Mg^{+} during anodic dissolution of magnesium in Na_2SO_4 and NaBr solutions could not be established, suggesting that this species is very rapidly removed by a homogeneous reaction (in times ≤ 0.1 s).[45,46] The formation of Bi^{+} ions during the anodic dissolution of the metal in concentrated perchloric acid has been observed[47], and the criteria for the electrochemical and for the chemical mechanism of formation of Cu^{+} in the reaction between Cu^{0} and Cu^{2+} in 1 *N* H_2SO_4 solution have been determined[48].

Current views on the step mechanisms of electrode processes, with formation of intermediate ions in unusual and unstable states of oxidation, are based on the application of multi-step mechanism criteria to a large number of electrochemical processes, not only on amalgam electrodes but also in the dissolution and deposition of multivalent metals on solid electrodes. A detailed discussion of the many publications on this topic lies beyond the scope of the present review, and is largely covered by previous reviews[1,49–52].

The results outlined above suggest that the role of multi-step reactions in electrochemical processes is an important, and even a dominant one. Hence the direct experimental observation of metal ions in intermediate valency states in aqueous or other solutions, even if prepared by non-electrochemical methods, and the study of the nature and properties of these ions may be of great value in the development and validation of our views on the mechanism of step reactions.

III. METAL IONS IN UNUSUAL AND UNSTABLE STATES OF OXIDATION

Recent developments in the pulse radiolysis method and in the matrix stabilisation of short-lived ions and radicals by low-temperature radiolysis have led to the preparation of many metal ions (in aqueous solutions) in unusual and unstable states of oxidation, and to studies of the properties of these ions.

1. Radiation-chemical Preparation

The hydrated electron e^{-}_{aq} and the hydroxyl radical OH, which are formed during the radiolysis of water and of aqueous solutions, have well defined reducing [$E^{0}(e^{-}_{aq}/\frac{1}{2}H_2) = -2.9$ V] and oxidising properties [$E^{0}(OH/H_2O) = 2.8$ V] respectively. Hence the irradiation of many salt solutions can yield, as a result of fast one-electron reduction of metal ions by hydrated electrons

$$M^{n+}_{aq} + e^{-}_{aq} \rightarrow M^{(n-1)+}_{aq} \qquad (10)$$

or fast one-electron oxidation by OH radicals

$$M^{n+}_{aq} + OH \rightarrow M^{(n+1)+}_{aq} , \qquad (11)$$

short-lived metal ions in intermediate states of oxidation which are chemically very active.

The nature and properties of these ions in liquid solutions have been studied by pulse radiolysis with fast recording of the optical spectra and of the changes in electrical conductivity of the medium associated with the formation of these ions[53–58]†. During low-temperature radiolysis of frozen (usually, at 77 K) aqueous salt solutions the metal ions produced by reactions (10) and (11) are stable and can be studied by conventional electron paramagnetic resonance (EPR) and optical spectroscopy methods[57]. The experimental conditions can be chosen so as to favour oxidation or reduction reactions almost totally: this is achieved by adding to the aqueous solution acceptors of e^{-}_{aq} or OH respectively, whose effect is to "transform" the reducing (e^{-}_{aq}) or the oxidising agent (OH) into an oxidising or a reducing agent respectively.

Thus, saturating the solution with N_2O produces the reaction

$$N_2O + e^{-}_{aq} \xrightarrow{H_2O} N_2 + OH + OH^{-} , \qquad (12)$$

as a result of which e^{-}_{aq} is transformed into the OH radical. If the solution is saturated with molecular hydrogen at high pressure the OH radicals give a fairly high yield of active reducing species (hydrogen atoms) by the reaction

$$H_2 + OH \rightarrow H + H_2O .$$

However, the most commonly used additives are organic compounds (RH) such as alcohols, formate ions, etc. which react with OH to give organic radicals R:

$$RH + OH \rightarrow R + H_2O . \qquad (13)$$

The reducing power of these radicals increases in the sequence

$$CH_2OH < CH_3\dot{C}HOH < (CH_3)_2\dot{C}OH < CO^{-}_2 .$$

Even the earliest experiments (in 1963–1965) by the pulse radiolysis method[59–67] demonstrated that e^{-}_{aq} is an active reducing agent towards many metal ions (Zn^{2+}, Cd^{2+}, Ni^{2+}, Co^{2+}, etc.) in deaerated neutral aqueous solutions of their salts. Later work was concerned with detailed studies of the mechanism of these reactions, and of the nature and properties of the species produced in aqueous solutions of Zn^{2+},[68–70] Cd^{2+},[68,69,71,72] Hg^{2+} and mercury compounds[73–82], Ga^{3+},[83,84] In^{3+},[83] Tl^{+} and Tl^{3+},[85–89] Pb^{2+},[90,91] Bi^{3+},[92] Mn^{2+},[93] Ni^{2+},[68,69,94] Co^{2+},[68,69] Cu^{2+},[95,96] Ag^{+},[97–99] Au^{3+},[100,101] and compounds of Pt[102–105] and Pd.[106]

As well as to these elements, the pulse radiolysis method has been applied to some lanthanides and actinides in unstable states of oxidation, and to a number of complexes (see review in Refs. 53 and 54). It was shown that most of the reactions of e^{-}_{aq} with aquo and chloro complexes of metals are diffusion controlled (10^{9}–10^{10} litre mole^{-1} s^{-1}). The reactivity decreases if water molecules in the coordination sphere of the metal ion are replaced by ligands such as OH^{-}, NH_3, ethylenediamine, glycine, etc. An interesting effect is observed: the rate constant of the reaction between e^{-}_{aq} and M^{n+} falls off most sharply when the last water molecule is replaced by a ligand[67]. Evidently, this arises because the water molecule acts as an electron carrier (from e^{-}_{aq} to the metal ion), being part of the hydration spheres of both species simultaneously. Thus the effect of many ligands (other than water) is to isolate the metal ion from reduction by the e^{-}_{aq} species.

2. Optical Properties

Metal ions in unstable states of oxidation usually absorb in the u.v. region of the optical spectrum with high extinction coefficients (Table 1). The absorption spectrum of metal aquo complexes with an electronic configuration of the outer shells of the $(N-1)d^{10}Ns^{1}$ type, where N is the number of the period (Ag^{0}, Zn^{+}, Ga^{2+}, etc.), consists of a single bell-shaped band. For ions having iso-electronic structures,

†The principles used in pulse radiolysis and various experimental approaches to the determination of the physicochemical parameters of short-lived particles are examined in detail in a special monograph[54].

i.e. for ions of elements in the same period, the absorption band is shifted towards the short-wavelength u.v. region as the charge on the aquo complex increases. An almost linear dependence of the optical transition energy ($E_{\lambda_{max}}$) on the ionic charge is observed[107,108].

The absorption of the aquo complexes of metals in the *s* and *p* blocks, i.e. elements in subgroups IB—VB of the Periodic Table, in the $^2S_{1/2}$ electronic state (with an unpaired electron in the *s* orbital), is due to a transition of the $a_{1g}^* \rightarrow t_{1u}^*$ type[108]. This transition can be interpreted qualitatively as the transfer of electron density from the central metal ion towards the ligands. In the case of aquo complexes with an octahedral structure a substantial covalent contribution to the formation of the M—OH_2 chemical bond has been demonstrated by the semi-empirical variant of the MO method. This contribution increases with the charge on the central metal ion.

The chloro complexes of Group IB—VB metals show a large number of absorption bands due to $2t_{1u} \rightarrow a_{1g}^*$ and $3t_{1u} \rightarrow a_{1g}^*$ transitions (for complexes with an octahedral structure), i.e. the electron transfer is from the ligands towards the central atom. In contrast to the aquo complexes, the energy of the optical transition ($E_{\lambda_{max}}$) decreases along an isoelectronic series of metal ions as the formal state of oxidation increases[109].

In the optical spectra of the hydroxo complexes (MOH^{m+}, where $m = [(n-1)\pm1]$) we observe a splitting of the fundamental band, characteristic of the $M^{(n\pm1)+}$ ions (Table 1). The compounds HgX (where X = Cl, Br, I, CN) behave similarly[81].

3. State of the Metal Ions in Aqueous Solutions

Metal ions in aqueous solutions react with water molecules or with the anions present in solution to give complexes whose composition and structure are determined to a large extent by the nature and concentration of the anions and by the pH. Reduction or oxidation of the metal ion alters its electronic configuration, often leading to a change in the coordination number, polarisability, and other related characteristics of the ion. The crystallographic radii of the metal ions of Groups IB—IVB in their higher state of oxidation [$(N-1)d^{10}$ electronic configuration] and in a state of oxidation one unit lower [$(N-1)d^{10}Ns^1$ electronic configuration] are compared in Table 2. In the latter case the radii for the iso-electronic series were calculated[108] by the Pauling formula[110]

$$r_Z = \frac{C_{N-}}{Z^*_{\text{eff}}} Z^{-2/(N_B-1)} ,$$

where Z^*_{eff} is the effective charge on the nucleus, Z is the atomic number of the element, N_B is the Born repulsion coefficient, and C_N is a constant coefficient for the iso-electronic series of ions of the elements of periods 4, 5, and 6, determined from the known radii of Cu^0, Ag^0, and Au^0. Since $r[M^{(n-1)+}] > r(M^{n+})$, we can expect the acid-base properties of metal ions in unusual states of oxidation to be different from those of the same ions in the higher states of oxidation. The tendency of the ions to form complexes with dissolved ligands, and other properties, will also be different. This conclusion is borne out by pulse radiolysis studies.

Table 2. Crystallographic radii of the ions of Group IB—IVB metals[108].

M^{n+}	Cu^+	Zn^{2+}	Ga^{3+}	Ge^{4+}	Ag^+	Cd^{2+}	In^{3+}	Sn^{4+}	Au^+	Hg^{2+}	Tl^{3+}	Pb^{4+}
$r(M^{n+})$	0.96	0.74	0.62	0.53	1.26	0.97	0.81	0.71	1.37	1.10	0.95	0.84
$M^{(n-1)+}$	Cu^0	Zn^+	Ga^{2+}	Ge^{3+}	Ag^0	Cd^+	In^{2+}	Sn^{3+}	Au^0	Hg^+	Tl^{2+}	Pb^{3+}
$r(M^{(n-1)+})$	1.278	1.063	0.908	0.791	1.445	1.224	1.059	0.934	1.442	1.244	1.094	0.975

Table 3. Stability constants of chloro complexes for Tl(I), Tl(II), and Tl(III) in aqueous solutions.

Complex	Medium	K_I	K_{II}	K_{III}	K_{IV}	Refs.
$TlCl_3^{2-}$	4 M $NaClO_4$	0.8	0.2	0.1	—	[111]
$TlCl_3^-$	1 M $HClO_4$	$6.2\cdot10^4$	$1.9\cdot10^3$	13	—	[87]
$TlCl_4^-$	0.5 M $HClO_4$	$5.2\cdot10^6$	$1.3\cdot10^5$	553	44	[112]

Dodson and Schwarz[87] studied the chloro complexes of Tl(II)# and calculated their stability constants:

$$Tl^{2+} + Cl^- \overset{K_I}{\rightleftarrows} TlCl^+ ,$$

$$TlCl^+ + Cl^- \overset{K_{II}}{\rightleftarrows} TlCl_2 ,$$

$$TlCl_2 + Cl^- \overset{K_{III}}{\rightleftarrows} TlCl_3^- .$$

#Throughout this paper we shall use a Roman numeral in brackets to denote the state of oxidation of the element.

The constants are compared in Table 3 with the corresponding values for the stable forms Tl(I) and Tl(III). We note that the stability constant increases very rapidly with the charge on the central thallium ion. The tendency of the metal ions to hydrolyse in aqueous solutions varies in a similar way.

For example, the pK values of the reaction

$$M(H_2O)_6^{n+} \rightleftarrows M(H_2O)_5OH^{(n-1)+} + H^+ \qquad (14)$$

for Hg^{2+}, Ga^{3+}, and Tl^{3+} are 3.5, 2.6, and 1.3 respectively[113], and those for Hg^+, Ga^{2+}, and Tl^{2+} are 5.1,[75] ≥3.3,[84] and 4.6.[88] Thus the tendency of metal ions to replace water molecules in their coordination sphere by OH^- ions is decreased by one-electron reduction of the ions, i.e. the ions become less hydrolysable than ions in the higher state of oxidation. Conversely, Cu^{3+} ions obtained from the oxidation of Cu^{2+} by OH radicals [reaction (11)] are more readily hydrolysed than Cu^{2+} ions. The pK of reaction (14) for Cu^{3+} is ~2.9,[64,95] i.e. it is much lower than the pK value for Cu^{2+} (given[113] as 7.5).

We should stress that the formation (during intermediate steps) of metal ions in unusual and unstable states of oxidation almost invariably makes the kinetics of the overall electrode process a function of pH and of the concentration of anions. This may be due to the large difference between the acid–base properties of metal ions in unusual states of oxidation and those of the same ions in their normal states of oxidation. Evidence for this suggestion was given above in connection with the discharge (ionisation) reactions of In [28,29] and Bi [30] on an amalgam electrode. The adsorption of OH^-, Cl^-, SO_4^{2-}, and other anions on the electrode surface and the formation of complexes with the metals in solution can affect the kinetics of the electrochemical act. It is thought, for example, that the adsorption of OH^- groups on an electrode assists the transfer of Fe,[114–116] Ni,[117] and Co [118] into the solution through the intermediate formation of the hydroxo complexes MOH, i.e. that the OH^- ions favour the dissolution of the metal by a multi-step mechanism (see reviews in Refs. 49–51).

The stability of metal ions in unusual states of oxidation in aqueous solutions is determined by the nature of the ligand and by the extent of complex formation by the ion. Thus, the rate constant of the disproportionation of the Tl^{2+}, $Tl(OH)^+$, and $Tl(OH)_2$ ions increases very markedly with the number of hydroxyl groups in the coordination sphere[89]. A similar effect is produced by Cl^- ions in the chloro complexes of Tl(II) [87] and Au(II).[101] Thus by varying the pH or the concentration of ions in solution we can influence the stability of metal ions in unusual states of oxidation, their steady-state concentration, and therefore also the kinetics of the electrode process.

4. Oxidation–Reduction Potentials

The step mechanism of complex electrochemical processes arises, essentially, from differences in the thermodynamic conditions appropriate to each of the constituent acts: in other words, if the redox potentials of the M^+/M and M^{2+}/M^+ pairs in the overall electrode process

$$M \rightleftarrows M^{2+} + 2e \qquad (15)$$

are significantly different we can expect a difference also in the rates of the ionisation and discharge reactions

$$M \rightleftarrows M^+ + e, \qquad (16)$$

$$M^+ \rightleftarrows M^{2+} + e. \qquad (17)$$

Of course, the probability of transfer of several electrons in the same elementary act is in general smaller than the probability of one-electron transfer. Furthermore, the activation energies for the one-step discharge of the M^{2+} ions may be higher than those for the multi-step process involving the formation of intermediate M^+ species[3]. The rate of the slowest step will determine the rate of the electrode process. We shall assume, as usual, that diffusional limitations are absent, i.e. that the reactants diffuse rapidly and their concentrations at the surface and in the volume of the solution are equal. For the metal ionisation–discharge reaction considered here the rates of steps (16) and (17) in the anodic and the cathodic process are given by Eqns.(6) and (7) respectively.

To determine the redox potential of the reaction

$$Red^- + Ox \underset{k_-}{\overset{k_+}{\rightleftarrows}} Red + Ox^- \qquad (18)$$

we need to know the equilibrium constant $K_p = k_+/k_-$. Since metal ions in unusual states of oxidation are active and short-lived particles, reactions involving these ions are usually irreversible, and it is very seldom possible to determine k_+ and k_- simultaneously. It is more usual to determine the rate constant of the forward reaction (for example, the reduction of the metal ions, or their oxidation by the OH radicals to ions in unstable states of oxidation) and that of the subsequent reaction (disproportionation, or interaction with other species present in solution). In any case, the concentrations of different participants in a fast reaction of the type of (18) are always difficult to measure simultaneously because of the overlap of the optical spectra, which interferes with the determination of K_p.

The equilibrium constant of the reaction

$$Tl^{3+} + Fe^{2+} \rightleftarrows Tl^{2+} + Fe^{3+}$$

was determined[86] as 4.1×10^{-8} in 1 M $HClO_4$ solution, and by combining this value with the potential of the Fe^{3+}/Fe^{2+} couple we obtain a potential of 0.3 V for the Tl^{3+}/Tl^{2+} couple. The reactions of Zn^+ and Cd^+ ions with $Co(NH_3)_6^{3+}$ were studied by Navon and Meyerstein[119]: using the standard rate constants for the $Co^{3+} \rightleftharpoons Co^{2+}$, $Zn^{2+} \rightleftharpoons Zn^+$, and $Cd^{2+} \rightleftharpoons Cd^+$ exchange reactions they determined K_p by the Marcus theory[120,121] and they calculated $E^0(Zn^{2+}/Zn^+) = -(2.0 \pm 0.4)$ V and $E^0(Cd^{2+}/Cd^+) = -(1.8 \pm 0.4)$ V. Systematic determinations of the potentials of metals in unusual oxidation states have been carried out by approximate theoretical methods as well as experimentally.

In order to calculate thermodynamically the redox potential of the $M^{n+}/M^{(n-1)+}$ couple we must evaluate the free energy ΔF of the reaction

$$M^{n+} + \frac{1}{2}H_2 \rightarrow M^{(n-1)+} + H^+. \qquad (19)$$

We therefore have to examine the constituent steps of the reaction, whose free energies are usually known [except that for the hydration of the $M^{(n-1)+}$ ion]. It has been assumed[122] that in a reaction such as (19), in which M^{n+} is a bivalent cation, the dependence of $\Delta G_{hydr}(M^+)$ on the ionic radius is the same as for the alkali metals. Furthermore, the M^+ radii were not known, and they had to be found by an approximate method. Thus, the radius of the Zn^+ ion was taken to be the mean of the Cu^+ and Zn^{2+} radii. In this way the $E^0(Zn^{2+}/Zn^+)$ potential was obtained from two values corresponding to the redox potentials of alkali metals having radii equal to those of Zn^{2+} and Cu^+. Similarly, for Cd^+, Pb^+, Mg^+, Ca^+, and Ba^+ the lower values of r_i were identified with those of the Cd^{2+}, Pb^{2+}, Mg^{2+}, Ca^{2+}, and Ba^{2+} ions, and the upper values with those of Ag^+, Tl^+, Na^+, K^+, and Cs^+ respectively. In the

case of Mn^+, Fe^+, Co^+, and Ni^+ the radii were assumed to be the same as for the same metals in the bivalent state.

Values of $E^0[M^{n+}/M^{(n-1)+}]$ obtained in this way are listed in Table 4. Obviously, these values are tentative, but nevertheless in many cases they agree well with experiment. For example, e^-_{aq} does reduce Zn^{2+}, Cd^{2+}, and Pb^{2+} but not Mg^{2+}, Ca^{2+}, or Ba^{2+}. On the other hand the E^0 values obtained for Mn^{2+}, Fe^{2+}, Co^{2+}, and Ni^{2+} are inconsistent with the observed, fast reactions of these ions with e^-_{aq}. Therefore this method is less attractive, on the whole, than the determination of the potentials by an approximate experimental method, consisting in studying the reactions with R radicals whose potentials (E) are known:

R	e^-_{aq}	H^-	CO_2^-	$(CH_3)_2COH$	CH_3CHOH	CH_2OH	OH	HO_2
E, V	−2.9	−2.3	−2.0	−1.8	−1.1	−0.97	2.8	1.7

*Obtained from published data on the reactions of M^{n+} with e^-_{aq}, H, and organic radicals.

**Obtained from the dependence of E^0 on the ionic charge in a period and in a group (see Figure).

A study by pulse radiolysis of aqueous solutions of Zn^{2+} has shown[70] that e^-_{aq} reacts with Zn^{2+} to give Zn^+. On the other hand, H atoms reduce Zn^{2+} either very slowly or not at all. Hence we may assume that $E^0(Zn^{2+}/Zn^+)$ is smaller than −2.9 V in absolute value, and close to −2.3 V. There is some justification for assuming a value of −(2.4 ± 0.2 V), which is consistent with that calculated by Navon[119] [−(2.0 ± 0.4) V].

The Cd^{2+} ion is reduced by H and by the CO_2^- radical as well as by e^-_{aq}, but not by alcohol radicals, which have been shown to oxidise Cd^{2+}. It was concluded[72] that $E^0(Cd^{2+}/Cd^+) \cong$ 1.9 V. Potentials determined by this method for metals in aqueous solutions are listed in Table 4.

The variation of these potentials with the charge on the ion is shown in the Figure for the iso-electronic series of ions of metals in periods 4, 5, and 6. The first members of these series are copper, silver, and gold respectively. The redox potentials usually quoted for these metals[123] apply to reactions on a metallic electrode. In the case of metal atoms produced in the volume of the solution the potential must be corrected for the free energy of sublimation at room temperature ΔG^0_{sub}. By subtracting $\Delta G^0_{sub}/e$ (where e is the charge) from $E^0(M^+/M_{sol})$ we obtain the following values of $E^0(M^+/M_{at})$ for copper, silver, and gold respectively: −2.7, −1.8, and −1.5 V.

Redox potential of the $M^{n+}/M^{(n-1)+}$ couple against charge n for ions of metals in the 4th period (Cu, Zn, Ga, curve *1*), the 5th period (Ag, Cd, In, Sn, curve *2*), and the 6th period (Au, Hg, Tl, Pb, curve *3*); see also text.

We note from the Figure that within each subgroup (i.e. for equally charged ions) the quantity $E^0[M^{n+}/M^{(n-1)+}]$ increases regularly with the period number. Furthermore, within any one period (i.e. for iso-electronic ions) the $E^0[M^{n+}/M^{(n-1)+}]$ value increases strongly with the charge on the cation. For example, the metal ions in the electronic $^2S_{1/2}$ state with an unpaired electron in the s orbital which occur in the second subgroup (Zn^+, Cd^+, and Hg^+) are strong reducing agents, whereas those in the fourth subgroup (Sn^{3+} and Pb^{3+}) act as effective oxidising agents.

Having established the dependence of E^0 on the position of the element in its period and subgroup we are able to predict values of the potential. Thus $E^0(Hg^{2+}/Hg^+)$ should be −(1.4 ± 0.3) V, and $E^0(Pb^{4+}/Pb^{3+})$ should be +(1.8 ± 0.3) V. Since $E^0(Pb^{4+}/Pb^{2+}) = 1.7$ V,[123] we can calculate the potential $E^0(Pb^{3+}/Pb^{2+})$: +(1.6 ± 0.3) V. This value is consistent with the earlier conclusion that the potential must lie between 1.5 and 2.6 V, since at pH ~4 the Pb^{2+} ions are oxidised by OH radicals but they are oxidised extremely slowly (if at all) by HO_2 radicals[91].

Thus the postulated formation of metal ions in unusual and unstable states of oxidation (Zn^+, In^{2+}, Cd^+, Ga^{2+}, Sn^+, Tl^{2+}, Pb^{3+}, and many others) during the intermediate steps of electrochemical processes is confirmed by radiation-chemical experiments.

IV. REACTIONS OF METAL IONS IN UNUSUAL AND UNSTABLE STATES OF OXIDATION

Special features of the chemical reactions of metal ions in intermediate states of oxidation with each other or with other species present in solution may determine the kinetics

of the electrode process. Reactions of this type taking place in the volume of the solution have been studied by pulse radiolysis in recent years.

1. Disproportionation and Dimerisation Reactions

As for any other chemical reaction, the condition for the spontaneous occurrence of a disproportionation reaction is a gain in energy, i.e. ΔG must be negative. We shall consider two variants of the change in redox potential accompanying an increase in the degree of oxidation of the metal. In the first variant successive increases in the degree of oxidation require increasingly large amounts of energy, i.e. the removal of each electron requires a greater expenditure of energy than that of the previous electron. Under these conditions the redox potential increases monotonically. It is easy to see that in this case the disproportionation reaction

$$2M^{(n-1)+} \rightarrow M^{n+} + M^{(n-2)+} \qquad (20)$$

is impossible: the transition of $M^{(n-1)+}$ to the more highly oxidised state M^{n+} is impossible because it is less exothermic than the transition $M^{(n-1)+} \rightarrow M^{(n-2)+}$ is endothermic. In the second variant the transition $M^{n+} \rightarrow M^{(n-1)+}$ requires a greater expenditure of energy than the transition $M^{(n-1)+} \rightarrow M^{(n-2)+}$, i.e. $E^0[M^{n+}/M^{(n-1)+}] > E^0[M^{(n-1)+}/M^{(n-2)+}]$. In this case the disproportionation reaction is possible, since it leads to a gain of energy in the system ($\Delta G < 0$).

Table 5. Rate constants (litre mole^{-1} s^{-1}) of the recombination of metal ions in unstable states in aqueous solutions.

Reaction	pH	$2k \cdot 10^{9}2k$	References

ditto	1—2	2.5	[102]
$2PtCl_4^{-} + Cl^{-} \rightarrow PtCl_4^{2-} + PtCl_6^{2-}$	~2	~1	[103]

Thus the condition for the disproportionation reaction is inversion of the potential energy levels of the system. By comparing the data in Table 4 with the potentials of the same metals in stable valence forms[123] we find level inversion for most of the metals in intermediate states of oxidation, i.e. we find conditions favourable to the fast disappearance of these ions by disproportionation reactions. Studies by the pulse radiolysis method of the disappearance of metal ions in unusual states of oxidation have shown that in most cases recombination is accompanied by disproportionation (Table 5).

An obvious exception to this rule are the metal ions having one unpaired electron in an *s* or *p* orbital and a low charge (0 or 1), such as Ag^0, Cd^+, and Hg^+ (whose electronic shell has the $(N-1)d^{10}Ns^1$ configuration), or Tl^0 and Pb^+ [$(N-1)d^{10}Ns^2Np^1$ shell]. These particles tend to form dimers in which the unpaired electrons are shared in σ_s or σ_{p_z} bonds. Thus, Cd^+ and Hg^+ ions undergo fast recombination, forming Cd_2^{2+} and Hg_2^{2+} ions. More surprisingly, Cd^+, Hg^+, and other ions of this type can also form unstable dimeric particles of the type of Cd_2^{3+}, Hg_2^{3+}, etc. in which the two atoms are joined by a one-electron bond (half a covalent bond). Thus it has been shown that Ag^0 atoms[97-99] and Tl^0 atoms[85-89] formed by the reduction of Hg^+ and Tl^+ ions (at concentration $>10^{-5}$ M) by hydrated electrons disappear by the pseudo-first order reaction

$$Ag^0 + Ag^+ \rightarrow Ag_2^+ ,$$
$$Tl^0 + Tl^+ \rightarrow Tl_2^+ .$$

Direct evidence of the existence of the Ag_2^+ ion has been obtained[126-128] by ESR during the low-temperature (77 K) radiolysis of aqueous solutions of Ag^+. The effect of the initial concentration of Cd^{2+} ions on the disappearance of Cd^+ ions in aqueous solutions containing methanol has been studied[69] by pulse radiolysis. In 0.1 M solutions of Cd^{2+} the Cd^+ ions disappear by a pseudo-first order reaction, and a relatively long-lived absorption at 280 nm is observed after the absorption corresponding to Cd^+ ions has completely disappeared. No suggestion has been put forward[69] as to the nature of this absorption. One possibility is the reaction of Cd^+ with Cd^{2+} ions:

$$Cd^+ + Cd^{2+} \rightarrow Cd_2^{3+} . \qquad (21)$$

The formation of paramagnetic dimeric Cd_2^{3+} ions has been detected by ESR and optical spectroscopy methods in glassy aqueous solutions containing 0.1 M $CdSO_4$ gamma-irradiated at 77 K.[129,130]. The maximum optical absorption of Cd_2^{3+} in the solid matrix also occurs at ~280 nm. This ion is stabilised, apparently, by the collectivisation of one unpaired electron on the Cd—Cd σ bond. The rate constant of reaction (21) is much lower than that of the recombination of Cd^+ ions, and therefore reaction (21) is predominant only at high concentrations of Cd^{2+} ions. The existence of Hg_2^{3+} particles also has been established by ESR and optical spectroscopy methods in the low-temperature gamma-radiolysis of aqueous solutions of Ag^{2+}.[129,130].

Pb^+ ions are structurally iso-electronic with Tl^0, and therefore we can expect them to decay by the following reaction at high concentrations of Pb^{2+} ions in solution:

$$Pb^+ + Pb^{2+} \rightarrow Pb_2^{3+} .$$

There are no data on this reaction for liquid aqueous solutions, but the formation of Pb_2^{3+} particles during the low-temperature gamma-radiolysis of acidic or alkaline solutions of Pb^{2+} has been observed by optical spectroscopy[131,132].

For the Ga^{2+}, In^{2+}, Tl^+ and other ions the formation of dimers by recombination is not typical, possibly owing to the predominance of electrostatic repulsion. We have shown[83,84] that the loss of Ga^{2+} and In^{2+} is by a second-order reaction, involving disproportionation or interaction with OH radicals. The reactions of Tl(II) have been studied by pulse radiolysis of deaerated aqueous solutions containing Tl(I) and Tl(III).[85-89] Under these conditions the reactions between

e^-_{aq} and Tl(III), and between OH and Tl(I), yield only Tl(II). The latter have been shown to disappear by the reaction

$$Tl(II) + Tl(II) \rightarrow Tl(I) + Tl(III)$$

whose rate constant is strongly influenced by the presence of Cl^- ions in the solution[87], and also by the pH.[88,89] Pb^+ ions disproportionate with formation of Pb^0, which gives an absorption with $\lambda_{max} < 250$ nm.[90]

In the absence of acceptors of OH radicals the disappearance of transition metal ions in unstable states of oxidation (Mn^+, Co^+, Ni^+, etc.) is by a second-order reaction[62-67,93,94], evidently through interaction of the ions with each other and with the OH radicals. In the presence of organic compounds (acceptors of OH radicals) the univalent ions disappear by more complex reactions with formation of metal–organic intermediates.

2. Reactions with Inorganic Compounds

The effect of various additives on the kinetics of electrode processes, and in particular on metal corrosion, may be related to the reactions of these additives with metal ions in unstable states. The mechanism of the reactions of Zn^+, Cd^+, and Ni^+, and of many other metal ions, with various inorganic compounds (O_2, H_2O_2, N_2O, NO_2^-, NO_3^-, BrO_3^-, IO_3^-, etc.) has been studied by the pulse radiolysis method[65,69,70,133-138]. The metal ions have been shown to reduce these compounds at fairly high rates. The rate constants of the reactions of Zn^+, Cd^+, Ni^+, and Co^+ ions with some inorganic compounds in aqueous solutions are compared in Table 6 with the corresponding rate constants for the strongly reducing agents e^-_{aq} and H.

The ions can be arranged in the following series in order of decreasing reactivity towards inorganic oxidising ions: $Zn^+ \geq Cd^+ > Co^+ > Pb^+ > Ni^+ > Hg^+ \geq Cr^{2+} > Cu^+$. However, there are many exceptions: for example, with molecular O_2 the Ni^+ ion reacts almost as fast as Zn^+ and Cd^+, and Co^+ reacts even faster. The reactivity is determined by the electronic structure of the ions, by the nature of the acceptor, and by the specific mechanism of the oxidation–reduction reaction. In the Zn^+ and Cd^+ ions the electron is localised on the outer *s* orbital, with a substantial shift into the outer sphere. As a result, these ions are strong reducing agents. However, even between Zn^+ and Cd^+ we observe a decrease in reactivity towards several oxidising agents (see Table 6).

This decrease is even more marked in Hg^+. Thus the rate constant of the reaction between Hg^+ and O_2 was found[80] to be 4×10^8 litre mole^{-1} s^{-1}, i.e. almost an order of magnitude smaller than the values for Zn^+ and Cd^+. This decrease in reactivity in the Zn–Cd–Hg group is easily explained by noting that the stability of the lower states of oxidation for this group of metals increases in the same sequence, and that the Hg^+ ion is a fairly stable species (for example, in the dimeric form). In the transition metals an additional electron is accommodated in an inner *d* orbital, and as a result the ions are less active as reducing agents than the Zn^+ or Cd^+ ions.

We should stress that the reactivity sequence of the $M^{(n-1)+}$ ions is not the inverse of the reactivity sequence of M^{n+} towards e^-_{aq}. No definite correlation has been noted between the relative rate constants for the reactions of e^-_{aq}, H, and the $M^{(n-1)+}$ ions, suggesting that different mechanisms may apply to the redox reactions of these particles. For example, $M^{(n-1)+}$ (unlike e^-_{aq}) reacts very slowly with H_3O^+, or not at all. A possible explanation is that the redox potential of the $M^{(n-1)+}$ ions is too low, in general, to allow these ions to reduce H_3O^+.

Because of their technological importance we shall examine in somewhat greater detail the reactions between the lower-valency forms of metals and molecular oxygen in corrosion processes, and we shall discuss their mechanism. The reactions of Ag^0, Hg^0, Zn^+, Cd^+, Pb^+, Cu^+, Co^+, Ni^+, and Cr^{2+} with molecular O_2 have been studied by pulse radiolysis, and their rate constants have been measured (Table 7). With the exception of Cu^+, Ni^+, and Cr^{2+} these ions were found to be oxidised with formation of the O_2^- ion radical:

$$M^{(n-1)+} + O_2 \rightarrow M^{n+} + O_2^- \quad . \qquad (22)$$

Table 7. Rate constants for the oxidation of metals in unstable states by O_2 in aqueous solutions (litre mole^{-1} s^{-1}).

Species*	$10^{-8}\,k$	Species	$10^{-8}\,k$
Ag_2^+	3.8 [133]	Hg_2 (I)	11 [82]
Au^0	36 [100]	HgCl	10 [75]
Cd^+	30 [138]	Ni^+	18 [65,133]
Co^+	60 [138]	Pb^+	39 [65]
Cr^{2+}	1.6 [137]	$Pt(CN)_4^{3-}$	0.18 [102]
Hg^+	4.0 [80]	Zn^+	28 [65,133]

*For Cu^+ we have $k \leq 10^{-6}$ litre mole^{-1} s^{-1}.[133]

Table 6. Rate constants of the reactions of e^-_{aq}, H, and $M^{(n-1)+}_{aq}$ with inorganic compounds in aqueous solutions (litre mole^{-1} s^{-1}).

Compound	e^-_{aq}*	H*	Zn+	Cd+	Ni+	Co+
N_2O	$5.6 \cdot 10^9$	$1.2 \cdot 10^4$	$1.3 \cdot 10^7$ [133]	$2 \cdot 10^6$ [133]	$6.3 \cdot 10^6$ [133]	$1.0 \cdot 10^9$ [138]
	—	—	$3.7 \cdot 10^6$ [138]	$3.5 \cdot 10^6$ [138]	$9.1 \cdot 10^6$ [138]	—

Cu^{2+}	$3.3 \cdot 10^{10}$	$6 \cdot 10^8$	$2.5 \cdot 10^8$ [133]	$1.2 \cdot 10^8$ [133]	$2.4 \cdot 10^7$ [133]	$4.1 \cdot 10^8$ [133]

*Rate constants given in Ref. 53.

For Ni^+ and Cr^{2+} the relatively stable complexes NiO_2^+ and CrO_2^{2+} were identified. The NiO_2^+ complex can be protonated (pK_a = 3.2), and both forms disappear by an intramolecular dissociation reaction giving Ni^{2+} and O_2^- or HO_2.[137-140] The interaction of Cu^+ with O_2 was found[137] to be either very slow or reversible (with a forward reaction much slower than the reverse reaction). The tabulated results show that the formation of stable complexes such as $MO_2^{(n-1)+}$ is characteristic of the transition metals with an unfilled inner *d* orbital. Complex formation involves the transfer of the unshared electron pair of the O_2 molecule to these levels.

The reaction of metals in unstable states of oxidation with H_2O_2 produces OH radicals[133,138]:

$$M^{(n-1)+} + H_2O_2 \rightarrow M^{n+} + OH + OH^- . \quad (23)$$

From the standpoint of corrosion processes reactions (22) and (23) can be interpreted as intermediate steps in the anodic dissolution of the metal. The O_2 and H_2O_2 are often treated as cathodic depolarisers. These species can be actively involved in the intermediate steps, and determine the rate of dissolution of the metal if the reactions take place directly on the anode.

The pulse radiolysis method has been used to prepare and investigate several metal ions in unstable states of oxidation showing strongly oxidising properties. One of these is the Cu(III) ion, which can oxidise the Br^- and NO_2^- ions, alcohols, and H_2O_2.[66,95] It has also been shown[95] that the Cu(III) ion can decompose water with formation of OH radicals by the reversible reaction

$$Cu(III) + H_2O \rightleftarrows Cu(II) + OH + H^+ .$$

The equilibrium constant calculated for this reaction at pH 3.65 (9.0×10^5 mole^{-1} litre) assumes that the redox potential of the Cu^{3+}/Cu^{2+} couple is only 0.2 V lower than the potential of the OH/H_2O couple.

3. Reactions with Organic Compounds

The effect of organic compounds on the kinetics of electrode (metal discharge and ionisation) reactions is usually ascribed to adsorption of these compounds on the electrode, formation of colloidal solutions, etc. Obviously, the participation of organic compounds in the intermediate steps by reaction with metal ions in unusual and unstable states of oxidation cannot be excluded. Reactions of this type have been studied by the pulse radiolysis method far less fully than reactions with inorganic compounds. It has been shown[141] that $M^{(n-1)+}$ is an effective reducing agent (by the one-electron mechanism) for aromatic dyes Ar:

$$M^{(n-1)+} + Ar \rightarrow M^{n+} + Ar^- .$$

The rate constants for the reaction of some ions with *p*-benzoquinone, menaquinone, and benzophenone in aqueous solutions at pH 5–6 are given in Table 8.

The mechanism of the interaction of metals with halogenated aliphatic acids has been shown[142] to include transfer of the halogen atom,

$$M^{(n-1)+} + XCH_2COOH \rightarrow [MXCH_2COOH]^{(n-1)+} ,$$

rather than electron transfer, i.e. the mechanism is the same as for the reaction with the H atom (but not for the reaction with e_{aq}^-).[143]

The Tl^{2+} and Ag^{2+} ions behave as "mild" oxidising agents, and they react with benzoic acid (BA) and methoxybenzoic acid (MBA) with very high rate constants (~10^9 litre mole^{-1} s^{-1}), forming short-lived anion radicals[144,145]:

$$BA(MBA) + Tl^{2+} (or\ Ag^{2+}) \rightarrow BA^{\cdot}(MBA^{\cdot}) + Tl^{+} (or\ Ag^{+}).$$

Derivatives of benzoic acid are widely used as corrosion inhibitors: their effect on the corrosion process may be due at least in part to reactions of this type.

Table 8. Rate constants (10^{-9} *k*, litre mole^{-1} s^{-1}) of the reactions of metal ions with organic compounds in aqueous solutions at pH ~5–6.[141]

Compounds	Cd+	Co+	Ni+	Pb+	Zn+
Benzoquinone	4.8	5.1	0.23	4.1	4.8
Menaquinone	4.6	4.0	2.4	3.7	3.8
Benzophenone	1.0	2.5	—	—	2.5

Note. For the reaction of 2-methoxybenzoic acid (pH ~3) with Ag^{2+} and Tl^{2+} the *k* values are 1.2×10^9 and 6.8×10^8 litre mole^{-1} s^{-1} respectively[144,145].

4. Formation of Intermediate Complexes

Metal ions tend to form unstable complexes in one-electron redox reactions with radicals (H, OH, alcohol radicals, etc.) or with molecular compounds. For example, in the fast oxidation of Fe^{2+} by OH radicals the $FeOH^{2+}$ ion is formed[146]. The reaction of Fe^{2+} with HO_2 radicals, and the reaction of Fe^{3+} with H_2O_2, yield the $Fe^{3+}...HO_2^-$ complex[125], which is unstable and dissociates by a first-order reaction whose rate constant is independent of the pH (in the range pH 0–2.1) and of the concentration of O_2 and Fe^{3+}, but increases slightly with the concentration of Fe^{2+}. The latter effect shows that the decomposition of the complex is catalysed by Fe^{2+} ions, whose participation in the intermediate step of the reaction yields the bridging compounds

$$[Fe^{3+} \ldots HO_2^-] + Fe^{2+} \rightarrow [Fe^{3+} \ldots HO_2^- \ldots Fe^{2+}] \rightarrow Fe^{2+} + Fe^{3+} + HO_2^- .$$

Other transition metal ions (M^{n+}) in aqueous solution react with O_2^- ion radicals to give $MO_2^{(n-1)+}$ complexes. For example, the species MnO_2^+ has been detected[93] by the pulse radiolysis method in aerated aqueous solutions of $Mn(ClO_4)_2$. The equilibrium constant of the reaction

$$MnO_2^+ \rightleftarrows Mn^{2+} + O_2^-$$

was found to be $(1.5 \pm 0.6) \times 10^4$ M^{-1}. As stated above, Ni^+ and Cr^{2+} also interact with molecular oxygen to form the intermediate complexes NiO_2^+ [137,138] and CrO_2^{2+}.[139,140] We must assume that these same complexes are formed by the reaction of Ni^{2+} and Cr^{3+} with the O_2^- ion radical.

Hydrogen atoms react with Fe^{2+} with formation of the unstable hydride FeH^{2+} which disappears by the reaction

$$H^+ + FeH^{2+} \rightarrow Fe^{3+} + H_2$$

with a rate constant of ~1×10^4 litre mole^{-1} s^{-1}.[125] Apparently hydride formation is characteristic also of other transition metals (Co^{2+}, Ni^{2+}, etc.) reacting with H atoms. These metals have an unfilled inner *d* shell. On the other hand, if the metal has a filled inner *d* shell (Hg, Cd, Zn, etc.) these reactions are not observed.

Our results are consistent with the traditional classification of metals into two groups with respect to their electrochemical properties[147,148]. The first group (metals of the platinum group and iron) has a high heat of adsorption of hydrogen atoms, and the rate of evolution of molecular hydrogen from these metals is limited by the chemical

dimerisation reaction of the hydrogen atoms. A likely explanation of these properties is the formation of fairly strong chemical bonds with the metal atoms on the surface of the electrode. The second group of metals (Hg, Cd, Zn, etc.) is characterised by weaker adsorption bonds with hydrogen atoms. The rate-limiting step in the evolution of hydrogen is a slow discharge process. We may assume that the hydrogenation of metals produced by various electrode processes is due to the step mechanism of the discharge (ionisation) reaction, involving the formation of hydride complexes during the intermediate steps.

Metals in unusual states of oxidation react with organic (e.g., alcohol) radicals to form unstable metal–organic compounds[69,72,77,94,149]:

$$M^{(n-1)+} + R \rightarrow MR^{(n-1)+} .$$

These compounds usually show characteristic optical absorption bands in the u.v. region of the spectrum. The life time of the intermediate complexes is determined by the rate of hydrolysis. For example, the cadmium-organic compounds CdR^+ decompose by the reaction

$$CdR^+ + H^+ \rightarrow Cd^{2+} + RH$$

with rate constants 161 s^{-1} for R = $(CH_3)_2COH$ and 257 s^{-1} for R = CH_3CHOH.[72] Nickel–organic compounds are more stable. Their lifetime is ~1 s when R is a methanol or ethanol radical, and even longer for more complex radicals[94]. Nickel compounds are easily oxidised in the presence of H_2O_2. In experiments with aqueous solutions of 2-methyl-2-propanol it was shown[94] that the resulting organic radicals react with Ni^+ to form isobutene:

$$Ni^+ + CH_2C(CH_3)_2OH \rightarrow Ni^{2+} + CH_2{=}C(CH_3)_2 + OH^- .$$

The rate constant of this reaction is 3×10^9 litre $mole^{-1}$ s^{-1}.

The formation of unstable metal–organic compounds has been demonstrated by pulse radiolysis for the reaction of alcohol radicals with Zn^+,[69] HgCN,[77] and the Cr^{2+} ion[149]. Chromium–organic compounds are more stable to hydrolysis than nickel–organic compounds. For example, the compound $CrCH_2OH^{2+}$ decomposes in water with a rate constant of ~7×10^5 s^{-1}.[149]

5. Reduction to Metals

The chemical reduction to a metal from aqueous solutions of its salts must occur through a number of intermediate steps in which the metal displays unusual valency forms. Radiation-chemical methods (and, in particular, the pulse radiolysis method) have proved very useful in studies of the reduction mechanism of the cations and of the nucleation of the metal in aqueous solutions. The chemical steps in the reduction are fairly specific for the individual cations (Ag^+, Cu^{2+}, Zn^{2+}, Cd^{2+}, Ni^{2+}, Pt^{2+}, etc.) and are usually complex. For example, the Ag^0 atoms produced by a 2 μs pulse of electrons on a 10^{-5} M solution of Ag^+ saturated with argon and containing 0.1 M CH_3OH disappear in a few tens of microseconds by reacting with the Ag^+ ions to form Ag_2^+. The disappearance of the latter is accompanied by the formation of two new particles:

$$Ag_2^+ + Ag^+ \rightarrow Ag^{2+} + Ag_2 .$$

The relatively slow removal of Ag_2 by a pseudo-first order reaction is markedly influenced by the concentration of Ag^+. The reaction is assumed to be

$$Ag_2 + Ag^+ \rightarrow Ag_3^+ .$$

After a few milliseconds we observe a long-lived optical absorption at 390 nm, assigned[97] to the association of Ag_3^+ particles to form agglomerates of metallic silver:

$$Ag_3^+ \rightarrow \text{metal}.$$

These results show that even an apparently simple process such as the nucleation of atomic silver in an aqueous solution of Ag^+ can be complex and involve a number of steps. The reduction of a cation to the metal includes a large number of intermediate steps: one-electron reduction of the cation, disproportionation or dimerisation of the reduction product, cluster formation and growth of the clusters to give massive metal particles. The radiation-chemical reduction of the cations and formation of a metallic deposit is most effective in deaerated, neutral aqueous solutions of the salts containing organic additives such as formate ions, alcohols, etc. The latter act as acceptors of OH radicals, thus preventing back oxidation of the metal ions reduced by solvated electrons or by H atoms.

The formation of metal granules by pulsed irradiation of aqueous salt solutions has been studied in more detail for the cadmium deposition system. It was found[71] that the optical absorption due to the short-lived Cd^+ and Cd_2^{2+} ions (which are the precursors of the metal atoms) disappears ~10^{-4} s after the application of the electron pulse, and the solution becomes fully transparent. The transparent state persists for ~0.1 s, after which a new absorption occurs over the whole of the optical region, increasing to a constant value in ~10 s. The optical density D increases with the fourth power of the wavelength in the u.v. region, a characteristic property of media containing suspended matter which scatters rather than absorbs light.

The effect of the ionic strength of the solution on the rate of formation of finely divided metallic cadmium suggests[72] that the metal is being deposited from complex cadmium clusters having an effective charge of +5.5. The time for nucleation and growth of the metal grains decreases as the supersaturation of the solution increases (i.e. in proportion to the dose of radiation per pulse). A few minutes after the appearance of turbidity in the solution, precipitation of the metal begins, accompanied by a decrease in absorption in the u.v. region of the spectrum and increased absorption at longer wavelengths[72], caused by the increase in size of the metallic agglomerates. The precipitation curves are accurately described by a pseudo-first order equation with respect to Cd^0 concentration, with a rate constant of $(5 \pm 2) \times 10^4$ s^{-1}.[71]

Similar effects have been observed in the formation and deposition of metal by the pulse radiolysis of aqueous solutions of Ag^+ and its ammine complex[97,98], and also of Ni^{2+}.[94] It has been shown[71] that under identical pulsed irradiation conditions the induction period t_0 (time of nucleation) of many salt solutions calculated from the experimentally observed delay in the appearance of turbidity depends on the nature of the cation and decreases in the sequence $Pb^{2+} \cong Cd^{2+} \gg Zn^{2+} > Ni^{2+} > Co^{2+}$.

6. Metal Dissolution

The stability of a metal and its rate of dissolution in aqueous or other solutions is determined by its electrode potential. The rate of dissolution decreases if the potential is shifted towards more negative values, and becomes zero when a definite value of the potential is reached. Alkali and alkaline-earth metals dissolve in water at approximately constant rates. Since their redox potential

is more negative than −2.9 V we can expect hydrated electrons to be formed during their dissolution.

The possibility of forming hydrated electrons by the reaction between sodium amalgam and water has been demonstrated[150,151] by the acceptor competition method:

$$Na\,(Hg) + H_2O \rightarrow Na^+ + e^-_{aq} \quad .$$

This conclusion was based on the detection of N_2 as the main reaction product in an aqueous solution containing N_2O and CH_3OH, by the reaction

$$N_2O + e^-_{aq} \rightarrow N_2 + O^-$$

rather than H_2, expected to be formed by the reaction

$$CH_3OH + H \rightarrow H_2 + CH_2OH$$

if the H atom had been a primary product of the dissolution of sodium amalgam. On the other hand, experiments with pure sodium suggest that several mechanisms contribute to the dissolution of this metal in water (see Ref.53).

It has been suggested[152,153] that the generation of e^-_{aq} can be induced by cathodic polarisation of an electrode. The same conclusion was reached from the observation of a substantial decrease (by ~35%) in the yield of H_2 from a smooth platinum electrode on adding N_2O to a neutral solution. On the other hand the presence of CH_3OH had no effect on the relative yields of N_2 and H_2. These results convincingly demonstrate the participation of an electron in the formation of N_2. However, there is reason to believe that the reaction involving the electron takes place directly on the cathode (with adsorbed N_2O), and not in the bulk of the solution (as it would if the hydrated electron was involved).

The important role of the e^-_{aq} species in the chemical dissolution of metals has been stressed[154], and used as a basis for discussing instability criteria. The first step in the dissolution was assumed to be the formation of an uncharged activated complex,

$$M + H_2O \rightarrow (MH_2O)^* \quad .$$

In the second step this complex dissociates into e^-_{aq} and the metal ion:

$$(MH_2O)^* \rightarrow M^{n+} + ne^-_{aq} \quad .$$

Neither of the steps is electrochemical, since no charge is transferred across the metal–solution interface, and therefore the rate of the overall process should be independent of the potential. However, the rate of dissolution can be expected to depend on the pH, on the nature of the surface, and on the overall current density, and these expectations have been confirmed experimentally.

According to Antropov[154] the condition for self-dissolution of the metal is

$$S_M + \sum_1^n I_{n+} \leqslant A^{H_2O}_{M^{n+}(r)} + nA^{H_2O}_{e^-(r)}$$

where S_M is the free energy of sublimation of the metal, $\sum_1^n I_{n+}$ is the sum of the ionisation potentials (from 1 to n) of the metal, and $A^{H_2O}_{M^{n+}(r)}$ and $A^{H_2O}_{e^-(r)}$ are the real free energies of hydrated M^{n+} ions and electrons respectively. This criterion has been tested for alkali and alkaline-earth metals. However, direct experimental evidence of the formation of e^-_{aq} during cathodic polarisation of the electrode or during chemical dissolution of the metals in water has not yet been obtained.

A detailed critical analysis of these hypotheses is given in Refs.155 and 156. The probability of thermionic emission of an electron into the aqueous solution is believed, on theoretical grounds[157], to be very low, and the contribution from this mechanism to the cathodic currents is probably negligible, even at high negative potentials. On the other hand, the probability of ordinary cathodic reactions (electron transfer to adsorbed ions or molecules) is quite high at these potentials.

Nevertheless the possible formation of e^-_{aq} during the reaction of some metals (such as alkali or alkaline-earth metals) with water cannot be excluded: this is shown, for example, by the reported[158] formation of e^-_{aq} during the condensation of finely divided sodium and potassium with water vapour on a surface cooled to 77 K. We should also note that the cathodic generation of solvated electrons was detected experimentally in solvents which are stable at large negative potentials (hexamethylphosphotriamide, liquid ammonia, some amines, etc.; see review in Ref.159).

Dependence of the rate of corrosion of metals on the nature of the anions suggests that the anions are directly involved in the reaction. According to Kolotyrkin and coworkers[49–51] the anodic dissolution of metals takes place through the formation of a complex the metal (M) and a ligand (L):

$$M + L \rightleftarrows ML \quad .$$

The adsorption of ligands lowers the electronic work function and accelerates the corrosion of the metal:

$$ML \rightarrow ML^{n+} + n\,e^- \quad .$$

The dissolution of iron in acid solutions is now believed[51] to take place through the formation of the unstable intermediate FeOH, in which the iron displays the unusual state of oxidation +1. Evidently, the formation of unstable coordination compounds of the ML^{n+} type during the intermediate stages of the electrochemical or chemical dissolution of metals is a fairly common phenomenon. In the first section of this review we had discussed experimental evidence for the formation of metals in unusual states of oxidation during electrochemical reactions (for example, Zn^+, In^{2+}, Tl^{2+}, etc.). Evidently, in many cases the disproportionation (or dimerisation) of these species is energetically more favourable than further ionisation (see Section IV, Pt.1).

It is important to note that when $E^0[M^{n+}/M^{(n-1)+}] \lesssim E^0(e^-_{aq}/\frac{1}{2}H_2)$ the ionisation of $M^{(n-1)+}$ in aqueous solutions (especially at high pH values) can yield a hydrated electron:

$$M^{(n-1)+}_{aq} \rightarrow M^{n+}_{aq} + e^-_{aq} \quad .$$

The possibility of these reversible reactions has been examined[160] in the case of the interaction of e^-_{aq} with Zn(II) and Al(III) in aqueous solutions of alkalis. More recently it has been shown by the pulse radiolysis method[161,162] that the rate of disappearance of e^-_{aq} decreases (as expected) as the concentration of Zn(II) increases. This effect was explained by postulating the equilibrium reaction

$$e^-_{aq} + Zn\,(OH)_4^{2-} \rightleftarrows Zn\,(OH)_3^{2-} + OH^- \quad . \qquad (24)$$

The equilibrium constant of this reaction for a 3 M solution of LiOH is 0.1 M^{-1}, i.e. the E^0[Zn(II)/Zn(I)] value under these conditions is only ~0.09 V more positive than $E^0(H_2O/e^-_{aq})$.

The redox potentials of the Zn^{2+}/Zn^0 and Al^{3+}/Al^0 couples in acid solution are −0.76 and −1.66 V respectively[123]. In an alkaline medium these metals exist as hydroxo complexes, and the potentials of the $Zn(OH)_4^{2-}/Zn^0$ and $Al(OH)_4^-/Al^0$ couples are more negative (−1.22 and −2.35 V respectively[123]). It follows that the potential of the $Zn(OH)_4^{2-}/Zn(OH)_4^{2-}$ couple also suffers a negative shift [as compared with the potential of the Zn^+/Zn^{2+} couple, ~(−2.4 V)], and thus becomes comparable with $E^0(H_2O/e^-_{aq})$. These considerations allow us to predict reversible reactions of the type of (24) not only for hydroxo complexes of metals in alkaline media but also

for cyano and other complexes in neutral solutions. The latter complexes also experience a large negative shift of the potential[123], and the following condition may apply:

$$E^0(MX_{m-n}^{n-}/MX_{n-n}^{(n+1)-}) \lesssim E^0(e_{aq}^-/{}^1/_2H_2)$$

* *
*

Thus the advances in radiation-chemical (and, in particular, in pulse radiolysis) techniques made in the last 15 years have markedly influenced the new developments in the chemistry of metals in unusual and unstable states of oxidation. The discovery of these short-lived particles, the study of their properties, and the formulation of rules governing those properties will undoubtedly stimulate further developments in the chemistry of the intermediate steps of redox reactions, involving metals in unstable valence forms. Of course, the preparation of various ions in unusual states of oxidation by radiation-chemical methods cannot in any way be taken as evidence for the formation of those same ions during electrochemical reactions. However, the generation of data on the properties of these intermediate particles should greatly assist the study of the mechanism of multi-step electrochemical processes.

The Reactivity of Hydrogen Atoms

E.S.Filatov, E.F.Simonov, and M.A.Orlova

Theoretical ideas about the reactions of thermal and "hot" hydrogen atoms are examined and experimental data, characterising the mode of reactions involving hydrogen atoms with different energies, are presented.
The bibliography includes 212 references.

IV. Conclusions 1146

I. INTRODUCTION

The hydrogen atom is the simplest chemical species and has for a long time attracted the attention of investigators endeavouring to understand elementary chemical processes. On the other hand, the role of hydrogen atoms in many processes occurring naturally or induced artificially is generally known: in space and in the upper layers of the atmosphere, in radiation chemistry and photochemistry, in the pyrolysis of substances, in hydrogenation reactions, in plasmas, and in thermonuclear processes. There is reason to believe that organic substances are formed on the planets of the solar system as a result of reactions of hydrogen atoms[1].

There are several ways of obtaining hydrogen atoms (and the atoms of hydrogen isotopes—deuterium and tritium): thermal dissociation, electric discharge, photolysis, radiolysis, nuclear reactions, and an acceleration technique. In the thermal dissociation of molecular hydrogen, one obtains thermal atoms and, since the source region is at a high temperature, approximtely 10% of the atoms are obtained with an energy of approximately 0.3-0.5 eV.[2] In the remaining instances, hydrogen atoms have a non-equilibrium distribution. In an electric discharge there is a possibility of the formation of excited atoms[3]. Hydrogen atoms in certain quantum states are obtained by the electron impact method[4] or in a proton transfer reaction[5]. Hydrogen atoms appear when gas flows from an ultrasonic nozzle[6]. Owing to the dissociation of C—H bonds, the radiolysis of hydrogen-containing organic compounds results in the appearance of hydrogen atoms with an energy of 1—3 eV.[7] In photolytic experiments the energy of hydrogen atoms varies from 0.1 to 6 eV.[8] Recoil tritium atoms with energies of 0.19 and 2.7 MeV can be obtained by the nuclear reactions $^3He(n,p)^3H$ and $^6Li(n,\alpha)^3H$.[9] The technique of "chemical" accelerators makes it possible to obtain hydrogen atoms with energies in the range from approximately 1 to 200 eV [10] and to investigate the angular distribution of the reaction products[11]. Thus present day investigators are able to obtain hydrogen atoms with energies ranging from approximately 0 to 2.7 MeV. There is a prospect of investigating reactions with reactants having different energies and known quantum states.

According to the classical Arrhenius equation, with increase of temperature (collision energy) the probability of the reaction should tend to a value equal to the steric factor. However, if high-energy atoms are generated in the system, the reactions do not obey the Arrhenius kinetics; the steric factor increases[12] when the probability of the reaction depends in a complex manner on the collision energy[12,13]. Thus the reactions occurring at different relative collision energies cannot be described in terms of a single mechanism.

Ideas borrowed from collison physics and nuclear physics throw a significant light on the nature of chemical reactions. This concerns concepts such as the reaction cross-section and the excitation function. The cross-section of a chemical reaction reflects its probability for a specific quantum state of the initial reactants and final products, while the excitation function describes the dependence of the cross-section on the collision energy. By integrating over all possible states, one obtains the overall reaction cross-section and, on multiplying by the relative velocity of the reacting species, one finds the rate coefficient—a quantity analogous to the rate constant for a chemical reaction. For the equilibrium distribution of the reacting species with respect to energies, the rate coefficient is the rate constant for the chemical reaction.

Appreciable advances have been made in recent years in the study of the excitation functions $\sigma(E)$ of chemical reactions in general and of the reactions of hydrogen atoms in particular. The chemical reaction thresholds have been determined; it has been shown that $\sigma(E)$ corresponding to a specific energy has a maximum, beyond which it decreases to $\sigma(E) \cong 0$. Taking this into account, it is possible to classify the interactions of hydrogen atoms which are generated in some way in the medium in terms of their energies and the nature of their energy spectrum. If the spectrum is of the Boltzmann type, then usually only a small proportion of the atoms enter the region $E_1 \leq E \leq E_2$, where the function $\sigma(E)$ is determined. In this case the classical description based on the Arrhenius equation is entirely applicable in the region of "moderate" temperatures (200—500 K). At low temperatures quantum corrections for the wave properties exhibited by the hydrogen atoms are necessary, while at high temperatures account must be taken of the breakdown of the Boltzmann distribution as a consequence of the "burning away" of the active species.

If atoms with an energy in the region $E_1 \leq E \leq E_2$ are generated in the system where the function $\sigma(E)$ is determined (this is usually 0.1—10 eV) and if there is no equilibrium in the energy distribution of the atoms, then the Arrhenius equation is inapplicable to the description of the kinetics of the reactions of such species, which are referred to as "hot". The reaction can occur in the first collision and also subsequently when the atom has lost part of its energy, but subject to the condition that the residual energy of the atom lies within the limits of the region $E_1 \leq E \leq E_2$. If atoms with $E > E_2$ act on a given substance, then in the first collision the reaction is impossible and the atoms must be retarded until the energy is $\leq E_2$. Subsequently the reaction proceeds

in the same way as that with atoms generated in the range of energies $E_1 < E \leq E_2$.

The rate of a reaction involving species with an energy can be expressed by the general equation

$$w = \int_{E_1}^{E_2} p(E')\, n(E, E')\, \mathrm{d}E' \,, \qquad (1)$$

where $p(E')$ is the probability of the reaction for a collision energy $E = E'$ and $n(E,e')$ is the collision density (the number of collisions per unit time per unit volume). The collision density in the range of energies dE' near E' in general depends on the energy of the species E, falling within this range on retardation.

If $E > E_1$, the probability of the reaction of thermal atoms is assumed to be independent of the collision energy; the collision density is calculated from the Boltzmann distribution of the species with respect to energies. Hence it is possible to derive the Arrhenius law from Eqn.(1). For "hot" species, the assumption that the reaction probability is independent of the energy is invalid, because a considerable proportion of the species (if not all) have an energy $E \gg E_1$. However, in an analytical form, the $p(E)$ relation is as a rule unknown, so that the concept of integral probability is used in the solution of Eqn.(1) and the function $n(E,E')$ is found by solving the transport equation for the species with certain assumptions about the nature of the retardation process.

The advances in the chemistry of thermal hydrogen atoms described in Dubinskaya's[14] and Thrush's[15] reviews and the reactions of "hot" atoms considered in a number of other reviews[16-20] will be touched on in the present survey only where necessary. Attention is concentrated on new investigations and also on studies which had not been considered before.

II. REACTIONS OF THERMAL HYDROGEN ATOMS

1. Modern Ideas about the Reactivity of Thermal Hydrogen Atoms

The reactivity of hydrogen atoms has always been and still is the subject of extensive investigations. In view of its characteristic features—a light nucleus with a single electron—the hydrogen atom constitutes a system suitable for testing the validity of any physicochemical theory of reactivity and the existence of hydrogen isotopes permits the study of quantum and isotope effects in the kinetics of chemical reactions[21]. The commonest reaction of hydrogen atoms is of the type $A + BC \rightarrow AB + C$, i.e. a bimolecular substitution reaction (when C contains more than one atom, this is referred to as the abstraction reaction). The transition state (TS) theory has found the most extensive applications in the description of bimolecular reactions. A deficiency of this theory for atom—molecule reactions consists in the neglect of the tunnelling effect, which leads to unduly low calculated reaction rate constants at low temperatures. The "quantum-mechanical" rate constant is as a rule 1—2 orders of magnitude greater than the constant calculated on the basis of the TS theory[22].

The introduction of various corrections, as well as calculations by the method of trajectories, significantly improve the agreement between the classical and quantum-chemical calculations. A version based on a simple physical modification of the usual tunnel corrections is used, which consists in the fact that, instead of the movement of the representative point in the saddle area of the potential surface, one calculates its path along the curve connecting the classical turning points[23]. This leads to the narrowing of the calculated barrier to reaction compared with that obtained on moving along the potential energy maximum. This reaction pathway is shorter, which improves the agreement with quantum-mechanical calculations, for example, for reactions of the type

$$H + H_2 \rightarrow H_2 + H \,. \qquad (2)$$

However, in the study of the role of various corrections in the TS theory it has been shown that, although the Wigner relation usually employed has no rigorous theoretical proof, it is more consistent than any other for a wide set of reactions[23]. An attempt has been made[24] to take into account the vibrational non-adiabatic conditions in the abstraction reaction and the possibility of tunnelling within the framework of the TS quantum theory. It has been suggested that the "best" tunnelling path, common to all reactions, does not exist.

Tunnelling corrections are introduced as a rule within the framework of the "direct" mechanism of the TS theory: one considers the surface dividing the space of the reactant products in which there is a single trajectory of the movement of the representative point. This model is valid for energies which do not greatly exceed the threshold energy E_1. On the other hand, the majority of reactions proceed via the formation of a long-lived complex[25]. In the theory combining both concepts of bimolecular reactions (the "direct mechanism" and the "long-lived complex") expressions have been derived for the probability of reaction and it has been shown that they can be deduced from a general model[26]. The application of this model to the reaction between H and H_2 has been considered[27].

Starting from the 1950's the molecular orbital (MO) method began to be incorporated in chemical kinetics. A general approach based on the MO method to the abstraction reactions has been developed[28,29]. Here one uses concepts such as the stabilisation energy of the radical ΔE, the delocalisability D_r, and also the concept of the linear relation between E_a and ΔE:

$$E_a = A - B \cdot \Delta E; \; D_r = \sum_j (C_r^j)^2; \; \Delta E = C \cdot D_r$$

where C_r^j is the coefficient of the atomic orbital (AO) in the jth molecular orbital; the summation is carried out over all occupied and unoccupied MO: A, B, and C are constants.

If one considers a series of substances, for example, hydrocarbons, then the product of the abstraction reaction is H_2 and E_a should depend solely on the stabilisation energy of the radicals ΔE. The higher the stability of the radical obtained, the lower the activation energy for the reaction—a fact which has long been known in chemical kinetics[30]. However, it was not until the 1960's that it was possible to characterise the stability of chemicals quantitatively by introducing the concept of delocalisability[31], which was calculated by the MO method[31,32]. The value of the calculations lies in the accuracy and reliability of the evaluation of the coefficients of the AO. Approximate quantum-chemical methods are usually employed and only a qualitative correlation between E_a and $\Delta E(D_r)$ is obtained[31-33].

In general the MO method usually provides a description of the reactions at an adequately high qualitative level. Satisfactory results have been obtained by combining the MO method with the technique of correlation diagrams, whose construction is based on the principle of the conservation of orbital symmetry in the reaction[34]. The hydrogen abstraction reactions are symmetry-allowed and the reactivity of the C—H bond in various compounds with respect to the given reaction is determined by the electron density in the occupied and unoccupied MO of the initial molecules and by the delocalisation energy of the unpaired electron in the radical formed.

Correlation diagrams assist in understanding the course of the reaction. The abstraction reaction takes place in three stages[35]: in the first stage an electron is transferred from the RH molecule to a partially occupied orbital of the H atom and in the second stage an electron is transferred from the H atom to the lowest vacant orbital of the molecule (the spin-delocalisation stage). A charge is then accumulated in the region between the hydrogen atoms and the C–H bond is formed by the "local triplet" of two electrons, which is responsible for the dissociation of the C–H bond in the concluding, third reaction stage. The process described proceeds most readily under the conditions of an axial attack.

The application of the principle of conservation of orbital symmetry to the abstraction reaction does not account for the origin of the activation energy but makes it possible to understand certain details of the formation and dissociation of the bonds. A more general principle of the description of chemical reactions, consisting in the fact that the reaction is regarded as allowed if the distortions occurring on a given pathway do not give rise to new nodal planes in the wave functions, has now been proposed. The principle of the conservation of orbital symmetry is a special case of a more general principle[36]. The fundamental feature of the proposed analysis of the reactions is the introduction of an operator which satisfies the requirements of the prohibition of a change in nodal structure (mapping operator). The reaction is allowed if the mapping function and the wave function of the putative product overlap.

Some investigators have developed an even more general approach to the study of the kinetics of chemical reactions[37–39]. On the basis of the general principles of wave mechanics, they assume that the probability of the reaction is proportional to the overlap integral of the wave functions of the initial and final states of the species. There is then no need to consider the usual reaction path as the movement of a point on the potential energy surface, to construct correlation diagrams, and to introduce corrections for reactions via other mechanisms, for example the tunnelling mechanism: within the framework of the proposed theory, the tunnelling process is inherently included. The conclusion that heat is evolved in an exothermic reaction mainly in the form of the internal energy of molecules is one of the consequences of the wave theory of chemical reactions, which has been confirmed experimentally.

2. The Reactions of Hydrogen Atoms with Inorganic Substances

An enormous number of studies have been made on reaction (2) and its isotopic variants. One of the latest reviews[21] considers the application of the collision theory to the activated complex theory taking into account the quantum and isotope effects. The reaction dynamics have been considered in a review[40] as a consequence of trajectory calculations. Quantum-mechanical calculations have been made on the cross-sections of reaction collisions and the differential cross-sections. the reaction threshold. and the quantum state of the products have been evaluated. Theoretical studies are usually preformed on the basis of a variant of the TS theory taking into account tunnelling effects at temperatures $T < 450$ K. A satisfactory agreement with experiment is then achieved[41]. Thus the isotope effects of the reactions between D and H_2 and between H and D_2 have been calculated[42] for the range 200–4000 K. An analogous study has been made for the reactions between H and H_2 and between D and D_2.[43]

Quantum-chemical calculations make it possible to calculate the reaction thresholds and to consider the reaction dynamics and the population of the states of the products. A three-dimensional quantum-chemical study has been made[44] of the reaction $D + H_2 \rightarrow HD + H$; the reaction threshold was estimated as 0.27 ev (which virtually agrees with experiment) and intense back-scattering (ricochet) and population of the lowest levels of the HD molecule were predicted.

Reactions of the type $X + H_2 \rightarrow$ and $H + X_2 \rightarrow$, where X = H, D, or ^3H, have been investigated by the method of classical trajectories for collinear collisions and for the three-dimensional case[45]. In the first case the reaction thresholds for different isotopes differ little (0.27–0.28 eV), but in the second case the differences are significant (for the reactions of H atoms with H_2, D_2, and $^3H_2$, the thresholds are 0.271, 0.192, and 0.157 eV respectively). The calculations showed that between 0.3 and 0.45 of the collision energy is converted into the internal energy of the product. It is of interest to note that the differences in the reactivity, which are usually attributed to thermal effects, are accounted for in this instance by simple dynamic effects on collision between the species.

A detailed experimental study of the reactions of hydrogen atoms with hydrogen molecules (and the molecules of its isotopes) has been made by the usual thermal techniques. However, only studies in beams make it possible to obtain information about the fine details of the reaction mechanisms and to answer the questions which modern theories of reactivity cannot answer. In connection with apparatus difficulties, only as late as 1970 was it shown that HD, the product of the reaction between D and H_2, is scatterd "backwards" in the centre of mass system and that the internal excitation of molecules is low[46]. Since hitherto it has not been possible to overcome the difficulties associated with the experiments in beams, particularly in the detection of products, it has been suggested that the reactions of hydrogen atoms with tritium molecules, i.e. $X + {}^3H_2 \rightarrow$ (X = H or D), be investigated with detection of the products on the basis of their radioactivity[47]. The forward scattering of tritium atoms in the reaction

$$H + {}^3H_2 \rightarrow H^3H + {}^3H$$

and the back-scattering of H^3H molecules were observed, i.e. the direct abstraction reaction was noted. The above report[47] contains valuable information about the angular distribution of products, but there are no data on the distribution with respect to velocities, which precludes any conclusions concerning the form of the potential energy surface.

At ultralow temperatures the hydrogen atoms in the molecular hydrogen matrix are stabilised[48] and at $T < 1$K an average concentration of hydrogen atoms of 0.01% was attained. Since the radicals were obtained in solid H_2 with the aid of the β-decomposition of ^3H, the local concentration [H] was much higher. The temperature T_R at which the H_2 specimen containing H atoms becomes unstable and spontaneous (or stimulated) evolution of energy takes place has been found. It has been noted that T_R decreases with increasing storage time of the specimens. The authors[48] concluded that the regions of a high concentration of H atoms behave similarly to ferromagnetic domains. Subsequently a study was made of the kinetics of the accumulation of hydrogen atoms in solid H_2 containing 2% $^3H_2$ at $T < 1$ K.[49] Hydrogen atoms are stabilised by the reactions

$$H + {}^3H_2 \rightarrow H^3 \cdot H_2 \quad \text{and} \quad H + H^3H \rightarrow H_2 \cdot {}^3H.$$

It was found that at $T \cong 0.17$ K the limiting concentration is $[H] \cong 5 \times 10^{19}$ atoms cm^{-3} or 2×10^{-3}M, i.e. a high concentration of hydrogen atoms is not reached.

A study of reactions of the type $H + X_2 \rightarrow$ (X = halogen) by methods of classical and quantum mechanics showed that the main discrepancy between their results occurs near the threshold owing to the neglect of the contribution of complex trajectories in the classical treatment of the reaction pathway[50,51]. The classical description with a more "accurate" treatment of the region of the threshold (for example with optimisation of the transition state) gives rise to a good agreement of the rate constants with experimental values for the reactions of hydrogen atoms with HBr, ^{3}HBr, F_2, and Cl_2.[52] The "accurate" treatment consisted in employing in the calculations two dividing surfaces: one for energies less than the energy at the saddle point and the other for higher energies.

Modern experimental data (vibrational excitation of products, rate constants, rate constant ratios, angular distribution) permit the calculation of parameters characterising the potential energy surface, for example, for the reaction between D(H) and X_2, where X = Cl or muonium[53]. In certain cases the same reaction products can be obtained via different channels, for example:

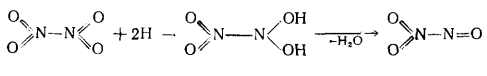
$$H + XY \begin{cases} \longrightarrow H\cdots XY \rightarrow HX + Y & (3) \\ \longrightarrow X{-}Y \rightarrow HX + Y \\ \quad\vdots \\ \quad H & (4) \end{cases}$$

Reaction (3) proceeds via the "direct" mechanism and reaction (4) involves the insertion mechanism. Theoretical study showed that the probability of reaction (3) increases and that of reaction (4) falls with increasing translational energy of the hydrogen atom[54].

A few studies of the interaction of hydrogen atoms with inorganic compounds have been described in the literature. Langmuir was the first to show[55] that atomic hydrogen reacts with phosphorus and reaction parameters have been given in a review[56] †:

$$H + NO_2 \xrightarrow{k} OH + NO, \quad \Delta H^0_{298} = 122 \text{ kJ mol}^{-1}, \quad k_{300} = 2\cdot 10^{13} \text{ cm}^3 \text{ s}^{-1} \text{ mol}^{-1};$$

$$H + ClNO \xrightarrow{k'} HCl + NO, \quad \Delta H^0_{298} = -273 \text{ kJ mol}^{-1}, \quad k' \simeq k.$$



The addtion of H atoms to O_2 and NO_2 has been considered[57] and the rate constants for the reactions of H and D atoms with NO_2, N_2H_4, Cl_2, NOCl, HBr, and DBr in the range 200–700 K have been published[58–62].

In the reaction of hydrogen atoms with carbon[63] in the range 300–1220 K the formation of CH_4 (91%), C_2H_6 (8.4%), C_3H_8 (0.6%), and secondary products (C_2H_4, C_3H_6, and C_4 hydrocarbons) has been observed[63]. With increase of temperature, the yield of hydrocarbons rose and the temperature dependence of the yield of CH_4 revealed three stages of the reaction, for which the activation energies were found: 4.5 ± 1.2, 0.15 ± 0.05 and 0.94 ± 0.20 kcal mol^{-1} for the temperature ranges 1000–1200, 500–1000, and 300–500 K respectively. At 300 K approximately 1% of hydrogen atoms interact with carbon, being converted into hydrocarbons; at 1220 K this fraction reaches 4%. Methane, being the primary reaction product, can probably react further with atomic hydrogen to form other hydrocarbons[54].

On interaction of hydrogen (and deuterium) atoms with solid N_2O_4 at 77–100 K, the following reaction was observed[65]:

$$N_2O_4 + 2H \rightarrow N_2O_3 + H_2O .$$

The authors[65] believed that the preferred mechanism of the reaction involves the reduction of nitrogen:

† Here and henceforth the units of energy are given in the same way as in the original communications.

Interesting studies have been made on the interaction of hydrogen atoms with cobalt(III) and copper(II) complexes[66]. It has been shown that for cobalt compounds the reduction of the complex-forming agent is preceded by a stage involving the dehydrogenation of the coordinated ligand. The reaction results in the formation of molecular hydrogen and a coordinated radical, which reduces cobalt(III) to cobalt(II) at the instant of its formation. The reduction of copper(II) in its complexes with aminoacids, which may be regarded as square-planar compounds, proceeds via an intermediate stage in which a hydride complex is formed, omitting the dehydrogenation of the coordinated ligand:

$$R_2 \,|\, Cu\,(II) \,|\, + H \rightarrow R_2 \,|\, Cu\overset{H}{\diagup}\,(II) \,|\, \rightarrow H^+ + R_2 \,|\, Cu\,(I) \,|\, \rightarrow R^- + R{-}Cu\,(I)\,,$$

where R is the aminoacid residue. As was to be expected, the rate constant for this reaction is independent of the chemical nature of the coordinated residues (glycine, alanine, and valine).

Since targets made up of substances subjected to the action of atomic hydrogen are as a rule deposited on glass, the interaction of glass with hydrogen atoms is of particular interest. Langmuir showed[55] that the rate of absorption of hydrogen by glass depends on the temperature of the source of atoms—a heated tungsten spiral, on the purity of the surface of the glass, and on its temperature. Later it was demonstrated[67] that only atomic hydrogen is absorbed; the absorption takes place at a temperature of the source of atoms ≥1300 K and only when the glass is cooled to 80 K. After heating the glass, the atoms recombine and the hydrogen is partly removed from its surface. Since repeated cooling of the glass (without atomisation) does not alter the hydrogen pressure, it follows that molecular hydrogen is desorbed. The H_2O, CO_2, and O_2 impurities are always present on the surface of the glass and prevent the adsorption of atomic hydrogen, being fully removed only after prolonged heating at approximately 600 K. The maximum number of atoms is approximately 1.5×10^{15} atoms cm^{-2},[55] while the number of tritium atoms on molybdenum glass is approximately 1×10^{16} atoms cm^{-2}, the sorption on glass being accompanied by the exchange of tritium for protium[68].

It has been found[69] that hydrogen atoms populate two states. The first state ($E_a = 25$ kcal mol^{-1}) is characterised by the formation of chemical bonds on the surface of the glass. The second rate ($E_a = 6.6$ kcal mol^{-1}) is determined by the van der Waals forces retaining the hydrogen atoms near the chemisorbed atoms. The populations of the two states are approximately the same. The rate of capture of thermal hydrogen atoms by Pyrex glass at 77 K and an initial hydrogen pressure of 5×10^{-2} mmHg is 2.8×10^{15} atoms cm^{-2} s^{-1}.[69] The adsorption of hydrogen atoms on zeolites depends greatly on the amount of water adsorbed on the surface[70], which can apparently be accounted for by the stabilisation of atoms on the acid surface centres. It may be that an analogous process also occurs on glass. Indeed the rate of capture of hydrogen atoms by glass differs by a factor of four for dry and wet surfaces[68].

In general the method of preliminary treatment of the surface has a major influence on the adsorption properties of the glass. The process is characterised in terms of the concept of the "recombination coefficient" γ, which is equal to the ratio of the number of atoms recombining on the surface to the total number of atoms impinging against the surface during the same period[71]. With increase of the temperature, we have $\gamma \rightarrow 1$.[15] Treatment of the glass with hydrofluoric or phosphoric acid reduces the value of γ.[72,73].

Treatment with acid apparently leads to an increase in the concentration of adsorbed atoms existing in a chemical state such that the atoms are incapable of impact recombination[68]. These conclusions have been confirmed by EPR data for the chemical state of sorbed hydrogen atoms. It has been found[72] that, as a result of sorption, the electron of the hydrogen atom is partly transferred to the *p* orbital, i.e. the properties of the sorbed species are altered (for example, the electrical properties of the solid phase, as a consequence of electron transfer to the valence band[74]). When tritium is used, this can be manifested by isotope exchange between ^3H and the molecules of substances containing "labile" hydrogen atoms[68,75].

Among reactions of hydrogen atoms with metals, the most detailed studies have been made of those with silver films on glass[76], the adsorption of hydrogen atoms on silver proceeding without an activation energy, and with sodium films at 78–178 K,[77] where low activation energies were observed. The efficiencies of the adsorption on palladium[78] of hydrogen atoms obtained in an electric discharge and by thermal dissociation have been compared. In the latter case a high efficiency was achieved and the ratio H/Pd was approximately 0.9, while the activation energy for the sorption of hydrogen by palladium proved to be 26.8 kcal mol^{-1}.

Qualitative conclusions have also been reached concerning the rates of reaction of hydrogen with COS, HN_3, and with a whole series of metals (Li, Na, Hg, Gd, Ga, Ca, Ba, Bi, Zn, Cu, and Mg) on the basis of observations of the changes in the hydrogen pressure in the system[79], but little information can be derived from these data.

It is of interest to use hydrogen atoms to investigate the surfaces of crystals[80]. The scattering from LiF crystals has been studied with the aid of monochromatic atoms. The Debye–Waller factor and the force parameter of the Morse function have been calculated from experimental data.

3. Reactions of Hydrogen Atoms with Organic Substances

(*a*) *Saturated aliphatic and cyclic hydrocarbons.* Theoretical studies on the reactions of hydrogen atoms have usually been made for the simplest hydrocarbon (methane) and in quantum-chemical calculations account has been taken of the polarisation of wave functions[81], which leads to a better agreement with experiment than the use of the London–Eyring–Polanyi–Sato (LEPS) potential[82]. The hydrogen abstraction reaction is believed to occur in a collinear collision and the exchange (substitution) is thought to proceed via a "trigonal bipyramidal" complex[81]. Since the latter process has $E_{thresh} \cong 35$ kcal mol^{-1}, it can only be induced by "hot" atoms. Theoretical studies on reactions with other hydrocarbons are limited by the possibilities of modern methods: in essence there have only been calculations by the MO method using the relation between the activation energy and certain reactivity indices, for example delocalisability[31–33].

The reactions of thermal hydrogen atoms with hydrocarbons may involve a process leading to the exchange of atoms but not via a single-stage substitution mechanism, involving instead consecutive abstraction and recombination reactions. Such reactions can be followed with the aid of an isotope technique. Apparently Shores and Moser[83] were the first to show that thermal tritium atoms can interact with saturated compounds such as n-hexane and cyclohexane. The kinetics of these reactions have not been studied and the reaction products have not been identified. The abstraction of a hydrogen atom from isobutane has been demonstrated[84].

The effect of thermal tritium atoms on propane has been studied in greater detail[85]. The activation energy for the reaction

$$H + C_3H_8 \rightarrow H_2 + C_3H_7^{\cdot}$$

is 7.1 kcal mol^{-1} at 480 K [86] and diminishes somewhat with decrease of temperature as a consequence of the different temperature dependences of the rates of reaction of hydrogen atoms with the CH_3 and CH_2 groups of propane. [^{3}H] propane can be formed as a result of a two-stage process—the formation of the propyl radical and its subsequent recombination, for which less energetic atoms are responsible, and also as a result of the direct substitution of hydrogen by tritium. The mechanism of the formation of side products, among which methane, ethane, ethylene, and propene have been found, can be represented schematically as follows:

$$H + C_3H_7^{\cdot} \rightarrow CH_3^{\cdot} + C_2H_5^{\cdot},$$
$$H + C_2H_5^{\cdot} \rightarrow 2CH_3^{\cdot},$$
$$H + CH_3^{\cdot} + A \rightarrow CH_4 + A \text{ etc.},$$

i.e. the rupture of C–C bonds in the radicals on collision of the latter with thermal hydrogen atoms is apparently possible. In addition one must take into account the occurrence of rapid substitution (exchange) reactions leading to the preferential rupture of secondary C–^{3}H bonds in alkanes[87].

The primary reaction of hydrogen atoms with cyclopropane[88] is the abstraction of hydrogen with formation of the cyclopropyl radical, the subsequent addition of hydrogen to which results in the formation of excited cyclopropane molecules. The excited molecules isomerise with formation of propene. Since the excitation energy after the addition of a hydrogen atom to the cyclopropyl radical is greater by approximately 35 kcal than the activation energy for the isomerisation of cyclopropane to propene, the probability of this process is fairly high.

The abstraction reaction has also been observed in the interaction of a stream of hydrogen atoms at a temperature of 2000 K with a cyclohexane target at 77 K; the activation energy for the abstraction of hydrogen was 6–8 kcal mol^{-1}.[89] This is the primary reaction and is followed by a disproportionation reaction (between a tritium atom and a cyclohexyl radical) with formation of cyclohexane, the addition of a tritium atom to which accounts for the appearance of labelled cyclohexyl radicals in subsequent processes. When the target is heated, the reactions of cyclohexyl radicals—disproportionation, recombination, and addition to a double bond—occur near the polymorphic transition temperature (160–190 K), which can be explained by the self-diffusion occurring near the phase transition temperatures[90]. The ratio of the disproportionation and recombination rate constants (k_{dispr} and k_{rec} respectively) for the cyclohexyl radicals at 77 K is approximately 5 ± 1, while E_a(rec.)–E_a(dispr.) $\cong$ 300–400 cal mol^{-1}. In a study of the temperature dependence of the destruction of cyclohexyl radicals in the range 70–145 K, it was found[91] that the yield of bicyclohexyl increases with increase of temperature, the increase being sharp as the phase transition temperature of cyclohexene is traversed and $k_{dispr}/k_{rec} \propto T^{-5.1}$. It has been suggested[91] that the "heating" of the molecular movement in the phase transition is manifested most effectively in the radical recombination reaction.

It is of interest that a high reactivity in the hydrogen abstraction reactions has been observed for a series of silanes [SiH_4, Si_2H_6, CH_3SiH_3, $(CH_3)_2SiH_2$] compared with the hydrogen analogoues[92,93]. Apparently the difference can be accounted for by the difference between the activation energies, since the pre-exponential factors are similar in the two cases and the decrease of the activation energy corresponds to the decrease of the Si–H bond energy.

(*b*) *Unsaturated hydrocarbons.* There have been few theoretical studies on the reactions of hydrogen atoms with unsaturated compounds. As a rule, they are confined to an examination of correlations between the rate constants and reactivity indices, for example, the localisation energy, calculated by simple MO methods. The height of the barrier to the reaction involving the addition of a hydrogen atom to ethylene has been calculated only recently by the Hartree–Fock method with optimisation of the geometry. The calculated barrier (5.1 kcal mol^{-1}) is close to the experimental value[94].

A number of investigators have proposed mechanisms of the possible reactions, devised by analysing the products of the reactions of hydrogen atoms with hydrocarbons, and also reaction parameters and EPR data[95–105]. These mechanisms have many features in common: in the first stage the hydrogen atom addition process results in the formation of radicals[96,104], which is followed by rapid secondary reactions—the disproportionation and recombination of the radicals with one another or with hydrogen atoms and, in the case of deuterium and tritium atoms, disproportionation and recombination of mixed radical species take place. Furthermore, in virtually all cases dimerisation reactions are observed, but the relative rate of the latter is low. For example, the ratio of the amount of propane obtained in the reaction of hydrogen atoms with propene to the amount of the dimerisation product (2,3-dimethylbutane) is approximately 9,[105] while the ratio to the total amount of all the hexane isomers obtained is approximately 11.[103]

For hydrocarbons with a carbon chain longer than that of propene, account must be taken of specific reactions associated with the position of the double bond. For example, a shift of the double bond with formation of *trans*-but-2-ene is characteristic of the reactions of hydrogen atoms with but-1-ene. The reactions of hydrogen atoms with buta-1,2-diene and buta-1,3-diene lead to different final products, since the addition of hydrogen to buta-1,3-diene can involve either double bond, while the "non-terminal" addition to buta-1,2-diene is energetically unfavourable, which leads to the formation of but-2-ene as the main product.

In the deuteration of a solid olefin there is a possibility of H–D exchange between the hydrogen atoms and the free alkyl radicals[106,107]:

$$\dot{R}_H + D \rightarrow \dot{R}_{(D)} + H \ .$$

On passing to unsaturated cyclic compounds, the same features are observed as for olefins. Thus, when tritium atoms reacted with cyclohexene[108], an addition reaction was observed and cyclohexane, cyclohexene, and bicyclohexyl, obtained as a result of consecutive recombination–disproportionation reactions, were found among the labelled reaction products. At low temperatures the rate constant for the recombination reaction is lower than that for the disproportionation reaction, but k_{rec} increases faster than k_{dispr} with increase of temperature. The activation energy for the addition of hydrogen atoms to cyclohexene is approximately 1.5–3.5 kcal mol^{-1},[108] which is consistent with the calculation based on the Semenov–Polanyi rule.

When tritium atoms were allowed to react with cyclohexylcyclohexene isomers, the formation of isomeric compounds together with hydrogenation products was observed. Furthermore, the proportions of the products and the ratios k_{dispr}/k_{rec} depend on the nature of the solvent, i.e. are related to the different rigidities of the maxtrix[109].

(*c*) *Compounds containing functional groups.* In the reactions of hydrogen atoms with alcohols the main process is the abstraction of hydrogen from the carbon atom in the α-position relative to the OH group and the subsequent formation of alkanes and aldehydes[110–112]:

$$H + CH_3OH \rightarrow H_2 + \dot{C}H_2OH \xrightarrow{H} \dot{C}H_3 + OH \ ;$$

$$H + CH_3CH_2OH \begin{cases} \rightarrow H_2O + C_2H_5 \xrightarrow{H} C_2H_6^* \rightarrow 2CH_3 \begin{cases} \rightarrow C_2H_6 \\ \xrightarrow{H} CH_4 \end{cases} ; \\ \rightarrow CH_3\dot{C}HOH + H_2 \begin{cases} \xrightarrow{H} CH_3CHO \\ \xrightarrow{H} CH_3\dot{C}H \rightarrow C_2H_4 \end{cases} ; \end{cases}$$

$$H(D) + CH_2{=}CHCH_2OH \rightarrow CH_2{=}C\dot{H}CHOH + H_2\ (HD) \ .$$

t-Butyl alcohol, where the abstraction of the OH group is the dominant process, constitutes an exception. The rate constants for the primary reactions are presented in Table 1. The secondary reactions are determined by the nature of the radical obtained. Thus the addition reaction with formation of propanol and propionaldehyde predominates for allyl alcohol.

Table 1. The rate constants for the reactions of hydrogen atoms with aliphatic alcohols [$k = A \exp(E/RT)$].

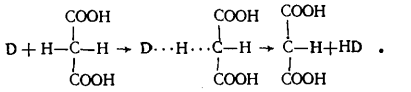
Alcohol	A, $cm^3\ s^{-1}\ mol^{-1}$	E, cal mol^{-1}	References
CH_3OH	$6.5 \cdot 10^{12}$	5440±150	[110]
	$1.3 \cdot 10^{13}$	5260	[212]
C_2H_5OH	$(4.2 \pm 0.4) \cdot 10^{19}$	4200±300	[112]
$(CH_3)_3COH$	$(4.0 \pm 0.4) \cdot 10^{13}$	8200±650	[112]

The mechanism of the reaction of hydrogen atoms with dimethyl ether has been published[110]:

$$H + CH_3OCH_3 \rightarrow \dot{C}H_2OCH_3 + H_2$$

$$CH_3OCH_3^* \xrightarrow{H} \rightarrow \dot{C}H_3 + \dot{O}CH_3 \begin{cases} \rightarrow CH_2O + H_2 \\ \rightarrow \dot{C}H_3 + OH \end{cases} .$$

According to the authors, the identity of the activation energies for this reaction and the reaction of atomic hydrogen with CH_3OH indicates the similarity of the mechanisms of these processes.



A characteristic reaction of hydrogen atoms with nitrocompounds (nitromethane, nitrobenzene, nitroethylene, and nitroisopropene) is the addition of a hydrogen atom to the nitro-group.

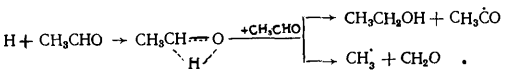
$$H + R{-}N\begin{matrix}O\\O\end{matrix} \rightarrow R{-}\dot{N}\begin{matrix}O\\OH\end{matrix} \ ,$$

which is a more effective hydrogen atom acceptor than the benzene ring and the C=C bond[113]. The NCO and NCS groups also effectively capture hydrogen atoms and the mode of reaction in this instance depends significantly on the nature and position of the subsequent substituent (if such exists) relative to the NCO (NCS) group. Thus a hydrogen atom adds to the benzene ring of phenyl isocyanate, but, after the introduction of a second functional group into the latter (CH_3, NO_2, $OCNC_6H_4CH_2$), the double bond of the NCO or NO_2 groups is attacked[113], since the second substituent alters significantly the distribution of electron density in the molecule.

When malonic and methylmalonic acids react with thermal hydrogen atoms, the C–H bond is ruptured, the dissociation of a carbon–carbon bond is not observed[114,115], and the

hydrogen atom of the methylene group is abstracted:

A similar reaction is characteristic also of malonamides.



If the initial acid contains double bonds, the latter are hydrogenated. For example, it has been observed that the main process in the reaction involving oleic acid[116] is the formation of stearic acid and the ratio of the contributions of the addition and substitution reactions was approximately 2.6.

The reaction of atomic hydrogen with aldehydes proceeds in the same way as for carboxylic acids, i.e. involves the abstraction of a methylene hydrogen atom, which leads to the formation of keten, methane, ethane, and carbon monoxide[117]:

$$\begin{gathered}
H + CH_3CHO \xrightarrow{k_1} CH_3\dot{C}O + H_2 \ , \\
CH_3\dot{C}O + H \begin{cases} \xrightarrow{k_2} CH_3 + CHO \\ \xrightarrow{k_3} CH_2CO + H_2 \end{cases} , \\
CHO + H \rightarrow CO + H_2 \ , \\
H + CH_3 + A \rightarrow CH_4 + A \ , \\
2CH_3 \rightarrow C_2H_6 \ , \\
H + CH_2CO \rightarrow CH_3 + CO \ ,
\end{gathered}$$

where $k_2/k_3 \cong 4.7$ and $k_1 = (2.6 \pm 0.2) \times 10^{12} \exp(-2600/RT)$ is close to the corresponding rate constant for the reaction of atomic hydrogen with methanol.

Virtually none of the communications concerning the action of atomic hydrogen on compounds containing the carbonyl group provides information about the addition of hydrogen atoms to the C=O bond. An impression has been created that the C=O bond differs so much from the C=C bond that the addition reaction is impossible. Only recently[118], in a study of the reactions between atomic hydrogen and acetaldehyde, was ethanol detected as the reduction product. To account for its formation, the authors[118] proposed the following mechanism:

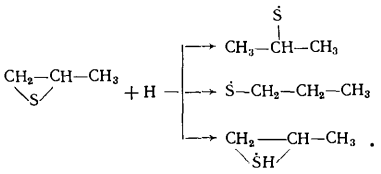
The excess energy evolved in the addition of hydrogen (21 kcal mol^{-1}) is sufficient for the occurrence of the above reactions.

When tritium atoms act on $C_5H_{11}X$ (X = SH, NH_2, OH, or COOH) at 77 K, pentane is formed, whose tritium content is correlated with the bond energies of the substituents[119].

(d) Aromatic and Heterocyclic compounds. When thermal hydrogen atoms react with aromatic compounds, the main reaction is the addition of a hydrogen atom to the benzene ring with formation of radicals of the cyclohexadienyl type[120]. Such reactions have been observed for a large number of substances[121-127], but in many instances the competitive abstraction of a hydrogen atom from the substituent or its addition to the C=C bond of the side chain takes place. For halogenotoluenes, the rate constant for the abstraction of a benzyl hydrogen atom is close to the value determined by diffusion[128].

The rates of abstraction reactions involving mesitylene, tetralin, phenylcyclohexane, and thiophenol are comparable to the rate of addition to the benzene ring and, in the case of phenol and benzyl alcohol, the abstraction of the OH group takes place together with addition to the benzene ring:

$$R{-}OH + H \rightarrow R^{\cdot} + H_2O \ .$$



The difference between the activation energies for the abstraction and addition reactions is 0.5 kcal mol^{-1}.[129] For aniline and benzyl chloride, the abstraction reactions are the main processes, while in the case of nitrobenzene and nitrosobenzene the reactions involving addition to the ring are not observed at all. Hydrogen atoms add almost completely to the N=O bond.[123]

When hydrogen atoms attack the side group, π-electron radicals are formed in which there is resonance interaction, according to EPR data, of the unshared electron with the π-electron system of the ring (phenol, which gives rise to σ-radicals, is an exception).

The kinetics of the accumulation of radicals are described satisfactorily in this case by a model taking into account the diffusion of hydrogen atoms from the gas phase to the solid phase and the occurrence of a first-order chemical reaction[97]. The low rate of accumulation of radicals observed for a series of substituted benzenes (amines and alcohols) compared with benzene is apparently associated with the fact that in these substances the diffusion coefficient of hydrogen atoms is low owing to the presence of hydrogen bonds[130].

When tritium atoms react with benzene at 77 K, ≤5% of the labelled parent compound is formed, while the remaining products are hydrogenation products, mainly [^{3}H] cyclohexene, which indicates a low rate of the disproportionation reaction[131]. Under the same conditions, considerable amounts of [^{3}H] toluene are formed from toluene[132]. In the reactions with benzene derivatives there is a possibility of the substitution of functional groups[133].

For heteroaromatic compounds, the same processes have been observed as for aromatic systems, i.e. the addition of a hydrogen atom to the unsaturated bonds in the ring[134]. For certain sulphur compounds, for example, methylthiiran, the addition of a hydrogen atom to the sulphur heteroatom has been observed[135]:

In the general case the dissociation of the C–H bond in the α-position relative to the heteroatom is characteristic of saturated heterocyclic compounds[126,135].

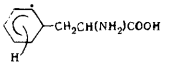
(e) Polymers. Substances of this class react with hydrogen atoms either with abstraction of hydrogen from the saturated molecules or via addition to the benzene ring, for example, in polystyrene[136], polymethylstyrene, and poly(ethylene terephthalate)[137,138]. Data for radicals detected by EPR in high-molecular-weight compounds have been examined in detail in two studies[139,140].

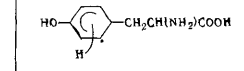
The activation energies for the abstraction of a hydrogen atom from the main polymer chain are, for example 2 and 1.2 kcal mol^{-1} for the reactions involving polyisobutylene and poly(ethylene oxide) respectively at 100–150 K and the temperature dependence of the rate constants does not obey the Arrhenius law[134]. These facts were explained by the considerable contribution of the tunnel transfer of hydrogen atoms to the rate of the process[141].

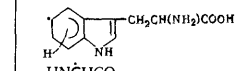
(f) Biologically active substances. The interaction of hydrogen atoms with biologically active compounds has been little studied. Moser and coworkers[75] were the first to obtain labelled sucrose, glucose, and starch by acting on frozen targets with "heated" tritium atoms. The reaction is believed to proceed in two stages: with abstraction of a hydrogen atom and subsequent recombination with a tritium atom. The same method has been used to obtain [^{3}H] alanine[142] and [^{3}H] ribonuclease[143] with a fairly high specific activity. Tritium-labelled adrenocorticotropin[144], morphine[145], and valine[116] with specific activities of 15, 2.7, and 3 mc mmol^{-1} respectively and certain peptides[146] have been obtained under the conditions of a microwave discharge. [^{3}H] ribonuclease with a specific activity of 1.5–3.5 mc mmol^{-1} has been obtained under conditions where tritium atoms were generated in a silent electric discharge[147]. A high specific activity of biologically active compounds can be achieved using an arc discharge[148].

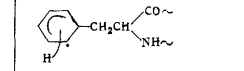
The complexity of the study of the mechanism of the interaction of hydrogen atoms with biological objects consists primarily in the presence in the latter of numerous functional groups and also of secondary and tertiary structures in proteins. The steric factor plays here a significant role and the conclusion that such reactions occur on the surfaces of large molecules is particularly important in this connection[75, 115].

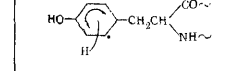
The formation of radicals from aminoacids (Table 2) is associated, as usual, with abstraction of hydrogen atoms from saturated molecules and their addition to unsaturated and aromatic molecules. However, the hydrogenation of aromatic bonds in the ring is negligible for phenylalanine[116], although radicals of the cyclohexadienyl type have been detected in reactions of atomic hydrogen with aromatic aminoacids (phenylalanine, tyrosine, and tryptophan)[149]. For proline, ring opening has been noted[150]. Furthermore, there is a possibility of deamination (and decarboxylation) processes associated with the addition of hydrogen atoms to the amino-group[142] (or with formation of radicals of the type $R-\dot{C}(=O^-)-OH$, which can be stabilised by protonation[151]).

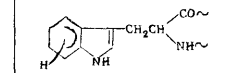


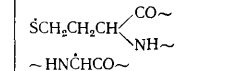


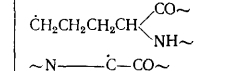


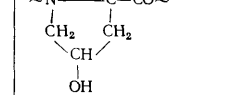


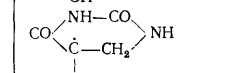












The action of hydrogen atoms on the peptide bond, leading to the formation of molecular fragments with a lower molecular weight, is important for polyaminoacids. The presence of aromatic aminoacid molecules in the chain leads to a greater stability of the polypeptide[152].

An important but little investigated process is the intramolecular distribution of tritium in labelled molecules obtained on treatment with tritium atoms. The α-, β-, and γ-positions in [^{3}H] valine contain 7.1, 32.7, and 60.2% of tritium respectively[116]. The predominant concentration of tritium in the β-position has also been observed in labelled L-isoleucine and L-alloleucine[152], which is due to differences between the bond energies and the activation energies for the abstraction of hydrogen from different positions in the molecule. In the cleavage of [^{3}H] ribonuclease[147] into individual aminoacids, the greatest proportion of tritium was found in methionine, glycine, and histidine, while the tritium content in threonine, serine, and arginine proved to be insignificant.

Apart from labelled parent compounds, products resulting from deamination, carboxylation, and the abstraction of the OH group, with a high specific activity, have been detected in the interaction of tritium atoms (0–0.2 eV), obtained by the thermal dissociation method, with aromatic aminoacids (tyrosine and phenylalanine)[154].

Tritium atoms with an average energy of approximately 0.02 eV mainly abstract hydrogen atoms from the β-position in the side chains of phenylalanine and tyrosine[155,156] which agrees qualitatively with calculations by the MO method[157,158].

In the temperature range 30–200 K tritium atoms also react with aminoacids and the experimental activation energies for these reactions are close to zero and below 60 K the limit of the chemical reaction rate is reached[156,159]. This makes it possible to suggest the occurrence of tunnel reactions and to estimate the parameters of the barrier. The probabilities of reactions involving the abstraction of hydrogen from different aminoacids by tritium atoms at 300 K have been compared[160] with the reactivity indices—the boundary electron density and delocalisability, a satisfactory qualitative agreement being found.

III. REACTIONS OF "HOT" HYDROGEN ATOMS

1. Models of Chemical Reactions Involving "Hot" Hydrogen Atoms

Theoretical studies of the reactions of atoms having an excess of kinetic energy have developed in two directions. On the one hand, attempts have been made to relate the yields of reactions to the characteristics of the moderation process and on the other it was endeavoured to understand the details of the mechanism of the elementary chemical reaction under the conditions of high energy.

In Eqn.(1) the probability of the reaction $p(E)$ can be represented by the relation

$$p(E)=\sigma_r(E)/[\sigma_r(E)+\sigma_n(E)],$$

where $\sigma_r(E)$ is the "reaction" collision cross-section, i.e. the cross-section of the collision leading to reaction, and $\sigma_n(E)$ is the cross-section of the "non-reaction" collision in which the "hot" atom loses energy without entering into a reaction with formation of a stable product. The main efforts were concentrated on the search for an analytical expression for $n(E,E')$. Thus Estrup and Wolfgang[161] used the ideas of the physics of the moderation of neutrons, from which it followed that, for neutral species generated with $E \gg E_2$ (E_2 is the "upper limit" to the occurrence of chemical reactions), the energy spectrum of the species can be described by the Fermi function

$$n(E, E')\,dE'=n(E')\,dE'=dE'/\alpha E',$$

where α is the average loss of energy determined as the retardation coefficient for two consecutive collisions: $E_{i+1}=E_iE^{-\alpha}$. An expression for α can be obtained by specifying the moderation mechanism. Since the form of the function $p(E)$ is not clear, the parameter

$$I=\int_0^\infty p(E)\,dE,$$

called the integral reaction probability, was introduced[162].

Using the concepts enumerated above, an expression was obtained for the yield of the reaction:

$$R=1-\exp\left(-\frac{f}{\alpha}I\right),$$

which is at present widely used in the chemistry of "hot" atoms (f is the geometrical probability of the collision calculated from the mole fractions of the substances and the covalent atomic radii). Subsequently the equation was supplemented by corrections for the influence of added substances and for the phenomenon of the "combustion" of the species in the course of the reaction[163]. The Wolfgang equation agrees satisfactorily with experiment, i.e. a relation of the type

$$-\ln(1-R)=\frac{f}{\alpha}I$$

persists when the ratio f/α is varied within wide limits.

The ratio f/α has been calculated from the experimental conditions and the efficiency of moderation. The quantity I has been determined graphically. The integral probabilities of many reactions of "hot" ^3H atoms have been found in this way. Thus $I=0.1$ for the reaction $^3H+CH_4 \rightarrow CH_3^3H+H$, i.e. approximately one of ten collisions leads to reaction[161]. The possibility of using the ideas of the physics of the moderation and reactions of neutrons for chemical reactions proved to be fruitful, because it was possible to replace the reaction cross-section by the integral probability and the moderation process by a simple collision model.

The Wolfgang equation holds better the higher the initial energy of the atoms and the smaller the influence of non-elastic collisions. In studies since 1969 α has been calculated on the basis of a retardation scheme for rigid spheres. Subsequently account was taken in the moderation model of the possibility of "soft" collisions and it was found that the reaction yield should increase for a "softer" potential[164]. After taking into account the scattering anisotropy, it was shown that α decreases under these conditions, but the form of the collision density function remains unaltered[165].

The models examined are valid for energy ranges remote from the energy of the source of "hot" atoms, i.e. $E \ll E_0$ (but $E_0 \gg E_2$)[166]. In the theory developed by Porter[167-169] these limitations were removed by solving the equation for the reaction probability as a function of energy; account was also taken of the thermal movement of the target species. Porter's equation for the yield of the reaction with formation of the ith product is

$$R_i(E)=p_i(E)+\left[1-\sum_j p_j(E)\right]\int_0^\infty R_i(E')\,W(E, E')\,dE', \qquad (5)$$

where $p_i(E)$ is the probability of the formation of the product in the first collision, $[1-\sum_j p_j(E)]$ the probability of avoiding reactions with formation of all the products, $W(E,E')$ the probability of a change in the energy of the atom ($E \rightarrow E'$) in a non-reactive collision, and $p_i(E')$ the probability of the reaction in the collision of reactants with $E=E'$. Porter derived Eqn.(5) by a rigorous mathematical procedure, although it can be formulated on the basis of the most general intuitive considerations. An analytical solution of this equation is possible on the assumption of a simple moderation model, namely collisions of the bard sphere type[170].

Thomsen[171] treated the reactions differently. His formulation of the problem differs by the fact that, instead of seeking a solution for the stationary distribution of "hot" atoms, he suggested that one determine the probability of the reaction for an individual atom in the course of its moderation. The moderation process was then modelled as a continuous process.

Theoretical studies have shown that the atomic spectrum depends greatly on the properties of the medium. It was concluded that the probabilities of the reactions of "hot" atoms with different substances should be compared by studying experimentally the yields of reactions in the presence of a moderating substance. Naturally the inert gases were chosen for this purpose. Different variants of stochastic methods began to be used for quantitative estimates. In particular, the collision densities at different temperatures of the gas medium have been calculated for ^3H atoms with "intermediate" energies (0.5–2 eV) and for three potentials (the solid sphere, Lennard–Jones, and $1/r^6$ potentials). It was shown that, for an energy of the source of 0.5 eV, oscillations in collision density are observed, which had been predicted theoretically for the moderation of neutrons[172], and for $E < 0.5$ eV a rapid approach to the collision density corresponding to the $1/E$ spectrum is observed. The influence of temperature is manifested by the fact that, in the energy distribution spectrum of the species, a "tail" appears in the high-energy region for $E > 0.5$ eV.[173]

Subsequently a stationary model of the moderation of "hot" species was proposed in which a Maxwell distribution of "hot" atoms with an average temperature $T_R(t)$, depending on the time elapsed from the instant of generation of the atoms, was assumed[174]. A stationary state obtains when $dT_R(t)/dt=0$. An analytical solution of the Boltzmann equation for the transport of the species is then possible, and the final expression is similar to the Arrhenius equation.

The condition for the attainment of a stationary state up to the instant when chemical reactions begin to occur to an appreciable extent is very important for the application of this model. However, it has been established by the Monte Carlo method that the stationary states do not obtain a retardation[175,176]. A study was therefore undertaken with the aim of a more accurate solution of the Boltzmann equation and a clear-cut framework has been found for the application of the proposed theory: the time scales in the description of the moderation processes and the reactions must be separated[177]. Conditions have been established under which the solution of the Boltzmann equation satisfies the calculations by the Monte Carlo method or agrees with the distribution of the species with respect to velocities corresponding to a Maxwell distribution at an effective temperature[178].

The transfer of the ideas of nuclear physics to moderation and the reactions of chemical species proved so productive that investigators were inspired to consider more far-reaching analogies between chemical and nuclear reactions. The description of resonance reactions involving neutrons is widely used in nuclear physics. The Breit–Wigner formula relates the reaction cross-section to the resonance parameters. It has been suggested that resonance scattering cross-sections and reactions involving a polyatomic molecule correspond to the resonance cross-section for the scattering of the "hot" atom by the attacked atom in the molecule and the case where the cross-sections for the reactive and non-reactive collisions of the "hot" atom with a molecule involve only one Breit–Wigner resonance was examined[37].

These qualitative ideas required a rigorous mathematical justification, which was subsequently provided[38]. The following expression has been obtained for the yield of the "hot" reaction:

$$R \propto \Gamma/\beta ,$$

where Γ is the width of the resonance, $\beta = \mu'/(\mu' + m)$ the "isotope" factor associated with the masses of the interacting atoms and characterising the degree of localisation of the "hot" reaction, μ' the mass of the part of the molecule involved in the formation of the resonance state, and m the mass of the "hot" atom. The authors[38] believe that the similarity of the mass μ' to the mass of the attacked atom (μ' was calculated from the isotope effect in the reactions involving the abstraction of hydrogen by "hot" tritium atoms) constitutes significant evidence for the occurrence of resonance in the reaction. The value of the proposed interpretation of the mechanism of "hot" reactions consists in the fact that, within the framework of the theory, one can find an explanation of the marked influence of the electronic structure of the molecules and of the difference between the bond energies on the yield of the reaction—a fact which is well known in the chemistry of "hot" species[179–181].

We shall consider the achievements of the theoretical studies in the chemistry of "hot" atoms in relation to two reactions, namely $H + H_2 \rightarrow H_2 + H$ and $H + CH_4 \rightarrow CH_3 + H_2$, and also substitution reactions of the type $^3H + CH_4 \rightarrow CH_3{}^3H + H$.

2. The $H + H_2 \rightarrow H_2 + H$ Reaction and Its Isotopic Variants

The ratio of the integral probabilities of the reactions of "hot" recoil atoms, i.e.

$$^3H + HD \begin{cases} \rightarrow H^3H + D \\ \rightarrow D^3H + H , \end{cases}$$

has been calculated[170] as $I_{H^3H}/I_{D^3H} = 0.62 \pm 0.06$; the corresponding value, calculated in another study[182] from the results of trajectory calculations, proved to be 0.7 ± 0.1.

For the reactions $^3H + H_2 \rightarrow H^3H + H$ and $^3H + D_2 \rightarrow D^3H + D$, experiment yielded $I_{H^3H}/I_{D^3H} = 1.14 \pm 0.06$, while the calculated value is 1.18 ± 0.05. Since a satisfactory agreement has been observed between the calculated and experimental data, it is reasonable to consider in greater detail the essential features of the calculations yielding valuable information about the details of the reaction mechanisms.

The potential surface for a reaction of the type $A + BC \rightarrow$ was constructed[182] on the basis of the Morse function taking into account the energy levels obtained in the solution of the secular equation and neglecting overlap (the Hückel method)[182]:

$$U = E_1 + E_2 + \sum_{ij} H_{ij};\ H_{ij} = -D_{ij} \exp\left[-\beta_{ij}(r_{ij} - r_{0ij})\right] ,$$

where D_{ij} is the dissociation energy, β_{ij} the Morse constant, and r_{0ij} the equilibrium distance. The usual procedure was used in the subsequent calculations. It was found that, for low energies of the ^3H atoms (approximately 10 eV), the reaction cross-sections are a maximum for attack along the H–H (H–D, D–D) bond. For energies of approximately 35 eV, the cross-section is a maximum when attack takes place at right-angles to the H–H bond. This collision, leading to the abstraction of an atom (the "stripping" mechanism), is related to the "spectator" model: the process takes place in such a way that one atom is assumed to be abstracted, while another behaves as a passive witness of the event. On further increase of E to approximately 100 eV, the cross-section shifts towards collision angles $>\pi/2$, which indicates back-scattering of the reaction product ("rebound stripping"). In this process the third atom is a partner in the removal of the excess energy transferred by the "hot" atom on collision. The product molecule, formed as a result of this process, has a lower energy than the molecule obtained via the "spectator" mechanism (for the same collision energy).

Detailed calculations for reactions of the type

$$^3H + HD \begin{cases} \rightarrow H^3H + D \\ \rightarrow D^3H + H \\ \rightarrow {}^3H + D + H \end{cases} \qquad (6)$$

have been made recently[170] by the trajectory method up to $E_H = 60$ eV and cross-sections [including the cross-section of reactions (6)] and the integral probabilities of reactions have been obtained taking into account the contribution of non-elastic collisions to the atom moderation spectrum. It was found that the calculated ratio $I_{H^3H}/I_{D^3H} = 0.7$ agrees fairly well with the results of calculations based on simpler mechanisms (collision of the solid sphere type) and with experiment only in the region of low energies (of the order of several eV). For ^3H atoms with $E = 60$ eV, the calculated ratio $I_{H^3H}/I_{D^3H} = 1.8$, which is greater than the experimental value (for "hot" recoil atoms) and the value calculated on the basis of a simpler model (0.8). According to the authors[170], the reason for this discrepancy consists in the fact that their model is based on the assumption of a small role of secondary dissociation reactions of the H^3H and ^3HD molecules. The agreement between the calculations based on the simple model and experiment is apparently attained as a result of the superposition of two errors—associated with the use of an incorrect function for the energy distribution of atoms (its calculation was based on the assumption of a moderation mechanism in accordance with the law governing hard sphere collisions) and the neglect of secondary dissociation.

Thus an exact description of the mechanism of even the simplest reactions is still not available, although there is no doubt that computational methods involving computers have thrown much light on it.

3. The Reaction $H + CH_4 \rightarrow H_2 + CH_3$ and Its Isotopic Variants

The abstraction reaction involving thermal hydrogen atoms is well known. For "hot" H*, D*, and ^3H* atoms, obtained by photolysis or via a nuclear reaction, channels other than the abstraction reaction

$$^3H + CH_4 \rightarrow CH_3 + H^3H, \quad (7)$$

have been discovered, namely

$$^3H + CH_4 \rightarrow CH_3{}^3H + H, \quad (8)$$

$$^3H + CH_4 \rightarrow CH_3 + H + {}^3H, \quad (9)$$
$$^3H + CH_4 \rightarrow CH_2{}^3H + 2H.$$

The calculation thresholds for the abstraction and substitution reactions, equal to 0.66 and 1.54 eV,[183] agree with experimental values of 0.3 and 1.5 eV.[8,184,185]. Experiments with $CH_4 + CD_4$ mixtures showed that $(H^3H/CH_4) : (H^3H/CD_4) = 1.4$, i.e. that CD_4 is somewhat less reactive in the abstraction reaction than CH_4. The ratio $(CH_3{}^3H/CH_4) : (CD_3{}^3H/CD_4) = 6.9$ shows that CD_4 is significantly less reactive in the substitution reaction than CH_4.[186]

In the first trajectory studies the CH_3 group was approximated by a structureless unit with a mass of 15 and the LEPS potential was adopted as the potential energy surface[187]. It was found that the abstraction and substitution reactions are of the "direct" and "concerted" type, i.e. they proceed without the formation of a long-lived complex: the length of the bond dissociated increases monotonically with the simultaneous formation of a new bond. This process is apparently valid for $E \cong 1.5$–2 eV. For a higher energy (~10–15 eV), abstraction again predominates, but the mechanism is in this instance different—this is a "stripping" reaction. Since the CH_3 group has been represented by a single species, the problem of the details of the mechanism (whether or not the Walden inversion occurs) was not discussed in the above investigation[187].

Certain theoretical evidence for the mechanism of the Walden inversion has been obtained by considering the movements of all the atoms in the reaction between H and CH_4 along an empirical potential surface (no account was then taken of the interaction between the displaced H atom and the other three hydrogen atoms)[188,189]. The threshold of the abstraction reaction has been estimated as 0.4 eV and the cross-section is a maximum ($3.5\ Å^2$) for 2.7 eV. The authors showed that the calculated ratio of the probabilities of reactions (8) and (7) is not 0.25, as was observed in the experiments. Since it was assumed in the calculations that there is no Walden inversion, the above discrepancy throws doubt on the validity of this assumption.

In subsequent studies this limitation in the interaction between atoms was abandoned and all the hydrogen atoms began to be regarded as equivalent. It was shown[190] that the substitution of hydrogen and deuterium in the reaction between ^3H and CH_2D_2 involving the Walden inversion must be equally probable, which agrees with experimental results[9,186]. However, the calculations were performed using data for the reactions of tritium atoms with CH_4 and CD_4, i.e. semiempirically. These studies were followed by a series of investigations by MO methods in terms of various approximations, which yielded contradictory information about the role of the Walden inversion in the reaction mechanism[191,192].

The most detailed study has been made by Raff[82], who calculated the minimum on the CH_5 potential energy surface and calculated the cross-sections by the method of trajectories. It was found that the threshold of the abstraction reaction corresponds to 0.25 eV, while that of the substitution reaction corresponds to 1.5–1.6 eV. The cross-section of the abstraction reaction is a maximum at 1.5 eV and that of the substitution reaction is a maximum at 6 eV. The fragmentation process (9) begins according to these calculations at $E \cong 5$ eV and reaches a maximum at 10 eV, its probability decreasing slowly up to 40 eV. In the substitution reactions there is not more than 50% inversion, i.e. the Walden inversion does not constitute the only reaction mechanism. This conclusion was reached after considering the ^3H–C–H angles in trajectory studies of substitution reactions. In order to compare the results of the calculations with the results of experiments carried out previously for recoil atoms, Raff used Porter's equation for a stationary target[167] in conjunction with his own data obtained from trajectory studies. The limit of the ratio $H^3H/CH_3{}^3H$ (for high values of E), equal to 0.79, proved to be in excellent agreement with Wolfgang's experimental data for recoil atoms[18]. The ratio $CD_3{}^3H/D^3H$ proved to be somewhat smaller than the experimental value. Agreement with experimental data has not been achieved for photolytic atoms ($E \cong 2.8$ eV): calculation yielded $H^3H/CH_3{}^3H = 8.7$, while the experimental value is ~4. This may be because the Walden inversion mechanism plays a major role for a low energy.

4. Abstraction Reactions and the Influence of the Bond Energy on Their Yield

In the chemistry of "hot" tritium atoms the influence on the abstraction reaction of a small change in the bond energy E_b of the abstracted atom is well known[9,180] and the cause of this phenomenon has been the subject of discussions[17,162,179–181,193]. According to one concept, the influence of the bond energy is seen when an intermediate collision complex is formed, while according to another this happens when the abstraction reaction proceeds via a "stripping" mechanism analogous to the familiar mechanism of nuclear reactions. The fact that the bond energy must influence the probability of the abstraction reaction when a collision complex is formed is so evident that it does not require elucidation. However, numerous data have shown that the reactions of "hot" atoms proceed via a "direct" mechanism. Therefore this explanation is not satisfactory.

The "stripping" mechanism explains the dependence of the abstraction cross-sections on the bond energy by the fact that the lower the value of E_b the greater the target distance over which an atom can be "stripped off", i.e. for the same reaction time the process can occur with a higher energy of the "hot" atom. Hence one may conclude that the excitation function for a chemical abstraction reaction $\sigma_{abs}(E)$ is determined over a wider energy range than the function for the substitution reaction $\sigma_{subs}(E)$, where the role of the bond energy is manifested to a much smaller extent. There is little information in the literature about the experimental measurement of the $\sigma_{abs}(E)$ and $\sigma_{subs}(E)$ relations over a wide energy range. Calculations by the method of trajectories using semiempirical potential energy surfaces have shown that the bond energy influences the cross-section for the abstraction reaction by altering the height of the barrier (confirmation of the Semenov–Polanyi rule). We may note yet another important factor, which follows from these calculations: for a lower barrier, the reaction takes place over longer target distances; for a high barrier (approximately

0.5 eV), the probability of the reaction diminishes with increase of the impact parameter and for a low barrier (approximately 0.2 eV) there is a probability maximum. Hence it follows that the conclusion concerning the dynamics of the abstraction reaction treated as a "stripping" process has been confirmed by trajectory calculations[179]

5. Substitution Reactions

Substitution reactions of the type $RX + H^* \rightarrow RH + X$ (X = H, etc), which are not observed in thermal chemistry, have aroused the greatest interest. It has been established that such a reaction results in the formation of vibrationally excited molecules, which decompose at low pressures. In the theoretical calculations of the yield of substitution reactions corrections are introduced for decomposition based on the ratio of the energy converted on collision into the internal energy of the molecules and the dissociation energy. The dependence on pressure and the concentration of other species is obtained experimentally and the contribution of the decomposition process is estimated. For the reactions of recoil tritium atoms with CH_3X (X = F, Cl, Br, or H), the observed yields of the product $CH_2{}^3HX$ were 58 ± 2, 40 ± 2, 33 ± 3, and 83 ± 3% respectively and the values corrected for decomposition (primary yields) were 64 ± 3, 75 ± 3, 78 ± 5, and 100 ± 5% relative to the yield of cyclo-$C_4H_9{}^3H$ formed from cyclo-C_4H_{10} used as a standard.

The results agree with the "impact" model[194]: the greater the radius of the shielding atom, the lower the yield of the hydrogen substitution reaction. However, conclusions corrected for decomposition indicate the opposite relation. Apparently the description of the substitution process adopted previously, in which account was taken only of the physical characteristics of the system—the masses of the atoms, their dimensions, the bond angles, and the angles of attack—is inadequate. More far-reaching driving forces were manifested in the substitution reaction, for example, the mutual influence of the atoms in the molecule on the reactivity of the "hot" atoms. The concept of the decisive influence of the electronegativity of the substituents on the hydrogen substitution process has been put forward[193]. The probability of the substitution of hydrogen depends on the electron density in the C–H bond: in CH_3F it is a minimum, which leads to the lowest yield of the substitution reaction. The yields of substitution reactions of the atoms X are 4.4, 7.1, 12.0. and 7.7%, which agrees with the changes in the C–X bond energy and not in the collision diameters, as was assumed previously on the basis of the collision model.

Certain details of the substitution processes become more understandable when isotope effects are investigated[9,186,190,193,195]. It has been found that the isotope effect in the substitution of H and D by ^3H is 1.30 ± 0.03 for different compounds. Initially this was attributed to differences between the retarding capacities of substances, which induce changes in the frequency of the collisions of "hot" atoms with molecules. However, for substances such as $(CH_3)_3CH$ and $(CH_3)_3CD$, $(CD_3)_3CH$, and $(CD_3)_3CD$, the isotope effects proved to be identical. Furthermore, the isotope effect in the substitution of fluorine in CH_3F and CD_3F is 1.4 ± 0.05.[196] Thus the isotope effect is manifested not only in the first stage of the process (the dislodgement of an atom), but also in the second stage involving the formation of a bond with the molecular residue. The formation of a bond in the substitution reaction obeys the "inertial" mechanism: the lighter the residue, the higher the rate of formation of a bond[194].

It would be very interesting to investigate the isotope effects in CH_2D_2: if the direct substitution process, i.e. the dislodgement of an atom, plays the main role, the isotope effect should be approximately 1.3, while in the case where the second stage (bond formation) is important, the yield of the substitution of deuterium should be approximately 10% higher by virtue of the "inertial" mechanism[17]. The technical difficulties in the separation of CH_2D^3H and CH^3HD_2 have now been overcome and it has been shown that their yields are identical, which demonstrates that both mechanisms operate, acting in opposite directions. The isotope effect for atoms with a lower energy is much greater: thus the ratio $(CH_3{}^3H/CH_4) : (CD_3{}^3H/CD_4)$ proved to be approximately 7 for ^3H atoms with $E = 2.8$ eV in the $CH_4 + CD_4$ mixture, the values for CH_3D and CH_2D_2 being 2.4 and 1.0. The overall yield of the substitution reaction falls with increase of the number of deuterium atoms in the molecule. The probability of the substitution reaction for an H atom is 1.6 ± 0.2 times greater than for a D atom regardless of whether the atom is substituted or remains in the residual radical, i.e. the two-stage mechanism of the substitution process has been confirmed[9].

The experimental threshold energy of the substitution of hydrogen in hydrocarbons by its isotopes is 1.5 eV.[184,186] For the substitution of hydrogen in 1-chlorobutane by ^3H atoms accelerated in a "chemical" accelerator, $E_{thresh} = 1.2$ eV has been obtained with a maximum reaction cross-section at 8 eV.[196] The threshold energy of the substitution of H by ^3H agrees with Eyring's theoretical estimate[197] for the substitution of H by D in CH_4, based on the assumption of an inversion mechanism. This was confirmed by certain subsequent investigations[190–191], but in others it was pointed out that a threshold energy of the substitution process of approximately 1.6 eV is obtained if the extent of inversion is not greater than 50%.[82] For bulky substituents in methane, the conservation of the initial configuration in substitution reactions has been demonstrated for a fairly large number of examples. This provided Wolfgang with justification to formulate, by analogy with the familiar Franck–Condon principle, the "golden rule of hot chemistry": "If the time required for the migration of atoms (with formation of a given reaction product) is greater than the collision time, the reaction is forbidden".[194]

One of the interesting features of the substitution reaction is the formation of excited molecules. The problem arises whether the energy is distributed among the degrees of freedom in such molecules before decomposition or before deactivation. Studies have shown that, as a result of the substitution of an H atom by a recoil ^3H atom, the molecules are vibrationally excited up to an energy of 5 eV, [16] and the hypothesis of a statistical distribution of energy proves to be valid. Indeed, according to the unimolecular decomposition theory[198], the probability of the decomposition is proportional to the energy excess over E_a:

$$k \simeq A[(E - E_a)/E]^{s-1},$$

where $s = \frac{1}{2}(3N-6)$ and N is the number of atoms in the molecule involved in the process. The probability of decomposition can be estimated from the yields of products and E_a is known from the "usual" chemistry. $E \cong 5$ eV have been calculated for the reactions of ^3H with cyclobutane[199] and methylcyclohexene[198]. In this case, the reaction mechanism is simple:

In a later study it was established that the reaction products can be obtained not only via unimolecular decomposition but also via a direct substitution reaction[200], i.e. after the substitution of H by ^3H the molecule can decompose until the

collision energy is uniformly distributed among all the vibrational degrees of freedom. This process can be described as a reaction involving the direct substitution of a group of atoms.

6. Addition Reactions

The reactions involving the addition of thermal hydrogen atoms to double bonds are accompanied by the liberation of a vibrational energy of approximately 30 kcal mol^{-1}. Some investigators have been interested in the possibility of obtaining superexcited radicals by the addition of "hot" atoms. In a series of studies[12,201], performed using photochemical atoms with $E = 1.8$ eV, the formation of such radicals was demonstrated by comparing the rate coefficients for the characteristic reactions of the radicals—the abstraction of hydrogen and recombination.

According to the Arrhenius equation, the probability of the reaction should approach the value of the steric factor as the interaction energy of the species increases. However, it has been shown in a number of investigations that the steric factors for the addition of hydrogen to ethylene increase by three orders of magnitude on passing from the thermal energy of hydrogen atoms, corresponding to room temperature, to 6 eV.[12] An analogous behaviour has been observed for the recoil tritium atoms in a cyclohexane-cyclohexene mixture[202]: the ratio of the rate coefficients for the abstraction and addition reactions was 0.34 ± 0.01, which exceeds by a factor of 100 the corresponding ratio for thermal atoms and by a factor of 5–20 the ratio of hydrogen atoms obtained in radiolysis under the influence of radiations of different types. The fraction of "hot" hydrogen atoms in the overall yield of hydrogen atoms in radiolysis (<15%) has been estimated from the data of Kukin and Filatov[202]. An analogous result had been obtained earlier for the CH_3OH–C_6H_6 mixture, where the corresponding ratio of the abstraction and addition rate constants was close to unity, while in radiolysis it was approximately 10^{-2}.[203] This agrees with quantitative estimates of the contribution of the reactions of "hot" atoms obtained in radiolysis to the yield of H_2.

Since the steric factor for an abstraction reaction involving thermal hydrogen atoms is 0.1–1 and that for an addition reaction is 10^{-3}–10^{-4}, it follows that k_{abs}/k_{add} should be 10^{-2}–10^{-4} for $E \gg E_a$. Since the experimental ratios of the rate coefficients for "hot" atoms are close to unity, the steric factors for the reactions apparently also depend on the energy.

7. Other Reactions of "Hot" Hydrogen Atoms

The reactions of "hot" hydrogen atoms not observed in the "usual" thermal chemistry have been noted in a number of studies: reactions involving the substitution of groups of atoms[9,17,162,204] and the dissociation of C–C bonds[205–207]. Certain polymerisation reactions with participation of "hot" tritium atoms have been studied[208,209]. These reactions, first noted for recoil tritium atoms, were subsequently investigated with the aid of the acceleration technique[10,210]. The energy thresholds of certain reactions, for example, the cyclohexane ring opening reaction (approximately 4.5 eV), have been found[210]. There are at present no clear ideas in the literature concerning the mechanisms of the above processes.

In the study of chemical processes from the standpoint of elementary reaction collision steps, the knowledge of the reaction cross-section is the most valuable. Classical experimental chemistry operates with the concept of the rate constant which is identical with the rate coefficient for the Maxwell–Boltzmann distribution of species. Information about the cross-section cannot be obtained from numerical rate constants, since the cross-section is a characteristic of the reaction for specific quantum states of the reactants and products.

The possibility of the calculation of the cross-sections and of estimating other reaction characteristics has been considered in detail in a review[211], where a table of the rate coefficients, the integral probabilities, and the cross-sections of the reactions of hydrogen atoms obtained by various procedures is compiled.

IV. CONCLUSIONS

Thermal hydrogen atoms exhibit a high reactivity up to approximately 30 K in relation to compounds of virtually all classes. The view that the reactions at low temperatures proceed via a tunnel mechanism is generally accepted, although it has been suggested that the deviation from the Arrhenius relation at low temperatures can be caused by a change in the activation energy in the solid state.

Significant advances in the understanding of the mechanisms of reactions involving hydrogen atoms have been made by virtue of the development of physical ideas about the reaction dynamics. The MO methods in combination with computer calculations are widely used. Calculations of the potential energy of the interaction of six bodies have now become possible, which greatly extends the applied scope of the calculations.

Apart from the familiar reaction channels, the following new channels have been established for "hot" hydrogen atoms: the substitution of atoms and groups of atoms. Since the products of the unimolecular decomposition of the initial molecules are present in the reactions of "hot" atoms, it is believed that substitution results in the formation of vibrationally excited molecules, the probability of the decomposition of which can be calculated. "Hot" atoms can add to the double bond with formation of vibrationally "superexcited" radicals. Concepts such as the reaction rate coefficient (and not the rate constant, since there is no Boltzmann distribution with respect to the energies), the reaction probability, and the reaction cross-section serve as quantitative characteristics of "hot" reactions. Their dependence on the collision energy is significant.

Studies with "hot" atoms stimulated the investigation of the dependence of reaction probability on the energy of the colliding species. A successful development of the relevant studies requires the theoretical knowledge of the form of the potential surfaces for the reactions. The dependence of the reaction cross-sections on the energy can be obtained by the method of trajectories. The conversion of the cross-sections into reaction probabilities and yields presents no difficulties. On the other hand, if account is taken of the orientation of the molecule relative to the velocity vector of the attacking species, it is possible to obtain the dependence of the differential reaction cross-section on the angle of attack. However, this is applicable only to a quantitative description of simple reactions. For more complex processes, there is a possibility of only a qualitative comparison with experiment. Nevertheless, computational methods have contributed much to the understanding of the dynamics of chemical reactions. Apparently Mulliken was right in predicting the onset of the era of "computing"chemists who will resort to computers in their hundreds and will achieve thereby a significant understanding of the reaction mechanisms.

Experimental studies with "hot" species require the construction of complex accelerators, because the traditional methods for the generation of species (photolysis, radiolysis, and nuclear reactions) cannot yield a stream of monochromatic atoms with a specified energy and the value of such experiments is therefore theoretically low. Information about the quantum states of the reactants and products is essential for a comparison of experimental data with theoretical calculations. This also requires a quantitatively new development of experimental techniques.

Methods of Synthesis and Properties of β-Dimethylaminoethyl and Choline Esters of Aminoacids and Peptides

O.L.Mndzhoyan and V.O.Topuzyan

The literature data on the synthesis of β-dimethylaminoethyl and choline esters of aminoacids and peptides are surveyed. The N-protecting groups used and methods for their removal as well as the physicochemical and biological properties of the above compounds are considered.
The bibliography includes 69 references.

I. INTRODUCTION

The choline esters of aminoacids and peptides have a comparatively short history. Their structure resembles that of acetylcholine (AC), which has aroused much interest in recent years in their synthesis and biological activity. After a comparatively short time, research into both active cholinomimetics, isolated from plant and animal raw materials[1-4], and synthetic choline esters of aminoacids and peptides developed on a fairly wide scale. Studies have also been made[5-7] in which dialkylaminoalkyl esters were used as C-protecting groups for peptide synthesis.

This review deals with methods of synthesis of β-dimethylaminoethyl and choline esters of aminoacids and peptides and also with their physicochemical and biological properties. In the development of methods of synthesis of dialkylaminoalkyl aminoacid and peptide esters use is made of the fundamental postulates of peptide chemistry according to which the appropriate protecting groups, methods of synthesis of the ester, and methods for the removal of the protecting group and the isolation of the final product are selected.

II. PROTECTING GROUPS

In peptide synthesis one of the main tasks is the protection of the amino-group of the aminoacid or peptide. This problem remains just as acute in the synthesis of choline and β-dialkylaminoalkyl esters of aminoacids and peptides.

The majority of investigators[5,8-14] used the benzyloxycarbonyl (Z) group† as the *N*-protecting group in the synthesis of the esters, its removal after the synthesis of the aminoesters being achieved by treatment with hydrogen bromide in glacial acetic acid[5,8-13] and by catalytic hydrogenolysis over palladium[5]; these groups have been removed from the choline esters of certain Z-aminoacids with phosphonium tri-iodide[15] or by hydrogenolysis over PtO_2.[16-19] It has been noted[16] that this involves partial cleavage of the ester linkage.

†Apart from the standard abbreviations recommended by the IUPAC-IUB Commission on Biochemical Nomenclature, the following abbreviations have been adopted here: Aba = aminobenzoic acid; ε-Aca = ε-aminocaproic acid; γ-A-β-Hbu = γ-amino-β-hydroxybutyric acid; ω-Ava = ω-aminovaleric acid.

The t-butoxycarbonyl (Boc) group[6,9,10,12,20] has been removed from β-dimethylaminoethyl esters by passing dry gaseous hydrogen chloride through an ethereal solution of the β-dimethylaminoethyl ester of the Boc-aminoacid[6] and also by treatment with trifluoracetic acid[9,12]. The protecting group has been removed from the choline ester of Boc-ε-aminocaproic acid[20] with a dilute solution of hydrogen bromide in acetic acid (10 min, 20 °C) or with a 48% solution of hydrogen bromide (2 min, 0 °C) and a 0.1 *N* solution of hydrogen chloride in formic acid (10 min, 20 °C).

The triphenylmethyl [trityl (Trit)] group has also been used successfully in the synthesis of the choline ester of glutamic acid; it was removed by treatment with hydrogen chloride[21] or acetic acid[22,23].

The possibility of using toluene-*p*-sulphonyl [tosyl (Tos)] and phthalyl (Pht) protecting groups has also been investigated[11]. It has been established that hydrazinolysis or acid hydrolysis under various conditions for the Pht group and reduction with sodium in liquid ammonia for the Tos group lead to partial cleavage of the ester linkage. According to the data of Mndzhoyan and Agadzhanyan[11], these protecting groups are less favourable for the synthesis of dialkylaminoalkyl esters of aminoacids with a free amino-group, in contrast to the Z and Boc groups. In the synthesis of the hydrochlorides of the β-dimethylaminoethyl and choline esters of glycine, the *o*-nitrobenzenesulphenyl (Nbs) group was used as the *N*-protecting group[24] and was removed by treatment with hydrogen chloride.

The majority of investigators using the acid chloride method for the synthesis of β-dimethylaminoethyl or choline esters of aminoacids protected the amino-group by protonation[15,25,26]. The study of Freundenberg and Keller[27], who used the acid chlorides of α-azidoacids, is unique in this respect (see Section III, 1 below). After the synthesis of the choline esters, the azido-group was converted into an amino-group by reduction over Pd/C in the presence of hydrogen chloride.

The dansyl (Dns) group has been used[28] in the synthesis of choline esters of certain aminoacids. In the synthesis of choline esters of aminoacids and peptides Kanaoka and coworkers[8,9] protected other functional groups as well as the amino-group, namely the hydroxy-group of tyrosine was protected by benzylation, the guanidino-group of arginine was protected by nitration, and the β- and γ-carboxy-groups of aspartic and glutamic acid were protected by benzylation. The β-carboxy-group of aspartic acid was protected[9] by t-butylation. The benzyl group has been used[6] to protect

the imidazole ring of histidine and the hydroxy-group of serine.

Table 1 presents data, in relation to glycine, concerning the use and conditions for the removal of various *N*-protecting groups in the synthesis of β-dimethylaminoethyl and choline esters by various methods. Evidently the best *N*-protecting groups which can be used in the synthesis of aminoesters of aminoacids and peptides are the Z, Boc, and Nbs groups: when they are removed, the final product is obtained in high yields.

Table 1. Conditions for the elimination of *N*-protecting groups from the β-dimethylaminoethyl and choline esters of *N*-protected glycines R-Gly-OCH_2CH_2X.

III. METHODS OF SYNTHESIS

1. The Acid Chloride Method

The acid chloride method was used mainly in early studies on the synthesis of choline esters of aminoacids and peptides. The hydrochlorides of the choline esters of glycine[15,25], glycylglycine[15], and methionine[26] were obtained by the reaction of the hydrochloride of the aminoacid chloride or peptide with choline on heating. The acid chlorides of *N*-protected aminoacids were used in the synthesis of both β-dimethylaminoethyl esters[11,15,29] and β-halogenoethyl esters[15], which are the starting materials in the synthesis of choline esters of aminoacids. It has been shown that the acid chloride method and the mixed anhydride method using the methyl ester of chlorocarbonic acid are approximately equally effective for the synthesis of the dialkylaminoalkyl esters of Tos- and Pht-glycine[11].

α-Azidoacyl chlorides[27] have also been used as the starting compounds for the synthesis of the choline esters of four aminoacids (glycine, DL-alanine, DL-leucine, and DL-valine):

Scheme 1

$$N_3\text{—}\underset{\displaystyle R}{\underset{|}{CH}}\text{—}CO\text{—}Cl + HOCH_2CH_2NMe_2 \rightarrow N_3\text{—}\underset{\displaystyle R}{\underset{|}{CH}}\text{—}COOCH_2CH_2NMe_2 \xrightarrow{MeI}$$

$$\rightarrow N_3\text{—}\underset{\displaystyle R}{\underset{|}{CH}}\text{—}COOCH_2CH_2\overset{+}{N}Me_3\bar{I} \xrightarrow{AgCl} N_3\text{—}\underset{\displaystyle R}{\underset{|}{CH}}\text{—}COOCH_2CH_2\overset{+}{N}Me_3\bar{Cl} \xrightarrow{Pd/H_2}$$

$$\rightarrow HCl\cdot H_2N\text{—}\underset{\displaystyle R}{\underset{|}{CH}}\text{—}COOCH_2CH_2\overset{+}{N}Me_3\bar{Cl}\ .$$

2. The Mixed Anhydride Method

This method has been used by many investigators in the synthesis of β-dimethylaminoethyl esters of *N*-protected aminoacids and peptides[5,10-13,30]. Mixed anhydrides obtained from *N*-acylaminoacids and benzenesulphonyl chloride, tosyl chloride, or methyl chlorocarbonate have been employed for the synthesis. However, in the case of the reaction of Pht-glycine with methyl chlorocarbonate the yield of the β-dimethylaminoethyl ester was insignificant[11]. Best results were obtained using isobutyl chlorocarbonate[12], but one should note that in this case the method involving the azeotropic distillation of water from the mixture of β-dimethylaminoethanol, *N*-acylaminoacid, and xylene proved to be more effective[13] than the mixed anhydride method.

It follows from a comparison of data published in different communications concerning the application of condensing agents in the synthesis of the β-dimethylaminoethyl ester of *N*-benzyloxycarbonylglycine by the mixed anhydride method (Table 2) that the best results are obtained when ethyl and isobutyl chlorocarbonates are used.

Table 2. The influence of substituents on the reactivity of mixed anhydrides in the synthesis of the β-dimethylaminoethyl ester of *N*-benzyloxycarbonylglycine via the mechanism Z-Gly-O—R + $HOCH_2CH_2NMe_2$ → Z-Gly-$OCH_2CH_2NMe_2$.

R	Yield, %	Refs.

n-$CH_3C_6H_4SO_2$	26	[10]
MeOOC	40	[10]
EtOOC	58	[5]
iso-BuOOC	61*	[12]

*According to Shamshin et al.[13], the yield is 23.8%.

It is noteworthy that the yield of the β-dimethylaminoethyl ester of Z-glycine, obtained using isobutyl chlorocarbonate, was only 23.8%.[13] However, in other studies[12,30], the β-dimethylaminoethyl esters of *N*-protected aminoacids and peptides were synthesised using this reagent in high yields, which also confirms the effectiveness of isobutyl chlorocarbonate in the synthesis of the above compounds.

Two versions of the synthesis of the β-dimethylaminoethyl ester of *N*-benzyloxycarbonylglycylglycine (I) by the mixed anhydride method were investigated[30]:

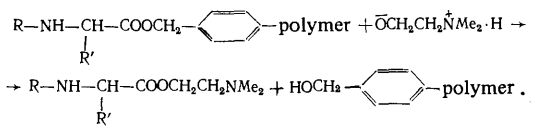
$$\left.\begin{array}{l} Z\text{—}Gly\text{—}OH + H\text{—}Gly\text{—}OCH_2CH_2NMe_2 \xrightarrow{a} \\ Z\text{—}Gly\text{—}Gly\text{—}OH + HOCH_2CH_2NMe_2 \xrightarrow{b} \end{array}\right\} \rightarrow Z\text{—}Gly\text{—}Gly\text{—}OCH_2CH_2NMe_2\ . \quad (I)$$

The results obtained[30] show that pathway *a* gives higher yields of compound (I).

3. The Carbodiimide Method

The carbodiimide method has been used in the synthesis of choline[8], β-halogenoethyl[20], and β-dimethylaminoethyl[10,12,24] esters of *N*-protected aminoacids and peptides[12,30]. *N,N'*-Dicyclohexylcarbodiimide (Dcc) has been largely used as the condensing agent.

Studies[10,12] in which the β-dimethylaminoethyl esters of Z-glycine and L-valylglycine as well as Boc-glycine were synthesised by both the mixed anhydride and carbodiimide methods have shown that the latter method is less effective.



It has been reported[10] that the yield of the β-dimethylaminoethyl ester of Z-glycine obtained by the condensation of Z-glycine and β-dimethylaminoethanol with the aid of Dcc varies with the reactant ratio and reaction time. The authors[10] noted the formation of an appreciable amount (up to 50%) of *N*-benzyloxycarbonylglycyldicyclohexylurea as a side product. They also noted that at a reduced temperature the yield of the β-dimethylaminoethyl ester increases.

Subsequently the carbodiimide method was used successfully[8] in the condensation of certain *N*-acylaminoacids with choline. The carbodiimide method has been employed for the cross-linking of the methobromide of the β-dimethylaminoethyl ether of ε-aminocaproic acid with Sepharose 2B.[20]

4. The Activated Ester or Transesterification Method

p-Nitrophenyl esters of *N*-protected aminoacids have been largely used in the synthesis of β-dimethylaminoethyl choline esters by the activated ester method. The method has been applied in the synthesis of the choline ester of Z-glycine[24]. The β-dimethylaminoethyl esters of Z-L-leucylglycine and of the γ-methyl ester of L-glutamylglycine have been obtained by the reaction of the β-dimethylaminoethyl ester of glycine with the *p*-nitrophenyl esters of Z-L-leucine and of the γ-methyl ester of L-glutamic acid[5]. The cyanomethyl ester has been employed in the synthesis of the β-dimethylaminoethyl ester of *N*-benzoylsarcosine[31].

After synthesis by the solid phase method, the peptide linked to the polymer in the form of the benzyl ester has been subjected[6] to transesterification by treatment with β-dimethylaminoethanol at room temperature in accordance with the following scheme:

The influence of the solvent on the transesterification process has been tested in relation to Boc-glycine[6]. It was established that treatment with a 1:1 (by volume) mixture of β-dimethylaminoethanol and dimethylformamide (DMF) in the course of 70 h ensures virtually quantitative transesterification. When dioxan or methylene chloride was used, the degree of transesterification of the Boc-Gly-O-polymer with β-dimethylaminoethanol was much lower. The rate of transesterification in DMF has been studied in greater detail[6] in relation to the polymer-bound pentapeptide Boc-O-Bzl-L-Ser-L-Gln-NO_2-L-Arg-N^{im}-Bzl-L-His-Gly-O-polymer. It was established that the length of the peptide chain does not affect the rate of transesterification. The authors[6] also point out that the reaction is hindered in the case of valine and proline. It has also been found in relation to the transesterification of the compound Boc-L-Leu-L-Ala-O-polymer with β-dimethylaminoethanol that the degree of racemisation is insignificant (approximately 0.3 ± 0.1%).

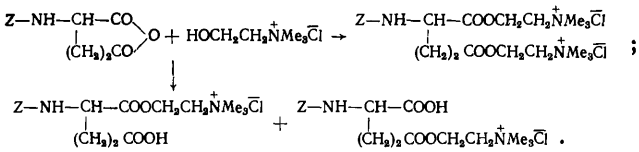
The β-dimethylaminoethyl esters of Tos-glycine[31], hippuric acid, and hippurylglycine[32] have been obtained by the transesterification method involving the reaction of the methyl or ethyl esters of the *N*-protected aminoacids with β-dimethylaminoethanol in the presence of potassium cyanide as the catalyst.

5. Methods Involving the Azeotropic Distillation of Water

The possibilities of the synthesis of dialkylaminoalkyl esters of *N*-protected aminoacids by this method have been studied in detail in relation to the synthesis of the β-dimethylaminoethyl ester of Z-glycine[10,11] using different solvents and reaction times (Table 3). According to Mndzhoyan and Agadzhanyan[11], charring takes place in *o*-dichlorobenzene, while an increase of the duration of distillation of the azeotropic mixture in toluene results in an increase of the yield of the β-dimethylaminoethyl ester of Z-glycine. Subsequently this method was used successfully to synthesise the β-dimethylaminoethyl esters of Z-α- and ω-aminoacids[13].

Table 3. The influence of the solvent and reaction time on the yield of the β-dimethylaminoethyl ester of *N*-benzyloxycarbonylglycine in the azeotropic distillation of water.

Solvent	Time, h	Yield, %	Refs.
Toluene	23	25	[10]
Toluene	56	60	[11]
o-Xylene	23	50	[11]
o-Dichlorobenzene	23	20	[11]
Xylene	15—18	76 4	[13]



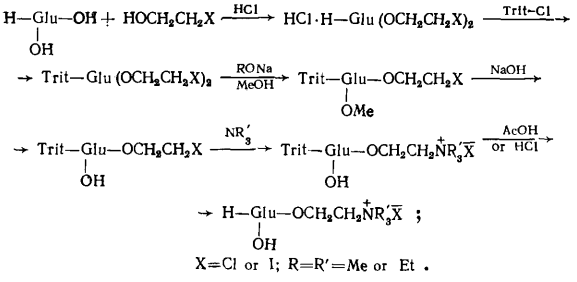
Comparison of the yields of the β-dimethylaminoethyl ester of *N*-benzyloxycarbonylglycine, synthesised by the method involving the azeotropic distillation of water from a mixture of the Z-aminoacid and the corresponding aminoalcohol in different solvents, makes it evident that xylene constitutes the best reaction medium.

6. Other Methods of Synthesis

One of the common methods of synthesis of β-dimethylaminoethyl esters of aminoacids and peptides involves the interaction of the *N*-protected aminoacids and peptides with dialkylaminoalkyl halides ($XCH_2CH_2NR_2$; X = Cl or Br) in the presence of bases such as triethylamine[8-10] or potassium carbonate[7,20,24]. The β-dimethylaminoethyl esters of di-, tri-, and tetra-peptides have been synthesised successfully by this method[9]. Good results have been obtained using potassium carbonate in the synthesis of the β-dimethylaminoethyl ester of Boc-ε-aminocaproic acid[20]. The β-dimethylaminoethyl ester of Nbs-glycine has been obtained analogously[24].

In a study of the degree of racemisation of the *C*-terminal aminoacid in the synthesis of choline esters, the authors[9] established in relation to Ac-L-Ile-$OCH_2CH_2\overset{+}{N}Me_3$.$Tos\bar{O}$ that the degree of racemisation does not exceed 1.2% for X = Br and 1.4% for X = Cl.

The interaction of one mole of the cyclic anhydride of Z-glutamic acid with two moles of choline yielded the corresponding dicholine ester[17,33]:



When equimolar amounts of the starting materials are used, a mixture of the α- and γ-choline ester is obtained[16,19,22].

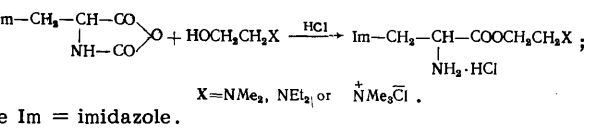
***Dicholine ester.
****Monocholine ester.



Another method of synthesis of the α-choline ester of glutamic acid has also been developed[21—33]:

Choline esters of hippuric acid[34] and certain Dns-aminoacids[28] have been synthesised analogously via β-halogenoethyl esters.

The synthesis of the hydrochlorides of the choline esters of γ-aminobutyric and β-hydroxy-γ-aminobutyric acids by the reaction of the corresponding acid and choline in the presence of gaseous hydrogen chloride in anhydrous dioxan has been described[35—37]. Choline esters of aminoacids can be obtained via their ammonium salts[26,33].

N-Carboxyanhydrides have been used[38] to synthesise the choline ester of L-histidine:

Here Im = imidazole.

Tables 4 and 5 present data on the synthesis of β-dialkylaminoethyl and choline esters of aminoacids and peptides.

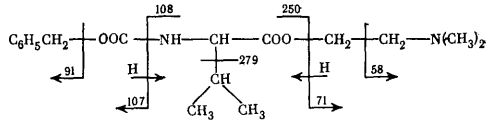
*Dicholine ester.
**Monocholine ester.
***R′ = Et.

IV. PHYSICOCHEMICAL PROPERTIES



1. Physical Properties

The β-dimethylaminoethyl esters of Z- and Boc-aminoacids and peptides are mainly oily substances. Their hydrochlorides and hydrobromides are crystalline substances. The hydrohalides of choline esters of aminoacids and the dihydrohalides of dialkylaminoalkyl esters of aminoacids are as a rule crystalline; however, we should note that some of them are very hygroscopic. The choline esters of *N*-protected aminoacids and peptides are also crystalline.

Infrared spectroscopy has been widely used to identify β-dimethylaminoethyl esters of *N*-protected and unprotected aminoacids and peptides. The infrared absorption spectra of the β-dimethylaminoethyl esters of acylaminoacids have been investigated in detail[12,13] and it has been observed that characteristic peaks occur in the ranges 1680—1760 and 1625—1725 cm^{-1} and refer to the amide and ester carbonyl groups respectively. The presence of the ester bond in the β-dimethylaminoethyl esters of aminoacids and peptides independently of the *N*-protecting group has been confirmed[12, 30] by observing an absorption peak at 1265 cm^{-1}.

NMR has also been used to identify β-dimethylaminoethyl and choline esters of aminoacids and their derivatives[6,8,13,20,28].

A mass-spectrometric study of the β-dimethylaminoethyl esters of Z-α- and Z-ω-aminoacids[13] showed that the molecular ion peaks for these compounds have a low intensity or in many instances are not observed at all. This phenomenon has been explained[13] in relation to the β-dimethylaminoethyl ester of Z-valine by the ease of its decomposition with formation of stable radicals of the type $CH_2{=}N(CH_3)_2^+$ (*m/e* 58), $CH_2{=}CH{-}N(CH_3)_2^+$ (*m/e* 71), $C_6H_5CH_2^+$ (*m/e* 91), and $C_6H_5CH_2O^+$ (*m/e* 108):

The β-dimethylaminoethyl esters of p-alkoxybenzoylglycylglycines have also been studied by mass spectrometry[39].

Thin-layer and paper chromatography constitute some of the widely used physical methods for the identification of the β-dimethylaminoethyl and choline esters of aminoacids and peptides[5,6,8,9,11—13,16,20,26,30,33,34,38].

2. Chemical Properties

A study of the hydrolysis of the β-dimethylaminoethyl ester of Z-glycine by a 2—4% solution of sodium bicarbonate[5] established that the complete cleavage of the ester linkage takes place in the course of 40—70 min at room temperature. The β-dimethylaminoethyl ester of Boc-glycine in DMF has been hydrolysed[6] in the presence of water. It was observed that the time of complete hydrolysis of the ester diminishes with increase of the amount of water; in the presence of imidazole (0.1 equiv.), the rate of hydrolysis increases.

The ester group hydrolyses on refluxing an acid solution of the β-dimethylaminoethyl ester of Pht-glycine and also on removal of the Tos group by treatment with sodium in liquid ammonia[11].

It has been found that the spontaneous hydrolysis of hippurylcholine in distilled water proceeds at the same rate as the hydrolysis of acetylcholine[34]. The hydrolysis of the choline esters of Tos-glycine[31], hippuric acid[31,32], and hippurylglycine[32] has been investigated. γ-Aminobutyrylcholine (GABC) is unstable at pH 5.5, and is almost completely hydrolysed by 1 *N* HCL at 100 °C in the course of 30 min.[40]

The hydrazinolysis of the γ-choline ester of glutamic acid yielded the corresponding hydrazide[41]. The aminoacid hydrazide is obtained when the Pht group is removed from the aminoester of *N*-phthalylglycine[11].

The aminolysis of the ester linkage in the choline esters of the aminoacids has been investigated. Treatment of the α- or γ-choline esters of *N*-protected glutamic acid with a methanol solution of ammonia[41] yielded the corresponding amides.

In the search for activated esters suitable for the synthesis of peptides, a study has been made[7] of the possibility of using the choline esters. The reaction of the methobromide of the β-dimethylaminoethyl ester of hippuric acid with benzyl-amine gave rise to the expected benzylamide of hippuric acid in a yield up to 34%.

V. BIOLOGICAL PROPERTIES

The biological properties of the choline esters of aminoacids and peptides have been investigated fairly widely. Frank and coworkers synthesised diazoacetylcholine[42-44] and ε-aminocaproylcholine[20,45] in order to isolate acetylcholinesterase (ACE) and other enzymes specific to acetylcholine from the electric organs of the *electrophorus electricus*. It was established that ε-aminocaproylcholine is a full cholinergic (nicotinic) agonist. Its activity varies between those of acetylcholine and carbocholine; it is not hydrolysed by ACE and is not its inhibitor, but bound to Sepharose 2B it is an effective agent for the isolation of acetylcholine-binding receptors. The choline ester of *N*-dansyl-ε-aminocaproic acid was synthesised for the same purpose[28,46].

The biological action of GABC has been studied in detail. According to the results[1], GABC in a dose of 5×10^{-2} M suppresses the contracting action of acetylcholine, in a dose of 5×10^{-3} M it suppresses the action of histamine, and in a dose of 1×10^{-4} M it suppresses the secretion of gastrin. Eserine enhances and *d*-tubocurarine and flaxedil weaken the inhibiting influence of GABC on the transmission of neuromuscular impulses[47]. At a concentration of 5×10^{-4} g ml^{-1}, GABC induces the contractions of the small intestine in the guinea-pig and rabbit[48], which are not suppressed by atropine, hexamethonium, phenazoline, or a high concentration of serotonin; morphine appreciably weakens the antiserotonin effect of GABC.

Apart from its inhibiting effect on respiration, GABC also influences the cardiovascular system. GABC and glycylcholine reduce the tonus and the [contraction] amplitude of the isolated heart of the molusc *Mepetrix lusoria*[49]. According to Asano et al.[49], the inhibiting effect of GABC is due to its anticholinergic activity. The neurotropic activity of GABC [50] and its influence on the electric activity of the brain cortex[51] and the central nervous system[52,53] have been investigated. It has been established that GABC reduces the blood supply to the brain[54] but increases the permeability of the membranes[55].

The anticonvulsant properties of GABC [56] have been studied on mice, rabbits, and dogs. Glutamylcholine and GABC have an inhibiting effect on the primary sensory potential when the contralateral peraneal nerve is stimulated[57]. According to Takahashi et al.[57], the absence of an effect by intravenously administered glutamylcholine and GABC on the discharges induced by a solution of corazole is associated with the decomposition of these substances in the blood. It has been shown[40] that GABC is not hydrolysed by the ACE of the blood erythrocytes or the enzyme from the electrical organ of the eel, but is partly susceptible to the action of butyryl cholinesterase of the plasma and tissues, not being, however, a physiological substrate of this enzyme. The enzymatic hydrolysis of GABC [40] is inhibited by inhibitors of cholinesterase—eserine and di-isopropyl phosphorofluoridate. In the presence of α-oxoglutaric acid the action of the guinea-pig brain transaminase on GABC is not accompanied by transamination[40]. It has been established[13] that the choline esters of α- and ω-aminoacids exhibit a weak anticonvulsant activity; some of them possess hypothermic properties.

The results of tests on the influence of the hydrobromides of the choline esters of α-aminoacids on the contraction of smooth muscles[8] have demonstrated a cholinomimetic activity intermediate between those of acetylcholine and choline. It has also been established that the choline esters of cysteine and cystine exhibit an oxytocin activity[15]. Hippurylcholine suppresses the activity of blood serum cholinesterase by 90%.[34]

The choline ester of Nbs-glycine possesses a cholinomimetic activity[24] and also exhibits a pronounced antibacterial activity *in vitro* against *Staphylococcus aureus*. The dihydrochloride of the choline ester of L-histidine in a dose of 2 mg litre^{-1} intensifies the contraction of the isolated rabbit intestine and, when the dose is increased (to 5, 10, and 20 mg litre^{-1}), its contraction is inhibited. The picrates of β-dimethyl- and β-diethyl-aminoethyl esters of L-histidine enhance the contraction of the rabbit intestine in doses of 1 and 5 mg litre^{-1} respectively[38]. The methiodides of the β-dimethylaminoethyl esters of certain aminoacids and peptides are inferior in their cholinomimetic activity to carbocholine, but are much less toxic than the latter[58].

The mutagenic activity of the hydrochlorides of the β-dimethylaminoethyl esters of *p*-alkoxybenzoylglycylglycines has also been studied[59]. It has been established that some of them exhibit a pronounced mutagenic activity and that the latter depends on the structure of the alkyl moiety of the alkoxy-group.

The hydrolysis of the choline esters of certain *N*-protected aminoacids by chymotrypsin has been investigated[32,60]. A detailed study has been made of the hydrolysis of the choline esters of *N*-substituted aminoacids by ACE and butyrylcholinesterase[61] and also of their influence on the hydrolysis of acetylcholine. The dimethiodide of the β-dimethylaminoethyl ester of *N,N*-dimethylaminopropionic acid has been used as a model compound in the study of the hydrolysis of the dicholine esters of dicarboxylic acids by butyrylcholinesterase[62]. It has been shown that Z-glutamylcholine increases the activity of transmethylase and choline oxidase, prevents the decrease in the amount of phospholipids, and prevents the accumulation of fats in the liver[63-69].

The Structure and Properties of Organocyclodisilazanes

Yu.M.Varezhkin, D.Ya.Zhinkin (deceased), and M.M.Morgunova

A survey and a systematic account of data on monomeric, oligomeric, and polymeric four-membered cyclic silazane systems are given and the fundamentals of the theory of their structure and reactivity are described. The physical and chemical properties, the methods of analysis, and certain aspects of the practical applications of these compounds are examined in detail. The review contains an exhaustive bibliography on organocyclodisilazane compounds starting from the first available information about them and extending up to 1978 (polycyclic systems in which the four-membered rings are linked via a silicon spiro-atom are excluded).
The bibliography includes 164 references.

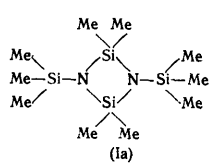
I. INTRODUCTION



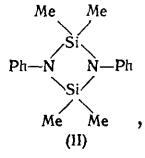
Continued progress in the modern chemistry of silicon- and nitrogen-containing compounds has led to the establishment and development of specific fields in this branch of chemistry such as the chemistry of four-membered cyclic silazane heterocycles—organocyclodisilazanes. This is associated both with the applied importance of compounds of this type, since they exhibit a high thermal stability, and with the interest in purely theoretical questions due to the somewhat unusual structure of these compounds.

A vigorous development of research not only into the synthesis of organocyclodisilazanes but also into the properties and structures of compounds of this class has taken place in recent years. In the study of these compounds almost the entire range of modern chemical methods has been used, including infrared Raman spectroscopy, ^{1}H NMR, mass spectrometry, and X-ray diffraction. Interesting data have been obtained but hitherto no attempts have been made to compile and survey all this information apart from a review published four years ago[1]. This review, which is devoted to the synthesis and applications of organocyclodisilazanes, covers a fairly wide range of problems and it is quite natural that many data concerning the structure and properties of these compounds have been omitted; furthermore, during the period which has elapsed since its publication, important new data have been obtained.

This review gives a systematic account and surveys the results of studies on the structures, properties, and reactivities of organocyclodisilazanes, and the possibilities of their practical applications are considered. Problems associated with the synthesis of monomers with the cyclodisilazane structure have already been described in detail[1-3].

II. THE STRUCTURE OF ORGANOCYCLODISILAZANES

Crystals of 1,3-Bis(trimethylsilyl)-2,2,4,4-tetramethylcyclodisilazane (Ia)



(Ia)

are monoclinic: $a = 6.75(2)$ Å, $b = 13.18(4)$ Å, $c = 11.22(3)$ Å, $\beta = 104°23' \pm 30'$, $V = 968.7$ Å^3, $D_m = 0.998$ (density determined by flotation in a diethylene glycol–methanol mixture), $Z = 2$, $D_c = 1.003$ (calculated density), space group $P2_1/n$ ($C_{2h}5$, No.14).[4]

Fig.1 shows that the silicon–nitrogen bonds in the cyclodisilazane ring are somewhat longer than exocyclic silicon–nitrogen bonds but shorter than the Si–N bonds in hexamethylcyclotrisilazane [1.78(3) Å].[5,6] The average length of the silicon–carbon bond (1.876 Å) corresponds to the usual values[7]. The distance between the opposite silicon atoms in the ring (2.476 Å) is somewhat greater than between the opposite nitrogen atoms (2.402 Å). The cyclodisilazane ring is highly strained compared with the hexamethylcyclotrisilazane (117° ± 4°) or octamethylcyclotetrasilazane (123° ± 4°) ring.[5,6] Compound (Ia) has a planar structure, which has been confirmed by ^{1}H NMR,[8] with the aid of which the unusually pronounced π-character of the exocyclic Si–N bond was observed in addition[9].

For 1,3-diphenyl-2,2,4,4-tetramethylcyclodisilazane (II)

(II)

the following parameters have been found: $a = 8.545(2)$ Å, $b = 16.820(3)$ Å, and $c = 11.622(2)$ Å; $V = 1670.38$ Å^3, $Z = 4$, $D_x = 1.187$, space group $Pbca$ (No.61).[10]

The molecule of compound (II) has a centre of symmetry; the cyclodisilazane ring is planar and the two benzene rings are parallel to one another. The length of the endocyclic Si–N bonds in compound (II) (see Fig.2) is greater than in compound (Ia); the length of the Si–N bonds is 1.728 Å in octamethylcyclotetrasilazane[11] and 1.732(2) Å in trisilylamine[12]. The distance between the opposite silicon atoms in the ring of compound (II) is 2.56 Å, which is somewhat greater than in compound (Ia), while the distance between the opposite nitrogen atoms (2.37 Å) is somewhat smaller.

The π-electron bond orders in compound (II) have been calculated by the Pariser–Parr–Pople (PPP) method: p(Si–N) = 0.346 and p(C–N) = 0.325. The latter agrees with the calculated value p(C–N) = 0.342, obtained[13] from

a modified Coulson formula. The results indicate a considerable contribution of the d_π–p_π interaction in the Si–N bond[10].

The structure of 1-methyldiphenylsilyl-3-(1,1,3-trimethyl-3,3-diphenylsilazanyl)-2,2,4,4-tetramethylcyclodisilazane (III) has been determined by X-ray diffraction[14,15]. The compound consists of colourless transparent monoclinic crystals: a = 15.790(10) Å, b = 8.443(5) Å, and c = 27.944(16) Å; β = 103.9(2)°, V = 3616.3 Å^3, D_m = 1.122 (determined by flotation), Z = 4, D_c = 1.124, space group $P2_1/c$ ($C_{2h}5$, No.14).[14]

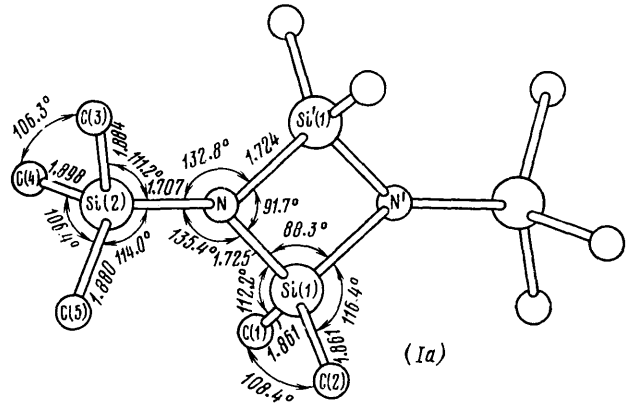


Figure 1. The bond lengths and angles in the 1,3-bis(trimethylsilyl)-2,2,4,4-tetramethylcyclodisilazane (Ia) molecule[4].

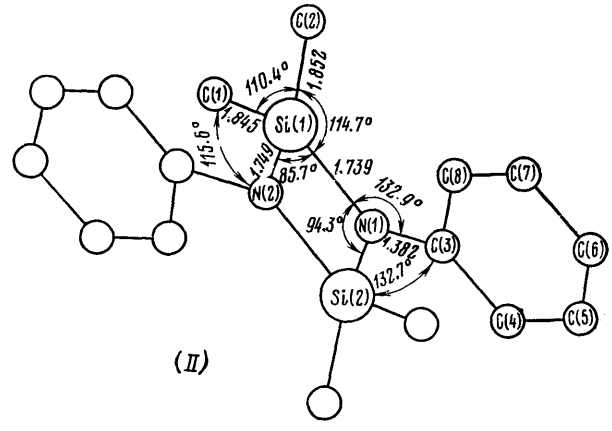

Figure 2. The bond lengths and angles in the 1,3-diphenyl-2,2,4,4-tetramethylcyclodisilazane (II) molecule[10].

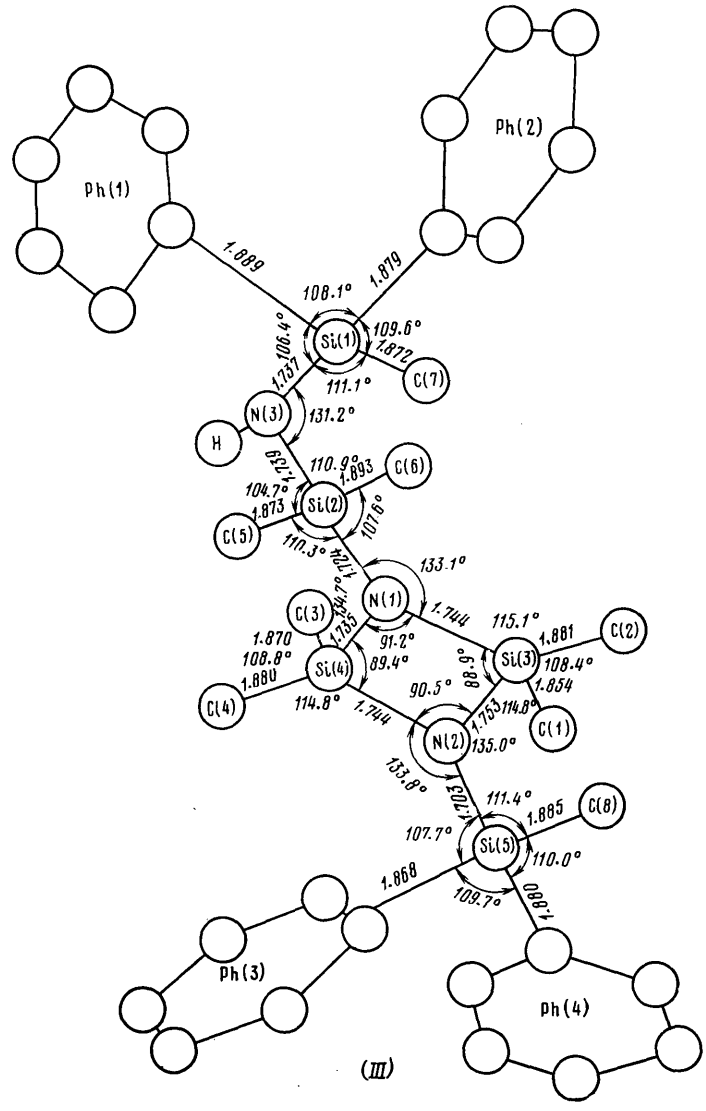

Figure 3. The bond lengths and angles in the 1-methyldiphenylsilyl-3-(1,1,3-trimethyl-3,3-diphenylsilazanyl)-2,2,4,4-tetramethylcyclodisilazane (III) molecule[14].

In compound (III) the average length of the Si–C(Me) bonds is the same as in compound (Ia) and corresponds to the usual value of 1.870 Å;[7] on the other hand, the Si–C(Ph) (1.879 Å) bond length is somewhat greater than the value usually adopted (1.843 Å).[7] The Si–N bonds in the ring are longer than the exocyclic bonds and than the Si–N bonds in the side chain (Fig.3). The distance between the opposite silicon atoms in the ring (2.484 Å) is greater, as in compound (Ia), than the distance between the opposite nitrogen atoms (2.448 Å). The torsional angles along the chain are Si(1)N(3)Si(2)N(1) = 80.19° and N(3)Si(2)N(1)Si(3) = 135.76°.[14]

The study of the crystal and molecular structures of 1,3-bis-(2,2,4,4,6-pentamethylcyclotrisiloxanyloxydimethylsilyl)-2,2,4,4-tetramethylcyclodisilazane (IV) showed[16] that the colourless crystals of this compound are triclinic, belong to the space group $P1$, and have the following parameters: a = 8.316(5) Å, b = 10.528(5) Å, and c = 12.320(4) Å; α = 76.65(3)°, β = 77.55(4)°, γ = 71.95(4)°, and Z = 1. The structure has been elucidated by a direct method and

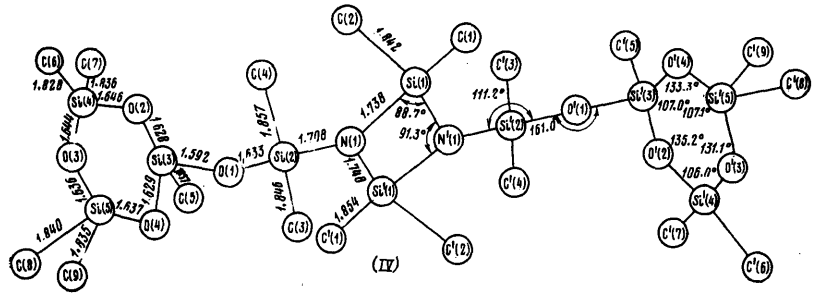

Figure 4. The molecular structure of 1,3-bis(2,2,4,4,6-pentamethylcyclotrisiloxanyloxydimethylsilyl)-2,2,4,4-tetramethylcyclodisilazane (IV).[16] The bond lengths (Å) and the valence angles (in degrees) are given on the left- and right-hand sides respectively.

has been refined by the method of least squares in terms of the full matrix anisotropic approximation up to $R = 0.038$ on the basis of 2866 reflections with $F^2 > 1.96\sigma$.

The molecule of compound (IV) is located at the centre of symmetry. The dihedral angle between the planes of the trisiloxane and disilazane rings is 21°. The bond lengths and angles in the cyclodisilazane (IV) molecule are presented in Fig. 4.[16]

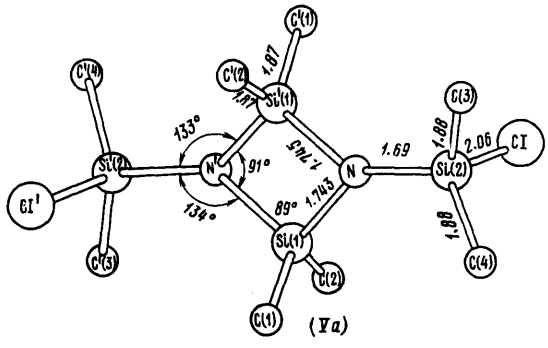

Figure 5. Stereochemistry of the 1,3-bis(chlorodimethylsilyl)-2,2,4,4-tetramethylcyclodisilazane (Va) molecule, bond lengths, and valence angles[18].

X-Ray diffraction study[17,18] of 1,3-bis(chlorodimethylsilyl)-2,2,4,4-tetramethylcyclodisilazane (Va) showed that crystals of this compound are monoclinic and have the lattice parameters $a = 6.653(3)$ Å, $b = 11.527(4)$ Å, and $c = 13.169(6)$ Å; $\gamma = 111.91(03)°$, space group $P2_{1/b}$, $Z = 2$. The structure has been elucidated by the direct method and has been refined by the method of least squares in terms of the anisotropic approximation up to an R factor of 6.9% using 1003 reflections. The four-membered disilazane ring is planar. No structural manifestations of the β-effect (the Cl → Si interaction) have been observed[18]. The bond lengths and valence angles are indicated in Fig. 5.

The amount of data available on the structure of phenylcyclodisilazanes is extremely small. Thus the crystal structure of 1,3-bis(chlorodiphenylsilyl)-2,2,4,4-tetraphenylcyclodisilazane (VI) has been determined[19] (Fig. 6). Crystals of compound (VI) are triclinic: $a = 11.192$ Å, $b = 12.016$ Å, $c = 9.707$ Å; $\alpha = 102.68°$, $\beta = 78.07°$, and $\gamma = 106.83°$. The structure has been refined up to an R factor of 10.6% on the basis of 1784 diffraction reflections with $I > 3\sigma$. It has been established that the crystals consist of a 1 : 1 solvate with benzene. The unit cell contains one formula unit, because both molecules are located at the centres of symmetry of the lattice (space group $P1$). The C(25), C(26), and C(27) atoms belong to the solvating benzene molecule located at the centre of symmetry (1/2; 1/2; 1/2).

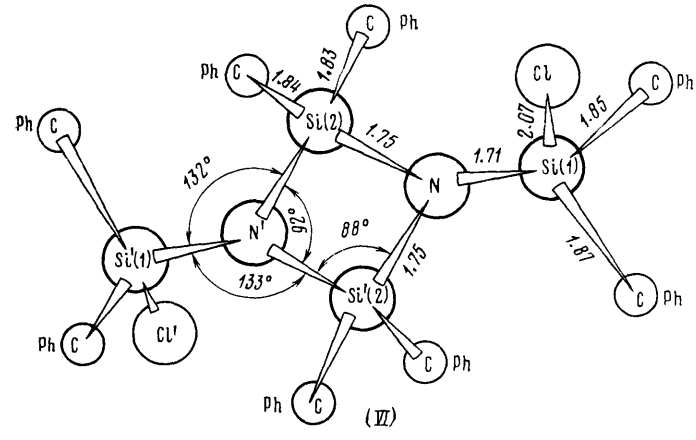

Figure 6. Stereochemistry of the 1,3-bis(chlorodiphenylsilyl)-2,2,4,4-tetraphenyldisilazane (VI) molecule, bond lengths and valence angles[19].

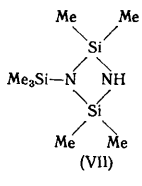
In conformity with symmetry requirements, the four-membered ring is planar. The Si–N bond lengths in the ring and the NSi(2)N′ and Si(2)NSi′(2) valence angles agree satisfactorily with other data[6,14]. The nitrogen atom has a nearly planar configuration (the sum of the valence angles is 357°), which indicates the delocalisation of its electron pair due to the d_π–p_π interaction with the Si(1), Si(2), and Si′(2) atoms. As in the previously investigated structures[4,14], the exocyclic Si(1)–N bond (1.713 Å) is shorter than the endocyclic Si(2)–N and Si′(2)–N bonds (1.746 and 1.750 Å respectively).

The observed Si(1)–Cl bond length, which is 2.072 Å, is appreciably greater than the normal value (2.01 Å);[20] nevertheless the compound exhibits an enhanced hydrolytic stability[17,19].

Thus the geometrical parameters of the molecules of the methyl- and phenyl-containing cyclodisilazanes (Va) and (VI) are in the main identical. The greatest differences were found on comparing the lengths of the exocyclic N–Si(R_2)Cl [1.690 Å for (Va) and 1.713 Å for (VI)] and Si–Cl [2.056 Å for (Va) and 2.072 Å for (VI)] bonds[18]. It is therefore impossible to observe a correlation between the differences in the reactivities and molecular geometries.



The infrared spectra of N-alkyl- or N-aryl-substituted cyclodisilazane have so far been inadequately investigated. It has been established that the nature of the substituents at the nitrogen atom affects the nature of the d_{π}–p_{π} bond and a corresponding shift of the region of asymmetric stretching vibrations of the Si–N bond in the Si(NSi) fragment of cyclodisilazane is observed[21–32].

The change in the nature of the organic group attached to the silicon atom[21] does not exert such an influence (Table 1).

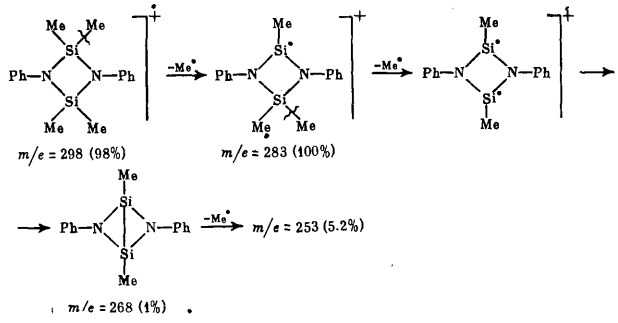
Table 1. The influence of the nature of the organic group in the cyclodisilazane on the shift of the stretching vibration frequency ν_{as}[Si(NSi)] (cm^{-1}).[21]

Fragment	R					
	Me	Et	n-Pr	n-Bu	n-C_6H_{11}	Ph
$(Me_2Si—NR)_2$	912	955	—	923	953	963
$(RSiNHPh—NPh)_2$	—	917	917	919	—	—

As mentioned previously[4], *N*-substituted and particularly *N*-triorganosilyl-substituted organocyclodisilazanes are stable compounds. However, since the cyclodisilazane ring is highly strained, the replacement of one of the substituents at the nitrogen atom by hydrogen leads to the formation of chemically fairly reactive compounds[4,33], which is manifested by the anomalous disposition of the absorption bands due to stretching vibrations. Thus in the spectrum of 1-trimethylsilyl-2,2,4,4-tetramethylcyclodisilazane (VII)

(VII)

the nearest ν(NH) band shifts to 3510 cm^{-1} (which indicates an increased acidity of the proton attached to the N atom) and there is a corresponding shift of the central band to 1000 cm^{-1}. The ν(Si–N–Si) absorption band, corresponding to asymmetric stretching vibrations, which is believed[4,34] to characterise also the cyclodisilazane ring, is located in the region of 870 cm^{-1}.



Analysis of the vibrational spectra of methylcyclodisilazanes showed[35] that vibrations due to individual Si–N bonds (endocyclic or exocyclic) cannot be isolated for the Si_4N_2 fragment (which can be treated to a first approximation independently of the vibrations of methyl groups and other functional groups attached to silicon atoms as a consequence of the so-called barrier effect of the silicon atom) and one must consider the vibrations of the fragment as a single whole. The wavenumbers 1050, 880, 770, 720, 460, and 430 cm^{-1} have been assigned to the stretching vibrations of the Si_4N_2 fragment. These wavenumbers do not in fact change as the functional groups at the silicon atom are varied. The bands in the region of 1050 cm^{-1}, which are intense in the infrared spectrum and are absent from the Raman spectrum, as well as the intense polarised bands in the region of 460 cm^{-1} in the Raman spectrum[35–37] can be specified as the most characteristic. It has been confirmed spectroscopically that the Si_4N_2 skeleton in 1,3-bis(chlorodimethylsilyl)-2,2,4,4-tetramethylcyclodisilazanes (Va) is planar, because the alternative prohibition rule holds for the stretching vibrations of the Si_4N_2 fragment, three of which (1050, 880, and 430 cm^{-1}) are active only in the infrared spectrum, while three others (770, 720, and 460 cm^{-1}) are active only in the Raman spectrum. This result agrees satisfactorily with X-ray diffraction data[17]. The deformation vibrations of the Si_4N_2 fragment are not considered, since they lie in the region of very low frequencies where their interpretation is difficult. Comparison of the spectra of liquids (melt at 100 °C) and crystals showed that significant changes are not observed in the transition from the liquid to the crystalline state[35].

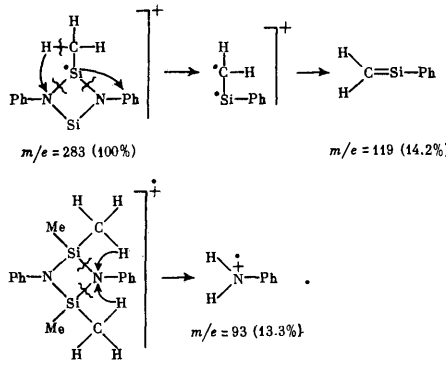
The vibrational spectra of phenylcyclodisilazanes have been interpreted by comparison with the spectra of diphenylsilane. The majority of the vibrations of the benzene rings are characteristic either in terms of frequency or in terms of frequency and mode, which makes it possible to separate them from the vibrations of the Si_4N_2 fragment. In the Raman spectra the bands corresponding to the vibration of the benzene rings are much more intense than those due to the stretching vibrations of the Si_4N_2 fragment. The wavenumbers 1020, 800, 720, 610, 540, and 400 cm^{-1} have been assigned to the stretching vibrations of the Si_4N_2 fragment[38].

The intense infrared band in the region of 800 cm^{-1} can be specified as the analytical band for phenylcyclodisilazanes. The changes in the frequency of this band as a function of the functional groups attached to the exocyclic silicon atom are 798 cm^{-1} when H is replaced by OH, 800 cm^{-1} for Cl, 801 cm^{-1} for OEt, and 824 cm^{-1} for NH_2.[39]

The vibrational spectroscopic data are satisfactorily consistent with the planar structure of the four-membered silazane ring in 1,3-bis(chlorophenylsilyl)-2,2,4,4-tetraphenylcyclodisilazane (VI). The alternative prohibition rule holds for the ν(Si–N) stretching vibrations: the frequencies corresponding to vibrations of the B_{2u} and B_{3u} symmetry types (540, 800, and 1020 cm^{-1}) are active only in the infrared spectra, while the frequencies corresponding to the vibrations of the A_g and B_{1g} symmetry type (400, 610, and 720 cm^{-1}) are active only in the Raman spectra[38].

The mass spectra of *N*-alkyl- and *N*-aryl-cyclodisilazanes as well as the interpretation of the differences between the mass spectroscopic fragmentations of organocyclodisilazanes have been described[21,31,40,41]. A characteristic feature of the mass spectrum of compound (II) is the high (98%) intensity of the peak due to the molecular ion whose decomposition takes place via the consecutive loss of methyl groups[40]. The transitions $M^+ \rightarrow (M - Me)^+ \rightarrow (M - 2Me)$ have been confirmed by the presence of the corresponding metastable peaks.

The *m/e* 149 peak (Table 2) corresponds to the doubly charged molecular ion M^{2+} and not to the singly charged ion formed as a result of the decomposition involving the dissociation of two Si–N bonds. The dissociation of the bonds in the ring leads to rearranged ions with *m/e* 119 and 93:



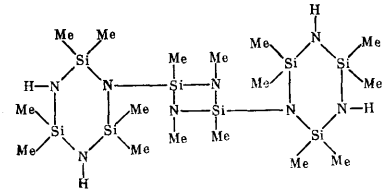


Table 2. Mass spectrometric data for 1,3-diphenyl-2,2,4,4-tetramethylcyclodisilazane (II).[40]

The mass spectrum of 1,3-dimethyl-2,4-bis(2,2,4,4,6,6-hexamethylcyclotrisilazanyl)-2,4-dimethylcyclodisilazane

is characterised by the following peaks: *m/e* 580 (6%) $[M]^+$; *m/e* 565 (49%) $[M - Me]^+$; *m/e* 548 (19%) $[M - Me, -NH_3]^+$; *m/e* 534 (100%) $[M - 2Me, -CH_2]^+$; *m/e* 519 (10%) $[M - 3Me, -CH_4]^+$; *m/e* 495 (9%), *m/e* 482 (15%), *m/e* 461 (14%), *m/e* 275 (12%).[41]

The principal ^1H NMR data for *N*-alkyl- and *N*-aryl-cyclodisilazanes have been published in a number of studies[2,22,26–28,41–53]. In the ^1H NMR spectra of cyclodisilazane derivatives of compound (Va) the chemical shift of the signals due to the protons in the methyl group linked to the silicon atom of the cyclodisilazane is $\tau = 9.76–9.79$; for the protons of the methyl groups linked to the exocyclic silicon atom, $\tau = 10.01–10.05$ (10% solution in CCl_4).[27,32] The following chemical shifts of the proton signals are characteristic of the ^1H NMR spectra of 1,3-dimethyl-2,4-bis(2,2,4,4,6,6-hexamethylcyclotrisilazanyl)-2,4-dimethylcyclodisilazane (solution in CH_2Cl_2, internal standard—$SiMe_4$):[41] $\tau = 9.96$ for the protons of the $SiMe_2$ group, $\tau = 9.89$ for the protons of $N(SiMe_2)_2$, $\tau = 9.83$ for the protons of SiMe, and $\tau = 7.43$ for the protons of NMe. The chemical shifts of the protons in the cyclodisilazane compounds with different organic groups are presented in Table 3.

Table 3. Chemical shifts of the proton signals of *N*-triorganosilyl-*N'*-organocyclodisilazanes (VIII)–(XI) [27,32]

Compound	R^1	R^2	R^3	R^4	$\tau_{(R^1)}$	$\tau_{(R^2)}$	$\tau^*_{(R^4)}$
(VIII)	Me	Me	Me	Me	9.85	10.04	7.55
(IX)	Me	Me	Me	Et	9.83	10.03	7.18 qu. 8.97 t.
(X)	Me	Me	Me	Ph	9.57	9.94	2.80—3.69 m.
(XI)	Me	Me	Ph	Me	9.87	9.72	7.53

*J = 7 Hz; notation: qu. = quartet, t. = triplet; m. = multiplet.

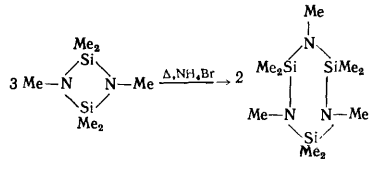
The chemical shift of the protons of the methyl groups linked to the endocyclic silicon atom is 9.85 for compound (VIII) and is intermediate between the values of τ for compound (Ia) (9.79) and 1,2,2,3,4,4-hexamethylcyclodisilazane (XII) (9.89), while the value for compound (XI) (9.57) is intermediate between 9.79 for compound (Ia) and 9.37 for compound (II).[26]

The photolysis of certain trialkylsilyl azides, such as trimethylsilyl azide or n-propyldimethylsilyl azide, results in the formation of cyclodisilazanes with different organic

groups[53]. Further photolysis of these cyclodisilazanes leads to the formation of high-molecular-weight alkylsilazanyl azides. The photolysis was carried out in a Rayonet reactor using Rayonet RPR-2737 lamps; the illumination periods ranged from 30 min to 65 h.[53]

There are no reports in the literature of systematic studies of organocyclodisilazanes by quantum-chemical methods. This is evidently because these methods have been introduced comparatively recently, but they permit a fairly correct analysis of the electronic structures of molecules. Quantum-mechanical methods have been used in terms of the approximation involving complete neglect of differential overlap and were not specially optimised for calculations on systems such as organocyclodisilazanes where the *d* atomic orbital of silicon plays a major role in the electronic structure and in which there is a marked charge separation in the Si–N bonds.

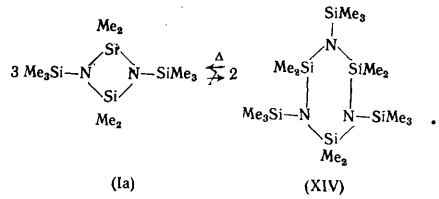
A version of the LCAO-MO SCF CNDO method[55] was used in one of the studies [54] and quantum-chemical calculations were made for cyclosilazanes. Compared with cyclosiloxanes, the quantum-chemical calculation for cyclosilazanes predicts a higher electron density at the silicon atom. As a result of the smaller charge separation in cyclosilazanes, the electrostatic component, which determines the dihedral angle involving the two silicon ring atoms, is smaller when the nitrogen atom is present at its vertex than in the compound with an oxygen atom. This is the cause of the formation of small SiNSi angles and relatively large SiOSi angles.



One of the factors which explains the cause of the stability of organocyclodisilazanes compared with organocyclodisiloxanes is the occurrence of strong additional endocyclic p_π–p_π interaction between opposite nitrogen atoms. The N...N bond index in cyclodisilazane is 0.478 a.u., which is approximately ten times greater than for the corresponding O...O interaction in cyclodisiloxane. In cyclosilazanes the extent of the N...N interaction diminishes rapidly with increasing ring size and in the eight-membered ring it already approaches the extent of the corresponding O...O interaction in cyclosiloxanes.

III. CHEMICAL REACTIONS AND PROPERTIES OF ORGANOCYCLODISILAZANES

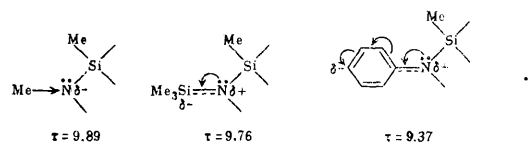
1. *N*-Alkyl- and *N*-Aryl-Cyclodisilazanes



It has been shown by X-ray diffraction[4,14] that the angle between the bonds at the nitrogen atom in cyclodisilazanes is distorted and approaches the angle corresponding to pure *p* orbitals. This is manifested by a weakening of the endocyclic Si–N bond on passing from compound (XII) to compound (Ia).[8,24] However, although the reactivity of this bond should have increased in this direction, in reality it diminishes. Thus compound (XII) is readily solvolysed[56], while compound (Ia) is more stable in relation to water and alkalis[2]. The stability of cyclodisilazanes with methyl substituents at the silicon atom in relation to acids varies in the following sequence as a function of the substituents at the nitrogen atom: alkyl < trimethylsilyl < aryl.

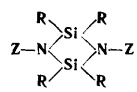
Heating of compound (XII) or other *N*-methylated cyclodisilazanes in the presence of a catalyst leads to the irreversible formation of a six-membered silazane ring[24,57]:

(XII) (XIII) (1)



On the other hand, compound (Ia) and *N*-phenylcyclodisilazanes do not undergo a rearrangement under similar conditions[2]:

(Ia) (XIV) (2)

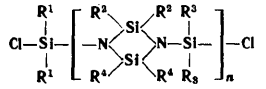


Compound (Ia) does not react with ammonium bromide [like compound (XII), which undergoes reaction (1)], while *N*-phenylcyclodisilazanes react only above 400 °C and very slowly, a mixture of products without a six-membered silazane ring being formed[2]. 1,3,5-Tris(trimethylsilyl)cyclotrisilazanes of type (XIV) are capable of being converted into cyclodisilazanes via reaction (2) at elevated temperatures (400–425 °C), but even at 450 °C the reaction does not go to completion[2].

The differences between the stabilities of cyclodisilazanes of different types can be accounted for by the different distributions of electron density in the molecule. Substituents at the nitrogen atom can increase or decrease the electron density as a result of the inductive influence. The reactions involving the Si–N bond, for example, hydrolysis, normally take place on protonation of the nitrogen atom and are facilitated by increasing nucleophilicity of the substituent. The electron density at the nitrogen atom and hence also the basicity decrease in the following sequence as a function of the substituent: Me > Me_3Si > Ph; the resistance of organocyclodisilazanes to electrophilic attack then increases. The d_π–p_π contribution to the Si–N bond in the ring decreases in the same sequence, which is confirmed by the changes in τ_{SiMe}:[2,8,24]

τ = 9.89 τ = 9.76 τ = 9.37

Table 4. Temperatures of the onset of decomposition of organocyclodisilazanes[58,59]



R	Z	*t*, °C	R	Z	*t*, °C	R	Z	*t*, °C
Ph	Me	392	Ph	Ph	455	Ph	*m*-C_6H_4F	418
Ph	Et	394	Me	*p*-$C_6H_5C_6H_4$	432	Ph	*m*-$(CF_3)_2C_6H_3$	384
Me	n-Bu	>223	Ph	*p*-$C_6H_5C_6H_4$	443	Me	$SiPh_2Me$	416
Me	C_6H_{11}	>317	Me	*m*-$C_6H_5OC_6H_4$	442	Me	$SiPh_3$	439
Me	Ph	481	Me	2,4,6-$(CH_3)_3C_6H_2$	365	Ph	$SiMe_3$	421

N-Phenyl- and *N*-trimethylsilyl-cyclodisilazanes exhibit a high thermal stability. An appreciable decomposition of the ring is not observed even at 450 °C.[58,59] Table 4 lists the temperature at which the test compounds lose 1% of their weight[58].

2. Reactions of α,ω-Diorganosilylcyclodisilazanes

The reactions of α,ω-diorganohalogenosilylcyclodisilazanes with electrophiles and nucleophiles, leading to different derivatives, are of great interest. In organocyclodisilazanes containing a chlorine atom in the side chain, for example, in compounds (Va)–(Vf), (VI), and (XV)–(XX) (Table 5), the latter is readily substituted by an organic group on treatment with an organometallic compound, for example, a Grignard reagent[27,34,60–63]. There is also a possibility of the replacement of only one Cl atom in compounds (XXII)–(XXIV) (Table 6) by selecting an appropriate reactant ratio[61,64]. The substitution of chlorine atoms by a triorganosiloxy-group can be achieved by allowing compounds of type (V) to react with the corresponding sodium triorganosilanoxides. The trimethylsiloxy- and methyldiphenylsiloxycyclodisilazanes (XXV) and (XXVI) obtained in this way are liquids; triphenylsiloxycyclodisilazanes (XXVII) are solids; oligomers with an odd number *n* are crystalline, while those with an even number *n* are waxy substances (Table 6).[61]

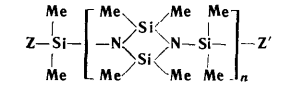
1,3-Bis(dimethylsilyl)-2,2,4,4-tetramethylcyclodisilazane (XXVIII) (Table 6) can be obtained from compound (Va) by reaction with lithium aluminium hydride[27,62,63] or by heating 1,1,3,3-tetramethyldisilazane in the presence of sodium methoxide or KOH;[65,66] 1,3-bis(diphenylsilyl)-2,2,4,4-tetraphenylcyclodisilazane (XLII) has been obtained by the interaction of diaminodiphenylsilane with diphenylsilane via reaction (3) using molar reactant ratios ranging from 1 : 3 to 1 : 4 in the presence of potassium trimethylsilanoxide as the catalyst[67,68].

(XLII)

(3)



Dehydrocondensation can be used for the specific synthesis of organocyclodisilazanes containing a hydrogen atom at the endocyclic Si atom, for example[69]:

(XLIII)

The interaction of organocyclodisilazanes (V) with ammonia, amines, or amides leads to the formation of the corresponding nitrogen-containing cyclodisilazanes (XXIX)–(XXXV) (Table 6).[27,33,61–63,70,71] Other organocyclodisilazanes with the groups NH_2, NHR, or NR_2 (R = Me, Et, n-Bu, t-Bu, Ph, or $SiMe_3$) are obtained by the thermal condensation of organoaminosilanes $R_nSi(NHSiR'_3)_{4-n}$ (*n* = 0–2) or tetra-alkyl(aryl)-aminosilanes[72–76].

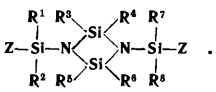
The hydroxycyclodisilazanes (XXXVI) (Table 6) and (XLIV) (Table 7) have been obtained by the hydrolysis of the organocyclodisilazanes (Va), (VI), (XV)–(XVIII), and (XXIX).[27,63,77–80].

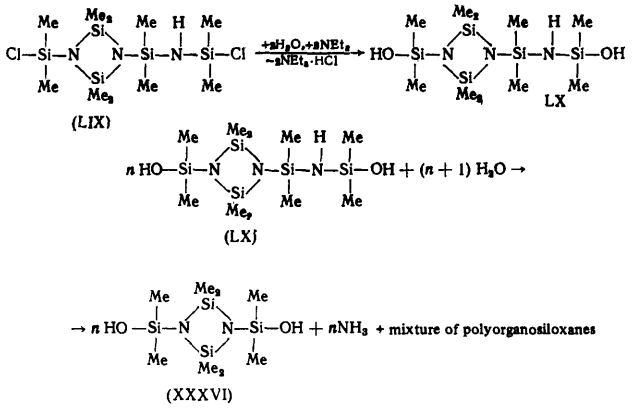
The study of the hydrolysis of organocyclodisilazanes showed[77,78] that the composition of the final hydrolysis products of compounds (V) and (XXIX) is influenced not only by the acidity of the medium and the amount of hydrolysing agent, as in the hydrolysis of aminosilanes and silazanes, but also by the order of mixing of the initial components. The mechanism of the hydrolysis has been established:

The opening of the cyclodisilazane ring in the hydrolysis of compound (Va) can be apparently accounted for by the effect of the hydrogen chloride evolved in the first instant of the reaction, while the formation of the silazanesiloxane ring of 2,2,4,4,6,6-hexamethyl-5-hydroxydimethylsilyl-1,3-dioxa-5-aza-2,4,6-trisilacyclohexane can be explained by the intermolecular condensation of the intermediates in reaction (4) under the influence of water.



The initial and final compounds were analysed on the basis of mass spectrometric[81] and X-ray diffraction[79] data. The structure of the hydrolysis product of compound (XXXVI) was established on the basis of the observed behaviour[81]. The presence in the mass spectrum of this compound of the peak due to a molecular ion with *m/e* 295 and the peak of the ion $(M-Me)^+$ with *m/e* 280, which has the maximum intensity, indicates unambiguously the presence in the molecule of three oxygen atoms and one nitrogen atom. The high intensity (12%) of the peak of the $(M-MeOSiMe_2)^+$ ion with *m/e* 206 indicates the presence of the hydroxydimethylsilyl group at the nitrogen atom in the ring. The loss of the end group in decomposition following electron impact is not characteristic of linear siloxanes. This makes it possible to rule out the alternative structure with a four-membered ring

proposed by Fink[80] and to confirm the structure of the six-membered ring of 2,2,4,4,6,6-hexamethyl-5-hydroxydimethylsilyl-1,3-dioxa-5-aza-2,4,6-trisilacyclohexane. Crystals of this compound (Fig. 7) are monoclinic with the lattice parameters $a = 6.866(2)$ Å, $b = 19.161(6)$ Å, and $c = 13.423(5)$ Å; $\beta = 105.25(10)°$, space group $P2_1/C$, $Z = 4$.



In the hydrolysis of 1-(3-chloro-1,1,3,3-tetramethyldisilazanyl)-3-chlorodimethylsilyl-2,2,4,4,-tetramethylcyclodisilazane (LIX) the reaction is influenced by the ratio of the amounts of the cyclodisilazane and the hydrolysing agent[82]; depending on the hydrolysis conditions, the product is either 1-(3-hydroxy-1,1,3,3-tetramethyldisilazanyl)-3-hydroxydimethylsilyl-2,2,4,4-tetramethylcyclodisilazane (LX) [reaction

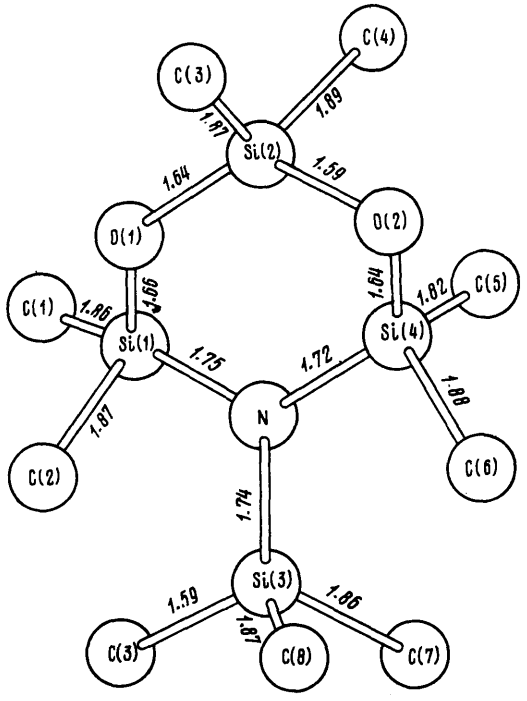
(5)] or the products of its further transformation into a mixture of polyorganosiloxanes[82] [reaction (6)]:

(5)

(6)



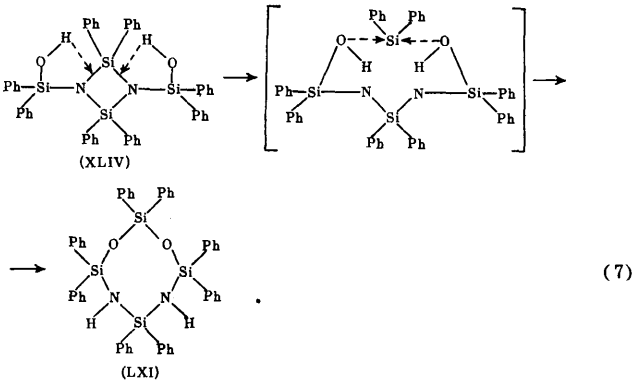


Figure 7. Stereochemistry of the 2,2,4,4,6,6-hexamethyl-5-hydroxydimethylsilyl-1,3-dioxa-5-aza-2,4,6-trisilacyclohexane molecule[81].

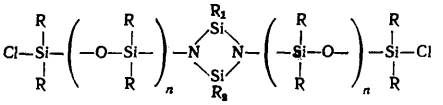
In contrast to methylcyclodisilazanes, the hydrolysis of 1,3-bis(diphenylsilyl)tetraphenylcyclodisilazanes proceeds with retention of the cyclodisilazane ring regardless of the conditions[39].

The study of the influence of the functional groups (Cl, H, OH, NH_2, OEt), linked to the exocyclic Si atom in phenylcyclodisilazanes (VI) (Table 5) and (XLII)–(XLVI) (Table 7), on their hydrolytic stability showed that the hydrolysis involving the functional groups Cl and NH_2 takes place over a period of time and the final product is a mixture of the initial compound and the hydrolysis product, which is difficult to separate. Phenylcyclodisilazanes with the OEt of H substituents are hydrolytically stable under the same conditions[39].

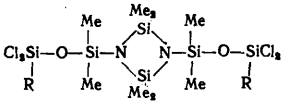
Approximately 2–3% of 2,2,4,4,6,6,8,8-octaphenyl-1,3-dioxa-5,7-diaza-2,4,6,8-tetrasilacyclo-octane (LXI) was isolated in the separation of the hydrolysis products of phenylcyclodisilazane. Thus the hydrolysis of phenylcyclodisilazanes at the Si–X bond (X = Cl or NH_2) is accompanied to a slight extent by hydrolytic cleavage at the Si–N bond [reaction (7)] regardless of the conditions under which it takes place. Reaction (7) leads to the expansion of the four-membered cyclodisilazane ring[83]:



(7)

It is noteworthy that the separation of compounds (XLIV) and (LXI) presents considerable difficulties and can be achieved only by repeated recrystallisation from benzene. The presence of compound (LXI) decreases the melting point of compound (LXIV) from 157–158° to 141–150 °C.[83]

The structure of the product (LXI) was established by X-ray diffraction. The crystals of compound (LXI) are triclinic, belong to the space group $P\bar{1}$, and have the lattice parameters a = 14.912 Å, b = 13.258 Å, and c = 14.218 Å; α = 124.61°, β = 104.64°, and γ = 91.24°. The structure was elucidated on the basis of 2827 reflections and was refined up to an R factor of 11.6% (Fig.8).[83]



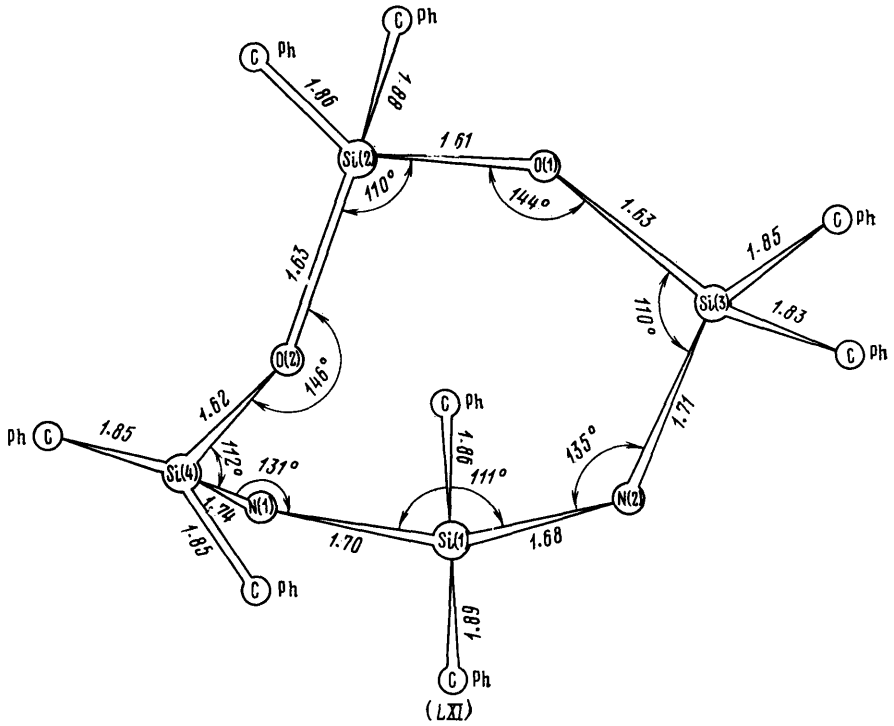
The hydrolysis of cyclodisilazane oligomers (LXII) yielded the corresponding α,ω-dihydroxy-derivatives[80,84,85], consisting of oily liquids:

(LXII)

R = Me, Et, CH_2 = CH or Ph; n = 1 – 3 .

The interaction of hydroxy-derivatives with trichloromethylsilane or trichlorophenylsilane in the presence of a hydrogen chloride acceptor gave rise to the tetrachloroderivatives (LXIII):[86]

(LXIII)



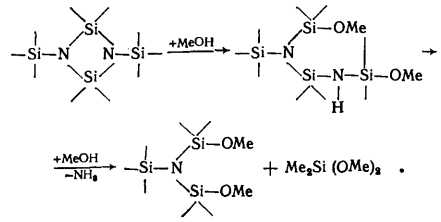


Figure 8. Stereochemistry of the 2,2,4,4,6,6,8,8-octaphenyl-1,3-dioxa-5,7-diaza-2,4,6,8-tetrasilacyclo-octane (LXI) molecule, bond lengths, and bond angles[72].

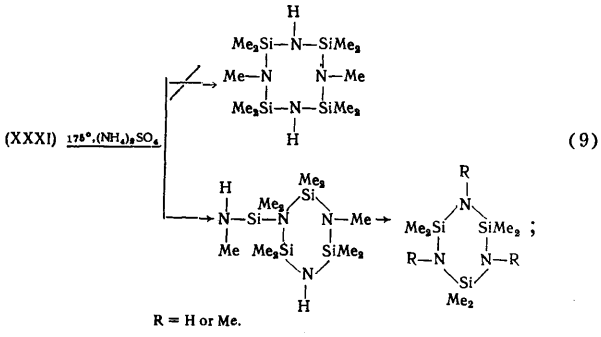
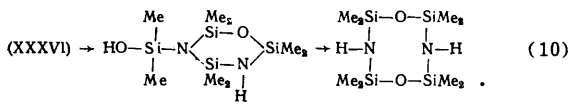
The interaction of organocyclodisilazanes with alcohols, phenol, and glacial acetic acid yielded the corresponding derivatives (XXXVII)–(XLI) (Table 6).[27,62,63]



The alcoholysis of organocyclodisilazanes [reaction (8)] with a large (16-fold) excess of an alcohol, for example, methanol, cleaves the Si–N ring bond and symmetrical and asymmetrical silylamines are formed[26]:

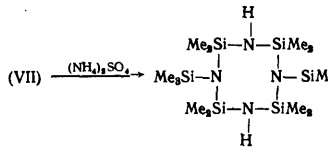
(8)



N,N'-Bis(diorganohalogenosilyl)cyclodisilazanes as well as the corresponding alkoxy- and phenoxy-derivatives (XXXVII)–(XL) (Table 6) remain unchanged on heating up to the boiling point in the presence of catalytic amounts of ammonium sulphate. Heating of 1,3-bis(dimethylaminosilyl)-2,2,4,4-tetramethylcyclodisilazane (XXIX) with ammonium sulphate (for 24 h at 200 °C) leads to a mixture of products, from which only hexamethylcyclotrisilazane was isolated (15%), although compound (XXIX) does not undergo any changes on refluxing (236 °C) without a catalyst[63].

It has been claimed[63] that, when 1,3-bis[dimethyl(methylamino)silyl]-2,2,4,4-tetramethylcyclodisilazane (XXXI) is heated to 175 °C with ammonium sulphate [reaction (9)], the ring expands and 1,2,2,4,4,5,6,6,8,8-decamethylcyclotetrasilazane is formed (38%). However, other workers[87] showed that this reaction results in the formation of a mixture of *N*-methylcyclotrisilazanes:

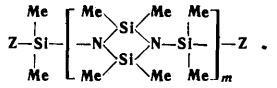
(9)



Andrianov et al.[88] showed that, on heating (1.5 h, 60 °C) in the presence of tetramethylammonium silanoxide (0.05%), compound (XXIX) undergoes reaction (10) and gives rise to octamethylcyclotetrasilazane (36%). A rearrangement with ring expansion is observed under the same conditions also for 1,3-bis(hydroxydimethylsilyl)-2,2,4,4-tetramethylcyclodisilazane (XXXVI):[88]

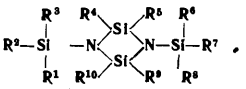
(10)

1-Trimethylsilyl-2,2,4,4-tetramethylcyclodisilazane (VII) remains unchanged on heating, but in the presence of ammonium sulphate (1%) at 190 °C is converted via reaction



(11) into a dimer with an eight-membered ring[89]:

(11)



The characteristics of derivatives of oligomeric α,ω-diorganosilylcyclodisilazanes are presented in Table 6 and 7. Data for the thermal stabilities of certain organocyclodisilazanes[58] are given in Tables 8–10.

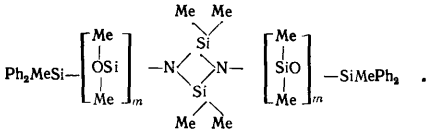
IV. POLYMERS CONTAINING CYCLODISILAZANE UNITS

The polymers (LXIV) (Table 11) are usually synthesised in two ways—by the polycondensation of aromatic diamines with diaminosilanes and by the catalytic silylation of aliphatic or aromatic diamines by the organosilanes R_nSiH_{4-n}, where $n = 1$ and 2.

1. Polycondensation of Aromatic Diamines with Diaminosilanes

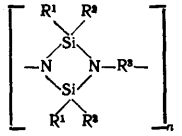


The polymers (LXIV, a–d) are formed via the following reaction with a reactant ratio of 2 : 1:[59,90]

(LXIV, a–d)

X=Ar; (Ia) — (Ib) : R=Me; (Id) : R=Ph; (12)
$n = 15 - 20$.

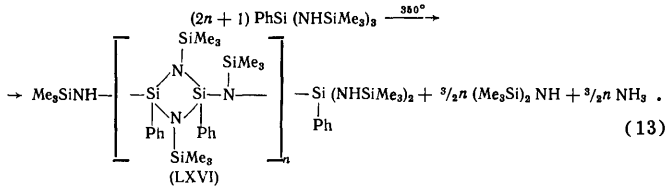
Table 10. Temperatures of the onset of decomposition of cyclodisilazanes[58]



m	1	2	3	4
t, °C	427	417	413	411

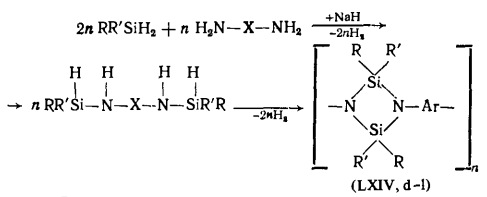
N,*N'*-Alkylethyldiaminosilanes, whose amino-residue is readily split off, are used as the silyl component. Among aromatic diamines, derivatives with functional groups in the 1,4-, 3,3'-, and 4,4'-positions have been used. The formation of an intermediate via reaction (12) proceeds readily at 135–260 °C (depending on *R*); the cyclisation requires higher temperatures (~400 °C). The reaction can be carried out in the melt or in a high-boiling solvent, but neither method is altogether satisfactory, since the yield does not exceed 75%. Further reaction is prevented by the marked increase of viscosity or by the insolubility of the products as the degree of condensation increases. The degree of condensation obtained for compounds (LXIV, a–d) is therefore only 15–20.

By heating to a high temperature a compound



which is formed in its turn by heating a compound $R^4HNSiR^1.R^2NHR^4$ with a diamine $H_2NR^3NH_2$, one can obtain similarly the cyclodisilazane polymers (LXV), where R^1, R^2 = F, H, alkyl, alkenyl, alkynyl, cycloalkyl, or aryl [or R^1, R^2 = $-(CH_2)_m-$] and R^3 = arylene or a bivalent polyarylene oxide, polyarylene sulphide, or polyarylene sulphone residue[90–95]:

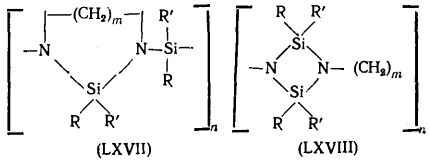
Solid not unduly brittle polymers with a slightly yellowish colour have been obtained. They are insoluble in various organic solvents and in water even after prolonged boiling. Such polymers do not melt up to 600 °C.



The thermal condensation of tris(trimethylsilylamino)phenylsilane leads to the formation of the oligomers (LXVI):[25]

(LXVI) (13)

2. Polycondensation of Aromatic and Aliphatic Diamines with Di- and Mono-organosilanes

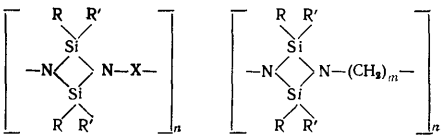


The polymers (LXIV, d–l) with a higher degree of polymerisation can be obtained by the catalytic silylation of primary aromatic diamines by di- and mono-organosilanes[59]:

(LXIV, d–l)

(LXIV, d–g); : R=R′=Ph; (LXIV, h–j); : R=H, R′=Ph;(LXIV, k and l): R= Me, R′=Ph . (14)

Reactions (14), catalysed by alkali metals or their hydrides, proceed very rapidly at 50–150 °C. Both polar (ether) and non-polar (benzene, xylene, etc.) solvents can be used. Only hydrogen is a side product of the reaction, the yield amounting to ~100%. The properties of the polymers (LXIV, d–l) are given in Table 11. α,ω-Polymethylenediamines condense with dihydro-organosilanes in the presence of catalysts (Na, K, NaH), forming polymers (LXVIII).[96] Fink[59] achieved the reactions of diphenylsilane with ethylenediamine, 1,3-diaminopropane, 1,4-diaminobutane, and 1,6-diaminohexane at 30° to 85 °C with quantitative conversions of the initial reactants. Whereas the rigidity of the benzene residue in aromatic 1,4-, 3,3′-, and 4,4′-diamines clearly determines the structure of the polymers (LXIV) formed by reaction (14), the flexibility of the methylene chain in aliphatic diamines permits in this instance the formation of two isomeric polymers:



(LXVII) (LXVIII)

The polymethylene chain is either a component part of the ring as in formula (LXVII) or it links disilazane rings [see formula (LXVIII), Table 11].

When the polymers (LXIV, a–l) are formed, they precipitate from the solution in the form of a light-coloured powder, which in most cases has a yellowish tint due to the charring of the amine. If the polycondensation is carried out in the melt, the polymers are obtained in a monolithic form with a very high viscosity. The polymers (LXVIII) are plastic and transparent. The solubility of the polymers (LXIV) in organic solvents is very low, with the exception of compounds (LXIVk) and (LXIVl); the polymers (LXVIII) readily dissolve in both aromatic and aliphatic solvents. The softening temperatures of some of the polymers (Table 11) lie above their decomposition temperatures, which can be explained by the reduced mobility and rigidity of the molecular chains[59].

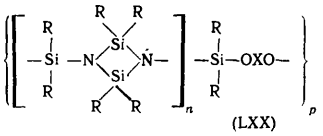
The thermal stabilities of the polymers (LXIV) and (LXVIII) have been studied in very great detail[59]. The polymers (LXIV, d–g) decompose at 360–380 °C in an atmosphere of nitrogen. The aromatic residue linked to the ring nitrogen atom has only a very slight influence on the stability of the polymers. The decomposition temperature changes little also when the substituents at the silicon atom are varied [polymers (LXIV, a, d, i, and k)]. Whereas the temperature of the onset of the thermal decomposition of all the polymers investigated is independent of the nature of the organic framework around the silicon atom, the degree of weight loss depends markedly on the nature of the organic groups. Thus compounds (LXIV, f, i, and j) lose at 600 °C up to 30–35% of their initial mass and then do not decompose further. The thermal stability of compound (LXVIII) is low and depends markedly on the length of the methylene chain.

Thermostable cyclodisilazane polymers (LXIX) can be obtained by heating a tetrasubstituted aminodisilane:

(LXIX)

$m = 0, 1, n > 10,$

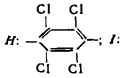


where Z is a primary amine residue, R^1 = alkyl, alkenyl, alkynyl, cycloalkyl, cycloalkenyl, arylalkyl, alkylaryl, alkenylaryl, alkynylaryl, or aryl, R^2 represents the same

groups or OR^1, and R^3 = alkylene, alkenylene, alkynylene, arylalkynylene, biarylene, etc.[97-101]

Such polymers are pale-yellow resins, which melt at ~350 °C and are insoluble in the usual organic solvents and water.

The polymers (LXX) ($p > 10$) (Table 12) are obtained by the polycondensation of cyclodisilazanes containing functional groups with bisphenols or bifunctional silanols. The α,ω-bis-(amino or chloro)silylcyclodisilazanes have been used as cyclodisilazanes with functional groups. The polycondensation is usually carried out in boiling xylene and the yield is 95–100% (calculated from the amount of amine evolved)[59,63,76,80,84-86,96-111].



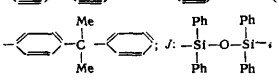


Table 12. Cyclodisilazane polymers[59]

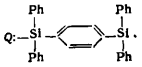

(LXX)

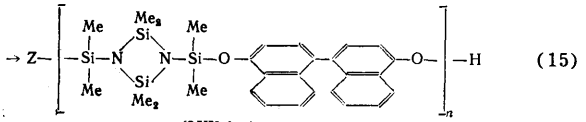
*Notation: *A*:  ; *D*: ; *G*: ;

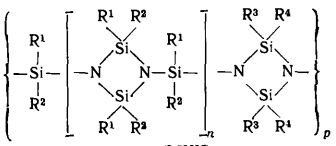


H:  ; *I*:  ; *J*: ;

Q:  .

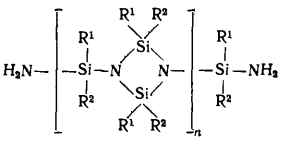
The polymers (LXX, a–d) are white or yellowish elastic products; the softening temperatures of the polymers with an even number of cyclodisilazane units in the chain are lower than those of the polymers with an odd number of units. Their plasticity as well as their solubility in aromatic solvents increase with n. On passing from *p*-cresol and *m*-cresol to 2,2-bis(4-hydroxyphenyl)propane, the polymers (LXX, f–h) become more elastic. When the cyclodisilazanes are fully phenylated, the polymers (LXX, j and k) consist of white brittle compounds with an extremely low solubility in the usual organic solvents. The polymers (LXX, a, e, and f) are able to swell in hexane and benzene.

An interesting group of polymers (LXX, l–o) have been obtained by the low-temperature (up to 150 °C) and high-temperature (150–200 °C) condensation of cyclodisilazane monomers containing functional groups with 4,4'-dihydroxy-1,1'-binaphthyl:[112]



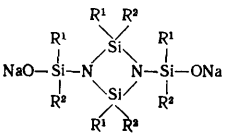
(LXX, l–o)

Z = Cl or NY; Y = H_2, Me_2, or HPh. (15)



The polymers (LXX, l–o) have a molecular weight of the order of thousands, are thermally stable up to ~500 °C, are readily soluble in benzene or ethyl methyl ketone, and do not decompose on treatment with methanol, which indicates an increase of the stability of the cyclodisilazane ring in a macromolecular chain of this type[112].

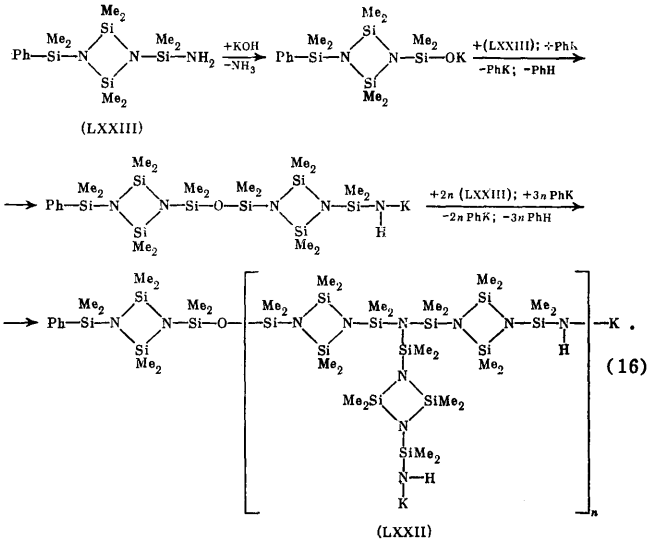
Polymers containing the fully methylated cyclodisilazane are as a rule stable on heating to 430–440 °C in nitrogen. At this temperature the polymers begin to decompose slowly: rapid decomposition takes place at 510–560 °C. The stability of such polymers is not influenced either by the nature of the groups -OXO-, linking the silazane rings, or by the increase of the fraction of silazane rings in the polymers resulting from the incorporation of oligomeric cyclodisilazanes. In the case of the fully phenylated polymers (LXX, j and k) the decomposition does not begin until 500 °C, which is the absolute maximum for polymers with Si–N bonds.



(LXXI)

The polymers (LXXI) are obtained by the interaction of α,ω-bisaminosilylated cyclodisilazanes

with the hydrosilanes $R^3R^4SiH_2$ (R^1, R^2, R^3, R^4 = H, F, a hydrocarbon group, or R^1R^2 and R^3R^4 = polymethylene group; n = 1–10) (molar ratio 2 : 1) in the presence of alkali and alkaline earth metals or their hydrides as catalysts[105,113-118], or by the condensation of the disodium or dilithium salts of 1,3-bis(diorganosilyl)cyclodisilazanes

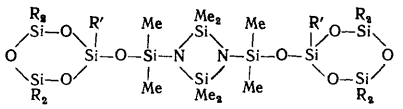


with dichlorodiorganosilanes $R^3R^4SiCl_2$ (with α,ω-dichlorodiorganosiloxanes) at 30–50 °C.[84,85,104,109,119,120]

The polymers (LXXI) are light-coloured brittle resins with softening temperatures in the range 80–100 °C. All the polymers (LXXI) obtained are thermally stable up to 450 °C.

The cyclodisilazane polymer (LXXII) with a branched structure has been obtained by the condensation of the monofunctional cyclodisilazane monomer (LXXIII) in the presence of KOH as the catalyst and without a solvent at 150–450 °C

in air or in an atmosphere of nitrogen at atmospheric pressure or *in vacuo*[112]:

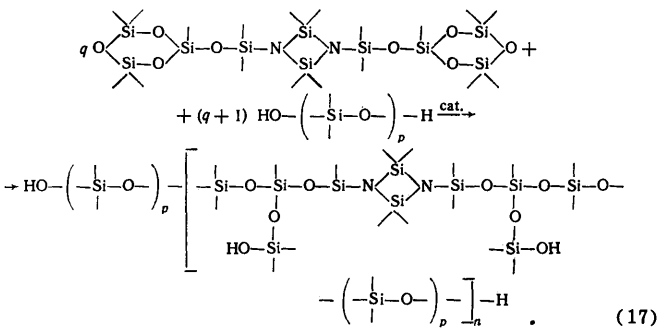


(LXXIII)

(LXXII)

(16)

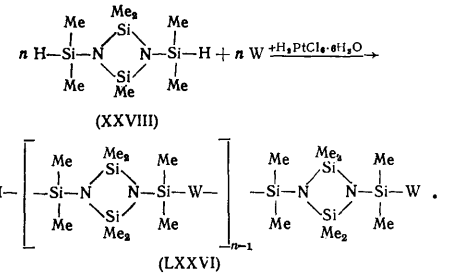
The reaction is catalysed by potassium hydroxide introduced initially into the reaction and (as suggested by Deyak et al.[112]), by the phenylpotassium and potassium silanoxide formed in the reaction, each catalyst playing a specific role at different stages of reaction (16). A polymer of this type is readily soluble and exhibits a fairly high thermal stability (up to ~500 °C).



Anionic copolymerisation of cyclodisilazanes (LXXIV) [86]

(LXXIV)

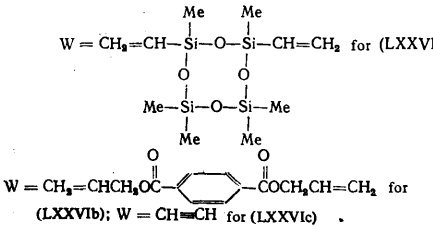
R=R′=Me; R=Me, R′=Ph; R=Ph, R′=Me,



and α,ω-dihydroxypolydimethylsiloxanes also yielded branched cyclodisilazane polymers (LXXV).[121,122] The reaction is carried out in the presence of a catalytic amount of the diammonium or dipotassium salt of polydimethylsiloxanediol at 60–80 °C or at 140 °C respectively. The copolymerisation is based on the fact that the proton of the hydroxy-group exchanges for the catalyst cation, as a result of which the active centres are transferred from the catalyst to the organosilicon diol, which acquires the ability to interact with the cyclodisilazane (LXXIV), opening the siloxane rings in the latter and forming a polymer[121]:

(17)

A soluble polymer is formed in the initial stage of reaction (17) and then passes to a structured state (a three-dimensional network) with a high content of the insoluble product. Thermo-oxidative degradation of the polymers (LXXV) showed that the main decomposition reaction of these polymers proceeds in the range 400–450 °C.[121]

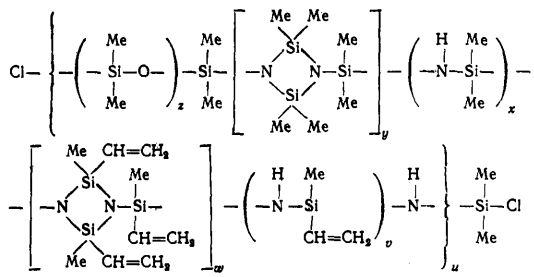


An interesting group of polymers (LXXVI) have been obtained by the reaction involving the polyaddition of 1,3-bis(dimethylsilyl)-2,2,4,4-tetramethylcyclodisilazane to unsaturated organosilicon and organic compounds in the presence of chloroplatinic acid and rhodium compounds[123]:

(XXVIII)

(LXXVI)

The polymer (LXXVIa), with an intrinsic viscosity $\eta = 0.28$, is formed in the course of 3.5 h after the introduction of $H_2PtCl_2.6H_2O$ (1.5×10^{-5} M), in the form of a 0.1 M solution in tetrahydrofuran, into the equimolar mixture and on heating the reaction mixture to 170 °C. The reaction with diallyl isophthalate, leading to the formation of the polymeric product (LXXVIb), takes place under the same conditions in the course of 20–25 min up to a conversion of 98% when 1×10^{-4} M $H_2PtCl_6.H_2O$ is introduced into the equimolar mixture (η = 0.41 dl g^{-1}) or after 15–20 s up to a conversion of 100% in the presence of acetylacetonatorhodium dicarbonyl and rhodium carbonyl at concentrations of the rhodium compounds changing from 1×10^{-4} to 1×10^{-5} M, but under these conditions $\eta \leq 0.2$ dl g^{-1}. 1,3-Bis(dimethylsilyl)-2,2,4,4-tetramethylcyclodisilazane (XXVIII) reacts with acetylene at the normal pressure in an acetylene atmosphere at 170 °C and an $H_2PtCl_6.6H_2O$ concentration of 5×10^{-4} M. This results in the formation after 6 h of a viscous product (LXXVIc) (after reprecipitation from toluene, its yield is 90%), which sets on cooling and has a glass point of 153 °C.



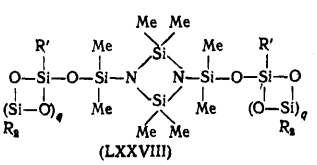
(LXXVIb); W = CH≡CH for (LXXVIc).

From the results obtained by Andrianov et al.[123], one may claim that 1,3-bis(dimethylsilyl)-2,2,4,4-tetramethylcyclodisilazane is highly reactive, but apparently one of the most important conditions for the polyaddition reaction is the occurrence of the stage involving the formation of an intermediate in the presence of catalysts. This has been confirmed by the study of the dependence of the induction period on the reaction temperature and catalyst concentration[123]. A change in process conditions and of the catalyst concentration does not then influence significantly the rate of reaction.

The thermo-oxidative degradation of the synthetic polymers (LXXVI, a–c) has been investigated on a DO-102 derivatograph in air in the range from 20° to 800 °C at a heating rate

of 5 K min^{-1}. Comparison of the results of the thermogravimetric analysis (TGA) for the polymers (LXXVI, a–c) shows that the resistance of the carbo-organosilazane polymers (LXXVI, b and c) to degradation is lower than that of the polymer (LXXVIa) with alternating cyclodisilazane and cyclosiloxane fragments. Thus a weight loss of only 10% is observed at 350 °C for the polymers (LXXVI, b and c), while the same weight loss by the polymer (LXXVIa) is reached at 480 °C. The results of differential thermographic analysis (DTA) also indicate an increase of the resistance of the polymers to thermo-oxidative degradation after the introduction of cyclodisilazane fragments into the polymer chain. Thus the maximum rate of decomposition of polymer (LXXVIa) occurs at 570 °C.

The organosilazoxane polymers (LXXVII), containing cyclodisilazane and linear silazane fragments with terminal chlorosilyl groups, have been obtained by the thermal condensation of organocyclotrisilazanes with α,ω-dichlorodiorganosiloxanes [124,125]:



$z = 1-4$; $y = 1.8-2.5$; $x = 0.5-2.6$; $w = v = 0-0.2$; $u = 0-2$.

The authors[124,125] showed that the degree of reaction increases with increasing temperature and with enhancement of the electron-accepting properties of the substituents at the silicon atoms in the organocyclosilazane and also that the reactivity of α,ω-dichlorodiorganosiloxanes is almost independent of chain length. However, in the study of this reaction a complete transformation of the secondary nitrogen atoms in the cyclotrisilazane into the tertiary nitrogen atoms of the cyclodisilazane could not be achieved, so that the final reaction products contained the linear silazane fragments ≡Si–NH–Si≡. The course of the reaction was followed in all cases from the change in the content of the NH groups in the reaction mixture. The polymers obtained by the thermal condensation of 1,3,5-trimethyl-1,3,5-trivinylcyclotrisilazane with α,ω-dichlorodiorganosiloxanes became subsequently structured, which may be accounted for by the partial polymerisation of the vinyl groups and the formation of a branched structure.

In order to eliminate low-molecular-weight products, the compounds (LXXVII, a–h) synthesised were evacuated to 5 mmHg at 200 °C, after which the content of active hydrogen was determined. The polymers (LXXVII, a–h) were identified from ^{1}H NMR and infrared spectroscopic data.

Polymers have been obtained[126] by the anionic polymerisation of tricyclic compounds (LXXVIII), whose molecules consist of two siloxane and one disilazane rings:

(LXXVIII)

$R = R' = Me$, $q = 2.3$; $R = Me$, $R' = Ph$, $q = 2$; $R = Ph$, $R' = Me$, $q = 2$.

The reaction takes place in the presence of the diammonium or dipotassium salts of polydimethylsiloxanediols at different temperatures in solution, in bulk, or in the solid state. The ratio of the soluble and insoluble fractions of the product then depends on the molecular structure of the initial compound (LXXVIII) and on its concentration.

Polymers with a branched macromolecular structure have been obtained[127,128] by the analogous reaction of 1,3-bis-(hydroxydimethylsilyl)-2,2,4,4-tetramethylcyclodisilazane (XXXVI) with hexamethylcyclotrisiloxane or octamethylcyclotetrasiloxane in the presence of tetramethylammonium siloxanedioxide with different initial reactant ratios. In both cases intramolecular rearrangements involving the expansion of both the disilazane and siloxane rings take place. This has been demonstrated by means of ^{1}H NMR spectra, in which a new peak due to methyl protons appears in a higher field than the peak of the methyl protons of the cyclodisilazane fragment; this new peak refers to the methyl protons in the trisilylamino-group of the expanded ring or the branched molecule[126]. The infrared spectra of such polymers were found to contain absorption bands in the range 930–950 cm^{-1}, characteristic of the Si–N bond and absent from the spectra of organocyclodisilazane compounds, as well as bands in the region of 1165, 1180, 3385, and 3420 cm^{-1}, characterising the deformation vibrations of the NH group and the stretching vibrations of the =N–H bond in the ≡Si–NH–Si≡ group[128].

The influence of the cyclodisilazane fragments on the hydrodynamic, conformational, and thermomechanical characteristics of polyorganosilazosiloxanes has been studied in relation to the products of the copolymerisation of 1,3-bis-(hydroxydimethylsilyl)-2,2,4,4-tetramethylcyclodisilazane and hexamethylcyclotrisiloxane or octamethylcyclotetrasiloxane introduced into the reaction mixture in molar proportions of 1 : 25, 1 : 50, 1 : 75, and 1 : 100.[127,128] The authors expected that the introduction of the cyclodisilazane fragments into the polydimethylsiloxane chain should influence the flexibility of the macromolecular chain and ultimately the mechanical properties of the polyorganosilazosiloxanes.

In order to determine the hydrodynamic, conformational, and molecular parameters, all the polymers were fractionated in the benzene–dioxan system. The molecular weights were measured in CCl_4 on a Sofica photogoniodiffusometer (the refractive index increment $dn/dc = 0.05$; 25 °C; wavelength $\lambda = 5460$ Å). The intrinsic viscosities were measured in toluene at 25 °C and in ethyl methyl ketone at 20 °C. The Mark–Kuhn–Houwink equations for the first two polyorganosilazosiloxanes (molar ratios 1 : 25 and 1 : 50) $[\eta] = 2.04 \times 10^{-5} M^{0.86}$ and $[\eta] = 1.09 \times 10^{-5} M^{0.92}$ are close to the analogous equation for polydimethylsiloxane $[\eta] = 1.10 \times 10^{-5} M^{0.92}$ in toluene at 25 °C, while at 20 °C in ethyl methyl ketone the equation is $[\eta] = 9.99 \times 10^{-4} M^{0.49}$ for the second polyorganosilazosiloxane (1 : 50) and $[\eta] = 8.90 \times 10^{-4} M^{0.50}$ for polydimethylsiloxane.

Calculation of the unperturbed molecular sizes from the Fixman–Stockmayer equation (which makes it possible to eliminate the effect of long range action) yielded a value of K_θ for the second polyorganosilazosiloxane (1 : 50) in agreement with K_θ for polydimethylsiloxane[127]. The conformational parameters obtained indicate a virtually complete agreement between the flexibility parameters of polyorganosilazosiloxanes and polydimethylsiloxane. The authors[127] adopted the following geometrical parameters for the calculation of the conformational parameters: Si–N and Si–O bond lengths 1.73 and 1.65 Å respectively and 90° angles in the disilazane ring. Consequently the flexibility of the polyorganosilazosiloxanes obtained is close to that of polydimethylsiloxane and the chosen ratios of the cyclodisilazane and dimethylsiloxane

fragments do not have a significant influence on the properties of the polymers. An estimate of the hydrodynamic and conformational parameters of polydimethylsilazosiloxanes from data concerning their behaviour in dilute solution showed that their macromolecules have a predominantly linear structure[128]. For ratios of 1 : 25 and 1 : 50, a unimodal distribution was observed both on molecular weight distribution curves obtained by fractionation and on curves obtained by gel chromatography. This shows that the polymer specimens contained macromolecules of the same type. For ratios of 1 : 75 and 1 : 100, a bimodal distribution was observed on the molecular weight distribution curves, which is undoubtedly due to the formation of two types of macromolecule—with linear and branched structures.

V. APPLICATIONS OF ORGANOCYCLODISILAZANES

Comparative tests on the thermal stabilities of a series of cyclic and linear silazanes and silylamines showed that only four-membered cyclodisilazane compounds are stable at ~500 °C.[129] Furthermore, organocyclodisilazanes exhibit effective separating properties and a high solubility in organic solvents. The physical properties of cyclodisilazane polymers vary as a function of the nature of the substituents: certain polymers exhibit a high elasticity, others are elastic and rubber-like, those of a third kind are transparent, and polymers of the fourth kind are characterised by effective antiadhesion properties which facilitate the removal of castings from moulds. Cyclodisilazane polymers may find the same applications in many branches of industry as siloxanes and may prove to be actually more effective[109,130–134].

The vast majority of studies on organocyclodisilazane compounds have been published in the form of patents. A considerable proportion of the information contained in the latter is extremely indefinite although optimistic; a number of valuable properties characteristic of these compounds have been described.

The heat and frost resistance, effective dielectric properties, the absence of adhesion, and the exceptional resistance to atmospheric conditions made it possible to use organocyclodisilazanes in the manufacture of insulating materials for electric cables employed in important branches of industry such as aeroplane construction and automobile, electrotechnical, and chemical industries.

Materials based on organocyclodisilazanes possess a unique combination of properties such as flexibility at a low temperature, thermal stability, and resistance to hot engine oil. This results not only in an improvement of operating characteristics but also in an increased reliability of many components used in aeroplane, bus, and automobile engines (seals, cooling hose, washers, etc.).

The possibility of using organocyclodisilazanes as coatings for paper is of interest. A fairly large amount of such paper is necessary in the processing and packing of a wide variety of sticky materials such as untreated raw rubber or confectionery with a high sugar content; however, the most important application involves the preparation of backs of labels, decorative coatings, etc.

Further possible applications of organocyclodisilazanes should be noted: (1) as high-temperature liquid heat exchangers[64,135–143]; (2) as lubricants and as additives to lubricating oils[64,137,138]; (3) as thermostable film-forming coatings[99,101,105,115,116]; (4) as adhesion-improving coatings[117]; (5) as impregnating compounds for fabrics imparting thermal stability[99,105]; (6) as impregnating compounds imparting thermal stability to other materials[101,113,115,116]; (7) as components of fibre-forming materials imparting thermal stability to the latter[101,113,115,116]; (8) as reagents for the improvement of the properties of paper and mica[99,113]; (9) as auxiliary materials in the leather industry[113]; (10) as casting resins[90]; (11) as dyes resistant to heat and atmospheric conditions[99,101,105,113,115,116]; (12) in the manufacture of plastics[69,91,101,113,115,116].

In certain reports the use of organocyclodisilazanes as stabilising, structure-forming, and covulcanising agents has been mentioned. Apart from the possible applications of organocyclodisilazanes described above, isolated claims have been made in the patent literature concerning the good prospects for their application in other fields.

---o0o---

During the preparation of the review for the press, a number of studies on organocyclodisilazanes were published.

It has been shown[144] that 1,3,2,2,4,4-hexaphenylcyclodisilazane forms monoclinic crystals with the lattice parameters $a = 10.471(2)$ Å, $b = 15.487(3)$ Å, and $c = 19.996(6)$ Å; $\beta = 108.06°$, $V = 3082.9(2.6)$ Å^3, $D_x = 1.178$, $Z = 4$, space group $C2/c$. The crystallographic twofold axis passes through the centre of the cyclodisilazane ring. The four-membered cyclodisilazane ring is not entirely flat: the dihedral angle, whose axis passes between two endocyclic Si atoms, is 1.2°. The *N*-phenyl fragments are almost coplanar with the plane of the cyclodisilazane ring (the dihedral angle between one of the halves of the cyclodisilazane ring and the phenyl group is 3.5°), demonstrating in its turn a characteristic feature of *N*-phenylcyclodisilazane derivatives, which consists in a favourable partial overlap of the π-electron system of the phenyl group with the unshared pair of *p* electrons of the nitrogen atom.

The crystal and molecular structures of 1,3-bis(chlorodimethylsilyl)-2,2,4,4-tetramethylcyclodisilazane have been examined in detail[145]. The principal structural parameters of the molecule agree satisfactorily with previous values.

The ^{1}H NMR, NMR, and infrared spectra of monomeric organocyclodisilazanes incorporating various groups (Me, Et, CH_2=CH, iso-Pr, F, Cl) have been published[146–150].

Reactions involving the hydride addition of 1,3-bis(dimethylsilyl)-2,2,4,4-tetramethylcyclodisilazane to pentamethylvinylcyclotrisiloxane and heptamethylvinylcyclotetrasiloxane in the presence of chloroplatinic acid (0.1 M solution of $H_2PtCl_6 \cdot 6H_2O$ in tetrahydrofuran; 0.5×10^{-5} g-atom Pt per litre of mixture) have been investigated[151] and mono- and di-addition products have been isolated.

The α,ω-bis(chlorodimethylsilyl)cyclodisilazane oligomers containing between 2 and 5 cyclodisilazane fragments in the molecular chain have been formed by the reaction of equimolar amounts of hexamethylcyclotrisilazane and dichlorodimethylsilane and characterised[152]. The hydrolysis of these oligomers[153] and the hydrolysis of oligomers containing the cyclosiloxane ring in addition to the cyclodisilazane fragment[154] have been investigated.

Oligomers with different lengths of the molecular chain have been obtained by the thermal condensation of tetrakis(trimethylsilylamino)silane[155], or 1,3-bis(hydroxydimethylsilyl)-2,2,4,4-tetramethylcyclodisilazane[156], or 1,3-bis(aminodimethylsilyl)-2,2,4,4-tetramethylcyclodisilazane[156], or α,ω-dichlorodiorganosiloxanes with organocyclodisilazanes[157]. An interesting group of oligomers have been obtained as a result of the anionic polymerisation of oligo-organocyclodisilazanes incorporating siloxane rings in the presence of the diammonium or dipotassium salts of polydimethylsiloxanediols[158] and also via the interaction of oligoamino-organocyclodisilazanes, dimethylsiloxane, diphenylsiloxane, and butadiene oligomers containing terminal hydroxy-groups[159].

The ammonolysis and aminolysis of chlorine-containing organocyclodisilazanes, which leads to monomeric and dimeric reaction products with amino-groups, have been studied in detail[160,161]. The composition and structure of the ammonolysis products are significantly influenced by the nature of the solvent employed and of the groups attached to the silicon atom.

It has been established that the interaction of methylcyclodisilazanes with anhydrous hydrogen chloride proceeds with dissociation of endocyclic Si–N bonds and the opening of the cyclodisilazane ring, while the interaction of phenylcyclodisilazanes takes place only via the functional groups with retention of the cyclodisilazane structure[162].

In the study of the alcoholysis and acidolysis of 1,3-bis(diorganosilyl)tetraorganocyclodisilazanes it was found that the mode and rate of these reactions are influenced significantly by the electronic nature of the organic and functional groups attached to the silicon atoms and also by the ratio of the initial reactants[163,164].

Reductive Polyheterocyclisation—New Method of Preparation of Polyheteroarylenes

V.V.Korshak, A.L.Rusanov, and D.S.Tugushi

Reduction and cyclisation of *o*-nitro-substituted heterochain polymers provides a new method for obtaining polyheteroarylenes of cyclochain structure. A large number of reactions demonstrate synthetic possibilities and show its advantages over traditional methods. A list of 90 references is included.

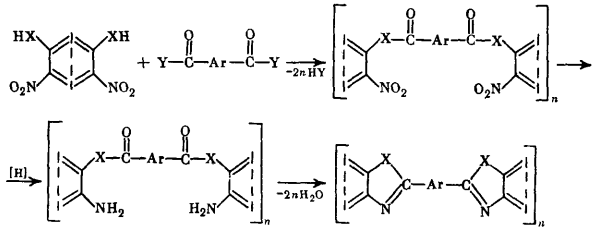
I. INTRODUCTION

The intense development of several modern industries—aviation, electronics, electrical technology, etc.—has made it necessary to produce polymeric materials combining high resistance to deformation with the ability to withstand prolonged operation at high temperatures. Solution of this problem is most directly related to the elaboration of new thermostable polymers, so that this has become a dominant trend in the development of the chemistry of macromolecular compounds during the past two decades[1-4].

The greatest progress in this field has been made in the development of polyheteroarylenes of cyclochain structure, compounds of high molecular weight containing in the main chains of the macromolecules alternating carbocyclic and heterocyclic aromatic ring systems[1-4]. Intense research on the synthesis of such polymers, undertaken in the USSR and abroad, has yielded a large number of products of this type, but only aromatic polyimides have become at all widely used[5,6], together with a few related systems made at present on an industrial or a semi-industrial scale. The overwhelming majority of polyheteroarylenes other than polyimides have not emerged beyond academic research or limited production on pilot plants. Yet many of these systems possess several important potential advantages over polyimides with respect to thermal and chemical stability, processability into articles, etc.

In most cases industrial exploitation of developments in the synthesis of polyheteroarylenes is difficult owing to the relative inaccessibility and inadequate stability of the initial monomers. A substantial obstacle is also the complexity of the technology involved in the principal methods for obtaining polyheteroarylenes, among which the most important are high-temperature polycyclocondensation in polyphosphoric acid[7-10], reaction in the melt followed by high-temperature solid-phase polycyclocondensation (Marvel's reaction),[11-13] and a multistage reaction involving a first stage under mild conditions, isolation of prepolymers, and their processing into articles followed by high-temperature cyclisation of the ready-made articles[1-6]. In the majority of cases the cyclisation stages are accomplished under severe conditions: the temperature usually exceeds 300 °C, which not only requires the use of special apparatus but also permits the occurrence of secondary processes—cross-linking, degradation, etc.—that have an unfavourable influence on the properties of the final products.

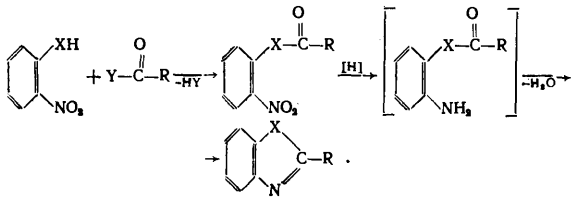
Typical examples of polyheteroarylenes are polybenzazoles[14-18]—a large family of thermostable polymers formed by reaction between *oo'*-disubstituted aromatic diamines and aromatic dicarboxylic acids or their derivatives:



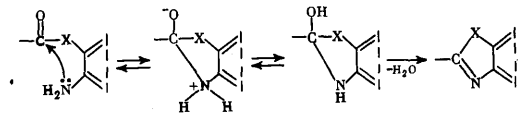
X = O, NR; Y = OH, OR', Cl; R = H, Alk, C_6H_5; R' = Alk, C_6H_5 . (1)

Replacement of the diamines by more accessible and stable monomers, and also elaboration of a technical method for synthesising these systems, may stimulate further development of the chemistry and technology of polybenzazoles. One solution to these problems is to synthesise them by reductive polyheterocyclisation.

II. REDUCTIVE POLYHETEROCYCLISATION



The synthesis of polybenzazoles by reductive polyheterocyclisation[19-28]

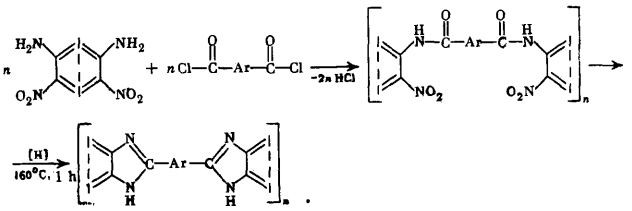


X = O, NR; Y = OR', Hal; R = H, C_6H_5, Alk; R' = Alk, C_6H_5 (2)

is based on well known reactions[29-31] in which benzazoles are formed by interaction of o-nitro-substituted amines and phenols with derivatives of carboxylic acids followed by

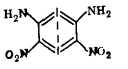
reduction and cyclisation of the products

Comparison of reductive polyheterocyclisation (2) with the traditional method (1) indicates that the former has several important advantages for the synthesis of polybenzazoles—(i) the use, instead of *oo'*-disubstituted aromatic diamines, of *oo'*-dinitro-substituted difunctional compounds, which are intermediates in the synthesis of the former[32], more accessible, cheaper, and more stable; (ii) the possibility of effecting the initial stages—synthesis of *o*-nitro-substituted heterochain polymers[19-28,33]—in the absence of competing reactions of acylation at two adjacent groups with branching and subsequent cross-linking of macromolecules[34,35], which permits the use as acylating agents of the most reactive derivatives of dicarboxylic acids, in particular their dichlorides; (iii) the possibility of using hydrogen chloride evolved as by-product in the early stages (when acid dichlorides are used as acylating agents) together with various metals, primarily activated iron[36], to reduce nitro to amino; and (iv) the possibility of using hydrogen chloride to catalyse polycyclisation[37,38], as a consequence of the increased electrophilic reactivity of the carbon atom in a protonated carbonyl group[39]

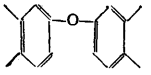


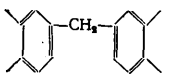
which enables the temperature of cyclisation to be lowered to 150–170 °C, with the possibility of ring-closure immediately after reduction of nitro to amino (which was responsible for the name *reductive polyheterocyclisation* for the whole process).

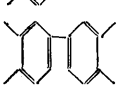
On the other hand, the process may be complicated by the possibility of incomplete reduction of nitro-groups and incomplete cyclisation of reduced and unreduced fragments, leading to an enhanced heterounit character of the polymers[39,40], which lowers the thermal stability, heat resistance, and chemical stability of the final products.



For maximum exploitation of the positive aspects of reductive polyheterocyclisation and elimination of inherent potential disadvantages it is advisable that all stages of the synthesis of polybenzazoles should be conducted as a continuous process in *N*-methylpyrrolid-2-one—an effective solvent for heterochain and heterocyclic polymers—with reduced iron and hydrogen chloride as reducing agents, the latter also catalysing cyclisation. Solubility of polymers at all stages of synthesis is especially important in reductive polyheterocyclisation, since polymers that separate out at any stage coat the iron and thus remove it from the sphere of reaction.







The presence in the monomers of nitro-groups, which are strongly electron-accepting substituents, has a decisive influence on the reactivity of fragments involved in polycondensation. In particular, the electronic and steric effects of *o*-nitro-substituents produce a sharp decrease in basicity and hence in nucleophilicity of diamines[20-22], and limit the possibility of using various bis-*o*-nitroanilines to obtain polybenzimidazoles by the reaction series

The highest (73 ± 3%) yields of dibenzimidazoles from bis-*o*-nitroanilines and benzoyl chloride are obtained[41] by the use as monomers of bis-*p*-amino-*m*-nitrophenyl ether and *mm'*-dinitrodiphenylmethane-*pp'*-diamine, which quantum-chemical calculations of potentiometric titration[21,22] show (Table 1) to be the most basic among the bis-*o*-nitroanilines used. The comparative basicity sequences of these latter compounds (Table 1) are identical with those of the structurally similar unsaturated aromatic diamines[42,43], among which the more basic are bis-*p*-aminophenyl ether and diphenylmethane-*pp'*-diamine. The comparatively high basicity of bis-*o*-nitroanilines containing ether and methylene bridging groups and also the high yields of dibenzimidazoles obtainable from them made it advisable to use such compounds for the synthesis of polybenzimidazoles. Another factor favouring their use in reductive polyheterocyclisation is the better solubility of the resulting polymers than of systems based on 3,3'-dinitrobenzidine and 4,6-dinitrophenylene-1,3-diamine, which enables the synthesis to be conducted in homogeneous solutions.

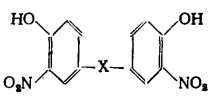
Table 1. Basicity and electron densities on nitrogen atoms for initial and monoacylated d_N^0 and d_N^m bis-*o*-nitroanilines of general formula[22]

	pK_a (in dimethylformamide)			d_N^0	d_N^m
	pK_{a_1}	pK_{a_2}	ΔpK_a *		
	2.64±0.20	1.81±0.20	0.83	1.785	1.690
	2.57±0.20	1.87±0.20	0.70	1.782	—
	2.35±0.20	1.59±0.20	0.76	1.775	1.680
	2.17±0.20	1.17±0.20	1.00	1.751	1.61

*Here and subsequently $\Delta pK_a = pK_{a_1} - pK_{a_2}$.

The structure of the acid dichlorides imposes no severe restriction on their use to obtain polybenzimidazoles: model compounds are obtained in high (80 ± 6%) yields from all acid dichlorides[41], but isophthaloyl and oxy-*pp'*-dibenzoyl chlorides are preferred as monomers, since the resulting polymers remain in solution at all stages of the synthesis. Furthermore, the weak electrophilicity of these compounds[44] is responsible for the diminished positive charge on the amide carbon atoms and the consequent greater resistance to hydrolysis and amidolysis during reductive cyclisation.

Table 2. Some characteristics of polybenzimidazoles of general formula[22]



X	Ar	Solubility in *						Decomp. temp., °C**

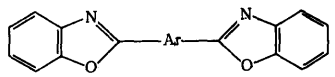
$C(CH_3)_2$	9.53	11.11	1.59
$-CH_2-$	9.73	11.22	1.69

The synthesis of polyimidazoles by reductive polyheterocyclisation is a simple and technically efficient process involving addition of a solid acid dichloride to an *N*-methylpyrrolid-2-one solution of a bis-*o*-nitroaniline, stirring for 10–12 h, saturating the solution with gaseous hydrogen chloride, and heating in a stream of nitrogen and hydrogen chloride at 160 °C for 1 h. The infrared spectra of polybenzimidazoles obtained in this way from isophthaloyl and oxy-*pp'*-dibenzoyl chlorides, i.e. with all stages taking place in solution, contain no absorption maxima that would indicate incomplete reduction of nitro-groups or polycyclodehydration. Table 2 lists several characteristics of these polymers.

The attainment of high degrees of cyclisation under very mild conditions (160 °C for 1 h) is one of the most important merits of reductive polyheterocyclisation. Furthermore, such conditions tend to suppress any secondary reactions and yield polymers having the same thermal stability as those obtained by traditional methods, but better solubility in organic solvents (Table 2) and lower softening temperatures. Thus catalytic cyclisation not only permits substantial moderation of the conditions for obtaining polybenzimidazoles but also yields polymers having better properties.

These considerations apply also to the production of polybenzoxazoles by the reactions[23–28,33]



The acidity of the bis-*o*-nitrophenols used for the synthesis of polybenzoxazoles varies within wide limits (Table 3). but it is not the limiting factor in the choice of monomers. Thus model reactions show that high yields of bisbenzoxazoles are obtained from all bis-*o*-nitrophenols[45], so that attention has been concentrated on obtaining polybenzoxazoles from the most readily available 3,3'-dinitrodiphenylmethane-4,4'-diol and 2,2-bis-(4-hydroxy-3-nitrophenyl)propane, which furthermore ensure homogeneous solutions during reductive polyheterocyclisation, together with isophthaloyl and oxy-*pp'*-dibenzoyl dichlorides.

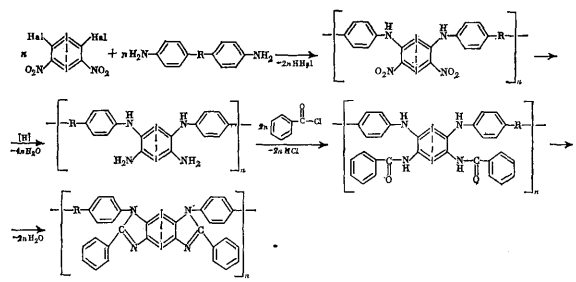
The procedure for obtaining polybenzoxazoles is essentially the same as that described above for polybenzimidazoles, except that the first stage—formation of poly-*o*-nitroesters—is accomplished in the presence of triethylamine, and the duration of the process does not exceed 30 min. The properties of the resulting polybenzoxazoles, shown by infrared spectroscopy to contain no "defective" monomer units, are given in Table 4. They differ from those obtained by traditional methods[46,47] in their solubility in trifluoroacetic acid, while systems containing isopropylidene groups are soluble in a 3:1 mixture of tetrachloroethane and phenol. The high viscosity characteristics of polybenzoxazoles, evidence of high molecular masses, are responsible for their film-forming properties.

When difficulties arise in obtaining *o*-nitro-substituted monomers or polymers, the required compounds can be produced by nitrating the corresponding unsubstituted heterochain polymers. Thus the nitration of aromatic polyamides[22], polyesters[48], and polythioesters[49] yields macromolecular poly-*o*-nitroamides, poly-*o*-nitroesters, and poly-*o*-nitrothioesters, reductive polyheterocyclisation

of which then gives polybenzimidazoles[22], polybenzoxazoles[48], and polybenzothiazoles[49]. However, the nitration of heterochain polymers may be ambiguous (i.e. it may not necessarily take place *ortho* to the main chains of the macromolecules), which leads to the formation of heterounit polymers[40], and furthermore such nitration is accompanied by a considerable decrease in viscosity.

Table 4. Some characteristics of polybenzoxazoles of general formula[26]

X	Ar	Softening temp., °C	Decomp. temp., °C	Film properties* σ_t, kg cm^{-2}	Film properties* ε, %
$C(CH_3)_2$		270—290	400—420	900	2.6
$C(CH_3)_2$		280—300	430—450	1200	3.0
$C(CH_3)_2$		250—270	395—410	800	3.1
$C(CH_3)_2$		250—260	410—420	1030	3.2
CH_2		260—260	420—430	1150	3.8
CH_2		270—280	410—420	1050	2.5

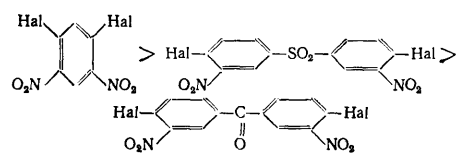


*Film parameters: σ_t = tensile strength; ε = elongation at break.

Thus the reactions represented by scheme (2) are preferred for the synthesis of polyheteroarylenes by reductive polyheterocyclisation. They not only have the disadvantages already mentioned but also somewhat restrict the set of structures obtainable; the nitro-groups have an adverse influence on the reactivity of fragments involved in polycondensation, which is especially marked when bis-*o*-nitroanilines are used as monomers. Processes of modified and combined reductive polyheterocyclisation are in considerable measure free from these defects.

III. MODIFIED AND COMBINED REDUCTIVE POLYHETEROCYCLISATION

Modified reductive polyheterocyclisation differs from the above processes[19–26] in the separation of cyclisation processes by one or more reactions (usually acylation) from nitro–amino reduction stages. As in the previous Section, the modified polymerisation has been conducted as continuous processes in *N*-methylpyrrolid-2-one with reduced iron and hydrogen chloride as reducing agents and the latter as cyclisation catalyst. Since such processes are most complete under homogeneous conditions, attention has been paid mainly to the synthesis of polyheteroarylenes having improved solubility in organic solvents, in particular of phenylated polyheteroarylenes considerably surpassing in solubility the unsubstituted analogues (as has been shown for polybenzimidazoles[50,51], polyquinoxalines[52,53], polyquinazolones[54,55], and several other systems).

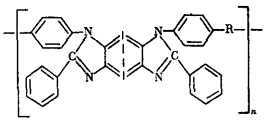


A typical example of modified reductive polyheterocyclisation is the synthesis of hitherto unreported *C*-phenylated polybenzimidazoles[27,28,56–64] by the action of aromatic diamines on activated di-(*o*-halogenonitro)arenes[27,28,56–62], reduction of the resulting poly-*o*-nitro-amines to poly-*o*-amino-amines[27,28,56–60,63], benzoylation of the latter[27,28,56–60,63], and cyclisation of the poly-*o*-benzamido-amines thus formed[27,28,56–60,64]:

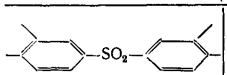
(3)

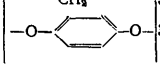
Successful examples of the activated components are 1,3-dihalogeno-4,6-dinitrobenzenes and also dinuclear compounds having electron-accepting bridges[65–71], the 3,3'-dinitro-derivatives of 4,4'-dichloro- and 4,4'-difluorodiphenyl sulphone and -benzophenone; from the above considerations the diamines used have been diphenylmethane-*pp'*-diamine, bis-*p*-aminophenyl ether, and *p*-diphenoxybenzene-*p'p''*-diamine.

A comparative study of the electrophilicity of the di-*o*-halogenonitro-arenes by the application of chlorine-35 nuclear quadrupole and fluorine-19 and carbon-13 nuclear magnetic resonance spectroscopy, and also the results of competitive amination, have shown[60] that the above examples form the reactivity sequence



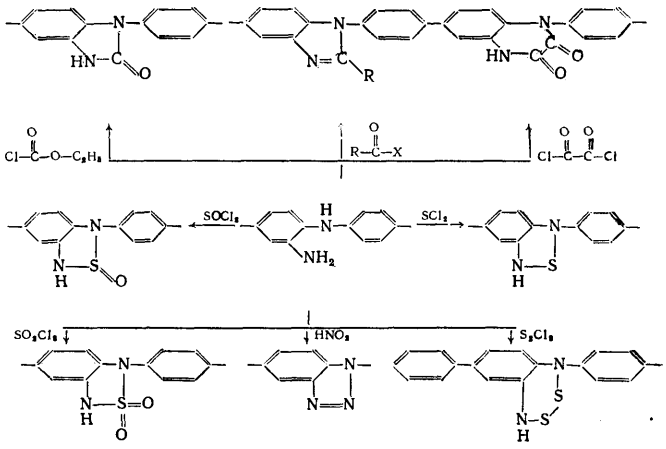
with fluorinated derivatives more reactive than the chlorinated compounds. Although 1,3-dihalogeno-4,6-dinitrobenzenes were the most reactive, attention was paid mainly to polymers from monomers based on diphenyl sulphone and benzophenone, since their "hinge" groups confer solubility in organic solvents on all intermediate and final polymer systems and hence the possibility of effecting synthesis under homogeneous conditions.





Like the synthesis of polybenzazoles by ordinary reductive polyheterocyclisation, that of *C*-phenylated polybenzimidazoles is an extremely simple process occurring under mild conditions: no stage of the process requires a temperature above 180 °C. The products are free from unreduced nitro-groups and uncyclised fragments (this was established by infrared spectroscopy);[60] their spectral characteristics are completely identical with those of corresponding model compounds.

The mild conditions of cyclisation, the presence of phenyl substituents, and the high content of "hinge" groups in the main chains are responsible for the good solubility of polybenzimidazoles in dipolar, aprotic, and phenolic solvents, while the high viscosity characteristics of these systems (Table 5) make it possible to obtain from them articles that are highly resistant to deformation. Because of the only slight heterounit character[40] the resulting polymers have high degradation temperatures under conditions of dynamic (Table 5) and isothermal thermogravimetric analysis: in

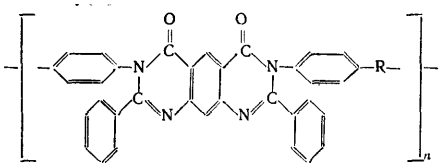


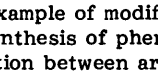
particular, polybenzimidazoles obtained by modified reductive polyheterocyclisation possess greater thermal stability in isothermal thermogravimetry than structurally similar poly-*N*-phenylbenzimidazoles obtained in two stages[50] [Scheme (1) with X = C_6H_5N].

Table 5. Some characteristics of *C*-phenylated polybenzimidazoles of general formula[60]

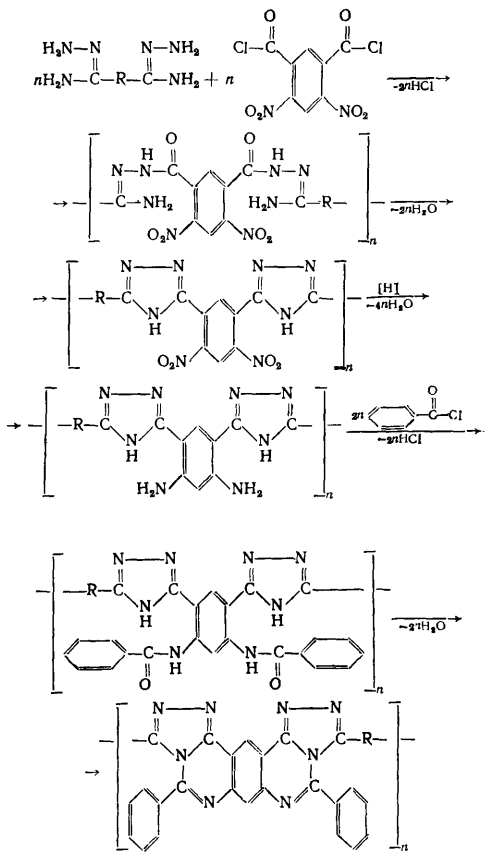
	R	Softening temp., °C	Decomp. temp., °C	Film properties at 25 °C σ_t, kg cm^{-2}	Film properties at 25 °C ε, %
	O	310—330	470	950	4
	CH_2	335—350	490	1040	3—4
		315—330	450	1050	4
	O	305—315	430	—	—
	CH_2	320—325	430	—	—
		300—320	420	990	5

The intermediate poly-o-amino-amides formed in the synthesis of *C*-phenylated polybenzimidazoles can be used to obtain a wide range of heterocyclic polymers[64]. In particular, if they are treated not with benzoyl chloride but with ethyl chlorocarbonate, oxalyl, thionyl, sulphuryl, sulphenyl, and sulphur chlorides, nitric acid, etc., subsequent cyclisation of the reaction products yields polybenzimidazolones, polyquinoxalidinediones, polybenzothiazolidine *S*-oxides, polybenzothiadiazolidine *S*-dioxides, polybenzothiadiazolidines, polybenzodithiadiazines, polybenzotriazoles, etc.:



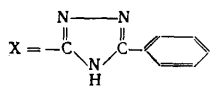


Another typical example of modified reductive polyheterocyclisation is the synthesis of phenylated polyquinazolones[72,73] by reaction between aromatic diamines and 4,6-dinitroisophthaloyl dichloride[74] followed by reduction of the resulting poly-o-nitro-amides to poly-o-amino-amides, benzoylation of the latter at the free amino-groups, and catalytic polycyclisation of the poly-o-benzamido-amines formed:



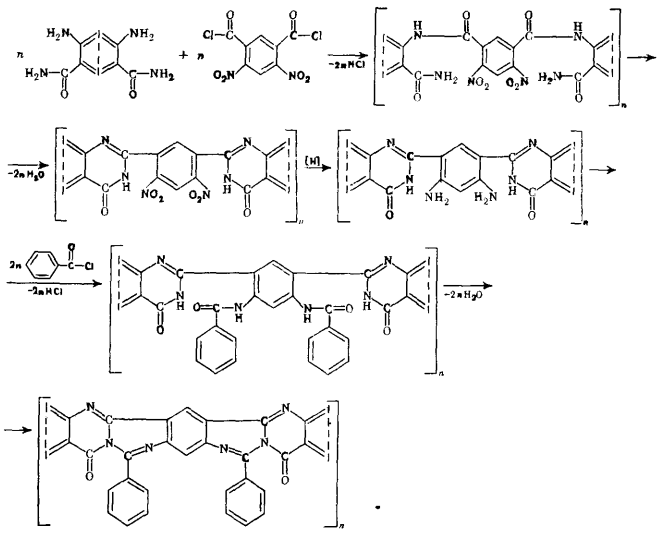
Like *C*-phenylated polybenzimidazoles, poly-2-phenylquinazolones obtained in the same way are free from unreduced nitro-groups and uncyclised fragments, as has been confirmed in particular by the identity of their spectra with those of model compounds[73]. The resulting polymers dissolved in strong acids, in phenolic solvents (Table 6), and on heating in aprotic dipolar solvents. Dynamic and isothermal thermogravimetry indicates that their thermal stability is comparable with that of identical systems obtained by earlier methods[54,55].

Table 6. Some characteristics of poly-2-phenylquinazolones of general formula[72]

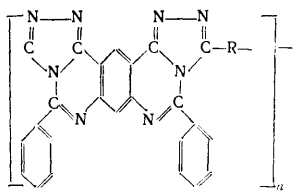


R	Softening temp., °C	Decomp. temp., °C	Film properties at 25 °C σ_t, kg cm^{-2}	Film properties at 25 °C ε, %
O	380—385	450	1200	8
CH_2	375—380	430	1100	8
	350—360	440	1100	12

The enhanced solubility of polyheteroarylenes synthesised by modified reductive polyheterocyclisation made it useful to extend this process to the production of ladder polyheteroarylenes, which are characterised by high heat resistance and thermal stability but unsatisfactory processability into articles[75–77]. With 4,6-dinitroisophthaloyl dichloride and a bisamidrazone of a dicarboxylic acid[78] as comonomers phenylated polybenzodi-sym-triazolopyrimidines were obtained[79,80]:



the products being isomeric with previously known systems[81,82] obtained by two-stage processes—scheme (1) with



Infrared spectra indicate that polyheteroarylenes obtained in this way are free from unreduced nitro-groups and uncyclised fragments. The presence of phenyl side-groups and the mild conditions of polycyclisation are responsible for the solubility of the resulting systems in acid solvents (sulphuric and trifluoroacetic acids) and a 3:1 tetrachloroethane–phenol mixture, and for their partial solubility in hot *N*-methylpyrrolid-2-one (Table 7). A dynamic (Table 7) and isothermal thermogravimetric study has shown the comparable thermal stabilities of polybenzobis-sym-triazolopyrimidines prepared by modified reductive polyheterocyclisation and by the two-stage method[81,82].

Another example of modified reductive polyheterocyclisation is the synthesis of polyquinazolinoquinazolones[83]:

The resulting polymers are soluble in acids, phenolic solvents, and hot *N*-methylpyrrolidone and dimethyl sulphoxide. Solutions in a 3:1 mixture of tetrachloroethane and phenol have viscosities $\eta = 0.96–1.30$ dl g^{-1}. At 25 °C films based on these polymers possess tensile strengths $\sigma_t = 850–950$ kg cm^{-2} and elongations at break $\varepsilon = 2–10\%$.[38]

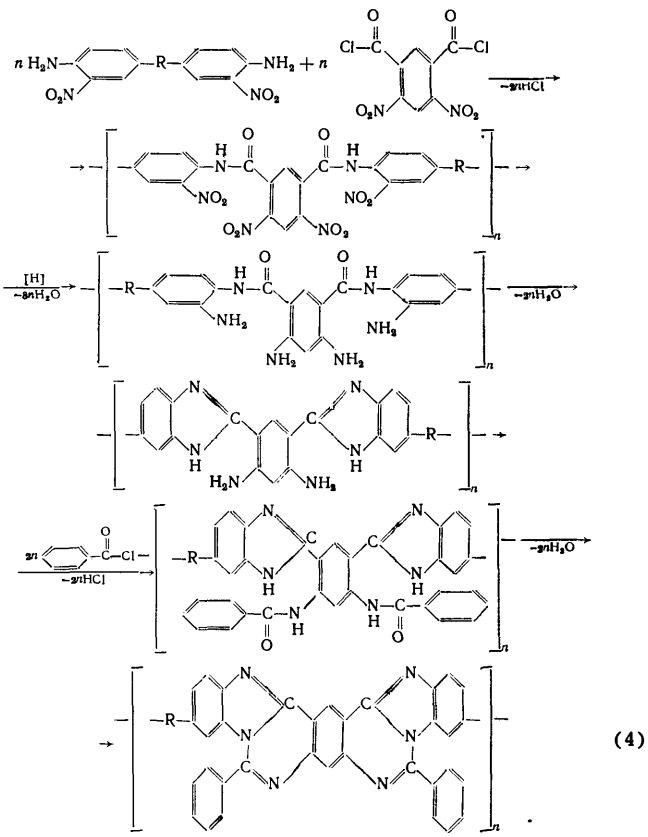


Table 7. Some characteristics of polybenzobis-sym-triazolopyrimidines of general formula[79]

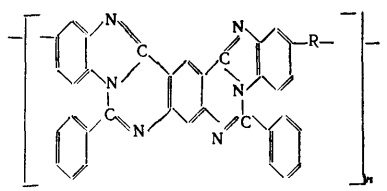
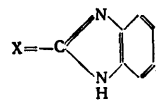
R	Softening temp., °C	Solubility in			
		H_2SO_4	CF_3COOH	$C_2H_2Cl_4 + C_6H_5OH$	MP
—	500	+	+	+	±
	505	+	+	+	+
	520	+	+	+	±
	475	+	+	+	+

Syntheses of ladder polyheteroarylenes have been effected also by combined processes involving true reductive polyheterocyclisation at one stage. A typical example is the synthesis of polybenzodi(pyrimidobenzimidazoles) from



bis-*o*-nitroanilines and 4,6-dinitroisophthaloyl dichloride[84,85]:

(4)

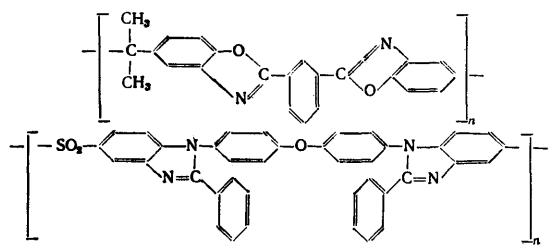


It is evident from (4) that the formation of poly-*o*-aminophenylbenzimidazoles is true reductive polyheterocyclisation, whereas that of the final structure is a modified reductive polyheterocyclisation.

Table 8. Some characteristics of polybenzodi(pyrimidobenzimidazoles) of general formula[84]

R	Softening temp., °C	Solubility in			
		H_2SO_4	CF_3COOH	$C_2H_2Cl_4 + C_6H_5OH$	MP
O	530	+	+	+	±
CH_2	520	+	+	+	±
—O—⟨⟩—O—	500	+	+	+	±

Like all the systems discussed already, polybenzodi(pyrimidobenzimidazoles) obtained by combined reductive polyheterocyclisation are, according to infrared spectral data, free from unreduced nitro-groups and uncyclised fragments. Those obtained by scheme (4) differ from corresponding polymers obtained in two stages[81,82], by scheme (1) with



as X, in containing phenyl substituents, which together with the mild conditions of polycyclisation confer solubility in a 3:1 tetrachloroethane–phenol mixture, sulphuric acid, or trifluoroacetic acid (Table 8). Polybenzodi(pyrimidobenzimidazoles) surpass in thermal stability other polyheteroarylenes obtained by modified reductive polyheterocyclisation (Tables 2–8) and are comparable under conditions of isothermal thermogravimetry with polymers obtained in two stages[81,82].

The above syntheses of polyheteroarylenes do not exhaust all the possibilities of modified and combined reductive polyheterocyclisation. Nevertheless, the results surveyed indicate the undoubted promise of such approaches to obtaining comparatively simple and more complicated polymer systems.

IV. CONCLUSION

Thus research during the past five years has developed a new method for synthesising polyheteroarylenes using as intermediates compounds employed in traditional methods. It involves also catalytic cyclisation, with consequent moderation of the reaction conditions and also improvement in the solubility of the resulting systems and their processability into articles.

Among the polymers that have been synthesised the greatest industrial promise is shown by polybenzoxazoles and *C*-phenylated polybenzimidazoles. In particular, those having the structural formula

are of considerable interest. The first system is obtained from 2,2-bis-(4-hydroxy-3-nitrophenyl)propane[86]—a product of the direct nitration of bisphenol A, the latter used in chemical industry to obtain polycarbonates[87] and polysulphones[4]—and isophthaloyl chloride, which finds employment in industry for the production of polyamides[88]. Synthesis of the second system is based on bis-4-chloro-3-nitrophenyl sulphone[89]—formed by the direct nitration of di-p-chlorophenyl sulphone, which is used in industry to obtain polysulphones[4]—and di-p-aminophenyl ether, employed in the manufacture of polyimides[5,6]. The combination in these systems of good solubility with high viscosity characteristics of the polymers makes it possible to obtain from them various materials—films, carbon plastics, gas-separating membranes[22,26,60]—suitable for operation at 250–300 °C. There have been indications

of the practical utilisation of other systems[90] obtained by reductive polyheterocyclisation.

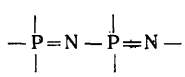
Oligomeric Alkoxyphosphazens

V.V.Kireev, V.I.Astrina, and E.A.Chernyshev



Methods of preparation, properties, and applications of oligomeric linear, cyclic, and cyclolinear alkoxy- and aryloxyphosphazens are surveyed. General syntheses of various types are suggested. A list of 164 references is included.

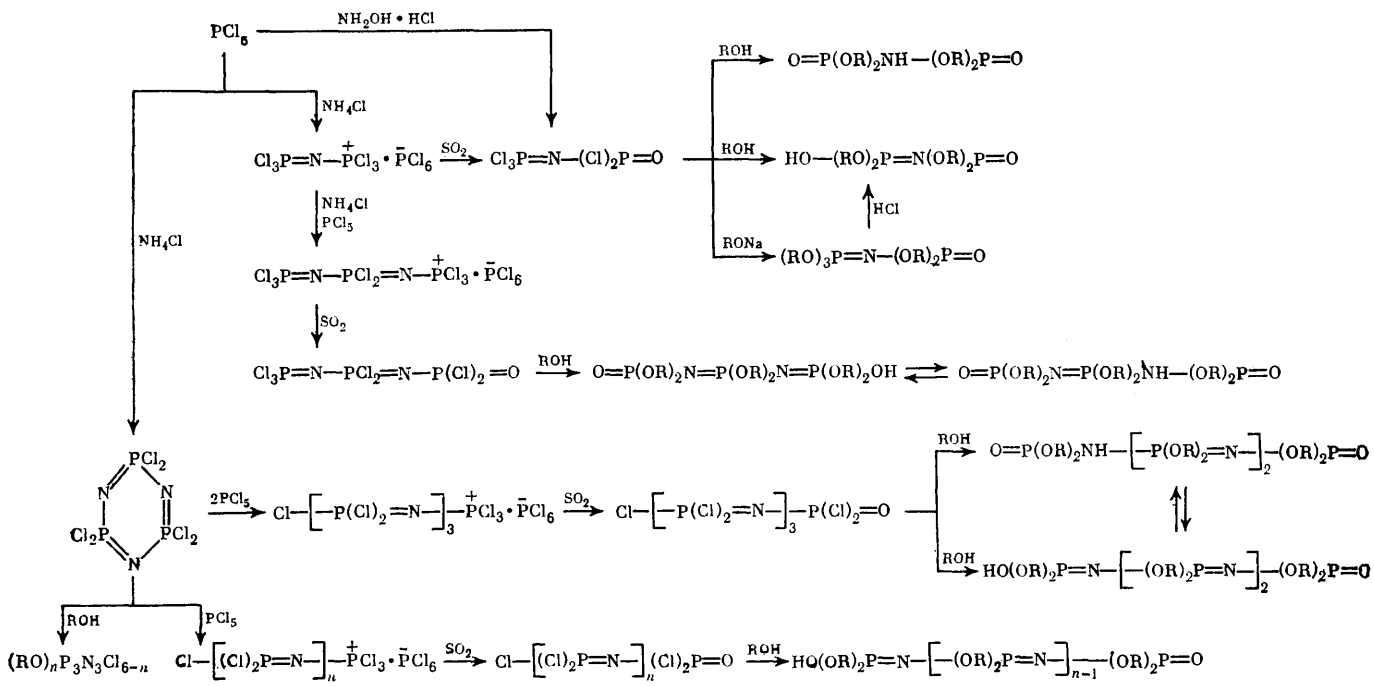
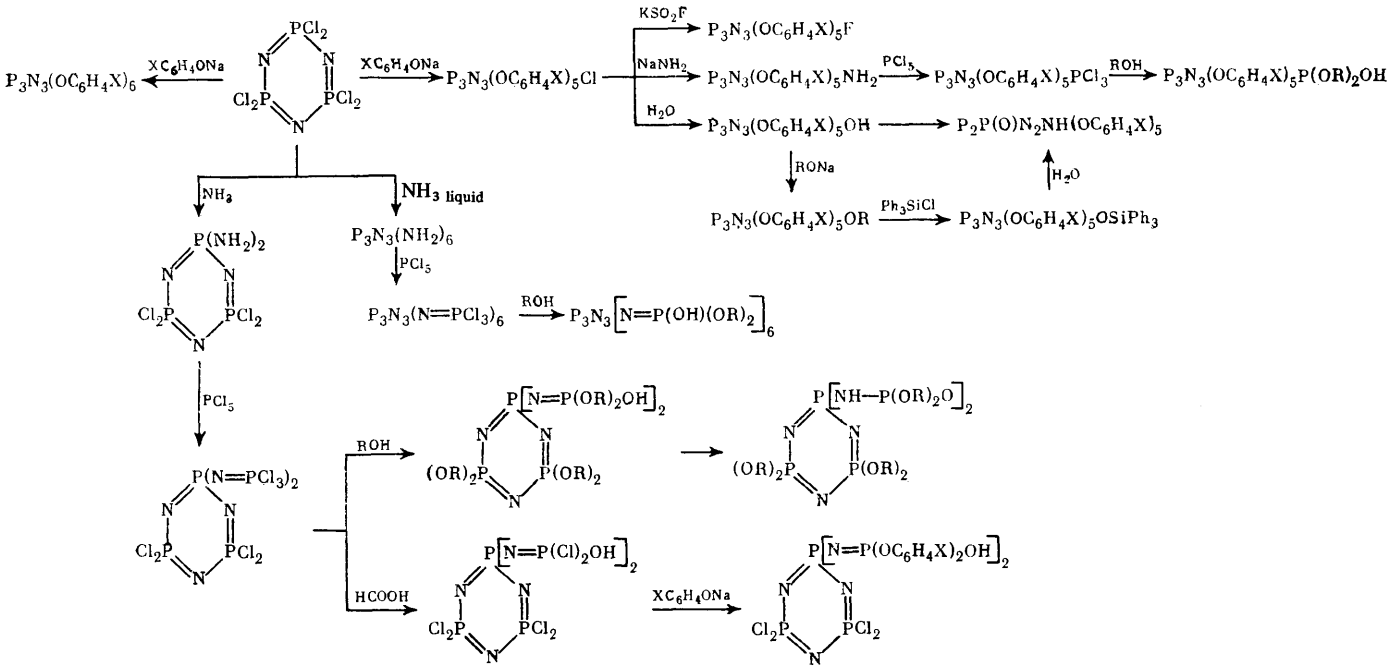
I. INTRODUCTION

The chemistry of oligomeric linear and cyclic phosphazens owes its intense development to the specific properties of this group of compounds, which are inorganic in nature but possess many of the properties of organic compounds. One of the chief problems in the chemistry of cyclotriphosphazens is to determine the nature and the character of the delocalisation of π electrons in the cyclic molecules. An important aspect of linear phosphazens is the character of the conjugation of double bonds in



systems and its influence on the chemical properties of various derivatives.

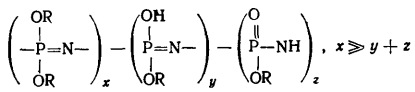


Because of the hydrolytic instability of most halogenophosphazens the most accessible and convenient compounds for investigation are linear and cyclic alkoxyphosphazens, which are formed by treating the corresponding halogenated compounds with alcohols, phenols, alkoxides, and phenoxides. Besides their scientific interest alkoxyphosphazens have recently acquired great practical value: they are finding increasing application as starting materials in the synthesis of polymers, chemically resistant and thermally stable oligomeric liquids for various purposes (hydraulic and lubricating oils, heat-transfer agents, plasticisers, complexing agents, etc.).

Individual aspects of the chemistry and application of alkoxyphosphazens have been partly surveyed[1-9]. During recent years much new information has accumulated in this field and additional interesting results have been obtained.

Scheme 1.

Scheme 2.

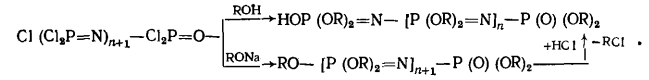


Our aim is to summarise recent advances in the synthesis, structure, properties, and application of oligomeric alkoxyphosphazens.

II. METHODS OF SYNTHESIS

Synthetic routes to oligomeric linear alkoxyphosphazens are summarised in Scheme 1, and those to the cyclic and cyclolinear oligomers in Scheme 2.

1. Linear Alkoxyphosphazens



Because of the great activity of the chlorine atoms in linear chlorophosphazens they begin to react with alcohols even at room temperature. The resulting mixture of homologues contains not only acidic alkoxyphosphazens but also decomposition products of chlorophosphazens extending to polyphosphinic acids. Thus alcoholysis with higher alcohols of a mixture of linear chlorophosphazens of mean degree of polymerisation 10—11 gives a mixture of products to which the formula

has been assigned[10].

The first individual linear phosphazens—dialkyl trialkoxyphosphazophosphates of general formula $(RO)_3P{:}N.PO(OR')_2$—have been synthesised by reaction between a trialkyl phosphite and dibutyl azidophosphate[11-13] or between an alkoxide and trichlorophosphazophosphonyl dichloride. Under the influence of hydrogen chloride these compounds readily eliminate an alkyl chloride and are converted into tetra-alkyl imidobisphosphates[11,12].

Imidobisphosphoric esters can be obtained by alcoholysis of trichlorophosphazophosphonyl dichloride with alcohols in the presence of a tertiary amine[14]. Homologues of general formula $HO.[P(OR)_2{:}N]_n.PO(OR')_2$ have also been synthesised from linear chlorophosphazens[15]. The series begins with tetra-alkyl imidobisphosphates:

Alcoholysis of the chlorophosphazophosphonyl dichloride was conducted in benzene or oxolan in the presence of triethylamine at temperatures from −5 to 0 °C. Rise in temperature causes partial depolymerisation, and also formation of P—O—P bonds.

Compounds prepared in the course of the investigations were alkyl imidobisphosphates ($n = 0$), dialkoxyphosphoriobisamidophosphates ($n = 1$), and nitridobisdialkoxophosphorioamidophosphates ($n = 2$), as well as oligomeric alkoxyphosphazens ($n > 5$). All these compounds are present as two tautomeric forms[12]—phosphazen and phosphazan:

$$-N{=}P(OR)_2OH \rightleftarrows -NH-P(O)(OR)_2,$$

which is confirmed by infrared and nuclear magnetic resonance spectroscopy.

2. Cyclic Alkoxyphosphazens

Tris- and tetrakis-phosphonitridic esters can be obtained by the action of hexachlorocyclotriphosphazen and of octachlorocyclotetraphosphazen on almost all stable alcohols and phenols (acceptor method) or even by the use of sodium alkoxides and phenoxides as nucleophiles (alkoxide method). In the former case a tertiary organic amine, such as

triethylamine or pyridine, or sodium carbonate must be added to remove the hydrogen halide that is formed[16-19].

For reactions of this type use can be made of various anhydrous solvents[4,20-26]—diethyl ether, oxolan, dioxan, benzene, toluene, xylene, acetone, butan-2-one, dimethylformamide, perfluoro-t-butylamine, pyridine, and also excess of the alcohol employed as substituting reagent—choice between which must take into account polarity and also ability to dissolve sodium alkoxides and phenoxides. Potentiometric titration has established[27] that the initial rate of reaction between hexachlorocyclotriphosphazen and sodium methoxide is considerably greater in dimethylformamide than in acetone, dioxan, butanol, and mixtures of dioxan with acetone and with butan-2-one. The rate of substitution decreases in the sequence of solvents—dimethylformamide at 100 °C ≫ boiling diglyme > boiling oxolan > boiling benzene > boiling diethyl ether[4].

(*a*) Completely substituted alkoxyphosphazens

The first individual hexamethoxy- and hexabutoxy-cyclotriphosphazens were obtained by the action of the alcohols on hexachlorocyclotriphosphazen in the presence of pyridine[28]. Hexaethoxycyclotriphosphazen was isolated by the action of sodium ethoxide in ethanol[29]. Hexapropoxyphosphazen was obtained in 94% yield by the action of sodium propoxide in heptane or octane[30,31]. Unusual alkoxy-derivatives have been obtained by reaction between sodium salts of cellulose and hexachlorocyclotriphosphazen in dioxan[32]; the activation energy is 35.6 kJ mole^{-1}.

A detailed investigation of the alcoholysis of hexachlorocyclotriphosphazen and octachlorocyclotetraphosphazen was undertaken by Shaw and his coworkers[33], who used the acceptor method to synthesise trimeric and tetrameric compounds by the action of ethyl, propyl, and butyl alcohols, and the alkoxide method for methyl and isopropyl alcohols, phenol, *p*-methoxyphenol, and 2-naphthol. The former method was more convenient with respect to preparation (it did not require synthesis of the alkoxide), but could not be applied in all cases. Hexamethoxycyclotriphosphazen can be obtained only via the methoxide, since the ether formed decomposes when the excess alcohol and the pyridine are distilled off. Secondary and higher alcohols react with greater difficulty, and here it is more convenient to use the alkoxide method[4].

(*b*) Partly substituted alkoxycyclophosphazens

Partly substituted alkoxycyclophosphazens have little thermal stability. Allyloxy- and propoxy-pentachlorocyclotriphosphazens have been obtained[34], as well as mono-, di-, tri-, tetra-, and penta-butyl ethers of hexachlorocyclotriphosphazen[26] by means of sodium butoxide in methanol. The hexachloro-phosphazen hardly reacts at all with butanol at 20 °C.[35] In the presence of pyridine under the same conditions only 50% reaction (based on substitution of one chlorine atom) has taken place after 3 h. Replacement of the first three chlorine atoms takes place non-geminally[35]. The rate drops sharply as chlorine atoms are substituted by alkoxy-groups[36].

Partly (geminally and non-geminally) alkoxylated phosphazens have been studied by mass spectrometry and by hydrogen-1 and phosphorus-31 nuclear magnetic resonance spectroscopy[37,38].

Methylaminopentapropoxycyclotriphosphazen has been obtained by reaction of hexachlorocyclotriphosphazen with sodium propoxide and with methylamine[39].

Chloroalkoxyphosphazens of general formula

$R=OCH_2CHClR'$, $R'=H$, Me, $ClCH_2$, Ph, $n \geqslant 1$

can be obtained by the action of oxirans

on hexachlorocyclotriphosphazen in the presence of aluminium trichloride[40].

(*c*) Alkoxyphosphazens with various substituents in aliphatic radicals

Mixed cyclophosphazens of general formula $N_4P_4(C_6H_5)_4 \cdot (OR)_4$, where R = CH_3, C_2H_5, C_6H_5, containing not only alkoxyl but also phenyl groups, have been prepared by alcoholysis of three geometrical isomers of tetrachlorotetraphenylcyclotetraphosphazen[41].

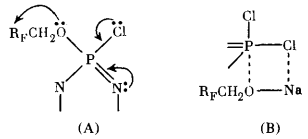
The action of equimolecular quantities of sodium *m*-fluorophenoxide and trifluoroethoxide on hexachlorocyclotriphosphazen gave a product containing aryloxy- and trifluoroethoxy-groups[42], but the positions of the substituents were not established. The end-product of the action of sodium phenoxide on the hexachloro-phosphazen in butanol contained both phenoxy- and butoxy-groups[26], but their relative contents were not given.

The alcoholysis of bis- and tris-dimethylaminocyclotriphosphazens and of tetrachlorodiphenylcyclotriphosphazen was studied[43], but the products were not separated into geometric isomers.

In the production of new pesticides by treating 2-monoalkylamido-6-chloro-2,4,4,6-tetrakis-*N*-dimethylamidocyclotriphosphazen with alkoxides of various alcohols derivatives of hexachlorocyclotriphosphazen containing one alkoxy-group and five *N*-substituted amino-groups were obtained[44].

(*d*) Fluorinated alkoxyphosphazens

The first fluorine-containing alkoxyphosphazens obtained[45] had the general formula $[NP(OCY_2[CF_2]_nCF_2X)_2]_m$ where Y = H, Cl; X = F, H; m = 3, 4; n = 0, 2 (when X = F) and n = 1, 3, 5, 7, 9 (when X = H).



In a combined study of the action of sodium trifluoroethoxide on hexachlorocyclotriphosphazen[46] compounds of general formula $N_3P_3Cl_{6-n}(OCH_2CF_3)_n$ were obtained with n = 1, 2 (two isomers), 3 (three), 4 (two), 5, or 6. Nuclear magnetic resonance spectroscopy was used to study the structure of derivatives having n = 2–4. The formation of predominantly *trans*-non-geminal isomers was attributed[46] to steric hindrance.

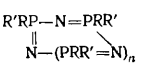
Chlorination of heptafluorobutyl heptafluoropropyl amidophosphonite followed by dehydrochlorination of the resulting aminodichlorophosphorane gave[47] a mixture of hitherto unknown trimeric and tetrameric heptafluorobutoxy-derivatives $[XCH_2OPNX]_n$, where X = C_3F_7 and n = 3 or 4.

Reaction of 2,4,6,6-tetrachloro-*trans*-2,4-bisdimethylaminocyclotriphosphazen with sodium trifluoroethoxide CF_3CH_2ONa yielded[48] products in which 2–4 chlorine atoms had been replaced by trifluoroethoxy-groups: the two chlorine atoms attached to the same phosphorus atom were replaced first, and then one *geminal* to a dimethylamino-group. In the series of compounds $N_3P_3H_nCl_{6-n}OCH_2CF_2 \cdot CF_3$ (n = 1–6) a non-geminal chlorine atom has a tendency to adopt a *trans*-configuration[49]. Compounds in which

n = 2–6 exist as an equilibrium mixture of several conformers.

In an investigation of the reaction of hexachlorocyclotriphosphazen with fluorinated sodium alkoxides $NaOR_F$, where R_F = $CH_2CF_2CF_2H$, $CH_2[CF_2]_3CF_2H$, $CH_2[CF_2]_5CF_2H$, a complete series of products $N_3P_3Cl_{6-n}(OR_F)_n$ (n = 1–6 and R_F = $CH_2CF_2CF_2H$) was isolated by gas–liquid chromatography[50]. It has been shown by ^{31}P n.m.r. spectroscopy that in the case of compounds having n = 2–4, as when R_F = CH_2CF_3,[46] mainly non-geminal isomers are formed[51]. The predominantly non-geminal character of the substitution of chlorine by the action of sodium and lithium fluoroalkoxides on hexachlorocyclotriphosphazen was explained[51] in terms of a four-centre transition complex. With a fluoroethoxy-group already attached the phosphorus–chlorine bond can be strengthened by p_π–d_π interaction; when neither chlorine atom has been replaced, the phosphorus–chlorine bond is readily polarised and capable of forming a transition complex of type (B):

(A) (B)

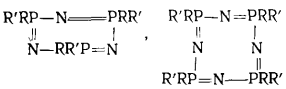


Examination of the infrared spectra of mixtures of fluorinated cyclophosphazens of types $N_3P_3(OCH_2R_F)_6$ and $N_3P_3Cl_3(OCH_2R_F)_3$, where R_F = C_2F_4H, C_2F_5, C_3F_7, revealed an enhancement of basicity on the replacement of chlorine by fluoroalkoxy-groups[52]. The aggregate inductive and resonance effects of the groups apparently increase the electron density on the phosphorus atom relative to the effect of chlorine, and the weakening of p_π–d_π interaction in the ring enhances the basicity of the nitrogen atom.

(*e*) Aryloxycyclophosphazens

Aryloxycyclophosphazens have attracted the attention of investigators by virtue of their specific properties, especially their thermal and chemical stability.

Phenoxy- and *p*-bromophenoxy-cyclotriphosphazens of all degrees of substitutions are now known[22]. The action of sodium and potassium phenoxides and *p*-bromophenoxides on hexachlorocyclotriphosphazen follows a non-geminal pattern in benzene, acetone, and oxolan[22,24,53,54]. In acetone *cis* substitution predominates over *trans*, which was discovered by displacing the remaining chlorine atoms by dimethylamino- and amino-groups[53] and analysing the high-resolution ^1H n.m.r. spectra. Reaction between 2,2-diphenyltetrachlorocyclotriphosphazen and sodium phenoxide involves non-geminal substitution of two chlorine atoms and formation of three-dimensional *cis–trans* isomers[23].



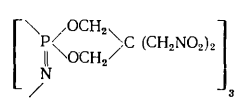
Halogenophenoxyphosphazens, used as flame-retardant additives in polyesters, have been obtained[55] by treating with sodium propoxide the reaction product from hexachlorocyclotriphosphazen and a halogenophenol. This process gave bromoarylphosphazens of general formula

in which R represents *p*-bromophenoxy, 2,4,6-tribromophenoxy, pentabromophenoxy, 2,4,6-tribromo-3-methylphenoxy, 1,4-dibromo-2-naphthyloxy; R' is either chloro or *p*-bromophenoxy; and $n \geq 1$.[56]

The action of *p*-nitrophenoxides on hexachlorocyclotriphosphazen and on octachlorocyclotetraphosphazen gives products of various degrees of substitution (other than 2 and 4). Replacement of the first three chlorine atoms (in the former compound) takes place non-geminally. Even in the presence of two geminal phenyl substituents phenolysis gives predominantly non-geminal compounds[57]. As with fluoroalkoxy-derivatives, this is due to the geometrical dimensions of the nucleophile[4]: bulky side-groups are most difficult to introduce as substituents in the phosphazen ring.

The action of sodium aryloxides on the above chlorocyclophosphazens on heating in a solvent gives aryloxy-derivatives of general formula $[NP(OAr)_2]_n$ (where with n = 3, Ar = *p*-ClC_6H_4, *p*-FC_6H_4, C_6F_5; and with n = 4, *p*-FC_6H_4, C_6F_5) [58] and also derivatives of the type

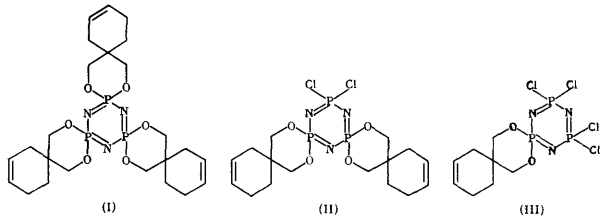
in which R = C_6H_5O, $CH_3C_6H_4O$ (*o*, *m*, *p*), 2-$C_{10}H_7O$ and R' = Cl or R.[59]



Aryloxyphosphazens containing various functional groups have been synthesised by reduction of nitrophenoxyphosphazens[25] followed by phosgenation[60] and also by hydroxyalkylation of aryloxyphosphazenamines[61]. The action of glycols on phenylchlorocyclophosphazens gives phenylcyclophosphazenoxyalkanols $P_nN_n(C_6H_5)_n(OROH)_n$, with R = $[CH_2]_2$, $[CH_2]_4$ and n = 3, 4.[62]

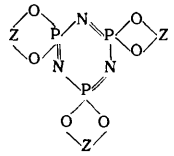
Completely substituted aryloxyphosphazens, containing either the same or different aryloxy-groups (phenoxy, *m*-trifluoromethoxyphenoxy) are produced[63,64] e.g. by boiling in xylene a mixture of potassium hydroxide, hexachlorocyclotriphosphazen, and *m*-trifluoromethoxyphenol and removing the water formed. Compounds of general formula $ROP_3N_3(OC_6H_5)_5$, in which R = *m*- or *p*-$C_6H_5OC_6H_4$, have been obtained[65]. Treatment of the chlorocyclophosphazen with phenoxides in oxolan yields a series of aryloxycyclotriphosphazens of general formula $(XC_6H_4O)_6P_3N_3$, where X = Cl, F, NH_2, AlkO, HO.

Aryloxy-derivatives *p*-$RC_6H_4ON_3P_3Cl_5$ (R = H, F, Cl, CH_3, CH_3O) have been obtained by reaction with the corresponding sodium aryloxides[66]. The trifluoroethoxide anion $CF_3CH_2O^-$ is able to replace aryloxy-groups[67], e.g. in $N_3P_3(OAr)_6$ to give a series of products $N_3P_3(OCH_2CF_3)_n(OAr)_{6-n}$, where Ar = *p*-$NO_2C_6H_4$ and n = 1–5. Ease of substitution diminishes in the Ar sequence *o*-, *p*-$NO_2C_6H_4$ > *p*-ClC_6H_4 ≥ C_6H_5.



3. Spiroalkoxycyclophosphazens

Spirocyclic compounds are of interest as intermediates in the synthesis of polymers[4]. Among the first to be isolated were[68,69]

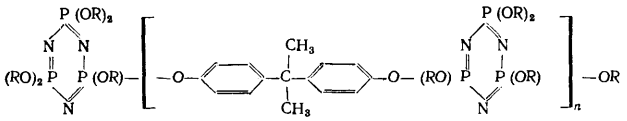


and also 2,2,4,4-tetrachloro-6,6-ethylenedioxycyclotriphosphazen[34]. Spiroalkoxycyclophosphazens have been obtained also by reaction of hexachlorocyclotriphosphazen and of octachlorocyclotetraphosphazen with glycols[70,71], hydroxyalkoxides[72], pyrocatechol[16,18,70,73], and *ortho*- or *ortho-ortho'*-substituted dihydroxynaphthalenes[74]. The tetrameric cyclic analogue is exceptionally unstable and difficult to isolate[4].

Several spiro-derivatives have been synthesised by treating hexachlorocyclotriphosphazen with sodium or triethylamine salts of fluoroglycols[45,51], 1″-hydroxy-2,2-dimethylpropane-1,1′-diyl-3-ylidyne pentanitrate[68], propane-1,2-diol, and cyclohexane-1,2-diol.[69] Reaction of the chlorocyclophosphazen with 4,4-bishydroxymethylcyclohexene yields[75] the completely and partly substituted spiro-compounds

(I) (II) (III)

Compound (I) can be obtained also from chloro-*o*-phenylenedioxyphosphine and trimethylsilyl azide[76]. With an aromatic diol and pyrocatechol compounds of type



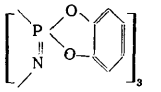
are formed, where Z = *o*-C_6H_4, 2,3- or 1,8-$C_{10}H_6$.[77]

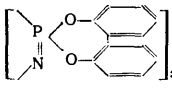
4. Cyclolinear Alkoxyphosphazens

Mixed phosphazens, containing linear phosphazo-groups as well as cyclic units, are extremely interesting, having conjugation between exocyclic phosphazo-groups and the phosphazen ring, as well as other interactions, and also the possibility of combining in a single compound the specific properties of cyclic and linear phosphazens.

Mixed alkoxyphosphazens of general formula $(RO)_{6-n}P_3N_3 \cdot [N{:}P(OR')_2OH]_n$ (where R, R′ = Alk, Ar, and n = 1, 2, 6) have been prepared[78,79] via the corresponding amino-chlorocyclophosphazens by Kirsanov's reaction followed by the replacement of chlorine by alcohol or phenol residues. Cyclophosphazens containing a single exocyclic phosphazo-group have been obtained via penta-aryloxychlorocyclophosphazens. Intermediate cyclolinear chlorophosphazens are hydrolytically unstable, and have not been isolated in pure form.

The action of phenol or a halogenophenol, bisphenol A, 4,4-dihydroxydiphenols, resourcinol on hexachlorocyclotriphosphazen gives an oligomeric product





used as flame-retardant additive in the production of polyester fibres[80,81].

III. PHYSICAL PROPERTIES

The majority of completely substituted alkoxy- and aryloxy-phosphazens are stable white crystals readily soluble in organic solvents, with the exception of spirocyclic compounds, which dissolve with difficulty in polar solvents. All the cyclolinear phosphazens that have been prepared and investigated are viscous liquids. Several alkoxyphosphazens, e.g. $[NP(OC_2H_5)_2]_3$, $[NP(OC_4H_9\text{-}n)_2]_3$, $[NP(OCH_3)_2]_{5,7}$, are colourless oily liquids at room temperature[82]. Substitution of fluoroalkoxy- or aryloxy-groups for halogen atoms in the trimeric or tetrameric ring lowers the melting point considerably[42,83].

In the infrared spectra of alkoxy- and aryloxy-cyclotriphosphazens the bands corresponding to vibrations of the trimeric and tetrameric rings are displaced in some measure to shorter wavelengths[84,85] relative to the initial chlorophosphazens (1218 and 1300 cm^{-1}). Table 1 gives several structural data obtained for alkoxyphosphazens by X-ray diffraction and by ultraviolet, infrared, and nuclear magnetic and nuclear quadrupole resonance spectroscopy.

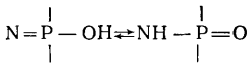


Table 1. Bond angles and lengths in some alkoxyphosphazens.

Compound	Bond lengths, Å		Bond angles, °				Ring or chain structure	Ref.
	P—N	P—O	N—P—N	P—N—P	P—O—C	O—P—O		
$[NP(OC_6H_5)_2]_3$	1.58	—	117.3	121.9	94.1	—	slightly buckled ring	[86]
$[NP(OCH_3)_2]_4$	1.58	—	122	132	105	—	buckled ring (saddle)	[87]
$[NP(OCH_3)_2]_6$	1.56	1.58	116.7	136.7	101.3	—	buckled ring	[88]
	1.58	1.59	117.5	122.5	109	97	—	[89]
	1.57	1.58	118.4	121.0	—	120.7	—	[90]

Study of the structure of spirocyclic compounds showed[89] that on formation of a five-membered cyclic system ∠OPO = 97°. Such a decrease in angle (relative to cyclophosphazens, in which ∠RPR ≈ 100° [4]) is due to the constricting influence of the five-membered ring. For a seven-membered exocyclic system[91] ∠OPO = 102.5°, the stress being diminished by rotation of the side-group. In trisdibenzodioxaphosphepinspirocyclotriphosphazen[90] two dibenzodioxaphosphepin units are each rotated successively through 43° in one direction, but the third is rotated through 52° in the opposite direction. The infrared and Raman spectra indicate that alkoxy-groups (fluoroalkoxy, phenoxy, methoxy, ethoxy, n-propoxy, n-butoxy) increase the strength of a skeletal bond[18,33,92,93].

Alkoxyphosphazens are intermediate between chloro- and amino-cyclophosphazens with respect to the basicity of the ring nitrogen atoms[94], which is weakened by electron-accepting substituents, but strengthened by electron-donor groups. In conformity with the variation of the inductive effects of the substituents the basicity of trimeric and tetrameric alkoxy- and aryloxy-phosphazens diminishes in the sequence isopropoxy > ethoxy ≈ n-butoxy > methoxy > benzyloxy > *p*-methoxyphenoxy > phenoxy > trifluoroethoxy, 2-naphthyloxy[94]. In general tetrameric alkoxyphosphazens are more basic than the corresponding trimeric compounds (where R = CH_3O, C_2H_5O, $(CH_3)_2CH.O$, n-C_4H_9O, $C_6H_5CH_2O$, *p*-$CH_3OC_6H_4O$). However, hexaphenoxycyclotriphosphazen is more basic than octaphenoxycyclotetraphosphazen[95].

Linear, cyclic, and cyclolinear alkoxyphosphazens containing P.OH groups are characterised by the amide–imide equilibrium

(a particular case of the phosphazen–phosphazan rearrangement), the position of which shifts according to the structure and nature of the substituting groups (Tables 2–4).

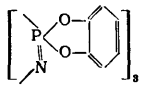
Linear alkoxylated hydroxyphosphazophosphinoyl derivatives are monobasic acids, which become weaker with increase in the number of phosphazo-groups. This is due to conjugation, which facilitates dissociation of the groups

and diminishes with increase in length of the phosphazen chain[96]. It is for this reason that the pK_a value changes so substantially on passing from mono- to di-phosphazophosphinoyl esters—from 6.0 to 7.2 (Tables 2 and 4). The nature of the organic groups has hardly an influence on the pK_a value, but affects the position of equilibrium significantly. When alkyl radicals are replaced by perfluoroalkyl, which are strong electron acceptors, the values for the phosphazo-compounds remain almost unchanged, but the amide–imide equilibrium is displaced towards the amide form.

The nature of the terminal atom attached to a phosphorus atom has an appreciable influence on the acidity of short phosphazen chains, an effect which diminishes sharply with increase in the number of phosphazo-groups. In cyclic compounds the amide–imide equilibrium is displaced towards the amide form[97]. Comparison of the ionisation constants (Table 3) indicates that the pK_a increases with the electron-donor properties of the radicals. Cyclic alkoxy-hydroxy-phosphazens are considerably less strongly acidic than short-chain linear analogues, owing to absence of the complete delocalisation of electrons in the ring that is characteristic of aromatic systems, and the consequent absence of conjugation.

Table 4. Ionisation constants and position of amide–imide equilibrium of alkoxyphosphazens.



Compound*	R	pK_a**	Amide / Imide
	Alk	6.0—7.0	(Am) + (Im)
	Alk	7.0—9.0	(Am) + (Im)
	Ar	8.5—10.0	(Am)

	Alk	10.7—11.4	(Im) > (Am)

*X = $HOP(OR)_2{:}N-$; X′ = $-P(OH)(OR){:}N-$. Different arrangements of the fragments X and X′ in the phosphazen molecules govern the value of pK_a.

**In ethanol at 25 °C.

Tables 3 and 4 illustrate the influence of the nature of organic substituents in exocyclic phosphazo-groups on the position of the amide–imide equilibrium. The amide form predominates in aryloxy-derivatives, and the imide form in the alkoxy-compounds. With the same number of exocyclic phosphazo-groups displacement of the equilibrium to one side or the other is determined by the nature of the alkoxy-group[98]. Cyclolinear alkoxyphosphazens are characterised by sharply diminished acidity in comparison with imidobisphosphoric esters (Tables 2–4). This confirms the absence of conjugation between exocyclic phosphazo-groups and the cyclotriphosphazen ring, and also supports the hypothesis[99] that π-electrons are not completely delocalised in this cyclic system.

Aryloxylated spiro-compounds containing a five-membered exocyclic system are able to form inclusion compounds with various organic solvents[100]. Thus tribenzodioxaphospholespirocyclotriphosphazen absorbs the vapours of many organic solvents (other than methanol, triethylamine, pyridine, and acetic acid). X-Ray diffraction indicates that the process is accompanied by a change in crystal structure from triclinic or monoclinic for the pure compound to hexagonal for the adduct, with the lattice containing one solvent molecule per two spirophosphazen molecules. Allcock[4] links inclusion with the dimensions of the side-groups and the deformability of the crystal lattice. Such an interpretation suggests that related cyclophosphazens containing bulky side-groups should behave similarly. The molecular structure of

has been determined by X-ray diffraction[101]: the P—N bond length is 1.59 Å, and the PNP angle is 122°; the position of benzene in the clathrate has not been determined accurately owing to the effect of rotation.

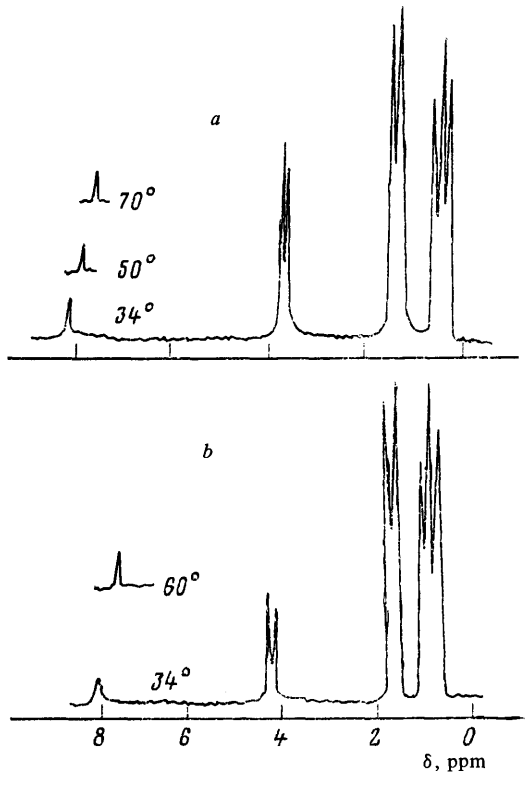

Figure 1. Spectra (^{1}H n.m.r.) [14] of: *a*) dibutyl hydrogen dibutoxyphosphinoylimidophosphate; *b*) bis-2-ethylhexyl hydrogen bis-2′-ethylhexyloxyphosphinoylimidophosphate.

Nuclear magnetic resonance spectroscopy has been used to establish the structure of many alkoxyphosphazens[14,102–106]. The proton chemical shifts δ are sufficiently characteristic of various groups. The ^{1}H n.m.r. spectra of linear alkoxyphosphazens confirm the presence of amide–imide equilibrium. Thus in the spectrum of dibutyl hydrogen dibutoxyphosphinoylimidophosphate (Fig.1*a*) signals corresponding to CH_3, CH_2, and CH_2O groups (0.95, 1.4, and 3.7–4.0 ppm) are accompanied by a signal having δ = 8.2 ppm (at 34 °C), which corresponds to the hydroxyl proton. On heating to 50 and 70 °C this signal shifts into the region of 8.0 and then δ = 7.85 ppm. Its intensity relative to that of the butoxy-protons is 1 : 36.[14] The same signals have been recorded in the ^{1}H n.m.r. spectrum of bis-2-ethylhexyl hydrogen bis-2′-ethylhexyloxyphosphinoylimidophosphate (Fig.1*b*), but the corresponding intensity ratio is 1 : 68.

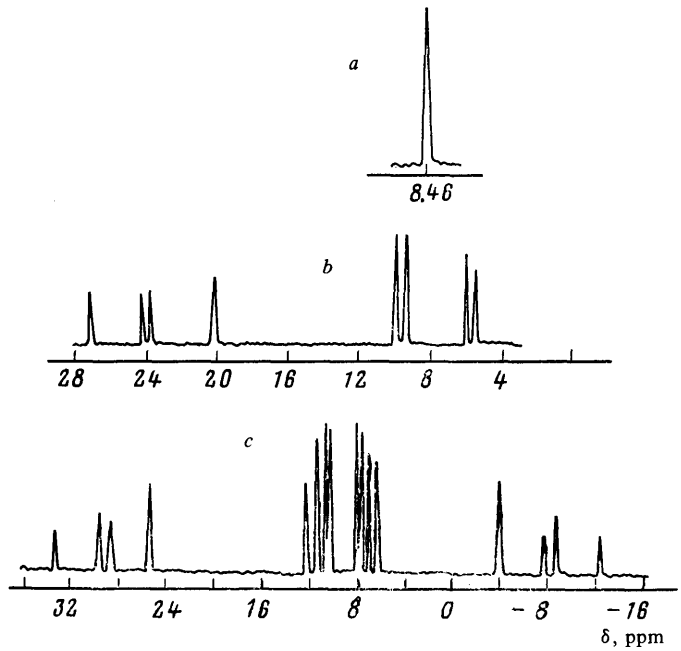

Figure 2. Spectra (^{31}P n.m.r.) of aryloxycyclotriphosphazens[102–104] of general formula $N_3P_3(OC_6H_4X)_5Y$ with X, Y: *a*) H, C_6H_5O; *b*) *p*-CH_3O, Cl; *c*) H, F.

Interesting information is provided by the ^{31}P n.m.r. spectra of aryloxycyclotriphosphazens (Fig.2).[102–104] Whereas those of the hexa-aryloxy-derivatives comprise a singlet with a chemical shift depending on the nature of the substituent in the phenoxy-groups (Fig.2*a*), the spectra of the penta-aryloxychlorocyclotriphosphazens were characteristic of an AB_2 system (Fig.2*b*), in which the A nucleus is the phosphorus atom attached to the chlorine atom, while the B nucleus is a phosphorus atom attached to two aryloxy-groups. The chemical shift of the phosphorus atom is determined by the surrounding distribution of electron density, but, despite the obvious dependence of the chemical shift of A on the character of the substituents in the phenoxy-groups, no correlation of δ_A and δ_B with their inductive constants σ is observed, apparently owing to a disregarded influence of substituents attached to the B nuclei[104].

The ^{19}F n.m.r. spectra of penta-aryloxyfluorocyclotriphosphazens[103], in which the fluorine atom is a magnetically active analogue of chlorine, contain two signals, corresponding to splitting on the nearest phosphorus atom, and represent an AB_2X system (Fig. 2c), in which A is the phosphorus atom combined with the fluorine atom, the B nuclei are phosphorus atoms attached to two aryloxy-groups, and X is the fluorine atom.

Investigation by n.m.r. spectroscopy of the structure of alkoxyphosphazens showed[105] that the chemical shift of the phosphorus atom bearing the substituent in the $N_3P_3Cl_5R$ molecule moves down-field in the sequence of substituents iso-C_3H_7O > C_2H_5O > CF_3CH_2O > CH_3O. The difference in chemical shifts between the fragments PClR and PCl_2 in the $N_3P_3Cl_5R$ molecule increases depending on the nature of R in the reverse sequence. Hence the action of the alkoxy-group in drawing electrons from the phosphorus atom promotes delocalisation of the lone pair on the ring nitrogen atom by displacing electron density towards the phosphorus atom.

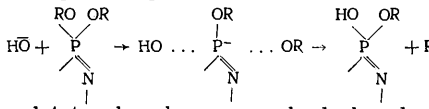
Spin–spin coupling constants J depend on the substituents attached to each of the phosphorus atoms. Interaction of alkoxy-hydrogen atoms with the nearest phosphorus atom has been observed in the alkoxyphosphazen $N_3P_3X_5R$.[105,106]. Methylene protons in ethoxyphosphazens interact with a phosphorus atom, but the methyl protons, more remote from the phosphorus atom, do not usually interact with it[106]. Weak interaction between methyl protons and phosphorus-31 nuclei has been noted only in the geminal derivative $N_3P_3(C_6H_5)_4(OC_2H_5)_2$ (J = 0.8 Hz).[106]

IV. CHEMICAL PROPERTIES

Oligomeric alkoxyphosphazens are less reactive than chlorophosphazens. They are among the most stable phosphorus–nitrogen derivatives known. Within this group, however, thermal stability and resistance to hydrolysis largely depend on the nature of the alkoxy-group.

1. Nucleophilic Substitution

(a) Hydrolysis



Trimeric and tetrameric alkoxyphosphazens $[NP(OR)_2]_n$ (R = CH_3, C_2H_5, iso-C_3H_7, C_4H_9; n = 3, 4) are not hydrolysed by water, but are decomposed by hot 10% hydrochloric acid. The corresponding benzyloxy-compounds behave similarly[33].

Fluoroalkoxyphosphazens $[NP(OCH_2CF_3)_2]_n$ (n = 3, 4) resist the action of concentrated hydrochloric and nitric acids, as well as aqueous alkalis[4,45], but undergo degradation in hot alcoholic alkalis. A detailed kinetic study of the alkaline hydrolysis of the series $[NP(OR)_2]_n$ (R = CF_3CH_2, $C_2F_5CH_2$, $C_3F_7CH_2$; n = 3, 4) showed[107] that under severe conditions (1 N alcoholic NaOH at 75 °C for 150 h) the compound $[NP(OCH_2CF_3)_2]_3$ forms the sodium salt of pentakistrifluoroethoxyhydroxycyclotriphosphazen. Increasing the duration of hydrolysis to 350 h yields the disodium salt of tetrakistrifluoroethoxydihydroxycyclotriphosphazen and the trisodium salt of tristrifluoroethoxytrihydroxycyclotriphosphazen. Under mild conditions (0.02 M NaOH in 25% aqueous diglyme at 80 °C for 24 h) the sodium salt of the monohydroxy-derivative is obtained[107,108]. Aryloxycyclophosphazens are hydrolysed similarly, those containing nitroaryloxy-groups especially readily[108].

A broad investigation of nucleophilic substitution in a series of aryloxyphosphazens $[NP(OAr)_2]_n$ (n = 3: Ar = p-ClC_6H_4, p-FC_6H_4, C_6F_5; n = 4: Ar = p-FC_6H_4, C_6H_5) studied[109] the action of sodium alkoxides, caesium fluoride, and potassium hydroxide in a polar solvent heated to 60–160 °C. It was assumed that the nucleophilic reagent replaced a phenoxy-group attached to a tetrahedral phosphorus atom in the phosphazen ring. The stability of the aryloxyphosphazens $(RO)_6N_3P_3$ to nucleophilic reagents diminishes in the sequence R = C_6H_5 > p-FC_6H_4 > p-ClC_6H_4 > p-$NO_2C_6H_4$ > m-$CF_3C_6H_4$ > C_6F_5. As the aryloxy-substituent becomes more acidic, the rate of nucleophilic substitution increases.

Alkaline hydrolysis of $(p\text{-}XC_6H_4O)_6N_3P_3$ (X = H, F, Cl) takes place under severe conditions (excess of alkali and moist diethylene glycol at 140–160 °C).[58] The resulting penta-aryloxycyclophosphazens $(p\text{-}XC_6H_4O)_5N_3P_3OH$ resist further hydrolysis. This is explained[58] by delocalisation of the negative charge of the anion over the phosphazen ring.

The rate of hydrolysis of alkoxycyclophosphazens increases with the electron-accepting power of the substituents. A tracer method has shown that hydrolytic cleavage takes place at a phosphorus–oxygen bond, not a carbon–oxygen bond. It has been suggested that hydrolysis takes place by an S_N2 mechanism with a five-coordinated trigonal–bipyramidal transition state[4]:

Alkoxycyclotetraphosphazens are hydrolysed considerably more rapidly than are the trimeric derivatives, as a consequence of the greater conformational freedom of the eight-membered ring[4].

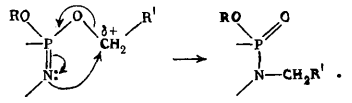
Alkaline hydrolysis of spirocyclic alkoxyphosphazens containing five-membered exocycles involves detachment of aryloxy-groups followed by replacement of hydroxy-hydrogen atoms by sodium atoms[107,110]. The rate of detachment of the first group during the hydrolysis of compounds $N_3P_3(O_6H_4R)_6$ in 25% aqueous diglyme depends on the nature and position of the substituents R and decreases in the sequence p-NO_2 > m-NO_2 > o-NO_2 ≫ H > p-CH_3. The second aryloxy-group is removed from the phosphorus atom with greater difficulty than is the first: thus in the alkaline hydrolysis of $[(p\text{-}NO_2C_6H_4O)_2NP]_3$ at 80 °C the first group is eliminated within 25 min, but the second group not till the process has continued for 48 h.[110] The greater rate of hydrolysis of spirophosphazens containing five-membered exocycles was attributed to steric stress in the ring. When the phosphorus atom forms part of a six- or seven-membered exocyclic ring, steric effects increasing the rate of the first stage of hydrolysis are absent.

(b) Exchange of organic groups

The action of sodium trifluoroethoxide on hexa-p-nitrophenoxycyclotriphosphazen in oxolan forms either completely or partly substituted trifluoroethoxyphosphazens depending on the temperature[67,111]. The relative sequence in which different groups are replaced correlates approximately with their electronegativities. The p-nitrophenoxide ion is displaced by phenoxide, ethoxide, trifluoroethoxide, amide, and anilide ions, but not by n-propylamine, aniline, dimethylamine, and o-aminophenoxide ions. Ease of substitution varies in the sequence[67] o,p-$NO_2C_6H_4O$ > p-ClC_6H_4O ≥ C_6H_5O.

Treatment of $[(p\text{-}NO_2C_6H_4O)_2NP]_3$, $[(o\text{-}NO_2C_6H_4O)_2NP]_3$, and $[(CF_3CH_2O)_2NP]_n$ (n = 3, 4) with phenylmagnesium bromide and with methyl- and phenyl-lithium produces fission of the phosphazen ring with formation of linear products[4].

In the reaction of spirocyclophosphazens $[C_6H_4O_2NP]_3$, which contain five-membered exocyclic groups, with the trifluoroethoxide ion and with n-propylamine, diethylamine, and piperidine one aryloxy-group is substituted on each phosphorus atom. Spirocyclophosphazens containing seven-membered exocycles, e.g. $[C_{12}H_8O_2NP]_3$, do not undergo such reactions[4].



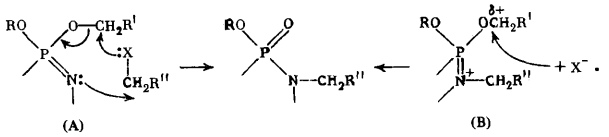
2. Electrophilic Substitution

Little published information is available on the electrophilic substitution of alkoxyphosphazens. Chlorination of the fluoroalkoxyphosphazens $N_3P_3(OCH_2C_3F_7)_6$, $N_3P_3.(OCH_2C_2F_5)_{6,8}$, and $[NP(OCH_2[CF_2]_9CF_2H_2)]_4$ on ultraviolet exposure in tetrachloromethane for 72 h has been described[4]; α-chlorofluoroalkoxy-derivatives are formed.

The nitration, chlorination, and bromination of hexaphenoxycyclotriphosphazen have been studied[109]. Nitration is effected with a mixture of sulphuric and nitric acids at 25 °C for 4–5 h. Chlorination was accomplished with chlorine in acetic acid at 25 °C for 25 h, or in the melt in the presence of iodine at 110–120 °C for 5 h. Bromination was carried out similarly. Only *para*-substituted aryloxycyclophosphazens were formed. Further substitution in an *ortho*-position took place only under severe conditions; *meta*-substitution was not observed. Preferential *para*-orientation was attributed[109] to electronic and steric effects. Electrophilic substitution of aryloxyphosphazens takes place under more severe conditions than for the corresponding reactions of aryl phosphates, cyanurates, and carboxylates.

3. Rearrangement of Alkoxyphosphazens into Oxophosphazans

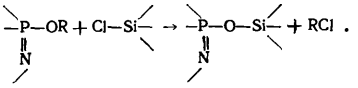
With rise in temperature hexa-alkoxyphosphazens undergo what has been termed the phosphazen–phosphazan rearrangement[112–114]:



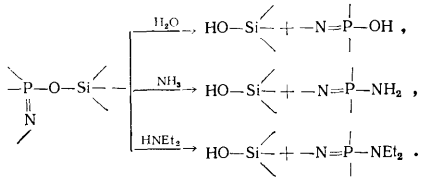
The process could occur either intramolecularly or intermolecularly, the latter being regarded as the more probable[112]. Thus when hexaethoxycyclotriphosphazen (a colourless liquid) is heated at 200 °C for 1 h, it passes into 2,4,6-triethoxy-1,3,5-triethyl-2,4,6-trioxocyclotriphosphazan (a white solid). Heating the corresponding tetramer at 200 °C for 4 h also results in formation of a phosphazan.

The same rearrangements have been noted when $[NP(OCH_3)_2]_{3,4}$ [113–115] and $[NP(OCH_2C_6H_5)_2]_3$ [112] are heated. Nevertheless, aryloxy- and perfluoroalkoxy-cyclophosphazens $[NP(OC_6H_5)_2]_{3,4}$ and $[NP(OCH_2CF_3)_2]_{3,4}$ do not undergo rearrangement even on prolonged heating at 300 °C.[4] Benzyloxycyclophosphazens $[NP(OCH_2C_6H_5)_2]_4$ occupy an intermediate position. Rearrangement is supposed[4] to be due to nucleophilic attack by the ring nitrogen atom on the α-carbon atom of the alkoxy-group. Thus ease of rearrangement depends on the basicity of the cyclic nitrogen atoms. Trifluoroethoxy- and phenoxy-groups tend to attract electrons from phosphorus and nitrogen atoms, thus lowering the basicity of the skeletal nitrogen atom and retarding nucleophilic attack (attack by nitrogen atoms on aromatic carbon is especially difficult).

The phosphazen–phosphazan rearrangement of hexamethoxycyclotriphosphazen and octamethoxycyclotetraphosphazen has been investigated by ^{13}C and ^{31}P n.m.r. spectroscopy at 140–160 °C.[115] Significant changes in the carbon-13 spectrum during rearrangement have enabled the kinetics to be assessed, the stages to be followed (rearrangement at one, two, or all three cyclic phosphorus atoms), and also the isomeric composition of the resulting cyclophosphazens to be determined. Rearrangement of octamethoxycyclotetraphosphazen produces only one of the three possible stereoisomers; subsequent heating at 160 °C for 24 h yields a second isomer. Rearrangement of both trimeric and tetrameric polymethoxycyclophosphazens is autocatalytic, with respective activation energies 134 and 133.6–144.4 kJ mole^{-1}.[115]



The rearrangement is accelerated by alkyl halides, additions of which lower the reaction temperature and increase the yield of phosphazans[116,117]. Since a cyclic nitrogen atom possesses increased electron density, rearrangement may involve either a six-membered transition state (A) or a quaternary compound (B), with subsequent nucleophilic attack by the halide ion on the α-carbon atom:



Several new compounds could be obtained by the use, as initiators of phosphazen–phosphazan rearrangement, of alkyl or aryl halides whose radicals differed in structure from the alkoxy-group in the initial phosphazen[117]. Thus isopropyl iodide reacts with hexaethoxycyclotriphosphazen to give an oxophosphazan containing *N*-isopropyl groups. *p*-Nitrobenzyl bromide reacts similarly. With the hexamethoxy-compound benzyl bromide yields a product containing only two benzyl groups. Partly rearranged alkoxycyclophosphazens have also been prepared[118], e.g. 2,2,4,4,6-pentaethoxy-5-ethyl-6-oxocyclotriphosphazo-1,3-dien. Bulky alkoxy-radicals in the phosphazen or in the alkyl halide hinder or completely inhibit rearrangement.

4. Action of Chlorosilanes and Alkylchlorosilanes on Alkoxyphosphazens

Investigation of the reactions between alkoxyphosphazens and halogenosilanes, leading to the formation of siloxyphosphazens containing P–O–Si and P–O–C–Si links[78,119–127], has provided new information on the transmission of inductive effects in molecules and opens up wide possibilities for the synthesis of difficultly accessible alkoxyphosphazen derivatives and also silicon-containing polyphosphazens. Oligomeric alkoxyphosphazens are fairly inert chemically, so that examination of the action of chlorosilanes was a convenient method for elucidating the structural dependence of the reactivity of the former:

The alkoxy-siloxyphosphazens were identified by infrared and n.m.r. (^{31}P and ^{1}H) spectroscopy, as well as by their reactions[122-124]

These processes confirmed the phosphazen (not phosphazan) structure of the products.

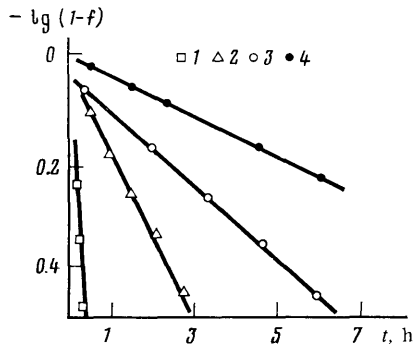


Figure 3. Variation with time of degree of conversion f in nitridobisdialkoxophosphorioamidophosphates[120,121] $HO[P(OR)_2{:}N]_3PO(OR)_2$ with R: *1*) n-C_4H_9; *2*) iso-C_4H_9; *3*) $CH_3OC_2H_4$; *4*) ClC_2H_4.

The reactions of halogenosilanes with alkoxyphosphazens are greatly influenced by the structure of the latter. Linear alkoxyphosphazens react with chlorosilanes even at 90–100 °C. The reaction has overall first order (Fig. 3), zero with respect to the chlorosilane and first with respect to the phosphazen[120,121]. With increase in chain length of the alkoxyphosphazen the rate constant undergoes extremal variation, passing through a maximum for dialkoxophosphoriobisamidophosphates and then decreasing monotonically with increase in the number of phosphorus and nitrogen atoms in the molecule (Table 5). Imidobisphosphoric and dialkoxophosphoriobisamidophosphoric esters exhibit linearity of free energies, and the rate constants of their reactions with chlorosilanes correlate with the sum of the inductive constants of the hydrocarbon substituents

$$\left(\sum \sigma^* = \sigma^*_{R'} + 2\sigma^*_H\right)$$

and the Kabachnik constants σ_{ph}, but such correlation is not observed for subsequent linear alkoxyphosphazen homologues. The reason is the complication of their structure and the progress of reactions at different rates (replacement of alkoxy-groups at outer and inner phosphorus atoms, as well as at a phosphorus atom already attached to a siloxy-group). The rate constant varies little with the nature of the alkoxychlorosilane. Table 5 lists rate constants and activation energies for the reaction between linear alkoxyphosphazens and chlorosilanes.

Cyclic alkoxyphosphazens react at an appreciable rate with chlorosilanes above 120 °C. The overall kinetic order is maintained, but the partial orders—zero with respect to phosphazen and first with respect to chlorosilane—are different[122-124]. On passing from hexafunctional alkoxycyclophosphazens to derivatives containing a smaller number of cyclic alkoxy-groups the reaction velocity drops appreciably, this being especially marked with alkoxypentaaryloxycyclotriphosphazens, which react with chlorosilanes only above 190 °C. The reactivity of the chlorosilanes used diminishes with increase in the number of phenyl groups attached to the silicon atom.

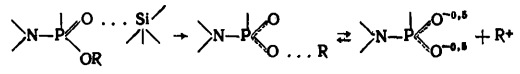

Table 5. Kinetic parameters (rate constant k and activation energy E) for the action of equimolecular proportions of chlorosilanes and chloroalkylsilanes on linear, cyclic, and cyclolinear alkoxyphosphazens $HOP(OR)_2{:}NPO(OR)_2$, $(RO)_5P_3N_3OC_4H_9$, and $(RO)_4P_3N_3$. $.[N{:}P(OR)_2OH)_2$.[120-125]

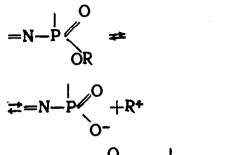
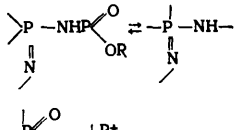
Cyclolinear alkoxyphosphazens also react with alkylchlorosilanes by a first-order mechanism under conditions closely similar to those for linear phosphazens, and with the same partial kinetic orders, which indicates substitution of alkoxy-radicals in exocyclic phosphazo-groups. However, replacement of alkoxy- by siloxy-groups takes place more slowly than in linear alkoxyphosphazens (Table 5), an effect of the phosphazen ring[78]. Yet activation energies are close to the corresponding values for linear alkoxyphosphazens. Rate constants for the reactions of cyclolinear alkoxyphosphazens with chlorosilanes do not correlate with the Kabachnik constants. As in the case of the ionisation constants of cyclolinear alkoxyphosphazens, these facts indicate absence of conjugation between exocyclic phosphazo-groups and the phosphazen ring.

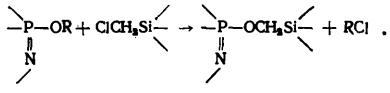
Kinetic study of the action of alkylchlorosilanes on alkoxyphosphazens varying in molecular structure (Table 5), together with examination of starting materials and reaction mixtures at various stages by infrared, ultraviolet, and

n.m.r. spectroscopy, suggested heterolytic mechanisms[76, 120–122]. In the case of linear and cyclolinear alkoxyphosphazens the initial compounds form an intermediate complex by coordination of the silicon atom with a phosphoryl group. Such coordination facilitates ionisation of the P–O–C link and formation of a carbocation



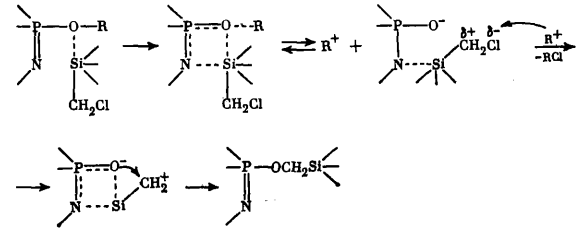


which is responsible for subsequent rapid reactions



The rate-determining stage in the overall unimolecular interaction of cyclic alkoxyphosphazens and alkylchlorosilanes is ionisation of the $\equiv$Si–Cl bond, which is followed by rapid attack by the siliconium cation on the oxygen atom in the P–O–C bond. Ionisation mechanisms of these reactions are due to the nature of the reactants involved: both alkylchlorosilanes and alkoxyphosphazens contain polar bonds of electropositive elements (phosphorus and silicon), which facilitates heterolytic processes.

Table 6. Comparative data for the reactions of alkoxyphosphazens with chlorosilanes and chloromethylsilanes[78,119–127].



Alkoxyphosphazens	Silanes	T_{min}, °C	Kinetic order* N_Σ	N_{Ph}	N_{Si}	E, kJ mole^{-1}	Slow stage
Cyclic	$\equiv$Si–Cl	120	1	0	1	62.9–104.8	
Cyclic	$\equiv$SiCH$_2$Cl	160	1	1	0	104.8	
Linear	$\equiv$Si–Cl	90	1	1	0	83.8–113.1	
Cyclolinear	$\equiv$Si–Cl	100	1	1	0	83.8–96.4	

*Order of reaction–overall N_Σ, with respect to phosphazen N_{Ph}, and with respect to silane N_{Si}.

Additional confirmation of the validity of the proposed mechanisms was obtained by studying the reaction between alkoxyphosphazens and chloromethylsilanes[125–127]:

The introduction of a methylene group between silicon and chlorine atoms produces sharp changes in the reaction conditions and characteristics: with both linear and cyclic alkoxyphosphazens reaction takes place above 150 °C, in both cases first order with respect to the phosphazen and zero order with respect to the silane (Table 6). Obviously here, too, heterolytic fission of the P–O–C link is involved followed by rapid reactions of the resulting carbocation. As in the action of chlorosilanes on alkoxyphosphazens, formation of the carbocation is facilitated by donor–acceptor interaction between the initial molecules, in particular coordination of the silicon atom with oxygen and nitrogen atoms of the alkoxyphosphazen. The mechanism

has been suggested[27] as the most probable for the action of choromethylsilanes on alkoxyphosphazens.

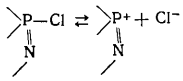
Thus all these reactions are characterised by the heterolytic nature of their slow stages.

5. Alkoxy- and Aryloxy-phosphazens in Polymer Formation

(*a*) Polymers based on linear alkoxyphosphazens

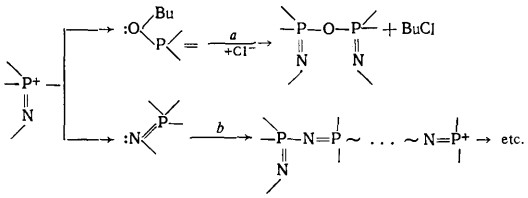
A new type of polymer—coordinated polyphosphazens—has been obtained[128] by the interaction of linear alkoxyphosphazens with compounds of transition metals:

Dibutyl hydrogen dibutoxyphosphinoylimidophosphate and tetrabutyl hydrogen nitrodobisdibutoxyphosphorioamidophosphate have been used as initial alkoxyphosphazens; the transition-metal salts were zinc and cobalt acetates. Reaction was conducted in the absence of a solvent or in anhydrous ethanol at 60 °C. The ratio of phosphazen and phosphazan bonds in the macromolecule can be changed by varying the process conditions.



The resulting coordinated polyalkoxyphosphazen polymers have comparatively low thermal stability, but the very fact of their formation has great value, and can be used to diminish the tendency of linear polydialkoxyphosphazens to depolymerise, by blocking their terminal groups (P–OH and P=O).

(*b*) Polymers based on cyclic alkoxyphosphazens

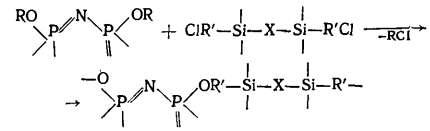


Most of the numerous attempts to accomplish the thermal and catalytic polymerisation of alkoxyphosphazens have been unsuccessful. Thus hexaphenoxycyclotriphosphazen withstands prolonged heating at 350 °C without polymerising[129]. In the presence of acid catalysts at temperatures up to 300 °C hexa-aryloxycyclotriphosphazens undergo oligomerisation with an insignificant yield of macromolecular compounds. N-Propoxy-, n-butoxy-, and cyclohexoxy-derivatives do not polymerise when heated in

the presence of benzoyl peroxide or aluminium chloride to 350 °C.[130] Fluoroalkoxycyclophosphazens $[NP(OCH_2R_F)_2]_n$ ($R_F = CF_3$, C_2F_5, C_3F_7; $n = 3, 4$) do not polymerise on prolonged heating at 250–300 °C.[4] An attempt[131] to obtain a linear polymer $[(C_6F_5O)_2PN]_n$ by heating gave a contaminated insoluble product. Incompletely substituted penta-, tetra-, and tri-chlorofluoroalkoxy-, as well as pentachloro-phenoxy-, pentachloro-*p*-halogenophenoxy-, and pentachloro-*p*-methoxyphenyl-phosphazens can be polymerised at temperatures not below 250 °C.[132–134]. Hexakistrifluoroethoxycyclotriphosphazen copolymerises with hexachlorocyclotriphosphazen when heated to 200 °C.[132,133]

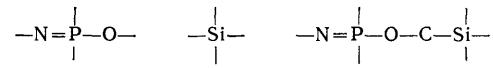
When tetrabutoxydichloro- and pentabutoxychloro-cyclotriphosphazens are heated in the absence of a catalyst in the melt or in a polar solvent at 150–200 °C, polymers are formed in which phosphazen rings are linked by P–O–P bonds[135]. The infrared spectra show that polycondensation is accompanied by partial polymerisation of butoxyphosphazen rings, with consequent inclusion of linear butoxyphosphazen fragments in the macromolecules. The rate-determining stage is ionisation of a phosphorus–chlorine bond

followed by rapid attack by the cyclic azophosphonium cation on the oxygen atom in a P–O–C link (path *a*) or on a cyclic nitrogen atom (path *b*)—nucleophilic centres of the butoxyphosphazen molecules



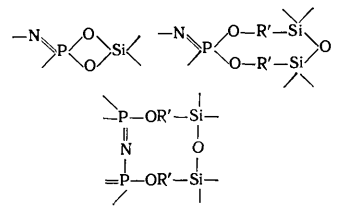
The presence of linear phosphazen fragments in the polymer macromolecules indicates that nitrogen atoms are more accessible to nucleophilic attack in butoxyphosphazen rings than in hexa-aryloxyphosphazens. An important role is played by steric effects and also the more strongly electron-donor character of butyl groups. Weakening of the nucleophilic character of the oxygen atoms in P–O–C links, e.g. in chloroperfluoroalkoxycyclotriphosphazens, increases the proportion of reactions following path *b*; this applies also to substituents that increase the electron density in the phosphazen ring.

(*c*) Alkoxyphosphazens containing spirocyclic groups at phosphorus atoms



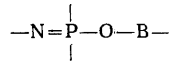
These compounds are capable of thermal polymerisation. For example, tripyrocatecholcyclotriphosphazen polymerises with opening of the phosphazen ring when heated above 250 °C.[136] However, related compounds having six- and seven-membered exocycles containing the phosphorus atom do not undergo thermal polymerisation, owing to repulsion of substituents in the polymer consequent on the large angle of rotation of biphenyl groups from the plane of the phosphazen ring[137].

(*d*) Synthesis of polyphosphazens containing silicon and boron

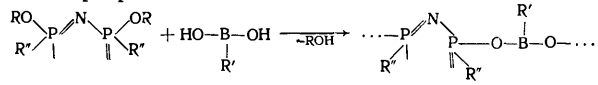


Phosphazen polymers containing silicon and boron are attracting increasing attention from research workers by virtue of their great thermal stability, resistance to radiation, and other valuable properties. Silicon-containing polyphosphazens have been obtained by the polycondensation of alkoxyphosphazens and organosilicon compounds[138,139]:

where R = Alk (e.g. n-C_4H_9); R′ = –, CH_2, $[CH_2]_3$; X = O, $[O.SiH_2]_n$. In the course of the reactions polyphosphazens containing the links



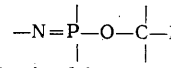
were obtained. A characteristic feature of the polycondensations is that spiran structures such as



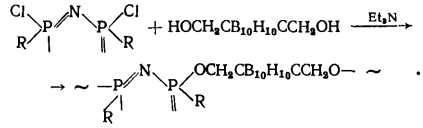
may be formed within the macromolecules.

Under otherwise similar conditions the most active among several initial butoxyphosphazens is the cyclic hexabutoxy-derivative; mixtures of oligomeric butoxyphosphazens in which the hexabutoxyphosphazen predominates are somewhat less reactive, as are also linear butoxyphosphazens, which is due to stabilisation of their functional groups by complex formation. The activity of chloromethylsiloxanes is determined by their molecular structure and the number of functional groups. Cyclic chloromethylsiloxanes or their mixtures with linear siloxanes are more reactive. In all cases investigated the process is first order (partial first order with respect to the phosphazen and zero order with respect to the siloxane) during the initial stages of polycondensation. The mechanism of polycondensation is analogous to that suggested for simple model compounds.

Boron-containing phosphazen polymers containing the links



have been prepared[140]:



R=Me, Bu; R′=OH, Bu, Ph; R″=Cl, OPh .

Those containing

links have been obtained by the polycondensation of alkoxyphosphazens and carboranediols[141]:

The reaction was conducted in the melt or in an inert solvent at temperatures up to 150 °C.[141]

As with silicon-containing polyphosphazens, heterolytic processes have a decisive role in the formation of polymers containing boron and phosphorus. A characteristic feature of the polycondensation is a well defined tendency to cyclisation and the inclusion of spirocyclic fragments

in the macromolecules. Polyphosphazens containing P–O–C–Si and P–O–C–B links possess good hydrolytic stability. The strength of the P–O–Si and P–O–B bonds can be enhanced significantly by attaching to the phosphorus, silicon, and boron atoms bulky substituents, which also lower the nucleophilicity of these atoms.

V. APPLICATIONS

The practical value of alkoxyphosphazens and polymers based on them is due to a number of specific properties—heat resistance, non-flammability, possibility of obtaining hyperelastic and hard materials having good mechanical and dielectric parameters, high chemical and radiation resistance, etc.

Alkoxycyclophosphazens are finding increasing application as high-temperature (up to 500 °C) heat-transfer agents, lubricating and transformer oils, hydraulic liquids having low solidification temperatures, and heat-resistant plasticisers. Aryloxy- and fluoroalkoxy-phosphazens are characterised by enhanced heat resistance[142–146]. They are distinguished by high chemical and thermal stability, high flash-points, low vapour pressures, and good lubricating properties; they do not cause metallic corrosion.

Including phenoxyhalogenophosphazens in the composition improves the flame-resistance of polyesters[147,148]; flame-resistant materials have been obtained by impregnating wool, cotton, polyamide, viscose, and polyurethane fibres and fabrics with fluoroalkoxy- and halogenophenoxy-phosphazens[149–157]. Pentakistetrafluoropropoxycyclotriphosphazen can be used as a modifying agent for phenol–formaldehyde resins[158]. Flame-resistant water-soluble liquids and greases can be based on aminophenoxyalkene oxide adducts of cyclophosphazens[159].

Introduction of alkoxycyclotriphosphazens into mineral oils not only enhances their heat and flame resistance but also diminishes the wear of rubbing components: thus additions of 0.7–3.0 mass % decrease wear by 20–40%, ethers of lower alcohols being the more effective[160]. Geminal difluorotetramethoxycyclotriphosphazens can be used as insecticides[161]. Hydroxy-derivatives of alkoxy-, amino-, and alkoxyamino-cyclotriphosphazens are strong complexing agents and have been used for the extraction of plutonium, neptunium, uranium, and platinum from aqueous solutions[162,163].

A promising use of alkoxyphosphazens is the preparation of various types of polymers. Thus novel silicon-containing phosphazen polymers can be used as dressings in the production of glass plastics[164]. In mechanical properties the products equal those obtained industrially with KM-9K organosilicon dressing, but surpass them in dielectric properties, especially at high temperatures.

Even this brief list of possible practical applications of alkoxyphosphazens reveals their great value for various branches of technology and the undoubted promise of further research on these lines.
